Only few of them present the use of inclinometers to determine deflections during static and dynamic load tests (Hou et al. 2005). Works using inclinometers to determine displacements under dynamic load and high-speed train passages are presented in (Hem et al. 2014, Martí-Vargas 2015).

Whereas the method presented here is based on the integration of the signals from inclinometers and accelerometers. Inclinometers are installed in one line on a span and accelerometer at the point of displacement examination. The signals from the inclinometers are used to determine the so called quasi-static component of a displacement, and the signal from the accelerometer to determine a dynamic component. The details of the method of determining displacements will be presented in a separate publication. A similar way of integrating the signals from an inclinometer and an accelerometer, used to determine lateral displacements of a railway bridge support is presented in (Ozdagli et al. 2016).

2 DESCRIPTION OF MONITORING SYSTEM

The developed prototype of the measuring system consists of a central unit and 4 measuring modules. A scheme of the set of equipment is presented in Figure 1.

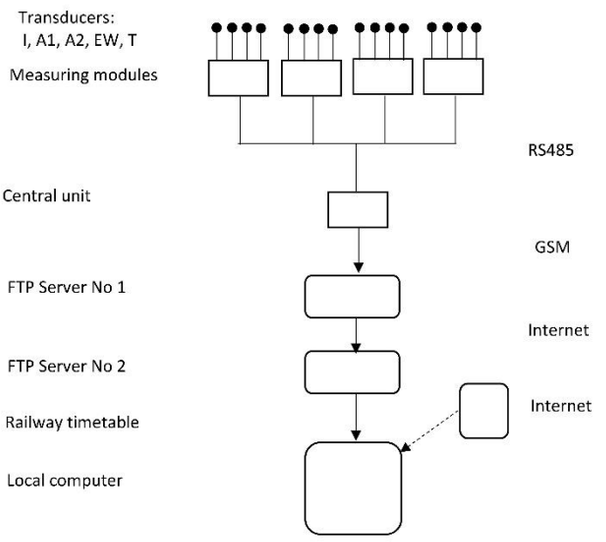

Figure 1. Scheme of the measuring system with indicated methods of data transmission; measuring transducers markings: I – inclinometer, A1 – accelerometer MEMS, A2 – piezoelectric accelerometer, EW – electric wire resistance strain gauge, T - temperature sensor.

Each measuring module comprises an 8-channel, 16-bit analog-digital transducer adapted to operate the following detectors:

- uniaxial gravity inclinometer with measuring range of ±1°;
- MEMS-type three-axis accelerometer with measuring range of ±3g;
- piezoelectric three-axis accelerometer with measuring range of ±5g;
- resistance strain gauge;
- temperature sensor with measuring range from -55°C to +125 °C.

The central unit which controls the measuring module activity consist of a microcontroller, local memory on a SD card, a real-time module and a GSM module. Communication with the measuring modules is established by means of RS485 protocol. The system is equipped with an algorithm of detecting trains' passages, thanks to which a loop of data acquisition is fully automated. The signals registered by the sensors during a train passage are sent as a text file to remote FTP server No. 1. The system works autonomously and the buffer power supply protects from power failures.

In order to ensure data safety, the complete (unprocessed) measuring signals are collaterally copied to server No. 2 located in a different place than server No. 1.

An analysis of the registered signals is made on a local computer using special platform developed in MATLAB environment (MATLAB 2017). The scheme of the platform activity is presented in Figure 2.

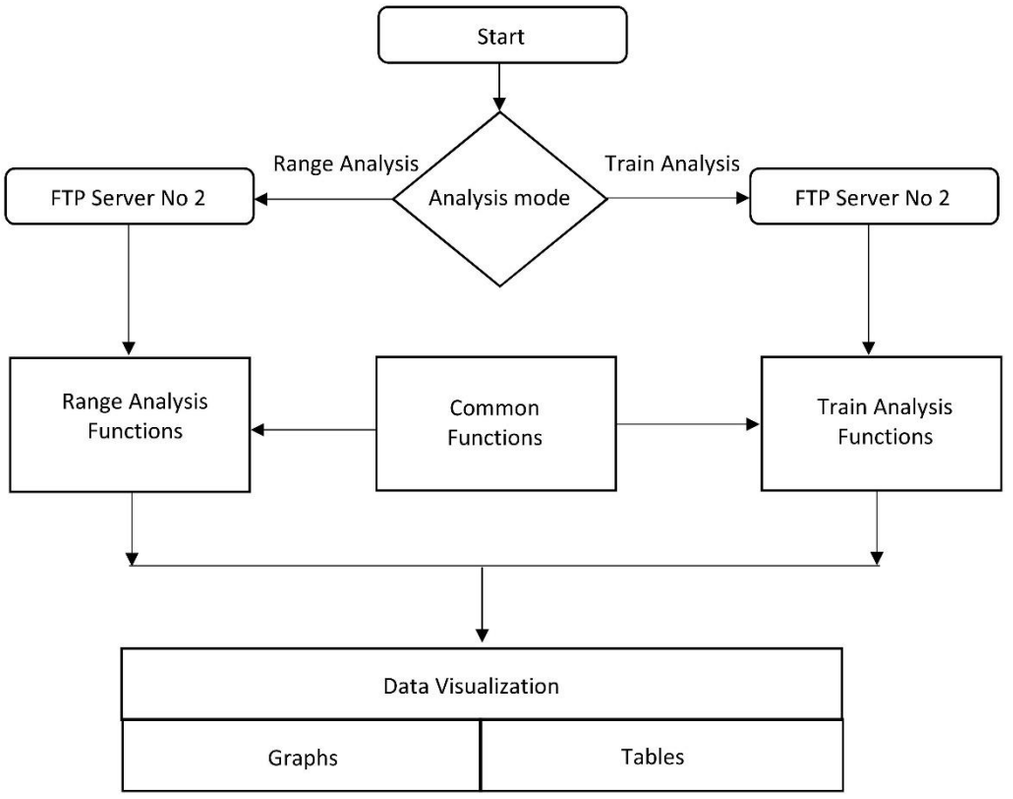

Figure 2. Scheme of platform activity to analyse data from the monitoring.

The platform enables transmission of the measuring data from the FTP server No. 2 to programming variables, and then theirs analyze and visualization in the form of graphs and tables.

The system presented herein was developed for scientific and research purposes and the platform is supposed to facilitate both the creation of new algorithms of processing measuring signals and the analysis of received results. While using the platform, a person who analyses the measuring signals only needs to enter a few commands of the program code in order to program the data readout and visualization of the data processing in the form of graphs or tables. Advantages of using such a developed platform are:

- it is easy to concentrate while creating and algorithm, not programming;
- availability of "ready" functions of processing MATLAB environment signals;
- it is easy to work in many teams while creating different functions for measurement analysis;
- it is easy to handle a big number of measurement data.

The data can be processed in a single train passage analysis mode (train analysis) or in a selected group of trains analysis mode (range analysis). The functions to analyse the measurement results are created in the form of plug-ins – separate files located in proper catalogues (train or range analysis). The trains are identified by the date and time of the initial registration.

After a platform user chooses an individual train passage or a group of trains passage all the functions from the proper catalogue are carried out automatically. The range or analysis functions can use common functions. Sample copies of a computer screen during work with the platform are presented in Figure 3.

The system also uses data about train passages from the Department of Handling the Systems and Individual Timetables, Railway Traffic Management Centre of PKP Polish Railway Company S.A. With respect to the safety requirements in the research and prototype solutions the data are entered to the system in an offline and semi-automatic mode. In the future it will probably be possible to automatically download those data from the PKP PLK SA internal network while developing an application monitoring system.

Figure 3. Sample copies a computer screen during work with the platform: at the top in the mode Train Analysis; at the bottom in the mode Range Analysis.

3 EXAMPLE OF THE BRIDGE MONITORING

The system presented herein was checked on arch bridge located in high speed railway (Fig. 4).

The bridge consists of two new steel arch structures (from 2014 and 2015) with span length of 75.00 m. The arch and the arch tie both have box cross-section. The arch ties are suspended at the arches using 13 pairs of steel hangers. The bridge has ballasted deck, cross-bars from double-tee plate girders and reinforced concrete slab floor. The structure was accepted for train speed up to 250 km/h.

Figure 4. View of the tested bridge: from the side and from the track level.

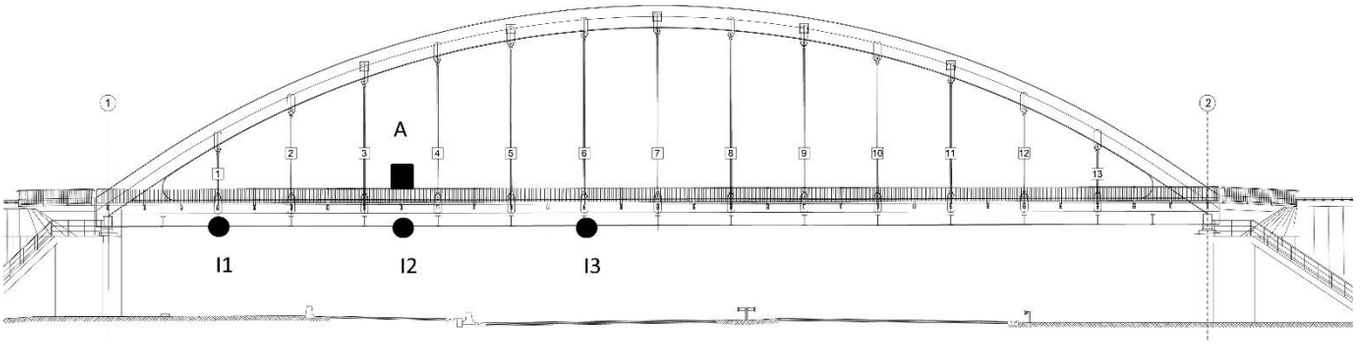

Figure 5. Scheme of inclinometers location (I1, I2, & I3) and accelerometer location (A) for continuous monitoring of the bridge deck.

At the case of arch bridge, the extreme deflection appears at about one a quarter span length. For preliminary testing it was enough to monitor half of the span. Three inclinometers were installed in one line at bridge deck and the accelerometer was located at one a quarter of a span length (Fig. 5).

An example of an analysis of a single registration and indirect determination of displacements is presented in Figure 6. The registration concerned a passenger train passage with the speed of about 160 km/h, consisting of a locomotive EP09 and cars of gross weight 427 tons and length of 246 m (data from the Railway Traffic Management Centre).

The graphs included herein present signals registered by the inclinometers and accelerometer as well as a quasi-static component of the displacement calculated on the basis of the signals from the inclinometers and a dynamic component calculated on the basis of the signals from the accelerometer.

The last graph presents the result of an indirect measurement of displacements compared with the reference time-history registered using a reference method – by means of an inductive transducer.

Relative measurement error using the indirect method in relation to a reference method did not exceed 4% for extreme value.

The installed monitoring system registers measurement data from all passing trains. Recently (September 2017) 35 trains were registered on average during 24-hours. The comparative tests using an inductive transducer were not conducted continuously. Over 6 months, on average once a month, the inductive transducer was installed under various weather conditions to measure displacements caused by passages of various types of passenger trains: separate locomotive and cars or multiple unit trains.

The relative measurement errors determined using the indirect method in relation to a reference method did not exceed 0.5%-7.0% for extreme values. Further works are being carried out in order to improve the accuracy of determining the displacements using the indirect method. The works include examination of different methods of filtering and separating the signals from the inclinometers and the signal from the accelerometer.

It is important to point out here that the tests were carried out with a minimum number of inclinometers. In case of the presented arch bridge 3 inclinometers were used to determine the line of deflection along the half of the span – ultimately it will be necessary to use 6 inclinometers to examine the whole span of such a bridge.

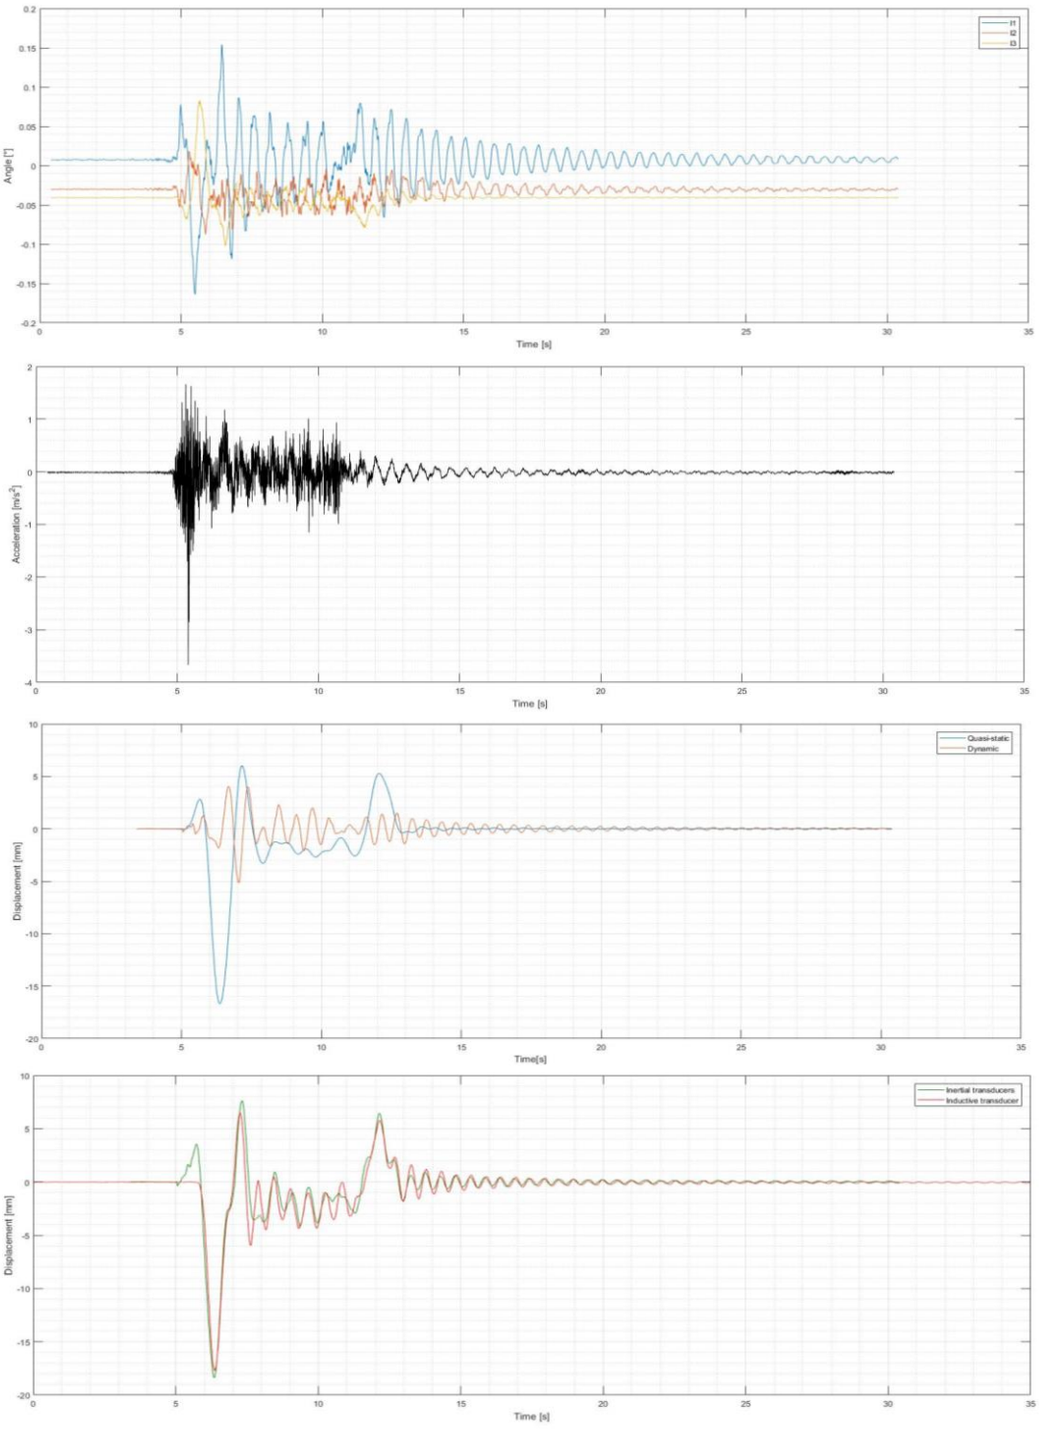

Figure 6. An example of an analysis of a single train; from the top: 1) signals from inclinometers, 2) a signal from an accelerometer, 3) determined quasi-static component (from inclinometers) and dynamic component (from an accelerometer), 4) result of an indirect measurement of displacements compared with the reference time-history registered using a reference method – by means of an inductive transducer.

The continuous monitoring system is supported by periodical total station measurements which aim to control the geometric parameters of the bridge structure in absolute coordinates (in a system connected with the local points of reference).

Figure 7 shows an example of an analysis of a train range monitored during one week. The first two graphs from top present determined values of extreme displacements and accelerations (using 30 Hz low-pass filtering) from all trains that passed during that time.

The displacement values determined by the monitoring system are comparable with the values determined using the numerical modelling (Olaszek et al. 2017).

The determined maximum peak values of bridge deck acceleration (using 30 Hz low-pass filtering) are comparable with the limits for ballasted track 3.5 m/s^2 (EN 1990:2002). In the presented example the registered maximum peak values did not exceed 2.0 m/s^2.

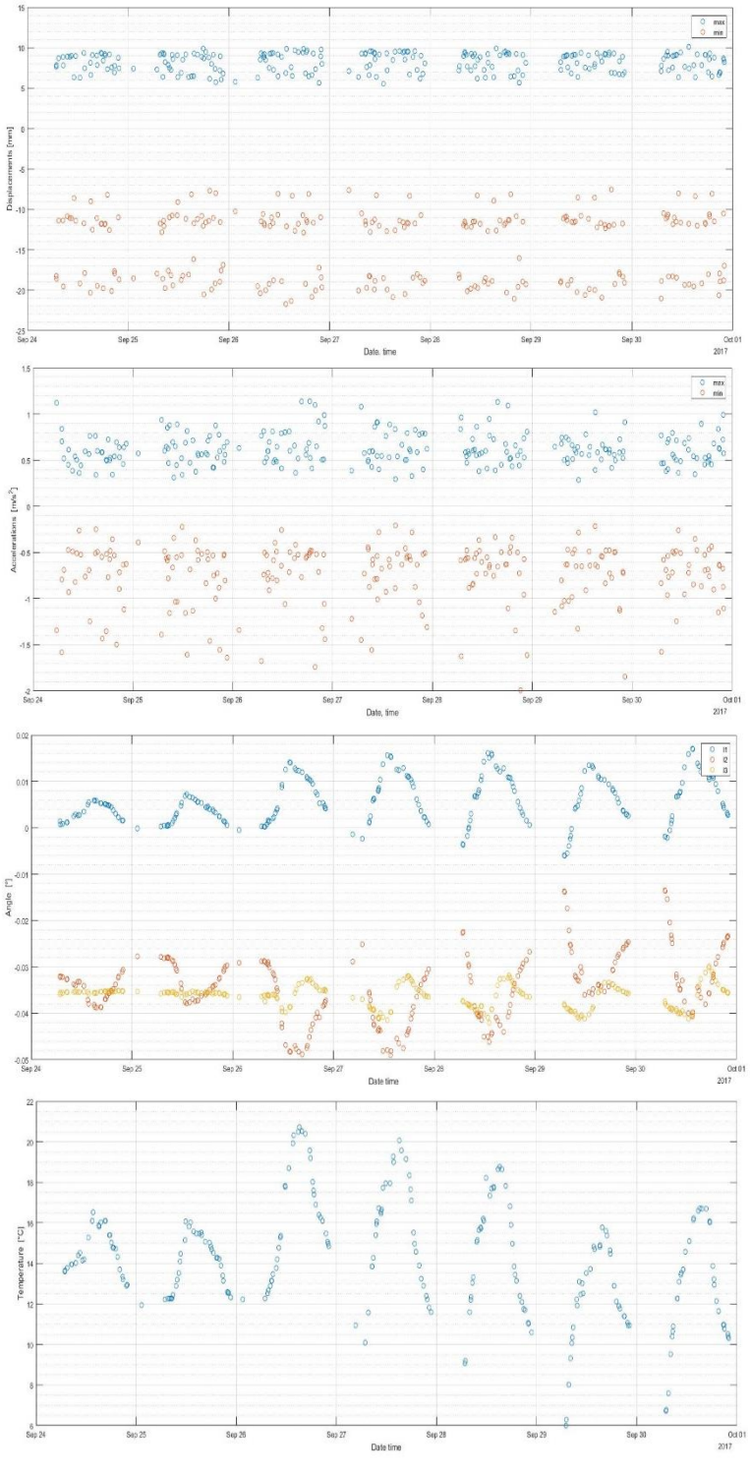

Figure 7. An example of an analysis of a train range monitored during one week: from the top: 1) determined values of extreme displacements, 2) accelerations (using 30 Hz low-pass filtering), 3) angle changes registered without train load (just before a train passage), 4) changes in the average temperature from measurement at a few points of the structure.

Two graphs from bottom (Fig. 7) show angle changes registered without any train load (just before a train passage) as well as changes in the average temperature measured at a few points of the bridge structure.

We can observe here the compliance between the seven-day changes in the angles and the changes in the temperature – maximum daily changes equal to about 10° C.

The numerical analyses of the construction deformations resulting from the changes in the temperature confirmed the conclusions from the monitoring activities – big sensitivity of the construction deformations of local and global character to the changes in the temperature. (Olaszek et al. 2017).

4 CONCLUSIONS

This article presents a bridge structure monitoring system whose main elements are inertial transducers used to determine vertical displacements using an indirect method. The so far tests of the system proved its usefulness for monitoring bridges in high speed railway as well as its possibility to achieve high accuracy while determining displacements using an indirect method.

ACKNOWLEDGEMENTS

The authors would like to thank the members of the team who completed the presented part of the project, including: Eng Robert Czachowski, MSc Eng Małgorzata Mazanek, PhD Eng Tomasz Wierzbicki, MSc Eng Paweł Nurek from the Road and Bridge Research Institute; Prof. PhD, Eng Jan Holnicki – Szulc, PhD, Eng Andrzej Świercz from the Institute of Fundamental Technological Research of the Polish Academy of Science; PhD, Eng Ireneusz Wyczałek from the Institute of Civil Engineering of the Poznań University of Technology; PhD, Eng Przemysław Kołakowski from Adaptronica Sp. z o.o.; MSc Joanna Wyroba from Oprogramowanie Naukowo-Techniczne Sp. z o.o. sp.k., MSc Kazimierz Szadkowski and Directors, Main Engineers and Bridge Diagnosticians from the Railway Track Development and Construction Unit of PKP Polish Railways S.A. in Warsaw and Skarżysko Kamienna.

The project is carried out within the frame of Applied Research Projects, financed by the National Centre for Research and Development in years 2015-2018.

Non-destructive testing of bridges – health assessment & monitoring

Chetan R. Raikar
Structwel Designers & Consultants Pvt. Ltd., Navi Mumbai, India

ABSTRACT: India has taken major leap into investing in road infrastructure & hence widening of existing roads and bridges is major construction activity. Health Assessment of Bridges hence is an extremely critical task ahead of Central Government and the State Governments of all the States.

As the reliance on infrastructure is growing, the engineered components of transportation infrastructure are aging, deteriorating, and exhausting their capacity to meet the everexpanding operational demands. The mammoth task of inventory preparation and health assessment of all the bridges across the country by is taken up by The Ministry of Transport.

Ensuring operational and structural safety and security of the transportation infrastructure is an essential task. Hence Health assessment and residual / remnant life assessment is needed to be carried out. Load carrying capacity and life cycle cost analysis of existing bridges is yet another area of consultancy needed.

In most cases, job of health assessment is yet left to the experienced engineer who visits the bridge for visual inspection. Sudden collapses of bridges and untimely / unplanned job of major repairs are common. There is a huge loss of human life, fuel and time of commuters due to the same.

Author proposes to cover various Non Destructive Testing (NDT) techniques used in India, methods for health assessment of bridges and few case studies in this article.

Keywords: Non Destructive Testing (NDT) of the bridges, In situ Permeability Tests of concrete, Ground penetrating Radar survey, Infrared Thermography, Load Test of bridges, Metro structures.

PREAMBLE

Health assessment of bridges is scientific process which requires great amount of experience. NDT plays very important role in assessing structural properties of various materials used in the bridges. NDT also assesses the integrity of various structural members of the bridge and their capability to cater to the load which they are expected to. Load rating of existing bridges, structural stability for increased load, and effectiveness of repairs are some of the other areas where NDT plays a major role.

There are several types of NDT to measure various properties of concrete like compressive strength, permeability, stress / strain, integrity, homogeneity, chemical deterioration etc. There are different instruments of NDT available to assess different properties of concrete.

NDT is being practiced in India for around three /four decades or more by now. **Most of the NDT techniques available across the world in developed countries are available in India**. The more advanced countries have long adopted continuous monitoring of stress, deflection/deformation, temperature and other properties of bridge components; in-situ during service life.

DIFFERENCE BETWEEN NDT ON BRIDGES AND ON OTHER STRUCTURES

As we all know, the major difference between loads on a bridge and that on any other structure; is the dynamic nature of the live load a bridge is expected to cater to; during its service life. Other structures like machine foundations also are subjected to dynamic loading of different levels and nature.

NDT on structures other than bridges are carried out, predominantly, to find out residual strength of material of construction like concrete, steel, wood, stone masonry etc. In very few structures (other than bridges); the techniques of NDT for stress measurement, deflection measurement etc; used to measure the structural properties of the members, are required to be deployed. Whereas, in a bridge it is equally important to know stress levels, internal cracking and deflection checks during service life to understand the serviceability of the bridge.

This is a major difference that makes NDT on bridges, entirely a different gamut than the routine

NDT carried out by most laboratories across the country on residential and other structures.

Why NDT on bridges?

Limitations of inspection

Visual inspection is one of the most important aspects of health assessment of structures. It is understood that there are more than 2,50,000 bridges, or more, on National Highways in the country. Surely so, India does not have so many Bridge Inspection Experts to inspect each and every bridge in a reasonable time-frame. The work of visual inspection of the bridges is, therefore, going to be carried out by junior level engineers who may or may not have sufficient and appropriate training to identify distresses by visual inspection.

Even an expert inspector will have several limitations either of access, of time, or of light intensity etc. those that may have limitations of visual assessment.

He/she may also want to additionally confirm the observations and quantify the areas of distresses identified by him/her.

NDT is extremely useful in these situations.

Non-availability of drawings

This is going to be a major challenge faced by the Bridge Engineering Consultants. During the passage of time, important data like drawings & maintenance registers of majority of the bridges has not been retained properly by the owners and the same has been lost.

Geometric survey of physical dimensions of superstructure of any bridge is still an easy task and can be carried out to a great degree of accuracy. Whereas, geometric survey **of substructure of perennial bridges and foundations; just cannot be done without the help of NDT** unfortunately, even NDT techniques have great limitations in supporting the bridge inspector in encompassing this challenge.

Quantum and location of reinforcement and prestressing tendons is another requirement when regression analysis of any bridge is required to be carried out to know its load-carrying capacity or the cause of failure. This task just cannot be completed without any of the most advanced NDT equipments.

Confirmation of visually observed distresses

As mentioned above, an expert bridge inspector would observe several types of distresses in a bridge structure. He/she may want to ignore some of the distresses which would not have any shortterm/long-term bearing on the life or performances of the bridge. Some of the distresses found may be of critical & of urgent / important nature, wherein he/she would suggest immediate measures.

There would be a third type of distress wherein the bridge inspector would like to quantify or reconfirm his/her observations. This is exactly where NDT would provide additional support. Rather, only NDT can bring in completeness to site investigation of health assessment of bridges. It would be prudent to mention here that more than 60% of distress observations by an expert bridge engineer would fall in this category which would need NDT on the same.

To cite some examples; a bridge inspector may want to confirm whether the cracking observed in the wearing course extends into the deck slab too or otherwise. He/she may also want to confirm the exact reason of cracking in concrete whether structural or material, to start with.

There can be several support areas where NDT can support the expert bridge inspector in confirming his observations and can provide extremely valuable data to take him/her further in concluding the health of the bridge structure.

NDT for material strength

NDT provides extremely useful data on strength of materials like concrete, steel etc. used in the construction of the Bridges. Concrete and steel both undergo macro and micro levels of cracking due to various reasons. Chemical infestation, over stressing, fatigue, other age-related distresses, fire, blast, impact due to an accident etc. are some of the reasons that may cause distress in a bridge. Under designed or marginally designed bridge & that is poorly constructed will show early major distress during service-life of the same. NDT will prove to be a useful tool in either altering the condition assessment of the bridge or investigative assessment in case of its early distress/collapse.

NDT for load rating of bridge

There is a constant dilemma in the minds of bridge owners about the current rating of bridges. NDT can be a very useful tool in upgrading or downgrading the rating of a bridge.

NDT on repaired components in bridge structures

Most of the bridges under health assessment would have undergone some form of repair or retrofit during their service-life. The records of **location and quantum of repair may or may not** be available to the bridge inspector. **NDT plays a major role in knowing the effectiveness of earlier repair work carried out**. Delamination **of Polymer modified mortar, Epoxy mortar and** other repair mortars used, delamination and tearing of fibre-wrapping and their effectiveness **in load transfer mechanism of the** bridge.

Table 1 :Non Destructive Tests recommended

Strength tests	Corrosion Assessment & r/f related tests	For detection of cracks/voids/ delamination	Laboratory Tests	Durability Test

Following are few case studies where Ground Penetrating RADAR, IR and Endoscopy are employed.

GROUND PENETRATING RADAR (GPR / RADAR)

Case Study 1:

Type of Bridge – Stone masonry arch bridge

Year of construction – 1896

Fig. 1: Remote view of river bridge

Fig 2: RADAR survey in horizontal direction on top of Deck Slab

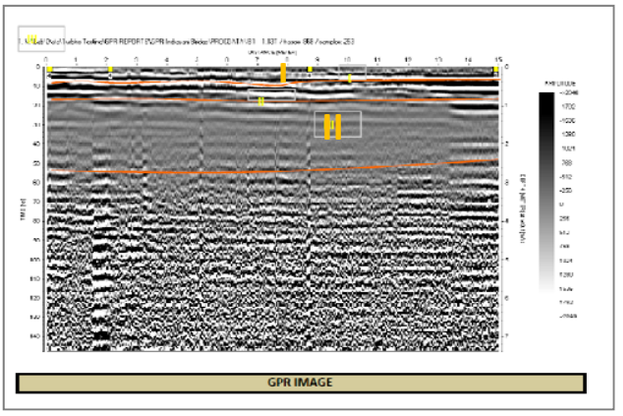

Fig 3: RADAR survey in horizontal direction on top of Deck Slab , I- Bituminous Layer, II Compacted fill

Conclusion:

RADAR tests revealed debonding between Wearing coat (Bituminous layers) and found depth of in filled materials etc.

I.R. (INFRARED THERMOGRAPHY) CAMERA –

Case Study 2:

Type of bridge - Composite structure having RCC Solid Deck Slab rested on Rubble Masonry Piers. The Stone masonry piers are provided at regular intervals in between the abutments.

Year of construction – 1977

Fig. 4: Pier of the bridge under consideration

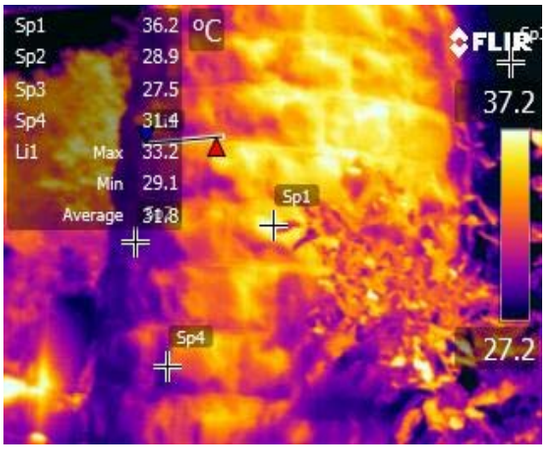

Fig.5: Thermography images of Masonry Piers & Deck slab

Conclusion: I.R. Camera test shows ingress of moisture to the surface of Masonry Piers below Pier caps and soffit of Solid Slabs at some locations.

ENDOSCOPY -

Case Study 3 -

Type of bridge - Composite structure having RCC Solid Deck Slab rested on Rubble Masonry Piers. The Stone masonry piers are provided at regular intervals in between the abutments.

Year of construction – 1977.

Fig.6 Endoscopy of bridge on river.

Fig.7 View under endoscope

Conclusion:

Endoscopy tests revealed voids to the internal area of Masonry at few locations, however Stone Masonry found in intact condition.

Case Study 4-

Location - Bridge on Metro rail

Type of bridge - Cable Stayed Bridge Between two piers (Span length 83 m)

Year of construction - 2013

The load test of bridge is conducted by using train as live load. Total station is used for deflection monitoring as it can measure deflection accurate to 0.2 millimeters. This monitoring system is much easier to set up and use, reducing labor and time requirements. The system has almost no site restrictions. Test conducted for 72 hours, readings are recorded for interval of one hour. Figure 5 illustrates the results of load testing bridge

Fig 8 Deflection monitoring

Fig .9 Close up view of Pylone, prism are fixed at regular interval

Conclusion:

Metro structure successfully passes the trial runs for deflection and stress levels.

Rating of Masonry Arch Bridges in USA

A.P. Ranasinghe
Jacobs Engineering
N.Y. Khadbai
Area Engineering
A.K. Ranasinghe
Jacobs Engineering

ABSTRACT:

Arch bridges are amongst the oldest types of bridges used by engineers. Some of the arch bridges built during the Roman Empire are still standing today. Arches have been commonly used in both highway and railroad bridges. Prior to the industrial revolution, arch bridges were built using stones or bricks. Then, steel and concrete arch bridges became more commonly used. The codes and guidelines used for designing these bridges are outdated and may not be compatible with the current design standards and moving load conditions. Many of these arch bridges have been in service for several decades and have experienced significant deterioration. Therefore, it is essential to perform load rating for these bridges to assess their load carrying capacity and evaluate the need for strengthening and repair work. This paper demonstrates the load rating of a major stone arch railroad bridge in the Northeast Corridor of the USA.

1 INRODUCTION

Arch bridges are amongst the oldest types of bridges used by engineers. Some of the arch bridges built during the Roman Empire, such as the Pont du Gard and the Pont Saint Martin, are still standing today. Prior to the industrial revolution, arch bridges were built using stones or bricks. Then, steel and concrete arch bridges became more commonly used. Steel arch bridges offer an economical advantage due to their use in longer spans.

Many of these arch bridges have been in service for several decades and have experienced significant deterioration. These bridges require accurate load rating to assess their condition and evaluate the need for maintenance and rehabilitation work. The load rating of arch bridges can be a challenging task due to the combined effects of axial forces, bending moments, temperature changes, and second-order moments from member buckling.

The codes and guidelines used for designing these bridges are outdated and may not be compatible with the current design standards and moving load conditions. Furthermore, these bridges may have experienced material losses and other deterioration effects that can reduce the load carrying capacity of the bridge. Therefore, it is essential to perform load rating for these bridges to determine the need for strengthening and repair work. This paper demonstrates the implementation of the load rating provisions for a major stone arch railroad bridge in the Northeast Corridor of the USA. The bridge is rated based on the load rating provisions in AREMA Manual for Railway Engineering (2012). The analysis procedure and application of the load rating equations in the code are demonstrated.

2 LOAD RATING METHODOLOGY

The total moment at a node of the arch due to dead and live loads can be written as

$$M_{Total} = (RF) \times (M_{LL+I}) + M_{DL} \quad (1)$$

Where RF is the Rating Factor

The total axial load at a node of the arch due to dead and live loads can be written as

$$P_{Total} = RF \times P_{LL+I} + P_{DL} \quad (2)$$

The eccentricity, $e = (M_{Total}) / (P_{Total})$ (3)

When, e < H / 6, the section is under full com pression as shown by Figure 1. The f_{max} due to dead load and live load (SDL & SLL+I) can be obtained separately by the equation,

f_{max} = P/A + M/S (4)

or f_{max} = P/BH + 6M/BH2 (5)

Where, B = Width of the section = 12”
H = Arch section thickness in inches

When, e > H / 6, the sectio n is not under full com pression as shown by Figure 2 and the joint is open. The f_{max} due to dead load and live load can be obtained separately by the equation,

f_{max} = P / (9H – 18M/P) (6)

AREMA (2012) provides two rating equations each for normal and maximum rating factors.

For normal rating select the lesser of,

(SLN) = [(Sf/1.2) – (SDL)] / [(SLL+I)] (7)

(SLN) = [(Sf) – (SDL)] / [(SLL+I)] (8)

For maximum rating select the lesser of,

(SLN) = [(Sf) – (SDL)] / [(SLL+I)] (9)

(SLN) = [(1.2Sf) – (SDL)] / [(SLL+I)] (10)

Where, Sf = Permissible Stress

It should be noted that ot her force effects such as buoyancy, stream force, longitudinal force, w ind, wind on live load, centrifugal, and friction have been removed from the AREMA equations above. If there are any effects from these, the co mplete AREMA equations should be used and the re sulting bending and axial stresses should be added to SDL appropriately.

A starting value of 0.2 is assum ed for RF in equation 1 and the rating factors given in equations 7 to 10 are calculated. Rating factor is increas ed in steps of 0.2 until the SLN val ue is 1.0 for equation 7 or 8 and also 1.0 for equation 9 or 10. Those RF values will be the normal and the m aximum rating factors for that nod e. This p rocedure will be repeated for other nodes for various li ve load positions along the bridge. This can be easily done by using a Microsoft Excel spreadsheet (2000). The m inimum rating factors from all the nodes from equation 7 or 8 and 9 or 10 will be the normal and maximum rating factors for the bridge.

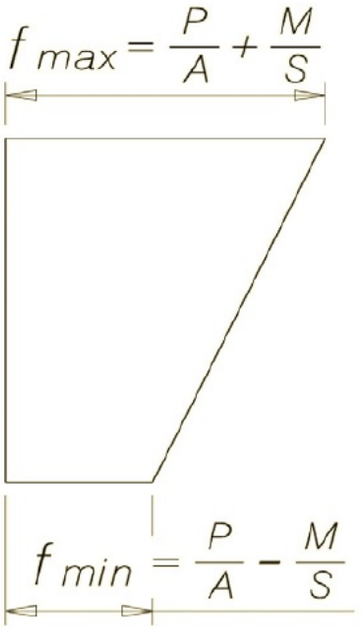

Figure 1. S tress Distribution with Total Com pression.

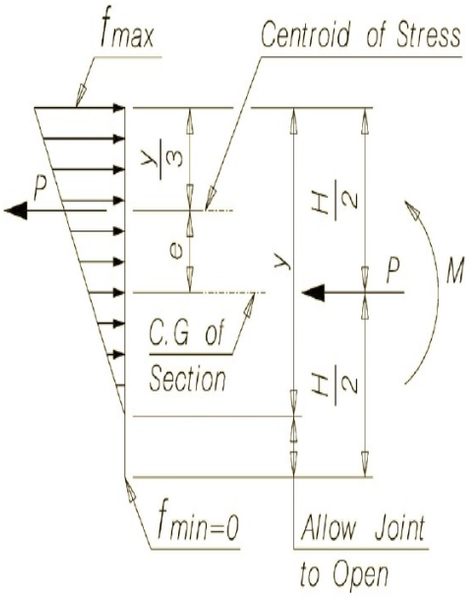

Figure 2. Stress Distribution with the Joint Open at a Node

3 APPLICATION OF THE LOAD RATING METHOD

The load rating process summarized above was applied to the load rating of the Northeast Corridor over Easton Avenue Bridge in New Brunswick, New Jersey, USA. (Figure3). The Northeast Corridor is the busiest rail corridor in the United States. It carries the AMTRAK and other regional rail traffic from Washington DC to Boston via Baltimore, Philadelphia, and New York (Figure 4).

The Northeast Corridor over Easton Avenue Bridge was built in 1902. This stone arch bridge carries four AMTRAK and New Jersey Transit Tracks in New Brunswick, New Jersey (Figure 5). The span length of the bridge is 65 feet and the width is 69 feet. The clear rise of the arch is 10 feet. The thickness of the arch is 4 feet.

The rating process begins by calculating the dead and live load on a one-foot wide section of the arch. Different live loading conditions were produced by moving the train live load over the entire length of the bridge. The bridge was loaded as per AREMA and the live load and impact where applicable. The train live load used was Cooper E80 train load. SDAAD.Pro Software (1998) was used to model the arch and to calculate the axial forces and the corresponding moments at the member nodes of the arch for both dead and live loads. Horizontal soil pressures were applied on the arch. Figure 6 shows the model used. Those loads were used to rate the arch using the method summarized previously. Axial loads and corresponding moments were obtained for two sets of soil pressures with Ke equal to 0.33 and 1.0. Table1 shows a summary of the results. The normal rating factor for the bridge is 1.4 and the maximum load rating is 1.8

Load Rating	ARCH LOADING (DEAD LOADING PLUS LIVE LOADING AS SHOWN BELOW)							
	1/4 SPAN IS LOADED		1/2 SPAN IS LOADED		3/4 SPAN IS LOADED		FULL SPAN IS LOADED	
	Ke = 0.33	Ke = 1.00	Ke = 0.33	Ke = 1.00	Ke = 0.33	Ke = 1.00	Ke = 0.33	Ke = 1.00
NORMAL LOAD RATING	2.4	2.8	1.4	1.4	1.5	1.5	1.5	1.4
MAXIMUM LOAD RATING	2.8	2.8	2.8	2	2	2	1.8	1.8

Table 1 Summary of Results.

4 CONCLUSIONS

Using a standard structural analysis tool (such as STAAD.Pro) to determine member nodal forces, a spreadsheet application (such as Microsoft Excel), and the method for rating summarized in this paper, rating of masonry arch bridges can be done very efficiently and in a standardized fashion.

Also, the effect of deterioration on the arch members, can be efficiently incorporated into the load rating to determine the as-inspected rating.

Further, the method for rating summarized in this paper can be extended to highway bridges also.

ABSTRACT: This paper presents a Finite Element Analysis(FEA)-based design of a health monitoring system for a structurally complex long-span bridge. The system consists of Bridge Weigh-in-Motion(BWIM), damage detection function and thermal behavior monitoring. To determinate the sensor position for BWIM, the strain response in the floor system is analyzed. Besides, FEA simulations are performed to grasp the damageable parts during an earthquake. Based on the analysis, a sensor arrangement for the bridge is proposed.

1 INTRODUTION

Planning of bridge health monitoring should take account of bridge environment that influences the structural damage or deterioration such as, disaster strikes, traffic volume of heavy trucks and a level of corrosive environment. Reasonable sensor selection, their arrangement and data acquisition would be proposed by considering damage modes. This study describes how to design bridge health monitoring with an example of a large-scale bridge. To identify monitoring items, the bridge condition is divided into in-service one and extreme loading one. For the monitoring for the in-service condition, BWIM is included for the evaluation of fatigue environment. Bearing function is also monitored. For the extreme-loading condition, the proposal of sensor arrangement is based on FEA dynamic simulation to reveal the bridge behavior and damaged bridge components when a strong earthquake strikes.

2 DESIGN CONCEPTS FOR THE MONITORING

As a case study of the monitoring design, Tokyo Gate Bridge(TGB), the construction of which completed in 2012, is targeted. Two reasons why the bridge was targeted as a monitoring design are, firstly it will be difficult to ensure the alternative paths due to its long span and the cross-linking location when a disaster strikes, secondly, structural behavior is unclear due to the characteristic base-isolation system and the application of newly developed high yield point steels. Note that the monitoring system implemented to the TGB is not exactly the same as the proposal of this study because of the bridge administrator's consideration. The TGB connects reclaimed lands in Tokyo bay (Figure 1), aiming to enhance smooth traffic flow in the water front area. Since the site is in only 7km from Haneda Airport, height restriction had to be taken into consideration. In addition, the clearance amounts to 50m for allowing passage of tall ships. By adding aesthetic examination as a symbol of the entryway in Tokyo port into the design, truss structure was chosen in the preliminary design, which reminds us a gantry crane.

There are several concerns about the maintenance management after opening for the TGB. It is anticipated that a large volume of freight cars would use the bridge to avoid traffic congestion in the cen-

(c) End pier (part A)

(b) Cross section at B

(d) Cross section of part C

Figure 2. Schematic view and dimensions of the TGB

ter of Tokyo, so that the consideration to fatigue damage is required. As to inspection, the TGB has large inspection areas, and also easy access are difficult in some bridge structures. In addition, Tokyo bay is under harsh condition in terms of disaster, such as an earthquake and a typhoon. Three main aims of the bridge health monitoring system are: (1) to grasp live loads dynamically by using Bridge Weigh-in-Motion (BWIM) for the evaluation of fatigue cause; (2) to diagnose the conditions to control traffic flow promptly in case of the strong level of disasters; (3) to obtain omens of structural degradation in the latent phase with thermal deformation monitoring.

Bridge health monitoring has been developed in three decades, especially for large-scale bridges and newly developed bridges such as integral abutment bridges. In the design of the structural health monitoring system, the selection of sensors, the sensor arrangement, and the data transfer are crucial. Koh et al. (2005) introduced a damage detection system in Gwangan bridge. In the system, health condition was investigated with some laser displacement meters. In suspension bridges, vibration responses in suspension bridges are considerable, Nagayama et al. (2005) proposed an identification method of structural integrity in a suspension bridge by using ambient vibration with accelerometers. In large-scale bridges, structural behaviors have been monitored with much regard for thermal deformation. Kobayashi et al. (2007) evaluated correlativity of temperature change, obtaining the structural behavior in the box girder bridge with thermometers in the box and displacement meters in the bearings. The monitoring system of Orange and Wendell Bridge (Sergio et al. 2007), the type of which is an integral abutment bridge, acquired bridge responses due to temperature for three years. In the meantime, utilization of higher speed network for structural health monitoring has been attempted.

3 BRIDGE DESCRIPTION

The main bridge consists of three-span continuous box girder built in truss structure (Figure 2). It is a 440m length interior span and two 160m long exterior spans for a total bridge length of 760m. The approach bridges adjacent to the main bridge are multi-span continuous box girder, which consists of 120m

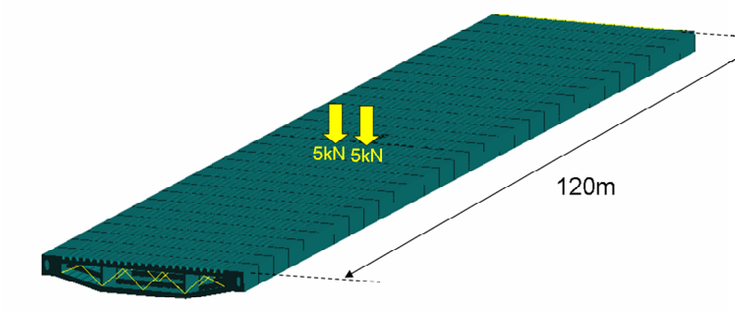

Figure 3. FE model

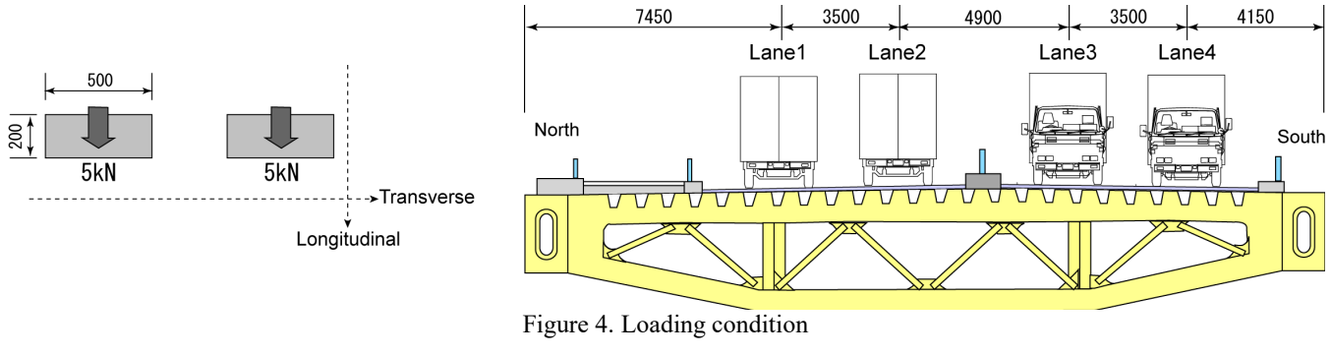

Figure 4. Loading condition

of each span. The one on the east wing is four curved spans and the other one on the west wing extends three straight spans.

The TGB has particular structures. First, in order to reduce weight of metal and save the maintenance cost for bearings supporting a deck, middle chord of the truss integrated with the box girder and orthotropic steel deck structure is adopted (Figure 2-c), instead of the conventional design in which a deck is placed on the lateral member of the truss. The integrated box girder is stiffened with a diaphragm of a sway bracing type tightly arranged every 4m intervals (Figure 2-d). This makes considerable constraints and stiffness in the floor system. Second, the trussed structure supporting the box girder induces negative reaction force at MP1 and MP4. As a countermeasure towards it, tie down cables with 20100(kN) in each are installed (Figure 2-a). Third, in the main bridge, isolation bases are employed on all the piers. The adoption of base isolation is based on the following reasons. 1) Since the piers are short in the large structural system, it may be difficult that effective plastic hinges arise in an extreme loading condition. 2) Deformation induced from plastic hinges is hard to get back to the former condition, because the dead loading acting on MP2 and MP3 exceeds 300,000(kN) in total and the tie down cables at MP1 and MP4 leads to 20,100 (kN) loading in each bearing. Lastly, for the purpose of damage control, side blocks of the bearings on MP1 and MP4 are designed to break when lateral force becomes 20,000(kN). Due to the above structural features, the behavior of the TGB can be complex.

4 SENSOR ARRANGEMENT FOR BWIM

Referring to the suggested BWIM instrumentation in an orthotropic steel deck (Kobayashi et al. 2003), trough ribs right under the axle passage position and a transverse rib are recommended as sensor installation points. The former is to obtain the information of axle positions, and the latter is to calculate the vehicle's weight. In the floor system of the TGB, the strain response in transverse rib might be insufficient due to the connected sway-bracing type diaphragm. Static FEA herein is used to consider suitable installation points, which provide strain data for total weight of the vehicle. Two requirements for the sensor position are that strain responses due to live loads are to be: (1) large as compared with circumjacent positions, (2) less sensitive to differences in vehicles' running positions to transverse direction.

Figure 3 illustrates the Finite Element(FE) model. The model represents a center part of the main bridge. The loading condition shown in Figure 4 is simulating a couple of tires. On each lane, a total of 10kN load is shifted to a transverse direction every 100mm up to 500mm.

Figure 5 shows the analysis results on the Lane 1, Lane 3 and Lane 4, respectively. Minus on the horizontal axes in those graphs means north side and plus on that means south. Two points indicated by the triangle mark means focusing points where strain response is large when the loading position is zero in transverse. About these parts, focusing was paid to two parts showing remarkable strain response in comparison with other ones.

In the Lane 1 (Figure 5), the strain response at position (A) is large. When a running position shifts to -300mm, the response decreases 40%. In contrast, the response of (B) is small in any position compared with (A), and the effect by the running positions is stable. Since the fluctuation of strain re-

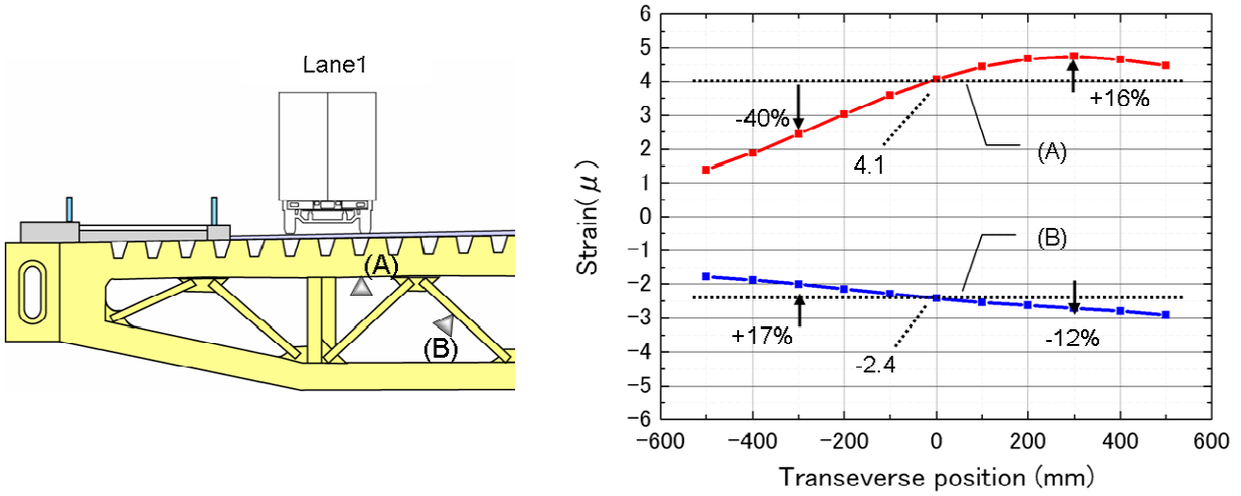

Figure 5. Strain response when loaded on the Lane 1

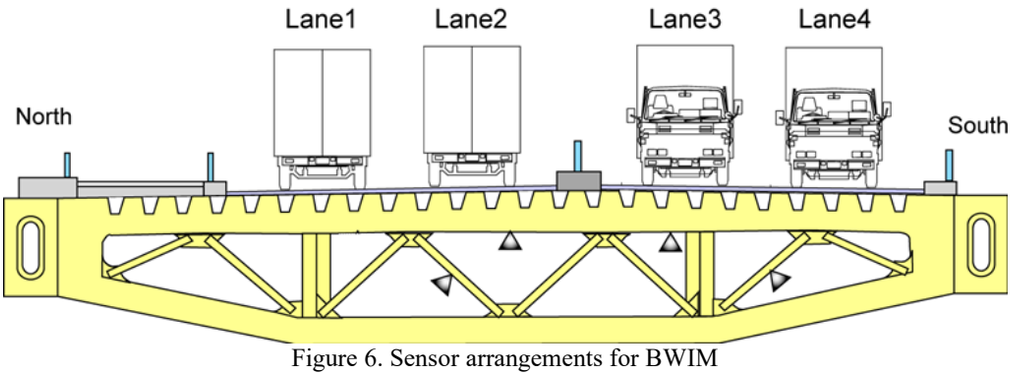

Figure 6. Sensor arrangements for BWIM

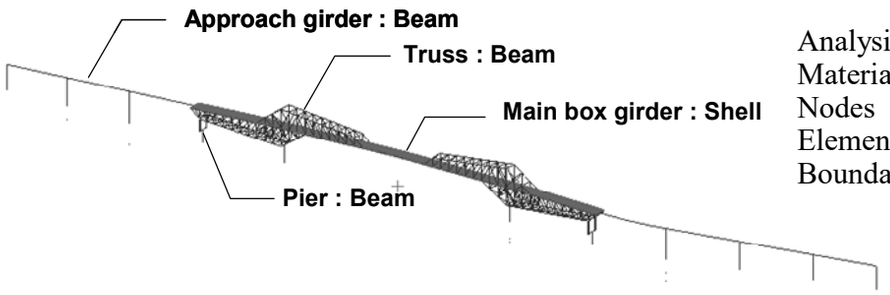
sponse at position (A) is significant, BWIM in Lane 1 is performed using strain data of position (B).

The response in the Lane 2 is sufficiently obtained in the transverse rib. The installation part for the Lane 2 is right under the reference running position.

As for the Lane 3 and Lane 4, similar analysis cases are performed; then, the sensor arrangement is determined. Finally, the sensor arrangements for weight-of-vehicle calculation is proposed as shown in Figure 6.



5 MONITORING DESIGN FOR DAMAGE DETECTION IN EXTREME LOADING CONDITION

In arrangement of sensors, it is necessary to duplicate the bridge behavior, including its nonlinearity, and then damaged area, the modes, and the sequence of the damage must be identified. FEA herein simulates damage occurrence, including the effects of the base isolation, tie-down cables, truss-box integrated structure and the damage control in the side blocks in the model.

5.1 *Finite element model*

In order to grasp critical parts during an earthquake, FE dynamic analysis was employed. The FE model involved the possibility of pounding effects between the bridge and the neighboring approach bridges due to the difference of eigenfrequencies, the FE model included approach bridges in both sides. In the model, shell elements were employed to take the torsion effects and local deformation into consideration. The truss members, piers and the approach bridges were modeled with beam elements as shown in Figure 7.

The applied base isolation system was illustrated in Figure 8. This system called “friction isolator” consists of a sliding part and a rubber buffer. In the sliding part, an interface plate covered with Teflon bottomed in the superstructure slides on a stainless-steel plate and the friction effects of the sliding is expected to have damping effects. The friction coefficient in the model is uniformly 0.15 to simplify dynamic analysis in design. The rubber buffer carries horizontal loads with linear restoring. Assuming these actions, the bearings are modeled by using connecter elements in ABAQUS with the constitutive law shown in Figure 9.

Analysis code : ABAQUS
Material : Linear condition
Nodes : 259988
Elements : 266493
Boundary : Full fixity at end points

Figure 7. FE model

For the pounding effects, pounding springs were defined in the model. Figure 10-a shows the spring model for expansion gap. For the pounding effects and constraint effects by seismic restrainers, the spring shows infinitive stiffness when the gap between the main bridge and the approach bridge reach 1300mm.

Bearings at MP1 and MP4 fix transverse movement of the superstructure with side blocks. This was modeled by using a spring element as shown in Figure 10-b. Considering 10mm gap between the shoe and the side block, the maximum response in the model is shown at 10mm. The side blocks ruptures when 20000kN acts

Structural damping in the propagation of earthquake motion was defined with the Rayleigh damping. The coefficients of the mass matrix and the stiffness matrix are determined from the modal participation factors and effective mass value obtained by eigenvalue analysis.

For the input of earthquake motion, the great hanshin earthquake recorded at the Higashi Kobe bridge and the assumed minami-kanto earthquake were used. In advance to the dynamic analysis, ground propagation analyses of those earthquakes were carried out, and then surface displacement waves were obtained. Accordingly, the surface wave contains the property of ground under each pier. The surface waves were input from the bottom of each pier through a ground spring and a ground dashpot.

Since the difference of mode value between longitudinal and transverse direction in large-scale bridges can be large, angle of incidence of an earthquake may affect those response. In this study, each wave was inputted, changing the angle of incidence as a parameter from 0 degree to 315 degrees every 45 degrees (Figure 11).

5.2 *Results and discussions*

Of the two earthquakes used as input waves, no damage was seen in the case of the assumed minami-kanto earthquake regardless of the angle of incidence.

In contrast, in the case of the great hanshin earthquake, damage was induced in the side blocks in the bearings on MP1 and MP4 and the lateral

bracings in lower chords. The damage aroused in the case of 0 degree, 45 degrees, 180 degrees and 225 degrees of angle of incidence. There was difference in the angle cases of damage occurrence as explained in Fig.14. The side blocks were damaged in the mentioned four angle cases. As opposed to it, damaged lateral bracings were different by the case.

In case of 45 degrees and 225 degrees, the largest number of members was damaged. The following discussion is mainly mentioned based on the harshest case.

Figure 12 shows the relative displacement in a transverse direction of the bearing at MP1. At the moment of 9.1 seconds from the analysis start, the behavior of the superstructure and that of substruc-

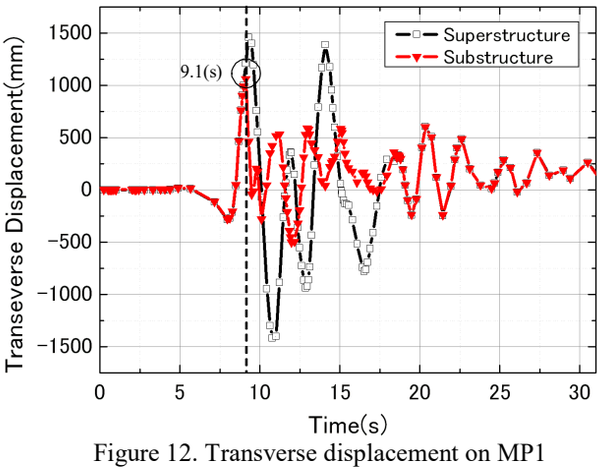

Figure 12. Transverse displacement on MP1

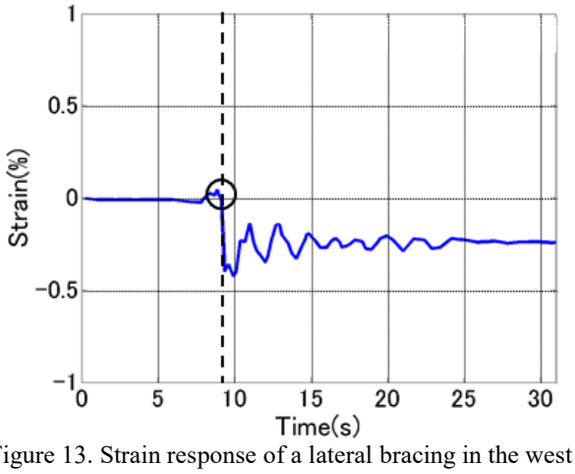

Figure 13. Strain response of a lateral bracing in the west side

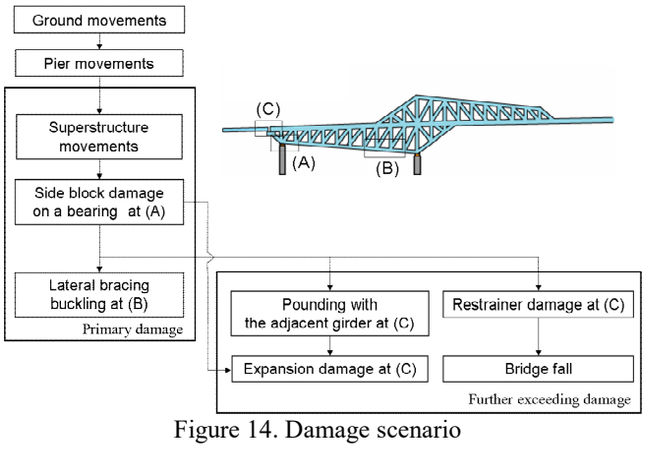

Figure 14. Damage scenario

ture started to show different response. This means that the side blocks fixing a transverse direction was broken at the time. Figure 13 shows the strain responses of lateral bracings at the lower chords. Notice that the moment when compressive damage occurred was right after the moment when the side blocks of the bearings damaged. The same damage scenario occurred at MP4 as well.

Although pounding effects at expansions were concerned, the damage of the adjacent approach bridge did not occur in all cases.

5.3 *Damage scenario*

From the result of the analysis, a damage scenario is drawn in Figure 14 with the order of events. The damage identified in the analyses is defined as primary damage herein. In the scenario, the ground shaking acts on the bases, then the piers are shaken. Due to the behavior of piers, damage arises in the side blocks of the bearings that fix transverse movement of the superstructure. When the side blocks are damaged, relative displacement in transverse direction occurs between the superstructure and the substructure on MP1 and MP4. As a result, lateral bracing buckling and damage in expansions are caused. As a further exceeding damage, pounding effects with adjacent bridges and damage in seismic restrainers can be led. In the considered further exceeding damage, the damage in seismic restrainer can lead bridge fall in the worst case.
In the procedure, it is clear that the damage in the side blocks is a trigger to the subsequent damage cases.

6 A PROPOSAL OF BRIDGE MONITORING

Based on the analysis results and discussions on the damage scenario, this study proposes the TGB health monitoring system. From the viewpoint of sensor durability, fiber optic sensors are appropriate to the structural monitoring system. This monitoring system uses FBG (Fiber Bragg Grating) strain sensors for BWIM and OTDR (Optical Time Domain Reflectometer) system for damage detection in extreme loading condition. Figure 15 illustrates the bridge instrumentation.

For BWIM, FBG strain sensors were employed in the box girder of the central part of the main span. In addition to the four strain sensors for the weight calculation arranged in the targeted diaphragm in the center, eight strain sensors are arranged in the trough ribs for grasping axle location of the vehicle. These sensors are installed at the position left 2m to the longitudinal direction before and behind of the BWIM instrumented diaphragm.

As for the damage detection in extreme loading condition, it is required to detect transverse transition of superstructure accompanied with the damage of the side blocks in the bearings on MP1 and MP4. About the lateral bracings, the damage mode was total buckling, and the detecting regions are too large, so that it is very difficult to detect them. This monitoring arranges the sensors only in side blocks and use the sensors as a trigger of damage initiation. The OTDR system is arranged in all bearings, which are fixed in transverse direction by side blocks.

In addition, 5 FBG sensors are arranged for the temperature measurement of the box and one FBG strain sensor is arranged in the bottom flange to de-

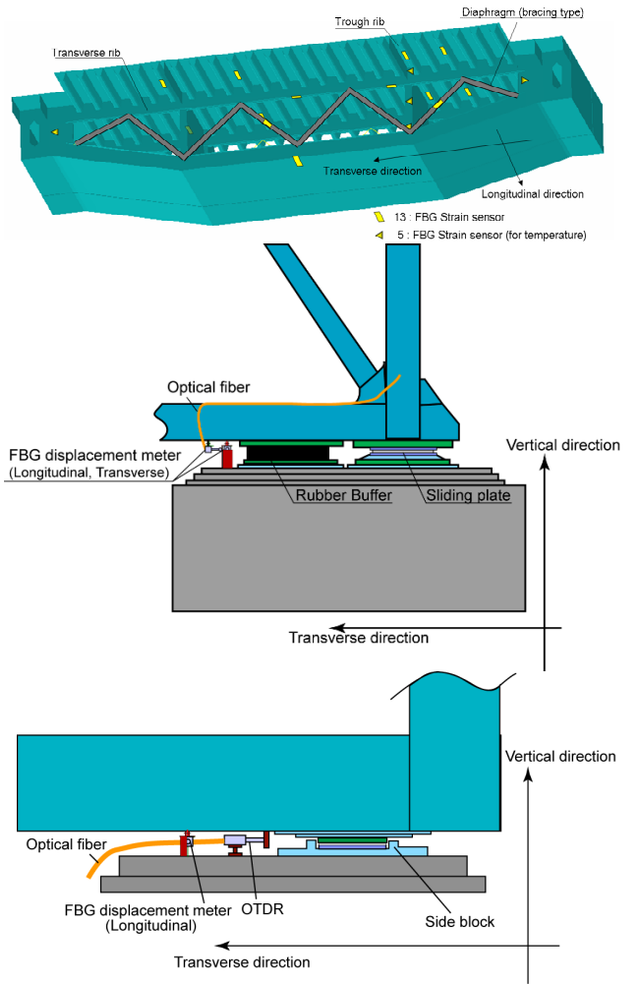

Figure 15. Sensor arrangements

tect thermal deformation. The thermal deformation is monitored with the FBG displacement sensors arranged in all bearings to movable directions.

The all sensors are connected by optical fibers. The optical fiber itself plays a roll of damage detection in this monitoring system. In case the optical fiber was cut, the location is able to be pinpointed from a remote station. Therefore, optical fibers run in the whole bridge to detect large deformation and breakage of the member.

Figure.16 illustrates the system flow from the data acquisition to indicated items by the monitoring system. In case OTDR detects the damage in the side blocks, the system immediately executes road closure and simultaneously indicates damaged parts.

7 CONCLUDING REMARKS

This paper described a design of a heath monitoring system for a base-isolated large-scale bridge. FEA revealed the structural responses, damage modes and those relations. Then, the sensor arrangement was proposed. Followings are the concluding remarks.

(1) For the sensor arrangement of BWIM, the effect of shift of the vehicle's running position on strain responses is clarified by using static FEA. The identified desirable points where the strain response is relatively large and less sensitive to the running position are: 1) in the bracings of the diaphragm for Lane 1 and Lane 4; 2) in the transverse rib for Lane 2 and Lane 3.

(2) The nonlinear dynamic FEA simulated the bridge behaviors, including the inelastic hysteretic property for the sliding part in the base isolation and the effects of attack angle of the earthquake. The results revealed that damage occurs initially at the side blocks in the bearings and secondary at the lateral bracings. Therefore, it is most important to detect damage of the side blocks which is the trigger of the subsequent damage procedure.

Testing of bridge structures using laser scanning method

W. Anigacz & D. Beben
Faculty of Civil Engineering and Architecture, Opole University of Technology, Opole, Poland
J. Kwiatkowski
J&L Consulting Jacek Kwiatkowski, Opole, Poland

ABSTRACT: The objective of the study was to compare and assess suitability of laser scanning method to determine geometric changes of the bridge structures. The laser scanning method was tested at two suspension bridges. First was a technological bridge (Chorula, Poland) with effective main span of 165 m, and second one was a historic cast iron bridge (Ozimek, Poland) with span of 27.7 m. The first measurements were conducted using a FARO Focus 3DX130 scanner. In the case of the second bridge (Ozimek), the results clearly indicate that reduced the distance to the bridge (40 m) allows to obtain satisfactory results, i.e. a full inventory of the bridge elements. Taking into account the above experience, the authors decided to use for the technological bridge examinations a Trimble TX8 scanner. It turned out that the Trimble TX8 scanner allows to obtain the technological bridge displacements under static loads. For the results analysis and point cloud pro-cessing, specifically designed the Trimble Real-Works 10.2 program was used. The software provides a complete solution to efficiently register, analyse, model and create deliverables using data from virtually any source. The software also allows for the automatic interpolation of the markers centre, which in this study constituted the measurement targets and white reference spheres (the same as in the photogrammetric method). The subsequent scans are matching to characteristic points (measurement targets and white reference spheres) in such a way that the next measurement sessions can be topologically consistent. This allows for significantly reduction of the working time on the measurement object. The obtained results were verified by the tachymetric method using the TC 2002 instrument. The presented approach to the bridge testing using scanner method can help in the bridges diagnostic, especially in the case there are not the technical project, for example for old bridges.

1 INTRODUCTION

Inventory measurements are usually performed on bridges in order to confirm project assumptions or as diagnostic tests to provide their proper maintenance. The results of bridge inspection are the basic source of information about technical conditions and occurred damages. They are obligatory in most countries all around the world and are performed on the basis of systematic strategy of transport infrastructure control. Typical measurements and research are usually conducted manually by bridge inspectors in several selected points. Most of inventory work requires a direct contact with structure, what, in some circumstances, may cause problems with object research availability and often requires scaffolding which increases inventory costs. In many cases of bridges, particularly historic ones, there is a lack of project documentation. It is a serious problem during modernization and/or conservation work. Inventory work performed with traditional methods is quite time consuming, especially when objects have complicated and complex structure, e.g. a truss structure. Non-contact tests methods of engineering structures have lately become very popular, for example the interferometric method (Anigacz et al. 2016, Beben 2011, Beben & Anigacz 2017) enables the bridge displacement monitoring even from a few hundred meters. Tachymetric and photogrammetric methods also experience revival thanks to modern equipments and computer analysis of results (Anigacz et al. 2018, Beshr 2015, Jauregui et al. 2003). The laser scanning method gives the possibility of obtaining a point cloud (Berényi et al. 2009, Kwiatkowski 2014, Shen-En 2012, Tang et al. 2006, Truong-Hong et al. 2016) and, as a result, this method may be successfully used in inventory of various engineering objects, particularly the ones with difficult access. Such action can be defined as a reverse engineering.

In this article the authors decided to verify the laser scanning method on the example of two suspension bridges. They analysed measurement capabilities of this method, i.e. the authors checked inventory work quality with the use of laser scanner

on a technological bridge (object #1) and historic cast iron bridge (object #2). Fast expanding measurement techniques, especially geodetic ones, in particular mass measurements enable obtaining complete information about an object and changes in its geometry. The measurements were conducted using FARO Focus 3DX130 and Trimble TX8 scanners.

2. SHORT DESCRIPTION OF BRIDGES

The studied structure no. 1 is a two-pylon steel suspension bridge over the Oder River intended for connecting the marl mine with cement factory with the transport line (Fig. 1). The bridge comprises five spans – four outmost flood spans and the river span. The structure of the transport gallery is suspended with hangers under the main bearing cables distributed over two pairs of pylons.

The load-carrying structure with span of 165.00 m is suspended on cables. The total length of the entire bridge structure is 285.00 m. The bridge was designed as a structure suspended on two steel pylons, through which a set of 2×6 bearing cables of 48 mm diameter. An orthotropic plate is placed directly on the longitudinal beams. The pylons with high of 26.50 m are supported by hinged steel bearings on reinforced concrete foundations. The cables are connected to the pylon in a fixed manner through a head and screwed connections that enable moving the cables on the pylon tip. The bridge is intended for transporting the limestone output with a belt conveyor placed in the transport gallery. Weight of the output transported through the bridge is 900–1100 Mg/hour, and the speed of the belt conveyor movement was 2 m/s.

Figure 1. Side view on the bridge in Chorula.

Object #2 is a historic suspension bridge in Ozimek (Fig. 2). Nowadays the bridge is intended for pedestrian traffic on the Mala Panew river. It was built in 1827 and is the oldest cast iron suspension bridge in Continental Europe. It is a suspension chain bridge completely made of iron (cast iron). Following this parameter it should be acknowledged as the oldest bridge of this type in the world existing till today. An older existing iron suspension bridge was built between 1819 and 1826 over the Menai Strait in Wales, however it is suspended on stone pylons. The parameters of the bridge are: a span – 27.7 m, axial spacing of pylons – 31.5 m, width of a bridge deck – 6.6 m. Complete renovation of the bridge was carried out between 2009 and 2010. It was disassembled, renovated and re-assembled. The bridge construction was strengthened with steal ropes.

Figure 2. Side view on the bridge in Ozimek.

3. RESEARCH METHODOLOGY

One of the most important factors determining a method selection is geometric specifics of an object. The analysed cases are linear objects with major spans of 165 m (bridge #1) and 27.7 m (bridge #2) in length. The span of a bridge is important because accurate determination of measurement point decreases with the increase of the distance. It should be considered in measurements of such type. The study was conducted after forty year of service of the bridge #1 and after a complete renovation of the bridge #2 carried out in 2010. The displacements of bridge #1 was observed during regular continuous 12-hour service loading. A displacements of river span was monitored. In the second case, due to the fact that the bridge is only a pedestrian crossing, the author used a laser scanning method as an inventory tool. The tests on both bridges were conducted for different distances between a scanner and a tested object, i.e. for the bridge in Chorula – about 110 m and for the one in Ozimek – 40 m.

a)

b)

Figure 3. View on the bridges in Ozimek and Chorula during testing using scanner: a) FARO Focus 3D X130, b) Trimble TX8.

The laser scanning method is a relatively new measurement method by means of which quasi-constant, spatial representation of a tested object can be obtained. It results in obtaining spatial point clouds of external surface of an object observed from the scanner position, i.e. in a central position. The accuracy of results depends mainly on the distance between a scanner and an object. In a last few years fast development of laser scanning has been observed. A scanner uses a laser beam which is reflected from the tested object and comes back to the scanner. The distance is determined by the difference in phase of sent and reflected radius. During the measurement a scanner can rotate 360 degrees horizontally. The horizontal and vertical angle settings of the scanner mirror and the information about measured distance are converted into local coordinates in the real time. FARO Focus 3DX130 scanner was used for the bridge testing (Fig. 3a) which measures to 1 million points per second and allows to create clouds exceeding a billion points. The producer's declared accuracy of distance measurement is ±2 mm and the angular resolution is 0.009° (0.16 [mrad].). Further scans are adjusted to characteristic points in the way the next measurement sessions are topologically coherent. It significantly reduces the fieldwork time.

It should be emphasized that the quality of the scan of the technological bridge was in the upper limit of this scanner coverage, i.e. 100-120 m. As it turned out later this limitation did not allow to obtain reliable results using this scanner. Taking into account the above experience, the authors decided to use for the bridge examinations a Trimble TX8 scanner (Fig. 3b).

This scanner measures up to 1 million of points per second and allows to create clouds of over a billion of points. The maximum scan range is 120 m, but it can be increased to 340 m. The wavelength of the laser is 1.5 μm and the scan frequency is equal 1 MHz. The declared accuracy of the measurement of the distance was ±2 mm, and angle resolution is 0.004° (0.08 [mrad]). The standard unit of resolution is dpi, so it means a dot per inch of the length. In the technical applications where the elements of the studied structures are located in different distances from the scanner, the angle resolution is the more convenient to use than the dpi which constantly changing with the change of the distance. The comparison of catalog data shows that the Trimble TX8 scanner has twice the angular resolution than the FARO Focus 3DX130 scanner.

For the results analysis and point cloud processing, specifically designed the Trimble RealWorks 10.2 (2017) program was used. The software provides a complete solution to efficiently register, analyze, model and create deliverables using data from virtually any source. The software also allows for the automatic interpolation of the markers center,

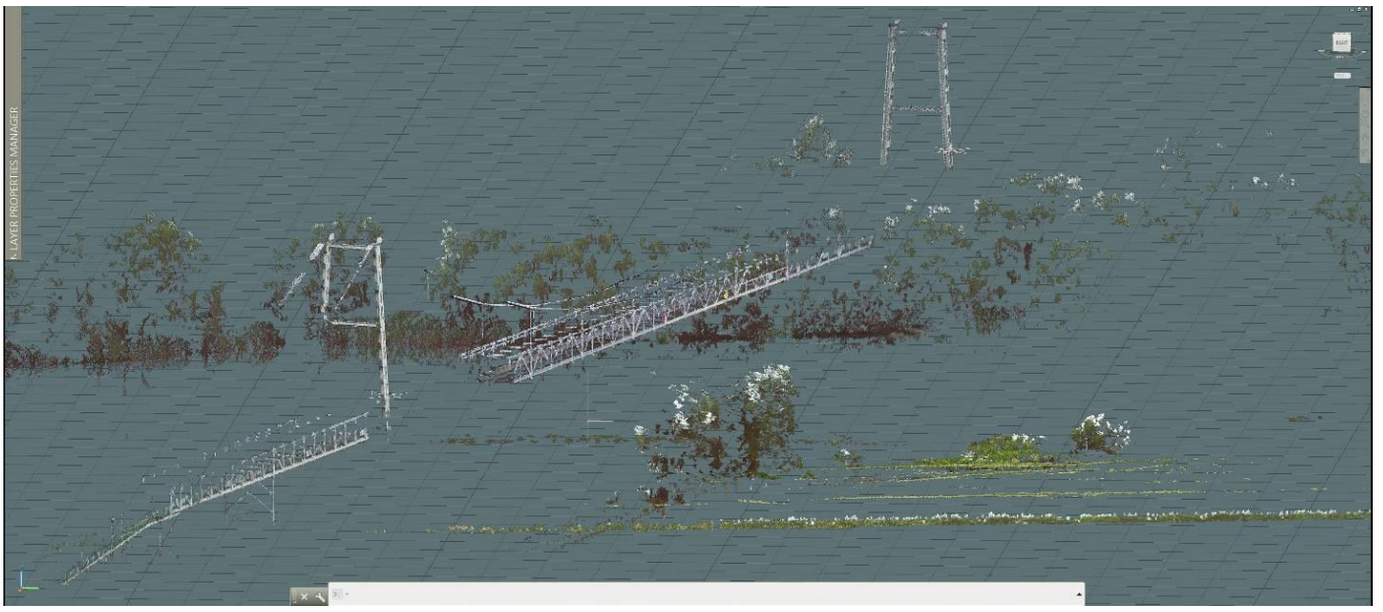

Figure 4. Scan of suspension bridge in Chorula using FARO Focus 3D X130 scanner.

which in this study constituted the measurement targets and white reference spheres (the same as in the photogrammetric method). Data from a scanner of such type are obtained in the .fls format. Conversion to the .rcs format was conducted with the ReCap360 software. Files with the extension .rcs are read by all the AutoDesk applications. The subsequent scans are matching to characteristic points (measurement targets and white reference spheres) in such a way that the next measurement sessions can be topologically consistent. This allows for significantly reduction of the working time on the measurement object (Kwiatkowski 2014).

The elaborated technology is particularly useful for a topologically complex structures. Automatically displaying colors using a calibrated map of the differences between scans (e.g. without and with load) allow to select the points on which should pay more attention.

4. TESTS RESULTS

During elaboration of results the scans were adjusted to characteristic points on a particular bridge in a way the following measurement sessions were topologically coherent. It significantly reduces the fieldwork time. It turned out that in case of the bridge #1 (in Chorula) the approach is inappropriate. The quality of the bridge scan was in the upper limit of reference range, i.e. 100-120 m. During the result analysis it occurred that the quality (points density) of a

Figure 5. Scan of suspension bridge in Ozimek using FARO Focus 3D X130 scanner.

Figure 6. 3D panoramic view of connected point clouds (FARO Focus 3D X130 scanner) for the Ozimek bridge.

scan is too low. Moreover, analysing the laser scanning bridge #1 test results it was stated that due to the lack of correlation (too big differences) with the results obtained from other methods the correctness is open to doubt (Fig. 4).

One of the most significant reasons of uncertain results of dislocation obtained from Faro Focus 3DX130 laser scanning was too large distance from the bridge #1 as well as the fact that the suspension bridge has an openwork structure which requires scans of bigger density than the ones obtained from the used scanner. To verify the test, the same scanner was used to conduct inventory work of a historic (the oldest in Europe) suspension cast iron bridge in Ozimek on the Mala Panew river. The tests were conducted at much shorter distance between the scanner and the bridge, i.e. 40 m. The recorded point cloud density allowed to identify the elements (details) of the bridge and in the result fully satisfactory results of bridge inventory were obtained (Figs 5-7).

As it was mentioned before, because of unsatisfactory measurement results taken with Faro Focus

Figure 7. Top view of the bridge in Ozimek using the FARO Focus 3D X130 scanner.

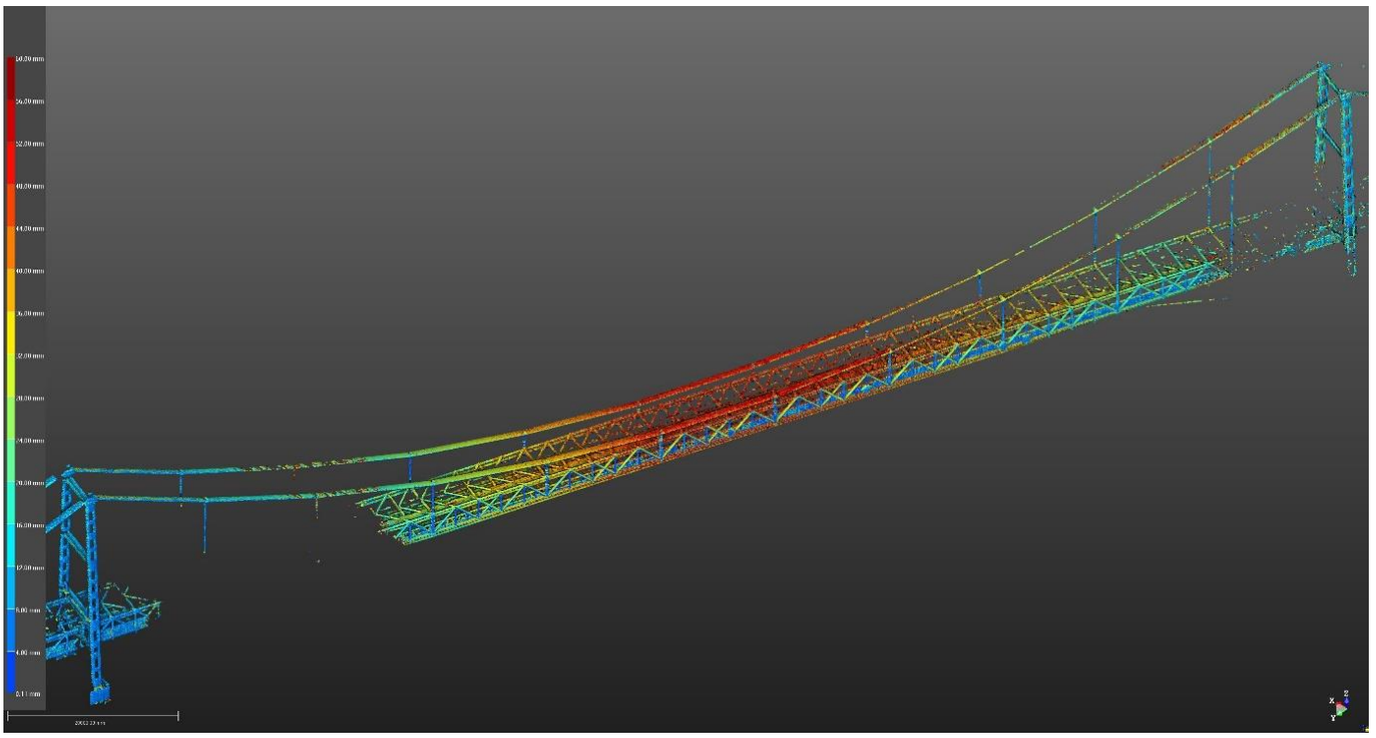

Figure 8. Chorula bridge deflections shown with using colours (a Trimble TX8 scanner).

3DX130 scanner, it was decided to repeat testing of the bridge #1 with the use of a different scanner, i.e. Trimble TX8 which has a wider range (up to 340 m). The obtained results of displacement from static load are satisfactory and fully convergent with the reference method (tachymetry method). Figure 8 presents an example bridge #1 scan with displacements as a map of colours. The red colour means the biggest displacements and the navy blue – the smallest ones. Maximum displacements of 49 mm were obtained in the middle of the main span and were recorded in a suspension cables and lower parts of transport gallery. Figure 9 shows the details of the Chorula bridge in the middle part of structure obtained by using a Trimble TX8 scanner. Table 1 presents the values of bridge 1 vertical displacements obtained by three compared methods for static load (conveyor belt with marl was stopped on the bridge).

The recorded laser scanner measurement session of the suspension bridge in Ozimek was supplemented with photogrammetric images of pixel size 0.5 mm (Fig. 10) and DISTO rangefinder direct

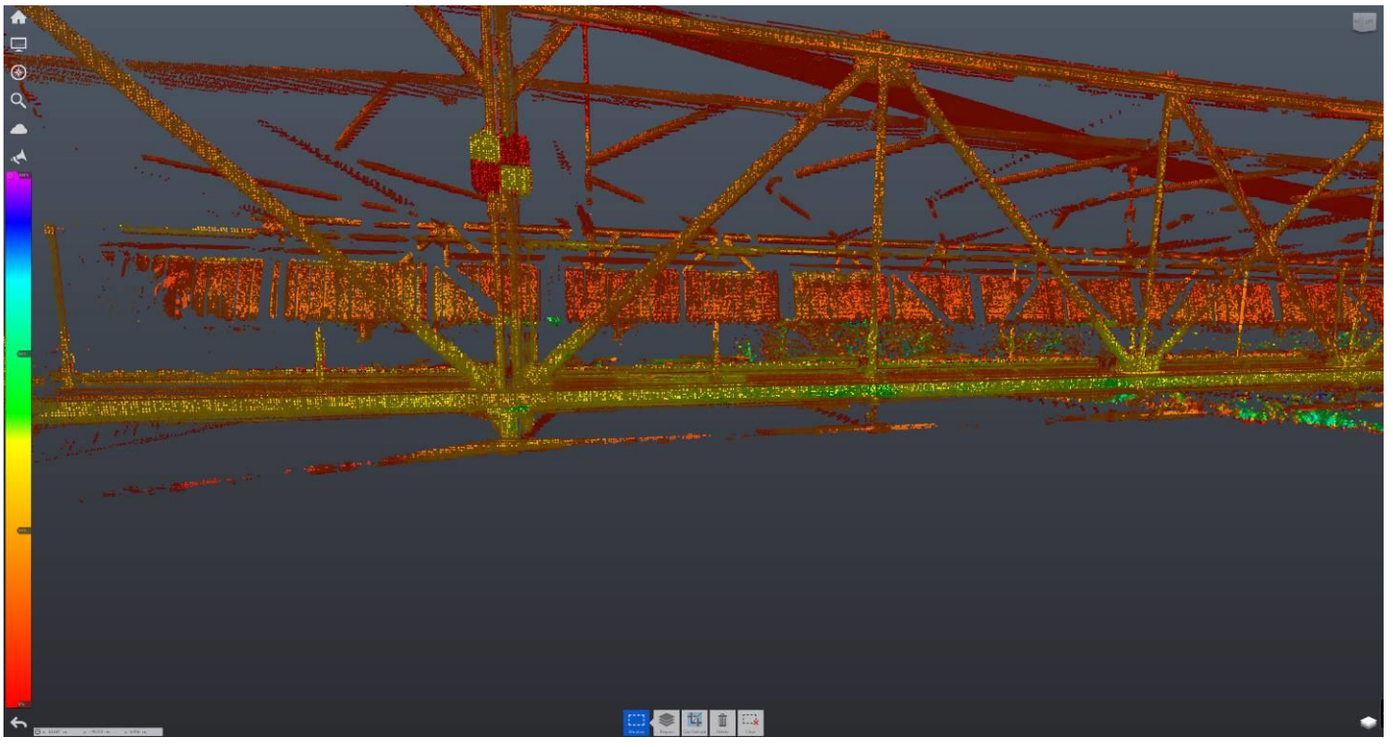

Figure 9. View of details of the Chorula bridge using a Trimble TX8 scanner.

Figure 10. The photogrammetric image of the bridge in Ozimek.

measurement. Considering the difficulties in distinguishing characteristic points, the differences between laser scanning results, photogrammetry and rangefinder measurements not exceeding 7 mm on the whole bridge length should be treated as fully acceptable.

Table 1. Comparison of the maximum registered displacements of the suspension bridge #1.

Measurement method	1/4 of span (mm)	1/2 of span (mm)	3/4 of span (mm)
Tachymetry	24.0	49.1	37.7
Photogrammetry	18	60	46
Laser scanning (FARO scanner)	*	*	*
Laser scanning (Trimble scanner)	19	49	38

Note: * - previous results obtained with the laser scanning using other scanner have been regarded as uncertain (too high discrepancy in comparison to other methods).

The bridge measurements in Chorula, was done with a Trimble TX8 scanner. Point clouds for the unloaded and loaded state clouds were obtained with a resolution of 5.7 mm at a distance of 30 m. This gave about 500 million of measurement points for a single scan. The unloaded state, has been registered on 5 measuring spheres to the loaded state with accuracy under 1 mm using the Trimble RealWorks Advanced Plant software version 10.3 (2017). Visualization of the deviation cloud between the unloaded and loaded state was obtained through an authoritative optimization approach that was then used for comparative analysis in the Trimble RealWorks Advanced Plant 10.3 (2017).

5. CONCLUSIONS

As a result of two suspension bridges measurements conducted with the use of laser scanning method, the following conclusions can be drawn:

1. Laser scanning method in case of Chorula bridge displacements measurements required the application of an adequate scanner, i.e. Trimble TX8. The results are convergent with the reference – tachymetry method. The use of Faro Focus 3DX130 scanner appeared to be less precise. It was the result of too large distance between the scanner and the bridge and too small angular resolution of a scanner (point density).
2. The measurements conducted on the bridge in Ozimek unequivocally indicate that decreasing the distance to a bridge (up to about 40 m) allows to obtain fully satisfactory inventory results. The scans present structure details with sufficient resolution and accuracy.
3. The obtained measurement results unequivocally indicate that there is no universal measurement device (a scanner) for different type of structures including bridges. Each time, before conducting such measurements, the type of a structure, its dimensions and estimated distance from a scanner should be considered. Thus it should be emphasised that the accuracy declared by producers is not always coherent with actual measurements. It is indicated in this paper, and one of the reasons could be a type of bridge construction, texture and colour of the surface.
4. The laser scanning method (the equipment and software) are currently one of the most expensive method of measurements. It would be ideal to use various methods (laser scanning, photogrammetry, tachymetry, and interferometry) at the same time when the bridge is examined.
5. The elaborated technology is particularly useful for a topologically complex structures like a truss bridges. Automatically displaying colors using a calibrated map of the differences between scans (e.g. without and with load) allow to select the points on which should pay more attention.

A study on diverse strategies for discriminating environmental from damage based variations in monitoring data

M. Baeßler & F. Hille
Department Safety of Structures
Bundesanstalt für Materialforschung und -prüfung (BAM), Germany.

ABSTRACT: Right from the beginning of applying SHM to bridge structures it was obvious that environmental based perturbations on the measurement significantly influence the ability to identify structural damage. Strategies are needed to classify such effects and consider them appropriately in SHM. Various methods have been developed and analyzed to separate environmental based effects from damage induced changes in the measures. Generally, two main approaches have emerged from research activity in this fields: (a) statistics based tools analyzing patterns in the data or in computed parameters and (b) methods, utilizing the structural model of the bridge taking into account environmental as well as damage based changes of stiffness values. With the back-ground of increasing affordability of sensing and computing technology, effort should be made to increase sensitivity, reliability and robustness of procedures, separating environmental from damage caused changes in SHM measures. The contribution describes both general strategies and points out their advantages and drawbacks. As basis, a review on relevant methods was conducted. The aim of the study is to classify approaches for separating damage describing information from environmental based perturbations in dependency of the SHM objective. And such, it is intended to describe a best practice in designing concepts for monitoring infrastructure, naturally effected by environmental influences.

1 INTRODUCTION

Conducting vibration based investigations on the steel-concrete composite Alamosa Canyon bridge in New Mexico, a research group of the Los Alamos National Laboratory reported in (Farrar et al. 1997, Cornwell et al. 1999) about significant variations of approximately 5% in the first mode frequency during a 24 h time period. They also observed similar variations for the frequencies of the other modes. Also investigating the influence of vehicle loads passing on the bridge but did not find a significant effect on the measured modal frequencies of the bridge. Another bridge, investigated by this research group was the I-40 Bridge over the Rio Grande in New Mexico, a steel-concrete composite bridge with welded steel girders. Artificial damage was induced to the bridge by making various torch cuts in the web and flange of the steel girders. In (Farrar and Jauregui 1996) it is reported that the effect of damage to the first three eigenfrequencies is in the same range then the effect of varying temperature.

Liu and DeWolf (2007) investigated the effect of temperature on modal variability of a three-span box girder reinforced concrete bridge. For the duration of one year they measured the dynamic response of the bridge to ambient excitation with accelerometers. They analyzed the first three modes and they found the maximum measured difference in the first three eigenfrequency during the year of about 5-6%. They proposed fitting a linear line to characterize the relationship between temperature and eigenfrequencies for the first three modes. Also on a skewed three-span box girder (Wahab and De Roeck 1997) investigated the seasonal effects of temperature variations and also reported changes in natural frequencies up to 5%. Fraser et al. (2010) determined the temperature based variations of the first four eigenfrequencies of a four-span concrete box girder bridge. The study revealed frequency variations of 7-13%. Peeters et al. (2001) determined the temperature based variations of the first four eigenfrequencies of Z-24 bridge, a post-tensioned concrete box girder bridge in Switzerland. The study revealed frequency variations of 14-18%.

Xu and Wu (2007) studied also the temperature based effect on mode shape curvature of a three-span cable-stayed bridge by numerical simulation and compared the effect of dam-age and temperature variations on these modal properties. They showed variations of the modal frequencies in the bridge of 2%

under variation in temperature of 40K and variations in the mode shape curvatures of 1-8% at different locations along the bridge. They also showed that frequency changes due to damages, induced in the bridge girders and cables, were less than those due to temperature variations. To eliminate the masking effect of temperature based variations on damage detection and condition assessment procedures in SHM different approaches have been proposed in the last decades by the research community. Generally, two different approaches are pursued, first utilizing statistical models to filter out the temperature induced perturbations on the monitoring data and second, utilizing physical models to compute the effect of varying temperature on the behavior of the structure. This paper shows an overview about ways gone to accounting for temperature as well as a set of questions regarding temperature loading, as occurred during application of SHM on bridge structures.

2 STATE OF THE ART

2.1 *Methods based on statistical models*

Statistical methods are solely based on measurement data without using any geometrical or material information describing the behavior of the observed structure. To eliminate the effect of varying environmental perturbation in time series signals and in damage indicating feature time series, data is processed utilizing statistical models. For sustaining robust and reliable results, continuous monitoring in an appropriate measurement period, generally several years, is mandatory.

During the recent decades, several algorithms utilizing different statistical models are adapted and analyzed by the research community. Principally, two different approaches can be distinguished, including or not including the environmental factors into the computation.

One of the most common used underlying statistical models are regression models (Laory et al. 2011, Peeters et al. 2001, Xia et al. 2012). Sohn et al. (1999) used a multiple linear regression model to vibration measurement data and analyzed, if new processed natural frequencies that model at a defined confidence level. Also in (Magalhes et al. 2012) a multiple linear regression model is used to remove the effects of environmental and operational based variations on a concrete arc bridge, taking into account 8 concrete temperature and one air temperature signals. Further, auto-regressive models (AR) and their derivatives are used to account for the relation between measured or processed structural parameters and temperature. Peeters et al. (2001) applied an auto-regressive model with an exogenous input (ARX) to detect damage on the Z-24 bridge utilizing vibration measurements. In (Omenzetter and Brownjohn 2006) the application of auto-regressive integrated moving average model is proposed to detect damage from strain measurement.

Since it is partial challenging to measure the acting environmental parameter statistical models were utilized which do not include direct measurements of these variables but instead treat them as embedded but hidden variables (Shokrani et al. 2016). Several statistical techniques have been developed to normalize data for filtering out periodical, temperature related effects.

In (Yan et al. 2005a, Yan et al. 2005b) the principal component analysis (PCA) is applied to separate the temperature effect and successfully detect damage on experimentally and numerically generated data. Figueiredo et al. (2011) proposes auto-associative neural networks (AANN) to characterize the dependency of the features on the unobserved environmental factors by treating it as hidden intrinsic variables in the network architecture. Kullaa (2003) and Lms and Kullaa (2007) employ factor analysis (FA) for removing varying effects from environmental influences. Factor analysis performs a decomposition of the correlation matrix of observed features.

In (Basseville et al. 2010) a subspace based damage detection method is extended by two statistical algorithms for handling the temperature effect. One approach updates the null-subspace of a matrix built on a reference model by data from different temperature scenarios. A second proposed approach handles the temperature effect as a nuisance parameter rejecting the temperature effect.

2.2 *Methods based on physical Models*

To identify and describe damage robust and reliable by structural health monitoring the utilization of physical models is mandatory. Especially when taking into account the environmental influence related variations in the structures response, the distribution of stiffness parameters of the structure need to be considered for localization and quantification of damage. The application of physical model often is a complex and costly for several reasons. To determine the distribution of stiffness related structural proper-ties of a civil engineering structure in an adequate detailedness and accuracy can be very challenging. Also, on the computational level, the solution of the model updating intrinsic inverse problems might also be a demanding task.

Physical model based approaches for the identification of structural damage with the consideration temperature caused disturbances are described in several publications. Rohrmann et al. (2000) analyzed the vibration response of the Westend bridge in Berlin using a used a thermo-mechanical model. It is shown, that the influence of the temperature depending stiffness of the asphalt layer is significant.

Meruane and Heylen (2012) developed a physical model based damage detection procedure which employs a genetic algorithm for optimization to solve the

inverse problem. They successfully tested the method on simulated and experimentally generated data of the steel-concrete composite I-40 bridge.

Gonzales et al. (2013) investigated a ballasted concrete railway bridge in north Sweden and proved large dependencies of the dynamic response by the temperature variations in the ballast and the ground, especially during frost. For model updating a Bayesian updating scheme was employed.

3 THERMAL STRESSING OF STRUCTURES

3.1 *Influences on the temperature field in bridge structures*

To include the effect of temperature loading to the computation of structural responses it is necessary to account for the influencing thermal processes and principles. For determination of the temperature field in a structure, the heat transfer on the structures surfaces together with the boundary conditions by the surrounding environment is decisive. Heat transfer describes the exchange of thermal energy between the physical systems and consists out of the three general parts: conduction, convection and radiation. The heat transfer of a structure exposed to the natural atmosphere is dependent on the following influences: ambient air temperature, wind speed, rain, ice, humidity, global radiation of the sun (direct and diffuse radiation), reflection of the global radiation of the sun, atmospheric radiation, radiation of the environment and reflection of the radiation, heat radiation of the component as well as evaporation and condensation (Figure 1).

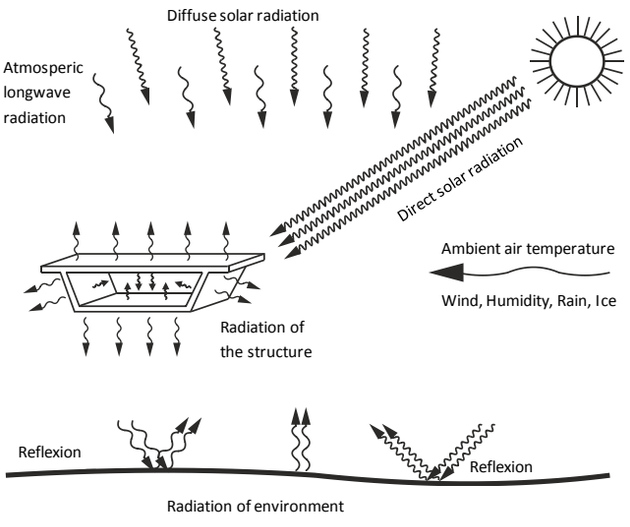

Figure 1: Influences on the heat transfer process

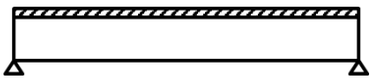

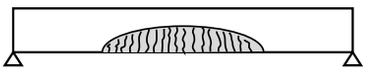

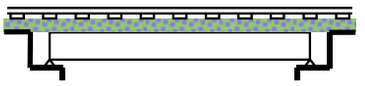

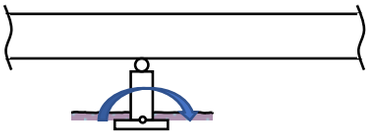

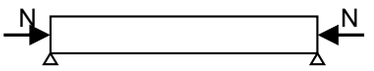

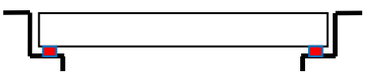

To determine the temperature field of a structure, the knowledge of the measured meteorological data in its characteristic course of the day and of the year as well as realistic data of the thermo-physical material characteristics such as emission coefficients, thermal conductivity or specific heat capacity are necessary.

But even accounting for the general thermal parameters in the temperature field computation, especially for comparative studies one should be aware, that most of the processes are transient and thus two equal states of temperature distribution on a bridge structure are hardly feasible.

3.2 *Thermal structural behavior*

Temperature changes on structural members cause mechanical stresses due to the thermal coefficient of expansion. For bridges, which generally act as beam-like structures, this can affect non-constrained strains, constrained and inherent thermal stresses as well as translational and/or rotational displacements of structural components or of the total structure. In reinforced concrete structures, thermal stresses can lead to the formation of cracks and therefore to temperature depending varying structural cross-sections (stiffness).

Table 1: Temperature influence on structural components.

a) Asphalt layer: strong dependency of stiffness on temperature 
b) Reinforced and prestressed concrete: stiffness can vary for E depends on temperature and humidity and cracks or coupling joints might open with temperature 
c) Ballasted Track: stiffness changes with temperature 
d) Structure soil interaction: stiffness at columns and at abutments can be frost dependent 
e) Axial forces: for constrained slender structures, axial forces and vibration modes are coupled 
f) Bearings: typical bearing materials can behave temperature dependent 

If the material behavior of a homogeneous region itself is temperature-dependent (e.g. asphalt layer),

additional considerations are necessary to assess the effect of the temperature field.

The compilation of temperature influences on structural components in Table 1 is based on experiences from bridge measurements combined with theoretical considerations.

4 EXAMPLES

4.1 *Indifferent: temperature-dependent behavior is low or eliminable*

Especially in the case of bridges that are free of constraints it is to be expected that the temperature influence can be neglected. Although, task depending, it can be necessary to eliminate the influence of temperature.

Figure 2: View and cross-section of Putlitz Bridge in Berlin

Figure 2 shows the view of the Putlitz Bridge in Berlin and its cross-section. Longterm measurements at the bridge deck have resulted in large temperature-dependent movements of the bridges end sections (Figure 3). The structure responds to the temperature effects with significant deformations. However, a consideration of the vibration behavior over the temperature of the structure shows only a weak influence of the temperature (Figure 4). It shows, that in this case an influence of the temperature on the load bearing behavior is negligible.

Performing load monitoring traffic induced strain and temperature signals can be separated without loss of information. The longterm daily and annual periodic variations then don't have to be accounted for.

4.2 *System identification of a temperature-dependent structural behavior*

Measurements are also carried out to identify a dynamic structural behavior. In the case of a dynamic structural analysis, there is no verification to the safer side, the dynamic behavior of the structure must be considered in its actual limits to take account of resonance effects.

For example, according to DIN EN 1990 A2 or DIN 1991-2 the dynamic behavior of the railway

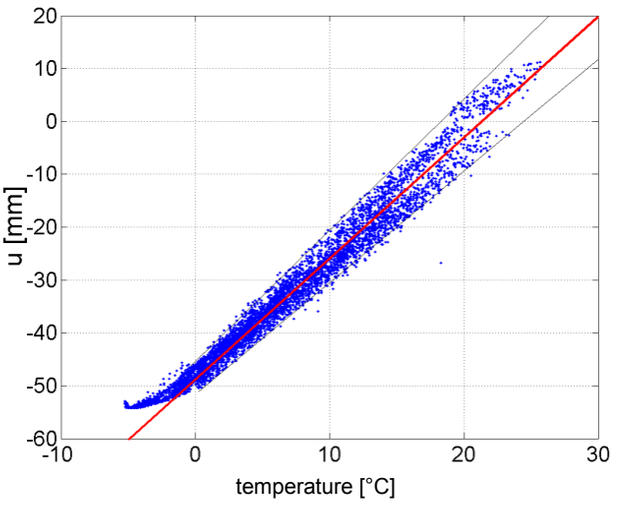

Figure 3: Temperature related movement of end sections of Putlitz Bridge

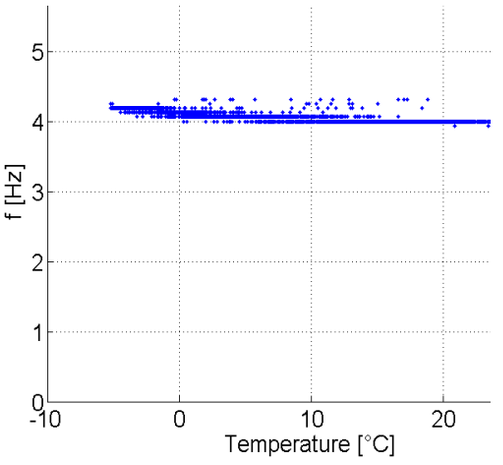

Figure 4: Temperature related natural frequency of Putlitz Bridge

bridges during the train crossing must be considered for the safety verification of high-speed railway bridges. Particularly, regarding fatigue and the limitation of maximum acceleration amplitudes of the bridge deck, considerable dependencies on modal parameters of the bridge structure can occur. In addition to the vehicle-related aspects such as axle loads and clearance as well as driving speed, realistic data of the bridge structures stiffness is fundamental. Structural measurements can be used to identify the real structural behavior.

However, it has been shown that the seasonal variation of the bridge stiffness parameter of have a strong effect on the dynamic response of the bridge structure. Gonzales et al. (2013) and Zabel et al. (2007) have reported on these seasonal influences in particular and determined the temperature-dependent behavior of the superstructure as decisive. However, an experimental proof of the described temperature dependent stiffness changes of the ballast superstructure still does not exists. Although, regardless of the physical matter, it is important to determine the structural behavior over the complete temperature range. Struc-

tural measurements are of great importance.

4.3 *Assessment of load bearing capacity*

The aim of Structural Health Monitoring (SHM) is the measurement based assessment of the load-bearing capacity of a structure.

In detail that means to detect damage, to identify changes in load bearing capacity and to determine the safety level. It is essential to correctly evaluate temperature influences. The basic principles of an SHM strategy are shown in Figure 5.

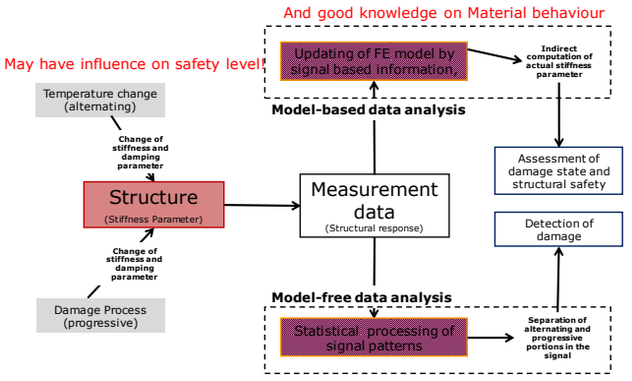

Figure 5: Schematic diagram of Structural Health Monitoring

Generally, the main challenge of a global state monitoring is the provision of an adequate sensitivity of the damage detection methodology for essential damage scenarios. Damages in their initial stage on robust structures as reinforced and prestressed bridges are normally not activated by existing traffic load. Accordingly, no changes in the stiffness ratios are detectable, and thus the damage cannot be detected by means of a measurement of global structural parameters based on the dynamic response. This situation must always be considered in planning monitoring systems for bridge structures.

For a physical model based monitoring of the structural state, a model in high quality is required to provide a connection between system identification and monitoring variables on the one hand and the related load-bearing evaluation on the other hand. For a typical reinforced concrete cross section, this also means that temperature dependent changes in the load bearing behavior must be assessed correctly. Figure 6 shows two cases: In case (1), the structure reacts stiffer due to the carrying effect of the asphalt layer. In terms of safety evaluation, however, this stiffness share is not taken into account. In case (2), the change in the load bearing behavior during crack formation, for example from temperature dependent constraints and inherent stresses, is shown. In the sense of safety assessment, this leads to a reduction of the load bearing capacity in the sense of stability assessment. Those distinctions are elementary for an evaluation.

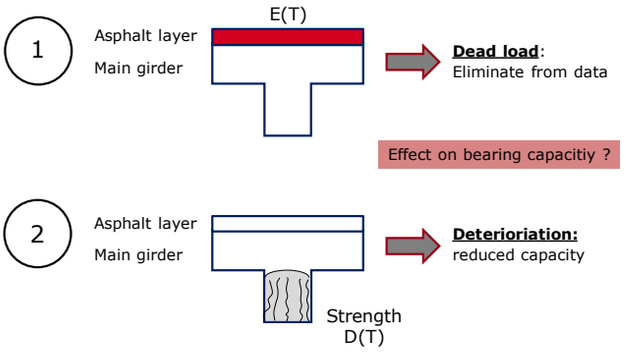

Figure 6: Stiffness changes with different relevance for structural safety

4.4 *Changing the stress situation and the load on coupling joints*

Due to constrained and internal stress conditions on reinforced concrete cross sections, changes in the stressing can occur. In particular in coupling joints, the durableness of the coupling element needs to be verified. Due to poor planning principles for temperature loading of bridges in earlier times, this issue has to be taken into account in particular in the cases of existing structures.

Figure 7: Westend bridge, Berlin

The Westend Bridge in Berlin (Figure 7), which is heavily traffic loaded for several decades, had suffered a series of damage since its erection. This repeatedly required strengthening actions to ensure an adequate load bearing capacity over time. Among other defects, it was found that the coupling joints of the bridge deck had opened. Under the influence of external loads and temperature changes, significant changes in the joint width were observed during inspection and finally monitored by measurement. It was found that, from a certain temperature the crack width of the joint increased disproportionately under traffic load. At the same time, selected vibration measures increased erratic. Obviously, the stress caused by traffic at high temperatures activates additional nonlinear deformation components, which lead to changes in the static dynamic system and are reflected in the additional expansion of the coupling joints. This effect can cause a strong fatigue-inducing effect on the prestressing reinforcement in the region of the coupling joints, especially as at the same time a corrosive attack of the tendons in the coupling joints

has been determined.

Furthermore, it was observed that during the summer months longitudinal cracks were formed in the floor and side slabs of the box girder, which most likely are originated in a temperature induced exceeding of the concretes tensile strength in these areas. The reason for those relatively high tensile stresses is the unfavorably flat cross section of the box girder bridge deck.

Here too, the question arises, to which amount those longitudinal cracks affect the static system (the stiffness of the box girder) and, in particular, lead to a change in the stress conditions under traffic loading.

4.5 *Physical relations from correlations*

For the evaluation of the structural behavior as a function of the temperature loading of a bridge it-self, it is important to establish a relationship be-tween the temperature load and the changed behavior of the structure. From the example of the frequency monitoring over several years at the Westend Bridge there is a significant dependency between frequency and temperature. However, the structure itself is conceivably unfavorable for a corresponding analysis. The flat cross section of the bridge deck is influenced by several non load carrying structural components such as caps, railings and asphalt layer. Due to the compact, multi-celled design, temperature load causes severe constraints within the cross section, which were not considered adequate in the bridges design. In addition, there are non-distinctive boundary conditions for further elements such as the columns, which are also influenced by the seasonal measures.

In order to understand the structural behavior, various attempts have been made in the past to model the structure. Among others a system identification of the thermal model was conducted using real meteorological data. In general, a very good conformity of the model based with the measurement based determined temperatures in the webs of the box girder was achieved. On this base temperature curves and derived parameters such as temperature gradients could be determined for several months periods.

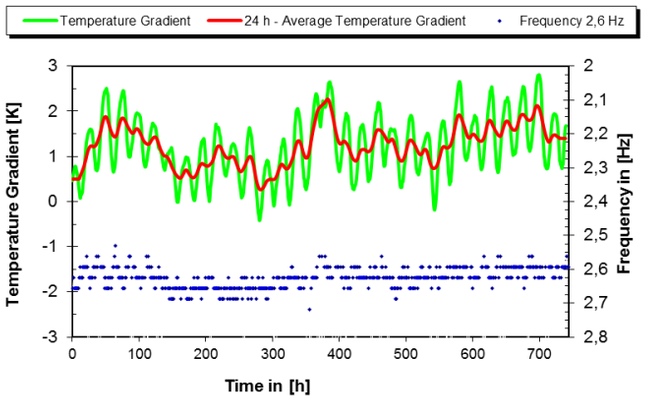

Figure 8: Vertical temperature gradients and natural frequency at 2.6 Hz

However, the example of the Westend bridge shows with the exemplary illustrations in Figure 8 for the temperature gradient and Figure 9 for the mean asphalt temperature that a simple and significant correlation between temperature characteristics and the measured values of the natural frequency in the given resolution is difficult. It is shown, that from the correlation of individual parameters alone a unique mode of action cannot be derived. It becomes comprehensible that probably several influences on the structural behavior do overlap. In the present case, the complex numerical model has too many influencing factors, so that a direct derivation of a temperature dependent structural behavior is not possible.

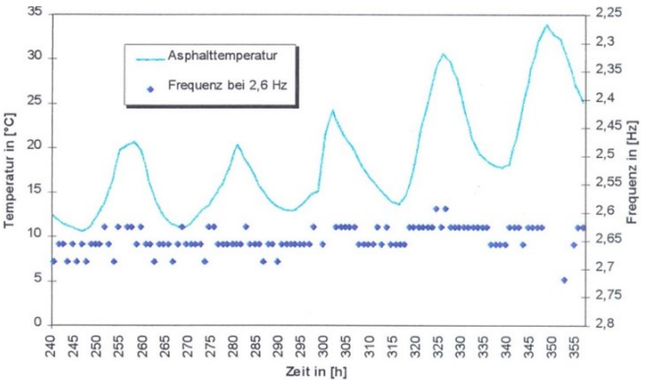

Figure 9: Asphalt temperature and natural frequency at 2.6 Hz

4.6 *Statistical Assessment*

If a simple correlation cannot be represented and a complete physical interpretation is not possible, (physical) model free statistical methods show that structural changes can be derived from longterm measurements. Although there won't be quantitative information of the present safety level, the added value exists for significant variations in the structural response can indicate damage based structural changes.

Utilizing statistical analysis of measured values or of signal-analytic computed dynamic parameters, it is possible to separate temperature-dependent periodic variations from changes caused by damage in the structure. Thereby the structural parameters of the system (geometry, material) and the corresponding physical model remain completely unconsidered. This can reach to a significant advantage compared to the (physical) model-based consideration of temperature influences, since in practice it is difficult or impossible to model the structure in sufficient accuracy. Since only changes in the time signals are analyzed by statistical methods, they are particularly suitable for long-term monitoring of civil engineering structures.

Hu et al. (2015) evaluates dynamic parameters of the Westend Bridge in Berlin for a period of 14 years (Figure 10). The non-linear relationship between the natural frequencies and temperature is determined utilizing a polynomial regression function of 4. order to

remove the temperature effect. For detecting structural changes in the system, the resulting residual is then examined by means of the novelty detection methodology. As shown in Figure 11, a change in the damage index can be shown statistically. Distinct changes in the index show the user that significant changes occurred in the chain from structural reaction to measure recording.

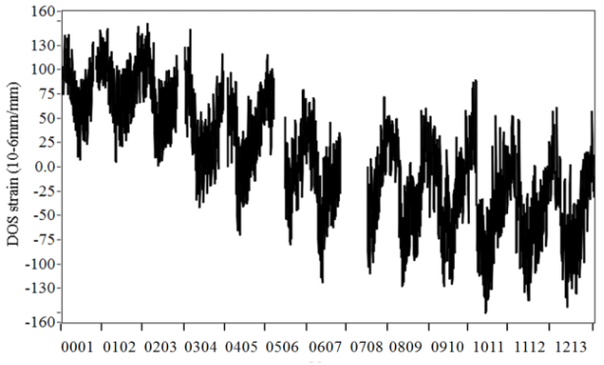

Figure 10: Decrease of strain in the prestressed cable

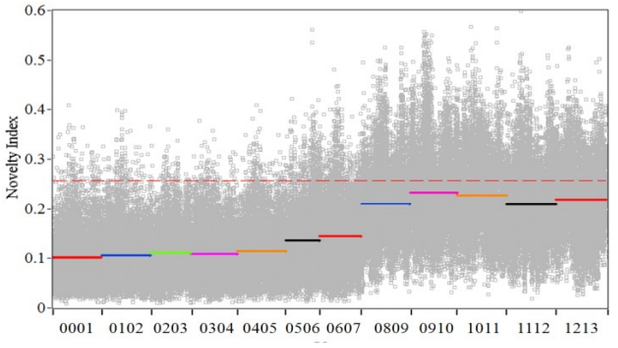

Figure 11: Variation of novelty index

5 CURRENT ACTIVITY

A better understanding of the physical behavior and how it is affected by temperature is crucial for an improvement of strategies dealing with environmental effects in SHM. Current research at BAM includes physical testing of specific materials and construction types relevant for bridge structures using laboratory test devices for thermo-mechanical loading. The aim is to classify and predict the various influence factors as given in table 1. Furthermore, research is focusing on damage detection methods with localization to specify where structural changes take place (Bhuyan et al. 2017, Viefhues et al. 2017). The influence on structural reaction needs to be understood for each individual bridge structure. Also, strategies for elimination or allowance of environmental effects have to be robust regarding measurements at real structures affected by complex environmental issues and other boundary conditions. As a first step research is under way with a test bridge (Figure 12) including various measurement devices and possibilities for loading and

Figure 12: Test (bridge) structure BAM project BLEIB

structural changes like lowering the prestressing. The future focus will also be on additional monitoring of exemplified real bridge structures sensitive to temperature loading.

6 CONCLUSIONS

On the basis of various examples, it was discussed how thermal stresses in a building monitoring system are visible and how they are to be assessed. In particular, the influence on the condition assessment in the sense of stability is often a great difficulty. For example, a fundamental possibility is to keep a load-bearing structure always at its weakest phase, that is, usually in the summer. As shown, statistical methods may also be suitable for detecting load-bearing changes.

Improved detection algorithms and improved physical models defining the mechanical behavior of structures are regarded as essential future tasks.

The acceptance of vibration-based methods for the detection and localization of damages in practical application is solely dependent on the ability to eliminate influences from changing environmental and operating conditions, but in particular from the temperature. Since the stochastic methods for damage detection and localization, which have become more and more important in recent years, use the (statistical) characteristic of the measured data implicitly, the development, adaptation and application of statistical algorithms to eliminate the varying environmental influences are obvious.

On the other hand, the seasonal influence on building surveys is presented in a large number of publications, and often reasoned physical connections are shown for the behavior. As a rule, however, the statements are not experimentally verified and of a rather general nature (“asphalt reacts temperature-dependent”). Objective-specific connections, determined, for example, by an attempt at representatives in the climate chamber, could be very helpful.

Automated operational modal analysis of a lively footbridge for tracking long term dynamic behaviour

De-hui Tang & Wei-hua Hu & Jun Teng
Harbin Institute of Technology Shenzhen Graduate School, ShenZhen, China
Elsa Caetano & Álvaro Cunha
Faculty of Engineering (FEUP), University of Porto, Porto, Portugal

ABSTRACT: A continuous dynamic monitoring system was installed at Pedro e Inês footbridge, located in Combra, Portugal, in 2007 by the CONSTRUCT/Vibest research group from the Faculty of Engineering of the University of Porto (FEUP). Such a system was further developed for research purpose by implementing an automated operational modal analysis procedure, in order to track the footbridge's long term dynamic properties and detect early structural modifications. Modal parameters are identified by automated Covariance based Stochastic Subspace Identification (SSI-COV) technique. Their variations are tracked and the influence of temperature is analyzed. With the final purpose of detecting potential structural modifications at an early stage, the Multiple Linear Regression (MLR) method is employed to effectively eliminate temperature effects. Novelty analysis on the residual errors of the MLR model is established to provide a statistical structural health index. During five years from 2007 to 2012, a clear deviation of the proposed health indicator suggests a slight long term modification of the footbridge.

1 INTRODUCTION

The new Pedro e Inês Footbridge was developed along the two banks of the Mondego River at Coimbra, Portugal, and opened to pedestrian traffic in April 2007. The total length of the bridge is 275 meters, consisting of a main shallow arch with 110 m chord and two half arches with chords of 95 m and 70 m.

A special feature of the bridge is the anti-symmetry of both arch and deck cross section along the longtitudinal axis in Figures 1. This particular geometry leads to the existence of a central plaza at mid-span and results in a complex torsional behaviour under vertical loads.

The central arch is supported by two groups of vertical piles with a depth of about 30 meters. The silt/clay soil layers beneath the river bed have poor mechanical characteristics and the horizontal stiffness provided by these foundations is low. Consequently, the arch-effect is expected to be reduced, leading to mixed arch/girder behaviour. The supports provided at the abutments and at the left bank intermediate column allow the longtitudinal displacement of the deck and block the transverse movements [1].

The east abutment contains two 6 meter spaced support alignments (alignment 1 and 2, Figure 3 and Figure 4). For structural reasons it was found adequate to establish symmetrical bridge behaviour in relation to the west side of the structure. For that purpose, a clamped support condition was designed. A vertical downward displacement was imposed in alignment 2 with resource to a post-tensioning system. The bridge deck was locked with bearing support devices which are free to move longitudinally. With this mechanism a binary of forces V was created providing a clamped support for the deck in the east abutment [1].

In order to investigate the long behaviour of the footbridge under operational conditions, six uniaxial piezoelectric accelerometers (PCB model 393C) are installed at the positions corresponding to the lateral and vertical TMDS. Five of them (AV1-AV3, AV5-AV6) are used to measure vertical acceleration while the last one (AT4) is used to measure the lateral response at mid span in Figure 2. Meanwhile, temperature sensors are installed to provide temperature data of ambient environment.

All the accelerometers are connected to a signal conditioning located at the east abutment. Then a digital computer which contains an analogue to digital converter is designed to store the resulting signals.

The integrated long-term dynamic acquisition system continuously records the structural response from the 6 accelerometers with a sampling frequency in 100Hz and 6 temperature sensors with a sampling frequency of 1/3600 Hz. The latest acceleration and temperature files are sent to a computer located at FEUP which is connected to internet. For faster

transmission, the acceleration signals are decimated to 20Hz. The system has been in operation from 1st of June 2007 to 1st of June 2012 and in particular has transmitted five years of continuous data except for occasional interruptions due to small technical problems.

To ensure a good performance of the stabilization diagram, the data in one hour is used for automatic identification of the natural frequencies, mode shapes and modal damping ratios based on Covariance-driven Stochastic Subspace Identification (SSI-COV) methods [2,3].

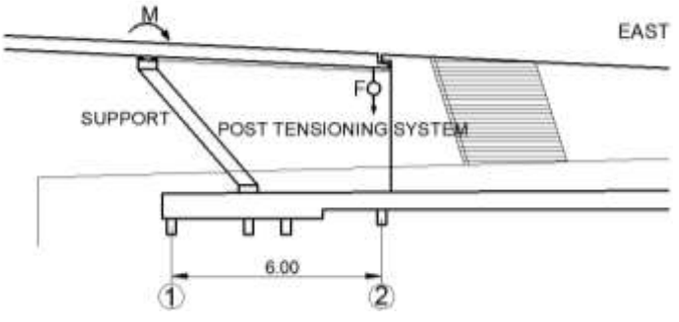

Figure 3. Imposed vertical displacement

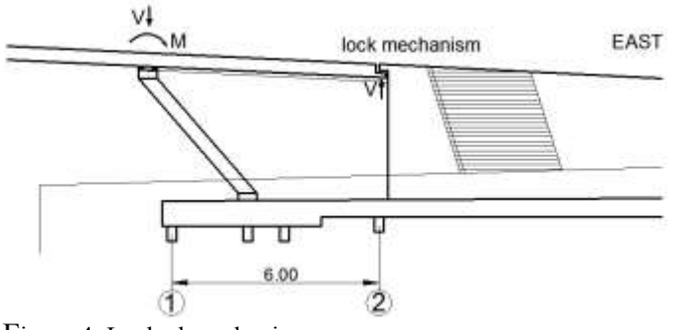

Figure 4. Locked mechanism

2 AUTOMATIC SSI-COV ALGORITHM

The automatic system identification procedure based on SSI-COV algorithm is implemented in the CSMI toolkit. It comprehends two steps: construction of stabilization diagram and cleaning of stabilization diagram.

2.1 *Construction of stabilization diagram*

Correlation functions with a maximum length of i points is used to estimate the state-space model. The minimum and maximum system order is m, n respectively and the stable poles are set in a fixed increment j (m, n, j). Poles are defined as stable pole when the relative differences in the natural frequency (δf), modal damping ratio ($\delta\xi$) and modal assurance criterion (MAC) values between poles of adjacent orders are below the following threshold values:

$$\delta f \le 1\% \tag{1}$$

$$\delta\xi \le 10\% \tag{2}$$

$$(1 - MAC) \times \% \le 5\% \tag{3}$$

In addition, the stable poles having unrealistic damping ratios (e.g. $\xi \ge 10\%$) are discarded.

2.2 *Cleaning of stabilization diagram*

As shown in the Figure 5, the stable poles are concentrated around the structural natural frequencies, while the spurious or numerical poles which interfere with the automated estimation of modal parameters are isolated. Irregular numerical poles between 2~4 Hz may induced by human walking, running and jumping and a few regular spurious poles may result from ambient noises. Comparing with the stable poles, the spurious poles distribute discretely, therefore, these spurious poles can be sort out by treating all poles between minimum and maximum order as follows:

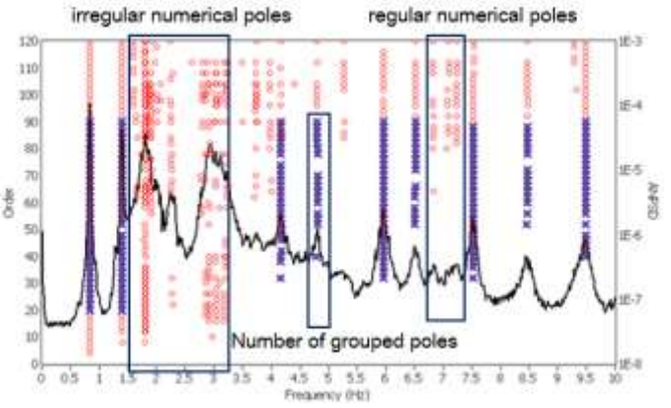

Figure 5. Stabilization diagram

(a) According to the different modal parameters represented by the poles in the minimum order, Poles are divided into different groups; (b) In the (m+j) order, if the relative difference of modal parameters is smaller than the threshold prescribed in (1), the new poles are incorporated into the corresponding groups, however, if there are any poles in (m+j) order which do not match with any groups defined in

the previous step, a new group is defined; (c) Applying Step (b) to the poles from ($m+2j$) to the maximum order and ensuring all poles are grouped; (d) Counting the number of poles inside each group and averaging all the modal parameters of the same group. (e) Finally, setting the threshold for the numbers of poles p, the groups whose poles numbers are smaller than the threshold are removed.

The parameters (*i, j, m, n* and *p*) which used for the automated modal identification in each application are defined according to the quality of the continuous dynamic monitoring results. The modal parameters are estimated by averaging the frequencies, damping ratio and mode shape vectors within the selected groups of poles.

2.3 *Automatic SSI-COV algorithm*

The modal parameters are identified from vibration signals acquired from the 6 accelerometers installed in the new Pedro e Inês Footbridge. In order to facilitate the automatic signal processing, three successive setup files acquired in 20 minutes are concatenated to obtain a one hour response file and obtain more stable results. The parameters *i, j, m, n* and *p* is optimizing to 1024, 2, 20, 90 respectively for the automatic signal processing program. An averaged normalized Power Spectrum Density (ANPSD) plot is overlapped 50% to reflect frequency domain information.

As shown in Figure 5, a very clear alignments of stable poles can be found in the frequency ranges 0-1.5Hz and 4-10Hz. The automatic SSI-COV algorithm capture all the natural modal frequencies automatically.

3 VARIATIONS OF TEMPERATURE, VIBRATION LEVEL AND FREQUENCY

Temperature at different positions has a similar trend. The sensor TC mounted on the south surface of the mid-span of the bridge has shown to provide the highest correlated temperature with the natural frequency estimates (9.428Hz) than other temperature sensors according to [3]. Therefore, temperature data provided by TC has been selected to investigate the temperature effects in Figure 6.

The annual change in temperature has the same tendency, and the temperature reached its maximum of 38.5℃ in July, 2007, while the minimum value of -1.8℃ occurred in December, 2009.

Figure 7 shows the variations of frequencies identified of the 9th bending modes over five years. An obvious trend can be found that the annual frequency estimates changes regularly. It may be concluded that temperature is the main environment factor in this footbridge which can affect the natural frequencies in higher modes easily.

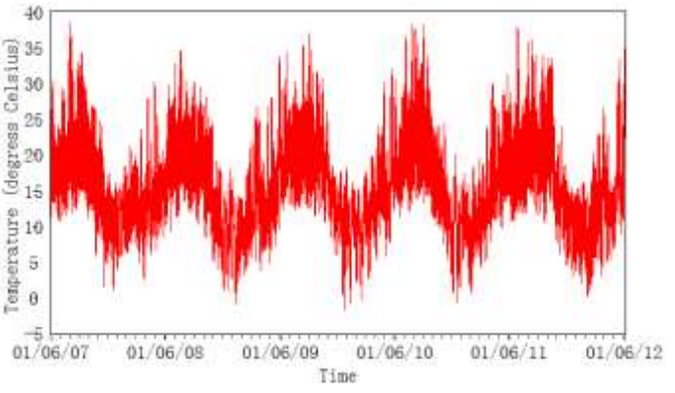

Figure 6. Variation of the temperature from 1st June 2007 to 1st June 2012

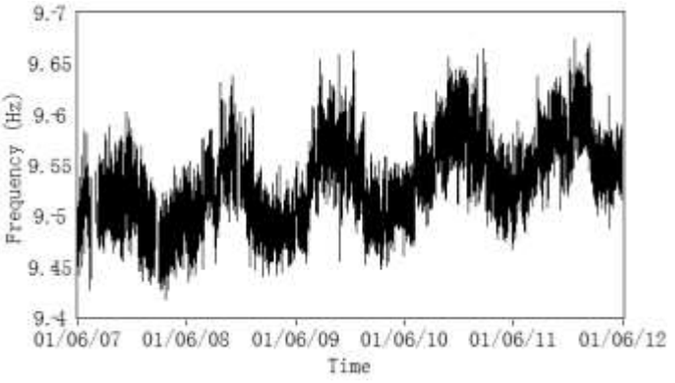

Figure 7. Variation of the estimated frequency from 1st June 2007 to 1st June 2012

4 DETECTION OF STRUCTURAL MODIFICATION DURING 5 YEARS

In the current research, the multiple linear regression (MLR) is used to remove the nonlinear influences of the temperature on the identified frequencies [4]. By selecting the mathematical model established by MLR method, the residual matrix with the environmental and operational effects has been removed. Novelty Detection technique which is simply to identify from measured data if a machine or structure has deviated from normal condition can be applied now to detect early structural modifications [5].

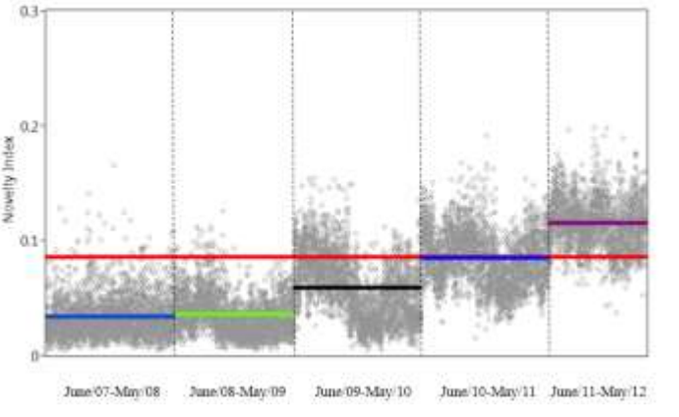

Figure 8. Calculated novelty indices and center lines using frequencies in 5 years

An internal representation Novelty Index (NI) is first built when the structure is under healthy conditions covering one full cycle of environmental and operational variations, and then data are subsequently examined to observe the possible occurrence of significant departure from the normal condition by using the outlier analysis. The Novelty Index (NI) can be defined as its Euclidean norm and is shown in Figure 8.

5 DISCUSSION OF RESULTS

Two possible reasons may have led to the increase of frequencies in each mode and need to be further investigated based on numerical simulation. On the one hand, given the small displacements and loads applied to the footbridge, the horizontal support, which was already modelled as a spring to calibrate the initial numerical model, may have become stiffer and contributed to aggravate the clamping effect at the east abutment.
On the other hand, the silt/clay soil layers beneath the river bed have poor mechanical characteristics but are designed to resist horizontal force produced by the central arch. The horizontal stiffness of the equivalent spring elements used to model the piles may have changed slowly under long-term load effects.

6 CONCLUSION

This paper briefly describes the Pedro e Inês Footbridge and its monitoring system. Data obtained from the system from 1st June 2007 to 1st June 2012 is shown to illustrate the relationship between temperature and frequency estimated, and a linear correlation between temperatures and frequency estimates is observed.
In addition, MLR method and Novelty Detection technique are applied in the paper to eliminate the environmental and operational effects on frequencies and reveal the early modification of structure. Although the possible reason for this modification requires further investigation, the results partially prove that the vibration monitoring system can capture early structural changes.

Damage detection under environmental variability using Bayesian virtual sensing

J. Kullaa
Metropolia University of Applied Sciences, Helsinki, Finland

ABSTRACT: Structural health monitoring is based on output-only vibration measurements. In order to get an early warning of structural failure, the signal-to-noise ratio of the measurement data should be high. This can be achieved by applying virtual sensing to a redundant sensor network. A Bayesian estimate of the signal of each sensor in the network was derived and proved to be more accurate than the actual measurement. Virtual sensor data replace the actual measurements in damage detection. Another issue is the environmental or operational influences, which can mask the effects of damage. They can be removed by acquiring training data under different conditions and utilizing correlation between the measured quantities. The measurement of the underlying variables is not necessary. Numerical simulations were performed for a structure subject to unknown random excitation and various environmental effects. Damage detection was performed in the time domain using the virtual sensor data.

1 INTRODUCTION

Structural health monitoring is based on output-only vibration measurements acquired by a sensor network. Changes in the dynamic characteristics are interpreted as an indication of damage. Because damage is often local, its effect on the dynamic characteristics is relatively small. In order to get an early warning of structural failure, the signal-to-noise ratio (SNR) of the measurement data should be high. With a large number of low-cost sensor nodes, the data accuracy may have to be compromised. Another issue is the environmental or operational variability, which affects the vibration characteristics of the structure and can thus mask the effects of damage.

Damage detection can be applied in the time-domain or in the feature-domain.

Feature-domain detection is probably more popular because of the following reasons. Statistical analysis is straightforward, because the features are "static". The features are compact: they need less storage capacity. Also, structural engineers are familiar with modal parameters, natural frequencies, mode shapes and damping.

Time-domain detection has also many advantages: The data dimensionality is relatively low (equal to the number of sensors), while the amount of data is very large (the number of samples). This is advantageous in statistical analysis. No system identification is needed, which reduces one possible source of error. The measurement variables are directly related to sensors, making it also possible to localize damage.

Environmental or operational variability affects the data in both domains. Many experimental studies have demonstrated the environmental effects on the dynamic characteristics of large civil engineering structures (Wahab & Roeck 1997; Farrar et al. 1997; Alampalli 1998; Cornwell et al. 1999; Peeters & de Roeck 2000; Rohrmann et al. 2000; Darbre & Proulx 2001; Kullaa 2002). The main underlying effect in most studies is temperature. Also in the last two references, respectively, the influence of the water level in the dam and the humidity on the wooden structure have been identified.

Because the underlying environmental or operational variables are not all known and their effects on the data are often complex, it may be difficult to build a model that predicts the variability in the data. Alternatively, the effects of environment can be removed using the vibration data alone by applying multivariate statistics, provided the data dimensionality is high enough to make the measurements redundant.

Many techniques have emerged to remove environmental or operational effects into account without measuring the underlying variables (Kullaa 2002, 2003, 2004, 2006a, 2009a, 2014; Manson 2002; Sohn et al. 2003; Vanlanduit et al. 2005; Yan et al. 2005a, b; Basseville et al. 2006; Yan & Go-

linval 2006; Lämsä & Kullaa 2007; Gorinevsky et al. 2007; Cross et al. 2011).

The same approach can be taken both in the time-domain and in the feature-domain. The number of static features must be higher than the number of underlying environmental or operational variables. The dimensionality in the time-domain must be higher, because the signals have normal time-variation in addition to the variability in the dynamic characteristics due to environmental or operational effects. Specifically, the number of sensors must be higher than the number of active modes plus the number of underlying variables when using time-domain analysis.

The environmental or operational influences are taken into account by acquiring training data under different conditions. Utilizing the correlation between the variables in the training data, those underlying influences can be eliminated. It is assumed that the sensor network is redundant, so that each sensor reading can be estimated using the covariance model. The residuals (the difference between the measured and estimated variables) are used in damage detection.

If the measurement data are very noisy, small damage may remain undetected. Therefore, a high SNR is important to get an early warning. This can be achieved e.g. by using high-quality sensors or by applying virtual sensing (VS) techniques to a redundant sensor network. In Bayesian VS, the signal of each sensor in the network is estimated using the whole sensor network data. Using Bayes' rule, the estimate can be shown to be more accurate than the actual measurement. Virtual sensing uses the same idea as in the removal of environmental or operational influences from the data discussed above. However, VS is applied independently to each measurement. Once processed, the data still include the prevailing dynamics and environmental or operational influences, as well as the effects of damage. Measurement error is only reduced. The measurement data are replaced with the virtual sensor data in the damage detection algorithm.

Empirical virtual sensing is traditionally used for sensor validation and sensor fault identification (Ray & Luck 1991; Dunia et al. 1996; Dunia & Qin 1998; Kerschen et al. 2005; Friswell & Inman 1999; Abdelghani & Friswell 2004, 2007; Hernandez-Garcia & Masri 2008; Kullaa 2006b, 2007, 2009b, 2010, 2013). Assuming the sensor network is redundant, it is possible to estimate the signal of a single sensor using the remaining sensors in the network. In the present study, all sensors in the network are used to reconstruct the sensor under investigation, including the sensor's own signal. Bayes' rule gives an optimal weighting to all sensors resulting in virtual sensors with the highest accuracy.

This paper is organised as follows. Bayesian virtual sensing is introduced in Section 2 and the posterior mean and variance are derived for the measured quantity of each sensor in the network. The virtual sensors are shown to be more accurate than the corresponding hardware. The strategy of using virtual sensors in damage detection is described in Section 3. In Section 4, numerical simulations are performed for a structure subject to unknown random loads and various environmental effects. Noisy response is measured with a sensor network. Damage detection is performed in the time domain using the virtual sensor data. The performance is compared to the case in which raw measurements are used instead. Finally, concluding remarks are given in Section 5.

2 BAYESIAN EMPIRICAL VIRTUAL SENSING

Virtual sensing techniques estimate quantities of interest using the available physical sensors. Empirical virtual sensing is based on available historical measurements of the same quantity that is being estimated. These measurement data are used to estimate the correlation between the measured quantities. Empirical virtual sensing uses regression techniques that can be implemented using different statistical methods, for example linear regression or neural network regression.

2.1 *Measurement model*

Consider a sensor network measuring p simultaneously sampled variables $\mathbf{y} = \mathbf{y}(t)$ at time instant t. Each measurement $\mathbf{y}$ includes independent measurement error $\mathbf{w} = \mathbf{w}(t)$:

$$\mathbf{y} = \mathbf{x}_m + \mathbf{w} \tag{1}$$

where $\mathbf{x}_m = \mathbf{x}_m(t)$ are the true values of the measured degrees of freedom. The objective is to find a less noisy estimate for the true values $\mathbf{x}_m$ utilizing the noisy measurements $\mathbf{y}$ from the sensor network.

2.2 *Bayes' rule*

From Bayes' rule,

$$p(\mathbf{x}_m \mid \mathbf{y}) = \frac{p(\mathbf{y} \mid \mathbf{x}_m)\, p(\mathbf{x}_m)}{p(\mathbf{y})} \tag{2}$$

This, however, cannot be evaluated, because the distributions are not available. To proceed, only a subset of the physical sensors is estimated by partitioning each observation into observed variables $\mathbf{v}$ and estimated variables $\mathbf{u}$ (typically a single sensor u). The partitioned variables are

$$\mathbf{y} = \begin{Bmatrix} \mathbf{y}_u \\ \mathbf{y}_v \end{Bmatrix},\ \mathbf{x}_m = \begin{Bmatrix} \mathbf{x}_{m,u} \\ \mathbf{x}_{m,v} \end{Bmatrix},\ \mathbf{w} = \begin{Bmatrix} \mathbf{w}_u \\ \mathbf{w}_v \end{Bmatrix} \tag{3}$$

Measurement error $\mathbf{w}$ is assumed to be zero mean, independent of $\mathbf{x}_m$, with a known covariance matrix

$$\boldsymbol{\Sigma}_w = E(\mathbf{w}\mathbf{w}^T) = \begin{bmatrix} \boldsymbol{\Sigma}_{w,uu} & \boldsymbol{\Sigma}_{w,uv} \\ \boldsymbol{\Sigma}_{w,vu} & \boldsymbol{\Sigma}_{w,vv} \end{bmatrix} \tag{4}$$

where $E(\cdot)$ denotes the expectation operator. After partitioning, all distributions are conditioned with $\mathbf{y}_v$. Bayes' rule becomes

$$\begin{aligned} p(\mathbf{x}_{m,u} \mid \mathbf{y}) &= p(\mathbf{x}_{m,u} \mid \mathbf{y}_u, \mathbf{y}_v) \\ &= \frac{p(\mathbf{y}_u \mid \mathbf{x}_{m,u}, \mathbf{y}_v) p(\mathbf{x}_{m,u} \mid \mathbf{y}_v)}{p(\mathbf{y}_u \mid \mathbf{y}_v)} \\ &= \frac{p(\mathbf{y}_u \mid \mathbf{x}_{m,u}) p(\mathbf{x}_{m,u} \mid \mathbf{y}_v)}{p(\mathbf{y}_u \mid \mathbf{y}_v)} \end{aligned} \tag{5}$$

The distributions in (5) can be evaluated as shown in the following.

2.3 *Likelihood*

Assuming Gaussian noise $\mathbf{w}$, the likelihood is obtained using Equation 1:

$$\begin{aligned} p(\mathbf{y}_u \mid \mathbf{x}_{m,u}) &= N(\mathbf{y}_u \mid \mathbf{x}_{m,u}, \boldsymbol{\Sigma}_{w,uu}) \\ &\propto \exp\left[-\frac{1}{2} (\mathbf{y}_u - \mathbf{x}_{m,u})^T \boldsymbol{\Sigma}_{w,uu}^{-1} (\mathbf{y}_u - \mathbf{x}_{m,u}) \right] \end{aligned} \tag{6}$$

2.4 *Evidence*

For simplicity but without loss of generality, assume zero-mean variables $\mathbf{y}$. The partitioned data covariance matrix $\boldsymbol{\Sigma}_y$ is

$$\boldsymbol{\Sigma}_y = E(\mathbf{y}\mathbf{y}^T) = \begin{bmatrix} \boldsymbol{\Sigma}_{y,uu} & \boldsymbol{\Sigma}_{y,uv} \\ \boldsymbol{\Sigma}_{y,vu} & \boldsymbol{\Sigma}_{y,vv} \end{bmatrix} \tag{7}$$

The precision matrix $\boldsymbol{\Gamma}_y$ is defined as the inverse of the covariance matrix $\boldsymbol{\Sigma}_y$ and is also written in partitioned form:

$$\boldsymbol{\Gamma}_y = \boldsymbol{\Sigma}_y^{-1} = \begin{bmatrix} \boldsymbol{\Gamma}_{y,uu} & \boldsymbol{\Gamma}_{y,uv} \\ \boldsymbol{\Gamma}_{y,vu} & \boldsymbol{\Gamma}_{y,vv} \end{bmatrix} \tag{8}$$

A linear minimum mean square error (LMMSE) estimate for $\mathbf{y}_u \mid \mathbf{y}_v$ is obtained by minimizing the mean-square error (MSE) and can be computed either using the covariance or precision matrix (Kullaa 2010, Bishop 2006). If each sensor signal is estimated in turn, the formulas based on the precision matrix result in a more efficient algorithm (Kullaa 2010). The expected value of the estimated variable is:

$$\hat{\mathbf{y}}_u = E(\mathbf{y}_u \mid \mathbf{y}_v) = -\boldsymbol{\Gamma}_{y,uu}^{-1} \boldsymbol{\Gamma}_{y,uv} \mathbf{y}_v = \mathbf{K}\mathbf{y}_v \tag{9}$$

where $\mathbf{K} = -\boldsymbol{\Gamma}_{y,uu}^{-1} \boldsymbol{\Gamma}_{y,uv}$, and the error covariance MSE is

$$\operatorname{cov}(\mathbf{y}_u \mid \mathbf{y}_v) = \boldsymbol{\Gamma}_{y,uu}^{-1} \tag{10}$$

Notice that the covariance is the error compared to the noisy measurement, not to the noiseless (true) value.

The evidence $p(\mathbf{y}_u \mid \mathbf{y}_v)$ is also Gaussian with the mean and covariance from Equations 9 and 10, respectively:

$$\begin{aligned} p(\mathbf{y}_u \mid \mathbf{y}_v) &= N(\mathbf{y}_u \mid \mathbf{K}\mathbf{y}_v, \boldsymbol{\Gamma}_{y,uu}^{-1}) \\ &\propto \exp\left[-\frac{1}{2} (\mathbf{y}_u - \mathbf{K}\mathbf{y}_v)^T \boldsymbol{\Gamma}_{y,uu} (\mathbf{y}_u - \mathbf{K}\mathbf{y}_v) \right] \end{aligned} \tag{11}$$

The evidence is merely a normalizing factor, independent of $\mathbf{x}_{m,u}$. However, evidence will be utilized in damage detection to remove the environmental or operational effects, which will be discussed in Section 3.

2.5 *Prior*

The prior distribution $p(\mathbf{x}_{m,u} \mid \mathbf{y}_v)$ is obtained from the measurement model (1) by partitioning and conditioning:

$$p(\mathbf{y}_u \mid \mathbf{y}_v) = p(\mathbf{x}_{m,u} \mid \mathbf{y}_v) + p(\mathbf{w}_u) \tag{12}$$

from which the prior mean is

$$\begin{aligned} E(\mathbf{x}_{m,u} \mid \mathbf{y}_v) &= E(\mathbf{y}_u \mid \mathbf{y}_v) - E(\mathbf{w}_u) \\ &= E(\mathbf{y}_u \mid \mathbf{y}_v) = \mathbf{K}\mathbf{y}_v \end{aligned} \tag{13}$$

and the prior covariance is obtained from

$$\operatorname{cov}(\mathbf{y}_u \mid \mathbf{y}_v) = \operatorname{cov}(\mathbf{x}_{m,u} \mid \mathbf{y}_v) + \boldsymbol{\Sigma}_{w,uu} \tag{14}$$

from which

$$\begin{aligned} \boldsymbol{\Sigma}_{\text{prior},uu} &= \operatorname{cov}(\mathbf{x}_{m,u} \mid \mathbf{y}_v) \\ &= \operatorname{cov}(\mathbf{y}_u \mid \mathbf{y}_v) - \boldsymbol{\Sigma}_{w,uu} = \boldsymbol{\Gamma}_{y,uu}^{-1} - \boldsymbol{\Sigma}_{w,uu} \end{aligned} \tag{15}$$

The prior distribution is also Gaussian:

$$\begin{aligned} p(\mathbf{x}_{m,u} \mid \mathbf{y}_v) &= N(\mathbf{x}_{m,u} \mid \mathbf{K}\mathbf{y}_v, \boldsymbol{\Sigma}_{\text{prior},uu}) \\ &\propto \exp\left[-\frac{1}{2} (\mathbf{x}_{m,u} - \mathbf{K}\mathbf{y}_v)^T \boldsymbol{\Sigma}_{\text{prior},uu}^{-1} (\mathbf{x}_{m,u} - \mathbf{K}\mathbf{y}_v) \right] \end{aligned} \tag{16}$$

Notice that the prior is not subjective. It is the distribution of the exact quantity, estimated without using the corresponding sensor signal.

2.6 *Posterior*

The posterior distribution (5) is obtained by some manipulation, resulting in

$$
\begin{aligned}
&p(\mathbf{x}_{m,u} \mid \mathbf{y}) = c_1 p(\mathbf{y}_u \mid \mathbf{x}_m) p(\mathbf{x}_{m,u} \mid \mathbf{y}_v) \\
&= c_2 \exp\Bigg[-\frac{1}{2}(\mathbf{y}_u - \mathbf{x}_{m,u})^T \boldsymbol{\Sigma}_{w,uu}^{-1} (\mathbf{y}_u - \mathbf{x}_{m,u}) \\
&-\frac{1}{2}(\mathbf{x}_{m,u} - \mathbf{K}\mathbf{y}_v)^T \boldsymbol{\Sigma}_{\text{prior},uu}^{-1} (\mathbf{x}_{m,u} - \mathbf{K}\mathbf{y}_v) \Bigg] \\
&= c_2 \exp\Bigg[-\frac{1}{2}(\mathbf{x}_{m,u} - \hat{\mathbf{x}}_{m,u})^T \boldsymbol{\Sigma}_{\text{post},uu}^{-1} (\mathbf{x}_{m,u} - \hat{\mathbf{x}}_{m,u}) \Bigg]
\end{aligned}
\tag{17}
$$

where c_1 and c_2 are constants and the posterior covariance $\boldsymbol{\Sigma}_{\text{post},uu}$ is

$$
\boldsymbol{\Sigma}_{\text{post},uu} = \text{cov}(\mathbf{x}_{m,u} \mid \mathbf{y}) = (\boldsymbol{\Sigma}_{w,uu}^{-1} + \boldsymbol{\Sigma}_{\text{prior},uu}^{-1})^{-1} \tag{18}
$$

and the posterior mean is

$$
\hat{\mathbf{x}}_{m,u} = E(\mathbf{x}_{m,u} \mid \mathbf{y}) = \boldsymbol{\Sigma}_{\text{post},uu} (\boldsymbol{\Sigma}_{w,uu}^{-1} \mathbf{y}_u + \boldsymbol{\Sigma}_{\text{prior},uu}^{-1} \mathbf{K}\mathbf{y}_v) \tag{19}
$$

Notice that the MSE of the posterior (18) is always less than that of the measurement error, $\boldsymbol{\Sigma}_{w,uu}$. Therefore, the posterior mean is more accurate than the actual measurement.

Equation 19 can also be written in the following form.

$$
\hat{\mathbf{x}}_{m,u} = \begin{bmatrix} \boldsymbol{\Sigma}_{\text{post},uu} \boldsymbol{\Sigma}_{w,uu}^{-1} & \boldsymbol{\Sigma}_{\text{post},uu} \boldsymbol{\Sigma}_{\text{prior},u}^{-1} \mathbf{K} \end{bmatrix} \begin{Bmatrix} \mathbf{y}_u \\ \mathbf{y}_v \end{Bmatrix} = \mathbf{a}_u^T \mathbf{y} \tag{20}
$$

where $\mathbf{a}_u^T$ is

$$
\mathbf{a}_u^T = \begin{bmatrix} \boldsymbol{\Sigma}_{\text{post},uu} \boldsymbol{\Sigma}_{w,uu}^{-1} & \boldsymbol{\Sigma}_{\text{post},uu} \boldsymbol{\Sigma}_{\text{prior},uu}^{-1} \mathbf{K} \end{bmatrix} \tag{21}
$$

Equation 20 shows that the posterior mean is a weighted sum of the measurements of all sensors in the network.

Generally, the predicted DOFs **u** may include several variables. In the sequel, **u** is one-dimensional including one sensor only. For each sensor u, a corresponding row vector $\mathbf{a}_u^T$ is computed. All these vectors can be assembled in a coefficient matrix **A** to estimate all virtual sensors simultaneously:

$$
\hat{\mathbf{x}}_m = \mathbf{A}\mathbf{y} \tag{22}
$$

where each row u of matrix **A** represents the corresponding sensor.

A diagonal covariance matrix is assumed with variances (18) in the corresponding row u.

2.7 *Application of virtual sensing*

Bayesian virtual sensing is applied to each measurement separately. Each measurement is assumed to be acquired under constant environmental or operational condition, so that the dynamic characteristics remain the same during the whole measurement period. Because the measurement period is typically of the order of a few seconds or minutes, this assumption is often valid. Therefore, the differences between measurements due to environmental or operational variability or damage remain in the data. The noise is only reduced.

Virtual sensors are then used in subsequent damage detection as follows.

3 DAMAGE DETECTION

Virtual sensors are used in damage detection as if they were physical hardware. The measurement data are replaced with the virtual sensor data ($\mathbf{y} \leftarrow \hat{\mathbf{x}}_m$). The damage detection algorithm used in this paper is briefly outlined. Each sensor in turn is estimated using the remaining sensors in the network. The residuals for each sensor are then generated:

$$
\boldsymbol{\varepsilon}_u = \mathbf{y}_u - \hat{\mathbf{y}}_u \tag{23}
$$

where $\mathbf{y}_u$ is a vector of virtual sensor data (Equation 19 or 20) and $\hat{\mathbf{y}}_u$ is the evidence mean (9), identified using training data (virtual sensors) from the undamaged structure. The training data consist of several measurements in order to take different environmental or operational conditions into account. Specifically, the data covariance matrix (7) is estimated using all training data. The environmental or operational influences can be eliminated using correlation between the features (Kullaa 2009a). Once damage occurs, the correlation structure does not fit the experimental data producing a larger residual, which will then trigger an alarm.

All residuals are standardized according to the training data. All samples, training and test data, are subjected to principal component analysis (PCA). The first principal component (PC) is retained in order to find the direction with the largest change in the data space, which is supposed to indicate damage. If the first PC scores of the residuals are not normally distributed and the distribution is unknown, a generalized extreme value distribution can be used regardless of the data distribution (Worden et al. 2002). The scores are divided into subgroups (of size n = 100) and the subgroup minima and maxima are recorded. Extreme value distributions are identified for both the subgroup minima and maxima of the in-control samples (training data). The control limits are computed to these distributions by choosing the probability of exceedance (here 0.001). The extreme values are plotted on a control chart (Montgomery 1997) to see if the test samples exceed the control limits thus indicating damage.

4 NUMERICAL EXAMPLE

As a structural health monitoring example, consider a simply-supported beam with length 1.4 m, a uniform rectangular cross-section of 50 mm × 5 mm (Fig. 1). The beam was also supported with a spring

612.5 mm from the support, with the spring constant k depending non-linearly on temperature:

$$k = k_0 + aT^3 \tag{24}$$

where k_0 = 100 kN/m, a = –0.8 (with compatible units), and T is temperature with a uniform random distribution between –20 and +40°C.

The beam was divided into three sections of equal length. The Young's modulus E_i at each section of the beam had a linear relationship with a corresponding independent and dimensionless unknown environmental variable z_i:

$$E_i = E_0 + \sigma_i z_i, \quad i = 1,2,3 \tag{25}$$

where E_0 = 207 GPa, z_i are standardized Gaussian variables: $z_i \sim N(0,1)$, and the standard deviations σ_i of different sections were: σ_1 = 5 GPa, σ_2 = 3 GPa, and σ_3 = 7 GPa.

The structure was modelled with 144 simple beam elements and one spring element. Independent random excitations with different realizations in each measurement were applied to the structure at three points (Fig. 1). Transverse acceleration was measured at 47 equidistant points along the beam. Gaussian noise was added to each sensor. The sampling frequency was 571 Hz and the number of samples in each measurement was 2859. The first 50 measurements were from the undamaged structure. A slow environmental variability was assumed, justifying a constant environment during each measurement.

As a conclusion, the environmental or operational variability thus introduced originated from (1) a variable spring with a non-linear relationship between temperature and the spring constant, (2) three regions with independently varying Young's moduli, and (3) independent random loads at three points.

Damage was a decrease in the beam depth at the spring support in two elements along a total length of 19.4 mm (Fig. 1). This type of damage could represent local corrosion around the spring joint. The height of the beam varied in five different levels: 4.5, 4, 3.5, 3, and 2.5 mm. Each damage level was monitored with two measurements at variable unknown environmental conditions.

The training data were the first 100,000 samples including almost the first 35 measurements. These were also used to design the control charts. The first principal component scores of the residuals (Equation 23) were plotted on the extreme value statistics (EVS) control chart using subgroups of size 100 (Kullaa et al. 2016).

Different amount of noise and different sensor arrangements were studied. A comparison was made between the proposed method using virtual sensors and a similar method but using raw measurements.

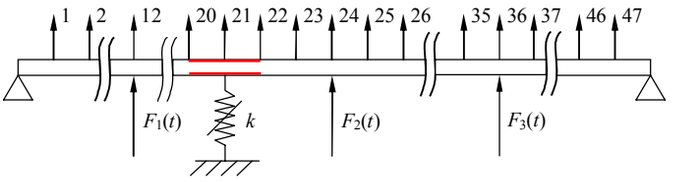

Figure 1. Beam structure with a variable spring. 47 sensors and 3 independent loadings. Damage location is shown in red.

First, optimal sensor placement (OSP) was performed using the effective independence algorithm (EFI) (Kammer 1991, 1992) starting from the initial sensor network with all 47 sensors and removing one sensor in each round until the required number of sensors remained.

In the first case, all 47 sensors were used. A high noise level, σ_w = 0.5 m/s^2 was added to all sensors. Figure 2 shows the EVS control chart when using the raw measurement data and Figure 3 is the corresponding control chart when using the virtual sensors. It can be seen that damage could not be detected from the original noisy data, whereas after noise reduction, four largest damage levels were detected and only the lowest level remained undetected. Occational false alarms appeared during one measurement. This is probably due to the fact that this measurement took place under a high temperature not present in the training data.

In the subsequent cases, the noise level was set to σ_w = 0.1 m/s^2. The effect of the number of sensors was studied using 10, 15, and 20 sensors at optimal positions (according to EFI).

Using raw measurements, hardly any damage levels could be detected with 10 sensors (Fig. 4), whereas damage levels 4 and 5 were detected with 15 or 20 sensors (Figs 6, 8).

Using virtual sensor data, damage levels 2–5 were detected with 10, 15, or 20 sensors (Figs 5, 7, 9). It is interesting that the performance did not improve much when increasing the number of virtual sensors. This may be because the extreme values do not seem identically distributed between measurements within the training data (Figs 5, 7, 9). The virtual sensors were estimated separately in each measurement, which may have resulted in different posterior distributions. Moreover, EFI may not have produced optimal sensor positions for damage detection.

On the other hand, when using the measurement data directly, the extreme values were more identically distributed (Figs 4, 6, 8), which is clearly an advantage in statistical analysis. However, despite the differences in the distributions, virtual sensors outperformed the raw measurements in damage detection. The investigation of different posterior distributions between the measurements is left for the future.

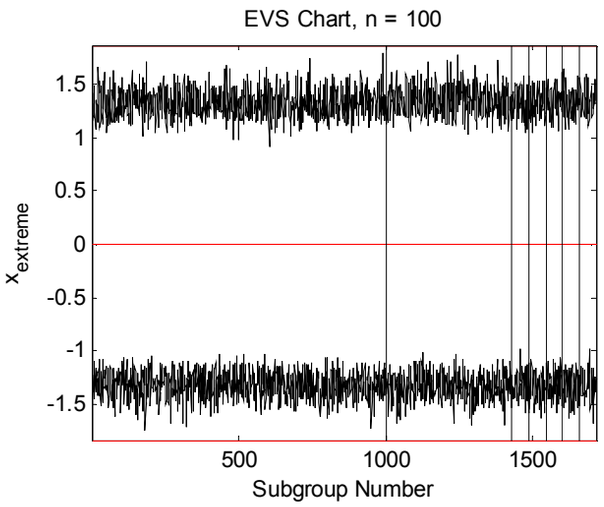

Figure 2. EVS control chart using raw measurements with 47 sensors. σ_w = 0.5 m/s^2. The data before the leftmost vertical line were used as training data, and the other vertical lines indicate the five damage levels with an increasing severity.

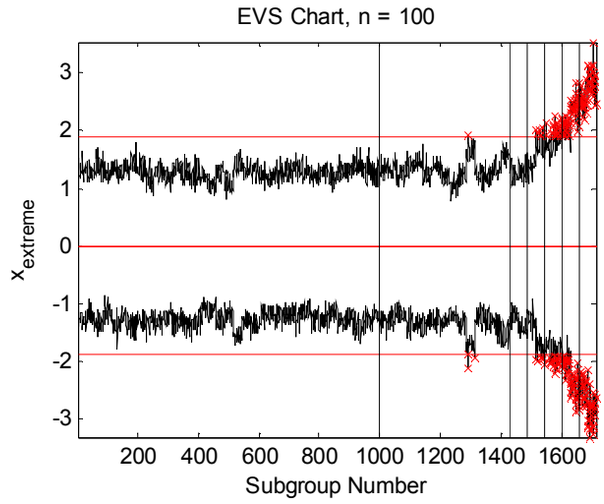

Figure 3. EVS control chart after noise reduction using 47 sensors. σ_w = 0.5 m/s^2.

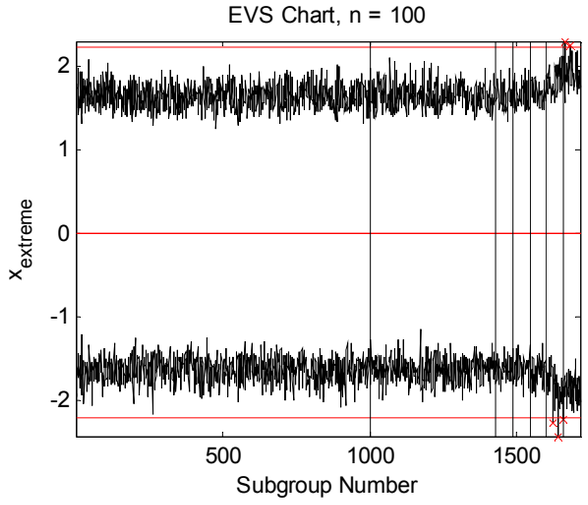

Figure 4. EVS control chart using raw measurements with 10 sensors. σ_w = 0.1 m/s^2.

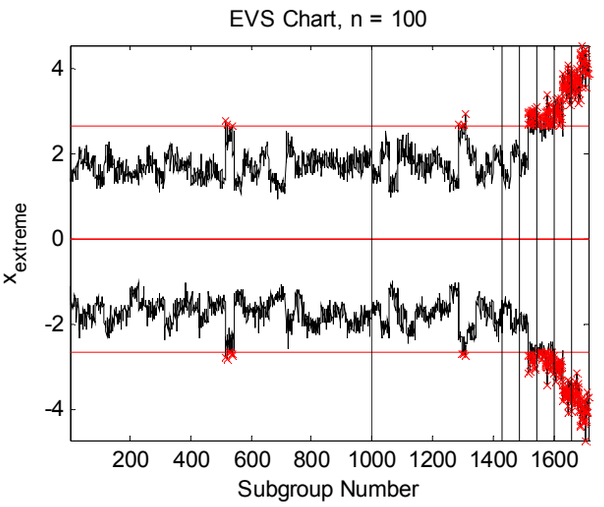

Figure 5. EVS control chart after noise reduction using 10 sensors. σ_w = 0.1 m/s^2.

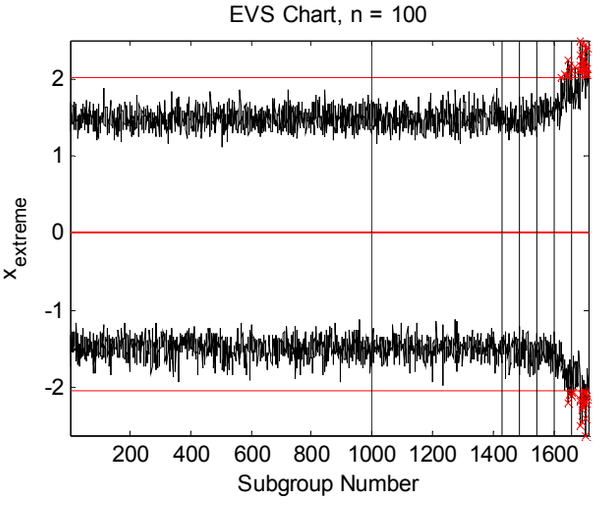

Figure 6. EVS control chart using raw measurements with 15 sensors. σ_w = 0.1 m/s^2.

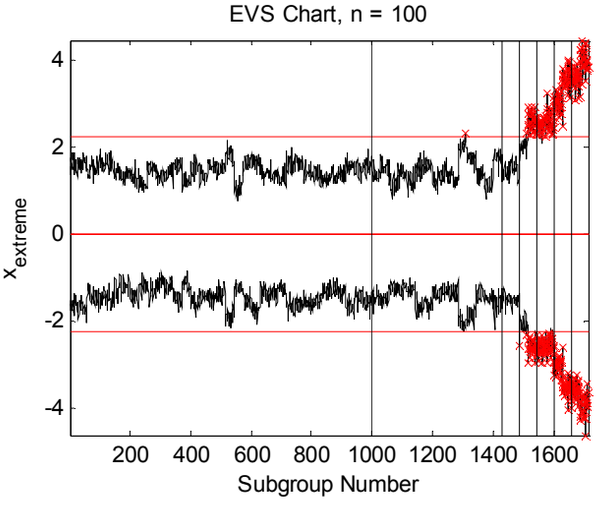

Figure 7. EVS control chart after noise reduction using 15 sensors. σ_w = 0.1 m/s^2.

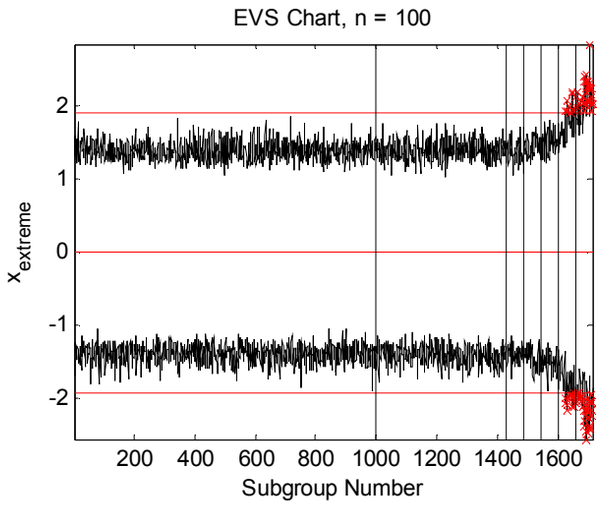

Figure 8. EVS control chart using raw measurements with 20 sensors. $\sigma_w = 0.1$ m/s^2.

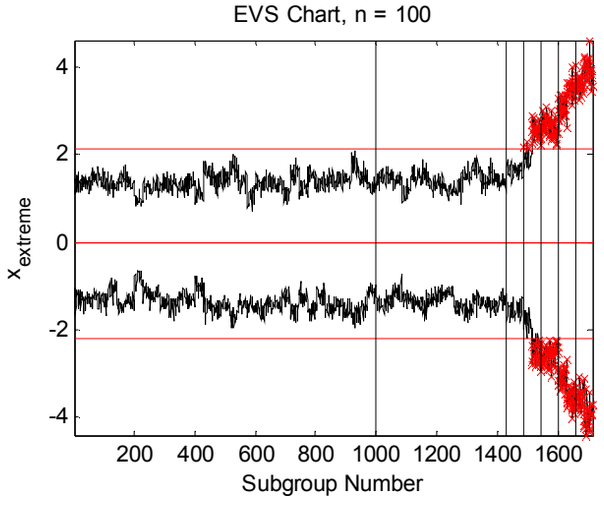

Figure 9. EVS control chart after noise reduction using 20 sensors. $\sigma_w = 0.1$ m/s^2.

5 CONCLUSION

Bayesian virtual sensing was applied to vibration-based structural health monitoring to reduce the measurement error in the sensor network. Bayesian virtual sensors are more accurate than the corresponding hardware and can replace the actual measurement data in any damage detection algorithm.

Damage detection was made in the time-domain. Environmental or operational influences were removed from the data using correlation between the measured variables. The residual was generated by subtracting the evidence mean from the virtual sensor data. The first principal component of the residual was then used as a damage-sensitive feature. An extreme value statistics control chart with appropriate control limits and subgroup size was plotted for damage detection.

Damage detection under variable environmental or operational conditions was successful, and the measurement of the underlying variables was not necessary. Virtual sensors outperformed the raw measurements in damage detection, making early warning more plausible.

The training data must include the underlying effects and the sensor network must be redundant. Experimental validation of the proposed method was left for a future study.

Assessment of MEMS-based sensors for inclination measurements

S. Rau & G. Morgenthal
Chair of Modelling and Simulation of Structures, Institute of Structural Engineering, Bauhaus University Weimar, Weimar, Germany

ABSTRACT: The condition assessment of critical infrastructure subjected to various environmental effects and extreme loadings such as aeging bridges becomes increasingly important. Monitoring provides the possibility to evaluate the structural performance and identify damage. Sensor-based monitoring systems typically measure accelerations, strains, displacements and inclinations. Whilst piezo-electric sensors are most commonly used in Structural Health Monitoring (SHM) systems, MEMS (microelectromechanical systems) based sensors are growing in popularity because they are small and inexpensive. Novel miniaturized accelerometers can be used to measure local rotation on a structure to determine the deformation state. In this paper, the effect of temperature and long-term stability of a MEMS-based accelerometer are systematically investigated on uncased and encased sensors. Possibilities for compensation are described, while several questions arise from the measured data, which are also presented. It is shown that due to the imperfection of the novel MEMS-based sensor, uncertainty is incorporated in the measurement. The application of these sensors during the construction of cable-stayed bridges is discussed.

1 INTRODUCTION

The condition assessment of bridges subjected to various environmental effects, extreme loading as well as aging becomes increasingly important. Structural Health Monitoring (SHM) provides the possibility to evaluate the structural performance and to identify damage on existing structures. Modern SHM concepts for long-span bridges integrate various types of sensors such as accelerometer, strain gauges, corrosion and load cells, GPS sensors and inclinometer amongst others. Additionally, anenometers, temperature sensors and hygrometers are utilized to determine environmental effects, which influence the measured accelerations, strains, displacements and inclinations. Temperature, wind and external vibrations manipulate recorded signals and further lead to deviations in the extracted parameters that describe the structural condition.

In the past few years MEMS (microelectromechanical system) based sensors are growing in popularity because they are small and inexpensive. For SHM purposes, most commonly piezo-electric sensors are used as they ensure reliable measurements and good long-term stability. Since the quality of MEMS-based sensors is increasing, new fields of application become possible. Apart from vibration measurements MEMS-accelerometer can be utilized to sense local rotations when applied to a structure.

Literature related to MEMS sensors is mainly focused on the technological development and not on the metrological performance, which is critical for application of these novel sensor types for monitoring of structures. Especially, the effect of temperature changes needs to be known, to allow for an appropriate compensation. The long-term stability of the sensors is impaired by sensor drift. In this regard, drift is the occurrence of slowly increasing changes of the measured quantity, e.g. acceleration or inclination, due to aging of the sensor leading to self-induced losses in accuracy.

In the present paper, the effect of temperature and the long-term stability of MEMS-based accelerometer used for inclination measurement are systematically investigated. In order to ascertain the suitability, the accuracy of uncased and encased sample sensors are determined. Suitable measures for temperature and drift compensation are discussed. Several questions arise from the data evaluation. These questions will be presented in the paper. It will be shown that due to the imperfectness of the novel MEMS-based sensor, uncertainty is incorporated in the measurement.

In existing cable-stayed bridges, inclinometer or tilt meter are applied to monitor local rotations of the pylon. As the pylon experiences small inclinations, highly accurate sensing is necessary. However, during construction of cable stayed bridges in balanced

cantilever method, large displacements at the tip of the deck appear. To ensure bridge girder alignment and correct stress distribution in the load-carrying elements, displacements of the bridge girder are monitored by tacheometric survey. Inclinations are the derivative of displacements. Since the girder experiences large deflections also inclinations are significant. Therefore, the question arises whether MEMS-based inclinometer, comprising measurement uncertainty, can be used as an additional method to determine deflections. Thereby the uncertainty in the measurement will yield uncertainty in the reconstructed deflected shape.

2 MEMS-BASED INCLINATION SENSORS

2.1 *MEMS-sensors*

Microelctromechanical systems (MEMS) are a key technology which nowadays has a wide application in automotive industry, automation and health sector allowing for economic monitoring and control within different processes. Mostly accelerometer, gyroscopes and pressure sensors are used. The MEMS-sensors are a few millimeters in size and most of the sensors integrate an electro-mechanical signal conversion and evaluation circuit within the chip. For SHM purposes piezo-electric sensors are most commonly used. In comparison to them, MEMS-based sensors grow in popularity because they are small, inexpensive and easy to include in embedded systems and cheap wireless sensor networks.

2.2 *Inclination sensing using accelerometer*

MEMS-based accelerometer can be used to determine inclinations. Thereby, the rotation with respect to gravity is measured when the sensor is stationary. The principle of the rotation sensing is schematically shown in Figure 1. At an inclined position the sensor measures the vectorial portion of the gravitational acceleration at the individual axes, which can be interpreted directly in terms of the inclination relative to a horizontal position.

The rotation angle φ can be determined based on the acceleration measured in the horizontal axis:

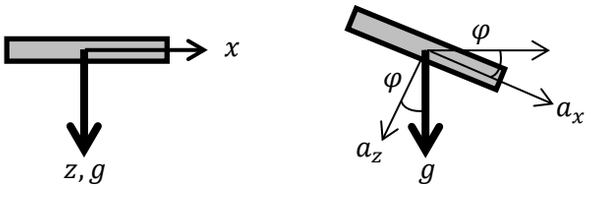

Figure 1. Principle of inclination sensing using accelerometer: initial position (left) and rotated position by angle φ (right).

$$\varphi = \arcsin\left(\frac{a_x}{1g}\right). \quad (1)$$

In the context of SHM, the inclinations to be measured are within the range of a few degrees for the most cases. Therefore, the sensors typically measure within a range of ±3° to ±5°.

Further, it should be noted that a sensor applied to the structure will not be fully aligned with the horizon. As a consequence the relative rotation regarding an initially displaced position has to be measured. The difference in the observed rotation will be the inclination as displayed in Equation (2) and Figure 2.

$$\Delta\varphi = \varphi_1 - \varphi_0 \quad (2)$$

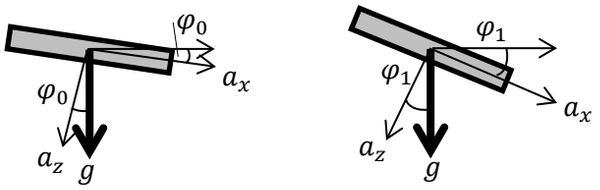

Figure 2. Determination of the relative rotation of the accelerometer: initial state (left) and displaced state (right).

2.3 *Sensor characteristics*

The studied MEMS-based accelerometer is using capacitive sensing techniques to detect accelerations, i.e. a motion-induced change of the position of the internal mass will result in a change of the capacity, which is converted in an electric signal.

The sensing element is produced using air gap insulated microstructure (AIM) technology, thus providing low noise, small cross-axis sensitivity and minimized parasitic capacitance (First Sensor 2016). Special modifications and signal processing methods are employed in this type of sensor to maximize its accuracy. With a temperature range of -45°C to 85°C and an adjustable measurement range (±1° to ±30°) along with a 24 bit analog-digital-conversion, the sensor is generally suitable for monitoring purposes on bridges. It should be noted that the novel MEMS-accelerometer is at design stage and not yet manufactured in mass production. The accuracy of the sensors and the long-term stability were investigated in order to evaluate the applicability of that sensor type for SHM purposes.

The MEMS-sensor is biaxial and measures accelerations in the two horizontal axes. The absolute acceleration can be determined from the electric output signal, which is expressed in terms of a digital integer value in LSB (least significant bit). Since the output signal Out is linear dependent on the applied acceleration a, the relation can be described by Equation (3):

$$Out = K_1 \cdot a + K_0 , \quad (3)$$

where K_1 is the slope and K_0 is the intercept of a linear function. Applying the parameter K_1 and K_0, which are also called Scale-Factor and Bias, the acceleration a can be obtained by Equation (4), wherefrom the angle of rotation can be determined by Equation (1).

$$a = \frac{Out - K_0}{K_1} , \quad (4)$$

Scale-Factor and Bias are sensor-specific and have to be determined by a calibration process under controlled environment. Using high precision turntables, the characteristic curve of the MEMS-accelerometer, wherefrom Scale and Bias are defined, can be found.

In comparison with high-quality piezo-electric sensors, the seismic mass is small and therefore MEMS-based sensors possess a worse signal-to-noise ratio. The noise density is typically 0,4m°/$\sqrt{\text{Hz}}$, i.e. for a measurement with 100 samples per seconds the RMS noise is about 4m° (First Sensor 2016). At that stage, no internal filters are applied to reduce noise. For sensing inclinations at quasi-static state it is assumed that the through averaging the noise-term can be cancelled out. The MEMS-accelerometer also possesses a temperature sensor, which is necessary to allow for temperature compensation further on.

2.4 *Investigation on temperature*

The characteristic relation between signal output and displacement of the seismic mass is affected by temperature as the Young's modulus of the silicon sensing element changes. The temperature effect on Scale-Factor and Bias was investigated in a laboratory test. It was thereby found, that the Scale-Factors and the Bias changes over the regarded temperature range from -15°C to 65°C.

Investigations were conducted for uncased and encased sensors. The thermal effect on the measured inclination is exemplarily shown for two encased sensors in Figure 3. Thereby a horizontally aligned sensor is assumed. It can be seen, that different sensors feature different behavior.

2.5 *Investigations on drift*

Further the long-term stability of the novel MEMS-based accelerometer was investigated on uncased and encapsulated sensors during HTOL (high temperature operation life) test. Thereby the sensors are tested for 1000 hours at an elevated temperature of 80°C in order simulate aging. Assuming a mean operating temperature of the sensor of 25°C (at the sensing element) the test duration corresponds to an equivalent operation time of 8 years. From the test it was evident that there is a great variation between the individual samples. Drift was found to be from –50m° to +50m° over the equivalent life time of the samples.

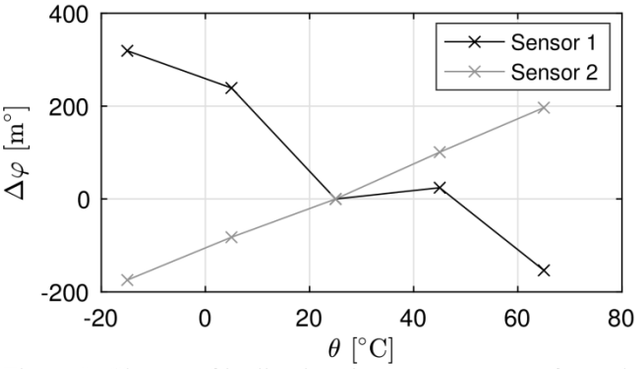

Figure 3. Change of inclination due to temperature for an horizontal aligned sensor at initial temperature of 25 °C.

Especially the great variation of the sensor performance between the different samples creates challenges for real applications. Without any further compensation of temperature and drift the accuracy of the sensor won't be better than ±50m°.

3 SHORT-TERM MEASUREMENTS

A three point bending test on a reinforced concrete beam has been performed to study the performance of the MEMS-based inclinometer. The beam with a dimension of 12 by 20 cm was reinforced with one rebar Ø 14 mm. The beam was simply supported and was loaded with a point load at midspan which was introduced by a hydraulic cylinder. At midspan an inductive displacement transducer (IDT) measured the deflection. The experimental setup is schematically shown in Figure 4.

The inclinations at both supports were recorded by the MEMS inclinometers which were further compared to measured rotations of high quality reference tilt meter. Both inclinometers were mounted to a base plate glued at the top of the beam. The reference sensor had a range of ±3° and a resolution of less than 0.3m°. The range of the MEMS-sensor was set to ±5°. For data acquisition, a microcontroller was used.

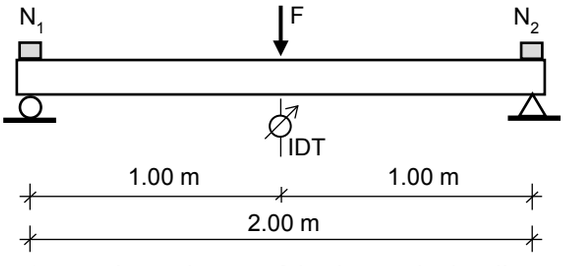

Figure 4: Experimental setup of the three-point bending test.

The load was introduced stepwise by loading ramps. At each ramp, the load was increased by 2.5 kN and the desired load level was held constant for 30 seconds. Initial cracking of the beam was observed at 7 kN at midspan. The beam was further loaded up to 31 kN where the beam reached yielding of the rebar.

A comparison of the inclinations measured by the MEMS-inclinometer and the reference tilt meter is shown in Figure 5 for the different load level. At each load level the average inclination was calculated, which is used therein. As the inclination data of the MEMS-sensor was recorded with a sampling rate of 100 Hz averaging was performed at the load level where the loading was static to eliminate the sensor noise.

Generally, there is a good agreement between the measured inclinations at both supports. For a better comparison, the absolute and relative deviation of the MEMS-inclinometer from the reference tilt meter is provided in Figure 6. It can be seen that the relative deviation is below $\pm$2m° on average with maximum deviations of 4.5m°. However, the relative deviation is smaller than 1 % except of the smallest load level, where the discrepancy can be attributed to the smaller level of inclinations.

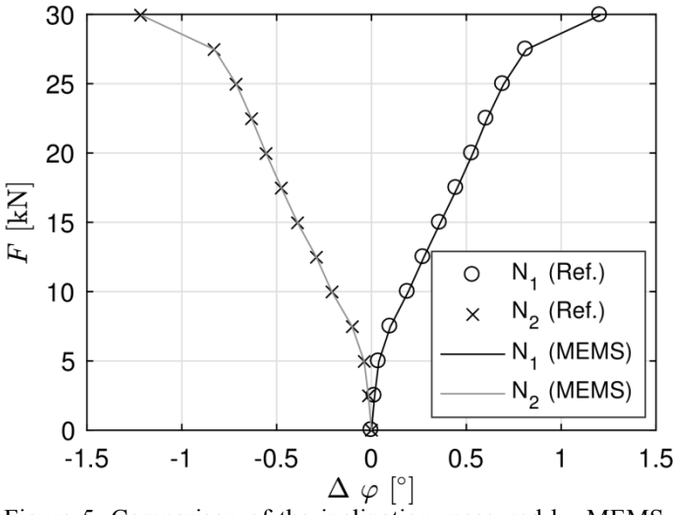

Figure 5. Comparison of the inclination measured by MEMS-inclinometer and reference tilt meter.

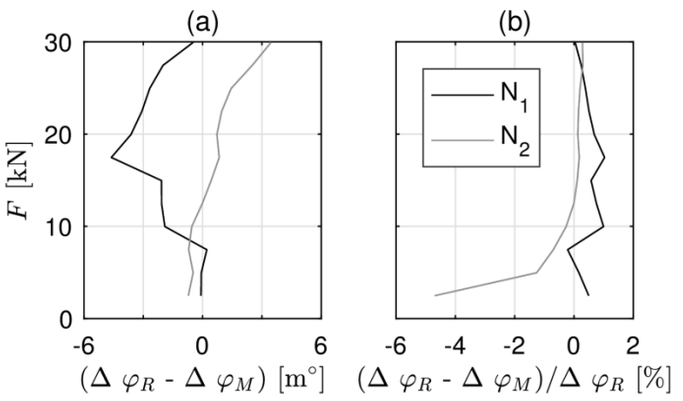

Figure 6. Absolute (a) and relative (b) deviation of the measured inclinations (R – Reference; M – MEMS).

During the test, there was a constant temperature and no significant warming of the sensors has been observed. Therefore, temperature effects as well as drift have not been studied here.

By means of a numerical model the inclinations at the supports have been calculated assuming homogeneous material properties leading to identical rotations at the support regarding their magnitude. However, small differences between the two measured rotations have been observed in the test. The nonlinear numerical model therefore comprises small uncertainty.

Applying the relation between the load-induced rotation at the support and the midspan deflection, which was obtain from the numerical simulation, the deformation u at midspan based on the recorded inclinations of the MEMS-sensor were determined. The comparison of the numerically obtained deflections and the measured deflections is shown for the different load level in Figure 7. It should be noted that the determination process includes model inaccuracies mentioned above such that the deviations cannot solely be attributed to the inclination measurement. The absolute deviation of the determined deflections tend to increase on the higher load levels, however, up the 15 kN, which signifies the serviceability limit state (SLS) of the tested beam, the deviations are within 0,25 mm.

In the flexural test, where inclinations up to 1.2° where applied to the specimen, good agreement between the measurements of the MEMS-based inclinometer and a high quality reference sensor was achieved. The observed difference was in the order of 2m° on average. The test showed the general applicability of the MEMS-devices for inclination sensing whilst containing measurement uncertainty.

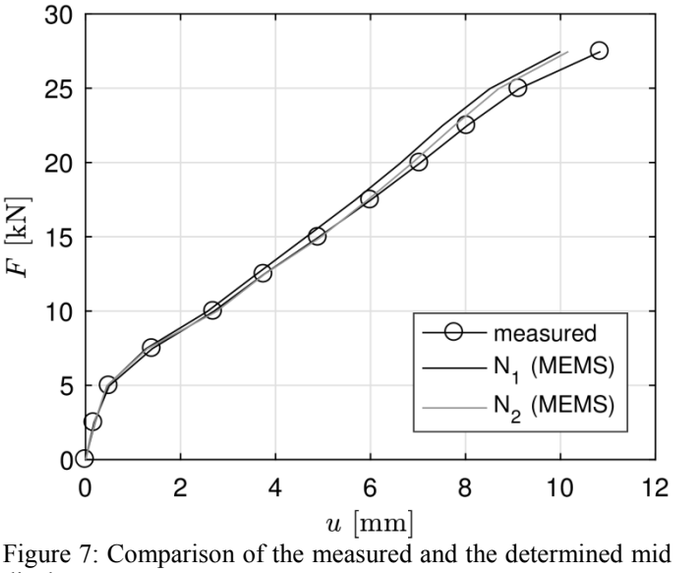

Figure 7: Comparison of the measured and the determined mid displacements.

4 LONG-TERM MEASUREMENTS

In order to observe the long-term stability of the novel MEMS-based accelerometer, several tests have been conducted using uncased and encased sensors under different environmental conditions. All the tests have in common that no rotation was applied to the sensor itself.

4.1 *Measurement with uncased MEMS-sensor*

In a first test the sensors have been mounted to a steel plate, which was rigidly connected to a massive steel platform resting on an individual block foundation. In the laboratory, a relative constant temperature was maintained. The sensor was configured for a range of ±1,7° to allow for high accuracy. The inclination in one axis and the temperature at the sensing element was recorded over the course of 80 days by an uncased sensor. In Figure 8 the time histories of the temperature and the measured inclination are shown. There is a clear similarity between the temperature and the measured inclination. As the temperature decreases the inclination decreases. Also the smaller temperature rises and descents appear correspondingly in the measured rotations. It is therefore assumed that the measured change in inclination, which is physically not present, is mainly introduced by temperature. The effect was then compensated assuming a linear temperature dependency leading to the time history of temperature compensated inclinations in Figure 9. Therein, the maximum deviation to the presumed non-rotating state lies below ±5m° over the course of 80 days.

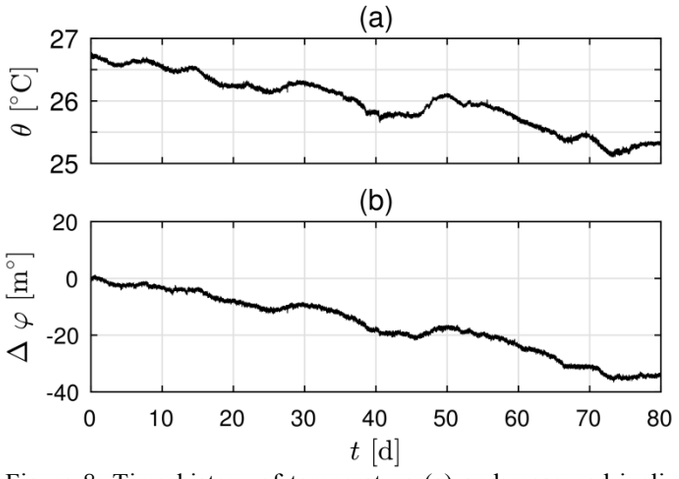

Figure 8: Time history of temperature (a) and measured inclination without compensation (b) until day 80.

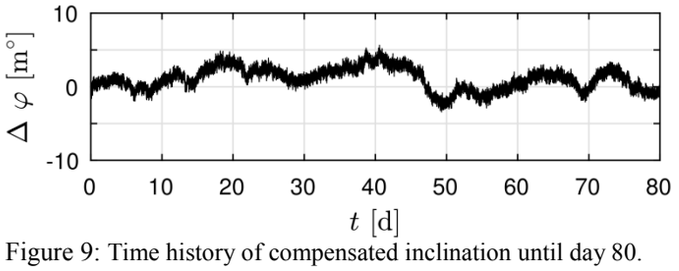

Figure 9: Time history of compensated inclination until day 80.

The relation of the sensor's output signal to the temperature is shown in Figure 10. Thereby, the start of the measurement is colored in black and the end is represented in grey. For a perfectly linearly temperature dependent, drift-free sensor there should be a clear linear relationship. However, at around 25.7°C and 26.2°C small level changes can be observed, yielding 3 different zones with different individual slopes. Here arises the question where these smaller jumps originate from. In Figure 8 (a) it can be seen that for these temperatures at day 26 and 46 temperature rises occurred.

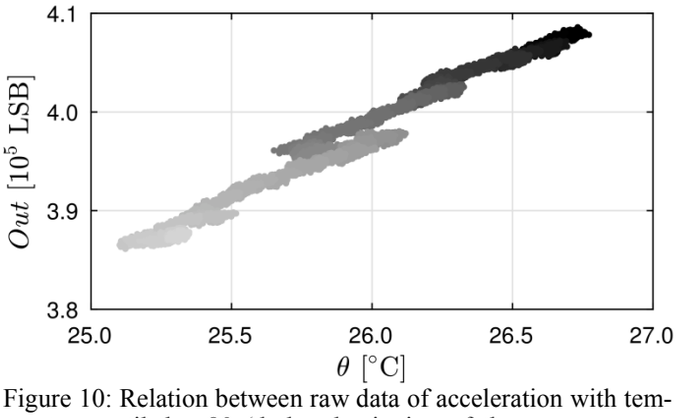

Figure 10: Relation between raw data of acceleration with temperature until day 80 (dark – beginning of the measurement; light – end of measurement)

After the period of 80 days the sensor broke and had to be replaced. The time history of the temperature and the recorded inclinations measured by the replacement sensor, starting at day 91, is provided in Figure 11. Again, a clear dependency between measured inclination and the temperature curve can be observed over the period of 208 days. This also applies to the second part of the measurement where greater variations in the temperature were present. A linear compensation of the temperature has been applied to the inclinations. By that, maximum deviations of 7m° were determined. Looking at the relation of the signal output to the temperature, two effects can be seen. At the beginning of the measurement (black area) there is some kind of warming-up stage of the sensor, where the initial slope is different from the overall slope during the measurement. At a later stage, a downward shift of the sensor's output signal can be observed. As the slope remains the same, this could be attributed to a change in the Bias K_0. However, at this stage it cannot be determined whether that observed signal shifts can be solely related to sensor drift. The temperature compensation by higher order approaches does not seem to be suited, as a short-termed shift appears yielding ambiguous results.

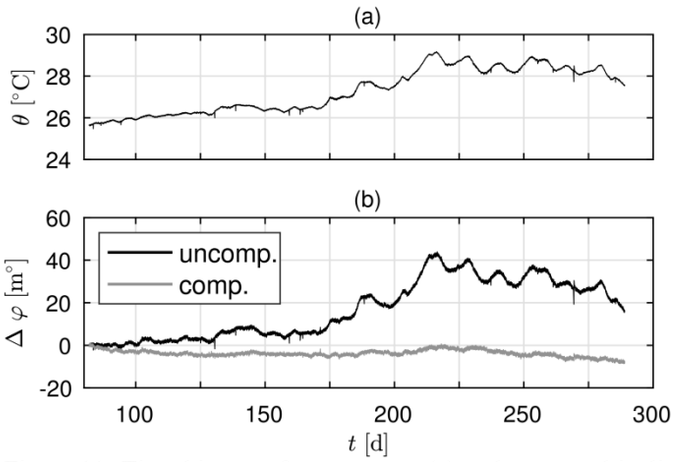

Figure 11: Time history of temperature (a) and measured inclination compensated and uncompensated (b): day 91 - 288

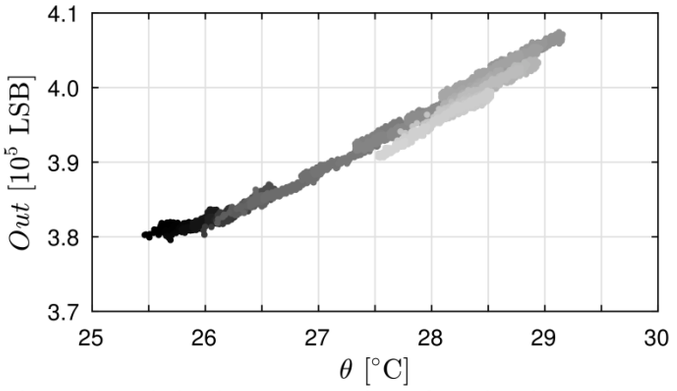

Figure 12: Relation between raw data of acceleration with temperature: day 91 – 288 (dark – beginning of the measurement; light – end of measurement)

4.2 *Measurements with encased MEMS-sensor*

Prior to an installation at a tower-like structure two encased MEMS-based accelerometer have been tested for long-term stability in a controlled environment. Two inclination sensors were housed with a casing whose material possesses a low thermal expansion coefficient. Both sensors measure rotations and temperature at the sensing element. The test was conducted in a lab with constant temperature of 20°C. It is again assumed, that no physical rotation of the sensors, mounted to a heavy steel angle, is applied or induced. Both sensors measure the rotation in different, orthogonal axes. The recorded time histories of the temperature and the inclination over the measurement period of 37 days are depicted in Figure 13. While the inclinations increase continuously, the temperature is increasing throughout except the period between day 25 and 30.

From a temperature calibration of the manufacturer the thermal effect on the Scale-Factor and Bias on the encased sensors was available. In Figure 3 the temperature-induced change of inclination of both encased sensors is shown in relation to an initially horizontally aligned sensor at 25°C. It should be noted, that the effect changes as the sensor is displaced from its initial position due to the trigonometric function in Equation (1). The inclinations before and after temperature compensation are compared in Figure 14.

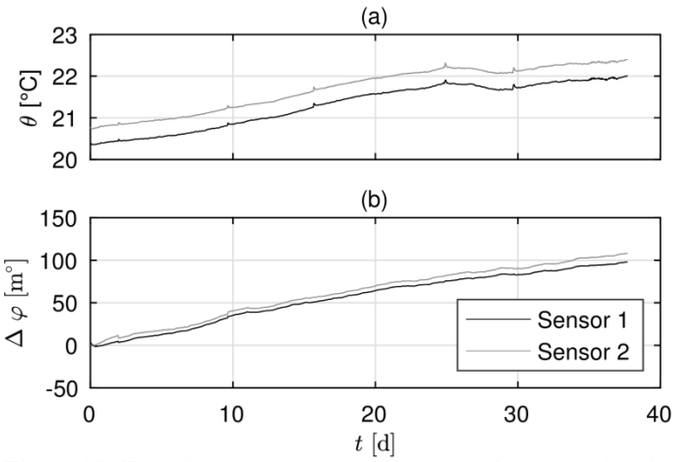

Figure 13: Time history of temperature (a) and measured inclination (b) of two encased MEMS-sensors.

It becomes clear that the temperature has a small effect on the measured deviation from the non-rotated state. In case of the examined, encased sensors temperature has a minor effect. After compensation the inclination of sensor 1 is reduced by 20% of the initial deviation and for sensor 2 it has increased. Since the sensors were mounted to a rigid body, the remaining deviations must be attributed to sensor drift. From HTOL-test (see Section 2.5) the drift was assumed to be linear. Here, linear drift compensation may be applied, but to some extend a flattening can be seen. Therefore a better approximation may be done by root functions.

For determination the long-term stability and quantity of the drift of a MEMS-based sensor in future tests, it is proposed that the sensor is tested under different temperature conditions. These tests should incorporate slow temperature changes including warmer as well as colder phases compared to a reference temperature. If also faster temperature changes are expected for the service life, they have to be imposed also during initial testing.

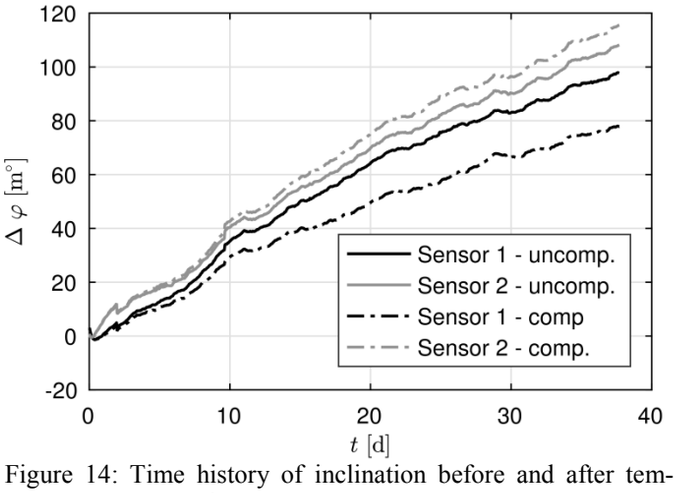

Figure 14: Time history of inclination before and after temperature compensation.

5 MEASUREMENT AT TOWER-LIKE STRUCTURE

The encased MEMS-based accelerometers were installed at a tower-like structure to measure the inclinations under real environmental conditions. Also a reference system based on high quality inclinometers with a range of ±3° and an accuracy of 0.3m° was installed. The inclinations in orthogonal horizontal directions of the structure N_1, N_2 and the temperature were recorded (see Figure 15). The temperature variation can be clearly seen. However, if considering the inclination of the reference sensor, it is also evident, that a drift effect is overlaid in the measured inclinations of the MEMS-inclinometer. The drift seems to be a linear up to day 75, after which the temperature decreases and the growth of the deviation is reduced. The question arises whether the drift reduces after a certain period or the reduction is due to the lower temperature level.

Since the drift was observed to decrease over time an exponential function $f(t)$ was fitted to the raw measurement data as indicated in Figure 16.

$$f(t) = a * e^{-b/t} \qquad a, b > 0 \tag{4}$$

Comparing the measured inclinations of the reference sensor in Figure 15 (b) and the compensated time history of the MEMS-inclinometer in Figure 16, it can be seen that the two curves are still different. The inclinations determined from the MEMS sensors, still contain temperature variations of ±10m° which do not appear in the reference time history. However, the diverging behavior in between the two axis N_1 and N_2 can be observed in both curves. The difference has approximately the same magnitude.

It can be concluded that due to the drift and the fact, that there is no precise information about the drift and how to compensate, the investigated MEMS accelerometer are not yet applicable for long-term monitoring at long-span bridges until now.

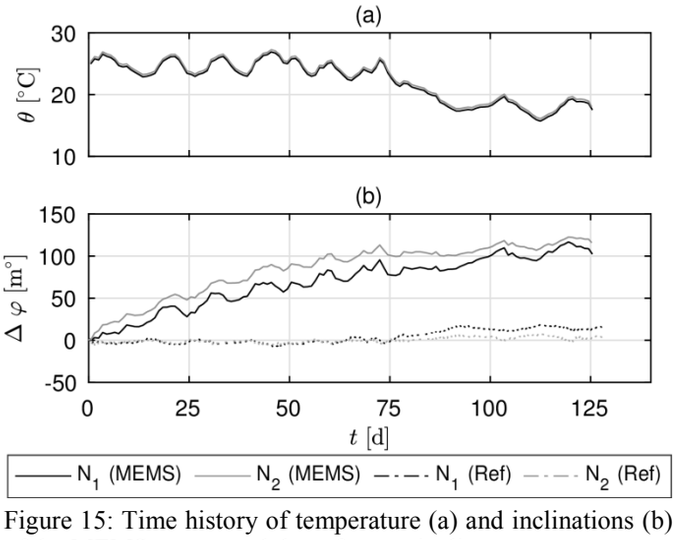

Figure 15: Time history of temperature (a) and inclinations (b) of the MEMS-sensor and the reference inclinometer.

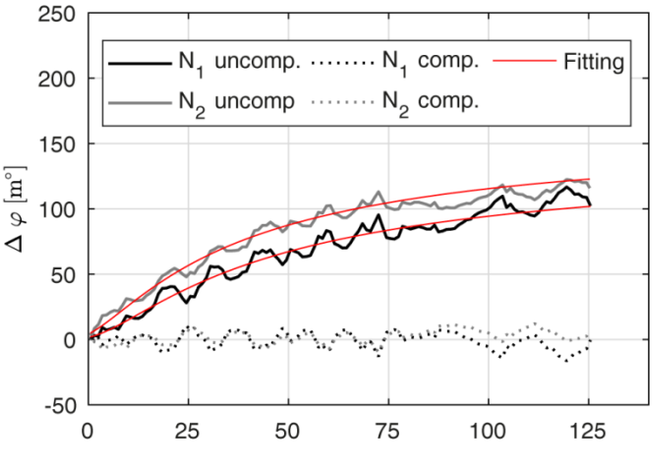

Figure 16. Time histories of the inclinations before and after compensation and indication of the fitting.

More research about the sensor drift needs to be carried out in order to answer the question, what the driving factors for sensor drift are and how an appropriate compensation can be conducted to obtain reliable results. However, in Section 3 it was demonstrated that during short-term measurements the accuracy was less than 5m° throughout all load stages during the bending test, where inclinations up to 1.3° were imposed to a beam. The application for short-term measurements seems therefore possible.

6 POSSIBLE APPLICATION

During the construction of cable-stayed bridges the measurement of stay-cable forces and deflections of the bridge girder are important to ensure bridge girder alignment and desired stress distribution in all bridge components. Right after new deck segments are lifted and before new stay cables are installed, large displacements at the tip of the cantilevered deck occur. Tacheometric survey is used to determine the displacements of the deck.

The inclination is the derivative of the displacement. As large deflections at the cantilever occur also significant inclinations are present during deck construction. Here, the question arises whether the MEMS-based sensors can be utilized in short-term measurements to determine deflections.

Bridge deflections can be evaluated based on polynomial functions, where local inclination measurements are used to define the slope of deflection curves at discrete locations. This method has been studied by Burdet 2000, Xingman 2005 and Zhang 2016. Besides inclinometer Sousa 2013 also applied strain gauges in the estimation process.

The applicability of the MEMS-based accelerometer shall be exemplarily shown for the Stonecutters Bridge, which is located in Hongkong and has a total length of 1596 m with a main span of 1018 m. The cable-stayed bridge was built with balanced cantilever method. At the stage when the longest cantilever (506.4 m) was constructed, the deck experienced

large deflections (Morgenthal 2010). The tip of the cantilever was displaced by more than 3 m yielding rotations of more than 2° (2,000m°). The numerically determined deflected shape and the corresponding inclinations are given in Figure 17.

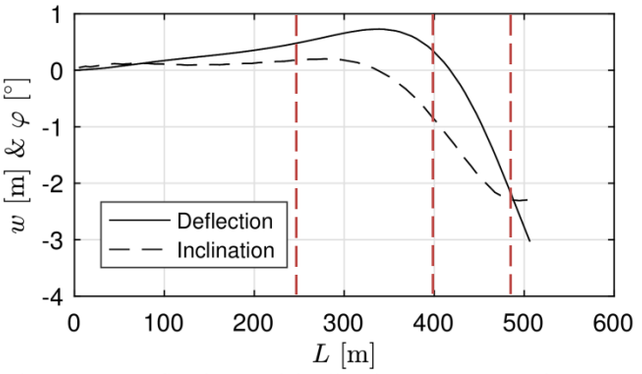

Figure 17. Deflection and inclination at construction stage of Stonecutters Bridge (Morgenthal 2010).

Three possible inclinometer positions are indicated with dashed lines in Figure 17. Being aware of the uncertainty that is related with the MEMS-based inclinometer, the estimation process will result uncertainty in the deflected shape, which can be visualized by envelopes. Since the MEMS-based inclinometers are low-cost compared to standard piezoelectric sensors, also the usage of multiple sensor shall be explored in the context of reduction of the uncertainty in the estimated deflections. Considering the increasing quality of the MEMS-based it is believed that MEMS-inclinometer can be used for bridge monitoring purposes in the near future when significant rotations are present.

7 CONCLUSIONS

The paper presented investigations on the temperature dependency and the drift on novel MEMS-based accelerometer utilized for inclination sensing. Different sensor behavior was observed. Firstly, there are great variations among the individual sensors in terms of temperature dependency as well as sensor drift. Secondly, in a long-term laboratory test, where small and slow temperature variations were observed, the temperature effect seemed to have a significant influence on the raw inclinations. Applied to a tower-like structure, where larger and faster temperature changes were present, the sensor drift had a dominant influence. The questions arising from the data evaluation have been presented in this paper. The imperfection of the miniaturized sensors was shown. The measurement of inclinations with MEMS-based sensors incorporates uncertainties. A flexural test of a beam showed up to 5m° deviations from reference measurements, when inclinations up to 1.2° where applied. One possible application during erection of cable-stayed bridges for short-term measurement to evaluate the deflected shape has been presented.

Q.L. Meng
School of Civil Engineering, Tianjin University, Tianjin, P.R. China

ABSTRACT: The dynamic properties of long-span suspension bridges were studied based on fine temperature effect analysis and thermal-eigenvalue problem. The heat transfer between structure and surrounding air was related to wind speed, atmospheric environment and thermal properties of ground surface. Temperature variations in cables and uneven heat transfer coefficients on the pylon were obtained with multi-scale modeling and CFD (Computational Fluid Dynamics) method, respectively. Then, based on the fine temperature distribution, the effect of temperature variations, temperature gradient and material properties on the structural dynamic properties were comparatively analyzed in different seasons. Consistent with other researches, an overall decrease in modal frequency was observed with the increase in temperature. Bur for long-span suspension bridges, the dynamic properties were mainly caused by the thermal stress and the corresponding deformations. The novelty of this work lies in the accurate description of the thermal gradient field, as well as the refined mechanical representation of time-varying thermo-dynamic properties for suspended-cable structures.

1 INTRODUCTION

During the service life of bridge structures, the local damage, as well as seismic behavior can be reflected by the changes in dynamic properties. Therefore, a successful condition assessment relies heavily on prediction accuracy of vibration properties. However, structural natural frequencies are sensitive to the complicated and changeable environments, such as temperature and humidity (Xia et al. 2006). Recently, more and more researches have focused on the effect of temperature gradient on the vibration properties of bridges (Zhou et al. 2014). If temperature-induced variations are not fully understood, structural identification may be determined with deviations and the proper maintenances will be missed.

However, most researches were based on relatively simplified numerical model and hypothetical temperature distribution. Although the fine numerical model and real temperature gradient were taken into account in some researches, only simply girder bridges were mainly focused on (Xia et al. 2011, Nandan et al. 2014, Carboni et al. 2012). Actually, with high flexibility and geometric nonlinearity, the local vibration induced by external excitations is highly obvious for long-span suspension bridges. Unfortunately, the effect of ambient factors on the dynamic properties of long-span suspension bridges is not very clear. Also, suspension bridges were usually simplified as a 3-D beam-shell element model (Wang et al. 2010) and the thermal boundaries were applied in a relatively simple way (Westgate et al. 2014) in some researches. So the temperature gradient and corresponding thermo-dynamic properties have not been studied finely for long-span suspension bridges.

2 THE THERMO-ELASTO-DYNAMIC PROBLEM

2.1 *Fine prediction of temperature distribution for suspension bridges under solar radiations*

2.1.1 *The simulation technique*

The fine simulation technology for predicting temperature distribution in the bridge proposed by Zhu (Zhu et al. 2017) was applied, including fine modeling, thermal loads package and 3-D sheltering algorithm. Based on the technology, some components were equivalent mechanically and the fine model of the suspended bridge was established. 3-D sunshine sheltering status on every surface was updated by calculating the transient solar elevation angle and hour angle in every time increment.

2.1.2 *Multi-scale modeling and temperature-varying in cables*

Many gaps among the internal steel strands exist in main and hanger cables. The air in these gaps, hav-

ing low thermal conductivity, decreases the heat transfer rate in cables. In order to obtain the equivalent thermo-physical parameters by an extensible way, temperature fields in two scale models of cable, containing the steel strand fine model and the steel strand equivalent model, were firstly analyzed. Then seasonal temperature variations in some characteristic cross sections of cables were calculated using the equivalent thermo-physical parameters. Finally, through four temperature points in characteristic cross sections, the spatial temperature-varying in the cables (cable model) was interpolated. Figure 1 describes the multi-scale modeling for cables.

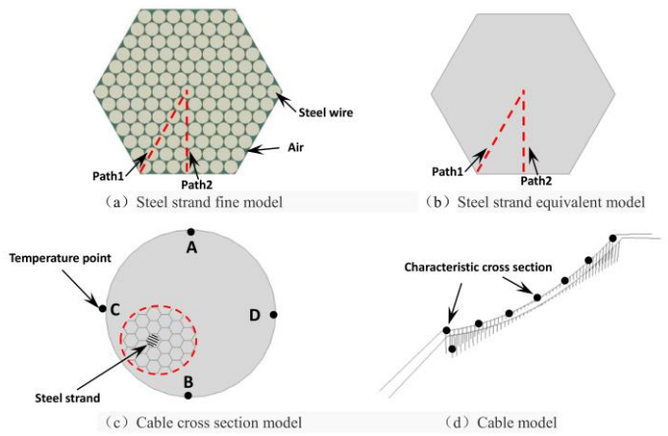

Figure 1. Multi-scale modeling of cables

2.1.3 *Surface transfer coefficient obtained with CFD method*

By establishing 2-D numerical model, which consisted of representative cross sections of python and surrounding air, the conservation equations of mass, momentum, and energy were solved.

2.2 *The thermo-dynamic properties of suspension bridges: finite element method*

Modal properties were provided by solution of the following eigenvalue problem:

$$(K-\omega^2 M)\phi = 0 \tag{1}$$

where M = the global mass matrix; K = stiffness matrix; ω is natural frequency vectors.

2.3 *The decomposition of stiffness matrix K*

Owing to the temperature effect, stiffness matrix K was decomposed into five parts: K_{ini}, the initial stiffness matrix without considering the temperature effect; the: dK_E^T matrix, corresponding to temperature dependence of elastic constants; dK_S^T matrix, which was induced by thermal stress, reflected by the so-called stress stiffening effect; dK_ε^T matrix, indicating the geometric nonlinearity effect and the temperature-induced deformation of bridges; dK_M^T matrix, caused by rigid motion of local materials, especially for cables. So the eigenvalue equation was rewritten:

$$[(K_{ini}+dK_E^T+dK_S^T+dK_\varepsilon^T+dK_M^T)-\omega^2 M]\phi = 0 \tag{2}$$

3 APPLICATION EXAMPLE

3.1 *The suspension bridge*

A suspension bridge (in Zhangjiakou, China) with 720m-length steel-concrete composite girder (see Fig. 4) is located at 109.6º E and 23.6º N, with an azimuth of 40.657º. The 33.6m-width girder is composed of transverse I-shaped steel beams, on which 20cm-thickness concrete slab and 3cm-thickness asphalt pavement are placed. The main cables, with 1/9.5 rise-to-span ratio and 18% internal porosity, contain 91 high strength steel wire strands. Each strand is also composed of 1275 25mm-diameter high strength steel wires. The 107.8m-height pylon was cast into gate-shaped frame.

3.2 *Numerical model*

Based on the mechanical equivalence for steel girder and cables, fine numerical model of the suspension bridge was established (see Fig. 2). The fine modeling not only involved the global features of bridges, such as the azimuth and location, but also contained the local configurations of components including the normal vectors of all surfaces, inclined angles of the outer surfaces, and the sheltering relationships.

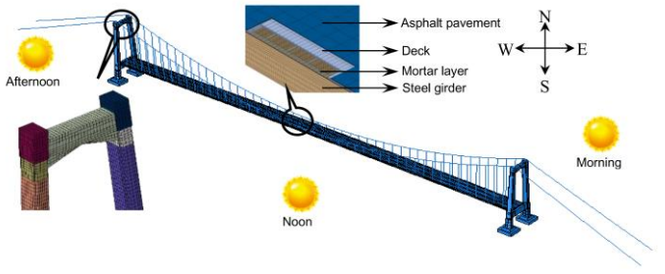

Figure 2. Finite-element model of example suspension bridge

3.3 *Climatic and boundary*

Thermal loads on bridge surfaces were classified into short-wave and long-wave radiations (Zhu et al. 2017), such as direct radiation, diffuse radiation, reflected radiation, atmospheric counter radiation, water radiation and surface radiation. Different from thermal loads, thermal boundaries were treated as the heat convection between surfaces and ambient air (Kehlbeck, in press).

To consider the seasonal effect, four representative days were investigated: the spring equinox, the summer solstice, the autumnal equinox, and the winter solstice (see Table 1).

Table 1. Climate at the bridge site.

Season(Date)	MaxT (℃)	MinT (℃)
Spring(15th April)	19	5
Summer(15thJuly)	30	19
Autumn(15thSeptember)	17	4
Winter(15thJanuary)	-1	-12

* MaxT represents the maximum temperature; MinT represents the minimum temperature

4 APPLICATION RESULTS

4.1 *Fine temperature distribution of suspension bridge*

4.1.1 *Temperature variations in the cables*

Based on a range of thermo-physical parameters, 2-D thermal transfer analysis was conducted in steel strand fine model and the steel strand equivalent model. Then, the equivalent thermo-physical parameters were determined by fitting temperature variations along two paths (see Fig. 1) between both models. The equivalent thermal conductivity and specific heat capacity along the path 1 were 26.2 W/(m℃) and 509.8J/(Kg℃) respectively, close to equivalent parameters 26 W/(℃) and 507.7J/(Kg℃) along path 2, so the finally parameters were selected as mean values of the two paths. Compared with the 50.7 W/(m℃) (Westgate et al. 2014) and 38 W/(m℃) (Fan et al. 2017) from previous test, the equivalent thermal conductivity was lower, which were within the reasonable range.

The temperature variations in cable cross section at different time are plotted in Figure 3(a)-(d). The simulated temperature variations were verified by the measurement temperature on a truncated main cable from Xihoumen Bridge [see Fig. 3(e)] (Yu et al. 2010). The point B was close to the ground during the measurement in which the ground radiation was not clear, so that the temperature variation at point B was different from the measured value during 10~25h. Apart from the difference above, the simulation temperature variations showed reasonable consistency with the field-measured data.

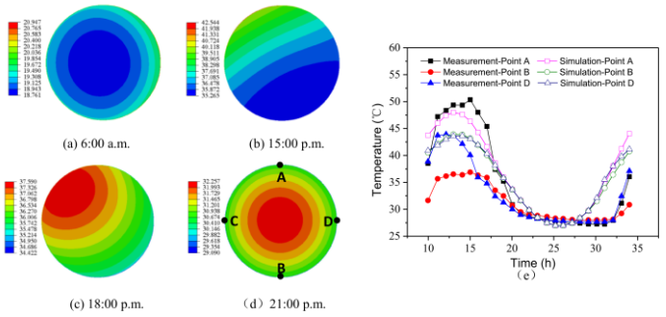

Figure 3. (a)-(d) Temperature distributions in cross section of mid-span main cable at different time (unit: ℃); (e) Contrasts between the simulated temperature and that from Xihoumen bridge

4.1.2 *Non-uniform heat transfer coefficients on the pylon*

As the application of convection heat transfer coefficients, we averaged the coefficients along the surface with the same normal direction, which were classified as east, south, west and north directions. The uneven heat transfer coefficients were quantized on the surface of pylon based on the environmental factors (see Fig. 4).

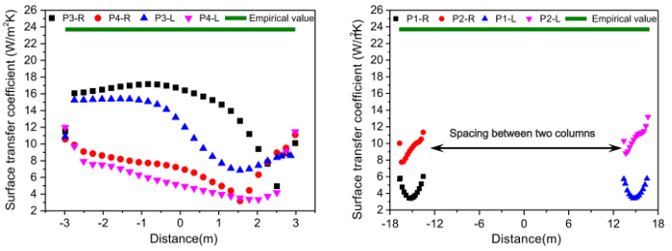

Figure 4. The surface heat transfer coefficients at section (at the height of 10.78m) in winter

4.1.3 *Non-uniform temperature distribution due to the sheltering effect*

Due to the mutual-sheltering, temperature on asphalt deck and pylon locally decreased about 15℃ and 10℃ respectively. The temperature distributions at 10:00 a.m. and 12:10 p.m. in the summer were shown in Figure 5. With the self-sheltering, temperature difference between the sunny and shady face of pylon gradually increased to 7℃ from 6:00 to 18:00. The cap of pylon was buried in soil without any solar radiations (in permanent sheltering).

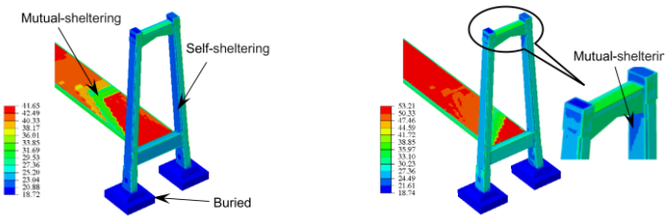

Figure 5. Temperature distributions of the stiffening girder and the main tower at different time in July 15th (unit: ℃)

4.2 *Thermo-dynamic properties of suspension bridge*

4.2.1 *The influence of temperature variations*

In this section, the temperature dependence of concrete elastic modulus was defined as Equation 3 (Xia et al. 2011). Furthermore, the varying elastic modulus for steel, asphalt and cables were listed in Table 2. For all building materials, the elastic modulus almost decreased with the rise of temperature.

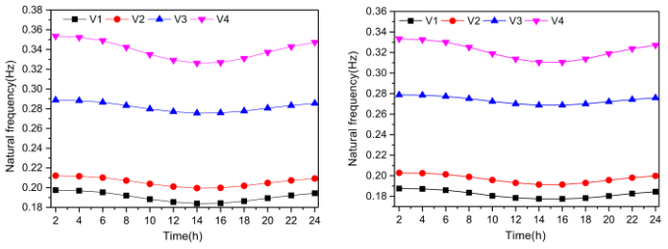
$$E(T) = E_{20°C}(1.09 - 0.0045T) \quad (3)$$

where T = temperature of the material; $E_{20°C}$ = Young's modulus of concrete at the temperature 20 ℃.

Table 2. Temperature-dependent elastic modulus of building materials

Temper-ature(℃)	Elastic modulus(MPa)		
	Steel	Asphalt	Cables
-10	-	25000	-
15	206000	16250	164800
20	-	6000	-
38	-	2000	-
100	180250	0	144200

Since the maximum daily temperature difference in four seasons was almost equal, the winter and summer solstice were selected to study the mechanism of thermo-dynamic properties of bridges in extreme temperature situation. Figure 6 shows the daily variations of natural frequencies corresponding to the first four order of bending vibration modes, V1-V4 represent 1-4th vertical bending modes.



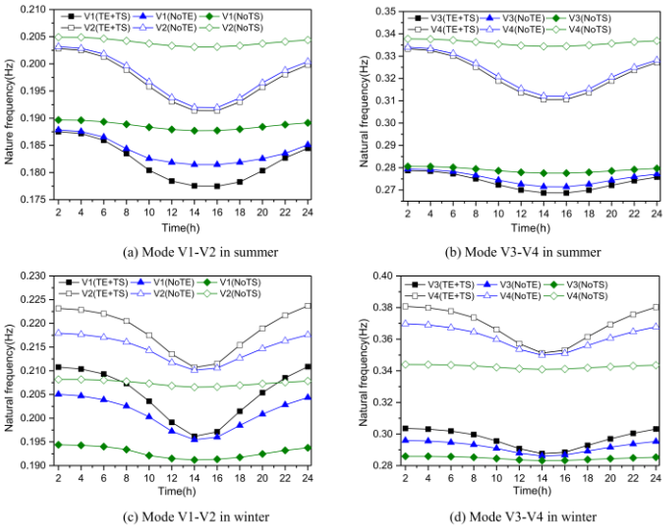


Figure 6. Daily variations of natural frequencies

Whatever seasons and vibration modes, the nature frequencies trended to decrease during 2-14h and increase during 14-24h. Since air temperature reached the maximum value at 14h, it was easier deduced that the modal frequencies decreased with the increase in temperature.

4.2.2 *The influence of material properties*

In order to study the temperature-dependence of materials, three circumstances were considered: (1) All temperature-dependent materials were included; (2) The temperature-dependence of elastic modulus of all materials were removed; (3)The expansion coefficient of all materials were set to 0, which meant no thermal stress induced by solar radiations. The daily variations of natural frequencies of the first four order bending vibration modes under three circumstances is plotted in Figure 7, TE and TS represent case1 and case 2 respectively.

(a) Mode V1-V2 in summer (b) Mode V3-V4 in summer

(c) Mode V1-V2 in winter (d) Mode V3-V4 in winter

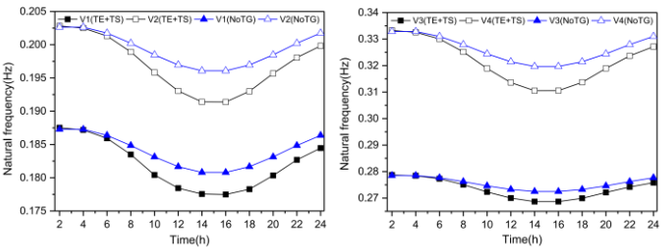

Figure 7. Daily variations of natural frequencies

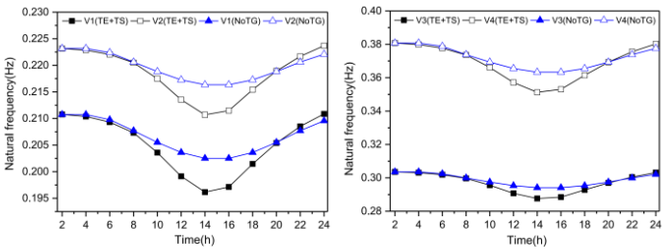
For all vibration modes as shown, the daily variations of natural frequencies draw back slightly (-1.35% for V1; 0.24% for V1; -0.75% for V1; 0.132% for V1) if elastic modulus remained constant. Smaller elastic modulus of materials corresponded to lower structural natural frequencies. However, the frequencies nearly unchanged when thermal stress was not considered, indicating that the thermo-elasto-dynamic problem was mainly governed by the stress stiffening and geometric nonlinearity effect for long span suspension bridges.



4.2.3 *The influence of temperature gradient*

The thermal loads and convection boundaries on the bridge surfaces were removed to eliminate internal temperature gradients. Air temperature was applied to the whole suspension bridge, in which the reference temperature of expansion coefficient was based on the design (15℃). The daily variations of natural frequencies without temperature gradient (TG) are plotted in Figure 8, only V1-V4 vibration modes were contained.

The influence of temperature gradients in the suspension bridge was obvious, although there were considerable decrease in natural frequencies. The reason that more contributions in winter might be relate to the higher stiffness of concrete and asphalt.

(a) Mode V1-V2 in summer (b) Mode V3-V4 in summer

(c) Mode V1-V2 in winter (d) Mode V3-V4 in winter

Figure 8. Daily variations of natural frequencies

5 DISCUSSION

The dynamic properties of bridges are affected by both local structural configuration and elastic constants of the materials. But unlike simple girder bridges mentioned in previous researches, the thermo-elasto-dynamic problem of suspension bridges are mainly governed through the stress stiffening and geometric nonlinearity effect. This means minimizing the temperature-induced deformation of suspension bridge can effectively control the meaningless variations in the structural modal parameters.

6 CONCLUSION

In the present study, a simulation technology is proposed to predict fine temperature distribution on suspension bridges. Temperature variations in cables and no-uniform surface transfer coefficient on the pylon were obtained with multi-scale modeling and thermal-fluid simulation method, respectively. On the basis of that, the time-varying thermo-dynamic properties were comparatively analyzed. Some conclusions were drawn from the technology application:

(1) With multi-scale modeling, the equivalent thermo-physical parameters of cables could be obtained (For cables in this paper, thermal conductivity=26.1W/(m℃) and specific heat capacity=508.7 J/(Kg℃)).

(2) Due to inverse air flow, the surface transfer coefficients were seriously uneven on the surface of pylon. Therefore, a great deviation would be produced if the heat transfer coefficient was considered uniform on the pylon surface.

(3) With the sheltering effect, temperature on the asphalt pavement and pylon locally decreased about 15℃ and 10℃ respectively. Temperature difference between the sunny and shady face of pylon gradually increased to 7℃.

(4) Under solar radiations, the modal frequencies of suspension bridge decreased with the increase in temperature, the percent of maximum decrease was 6.9%.The influence of temperature gradients was also obvious (The maximum percent of contribution was 44% in winter).

Inverse analysis using compatible displacements

Jun Lei & Dong Xu
Tongji University, Shanghai, China

Jose Turmo
Universitat Politècnica de Catalunya, Barcelona, Spain

ABSTRACT: To avoid potential life and economic loss, structural health monitoring has become increasingly important for bridge systems. As a key component of structural health monitoring, structural system identification (SSI) tries to identify the structural parameters through the measured response. However, due to the ill-posedness of inverse analysis, the estimation of parameters is greatly affected by measurement errors. To alleviate the adverse effect of errors, the relations among the displacements in beam structures (for instance bridges), compatibility conditions, are derived analytically via a symbolical approach. Then a set of compatible displacements is obtained by an optimization procedure that finds the closest compatible deformation shape to the measured one. The final estimations of the parameters are obtained by providing the compatible displacements to SSI. The proposed method is validated by the numerical simulations on a simply supported bridge and on a continuous bridge.

1 INTRODUCTION

As a powerful tool for condition assessment, Structural System Identification (SSI) has drawn great attention in the past decades. SSI can be summarized as structural parameter estimation using discrete measurements of the structural response.

Based on different criteria, SSI methods are categorized as dynamic or static, parametric and non-parametric, deterministic and probabilistic.

In the parametric methods, the parameters directly represent the physical parameters (e.g. elastic moduli, areas, flexural/torsional inertias), like the ones used in finite element models. Non-parametric methods use basis functions to regress the response of the structure, e.g. autoregressive models (Su et al. 2014; Huang et al. 2009; Mei et al. 2016; Lakshmi et al. 2016) or rational fractional polynomials (Okada et al. 2006).

Concerning probabilistic SSI, mainly the Bayesian approach, posterior distributions of the parameters are obtained by updating the assumed distributions of the parameters with discrete measurements of the response (Beck & Katafygiotis 1998; Zhang et al. 2016; Sun et al. 2015; Beck & Au 2002; Behmanesh & Moaveni 2015). The estimates of the parameters might be obtained by point estimate (e.g. mean, median) or interval estimate (confidence interval) based on the posterior distributions of the parameters. On the contrary, deterministic method tries to pinpoint a unique solution of the problem (Lozano-Galant et al. 2013; Sun et al. 2013; Law & Yong 2011; Marano et al. 2011; Raich & Liszkai 2012; Eskew & Jang 2017; Sevillano et al. 2016; Jeong et al. 2013). In both probabilistic and deterministic methods, optimization technique is closely involved. The objective of the optimization might be minimizing the discrepancy between the measurements and the predicted response, e.g. displacements(Sevillano et al. 2016; Marano et al. 2011), acceleration (Marano et al. 2011), mode shapes and frequencies (Eskew & Jang 2017; Jeong et al. 2013), or maximizing the sensitivity of the frequency response functions (Raich & Liszkai 2012).

Observability method (OM) is a mathematical method dealing with the existence and the uniqueness of the solution of system of equations (or a subset of it) (Castillo et al. 2007). The first application of OM in SSI using static tests is introduced in (Lozano-Galant et al. 2013). In the proposed formulation, a finite element model (FEM) of the structure has to be defined first. Subsequently, the equilibrium equaitons are obatined. A series algebraic operations are applied in the resulting system so that the known and the unknown information will be well separated on different sides of the equations. This known information may include the applied external loads, the meausrements of the structural response (deflections, rotations), the boundary conditions. The unkonwn may include the structural parameters, the unmeasured displacements, the reactions. Hereafter, this system of equations is referred as the observability equations. From the perspective of SSI, the

observablity of structural parameters is related to the question that whether the solution or a subset of it can be uniquely determined with a given measurement set. This can be solved by checking the null space of the coefficient matrix of the observability equations.

2 STRUCTURAL SYSTEM IDENTIFICATION BY OBSERVABILITIY METHOD

2.1 *Equilibrium equations from direct analysis*

First, a FEM for the structure to be analyzed is defined according to the desired accuracy. This is related with the number of parameters and the available measurements. The more parameters assumed, the more measurements required. The equilibrium equations can be given as follows:

$$K \cdot \delta = f \tag{1}$$

$$\begin{pmatrix} K_{00}^{p\times r} & K_{01}^{p\times s} \\ K_{10}^{q\times r} & K_{11}^{q\times s} \end{pmatrix} \begin{Bmatrix} \delta_0^{r\times 1} \\ \delta_1^{s\times 1} \end{Bmatrix} = \begin{Bmatrix} f_0^{p\times 1} \\ f_1^{q\times 1} \end{Bmatrix} \tag{2}$$

In Eq. (1), K, δ and f, respectively, represent the global stiffness matrix, the nodal displacements and the nodal forces. For a 2D model with beam elements, all the entries in the global stiffness matrix K are composed of the characteristics of the beams (i.e. length L, elastic moduli E, area A and inertia I). Displacements δ include horizontal displacements u, vertical deflection v and rotation w whereas the quantities in the concentrated forces f include horizontal forces H, vertical forces V and moments M. Hence, all the quantities involved in the equations are {*E, A, I, L, u, v, w, H, V* and *M*}. From these, some of them are known and some are unknown. The known and the unknown quantities are indicated by the subscripts 1 and 0 in Eq. (2), respectively

In direct analysis, it is assumed that the parameters {*E, A, I* and *L*} for every element are known and thereby the global stiffness matrix is always available for structural analysis. Regarding displacements δ, except for the displacements of the restrained nodes, δ_1,at the boundary, the displacements of the remaining free nodes, δ_0, are unknown. In addition, with respect to the forces f, except for the applied external forces f_1, the reactions f_0 at the boundaries are unknown. In direct analysis, these unknowns, i.e. f_0 and δ_0, will be solved in Eq. (1). In SSI by OM, which is an inverse analysis, the assumption that the length L and the applied static external force f_1 are known still applies. Besides, since a subset of the displacements of the free nodes are measured in real-life, the set of known displacements δ_1 is enlarged. Then elastic moduli, E, areas, A, inertias, I, and the remaining unknown displacements δ_0 are to be determined. It should be noted that one of the main objective of SSI is to assess the condition of the structure. That is, the estimations of axial stiffnesses *EA* and flexural stiffnesses *EI* are of primary importance. In order to reduce unknowns, *EA* and *EI*, instead of being regarded as the product of two unknowns, are regarded as one unknown.

To carry out SSI by OM, Eq. (2) needs to be transformed into an equivalent form, Eq. (3), by several algebraic operations.

$$B \cdot z = \begin{bmatrix} K_{10}^{q\times r} & 0^{q\times p} \\ K_{00}^{p\times r} & -I^{p\times p} \end{bmatrix} \begin{Bmatrix} \delta_0^{r\times 1} \\ f_0^{p\times 1} \end{Bmatrix} = \begin{Bmatrix} f_1^{q\times 1} - K_{11}^{q\times s}\delta_1^{s\times 1} \\ -K_{01}^{p\times s}\delta_1^{s\times 1} \end{Bmatrix} = D \tag{3}$$

These operations include the separation of the columns, wherein some entries are the sum of different variables, into several single columns related with different variables, the elimination of duplicated variables, the merge of associated columns, extracting the measured displacement from original δ and place them into the associated columns (Lozano-Galant et al. 2013). In the resultant system of equations, regarding the physical meaning of the unknowns, these unknowns are of two types: (1) those unknowns containing the information of displacements, *u, v* or *w*, or stiffnesses, *EA* or *EI*, or the products of both, (*EAu, EAv, EAw, EIu, EIv* or *EIw*); or (2) the unknown reactions at the boundaries, *H, V* and *M*. In the coefficient matrix, only the known quantities, i.e. the measured displacements (might be *u, v* or *w*) and the length of the elements, *L*, remain. Meanwhile, the entries of the vector on the right side of the equation, D, are the result of the external loads f_1 and the equivalent nodal forces, might be $K_{11}\delta_1$ or $K_{01}\delta_1$. The transformation from Eq. (2) to Eq. (3) collects all unknowns in z and renders both B and D known.

However, due to the existence of errors, Eq. (3) does not necessarily have an exact solution. This is to say, system of equations presented in Eq. (3) is not always compatible. In fact, to yield a solution of Eq. (3), D must satisfy some conditions. That is, the null space N of matrix B has to satisfy that $N \cdot D = 0$. If this holds, Eq. (3) is compatible; otherwise, no solution exists (Castillo et al. 2007).

The structure of the general solution (the set of all solutions), z_g, of Eq. (3) is presented in Eq. (4).

$$z_g = z_p + \boldsymbol{N} \cdot \rho = \begin{Bmatrix} \delta_0^* \\ f_0 \end{Bmatrix}_p + \boldsymbol{N} \cdot \rho \tag{4}$$

The general solution z_g is the sum of a particular solution z_p, and the product of a vector of arbitrary values, ρ, and the null space of the coefficient matrix B in Eq. (3), N. The particular solution z_p can be obtained by dividing the vector D by the coefficient

matrix B. This operation can be achieved in many commercial packages, like Matlab (The MathWorks 2015) and Mathematica (Wolfram 1999). $N{\cdot}\rho$ is the set of all solutions of the associated homogeneous system of equations (a linear space of solutions, wherein the columns of N are vectorial bases, and the entries of the vector ρ are arbitrary values functioning as the coefficients of all possible linear combinations). If any row of the null space N is composed of only zeros, then the scalar in the same row of the product of $N{\cdot}\rho$ will also be zero, and thereby the particular solution specifies the unique solution of this unknown. Namely, any unknown associated with a null row in the null space N is observable, i.e. it exists and it is determined and unique. One special case is that the null space $\mathcal{1}$ of coefficient matrix B does not exist. This means that all the unknowns are observable.

3 COMPATIBILITY CONDITION

In order to demonstrate the idea of compatibility condition, consider the simply supported beam in Figure 1.

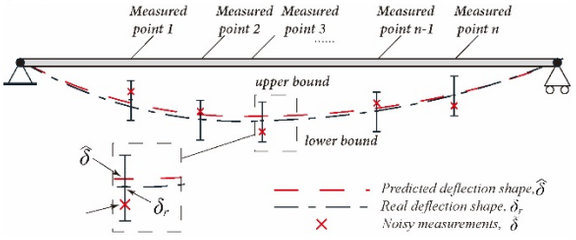

Figure 1. Compatibility condition

The true deflection shape, $\boldsymbol{\delta_r}$, of the structure is indicated by the red dot-dashed line. Due to the physical law, the true displacements should following some compatibility conditions.

However, measurement errors are inevitable in real-life. Assuming that the measurement error follows the normal distribution, the measured displacements $\tilde{\delta}$ can be given as:

$$\tilde{\delta} = (1 + E_{level} \cdot \xi) \cdot \delta_r \tag{5}$$

where E_{level} is the error level in percentage and ξ is a random number following the normal distribution with zero mean and standard deviation of 0.5.

Due to the existence of measurement errors, the measured displacements (indicated by the crossed circle) do not lie on the true deflection shape. Hence, violation of the physical law that the true deformation should satisfy, which is referred as the incompatibility, arises. To smooth away the incompatibility in the measurements, the compatibility conditions among the displacements are derived by the SSI by OM in this section.

3.1 *Derivation of the compatibility condition*

The example of an 18-m simply supported beam is used to show the derivation of the compatibility condition and the associated FEM is given in Figure 2. This FEM has 18 beam elements and the length of each element is 1m. These elements are numbered as 1 to 18 from left to right.

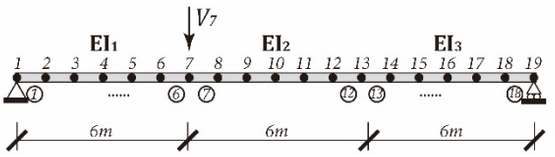

Figure 2. The finite element model for the 18-m simply supported beam

The flexural stiffnesses for elements 1~6, 7~12 and 13~18 are EI_1, EI_2 and EI_3, respectively. The measurable displacements in this structure include 17 deflections, v_2 to v_{18}, and 19 rotations, w_1 to w_{19}. In order to derive the symbolical expression for the unknowns, the essential measurement sets are used (Lei, Nogal, et al. 2017). Without loss of generality, the derivation of this relationship using a given measurement set of three measurements $\{w_7, v_{10}, w_{13}\}$ is exemplified here.

Applying the algebraic operations mentioned in section 2.1, the observability equations corresponding to the measurements $\{w_7, v_{10}, w_{13}\}$ can be obtained. In this system of equations, the unknowns includes the reactions V_1 and V_{19}, the structural parameters EI_1, EI_2 and EI_3, and the coupled variables (e.g. EI_1v_2, EI_1v_3, EI_2v_7…). In the null space of the coefficient matrix, it is found that all the rows related with EI_2 and associated products (i.e. EI_2v_7~ EI_2v_{13}, and EI_2w_8~ EI_2w_{12}) are zeros. This is to say, unknowns EI_2, EI_2v_7~ EI_2v_{13}, and EI_2w_8~ EI_2w_{12} are observable when $\{w_7, v_{10}, w_{13}\}$ are measured. Also, reactions, V_1 and V_{19} are also observable since this is a statically determinate structure. However, all the other variables are not observable.

By solving the observability equations symbolically using Gaussian elimination, a particular solution for all unknowns can be obtained. For instance,

$$\widehat{EI_2} = \frac{18V_7L}{\frac{(w_7 - w_{13})}{L}} \tag{6}$$

$$\widehat{EI_2v_7} = -\frac{3V_7L^3(25w_7 - 12v_{10} + 11w_{13})}{2(w_7 - w_{13})} \tag{7}$$

where the hat, ^, indicates an estimation of the unknowns. The deflection of node 7, v_7, can be obtained by dividing $\widehat{EI_2v_7}$ with $\widehat{EI_2}$. The result is presented in Eq. (8), which specifies the compatible condition that $\{v_7, w_7, v_{10}$ and $w_{13}\}$ should satisfy.

$$12v_7 - 12v_{10} + 25w_7 + 11w_{13} = 0 \quad (8)$$

Similarly, the explicit geometrical relations among different displacements, i.e. the compatibility conditions, can be obtained for the elements within the same element. This is to say, they can be found among the displacements of nodes 1~7 for elements of EI_1 and among the displacements of nodes 13~19 for elements of EI_3. From the previous paragraph, it is clear that displacements of the elements with the same parameter is dependent of three displacements within these elements (being aware that boundary conditions can reduce this number). In the more general case, from the results at element level, at least a set of 7 adequate measurements will be needed. For example, $\{w_1, w_3, w_8, v_9, w_{11}, w_{15}$ and $w_{19}\}$. $\{w_1, w_3\}$ for EI_1, $\{w_8, v_9, w_{11}\}$ for EI_2 and $\{w_{15}, w_{19}\}$ for EI_3. Further, it should be noted that the compatibility condition at the joint nodes should be the same. That is, four more equations can be imposed in this case, which are $v_7(w_1, w_3)=v_7(w_8, v_9, w_{11})$, $w_7(w_1, w_3) = w_7(w_8, w_{11})$, $v_{13}(w_8, v_9, w_{11})=v_{13}(w_{15}, w_{19})$ and $w_{13}(w_8, w_{11})=w_{13}(w_{15}, w_{19})$. Combining all compatibility equations and these four additional equations leads to a system of four equations and seven unknown displacements, the unknowns can be reduced to three displacements that is denoted as the condensed measurement set later. Note that, the number of measurements in this condensed set is the same as the number of parameters. When only three measured displacements are available, the compatibility among these displacements can always be satisfied strictly and a particular set of structural parameters exactly leading to these displacements are always available.

Until now, every displacement in the FEM in Figure 1.c can be expressed as function of $\{w_1, v_9$ and $w_{19}\}$. The associated expression for $\mathbf{EI}_1$, $\mathbf{EI}_2$ and $\mathbf{EI}_3$ can be obtained using these displacements.

3.2 *Imposing compatibility condition*

From 3.1, it is seen that all the displacements within the structure can be expressed by the condensed set. Also, some displacements are measured during the non-destructive static test. Hence, to remove the incompatibility in the measurements, an optimization procedure can be applied. The objective function (see Eq. (9)) of the optimization is the square sum of the proportional deviation of the i^{th} compatible displacements, $\hat{\delta}_i$, from the i^{th} measured measurements, $\tilde{\delta}_i$. N_m is the number of available measurements. The best estimates of the stiffnesses can be determined by providing the optimal $\hat{\delta}_s$ to SSI by OM.

$$F(\hat{\delta}_s) = \sum_{i=1}^{N_m} \left(\frac{\hat{\delta}_i}{\tilde{\delta}_i} - 1\right)^2 = \sum_{i=1}^{N_m} \left(\frac{f(\hat{\delta}_c)}{\tilde{\delta}_i} - 1\right)^2 \quad (9)$$

A flowchart summarizing all the procedures mentioned above can be found in (Lei, Xu, et al. 2017).

4 APPLICTION OF THE PROPOSED METHOD

4.1 *Example 1: Simply supported beam*

In this part, the method is applied in the structure depicted in Figure 2. The effect of the number of measurements, error levels and loading cases are studied.

4.1.1 *Effect of number of measurements*

Regarding the number of measurements, N_m, Three different measurement sets are considered here. $\{v_3, v_5, v_7, v_9, v_{11}, v_{13}, v_{15}, v_{17}\}$ (N_m=8), $\{v_3$~v_5, v_7, v_9~v_{11}, v_{13}, v_{15}~$v_{17}\}$ (N_m=11) and $\{v_2$~$v_{18}\}$ (N_m=17). Errors are introduced by Eq. (5). The results are presented in Figure 3. In addition, the result without applying compatibility condition is also provided when measurement set N_m=8 is used.

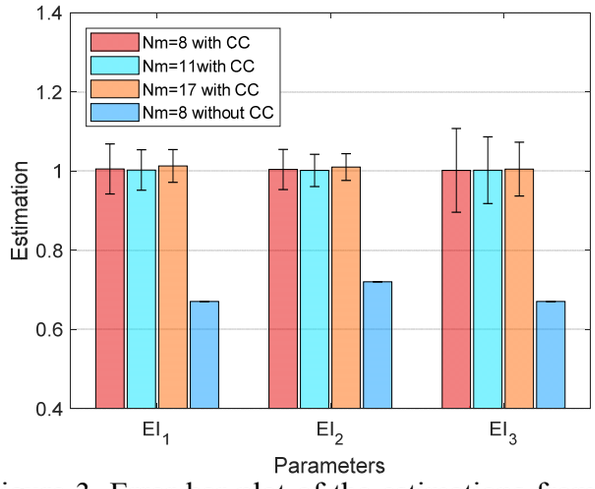

Figure 3. Error bar plot of the estimations from different measurement set with/without compatibility condition (CC).

It is found that the parameters are greatly underestimated using the SSI by OM with redundant measurements. Also the associated variation is very large and hence not shown here. When compatibility conditions are imposed, it is seen that 8 measurements are sufficient to estimate EI_1 and EI_2 accurately with a low dispersion of the estimate. In the case of EI_3, a slight overestimate of 1.3% is observed, which is acceptable. However, the coefficient of variance of the estimates in EI_3 is 0.112, which might not be negligible. When the number of measurement increases, both the mean and the COVs of the normalized estimates of the stiffnesses decrease. With regard to the mean of the estimate, mean of the normalized parameters becomes closer to one and the improvement in EI_3 is relatively large while the improve-

ments in EI_1 and EI_2 are smaller. In Figure 2.b, the drop of COV for EI_3 is roughly twice the drop of COV in EI_1 and EI_2 when the number of measurements increases. However, despite the fact that using more measurements will reduce the extent of dispersion, the COV of the estimates of EI_3 using 17 measurements is still higher than the COV of the estimates of EI_1 using 8 measurements.

4.1.2 *Effect of loading cases*

The effect of the loading case is studied by changing the location of the loads. The studied structure is the one depicted in Figure 2. Nine loading cases are studied here. For each loading case, a vertical load is applied at one point ranging from node 2 to node 10, as indicated in Figure 4. The measurement set $\{v_3, v_5, v_7, v_9, v_{11}, v_{13}, v_{15}, v_{17}\}$ (N_m=8) is used here. Measurements are marked by the red arrows in this figure. For each of these load cases, 2000 measured displacements are generated using Eq. (5) with the error level of 4%, and are taken as input into SSI by compatible OM.

The mean and the coefficient of variation for the 2000 estimations are summarized in Figure 4.

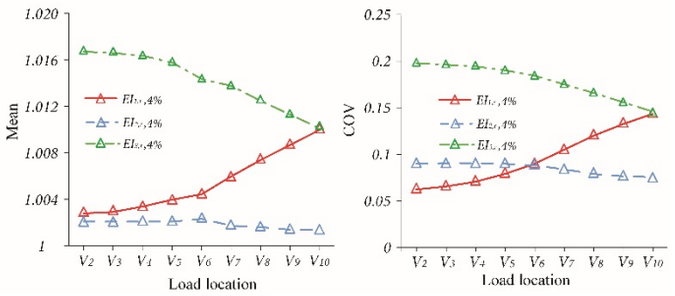

Figure 4. Mean and coefficient of variations of the estimations using $\{v_3, v_5, v_7, v_9, v_{11}, v_{13}, v_{15}, v_{17}\}$ with 4% errors

When the structure is subjected to V_2, the flexural behavior of elements of EI_1 is quite activated. The associated mean for EI_1 is 1.003, which is insensitive to errors. However, in the case of EI_3, a higher overestimation can be observed when high errors exist in the measurements. The associated mean for EI_3 is 1.017. It should be noticed that the flexural behavior of the elements of EI_3, i.e. elements 13~18, is not activated much in this load case. When the load moves from node 2 to node 10, the curvature of the elements of EI_1 decreases while the curvature of the elements of EI_3 increases. Correspondingly, an overestimation of EI_1 arises and escalates while the overestimation of EI_3 becomes less severe. Similar variation is found in the COV of EI_1 and EI_3 in Figure 4.b. For the loading case V_{10}, EI_1 and EI_3 have the same mean. This is because the curvature for elements of EI_1 and the curvature for elements of EI_3 are the same in this load case. Also, the COV of both EI_1 and EI_3 are the same. The flexural behavior of elements of EI_2 is quite activated under each load case. Consequently, the mean and the COV of EI_2 are lower than those of EI_1 and EI_3. When the load moves from node 2 to node 10, which is to become closer to the elements of EI_2, the curvature of these elements becomes even bigger. As a result, a small but perceptible improvement is seen in both the mean and the COV of EI_2 In conclusion, it is advisable to apply different load cases to study different zones of the beam.

5 CONCLUSIONS

This paper proposes a novel approach for identifying compatibility conditions, the relations among displacements, in beam - like structure using observability method. By solving an underdetermined system of equations formulated by compatibility conditions, it is shown that all displacements in a beam - like structure are functions of a subset of these displacements. Then, an optimization procedure is introduced to reduce the measurement errors by minimizing the square sum of the proportional deviation of the measured displacements and those compatible displacements. The effectiveness of this method is validated in a simply supported beam. A two span continuous bridge example will be presented during the conference.

Combined structural and traffic monitoring of steel suspension bridge

P. Hradil & K. Koski
VTT Technical Research Centre of Finland

ABSTRACT: The present paper discusses the possibility of using structural monitoring sensors such as strain gages attached to the main girders of steel bridges to collect the data about the traffic on the bridge deck. Obtaining useful data is challenging task since the load is typically transferred from the deck to the main load-carrying structure through several intermediate structural members. The main parameters affecting the reliability of such results are the number, position and type of sensors used. The additional requirements might lead to a more complicated planning of the bridge instrumentation. On the other hand, this method can result in substantial savings in planned monitoring systems and will increase the value of monitoring data from already instrumented bridges. The method is demonstrated on a steel suspension bridge located in western Finland.

1 INTRODUCTION

Structural monitoring of long-span road and railway bridges is a common approach to continuously collect data about strains, deflections and other parameters on specific locations of the load-carrying structure. At the same time, the bridge can be instrumented to monitor the traffic, especially weights, speeds and axle distances of passing vehicles. In both cases, the amount of data is usually huge, and many methods have been recently developed to evaluate the results in a real time. However, sensors intended for traffic monitoring are typically close to the surface, while the structural sensors are attached to the load-carrying structural members.

The goal of this study was to develop a calculation method to predict the mass of passing vehicles from multiple measured strains on the bridge and to calibrate its parameters to the existing loading tests.

The demonstration case is for the presented approach is steel suspension bridge in Kirjalansalmi that has been continuously monitored more than seven years. The bridge has a long history of repeated loading test, which are very useful for the calibration of traffic monitoring algorithms. Kirjalansalmi Bridge is owned and maintained by Finnish Transport Agency (Liikennevirasto) that is acknowledged here for its support for the development and prototyping of the monitoring methods and associated software.

2 KIRJALANSALMI BRIDGE

Kirjalansalmi Bridge (Figure 1) is a suspension bridge situated in south-western part of Finland near the city of Turku. The bridge was built in 1963. It is spanning 220 m between the towers and its 12.7 m wide deck is supported by the system of steel truss girders. Most of the truss connections are welded or riveted with heavy connection plates, and therefore are susceptible to the fatigue damage. The bridge supporting system has been renovated in 2005. As the result, the whole deck is now placed on the rubber bearings inserted between the longitudinal secondary beams and cross girders.

Figure 1 Kirjalansalmi Bridge

The bridge was instrumented with strain gauges, deflection sensors and video camera. The whole system was originally maintained and controlled by VTT's computer that collected the strain and displacement data continuously every 10 minutes and if the strain reached the critical level, a 30 seconds long "event" was recorded with the sampling frequency 100 Hz. The video was recorded at the same time and saved together with the measured data.

3 BRIDGE WEIGHTING IN MOTION METHOD

We proposed a simple equation to obtain the estimated vehicle mass from the measured strain, vehicle length and its relative position to the sensor. We have optimized the equation parameters to minimize the prediction error of selected sensors (see Table 1) against the results of loading tests (see Table 2). It should be noted that the sensor names might have been different during the test loads.

Table 1. Selected sensors location

Sensor	Girder	Position
Sg01	West	Upper Chord, North (1/4 span)
Sg08	East	Upper Chord, North (1/4 span)
Sg25	East	Upper Chord, North (1/4 span)
Sg31	West	Upper Chord, South (3/4 span)
Sg32	East	Upper Chord, South (3/4 span)

It can be seen that sensors Sg01 and Sg08 (or Sg25), are symmetrical as well as Sg31 and Sg32. Therefore, their data can be used for the estimation of transverse position of the vehicle.

The prediction equations are based on 112 existing loading tests from 1998 (Tirkkonen, 1999), 2000 (Tirkkonen, 2001), 2005 (Hakola, 2005) to 2007 (Hakola, 2008, Lampi, 2007), 2009 (Hakola and Mäkinen, 2010, Turunen, 2009), 2013 (Hakola et al., 2014a) and 2016. The tests were performed with 1 to 4 vehicles driving either at walking speed (static tests) or up to 60 km/h (dynamic tests). The total load was between 60 and 276 t.

Table 2. Loading tests

Date	Static tests	Dynamic tests	Speed (km/h)	Weight (t)
11.9.1998	4	4	10 – 60	61 – 174
20.9.2000	6	7	0 – 60	99 – 198
11.8.2005	5	5	5 – 60	154 – 213
30.8.2007	6	7	40 – 60	61 – 122
29.10.2009	10	9	40 – 60	60 – 127
3.9.2013	12	3	60	61 – 276
29.9.2016	n/a	18	60	76
7.10.2016	n/a	16	60	76

The measurements in 1998 and 2000 were performed before the installation of the rubber supports under the bridge secondary beams. Therefore, their results do not accurately correspond to the current situation and are excluded from the calibration of the weight-in-motion calculation model.

The prediction is limited to the data obtained by the selected sensors (see Figures 2 and 3). Therefore, the best prediction of the vehicle mass, speed and position would be in the studied ranges of test loads. However, the extrapolation of the results for lighter or faster vehicles is also possible and it is used in the real-time evaluation of the measured data.

The sensor Sg25 has more data reported than Sg08 and because both are placed in the same location, only Sg25 was be used in the evaluation of vehicle's mass, speed and direction. The calculation parameters are, however, calibrated for both sensors in case that one of them will be removed in the future.

3.1 *Basic equations*

We have reviewed the basic weighting-in-motion (WIM) equation applied in Kirjalansalmi Bridge (Hakola and Halonen, 2013, Hradil, 2016) and modified it to the format used in Jännenvirta Bridge (Hakola et al., 2014b, Hradil, 2015), which is more reflecting the physical meaning of the measured parameters. The general form of the WIM calculation is in Eq. (1).

$$m = A\bar{\sigma}\,, \tag{1}$$

where $\bar{\sigma}$ is the stress range of the equivalent load moving in the center of the bridge with negligible (infinitely small) speed. The correction for the load position is given by coefficient k and the effect of vehicle speed is taken into account by the factor δ with the speed measured directly from the difference between stress peaks of two sensors on the opposite side of the bridge.

$$m = A\frac{\sigma - Bk}{\delta} \tag{2}$$

Since the equation is calibrated on four sensors, the predicted mass is the weighted average from all of the sensors:

$$m = \sum_{i=1}^{4} m_i w_i \tag{3}$$

with the weighting factors w proportional to the total error R of the predictions in all of the evaluated loading tests:

$$w_i = \frac{1/R_i}{\sum_{j=1}^{4} 1/R_j} \tag{4}$$

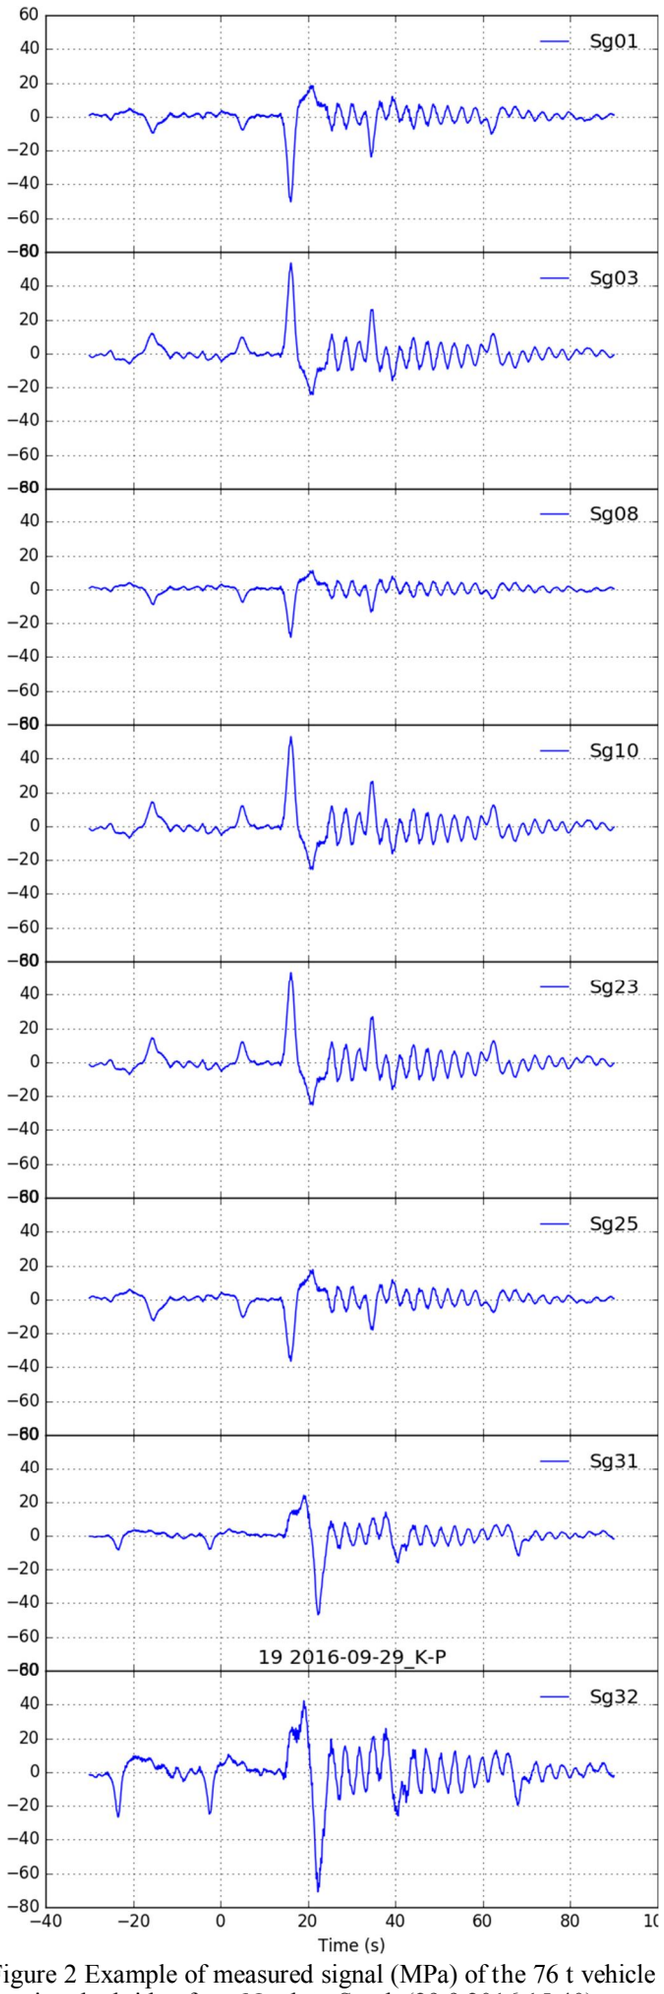

Figure 2 Example of measured signal (MPa) of the 76 t vehicle passing the bridge from North to South (29.9.2016 15:40)

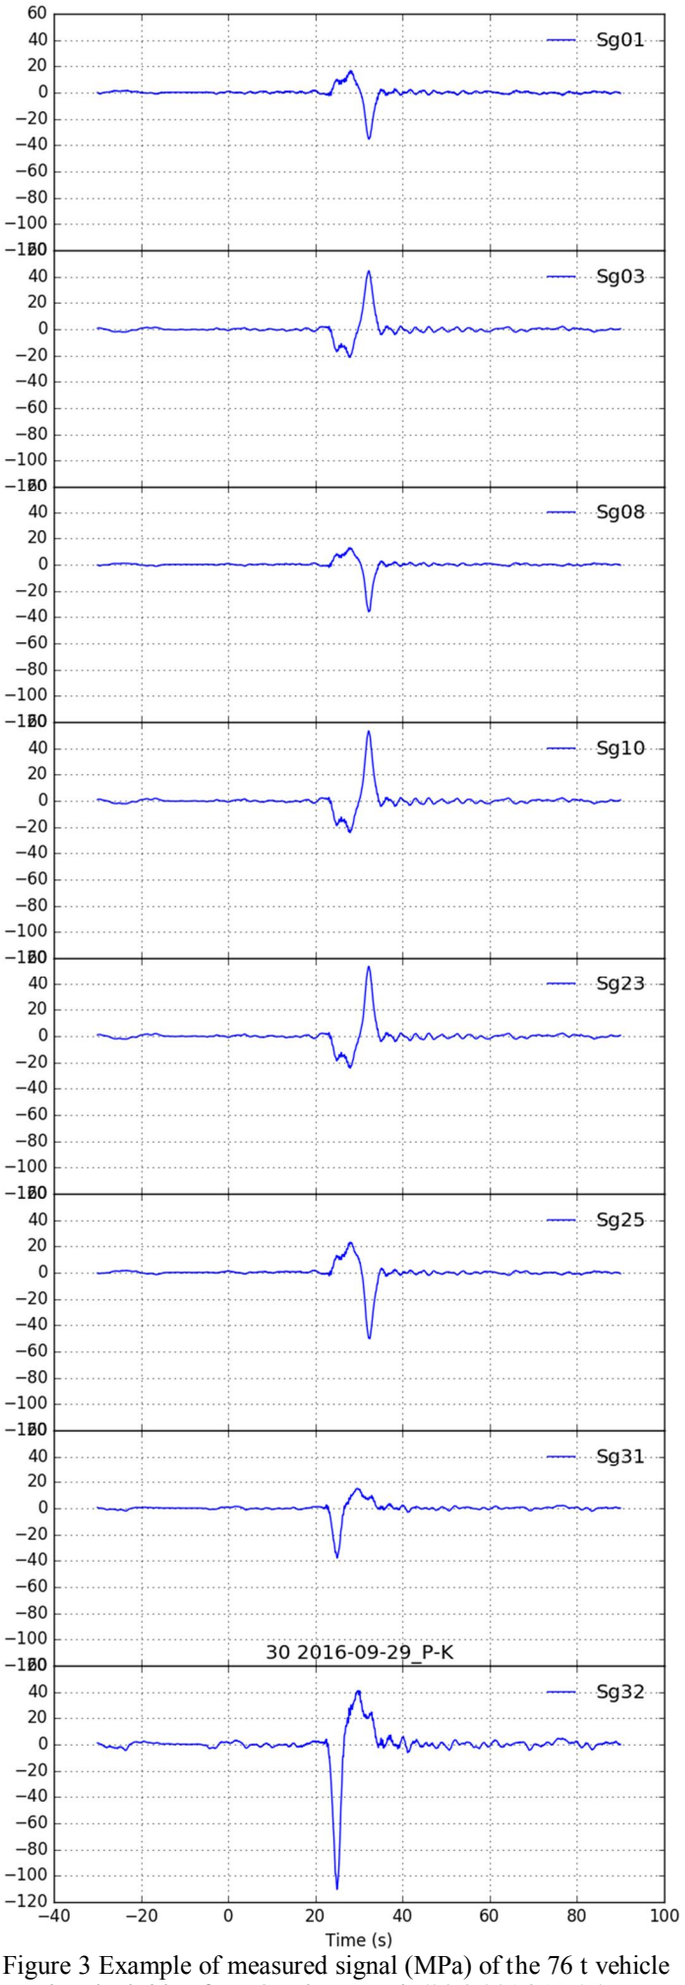

Figure 3 Example of measured signal (MPa) of the 76 t vehicle passing the bridge from South to North (29.9.2016 15:47)

The average prediction error R_i in Equation (4) is based on the sum of squares of particular errors $r_{i,j}$ in prediction for sensor i and test j:

$$R_i = \frac{1}{n}\sqrt{\sum_{j=1}^{n} r_{i,j}^2} \quad (5)$$

where n is the number of loading tests valid for the i-th sensor.

3.2 *Effect of the vehicle speed and position*

The dynamic reduction factor δ of measured stress range should be 1 in the static tests. Additionally, it is assumed that the factor is growing proportionally to the vehicle speed v, resulting in the following equation:

$$\delta = Cv + 1 \quad (6)$$

The coefficient C from Eq. (6) is calibrated on the loading tests, with the same weight, length and position of the vehicle.

Similarly, the coefficient B for the position of the vehicle in the transverse direction was calibrated on the loading tests, when the same vehicles were driving at different bridge sides. As a result, also coefficient A was determined from those tests. Linear approximation was used in both cases.

3.3 *Prediction of the vehicle speed and position*

The data from symmetrically placed sensors served as an estimation of the vehicle transverse position. The transverse factor k was then calculated based on the following equation:

$$k = \frac{A_E\sigma_E/\delta_E - A_W\sigma_W/\delta_W}{A_E B_E/\delta_E - A_W B_W/\delta_W} \quad (7)$$

where indexes E and W correspond to the east and west side of the bridge respectively. This coefficient is typically equal to 1 or -1 if the vehicle is in the middle of eastern lane or western lane respectively, but in reality the value ranges between -1.2 and 1.2.

4 EFFECT OF THE VEHICLE SPEED

In order to assess the vehicle speed, a series of tests with the identical load and position on the bridge was needed. Moreover, the tests with multiple vehicles in the row were excluded, because the gap between the vehicles was too significant to be neglected, and the resulting stress ranges were lower at higher speeds.

Table 3. Loading tests applicable for the speed calibration

Loading tests	Weight (t)	Position index	Speed (km/h)	Sensors used
2009-2, 11, 13	63	0	0, 40, 60	01,08,25
2009-9, 18	72	0	0, 40	01, 08, 25
2009-10, 19	72	-1	0, 40	01, 08, 25
2013-3, 13, 14	61	1 to 1.2[1)]	0, 60	25

[1)] vehicle driving near the bridge edge

Table 3 shows that there is a lack of data needed for the individual calibration of each sensor. The data quality is also relatively low. Therefore, a single parameter was calculated to be used in all locations.

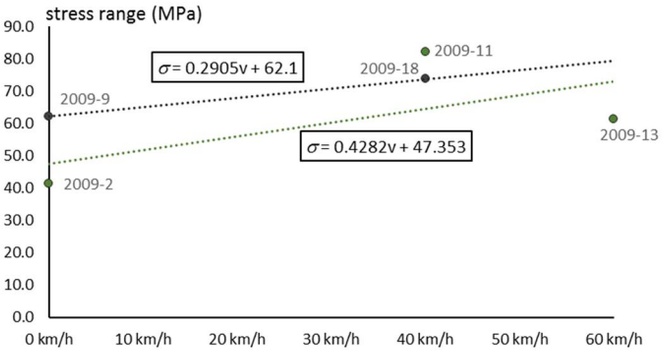

Figure 4. The effect of vehicle speed on sensor Sg01

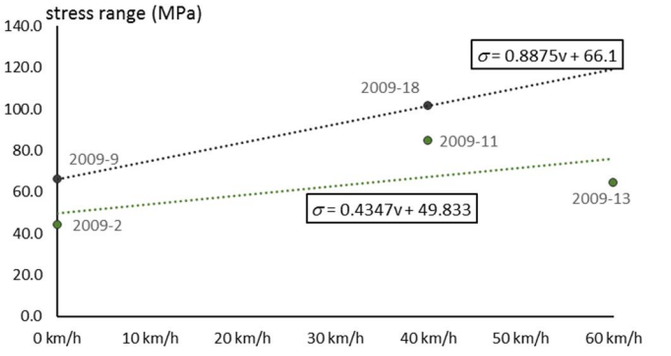

Figure 5. The effect of vehicle speed on sensor Sg08

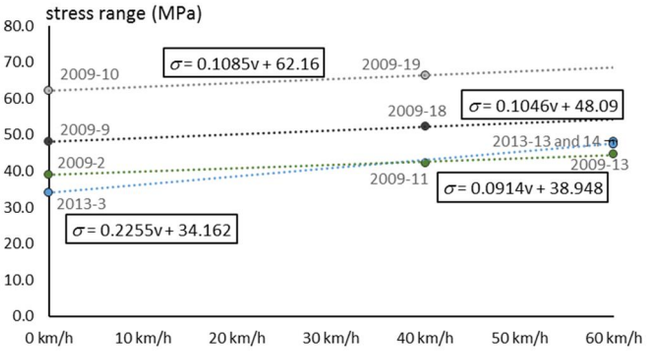

Figure 6. The effect of vehicle speed on sensor Sg25

The results in Figures 4 to 4 are expressed as:

$$\sigma = c_1 v + c_2 \quad (8)$$

Then the dynamic factor δ can be calculated as:

$$\delta = Cv + 1, \text{ where } C = c_1/c_2 \quad (9)$$

The weighted average of the factor C is 0.00621 h/km based on the available loading tests results.

5 EFFECT OF THE VEHICLE POSITION

The position of the load in the transverse direction affects the measured stress ranges. Therefore, coefficient B had to be calibrated on the loading tests with different position of the same load crossing the bridge at the same speed.

Table 4. Loading tests applicable for the vehicle position calibration

Loading tests	Weight (t)	Position index	Speed (km/h)	Sensors used
2007-1a, 1b, 1c	62	-1, 0, 1.2[1)]	-	01, 08
2009-2e, 2f	127	-1, 1	40	01, 08
2013-1, 2, 3	61	-1.2[1)], 0, 1.2[1)]	-	25
2016-1 to 34	76	-1, 1	60	all

[1)] vehicle driving near the bridge edge

It was assumed that the relation between the stress range σ and coefficient k is linear. The results are shown in Figures 6 to 11 and Table 5.

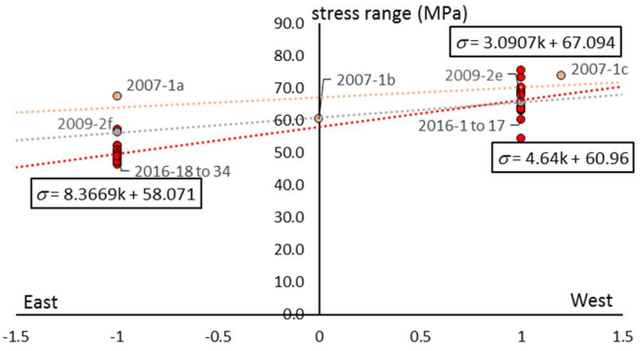

Figure 7. The effect of vehicle position on sensor Sg01

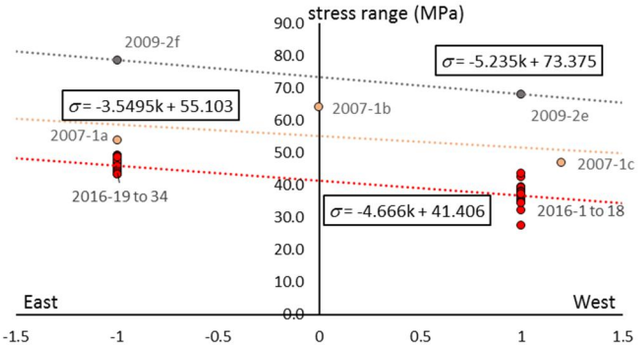

Figure 8. The effect of vehicle position on sensor Sg08

The results in the graphs are expressed as stress range σ being a function of position index k:

$$\sigma = c_3 k + c_4 \tag{10}$$

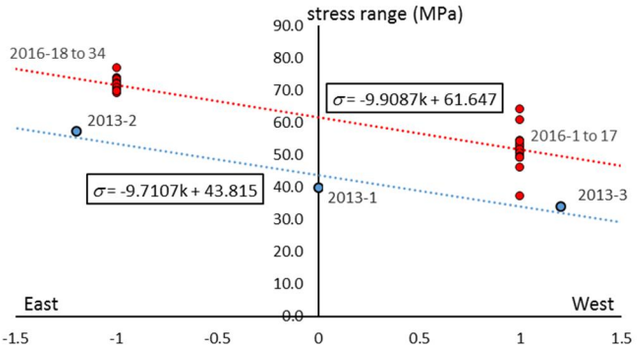

Figure 9. The effect of vehicle position on sensor Sg25

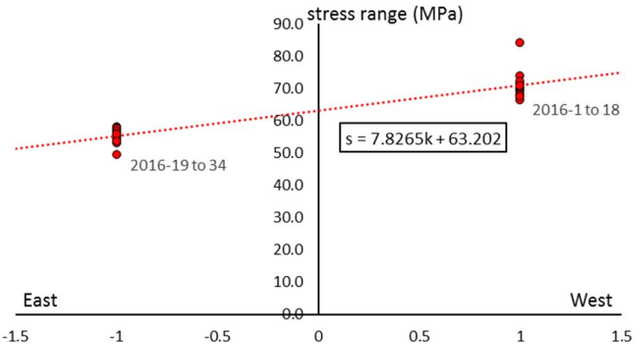

Figure 10. The effect of vehicle position on sensor Sg31

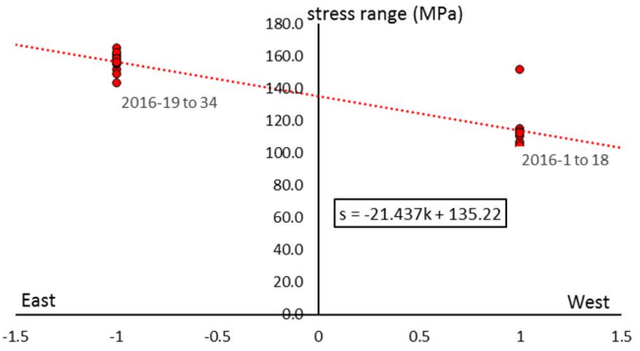

Figure 11. The effect of vehicle position on sensor Sg32

After substituting Eq. (1) in this relationship, one can obtain:

$$A = \frac{\delta m}{c_4} = \frac{(0.00621v + 1)m}{c_4} \text{ and } B = c_3 \tag{11}$$

Table 5 shows the weighted average values of the main equation parameters A (of the vehicle weight) and B (related to the vehicle transverse position). The negative value of B in sensors Sg08, Sg25 and Sg32 corresponds to their placement on the opposite side of the bridge than the other sensors (Sg01 and Sg31).

Table 5. Average coefficients A and B for different sensors

	Sg01	Sg08	Sg25	Sg31	Sg32
A (t/MPa)	1.78	2.58	1.72	1.71	0.80
B (MPa)	7.92	-4.71	-9.95	7.83	-21.44

6 PREDICTION OF THE VEHICLE POSITION AND WEIGHT

Since there is possible to recognize one sensor couple on the north side of the bridge and another couple one on the south side, the position index k is average from two factors calculated according to Eq. (7). This Equation can be, however, simplified because of the single parameter C used in the calculation of the dynamic effect δ. From the two options of north-east located sensors, Sg25 was selected. Then the calculation of the k factor turns into:

$$k = 0.5\left(\frac{A_{SG25}\sigma_{SG25} - A_{SG01}\sigma_{SG01}}{A_{SG25}B_{SG25} - A_{SG01}B_{SG01}} + \right. \\ \left. + \frac{A_{SG32}\sigma_{SG32} - A_{SG31}\sigma_{SG31}}{A_{SG32}B_{SG32} - A_{SG31}B_{SG31}} \right) \quad (12)$$

The optimized parameters produced the set o f five Equations (13) to (17); one for each sensor.

$$m_{01} = 1.78\left(\sigma_{SG01} - 7.92k\right)/(0.00621v + 1) \quad (13)$$

$$m_{08} = 2.58\left(\sigma_{SG08} + 4.71k\right)/(0.00621v + 1) \quad (14)$$

$$m_{25} = 1.72\left(\sigma_{SG25} + 9.95k\right)/(0.00621v + 1) \quad (15)$$

$$m_{31} = 1.71\left(\sigma_{SG31} - 7.83k\right)/(0.00621v + 1) \quad (16)$$

$$m_{32} = 0.80\left(\sigma_{SG32} + 21.44k\right)/(0.00621v + 1) \quad (17)$$

The weights estimated at each sensor from the measured stress ranges were compared to the real weights of the loading tests. The average prediction errors and the corresponding weighting factors are presented in Table 6.

Table 6. Average prediction error R, the weighting factor w and the number of loading tests n used for its calibration at different sensors

	Sg01	Sg08	Sg25	Sg31	Sg32
R (t)	5.81	5.61	8.29	3.79	4.41
w	0.220	-	0.154	0.337	0.290
n	34	34	55	34	34

Then the estimation of the vehicle mass will be based on the following equation:

$$m = 0.22m_{01} + 0.154m_{25} + 0.337m_{31} + 0.29m_{32} \quad (18)$$

7 VALIDATION OF THE RESULTS

The position of the vehicle on the bridge was calculated using Equation (11). The results are presented in Table 7. It can be concluded that the prediction is good; however, it is based only on the tests with 76 t vehicle when all four sensors were active.

Table 7. Validation of predicted position of the vehicle

Test	Predicted k	Reported position index
2016-1	0.97	1
2016-2	0.88	1
2016-3	0.99	1
2016-4	0.95	1

8 IMPLEMENTATION IN REAL-TIME MONITORING

The evaluation of real-time data is based on the same inputs and produces the same kind of outputs as the previous versions described in Hradil (2016). However, its internal calculation is now based on the data from four sensors, and therefore the calculation time is proportionally longer.

The real-time data has many disadvantages compared to the load test results. The measured ranges are often biased by several vehicles passing over the bridge at the same time and the typical weights of the vehicles are smaller than the test loads. Those two factors contribute to the fact that many times the identification of all four corresponding signal peaks is impossible. Therefore, the methodology described in this paper was improved to provide results also for the cases with three, two or even a single sensor measurement. It should be noted that such results tend to be less accurate.

The statistics about traffic on the bridge are presented in Figures 12 to 14. They represent the distribution of calculated vehicle weights and speeds during one month. The barcode chart in Figure 14 shows the traffic density during the day.

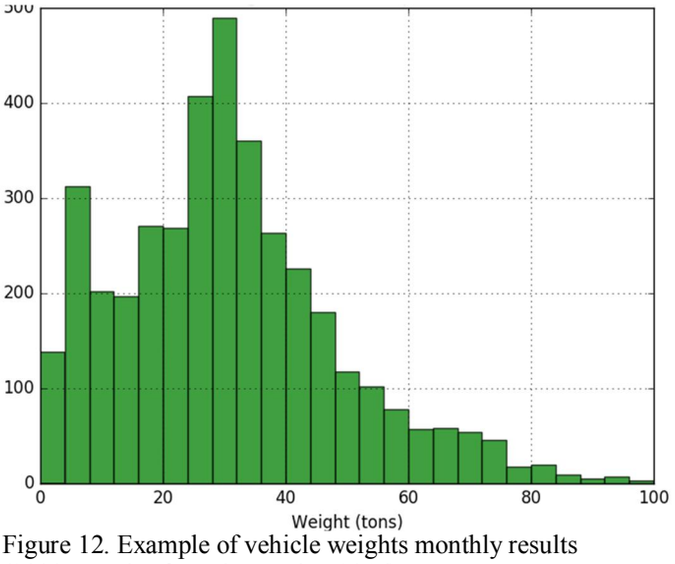

Figure 12. Example of vehicle weights monthly results (3899 samples from September 2016)

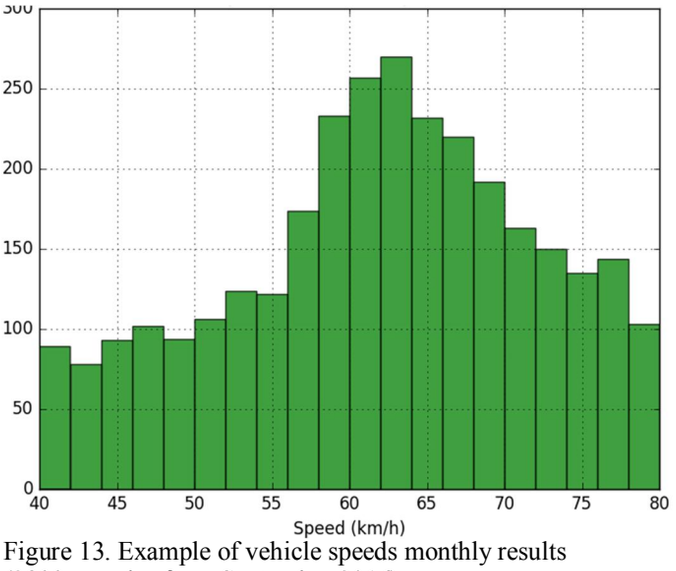

Figure 13. Example of vehicle speeds monthly results (3899 samples from September 2016)

Figure 14. Example of registered events density daily results (22.9.2016)

9 CONCLUSIONS

The weighting-in-motion calculation method was adapted from the previous Kirjalansalmi Bridge calculations (Hradil, 2016), improved and tested on Jännenvirta Bridge (Hradil, 2015) and extended with the effect of vehicle speed obtained from multiple sensors. The weighted average of results based on the optimization errors was also introduced because of data originating from multiple sensors. The method was validated against the real load tests on which it was calibrated.

It can be concluded that the results of the proposed weight calculation show relatively good correlation to the loading tests. The accuracy of the results is sufficient for the purpose of long-term monitoring of the traffic on the bridge deck. Since the bridge was already instrumented to monitor the structural loads on the main girder, the presented data were obtained without any additional sensors and, in fact, without a need to physically visit the bridge.

ACKNOWLEDGEMENTS

We would like to thank to Timo Tirkkonen from Finnish Transport Agency for the loading tests data from 2016 and overall support throughout this study. Our thanks also belong to Pekka Toivola, Markko Turunen and Mikko Lampi from Savcor Oy, who have provided access to the data from their real-time structural monitoring of Kirjalansalmi Bridge.

"Pocket-Monitoring" for the fatigue safety verification of bridge members in steel and reinforced concrete

E. Brühwiler
Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland

ABSTRACT: The fatigue safety of the reinforced concrete deck slab of a sixty-year-old steel-concrete road viaduct as well as the riveted steel girders of a 130 year old railway bridge was questioned based on the results of conventional assessment consisting in "re-calculation" using traffic models given by codes. Subsequently, examination of the fatigue action effect was performed using data obtained from "pocket-monitoring" which is a rational and ready-to-use, cost-effective monitoring device. The "pocket-monitoring" concept for the determination of fatigue action effects in the two present cases revealed fatigue relevant stresses that were lower than the fatigue limit of the critical fatigue details. Consequently, there is no fatigue damage in these details, and the fatigue relevant element of the two bridge structures is safe for a next long service duration of unrestricted traffic loads. The large discrepancy in the results between the presented monitoring method and conventional assessment is attributed to over-conservative code provisions.

1 INTRODUCTION

1.1 *Motivation*

In many countries, civil structures have been in service already for several generations. As part of the transportation infrastructure, bridges add value to the public economy. Therefore, there is high interest in economic performance while providing unrestricted use (e.g. without limitation of traffic loads). Obviously, there is a need to extend the service life of civil structures significantly beyond 70 to 100 years (which often is the arbitrarily presumed service life of structures).

Structural engineers were educated to design and build new structures. When they deal with existing structures, they perform so-called "assessments" or "re-calculations" like for the design of new structures. Many of these structural engineers implicitly think that the lifespan of a bridge is finite and similar to the one of a human being, i.e. 70 to 100 years. The same structural engineers often consider a bridge that is in service for more than 50 years as being "old". Implicitly it is assumed that an "old" bridge needs to be dismantled, and any "repair" or "retrofit" to survive the "remaining service life" (of maybe 20 years) would be the goal.

This irrational approach is outdated, also because for economic and technical reasons, it is neither justified nor possible to replace existing structures simply because they reach what might be considered their "design life" (of 70 to 100 years).

Instead, when dealing with existing structures in terms of future service duration, the structural engineer has to device ways to examine and – if necessary – enhance the existing structure in view of a second service duration, rather than demolishing and replacing the existing structure by a new one (Brühwiler 2017).

In addition to the cost argument, often there are significant cultural values involved in existing structures, and these cultural values have to be respected accordingly, not only for the interest of society but also for the sake of the structural engineering culture and profession.

1.2 *Limits of conventional assessment*

The current approach to "assess" the structural safety of existing bridges, is similar to the methodology used for the design of a new bridge, i.e. a load model (supposed to represent traffic loads) is imposed on a (computational) structural model in order to calculate sectional forces and deformations, to obtain the so-called action effect. These are then compared with the resistance of the structural members. These calculated results are often obtained without visiting the existing bridge to evaluate its condition.

In some countries, the current methodology for existing structures is awkwardly called "re-calculation" referring to the fact that the structure was first calculated when it was designed. This term betrays the way of thinking, and actually, the current approach is

rightly called "assessment". The existence of the existing structure is not exploited, and thus this pure calculation method – even when precisely performed using refined models – cannot produce better than "guesswork". Obviously, the current "assessment" approach should be abandoned.

1.3 *Objectives*

This paper suggests a novel methodology with the objective to exploit the existence of the existing bridge structure to determine the effective structural performance, f.ex. in terms of fatigue behavior.

The basic idea is to accurately determine in-situ structural behavior (rather than calculating it) in order to be able to perform more precise and realistic verification of structural and fatigue safety. The ultimate goal is to avoid or limit construction intervention to a strict minimum while verifying sufficient fatigue safety allowing for a second long future service duration. We call this approach examination engineering (short: Examineering). "Examineering" is a concept allowing to leave the outdated "assessment" approach.

More specifically, this paper highlights a methodology to examine the fatigue safety of existing bridges using explicitly data obtained from "pocket-monitoring" of structural behaviour of fatigue relevant elements of the existing bridge. The benefits of the proposed methodology are illustrated by means of two recent applications in Switzerland.

2 DETERMINATION OF ACCURATE ACTION EFFECTS BY MONITORING

2.1 *Basic concept*

The contemporary approach to existing structures is based on updating, which means collecting and exploiting detailed in-situ information from the existing structure while reducing uncertainties in structural parameters (Brühwiler et al. 2012, SIA269 2011).

The controlling parameters are determined as precisely as needed following a stepwise procedure with increasing focus on details. The structural safety verification is performed using updated values, called examination values.

The notion of degree of compliance n is introduced in the deterministic verification of the structural safety:

$$n = \frac{R_{d,updated}}{E_{d,updated}} \quad (1)$$

where $R_{d,updated}$ and $E_{d,updated}$ are the examination values of resistance and action effect, respectively.

The degree of compliance is a numerical statement showing the extent to which an existing structure fulfils the structural safety requirements. This formulation not only gives the information whether the structural safety is fulfilled. It also indicates by how much the verification is fulfilled (or not). The latter is necessary for the evaluation of results and in view of the planning of interventions.

In the context of this paper, monitoring of structural behavior has the general objective to determine more accurately effective action effects in terms of measured strains (stresses), displacements or accelerations, acting on structural elements.

2.2 *Stepwise procedure*

In a first step of verification on Level 1 (general ex-amination), the examination value of action effect $E_{d,updated}$ is determined using updated load models (for permanent and live loads) which are applied to a structural model to obtain sectional forces, stresses and strains, i.e. action effects, through structural analysis (Fig. 1).

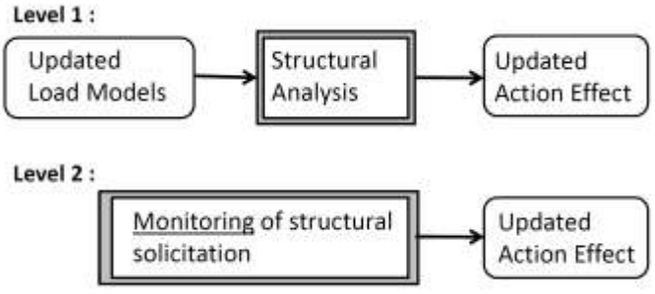

Figure 1. Determination of updated action effect.

This approach is analogous to the one generally applied for the design of new structures. The first objective is to identify critical sections and structural elements. Secondly, this simple and pragmatic approach may already lead suitable results, i.e., showing that structural safety is fulfilled).

If the safety verification is not conclusive on Level 1, further updating needs to be performed on Level 2 in a detailed examination by performing monitoring of action effects due to live loads (Fig. 1). In this way, action effects are directly measured by monitoring while significantly reducing uncertainties inherent with the approach on Level 1.

However, it may not be possible to obtain monitored data directly from critical cross sections determinant for the structural safety verification. In addition, action effect due to permanent load (dead load) is not recorded by monitoring.

Structural analysis using refined numerical models is thus needed to "translate" monitored data to sections determinant for the structural safety verification (Fig. 2) and to determine the solicitation of the existing structure due to permanent loads.

Consequently, the use of structural models changes its significance when compared to structural analyses for the design of new structures.

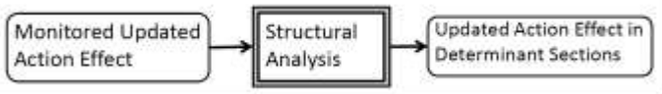

Figure 2. Translation of monitored data to sections determinant for structural safety.

In addition, monitored data are used to calibrate the structural model with the objective to obtain as accurate sectional forces as possible reducing thereby un-certainty usually implied in structural models. Such a calibrated structural model may then be used to determine, for example, fatigue action effects of future traffic scenarios.

It is interesting to note that following the approach on Level 2, no more load model is needed since solicitation of structural elements is directly recorded which obviously is the most direct and reliable information to verify structural safety.

The structural safety requirements imposed on an existing structure need to be clearly defined. Monitoring of action effects on structural elements reduces uncertainties. Yet, some safety margin must be respected, either by considering some partial safety factor or, in the case of fatigue safety verification, by some criterion of target level of acceptable fatigue damage.

2.3 *Pocket Monitoring*

An important feature of existing bridge safety verification is that the existing bridge can be monitored to determine the real 'action effects' it experiences. The advent of cheap and high storage capacity hardware in recent years means that direct measurement of elemental action effects via structural monitoring is now a viable option.

Monitoring can overcome limitations of accurately modelling in-service behavior. For example, material properties may change over time and secondary elements may reduce the stress levels in the structural parts that can provide uncertainty in modelling but these effects are inherent in the measured data.

"Pocket-monitoring" is a rational and ready-to-use structural monitoring tool of reasonable cost that will be used on a routinely basis by the structural engineer commissioned to perform an examination of an existing structure. "Pocket-monitoring" is opposed to many structural monitoring methods that are elaborate, complex, expensive and thus finally uninteresting for practical application. "Pocket monitoring" includes a straightforward low cost measuring equipment that any structural engineer is supposed to be equipped with (in addition to numerical codes for structural analysis).

In this way, structural monitoring shall become as self-evident for the structural engineer as f.ex. software of Finite Element models which nowadays are used on a routinely basis.

"Pocket-monitoring" is also a counter argument against current practitioners' perception of monitoring and so-called "structural health monitoring" as being complex, costly and not yet ready for practical application.

The potential of "pocket-monitoring" will be illustrated by means of the following two examples.

3 EXAMPLE 1: RC DECKS SLAB OF A STEEL – CONCRETE COMPOSITE BRIDGE

3.1 *Motivation and objectives*

A 182m long steel–concrete composite road viaduct built, in service for 60 years, was "assessed" with regards to its structural and fatigue safety (Fig. 3).

Figure 3. Steel – concrete composite road viaduct from 1957, located in Switzerland: overall view and test truck on the viaduct.

The up to 17cm thin reinforced concrete slab acts in the longitudinal direction in composite action with the two steel boxes (Fig. 4). In the main load bearing transverse direction, the slab is fixed by means of steel rebars welded to the top flange of the two steel boxes. The span in the transverse direction is 7.1m apart (equal to the distance between the axes of the two boxes).

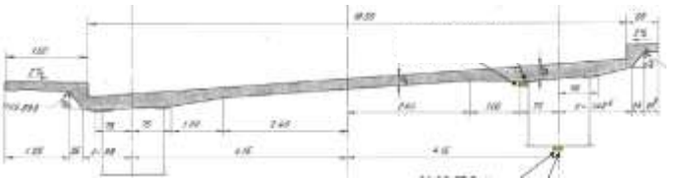

Figure 4. Cross section of the viaduct.

The assessment of the structure was performed using the updated load model according to the Swiss Standard for existing structures (SIA 269/1 2011), thus following Level 1 according to Fig. 1.

The assessment revealed sufficient structural and fatigue safety for the steel structure. The reinforced concrete slab however did not fulfil the safety verifications. In particular, there was uncertainty about the effectiveness of the fixation of the slab on the boxes since the calculated stresses in the rebars significantly depend on the degree of fixity of the slab with the boxes.

Subsequently, it was decided to proceed to an examination by means of pocket-monitoring instrumentation. The objectives were to determine the effective structural behavior, in particular the degree of fixity of the slab, as well as the fatigue relevant stresses in the steel rebars.

3.2 *Monitoring system*

The monitoring followed three steps: 1) installation of the measurement system, 2) load test for calibration of the measurement system, 3) permanent recording of measured values during 12 months.

Remark: In reality, a more complete system of measuring sensors was deployed on the structure in order to exploit measurement results for research purpose. In this paper, only the results as obtained by the "pocket-monitoring" are presented.

3.2.1 *Installation of the measurement system*

Two identical arrangements of sensors were installed in two slab zones of the cross sections at mid-span of two different spans. The acquisition system consisted of three apparatuses, one for electrical strain gauges, one for thermocouples and one serving as unit for storing the continuously recorded data by means of a portable computer. This equipment was safely placed in a solid container fixed to one pier of the viaduct. The monitoring was supervised through internet connection.

Electrical strain gauges (in half-bridge configuration and 5-wire mounting to compensate temperature effects) were installed directly on 4 rebars of each slab zone (after carefully chiseling off of the cover concrete) at the bottom face of the slab (Fig. 5). In addition, strain gauges were also mounted on the flanges and webs of the steel boxes. All strain gauges were protected from humidity by means of a silicone gel and covered with an isolating pad. Measurement frequency was 100Hz.

With this strain gauge arrangement, longitudinal and transversal deformation of the slab is measured and could be related to the deformation measurements of the steel boxes.

In order to account for temperature effects on the structure and on the strain gages, thermocouples were installed at locations close to the strain gages to measure the temperature about 4 centimeters inside the concrete of the slab.

In addition, LVDTs (linear variable differential transducers) were installed to measure the deflection of the slab.

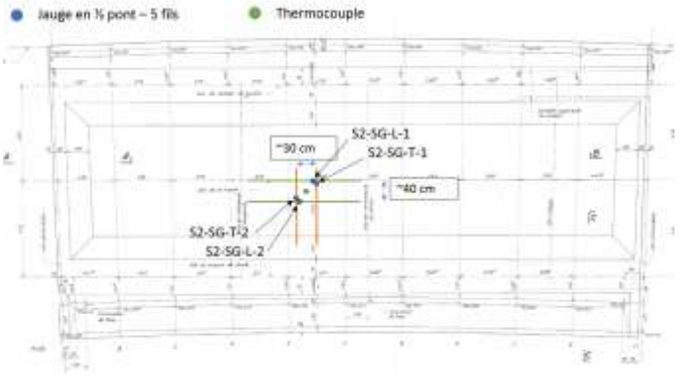

Figure 5. Arrangement of strain gauges on rebars and thermocouples (temperature sensors).

3.2.2 *Load test*

A load test was performed using a loaded truck with 5 axles (Fig. 3) of exactly known load and spacing, totaling a load of 400kN (which is the maximum admissible load on this road). This test track circulated on predefined trajectories on the slab and at different speeds. During the truck passage, regular traffic was temporarily interrupted.

The measurements due to the truck passage served as reference for the measurements obtained from regular traffic. These measurements also served to calibrate a refined FE-Model of the structure to investigate the degree of fixity of the slab.

3.2.3 *Long term monitoring*

Long-term monitoring during 303 days (in the period from August 2016 to July 2017), i.e. there were some interruptions of measurements due to problems with power supply and big data storage.

This monitoring campaign allowed to obtain the histogram of stress amplitudes due to the passage of vehicles due to the effective road traffic that was used for the fatigue evaluation of the RC slab. First fatigue evaluation was already done with the collected stress amplitudes after one month. (Remark: For research purposes, the measurement system is still active.)

3.3 *Results*

The recorded strain amplitudes due to the traffic action effect only were transferred into stress ranges using Hooke's law and a modulus of elasticity of the steel rebar of 205GPa. Rainflow method was used to determine stress amplitudes and number of cycles (Fig. 6).

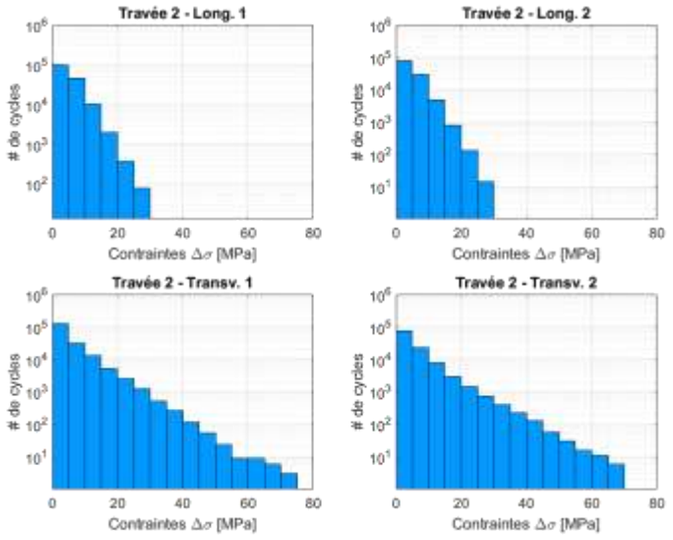

Figure 6. Annual histograms of tensile stress amplitudes for the four instrumented rebars at one slab zone (Fig. 5).

As expected, recorded tensile stresses in the longitudinal slab direction were significantly smaller than the ones in the transverse direction. Largest recorded stress amplitudes were 70MPa, which is a relatively small value with respect to the fatigue strength of straight rebars.

The indication of relatively small stresses was already obtained after the load test and first weeks of readings. This first information was important for the owner to take appropriate action.

The results from the truck load test were used to calibrate a detailed FE Model for the analysis of structural behavior. It was confirmed that the RC slab is fully fixed to the two steel boxes. Full fixity is however only provided if there is no fatigue damage.

3.4 *Verification of fatigue safety*

Verification of fatigue safety is basically following a stepwise procedure consisting of two levels:

- Level 1: verification with respect to the fatigue limit of the considered rebars,
- Level 2: damage accumulation calculation using Palmgren-Miner Law and the appropriate S-N-curve for the rebar detail.

Verification of the fatigue safety of concrete under compression and shear stress amplitudes was not performed. The fatigue related stresses in the concrete of the present slab are significantly lower than 50% of the compressive strength and thus concrete fatigue is not relevant.

Regarding the *fatigue strength of the rebar details*, the values according to the Swiss Standard (SIA269/2 2011) were assumed. In the present case, two different details need to be verified:

- for straight rebars at the bottom face of the slab at mid-span, a fatigue strength (detail category) of 150MPa at 2 million cycles with a slope of m=4 for the fatigue resistance line in the double logarithmic S-N diagram; this results in a fatigue limit at 120MPa (at 5 million cycles).
- for welded rebar at the top flange of the steel box, a fatigue resistance category of 70MPa with a fatigue limit at 56MPa was assumed.

For both details, the assumed fatigue strengths are conservative. Literature indicates higher fatigue resistance, in particular in the domain of small stress amplitudes, f.ex. (Tilly 1979). Therefore, higher values for the fatigue limit could be justified.

Nevertheless, the *fatigue verification* was performed with the conservative fatigue strength values for the two rebar details:

Straight rebars: The results shown in Fig. 6 show measured stress amplitudes smaller than 70MPa and thus significantly smaller than the fatigue limit. Consequently, the fatigue safety of the rebars at mid-transverse span of the slab experienced most likely no fatigue relevant stresses during the previous service life. The fatigue damage is negligible. The fatigue verification is thus fulfilled at Level 1 with respect to the fatigue limit.

Welded rebars: Since the fatigue strength of the rebars welded on the top flange of the steel boxes is significantly lower than for straight rebars, stress amplitudes at this critical detail was performed. Measured stresses were "extrapolated" to this critical detail by means of a detailed FE analysis of the slab – box system. The determined stress amplitudes in the welds were 25% higher than the ones measured in the straight rebars at mid-span. Since these extrapolated stress amplitudes are higher than the fatigue limit of 56MPa, Level 2 fatigue verification was needed. Palmgren-Miner fatigue damage calculation was performed leading to values of about 10^{-3} per year, which is close to zero. Information from the literature suggests a detail category of 100MPa to be more realistic than the assumed one of 70MPa, which would lead to negligible accumulated fatigue damage. It could be concluded that also the critical welded rebar details most likely do not present any fatigue damage and guarantee thus full fixity of the slab.

Temperature effects often have a significant effect on the overall structural behavior and thus on stress levels in the rebars of the slab. These temperature effects need to be carefully considered in order to precisely identify the stress amplitudes due to traffic effects. In the present case of the reinforced concrete slab of the composite structure, it was necessary to analyze measured data over one year in order to reliably capture the effect of seasonal temperature variation on stress amplitudes in the rebars.

3.5 *Findings*

The pocket-monitoring campaign revealed relatively small fatigue related stress amplitudes in the critical steel rebar details. The reinforced concrete slab shows no fatigue damage after 60 years of service duration. Future long-term service duration of the viaduct is thus feasible.

This result is in strong contradiction to the calculated results from the assessment. The discrepancy could be explained by the assumed over-conservative fatigue load model and conservative assumptions for the structural model and the fixity of the RC slab on the steel boxes.

4 EXAMPLE 2: RIVETED STEEL GIRDERS OF A RAILWAY BRIDGE

4.1 *Motivation and objectives*

The 93m long railway bridge in Switzerland is in service for 120 years (Fig. 7). The riveted early steel bridge structure consists of an arch of 48m span and 14.8m rise over a river. The structure is carrying a single lane open, normal-gauge railway track that is fixed to two parallel girders of 0.86m constant height and being 1.8m apart.

These girders have a regular span of 10.0m and are supported by columns and at the arch crown. These girders were designed as single span girders but for constructive reasons some details provide a certain continuity over the supports of the girder system. The bridge abutments are built in natural stone masonry.

Fig. 7. Riveted steel railway bridge built in and in service since 1897; this bridge has a high value as cultural heritage structure.

The assessment of the bridge structure at Level 1 was performed using the updated rail traffic model according to the Swiss Standard for existing structures (SIA269/1 2011). The calculated results showed sufficient structural and fatigue safety for the arch and the columns. Sufficient structural safety at ULS (sectional resistance) was also obtained for the girders assumed as single span girders. However, the fatigue safety could not be verified under these assumptions.

Subsequently, it was decided to proceed to an examination by means of "pocket-monitoring". The objectives were to measure the fatigue relevant stresses in the girders and to determine the effective structural behavior of the girder system in terms of a continuous girder system under service loading.

4.2 *Monitoring system*

Because of easy access, the first span near one abutment was chosen to install the monitoring system (Fig. 8) in May 2017.

Figure 8. Edge girder field and scaffold for access to the monitoring system (sensor locations indicated by red rectangles).

During one day, 18 sensors consisting of 14 strain gauges, 2 clip gauges (to measure gap opening displacement between two girders above the support) and 2 temperature gauges, were installed together with two data amplifier/acquisition systems including a portable computer for data storage. Four cross sections, one at mid-span and three close to the intermediate girder support above the first column, were equipped (Fig. 9). The frequency of measurement was 300Hz.

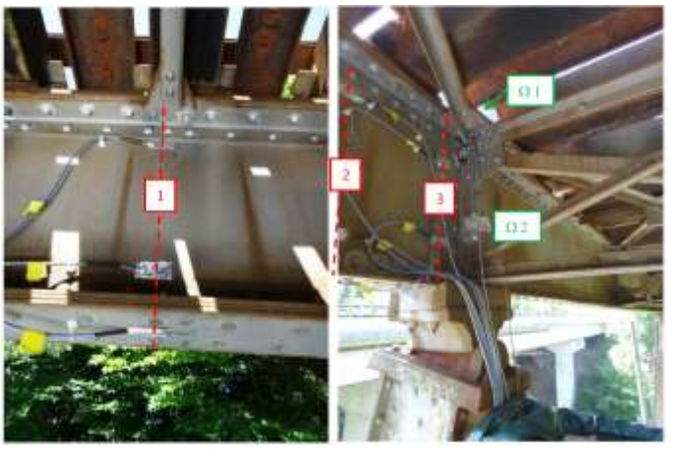

Figure 9. Cross sections and installed sensors.

Continuous measurement readings of train passages were recorded during 4 weeks only. Because of the present type of lightweight structure, it could be anticipated that seasonal temperature effects would not

significantly affect the overall structural response of the bridge structure. This assumption was confirmed by equal histograms of recorded stress amplitudes after 1, 2 and 4 weeks.

In addition, the bridge is exclusively used by only two different types of passenger trains. There are no freight trains. This led to repetitive readings of similar values.

4.3 *Results*

The bending moments deduced from the measured strains evidenced structural behavior similar to a continuous girder system.

The recorded strain history of the train passages showed no dynamic effects (Fig. 10). This is rather surprising since dynamic effects may be expected in the case of an open railway track fixed to a lightweight structure. However, the effect of continuous rails of good surface quality seems to have a favorable effect.

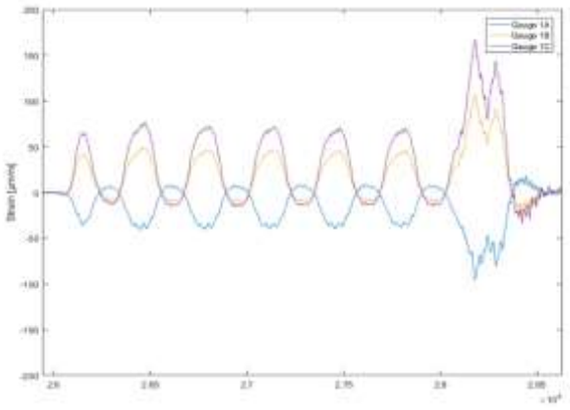

Figure 10. Strain versus time record (structural response) due to the passage of a train hauled by a locomotive (with 4 axles of 200kN) followed by passenger wagons (Fig. 8).

The histogram of fatigue relevant stress amplitudes in the critical cross section at the bottom flange at mid-span of the girder revealed relatively small maximum stress values of 42.5MPa (Fig. 11).

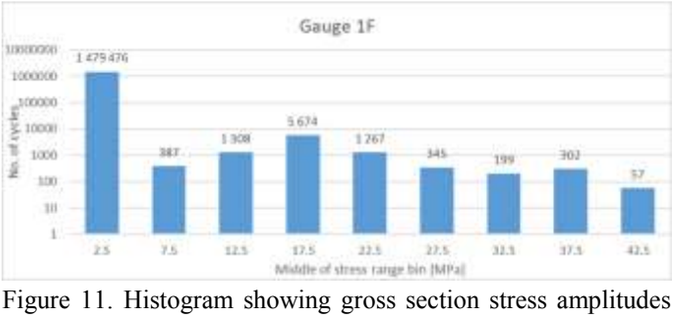

Figure 11. Histogram showing gross section stress amplitudes measured during 4 weeks in the critical cross section at mid-span of one girder.

4.4 *Verification of fatigue safety*

Again, the concept of stepwise verification was applied with the first objective, at Level 1, to verify the measured stress amplitudes with respect to the fatigue limit of the critical detail.

According to the Standard (SIA 269/3 2011), the fatigue detail category for the riveted girder is 80MPa with a fatigue limit of 56MPa.

The measured gross section stress values were modified for considering net section stresses leading a maximum fatigue stress amplitude of 52MPa to be considered for the verification.

In addition, past railway traffic was analyzed in terms of axle loads and axle configurations of previous trains. The railway owner has no plans to increase the trainloads in the mid-term future. From this follows, that most likely there was and will be no fatigue stress amplitude larger than 52MPa.

The fatigue safety on Level 1 with respect to the fatigue limit is verified graphically according to Figure 12:

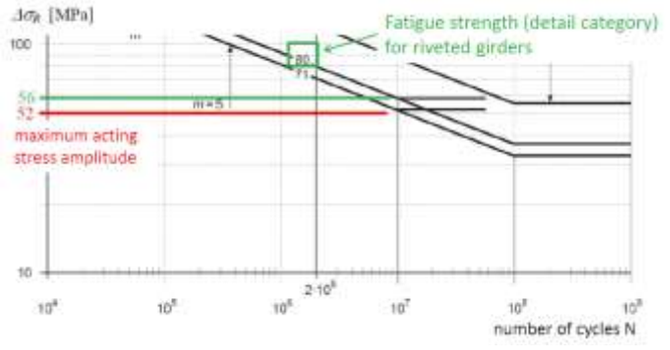

Figure 12. Graphic fatigue verification of the riveted girder, at Level 1, with respect to the fatigue limit.

4.5 *Findings*

Similar to the first example, the pocket-monitoring campaign revealed relatively small fatigue related stress amplitudes in the critical riveted details at the bottom flange of the girder and for the details in the support zone over the column.

These determined fatigue stresses are smaller than the fatigue limit of the detail, and thus there is no fatigue damage in the riveted structure even after 120 years of service duration.

In addition, the measurements allowed unveiling the real structural behavior of the girder system.

Again, these findings are in strong contradiction with the "re-calculation" in the context of the assessment. The discrepancy was explained by the over-conservative rail traffic load model given in (SIA 269/1 2011), the absence of dynamic effects and conservative assumptions in the structural analysis model.

5 DISCUSSION

The two examples show that regarding existing bridges, a greater source of uncertainty lies in the *modeling of traffic loading* and the determination of

the action effects arriving in the structural elements, i.e. in the steel rebar and in the riveted joint detail.

In recent years, increasingly sophisticated approaches have emerged for load effect estimation using traffic simulations incorporating Weigh-in-Motion (WIM) data which form the basis of load models in design and "assessment" codes. While vital for design of new bridges, these codes are based on generic heavy vehicle data from a range of locations and therefore may not always represent the site conditions at the existing bridge under investigation. In addition, codes include provisions for illegally overloaded vehicles which could be reduced substantially through adequate policing (on roads and also on railways).

"Re-calculation" using "assessment" codes are therefore to over-conservative, in particular in the context of fatigue safety verification. Current methods should thus be replaced by more realistic methodology relying on data from monitoring of real structural behavior of the existing bridge in question.

Regarding *sensor technology for monitoring*, electric strain gauges, like the ones used in the presented two examples, actually suffer from a bad reputation. Strain gauges are considered as an "old technology" that is not reliable on the long-term (excessive drift) and too difficult to compensate for temperature effects. As a result, strain gauges are not used for monitoring or they are used only for very short periods of measurements.

Our experience is that correctly installed and protected, temperature compensated strain gauges withstand a full year (and longer) of measurements without significant drift or any other non-structural effect. In addition, a defect resulting from poor glued bonding or welding of the gauge and local magnetic interferences would be immediately visible on the signal.

If temperature and long-term effects are reliably mastered using strain gauges fully compensated for drift and temperature, measurement uncertainties are limited and the measurement results are precise and reliable (Loraux 2018).

6 CONCLUSIONS

The methodology of "pocket-monitoring" has been introduced to examine the fatigue safety of critical details of existing bridges. The following conclusions are:

The monitoring allows to determine real structural behavior and realistic fatigue relevant stresses. In addition, uncertainty in structural behavior could be reduced and refined numerical structural models could be calibrated to account for real behavior. Monitoring thus allows to gain much more precise and realistic information.

The two presented pocket-monitoring devices turned out to be relatively easy to install and robust, leading to reliable readings.

Overall, examination by means of pocket monitoring is highly economic since the results in both presented examples showed largely sufficient fatigue safety, and thus no intervention is needed (while conventional "assessment" by "re-calculation" recommended costly interventions).

Structural risk assessment and management through the capture of dynamic movement.

M. Kudrenko
Mainmark, Melbourne, Australia

ABSTRACT: Mainmark have introduced the STRAAM system of full scale structural integrity assessment and continuous monitoring for dams, buildings and bridges into Australia and New Zealand. Advances in measuring extremely low amplitude vibrations combined with methods for extracting the unique dynamic signature have now enabled the rapid measurement of the response of steel and concrete structures. The STRAAM method utilises the normal traffic conditions and wind loads on the structure to measure the frequency response of the structure. This allows the quick calibration of Finite Element Models that can be used to accurately assess the strength of the structure. Furthermore, this information allows asset owners to efficiently track changes in the capacity of their structures due to aging, impact, earthquake or flood activity through changes in the vibration of the structure and associated natural frequencies, mode shapes and damping ratios.

1 INTRODUCTION

1.1 *Mainmark and STRAAM*

Mainmark have partnered with STRAAM Group from New York to introduce the STRAAM structural risk assessment and management system for structures into Australia and New Zealand. The STRAAM system allows for rapid, non-invasive assessment of a structure's current status.

1.2 *Non-intrusive & non-destructive assessments*

The testing of steel and concrete structures using high technology has become fast, cheap and precise. At the same time, it is non-intrusive and gives both basic information and information that would be difficult to obtain by conventionally assessments. This has been enabled by the use of induced vibration testing of a series of structures both in Europe and the USA. With the increasing availability of high precision accelerometers, microscopic movements of structures can be recorded and analysed. As a result, it is possible to use the simple methodology associated with naturally occurring excitation to decode the state of health of the structure and view its performance objectively.

2 DYNAMIC MEASURMENTS

2.1 *Philosophy of assessment with STRAAM*

With the developments of electronics and sensor technology, the ability to record very precise measurement properties of monolithic structures has led to a rationale for the management of such facilities with a methodology that enables the augmentation and enhancement of traditional visual inspections (Jeary et al).

Newton's second law of motion is used for the basis of the equations of structures in dynamic motion. This is also applied to a structures individual modes of vibration. The equation to express this sort of motion, under each mode 'r', can be presented as:

$$m_r = \frac{\hat{\mathrm{F}}_r}{\hat{x}_r \, 8 \, \zeta_r \, \pi^2 \, f_{r^2}} \qquad (1)$$

Where, the displacement is x_r from mode 'r' for and applied for of F_r. The dampening ratio is f_r and the frequency of resonance is F_r.

2.2 *Dampening and displacement*

For application however we are generally most interested in the dampening value and the displacement per unit force value; the reason being is that a dampening value is used as a parameter to give the measurement of energy dissipation on a structure, where the displacement per unit force allows for a comparison with the requirements of design construction. As the modal mass, m_r, does not change in the elastic regime for any single mode, measurements of non-linear dampening characteristics and frequency of resonance provide

the necessary information to compare the capacity ratio to the demand. Every structure type has a characteristic vibration modes, which requires that the deflected mode shape that is representative of mode 'r' also needs to be assessed as all of the above parameters apply to individual modes of vibration. For this reason, this method can be applied to many types structures whether they contain stone, steel, timber or concrete.

2.3 *Forced excitation*

Previous works of calibrating forced excitation against natural excitation have existed for some time now (Ellis et al) and the calibration of the non-intrusive simple methodology against the induced vibration approach is detailed here. As a result, it has made it possible to use the simple methodology associated with naturally occurring excitation to decode the state of health of structures. A typical methodology for the induced vibration testing can be described as follows:

1. Vibrators were located a strategic sections of a structure. The frequency of excitation is incremented sequentially and a response/frequency curve was obtained;
2. A frequency of resonance is selected and the vibrators are set to operate at this frequency;
3. An accelerometer is taken to various locations of interest, in turn, and the vibration amplitude is measured at each position, both longitudinally and across the structure;
4. The vibrators are suddenly switched off, and the ensuing decay of oscillation is used to estimate the damping ratio for this mode of vibration;
5. Steps 2, 3 and 4 are repeated for each resonance in turn;
6. The vibrators are redeployed in different locations and Steps 1-5 inclusive were repeated for further modes of vibration;
7. Step 6 was repeated with a further redeployment of the vibrators
8. A recording of the ambient response was made for a period of about 12 hours.

A certain amount of background vibration is observed which, on occasions, made the measuring of the lower frequency responses rather difficult.
For the use of ambient excitation step 8 only is required, although the necessary recording time is dictated by the lowest frequency of resonance of the structure.

2.4 *Utilising natural excitation*

The methodology requires a force to be applied to the structure. Because a series of structures were tested using induced vibration testing (with a large vibrator system), and these results were correlated against the response of structures from naturally occurring forces, then the non-intrusive methodology has been calibrated in the most precise way possible. Examples of naturally occurring forces include wind, traffic and micro-seismic activity. Because of the precision of the instrumentation used it is no longer necessary to wait for an event such as an earthquake for the state of health of the structure to be assessed. In this way regular or continuous monitoring can also be used to show the gradual ageing process for the structure. Such detailed information allows the management of facilities and the planning of necessary maintenance that is informed by measurement. This type of measurement is capable of discerning information about problem areas of a structure that are not apparent to a visual observation, and therefore offers a significant advantage over a more conventional type of inspection. This type of measurement can also be performed quite quickly structure and is economically efficient.

In practice, the force can be applied from natural sources such as air movement, traffic or other human agency.

The following describes the response of as single degree of freedom (mode 'r').

$$\boldsymbol{X_r} = \frac{F_r}{8 f_r^2 \zeta_r M_r \pi^2} \tag{2}$$

Where for mode 'r'
M is the participating mass
f is the frequency of resonance
F is the force
Ϛ is the damping ratio of mode r

Thus the displacement per unit force can be defined as:

$$\frac{X_r}{F_r} = \frac{1}{8 \zeta_r f_r^2 M_r \pi^2} \tag{3}$$

- The displacement per unit force is inversely proportional to the damping times the stiffness.
- If the modal mass is unchanging, and the mode shape is unchanging then for a given frequency and damping for a mode 'r' the displacement per unit force will remain unchanged up to the elastic limit.
- In practice there may be small changes in the frequency of resonance (as a function of amplitude – not as a function of time). There

will be changes to damping with amplitude. However, we can compensate for such effects by measuring the non-linear damping.

2.5 *Dynamic response to 'dynamic signature'*

There are several system-level parameters which aid in the conversion from dynamic response (acceleration records) to Dynamic Signature, and identification of damage in a structure during a STRAAM structural assessment. These include:

1. Gross migration of frequency of resonance away from the expected response. In particular, the loss of stiffness in each mode of vibration can be estimated by comparing the differences in measured frequencies of resonance from the expected values. Lower frequencies indicate a loss of stiffness in a particular mode of vibration.
2. Spectral bifurcations whereby a principal mode of vibration shows signs of splitting into several modes of vibration. This indicates that the structure is forming mechanisms and that local resonances are forming.
3. Changes in modal amplitude ratios can be tracked over time to show indications of changes to particular modes of vibration which can indicate that parts of the structure are responding differently from previously. Inferences of damage or strengthening can be made utilizing these changes along with other observations.
4. Energy dissipation as measured through the nonlinear damping parameter. Damping values which are higher than expected are clear indications that energy is being dissipated through cracking, rubbing of structural members or unexpected soil-structure interaction (foundation damage). This measure generally requires a long duration of measurement such as that obtained with continuous monitoring in order to establish the full amplitude dependent damping behaviour.

3 DIGITAL SIGNAL PROCESSING

3.1 *Baseline Spectral Response Analysis*

The on-site measurements of acceleration are processed using standard and proprietary digital signal processing (DSP) techniques to facilitate the extraction of relevant dynamic properties of the structural system. The main output of the DSP process is the decomposition of the time-series acceleration data into its frequency content (Power Spectral Density). The spectrum is interpreted to identify the modes of vibration (frequencies of resonance, amplitudes and modal ratios) of the structure. This forms the baseline Dynamic Signature and is essentially a fingerprint of how the structure is currently behaving with resonances appearing as isolated peaks in the plots. This baseline Dynamic Signature provides the datum with which future dynamic responses can be compared for assessment of changes to the structure's performance.

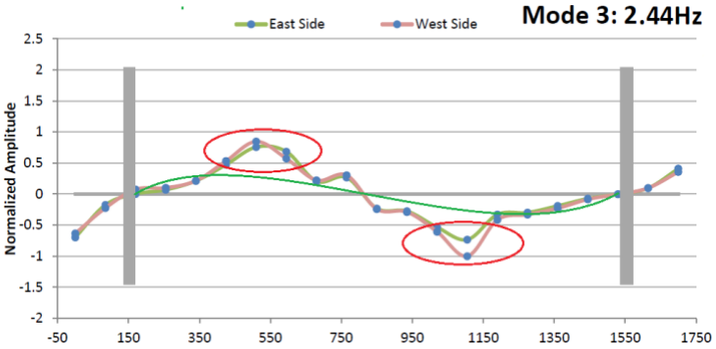

Figure 1. Example of a 2nd Order mode showing stiffness anomalies

3.2 *'Baseline' methodology*

STRAAM uses a systematic approach, called the STRAAM Protocol, to understand how a structure behaves and for developing the best approach of monitoring the structure for an assessment and then long term monitoring. The STRAAM Protocol involves several steps necessary to establish the baseline Dynamic Signature of the structure:

1. Step 1 (Site Survey, Photos, Drawings, Reports) is to gather field information so that the monitoring plan will achieve the project goals efficiently and the transfer of design drawings and photos. This is accomplished through interaction with project stakeholders prior to data recording.
2. Step 2 (Structural Model and Frequency Range Identification) we will use the existing FEM (or construct our own internally) to understand the expected response, mode shapes and frequency ranges for the structure. Additionally, it can help locate areas of the structure which will provide the greatest response for our instruments. This is all integrated into an advanced monitoring plan that is designed to best achieve the project goals.
3. Step 3 (Data collection/ Signal Conditioning) we proceed to the field to capture response information from the structure in an efficient and effective manner. When monitoring, we record acceleration with highly sensitive acclerometers (along the X, Y and Z axis) and temperature at a rate of 200 samples per second for the acceleration, and 1 sample per second for the temperature. The sensitivity of

the instruments allows STRAAM to capture low amplitude response information to be used for analysis. Local excitation (wind loading and nearby traffic for example) is all that is require to capture acceleration response, although known force can also be applied to drive excitation.

We then proceeded with steps 4-7 of the STRAAM Protocol where we process the data into the response spectra and compare the dynamic resonant frequencies in various modes and various conditions. This iterative process completely correlates the measured response with the expected response from the model. For most structures, the baseline data recoding can be completed in as little time as a day.

3.3 *Continuous monitoring methodology*

Continuous monitoring of a structure follows similarly to that of the baseline recording of a structure, however the data collection phase remains on going for the duration of the project. This is useful as it allows for the real time monitoring of structures and how their dynamic response may change over time due to external influences. Examples of this could be nearby constructions works or seismic events impacting structures foundations, the effect of a severe weather event or even the increase in loading on structural elements.

4 RECENT STRAAM APPLICATIONS

4.1 *Bridge Spanning Dandenong Creek, VIC*

A Super-T, duel lane single span bridge crossing Dandenong Creek in Victoria required ground works to correct sunken approach slabs to the bridge deck.

The STRAAM system was used at this site before works to calibrate a FEM model using a known load passing over the bridge. The bridge then has sensors strategically placed to capture the baseline dynamic signature of the structure and then monitor in real-time the dynamic effects of the ground correction works on the bridge.

This gave the ground works contractor certainty in knowing they were not causing damage to the bridge as a result of there earth works.

4.2 *Camperdown Childcare Centre, NSW*

The Guardian Early Learning Centre in Camperdown, New South Wales is an inner-city childcare facility that provides day care for children from infants to pre-school age. Due to its urban location, the centre wanted to utilise its roof area to create an extra play space for the children.

The rooftop had been added onto the building's original roof structure as an open space area that could be walked on. The Guardian Early Learning Centre wanted to add landscaping and additional play equipment to the rooftop area, while ensuring it remained within Australian Standards for safety.

Adding higher loads, such as saturated soils and other landscaping materials that might hold water, could significantly increase the loading on the roof. The Guardian Early Learning Centre had limited information on the roof's design capacity and needed to understand, with certainty, how much load the roof could safely bear to help determine landscaping decisions.

The consulting engineer engaged Mainmark to provide a structural capacity assessment of the roof using its unique Structural Risk Assessment and Management (STRAAM) technology. Mainmark recorded the building's natural vibration frequency and determined a baseline dynamic signature, then performed a random decrement algorithm (RANDEC) to evaluate the direct measure of the structure's non-linear damping response.

Data was collected over the course of two days and analysed to determine the roof's likely performance under additional loads. Based on the results, the Guardian Early Learning Centre has could proceed safely with its landscaping project.

4.3 *Hong Kong Office Building*

During the construction of a MTR rail tunnel, a partial collapse of the ground at the face of the TBM occurred. This ground movement was observed as a loss of support at a high rise office building approximately 400 m away from the TBM location. The movement of the office building was perceivable, and damage to the façade was observed. The building was evacuated at the time.

The STRAAM sensors were monitoring the structure at the time to determine the structural condition of the building. The random decrement graph (damping vs amplitude) picked up the loss of capacity in the structure. At the time of the event, the structure exhibited significant loss of damping at low amplitudes, indicating probable loss of load bearing at the supports due to the ground movement.

In the following month, the low amplitude damping improved for the structure, most likely due to load redistribution through the concrete frame. The high amplitude damping was approximately 10%

lower after the event; which represents a 10% loss in wind loading, usually the critical load case for Hong Kong structures. However, the building had sufficient over design to cope with the 10% loss.

4.4 *High School, Houston*

A three storey, brick high school was assessed using STRAAM prior to a substantial redevelopment. The purpose was to conduct a Dynamic Baseline Assessment that could be then used to monitor the risk as the redevelopment progressed and to observe the efficiency of the redevelopment after it was completed.

The modes of vibration were identified for the structure. The frequency and damping values obtained indicate the building is generally in good condition, without significant damage.

Anomalies were identified at a few locations. Vertical movement on the north elevation indicates a possible concern with soil conditions or foundations at this location; a possible source of future façade cracking if not addressed. A remnant low amplitude response at the third floor of the centre stairwell suggests a possible crack between the third floor and the roof at this location. The identification of these anomalies, showing some degradation in specific areas, were inputs to the redevelopment works.

4.5 *Bridge 329, Chicago*

Bridge 329, owned by the Illinois Highway Authority. carries traffic in an area near Chicago in the USA. The bridge is a four-lane highway with a further lane acting as a hard shoulder. The deck of the bridge is supported by 10 precast, pre-stressed girders that are standard for this type of bridge.

The purpose of the investigation of the dynamic behaviour of Bridge 329 on the Illinois Highway Authority's Network was to investigate whether the bridge was behaving normally or whether it had suffered unseen damage due to an electric current that flowed through the bridge. STRAAM performed a finite element calibration exercise on the bridge. The STRAAM measurements of the bridge were undertaken in a single day in December 2009.

The calibration exercise was detailed and accurate to within 5%. The simplicity of the structure and of its behaviour showed that producing models of such structures are accurate and simple. The finite element model is adjusted by changing the element masses and stiffnesses until the predicted frequencies of vibration correlate well with the measured frequencies from the field. The target is to have the model correspond to within 5% of the fundamental frequency and within 10% of the other lower order recorded frequencies.

The assessment determined the bridge was working within the elastic range and performing as designed.

5 CONCLUSION

Structural risk management assessment and management provide by Mainmark through STRAAM allows for rapid, real time assessment and then reporting of structures. Through measurements of highly sensitive accelerometers and strategic placement, a baseline record of the structure can be obtained and built into a finite element model and calibrated against the structures recorded response, greatly increasing the accuracy of the generated model. From the FEM, serviceability and loading conditions can then be modeled and assessed to allow for the concerned parties to have objective information regarding their asset and make informed decisions based on the actual condition of the structure.

Continuous structural health monitoring for short and medium span bridges

A. Miyamoto
Professor Emeritus of Yamaguchi University, Ube, Japan
(Visiting Professor of EPFL, Lausanne, Switzerland)

ABSTRACT: In this paper, although there are some useful monitoring methods for short and medium span(10-20m) bridges based on the qualitative or quantitative information, mainly two advanced structural health monitoring systems are described to review and analyses the potential of utilizing the long term health monitoring in safety assessment and management issues for short and medium span bridge. The first system is a special designed mobile in situ loading device (vehicle) for short and medium span road bridges to assess the structural safety (performance) and derive optimal strategies for maintenance using reliability based method. The second system is a long term health monitoring method by using public buses as part of a public transit system (called "bus monitoring system") to be applied mainly to short and medium span bridges, along with a safety index, namely, "characteristic deflection" which is relatively free from the influence of dynamic disturbances due to such factors as the roughness of the road surface, and a structural anomaly parameter.

1 INTRODUCTION

It is becoming an important social problem to make maintenance and rehabilitation of the existing short and medium span(10-20m) bridges because there are a huge amount of short and medium span bridges in service in the world. This paper describes a frontier of continuous bridge health monitoring system for not only a rational bridge health monitoring system incorporate with the information and communication technologies for lifetime management of the existing short and medium span bridges but also a data collecting system designed for bridge health monitoring of mainly short and medium span bridges. In this paper, although there are some useful monitoring methods for short and medium span bridges based on the qualitative or quantitative information, mainly two advanced structural health monitoring systems are described to review and analyses the potential of utilizing the long term health monitoring in safety assessment and management issues for short and medium span bridge. The first is a special designed mobile in-situ loading device (vehicle) for short and medium spam road bridges to assess the structural safety (performance) and derive optimal strategies for maintenance using reliability based method. In here, the concept of experimental safety evaluation will be discussed; the loading vehicle for short and medium span road bridge testing as well as essential operating experiences gained in practice will be described (Gutermann & Schröder 2013, Gutermann et al. 2003). The second is a long term health monitoring method using public buses as part of a public transit system (called "bus monitoring system") to be applied mainly to short and medium span bridges, along with a safety index, namely, "characteristic deflection" which is relatively free from the influence of dynamic disturbances due to such factors as the roughness of the road surface, and a structural anomaly parameter (Miyamoto & Yabe 2012). In here, it will be described the details of how to assess the bridge condition by public bus vibration measured in operating on an Ube City bus network in Japan, as a specific example for verify the system.

2 IN-SITU SAFETY EVALUATION SYSTEM BY A LOADING VEHICLE

As one of the useful data collecting systems related to structural safety assessment such as load carrying capacity or durability in existing bridge site, a German research team dealt with an unique experimental safety evaluation system (loading vehicle and measuring equipment) by in-situ loading tests for mainly short and medium span bridges (Gutermann & Schröder 2013, Gutermann & Schröder 2012). In order to optimize the assessment procedure, methods and equipment of the system have been established for increasing refinement and complexity from following points of view:

① to adequate the formulation of a German national technical guideline for loading tests (DAfStb 2000); load tests up to service load (e.g. under normal traffic operation) ,

② to make clear the assessment procedure of the actual load carrying capacity may prove directly by using a special designed loading vehicles and special loading technology for mainly short and medium span bridges , and

③ to determine the structural safety experimentally by performing an in-situ loading test without causing any damage which would impair the safety or the durability of the target bridge.

2.1 *Concept of the Experimental Safety Evaluation by an In-situ Loading Vehicle, BELFA*(Gutermann & Schröder 2013)

For purpose of experimental safety evaluation in-situ for a target bridge as a structural health monitoring system, a special designed (mobile) loading vehicle has been developed for performing loading tests at the road bridge site in a more effective way (Gutermann 2003). It is named "*BELFA*" after the German word "Belastungsfahrzeug" for loading vehicle and may be moved on public roads. It allows conducting these experiments without the cost and timing consuming construction of reaction frames [*www.belfa.eu*]. The project was funded by the Bundesministerium für Bildung und Forschung BMBF (about 1.85 million euros). The loading vehicle as the final design, *BELFA*, consists of a tractor truck with 4 axels and a special semi-trailer with 5 axles as shown in Fig. 1. *BELFA* has 80 tons in total weights, the length amount to 22.5 m in transportation mode and up to 35.5 m in testing mode (see Table 1). It may be also used to apply loads up to 1500 kN so that the common load levels and loading diagrams can be conducted (e.g. in Germany: bridge class 60, which is the highest bridge class in the German standard DIN 1072). As shown in Table 1, *BELFA* has generally the technical limitations that a span of target bridges has to be less than 18m, that is short and medium span bridge, and to be smaller than Germany bridge class 60 loads as the maximum applied load in-situ.

As the operation sequence, the loading vehicle, *BELFA* is driven to the target bridge using its own tractor truck. A special driving permission is needed every time since *BELFA* has over length and overweight. It stops in front of the bridge where the truck is pulling out the front part while the rear axles are blocked. The saddle score of the truck can be reduced additionally by de-airing the pneumatic shock absorption of the last three axles. Thus the truck may cross the bridge, which load carrying capacity is still unknown, with the lowest possible weight. To ensure a riskless crossing it is expedient to assess the structural behavior using the measurement equipment that was installed before. When the first of the rear axles is reaching the bridge, they are blocked again and the middle part is pulled out, too. *BELFA* is placed in the right position and fixed in the desired length. The maximum distance between these supports amounts to 18 m which limits the span of the bridges to be tested to this length. The correct position and length is important since the centre of mass must be in accordance with the planned loading positions. Afterwards all axles are de-aired and are fixed to the vehicle chassis in order that all of the masses were usable as counter-force for the test loading. Four hydraulic jacks, two in the front and two in the rear, are lifting up the whole vehicle so that it serves like a reaction frame. Now starts the self-driving deck crane, which can be moved in the longitudinal direction, to place entrained weights on the chassis. If this weight is not sufficient for compensating the test loads applied, additional ballast weight is required. For that, an on-board water bag may be

Table 1. Essential data of *BELFA* (Gutermann & Schröder 2013)

Length in transportation mode:	22.5 m
Max. length in working position:	35.5 m
Max. distance between supports	18.0 m
Total weight	approx. 84.5 t
Max. test load (without additional dead freight)	approx. 750 kN
Max. permissible test load	1500 kN

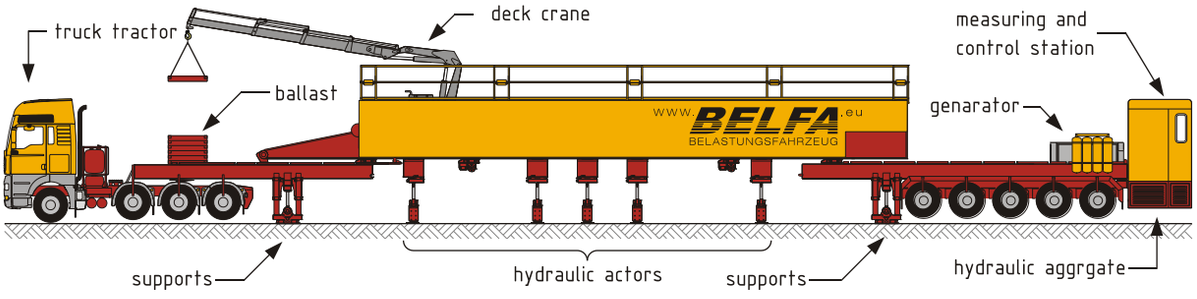

Figure 1. Basic elements of *BELFA* in working position (Gutermann & Schröder 2013)

filled with up to 20 tons of water. If still the reaction force is too low, the *BELFA* may be anchored at the bridge supports by using high-strength steel bars or may be ballasted additionally with external weight. Doing so, the centre of mass must be adjusted to the desired position. The hydraulic actors were moved to the test position, which may be at any point between the supports, and their load distribution beams were lowered to the pavement.

During a load test at the bridge site as shown in Fig. 2, the existing bridge components such as main girders and slabs with an unknown effective load carrying capacity is assessed. Though the effects of loading on the bridge (e.g. deformations) can be measured, the magnitude of the present dead load as well as the ultimate strength is unknown. All equipment must work electronically and has to be integrated in an online measurement system to ensure that the critical load level is definitely identified, which is characterised by beginning damage processes. The experimental safety evaluation without causing any damage is tied to two important technical prerequisites:

① The application of the test loads has to be undertaken in a way that sudden failure of the structure is avoided even in the case of unexpected damage.

② During test loading, the behaviour of the structure has to be monitored continuously and evaluated in real time (e.g. deformations and micro crack formation). In this way, critical load levels are identified and the loading program may be altered in order to avoid damage to the structure. Limit criteria have to be determined prior to the test according to the recommendations (DAfStb 2000).

The best results concerning a safety evaluation are obtained if the structural behaviour above the service load level can be assessed experimentally.

2.2 *Safety Assessment and Application to Actual Bridges* (Gutermann & Schröder 2013)

The German guideline for loading tests (DIN 1072 1985) shows the equation how to calculate the applied test load, $ext\ F_{target}$ for the target bridge,

$$ext\ F_{target} = \sum_{j>1} \gamma_{g,j} \cdot G_{k,j} + \gamma_{q,1} \cdot Q_{k,1} + \sum_{i>1} \gamma_{q,i} \cdot \psi_{o,i} \cdot Q_{k,i} \quad (1)$$

where,

$0{,}35\ G_{k,1} \leq ext\ F_{target} \leq ext\ F_{lim}$,

$G_{k,1}$:Characteristic value of existing structural permanent action,

$G_{k,j}$:Characteristic value of additional self-weight *j,*

$Q_{k,1}$, $Q_{k,I}$:Characteristic value of variable action (traffic loads) respectively of main variable action *i,*

$\gamma_{g,j}$: Partial safety factor of permanent action *G,*

$\gamma_{Q,1}$, $\gamma_{Q,I}$: Partial safety factor of variable action *Q,*

$\psi_{o,I}$: Combination coefficient in case of several variable action *Q.*

The particular values for partial safety factors and for combination coefficient can be found in pertinent recommendations or national appendices (DIN EN 1990 2010). However one special feature of load tests is that the target bridge exists and the self-weight is already acting. Thus this safety margin must not be included in the calculation of the test target load $ext\ F_{target}$ ($\gamma_{g,I}$=1.0). Dynamic effects also are considered by increasing the variable action using a dynamic coefficient, φ which is dependent on the bridge span. The maximum value of φ is 1.4 for short bridges and cannot fall below 1.0 if the span exceeds 50 m (DIN 1072 1985).

During the loading test, influential factors can reduce the stress level, thus the attempted load conditions in the structure are not reached, e.g.

- system influences (part restraint, abutment settlement, lateral distribution),
- structural layers (sealing, slope/safety concrete, pavement concrete, road surfaces),
- formation of the cantilevers and caps (incl. solid railings),
- ambient influences (e.g. temperature).

If they do not have the same permanent effect on the structure, the test target load must be increased by an overload ΔF to compensate this reduction (Gutermann 2004). Then the effective applied test load for the target bridge is $ext\ F_{target}=F+\Delta F$ and generates the stress level in the structure to be verified according to the recommendations. Prior investigations have shown that e.g. pavement acts as a quasi-monolithic strengthening of the structure.

As an example of applying the *BERFA* in-situ loading system to the target bridge which constructed in 1970 and crossed a river in Germany (BS-bridge) with a span of 12 m length. Its cross section consisted of 19 prestressed precast concrete beams which were completed with poured in-situ concrete. Identical loading tests (place and magnitude) were performed in the following conditions of the bridge structure (see Fig. 3):

① initial condition(1),

② after removing the asphalt(2),

③ after removing asphalt and protection/sloping concrete(3),

④ after removing asphalt, protection/sloping concrete, pavement concrete(4).

As a result, Fig. 3 shows the load deflection curves of first loading cycle at midspan under above

four conditions. In this case the determined overload factor was 1.04 (ΔF=0.04 × F) taking only the influence of asphalt into account. Further studies have shown that the coefficient can rise up to 1.26. In the case of constant factors such as restraint effects from concrete joints or earth resistance on the abutments, it is presumed that this influence has the same favourable effects for the residual use period. These influences do not have to be taken into account in the form of an overload and can be used therefore as potential for a higher experimental bridge rating.

3 HEALTH MONITORING SYSTEM BY USING PUBLIC BUSES

In order to properly maintain numerous short and medium span bridges in Japan by conducting periodic inspections, it is necessary to develop an easy-to-use and efficient bridge monitoring system (Chang et al. 2014). The author is developing a short and medium span bridge monitoring system for detecting deterioration in safety and other performance of existing bridges by use of under-rear-wheel-spring acceleration sensors installed on fixed-route buses (called "bus monitoring system") (Miyamoto & Yabe 2012). The proposed monitoring system represents a monitoring system, to be applied mainly to short and medium span bridges, making use of a fixed-route bus operated as part of a public transit system. The aim of the proposed system is to detect the transition from the "acceleration stage," in which the safety performance of a bridge sharply declines because of aging, to the "deterioration stage". This paper presents the result of a three-year field test of the bus monitoring system conducted by using an in-service fixed-route bus in Ube City, Japan. For the bus monitoring system, "characteristic deflection" was defined as an indicator that may be useful in efficiently detecting a structural anomaly of a bridge. For the purpose of examining the sensitivity of characteristic deflection, the effect of artificial damage (bridge guardrail removal) on characteristic deflection was evaluated by using an out-of-service bridge being removed.

Figure 2. View of in-situ loading test by BELFA for an existing bridge (Gutermann & Schröder 2013)

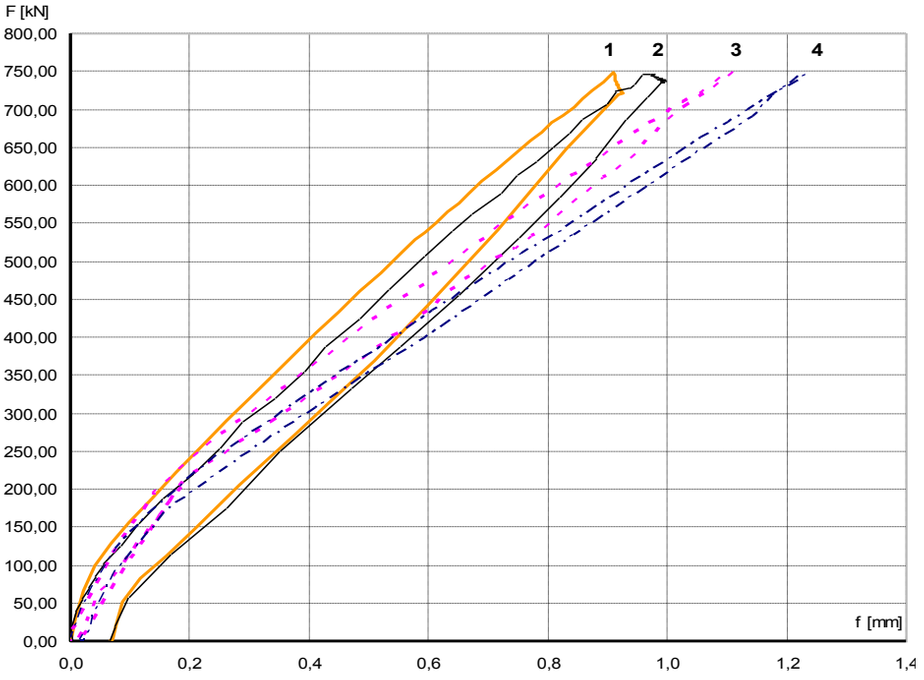

Figure 3. Example of load deflection curves at midspan by BELFA under four various conditions *(Gutermann & Schröder 2013)*

3.1 *Principle & Outline of Bus Monitoring System*

The bus monitoring system has been developed by the method of monitoring short and medium span bridges by using fixed-route buses operated as part of public transport systems. Fig. 4 illustrates a basic concept and damage detection flow of the bus monitoring system. Main reasons why the use of fixed-route buses, which are large and heavy vehicles, was considered are as follows:

① If a large vehicle about 10 m in length is used for on-the-move measurement on a short or medium span bridge, that vehicle is likely to be the only vehicle passing over the bridge at point in time.

② In order to make a short or medium span bridge, whose stiffness is relatively high, it is necessary to use a reasonably heavyweight vehicle.

③ Large vehicles used to vibrate bridges make it easier to reproduce measuring conditions such as travel time, route, frequency of passages and vehicle speed.

④ By using a fixed-route bus equipped with acceleration sensors, main short and medium span bridges in the area of interest can be monitored on a regular basis. By so doing, monitoring cost would be substantially less than in the case where sensors were installed at all bridges.

⑤ Power for the measuring devices can be supplied from the power supply available in the bus.

The vertical displacement, $\delta_a(t)$ of the bridge and the bus under its rear wheel springs is an estimated deflection obtainable by integrating the vertical acceleration waveform twice. That displacement can be expressed, as the sum of (1) the static displacement, $\delta_{sa}(t)$ dependent on bridge stiffness and bus weight, (2) a non-steady-state vibration component having a stochastic nature characterized as a Gaussian process attributable to a rough road

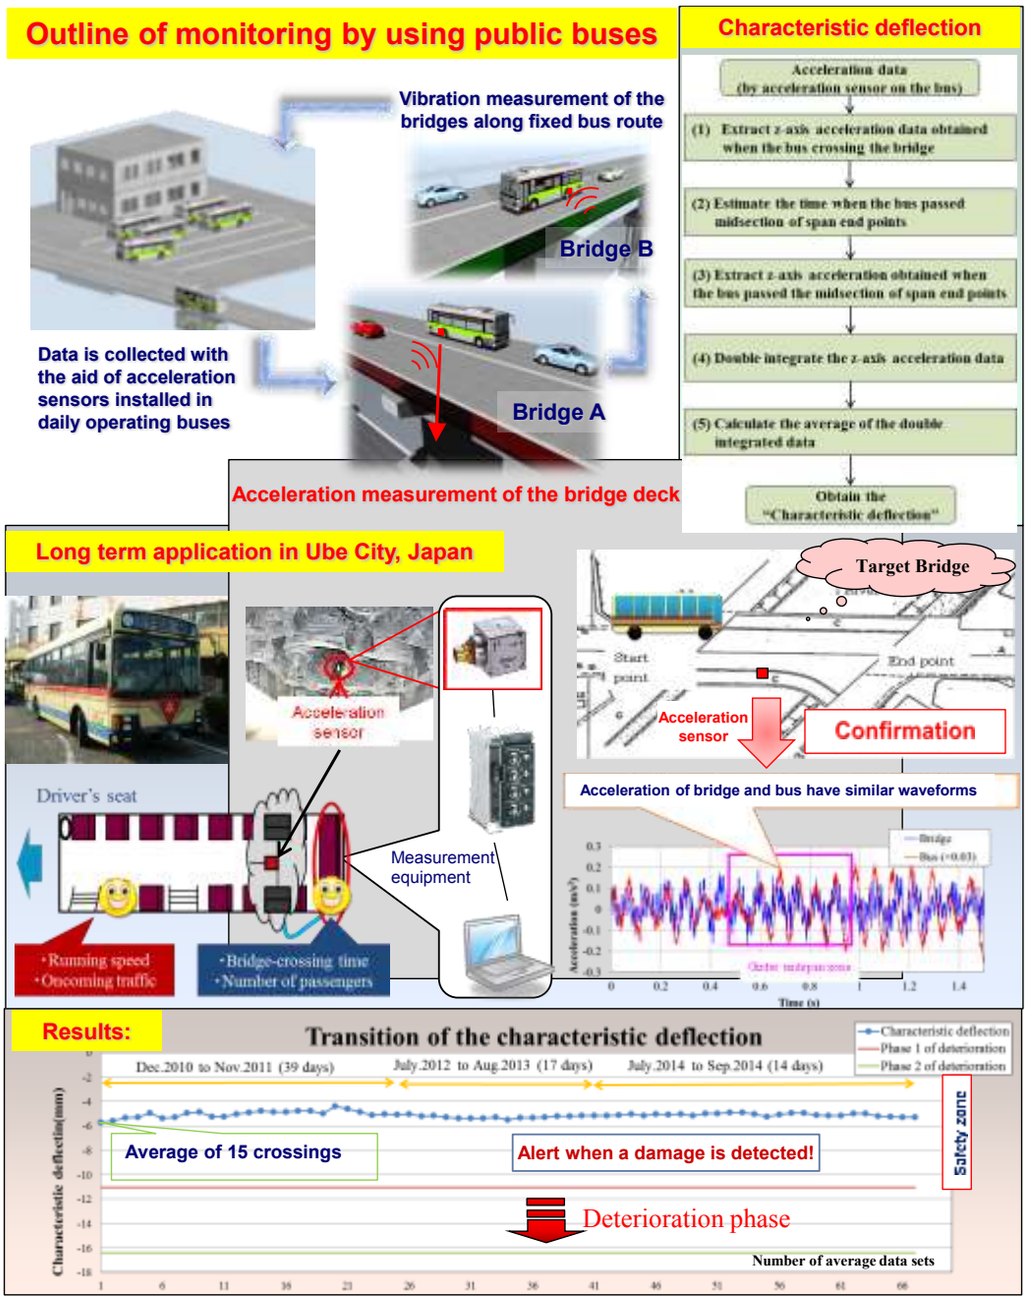

Figure 4. Basic concept and damage detection flow of the bus monitoring system

surface and having a mean value of 0, (3) vibration components governed by the equation of motion such as the bridge and the vehicle, and (4) external disturbance factors, $\delta_x(t)$ due to differences in the operating conditions of the bus and differences in data extraction and processing methods, as follows:

$$\delta_a(t) = \delta_{sa}(t) + S_r(\Omega, t) + \int_{-\infty}^{+\infty} X(f) \cdot e^{2\pi f t i} df + \delta_x(t) \quad (2)$$

where,

$S_r(\Omega, t)$: density function of road roughness,
Ω: spatial frequency of road surface,
$X(f)$: Fourier coefficient.

For the purposes of this study, characteristic deflection, μ_a (Miyamoto & Yabe 2012) is defined as the estimated deflection obtained from Eq. (2) averaged in the bridge section of the road. Studies have shown that characteristic deflection can be made to converge to the extent that anomaly evaluation results are not affected by increasing the number of samples, N, by using the central limit theorem, in order to allow for the influence of various external disturbance factors, $\delta_x(t)$, including the operating conditions of the bus. In this study, the authors used the moving average method to process characteristic deflection data and see what happens. In the moving average method, averages are calculated for incrementally shifted data sections. Fig. 5 shows standard deviations of characteristic deflection values obtained by calculating characteristic deflection averages for incrementally shifted data sections. As shown in Fig. 5, as data sections become larger, standard deviations tend to decrease. It can also be seen that after data section size exceeds a certain limit, standard deviations do not change significantly thereafter. This indicates that by the moving average method mentioned above, the variability of characteristic deflection values decreased and converged so that anomalies can be detected by observing such changes.

3.2 *Long-term Health Monitoring on Bus Routes in Ube City, Japan*

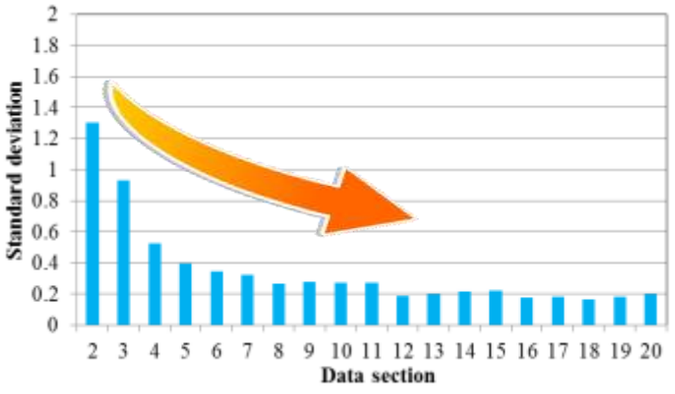

Figure 5. Changes in standard deviation estimated by the moving average method

Figure 6. Fixed-route bus & sensor for long-term field testing

3.2.1 *Field test*

As a long-term application of the bus monitoring method of measurement, a field test utilizing Ube City's bus routes has been underway. The long-term experiment, which uses fixed-route buses being operated in the city, has been continued for about three years since December 2010 and is supposed to be continued in the years to come. Fig. 6 shows the fixed-route bus used in the experiment and the under-rear-wheel-spring acceleration sensors installed to the bus. The acceleration sensors were bonded to the under-rear-wheel-spring section of the bus and was coated with epoxy resin for protection over a long period of time. The sensors used consisted of a triaxial acceleration sensor and uniaxial acceleration sensors (backups). These sensors were oriented along the direction of travel of the bus (X-axis), the transverse direction (Y-axis) and the vertical direction (Z-axis). The acceleration sensor cables were passed through the floor drain of the bus. Thus, the acceleration sensors are connected to the data logger and the computer in the bus so that the vibration of the bus crossing the bridge can be monitored in real time. Although the acceleration sensors, the data logger and the computer are designed to be powered by the power source of the bus, in the experiment a portable rechargeable battery was used. Table 2 lists main bridges of interest located on the bus routes and summarizes data on those bridges. As an example of measurement data, this paper shows the measurements results obtained from the Shingondai Bridge (see Fig. 7), one of the bridges (prestressed

concrete(PC) girder bridge) managed by Ube City, Japan on the bus routes.

3.2.2 *Characteristic deflection calculation method*

This section describes how to calculate characteristic deflection, an indicator of bridge performance used by the bus monitoring system. A flow diagram for the calculation of characteristic deflection following measurement data acquisition is shown in Fig. 4, and each step is described in detail below. The steps (1) through (5) shown below correspond to the numbers shown in Fig. 4.

3.2.3 *Extract data on vertical acceleration during bridge crossing*

Extract data on vertical acceleration during the crossing of the bridge from the acceleration measurement data by referring to the combination of the time at which the bus crossed the bridge and GPS data.

3.2.4 *Estimate the time when the bus passed midspan points*

The extracted data on acceleration during the crossing of the bridge include data on strong vibrations recorded at bridge joints. It is therefore necessary to use girder midspan acceleration data that do not include such joint vibration data. The time when the midspan point of a girder is passed can be estimated by extracting data for between-joint data meeting certain criteria such as time intervals (sec) and the number of waves. Since, however, acceleration data vary considerably in magnitude depending on such factors as the operating conditions of the bus, it may be difficult to identify joint-zone data. In order to accurately estimate the time when the midspan point of a girder is passed, attention was paid to deflection estimates that can be obtained by integrating vertical acceleration data twice.

3.2.5 *Extract midspan vertical acceleration data*

Extract the midspan vertical acceleration data determined as described in Step (2) (see Fig. 4). Fig. 8 shows an example of both side expansion joints and midspan portions of vertical acceleration data. In the example shown in Fig. 8, a portion of midspan region data corresponding to about 0.8 sec (about 10 waves) was identified as data to be extracted. The most important thing in calculating the characteristics deflection is to determine the range of data to be extracted according to such criteria as the number of waves and time(sec) and extract acceleration waveforms from the same regions every time.

3.2.6 *Integrate extracted acceleration data twice*

Extracted acceleration data are converted to velocity by the first integration and to displacement by the second integration. At this step, the vertical displacement obtained by integrating vertical

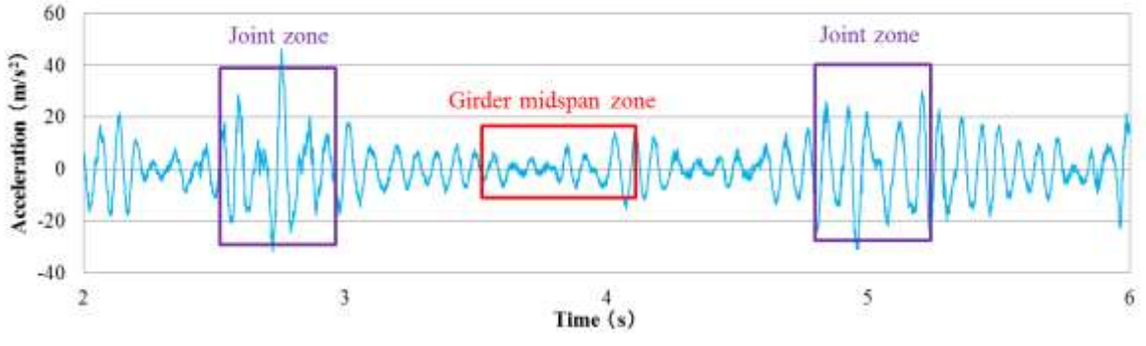

Figure 8. Example of determination of acceleration data extraction range

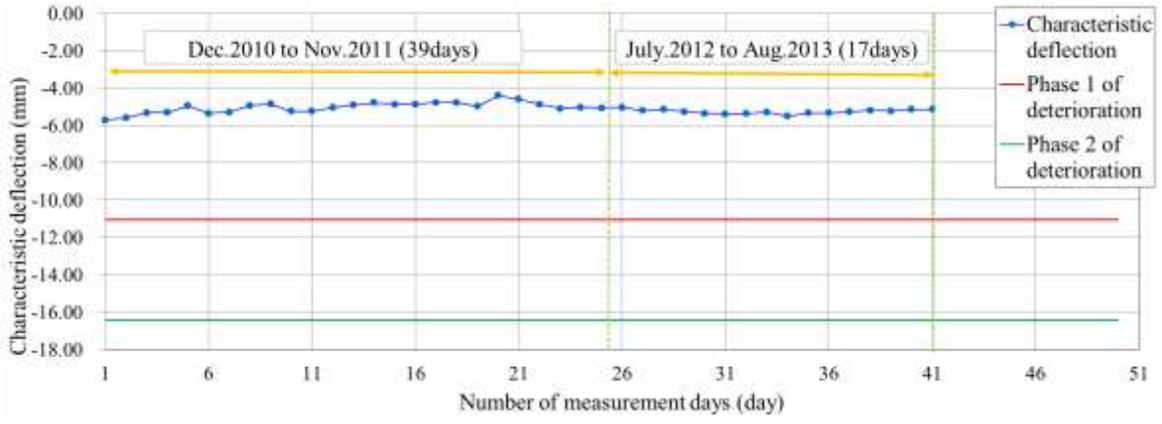
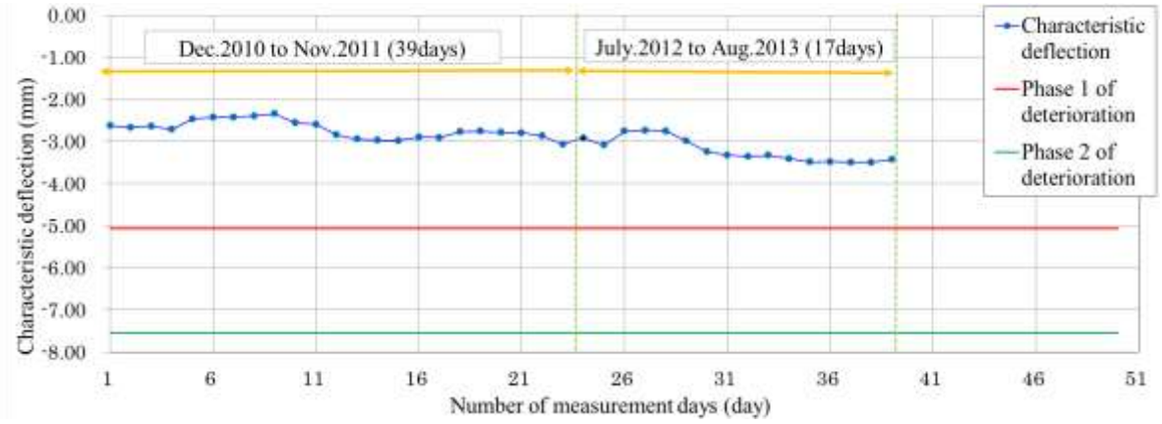
acceleration twice is taken as an estimated deflection.



3.2.7 *Average estimated deflection*

Calculate characteristic deflection by averaging the deflection estimates shown in the graph obtained at Step (4) in the direction of time (Fig. 4).



3.2.8 *Test results and discussions*

First of all, let us consider whether or not it is possible, in the event of a structural anomaly of the bridge of interest, to detect the anomaly from the under-rear-wheel-spring acceleration response of the bus. In a previous study, vibration analysis using FSWT (Frequency Slice Wavelet Transform), a time–frequency analysis method, was conducted to analyze acceleration response (Yan et al. 2009). The FSWT analysis of the girder-midspan and under-rear-wheel-spring acceleration responses conducted in this study indicated that the under-rear-wheel-spring region of the bus was always vibrating at around 12 Hz, regardless of whether or not the bus was crossing the bridge. On the other hand, with respect to the acceleration response of the bridge, it has been confirmed that the girder-midspan region of the bridge was actually vibrating at around 12 Hz (Yabe et al. 2012). Fig. 4 shows the acceleration responses of the under-rear-wheel-spring region of the bus and the girder midspan region of the bridge observed when the bus passed the girder midspan section of the bridge. It can be seen that in terms of the magnitude of acceleration response, the two waveforms show a fair degree of similarity although the under-rear-wheel-spring response values tend to be larger. From these results, it can be concluded that the vibration properties of the bridge of interest can be identified according to the under-rear-wheel-spring vibration of the bus.

Next, let us consider characteristic deflection calculation results. Figs. 9(a) and (b) show changes in characteristic deflection at the Shingondai Bridge during the initial and return trips, respectively, of the bus calculated from the measurement data obtained during a total of 56 days in 2010 to 2013. There are differences in the number of data sets between initial trip data and return trip data because there were some invalid cases such as a case in which the bus stopped on a bridge. The data shown in Figs. 9(a) and (b) were obtained by applying a serious deterioration threshold specifying the limit of the degree of seriousness of bridge anomalies. In this connection, it has been found that characteristic deflection increases to 193% in the event of deterioration that causes the introduced prestressing force to decrease by 50% and to 286% in the event of deterioration that causes the introduced prestressing force to decrease by 90%. It was therefore decided to calculate the average of the

(a) Tokonami→Nishikiwa Gakkomae

(b) Nishikiwa Gakkomae→Tokonami

Figure 9. Long-term changes in characteristic deflection (Shingondai Bridge)

characteristic deflection values obtained from the first 15 measurements and use the characteristic deflection value equal to 1.93 times the average value as the threshold level for Phase 1 deterioration (red line) and the characteristic deflection value equal to 2.86 times the average value as the threshold level for Phase 2 deterioration (green line). The actual procedure is to measure characteristic deflection on a continual basis and, if the threshold level is reached or exceeded, suspect the occurrence of some kind of serious damage to the bridge of interest and conduct visual inspection immediately. Inspection needs to be conducted when characteristic deflection has reached or exceeded the threshold level on the initial or return trip. Characteristic deflections in "Data Section 15" obtained by the moving average method are shown in Fig. 9, where a single characteristic deflection point represents the average of 15 measurement results. Comparison of Figs. 9(a) and (b) reveal that characteristic deflection values differ between the initial trip and the return trip. This is thought to be because the Shingondai Bridge is not symmetrical as shown in Fig. 7. Long-term changes in characteristic deflection showed little change although Fig. 9(a) shows slight changes. In contrast, Fig. 9(b) shows that the lowest value of characteristic deflection decreased gradually. Nevertheless, in both cases, the serious deterioration threshold was not reached or exceeded. It can therefore be concluded that serious damage has not yet occurred on the initial trip route or on the return trip route.

4 CONCLUDING REMARKS

Bridge health monitoring using the latest information technology and sensors will be becoming more challenging issues in the future for maintenance and rehabilitation of existing bridges. In this paper, although several methods are available for monitoring and assessment of existing short and medium span bridges, two advanced structural health monitoring systems were introduced.

In the first part of this paper, as one of the advanced data collecting system for experimental safety evaluation developed by German research team, a special designed in-situ loading vehicle, *BELFA* which is available for assessment quantitatively of load carrying capacity of the target bridge was discussed as a structural health monitoring system at the bridge site. The proposed method was applied to a few actual existing concrete bridges in a rural area of Germany as a specific example to verify its effectiveness. As the results, it will be able to make a rational periodical health monitoring system for existing short and medium span bridges, and then the method helps bridge administrators to establish the rational maintenance strategies.

In the second part, as one solution to the problem for condition assessment of existing short and medium span reinforced and prestressed concrete bridges, a new long term monitoring method using a public bus as part of a public transit system (bus monitoring system) was introduced, along with safety indices, namely, characteristic deflection, which is relatively free from the influence of dynamic disturbances due to such factors as the roughness of the road surface, and a structural anomaly parameter. Moreover, the details of not only how to assess the bridge condition by public bus vibration measured in operating on Ube City bus network as a specific example for verify the system but also what kind of consideration we need to apply the system to existing bridges in overseas country were discussed.

The author would hope that this paper would be of some help in this field in the future.

ABSTRACT:
Structural analyses of old and often already damaged bridges are expensive and time-consuming. Hence, there is a huge demand for structural health monitoring systems that can be retrofitted on existing bridges to achieve information if damages jeopardize a future use. The authors present a data-driven analyzing method for detecting and assessing structural damages in a two-span concrete beam bridge that is equipped with distributed strain sensors below the decks of the bridge segments. The method makes use of bridge excitations caused by single vehicles (with unknown load and velocity) along both spans and their induced strains at various sensor locations.
Computer simulations of vehicle crossings over a bridge model with varying damage scenarios are used to validate the method. Supporting validations are conducted based on data of a real national highway bridge, which has been approved for scientific experiments including the infliction of damages. Results are promising in effectively detecting and assessing different damages using the proposed method.

1 INTRODUCTION

Bridges are critical infrastructure elements, for safety reasons and due to their economic importance. However, the average age of bridges in Germany (already about 40 years) is increasing. Additionally, higher traffic frequencies and increased vehicle sizes and weights have changed the loading conditions of these bridges. Both aspects raise the number and severity of structural damages in bridges (BASt, 2017). Structural analysis of bridges taking into account damages are expensive and time-consuming. Thus, there is a high demand for low-cost (semi-) automated structural health monitoring systems that can be retrofitted on existing bridges.

The data analyzing method presented in this contribution enables the detection, localization and assessment of structural damages in a two-span beam bridge. COTS strain sensors, which are installed below the decks of the bridge spans provide the data basis. Frequently occurring single truck crossings with unknown velocity and weights are used as excitation of the bridge. Extracting data-based features from the measured time series data allows to distinguish between damage severities and damage locations. Our method makes use of the characteristics of two-span beam bridge structures, which lead to specific strain data.

The method is validated with computer simulations of vehicle crossings of a FEM bridge model, in which damages with varying severities and locations were taken into account. Data of a real national highway bridge that has been approved for scientific experiments provide the basis to prove the applicability of the developed method. I.e. after closing the bridge for public traffic, structural damages have been gradually inflicted into the bridge in between numerous bridge crossings.

Eventually, the authors demonstrate that the presented sensor system combined with the developed analysis method allow a subsequent upgrade of existing two-span beam bridges with an effective structural health monitoring. Thus, this approach represents an economic solution for retrofitting bridges with a monitoring and damage detection system.

1.1 *Related Work*

Four categories of structural health monitoring systems are usually distinguished, where most systems fall into the first three categories (Rytter, 1993):
Detecting the damage (1), localizing the damage (2), quantifying the damage severity (3), and predicting the remaining service life (4).

Many methods of structural health monitoring analyze the measured vibration response of the structure. The relation between physical properties and

modal parameters forms the basis of these approaches (e.g. Doebling et al., 1998; Fan & Qiao 2011). Besides these methods that are relying on sensor installations on a bridge, numerous methods exist, which extract dynamic properties of a bridge structure from the dynamic response of a crossing vehicle. (e.g. Yang et al., 2004 & Malekjafarian et al., 2015)

1.2 *Paper outline*

In Section 2 the authors describe briefly the test bridge and the sensor system, which provide the basis for the development of the algorithms. Section 3 addresses the bridge model and the simulation properties. In Section 4 the experiments at the test bridge are outlined. The developed algorithms for the detection and assessment of structural damages are described in Section 5. Section 6 addresses the results of the validation with simulation data and experimental data.

2 TEST BRIDGE

A national highway bridge in Germany has been selected as test bridge based on its representative properties as well as for technical measurement reasons. The bridge type is a pre-stressed two-span beam structure with two lanes (Fig. 1). The length of the bridge is 50 meters and the width is 10 meters. The year of construction is 1962. The bridge is part of a rural arterial road and consequently under intensive usage of about 20,000 vehicles of various types per day.

A scheduled reconstruction of the bridge during the project duration has offered the unique possibility to conduct destructive experiments with the infliction of controlled damages into the bridge. After the bridge closure for public usage, dummy vehicle crossings have been performed.

Figure 1. Test bridge.

2.1 *Sensor system*

The sensor system consists of 18 linear strain gauges (HBM 1-LY41-50/120) which are installed below the deck of the bridge and which are connected to a universal amplifier (HBM QuantumX MX840B and MX1615B).

The measuring range of the strain sensor is -50,000 to 50,000µstrain with a measuring accuracy of ±0.02µstrain. The recording frequency of the sensor data is 200 Hz.

Figure 2 illustrates the position and label of each instrumented sensor on the bridge.

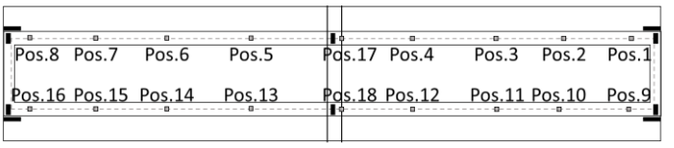

Figure 2. Strain sensor positions below bridge.

3 NUMERICAL MODEL AND SIMULATION

The validation of the algorithms required the development of a bridge model with the possibility to consider structural damages as well as simulations of vehicle crossings. The test bridge described above provides the basis for the FEM mathematical bridge model. Statistical traffic data constitutes the preparation of the vehicle bridge crossing simulation data.

3.1 *Bridge model parameters*

The bridge model has been built with the finite element analysis and CAD software SOFiSTiK. Two calculation models have been developed for structural dynamic analysis: A simplified model consisting of 40 beam elements and a more detailed 3D model consisting of about 2,000 shell elements for nonlinear analysis. Figure 3 depicts the cross section of the bridge. The bridge supports are roller bearings and hence abutments are not taken into account.

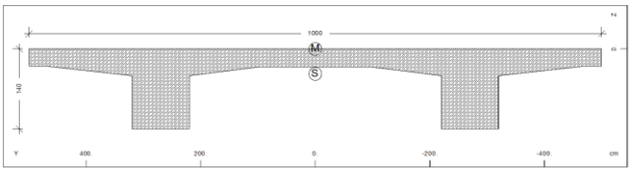

Figure 3. Cross-section of bridge model.

Two commonly occurring structural damages with increasing severity are modelled:

Damage 1 is located above the central bridge bearing. Damage 2 is located at a center span. (Fig. 4)

The severities of both damages are subdivided into four increments: Severity 1 (5%), severity 2 (20%), severity 3 (35%) and severity 4 (50%). The percentage indicates the partial loss of each element's load-bearing capacity.

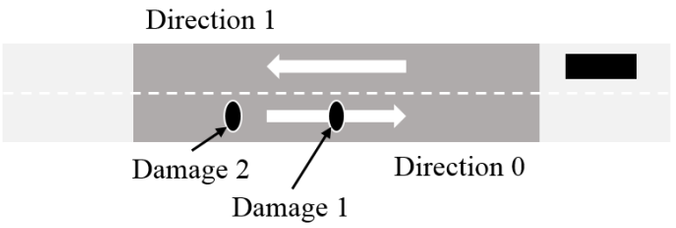

Figure 4. Damage locations in simulation data.

3.2 *Vehicle parameters*

Based on preliminary results, the data of single vehicle crossings of heavy trucks are considered as data basis for the simulations. Therefore, the simulations focus on bridge crossings of 5-axis trucks to build up this data basis. It is possible to detect single vehicle crossings of heavy trucks based on strain data amplitudes easily. Additionally, many single truck crossings occur at the test bridge especially during the night. Therefore, focusing on single truck crossings does not represent a strict restriction for the monitoring system. The vehicle crossings are simulated with varying vehicle characteristics that are derived on statistical traffic data (Geissler, 2014).

In order to cover a wide range of scenarios, the variation of vehicle characteristics in the simulation data comprises the following properties:

- Weight
- Length
- Vehicle velocity: Mean 60km/h; Standard deviation 9.5km/h
- Wheelbase
- Natural frequencies of wheel suspensions
- Attenuation constants of wheel suspensions
- Vehicle width
- Deviation from ideal track

All simulated vehicle bridge crossings follow *direction 1* (Fig. 4).

To validate the performance of the developed method with respect to the detection and assessment of bridge damages, the following number of simulations of vehicle crossings in different damage classes have been conducted:

- 800 vehicle crossings with no damage (Damage class: 0)
- 4x90 vehicle crossings with damage 1 in four severity steps (Damage classes : 1.1, 1.2, 1.3, 1.4)
- 4x90 vehicle crossings with damage 2 in four severity steps (Damage classes : 2.1, 2.2, 2.3, 2.4)

Figure 5 illustrates the variance in the simulation data (undamaged bridge) for the sensor at position 3.

The entire vehicle crossing simulation data comprises 1520 vehicle crossings with 1400 data points (corresponding to 0…7s) for each sensor (sensor position 1…17; data of sensor 18 is corrupt).

4 TEST BRIDGE EXPERIMENTS

Due to the officially scheduled reconstruction of the test bridge, there has been the unique opportunity for running extensive custom experiments with the bridge. These numerous experiments have included the manual infliction of damages into the bridge as well as the excitation of the bridge with a 20t vehicle passing the bridge repeatedly.

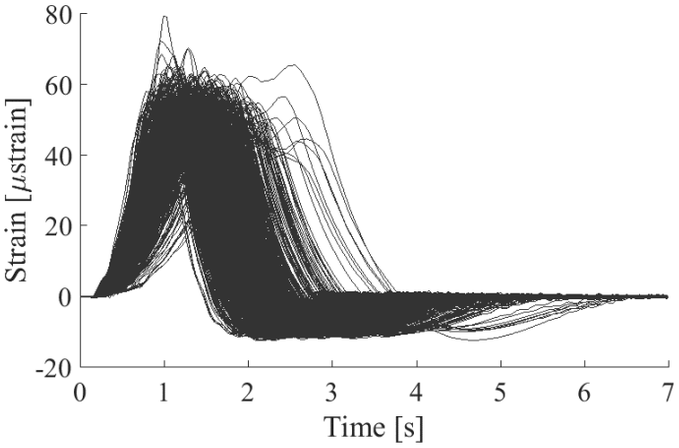

Figure 5. Strain values at sensor position 3 of all simulated bridge crossings with damage class 0 (undamaged bridge model)

Currently, a part of the acquired experimental data have been preprocessed and analyzed. Available preprocessed data includes experiments with cutting tendon cables, corresponding to damage 2 in the simulation data. This damage could be the consequence of a hydrogen embrittlement under real conditions (Fig. 6). In Figure 7 the cutting of tendon cables is shown.

Figure 6. Damage location in experimental data.

The following data sets have been recorded:

- 25 vehicle crossings without damage (Damage class: 0),
- 25 vehicle crossings with three removed tendon cables (Damage class: 3.1) and
- 23 vehicle crossings with six removed tendon cables (Damage class: 3.2).

5 METHOD

In this section, the authors describe the data processing steps that are required to discriminate different damage classes based on the simulation and the experimental data.

Figure 7. Cutting of three tendon cables at the test bridge.

Figure 8 shows a typical signal of a vehicle crossing of the analyzed two-span beam bridge. As the vehicle enters the bridge, the strain value increases at the span where the sensor is located. After leaving the span to the next bridge segment, the strain value gets negative. This measurable feedback to the other segment is caused by the two-span beam structure's lever action across the middle support. Utilizing this inherent property forms the basis of two extracted features. After the vehicle passage, the free oscillations of the bridge without exciting force i.e. the damped natural frequencies are analyzable. Two extracted features are based on these signal parts.

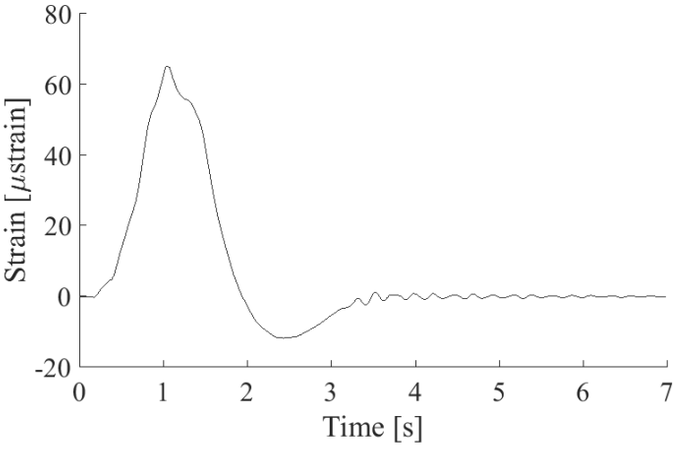

Figure 8. Simulated strain signal at sensor position 5 of one vehicle crossing (damage class: 0).

At first, a data preprocessing step is required to normalize the data sets. Subsequently, the feature extraction is executed which aims to reduce the data dimension to few characteristic features. These features should still possess all the information about bridge damages and damage locations and exclude all irrelevant information. This property is evaluated for four extracted features using an analysis of variances approach.

5.1 *Data Preprocessing*

In order to acquire data sets of the sensor signals similar to the one in Figure 8 for the real bridge experiments, an event detection is implemented. This event detection uses ring buffering and a peak detection in the data sets. Prospectively, the event detection could be upgraded to automatically detect, segment and classify single truck crossings.

Due to various reasons, such as temperature effects or sensor drifts, the measured strain values can be biased. In order to normalize the data, this bias has to be removed from the data sets. The applied method calculates the median strain value of the data before and after the excitation by a vehicle bridge crossing and subtracts it from the analyzed data set. The normalized data can be used for further processing steps.

5.2 *Feature extraction*

Each data set of one vehicle bridge crossing consists of a time series with 1,400 data points. This can be regarded as a 1,400-dimensional feature space, in which each data set reflects one position. Distinguishing between different damage classes means finding clusters of data sets in this high-dimensional feature space. However, this approach does not offer insight into the data structure. E.g., it is not clear, if minor variations end up in different classes. In addition, vehicles with different weights would end up in different clusters. The variation in the data caused by different vehicle masses or velocities are obviously higher than the variation caused by small damages.

In an online system, vehicle mass and vehicle velocity are unknowns. Therefore, it is appropriate to extract features from the data that are independent of the vehicle's mass and velocity. These features should still contain all the information about the bridge damages and allow an accurate discrimination of the different damage classes. Mathematically speaking, the extraction of one feature from the data is a reduction of the data dimension from 1,400 to one.

Here, we propose four features and evaluate their performance afterwards. The first two features are based on the data after the excitation by the vehicle, i.e. after the vehicle has passed the bridge. For this reason, an automatic detection of the point of time, when a vehicle leaves the bridge in the analyzed time-series data is implemented. The third and the fourth feature are based on the entire signal and use ratios to ensure independence from velocity and mass.

- Exponential decay

The upper and lower envelope of the decaying signal are calculated using the Hilbert transformation. A curve fit is implemented which estimates the parameters a and b of the following equation for both envelopes.

$$y(t) = a \cdot e^{-b \cdot t} \quad (1)$$

The exponential decay constant b is similar for both upper and lower envelope. Thus, the extracted feature f_1 is the exponential decay constant b of the upper envelope.

- Natural frequencies

Using the Fourier transformation, the natural frequencies of the bridge can be estimated. In the bridge model, the first mode is at 4.175 Hz. Assuming there are damage-based variations in the modal properties, the first mode is extracted as feature f_2. The implemented algorithm detects the frequency with the highest power spectrum amplitude between 4 and 5 Hz in the data sets.

- Min/max-ratio

The min/max-ratio reflects the quotient of the absolute value of the minimum strain and the maximum strain value during one bridge crossing of a vehicle.

$$f_3 = \frac{|\min(\varepsilon)|}{|\max(\varepsilon)|} \quad (2)$$

Using the ratio, there is no influence by vehicle mass and velocity since the mass and velocity influences the minimum and maximum equally and can thus be eliminated from the quotient.

- Area ratio

The feature area ratio is the quotient of the summarized positive strain and the summarized negative strain in one data set.

$$f_4 = \frac{\left| \sum_{k=t_{ss,1}}^{t_{ss,2}} \varepsilon(t_k) \right|}{\left| \sum_{k=t_{os,1}}^{t_{os,2}} \varepsilon(t_k) \right|} \quad (3)$$

Here, $t_{ss,1}$ indicates, when the vehicle enters the same bridge span where the sensor is located. The vehicle leaves this bridge segment at $t_{ss,2}$. The point in time when the vehicle enters the span where the sensor is not present is $t_{so,1}$ and it leaves this segment at the point in time $t_{so,2}$. Depending on sensor location and vehicle direction the parameters $t_{ss,2}$ and $t_{so,1}$ or $t_{so,2}$ and $t_{ss,1}$ are equal.

5.3 *Feature evaluation*

In order to evaluate the extracted features, the analysis of variances method (ANOVA) is conducted. This method examines whether (and if so how) the expectation values of the measured feature values vary in different damage classes. It is based on the calculation of the ratio between the inner-class variation and the variation between classes. A subsequent test for statistical significance allows determining, whether the classes differ significantly or not and hence defines the quality of a feature.

It is assumed that the prerequisite of ANOVA - measurement data follow a normal distribution- is fulfilled. As the evaluation measure the following value is used

$$Q = 1 - \frac{SSW}{SSB + SSW} \quad (4)$$

where *SSW* reflects the *S*um of *S*quares *W*ithin groups and *SSB* is the *S*um of *S*quares *B*etween groups. A value of Q close to one means that the feature's performance to discriminate all classes is high. A value close to zero means the feature is not suited for discriminating different damage classes (damage severity and damage position).

6 RESULTS AND DISCUSSION

The features described in Section 5 are calculated for the simulation data as well as for the experimental data. The calculation of the ANOVA-based quality measure Q is additionally subdivided into each sensor position. Hence, the evaluation of the results allows defining the best combination of sensor position and extracted feature regarding the discriminability of the damage classes.

6.1 *Simulation data*

The ANOVA-based measures Q for each feature at each sensor position are presented in Table 1. The features f_1 and f_2 yield values near zero for all sensor positions, reflecting a low potential to discriminate the different damage classes. Due to its location at the center bearing, sensor position 17 is not suitable for calculating the exponential decay.

The results of feature 3 and feature 4 range above 0.7 for several sensors and almost reach 1 for their combinations: sensor pos. 4/5 and feature 4.

In Figure 9 the box plots for feature f_4 at sensor position 5 is shown. Each damage class possesses a different median value and has low inner-class variances. Discriminating the damage classes is easily achievable via simple thresholding.

Figure 10 depicts the results of the feature min/max ratio f_3 for sensor position 7.

Table 1. Results of feature evaluation for the simulation data represented by the measure Q which ranges from 0 (worst) to 1 (best). The maximum values of each feature/sensor combination are highlighted.

6.2 *Experimental data*

Facing experimental sensor data, it turned out that the extraction of the exponential damping factor is not reliable when it is exclusively based on strain data. Figure 11 shows a signal after the vehicle passage. Fitting envelopes into this signal part fails to yield reasonable results.

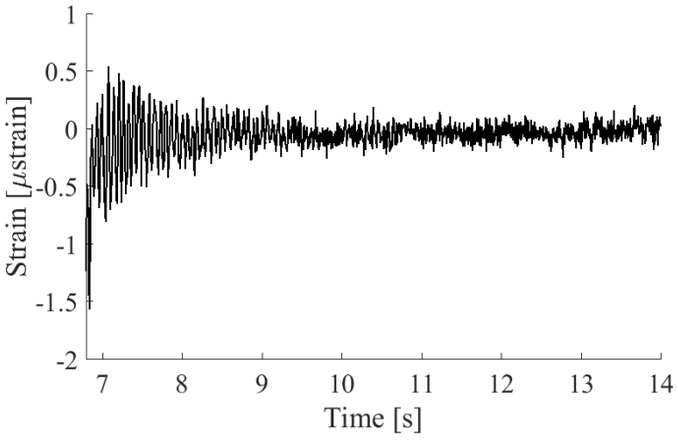

Figure 11. Sensor signal after the vehicle left the bridge (experimental data).

In Table 2 the results of the feature evaluation are presented. Regarding the experimental data, the feature min/max ratio f_3 performs slightly better than the feature area ratio f_4. Both are near 1 for specific sensor positions; therefore, they offer a high discriminability between the damage classes. The performance of the frequency-based feature f_2 reaches only low values for Q through all sensor positions. The damping factor f_1 is not analyzed in the experimental data.

Table 2. Results of feature evaluation for the experimental data represented by the measure Q which ranges from 0 (worst) to 1 (best). The maximum values of each feature/sensor combination are highlighted.

Sensor pos.	f_1	f_2	f_3	f_4
1	N/A	0.11	0.88	0.83
2	N/A	0.02	0.08	0.02
3	N/A	0.02	0.83	0.79
4	N/A	**0.15**	0.90	**0.92**
5	N/A	0.13	**0.96**	0.90
6	N/A	0.03	0.86	0.75
7	N/A	0.15	0.76	0.49
8	N/A	0.01	0.80	0.48
9	N/A	0.13	0.28	0.16
10	N/A	0.03	0.37	0.02
11	N/A	0.03	0.41	0.65
12	N/A	0.01	0.63	0.38
13	N/A	0.02	0.93	0.81
14	N/A	0.10	0.79	0.80
15	N/A	0.06	0.42	0.23
16	N/A	0.05	0.10	0.12
17	N/A	0.07	0.25	0.43
18	N/A	0.06	0.65	0.63

Box plots of the best sensor position for the features min/max ratio f_3 and area ratio f_4 are presented in Figure 12 and Figure 13. Similar to the simulation data, the different damage classes turn out to be well discriminable. In both features the different damage classes are reflected by different median values in combination with low variances.

6.3 *Discussion*

The results demonstrate that the applied feature extraction allows a reduction of the high dimensional data to single dimension variables, while still keeping and even emphasizing the differences between various damage classes. This approach works with both ratio-based features. The features based on the free oscillations of the bridge resulted in a poor discriminability using strain sensor data.

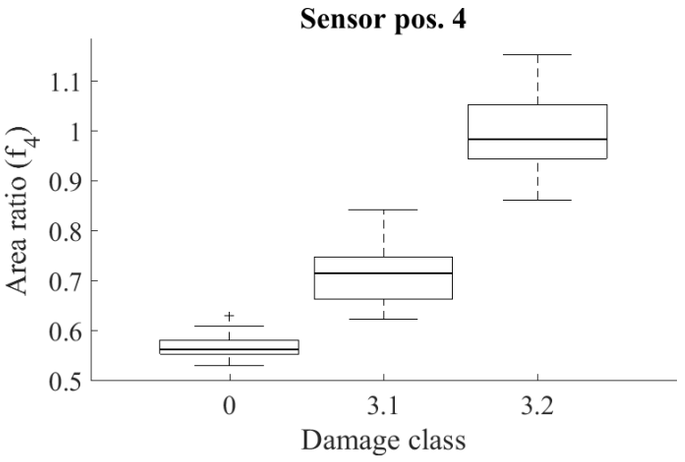

Figure 12. Box plot of feature min/max ratio f_4 for the sensor at position 4 based on experimental data.

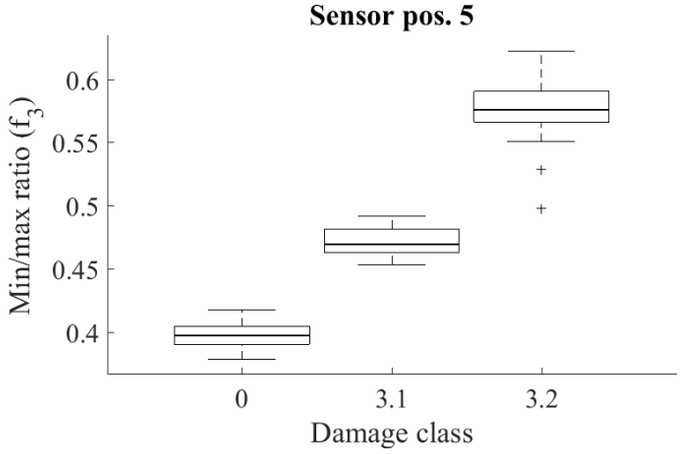

Figure 13. Box plot of feature area ratio f_3 for the sensor at position 5 based on experimental data.

Extracting the features area ratio or the min/max ratio, it is possible to discriminate damage severities and damage locations with only one strain sensor at a specific position.

Still, a few restrictions have to be retained at the current state of the method devolvement. Two damage classes in the simulation data and one in the experimental data have been considered. Further damage scenarios could result in similar feature values and therefore prevent a successful classification. Nevertheless, the authors assume that an adequate classification could follow up by using more than one sensor in the classification step. The presented approach considers so far vehicle passages in just one direction. Adding information by integrating vehicle crossings could additionally improve the performance. In future research, the authors address these additional aspects.

Compared to traditional visual inspections of the bridge, the presented approach offers several advantages. Once the sensor system is installed, data is acquired 24/7. This allows a continuous tracking of the bridge state with little effort. In addition, the system represents a low-cost solution for bridge monitoring, as it requires only few strain sensors and an analysis unit for data processing, data archiving and data access.

7 CONCLUSION

A structural health monitoring system for bridges requires the reliable detection, localization and assessment of damages in the bridge structure. In this paper, an approach for a two-span beam bridge based on strain sensor data and subsequent data processing is proposed. The authors demonstrate that the extraction of features based on strain sensor data at specific sensor positions achieves a high performance in discriminating different damage locations and severities. Using ratios in the data signals, the extracted features are independent from vehicle masses and vehicle velocities, two variables that are usually unknowns in real traffic scenarios.

The method is validated with simulation data as well as with experimental data from a real bridge with inflicted damages. The validation results demonstrate the applicability of the developed method.

Automatic Data Collection System for Structural Health Monitoring

Akito Yabe, Tetsuya Iye
KOZO KEIKAKU Engineering Inc. Tokyo, Japan
Ayaho Miyamoto
Yamaguchi University Yamaguchi, Japan

ABSTRACT: In Japan, a great number of short and medium span bridges is managed by local government on a limited budget and limited number of expert engineers. More reasonable and efficient than conventional visual inspection or monitoring systems methods of the condition assessment have been needed. Therefore, a method of the condition assessment system based on monitoring data from public bus vibration was developed for existing short span (10m～20m span length) RC bridges. Due to the fact that this system is only composed of an acceleration sensor and a manual operation data collection system, a reasonable and efficient automatic data collection system is considered. In this paper, a method of automatic data collection system using GPS sensor is proposed. This system which is installed on the public bus changes a manual and non-efficient operation into an automatic and low cost one.

1 INTORODUCTION

1.1 *Summary of the condition assessment system based on monitoring data from public bus*

In Japan, about 70 percent of nearly 670,000 bridges were constructed in the 1960s and 1970s. Most of them are short- or medium-span (10–20 m) bridges. This great number of short and medium span bridges is managed by local government on a limited budget and limited number of expert engineers. That is why, the number of carried out inspections is insufficient. In the future, due to reconstruction of government finances and declining birth rate the bridge management will become even more difficult. Therefore more reasonable and efficient than conventional visual inspection or monitoring systems methods of the condition assessment have been needed. In view of such situation a method of the condition assessment system based on monitoring data from public bus vibration as shown in **Figure 1** was developed for existing short span RC bridges. This system has applied a method of extracting safety indices, namely "Characteristic Deflection" (shortened to CD) which is relatively free from the influence of dynamic disturbances due to such factors as the unevenness of the road surface, and a structural anomaly parameter. The system is only composed of an acceleration sensor and a manual operation data collection system. While measuring the acceleration of bus vibration, an operator has to be on the bus to make a note of a time when the vehicle is passing over the target bridge. After measuring, CD is extracted from acceleration data by manual operation. Due to the operating cost of this process, an automatic data collection system seems to be more reasonable and efficient monitoring system. This paper focuses on a method of automatic data collection system using Global Positioning System (GPS). This system is pinpointing bus's position by GPS sensor data and detecting ups or downs of a road. If the bus is over the target bridge, this system automatically measures acceleration data. It is expected that this automatic data collection system will enable to create low cost bridge management system.

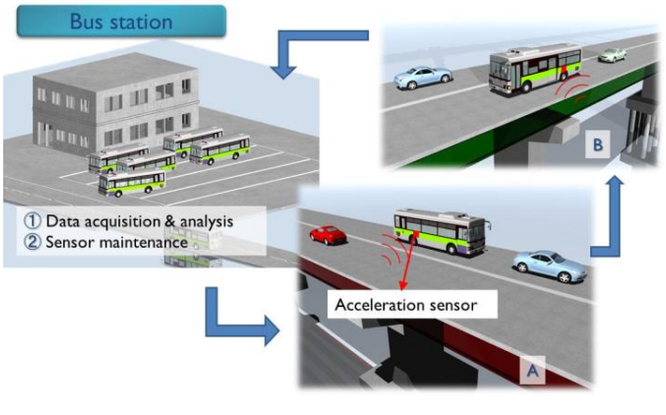

Figure 1. Concept of bus monitoring system for short- and medium-span bridges.

1.2 *Concerning the theory of "Characteristic Deflection"*

The calculating CD process is one of the rational methods for extracting damage/deterioration-related information from measured rear wheel vibrations of a bus without being affected by the dynamic characteristics of the bridge and the vehicle and the road surface profile. A summary of the rationale for extracting CD is shown **Figure 2**.

The rear wheel vertical vibration $\delta_a(t)$ of a bus running at a constant speed can be expressed as the sum of static displacement $\delta_{sa}(t)$, which is dependent on the measured rear wheel vertical vibration of the bus, and dynamic displacement $\delta_{da}(t)$, which is dependent on the road surface profile and the vibration characteristics of the bridge and the vehicle:

$$\delta_a(t) = \delta_{sa}(t) + \delta_{da}(t) \quad (1)$$

If it is assumed that the unevenness of the road surface can be expressed as a steady-state random Gaussian process with an average value of 0 and that dynamic displacement including bridge–vehicle interaction is ergodic and Fourier-series-expandable, the dynamic displacement $\delta_{da}(t)$ can be expressed as their sum:

$$\delta_{da}(t) = S_r(\Omega, t) + \int_{-\infty}^{+\infty} X(f) \cdot e^{2\pi f t i} df \quad (2)$$

where

$S_r(\Omega, t)$: density function for unevenness of road surface.

Ω: spatial frequency of road surface profile.

$X(f)$: Fourier coefficient.

In Eq. (2), the sample mean in the second term is 0. The mean of a sufficient number (N) of samples obtained from $\delta_{da}(t)$ can be expressed as

$$\frac{\sum_{t=1}^{N} \delta_{da}(t)}{N} \fallingdotseq 0 \quad (3)$$

Next, k samples are taken from measured values obtained from $\delta_a(t)$, and their mean is expressed as : $\overline{\delta a\ (t)}$

$$\overline{\delta a\ (t)} = \frac{\sum_{j=1}^{k} \delta_a(j)}{k} \quad (4)$$

Because the sample mean follows a normal distribution in accordance with the central limit theorem, $\overline{\delta a\ (t)}$ converges to a certain value (μ_a). For the sample mean $\delta_a(j)$ of a sufficient number (n) of samples, the following equation holds true:

$$\mu_a = \frac{\sum_{i=1}^{n} \overline{\delta a\ (t)}_i}{n} = \frac{\sum_{i=1}^{nk} (\delta_a(j))_i}{nk} \quad (5)$$

Sampling is made so that there is no overlap in the samples. If N is sufficiently large for $nk = N$ and $t = 1 \sim N$, the following approximation can be made:

$$\mu_a \fallingdotseq \frac{\sum_{t=1}^{N} \delta_a(j)_t}{N} \quad (6)$$

This expresses the mean displacement of the rear axle of the bus passing over the bridge. From Eqs. (1) and (3), the following equation can be derived:

$$\mu_a \fallingdotseq \frac{\sum_{t=1}^{N} \delta_{sa}(t)}{N} \quad (7)$$

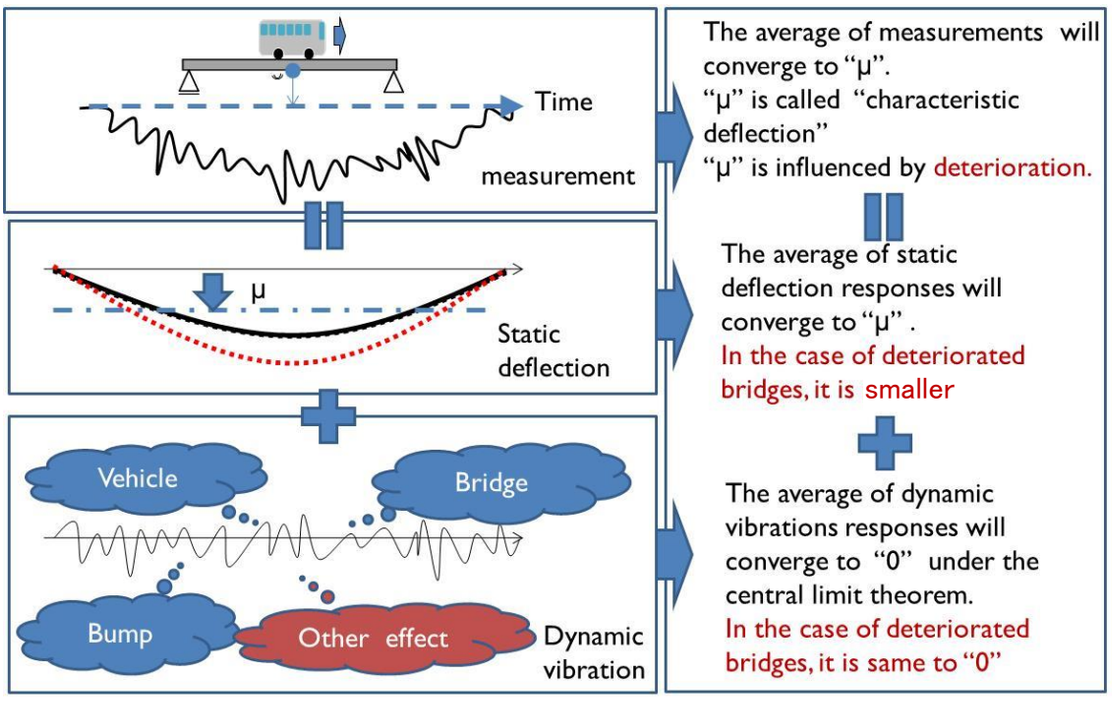

Figure 1. A summary of the rationale for extracting CD

This means that the mean displacement of the rear axle of the bus passing over the bridge obtained from a sufficient number (N) of samples can be extracted as a value, μ_a (referred to as "Characteristic Deflection value"), that is relatively free from the influence of the vibration characteristics of the bridge and the vehicle and the dynamic displacement due to the unevenness of the road surface. Since the values of μ_a are extracted from measurements taken when the bridge under consideration is in a sound condition, values extracted from a measurement taken after the occurrence of deterioration or damage are represented by μ_a'Then, the following equation can be defined :

$$\alpha = \frac{\mu_a'}{\mu_a} \qquad (8)$$

The rate of change α expressed by Eq. (8) is defined as the structural anomaly parameter. After a given value of α is set, the characteristic deflection is monitored continuously. When the characteristic deflection has exceeded a certain limit, it can be detecting that the bridge of interest has moved from the acceleration stage to the deterioration stage.
From the above, CD was calculated based on the law of classical mechanics such as Hooke's law and statistical feature data. If the condition is satisfied which means Hooke's law influence is greater than others in measured rear wheel vibrations, only CD has the significant information of damage/deterioration. Therefore, rear wheel vibrations have to be measured by a heavy vehicle such as a bus.

2 SUMMARY OF AUTOMATIC DATA COLLECTION SYSTEM

2.1 *Composition of automatic data collection system*

Conventional data collection system is composed by an acceleration sensor, a data logger, a personal computer and a battery. This system data logging sampling frequency is 1000Hz, so collecting a huge number of acceleration data is impossible. The system is operated manually. That is why, when measuring the acceleration of bus vibration, one operator is always checking whether the bus is approaching the target bridges, while another operator is responsible for pushing the start button and making a note of a time when the bus enters the target bridge. New data collection system is created by adding GPS sensor and USB camera to the conventional system, as presented in Figure 3. An acceleration sensor and a GPS sensor performance are shown in **Table 1.** GPS sensor has two operating functions. One function is detecting that the bus is approaching the target bridges with detecting the ups or downs of a road. Another function is a trigger for the start of measuring the acceleration of bus vibration.

2.2 *A method of the target bridge detection*

In the case of detecting the measurement target bridge using GPS data there are three important aspects: detection of approaching to the target bridge, detection of the ups or downs and relation with acceleration data. A detection method of vehicle approaching to the target bridge is shown in **Figure 4**. The two position area data were prepared for picking up GPS in the automatic data collection system in order to detect the ups or downs and solve a time lag of data acquisition. As shown in Figure 3, when the bus is going into the Picking up area 1 on the ups side lane, the system state becomes "Ready". Later, when it is going into the Picking up area 2, the system state becomes "Measurement Start". An acceleration data is logging time to pass the bridge. When in the state of "Measurement" in the area 2, the trigger is off to change the state.

Figure 3. A new automatic data collection system.

Table 1. An acceleration sensor

Acceleration sensor

After logging data, the state becomes “Idle” and waiting to become “Ready” in the next area. On the bottom of the figure, a bus approaching from another direction is presented. The system is able to detect the ups or the downs and detect approaching the target bridge.

The system has data base of relation between picking up area numbers and the all target bridges. That is why, every measured data is linked to the target bridge with a time stamp.

2.3 *An automatic data collection system program*

An automatic data collection program flow is shown in **Figure 5**. This program is composed of three modules and one database. These modules are a picking up area verification module, a state management module, an acceleration logging module and target bridges position data base.

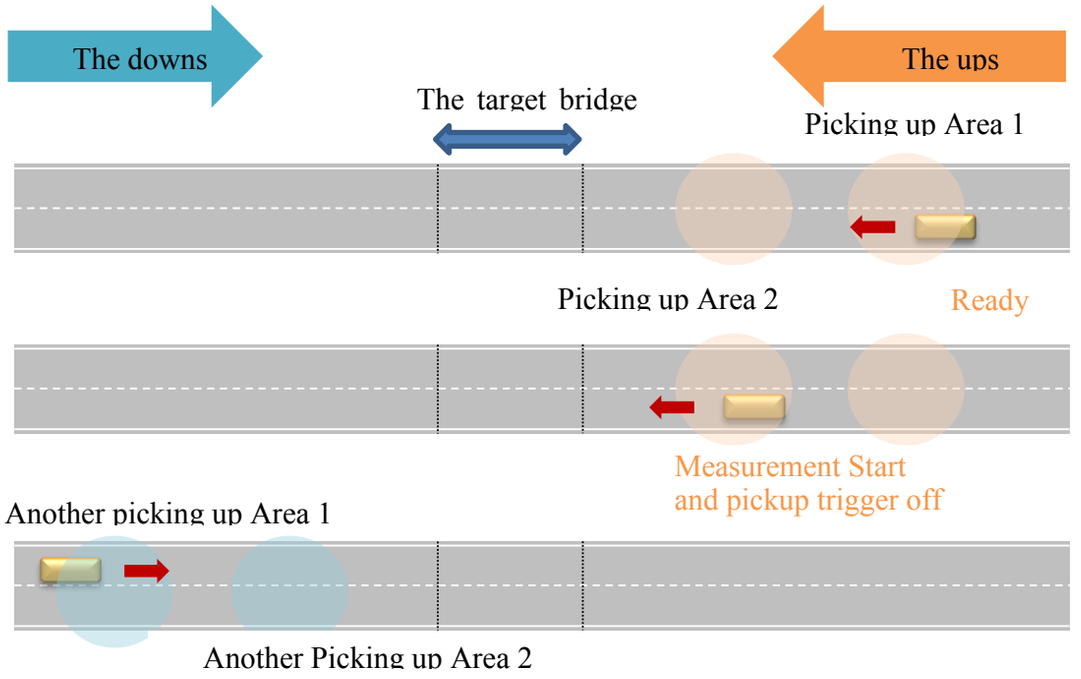

Figure 4. A detection method of vehicle approaching the target bridge

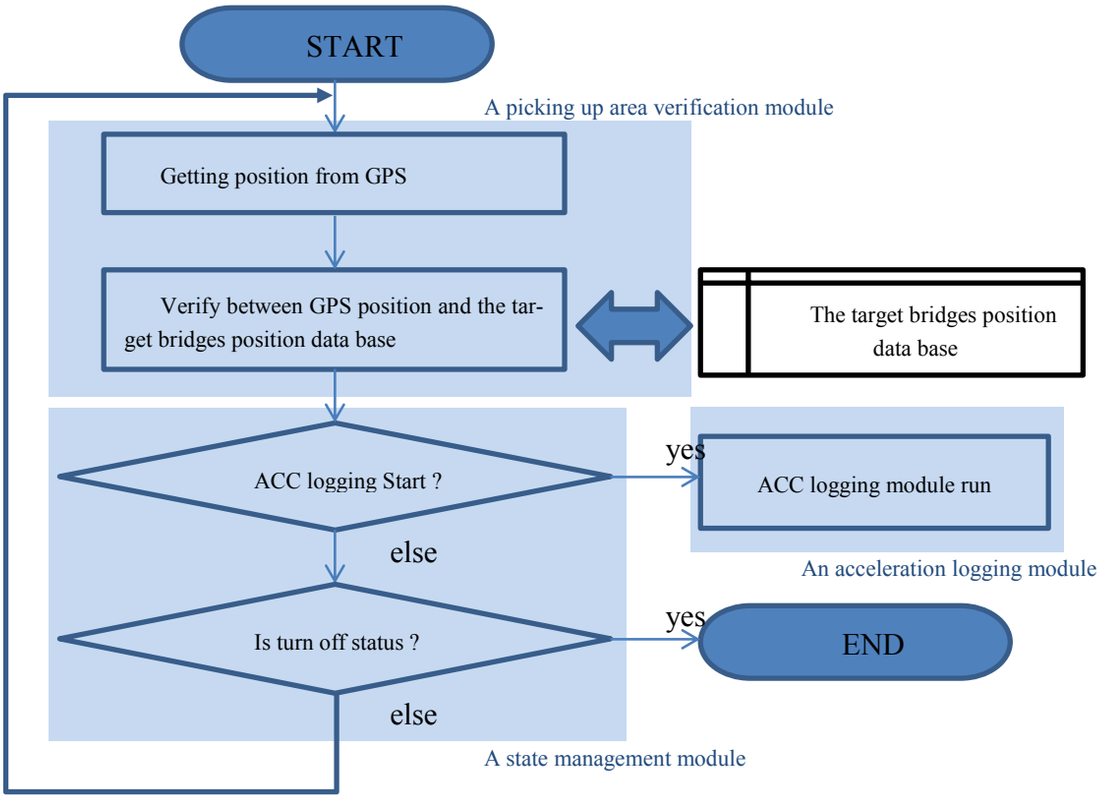

Figure 5. An automatic data collection program flow bridge

A picking area verification module is verifying GPS data and target bridges position while running. A state management module is changing system states in order of passed picking area numbers. An acceleration logging module saves acceleration data according to state management module. This program substitutes manual operations for an automatic cooperation of modules. The target bridges position data base has 5 major items. Their items are shown in **Table 3.**

3 TEST OF AUTOMATIC DATA COLLECTION SYSTEM

3.1 *Data collecting test on "Shingondai-bridge"*

In this case the operating city bus was used. The one-day route of a city bus in the Ube city is shown in Figure 6. The field test started at 7:00 and ended at 19:00. The data collecting test was carried out on "Shingondai-bridge" (Figure 7). The position of "Shingondai-bridge" is presented by a red circle on the Figure 6. "Shingondai-bridge" was constructed in ~~at~~ 1998. This bridge is a simple girder bridge with 22.4m span. In this test case a radius of a picking up circle area is 40m. The distance between Area1, Area2 and the target bridge was set to 50m. These radiuses and distances depend on GPS sampling frequency and the bus running speed. In this test, this system was used to collect data for several seconds while passing through "Shingondai bridge" and identifying the up line and the down line automatically (Figure 8).
Figure 9 shows trajectories of passing through "Shingondai bridge" by this system. Figure 10 shows the one of the acceleration data of passing through "Shingondai bridge".

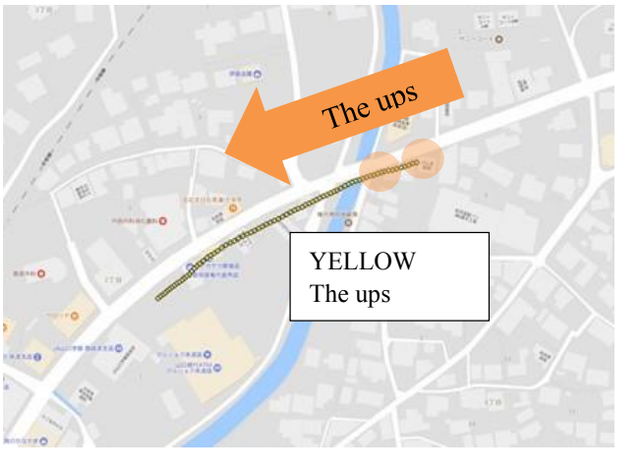

Figure 9. Trajectories of passing through "Shingondai bridge" by this system.

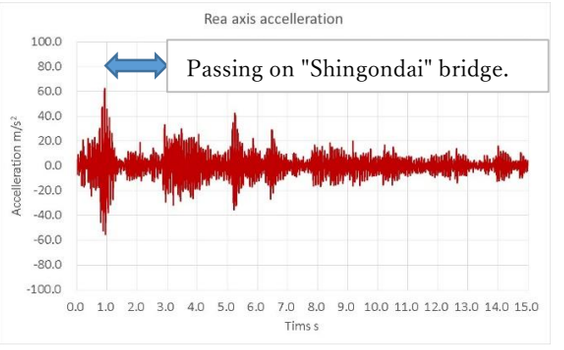

Figure 10. One of the acceleration data of passing through "Shingondai bridge" ~~by this system~~.

3.2 *Testing the completely automatic data collection system*

In the case of Ube city bus, system needed another power supply other than the vehicle battery and human operation at starting and ending. That is why an automatically start-up and shut-down function was needed. In order to implement this function, we focused on the car accessories power supply. A diagram for realizing the function is shown in Figure 11. It needs two BIOS functions on the personal computer which are "(a)power on when AC is detected" and "(b)initiate automatic shutdown when AC is removed". This test was carried out on "Ougi brige" from 17 May 2017 until 12 July 2017 at Kawasaki in Kanagawa Prefecture (Figure 12). Implementation of these functions was tested on a crane car (13) during a one-month trial period. The purpose was to check and eliminate potential errors which could create problems on the city bus, largely impacting transportation infrastructure. Figure 14 is shown the fuse box of the crane car. This system was suppled power from accessories power supply. Figure 15 shows the component of data collection system. This is composed ~~by~~ of PC, a logger unit and GPS unit connected to USB. This component is fixed strictly for anti-theft. This system was left while for around a month in the car.

Figure 14. The fuse box of the crane car.

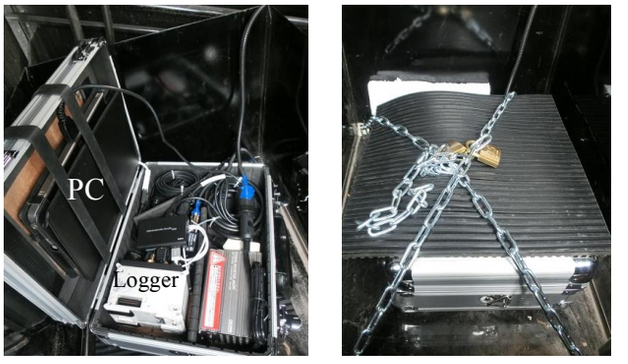

Figure 15. Components of the system.

Figure 15 shows components of used system. Figure 16 shows trajectories of passing through "Ougi bridge" by the system. The system also succeeded in collecting data automatically without human operation.

4 CONCLUSION

This paper focused on a method of automatic data collection system using GPS, and introduced an automatic data collection program. Systems were tested in the field with good results. Main conclusions reached the results of verification experiments and are summarized as follows:

1) Under certain conditions using GPS is feasible for the automatic data collection system.

2) A running to the ups or the downs is able to ~~detect~~ be detected by picking up Area1 and Area2 in this system.

3) Under certain conditions using power supply from the vehicle is feasible for the completely automatic data collection system.

The automatic data collection system has some problems which will be solved in the future. What is more, it is important to answer to the following questions. What are the rational parameters for this system for any kind of the bridge? What kind of method should be applied to transfer the huge data from this system? How to extract CD from acceleration data automatically?

ABSTRACT: Many bridges in the United States (US) are located in areas prone to storm surge and sea level rise. Past events have highlighted the structural vulnerability of these structures when subjected to hurricanes, triggering the development of fragility models for bridges subjected to hurricane-induced surge and waves. However, parameterized fragility models are lacking for a range of different bridge configurations to enable rapid application across a region and/or to explore climate change effects on bridge damage risks. In addition, fragility models assuming the same superstructure across a bridge for developing fragility curves may not provide full information on vulnerability given that different types of superstructures may exist within a single bridge. Thus, this study assesses the fragility of individual spans for different bridge classes subjected to storm surge and waves. The bridge deck is modeled as a grillage and wave force time-history analysis is conducted on bridge models from each class generated through Latin hypercube sampling. Logistic regression is applied to derive parameterized fragilities given hurricane intensity measures. This paper then incorporates the new models in a case study along the Houston-Galveston region of Texas for storm scenarios with and without sea level rise. The results show the variation in failure probability across different bridge classes and the dependence of these differences on the intensity of the hazard. In addition, the results reveal the anticipated increase in failure probability that may be expected with alternative climate change scenarios in which sea level rise is incorporated in the hurricane hazard model used for the scenario risk assessment.

1 INTRODUCTION

Bridges are a vital component of the transportation network to ensure connectivity in areas damaged by natural hazards (Padgett et al., 2008). Past events have highlighted the structural vulnerability of bridges when exposed to natural hazards, e.g. hurricanes, with dramatic consequences to the functionality of the transportation network (Gidaris et al., 2017). For example, Hurricane Katrina in 2005 caused significant damaged to bridges with an overall cost of repair/replace over $1 billion (Padgett et al., 2008). Many bridges located in the Houston-Galveston region of Texas were damaged by storm surge and waves produced by Hurricane Ike in 2008 (Stearns and Padgett, 2011). Therefore, bridge damage related to coastal events have increased the interest of the scientific community for quantifying the vulnerability of the bridge structures. A discussion of these studies is provided below, while a more thorough review can be found in Gidaris et al. (2017).

Padgett et al. (2012) developed empirical fragilities for water crossing multi-span simply supported (MSSS) concrete girder bridges subjected to hurricane hazards, for the Mississippi and Louisiana Katrina exposed region. These fragilities were developed through a statistical analysis for four damage states and a single hurricane hazard, i.e. the empirical probability of the bridge being in or exceeding a damage state was conditioned on the hurricane surge elevation.

Ataei and Padgett (2012) proposed a probabilistic framework for bridge deck unseating when subjected to hurricane hazards. The proposed framework uses analytical expressions for estimating the uplift probability of each bridge span. Then, the bridge failure is estimated in series, i.e. uplift of any span constitutes bridge failure. The authors applied the framework to a number of bridges located in the Houston-Galveston region of Texas. For the developed fragilities the probability of deck unseating was conditioned on two hurricane hazard intensity measures, i.e. wave height and relative surge elevation. In addition the authors developed a rapid-approximation fragility model that depends on the bridge span mass per unit length and estimates the probability of failure using an analytical expression with coefficients derived based on regression analysis.

Kameshwar and Padgett (2014) proposed a multi-hazard risk assessment framework for highway

bridges. The proposed multi-hazard framework was implement to MSSS concrete girder bridges in South Carolina for both earthquakes and hurricanes. A single damage state was considered similar to Ataei and Padgett (2012), i.e. bridge failure estimated in series based on deck uplift/unseating. However, a nonlinear dynamic analysis was performed using OpenSees (Mazzoni et al., 2006), i.e. bridge models were subjected to wave force time histories, contrary to Ataei and Padgett (2012) where the bridge models were subjected to static analysis. In addition, the bridge failure probability was conditioned on three parameters, namely surge height, wave height and bridge height.

Ataei and Padgett (2015) proposed a numerical model which takes into account the fluid-structure interaction (FSI) for evaluating bridge fragility in hurricane events. The model was utilized for a water crossing MSSS concrete girder bridge in the Houston area. A single damage state was considered, i.e. deck uplift, and the probability of the bridge failure was conditioned on wave height and relative surge elevation.

Anarde et al. (2017) proposed an integrated model for assessing bridge vulnerability exposed to hurricanes. The authors investigated the effect of climate change on local geomorphology and associated changes in storm surge and waves. Thus, the model takes into account landscape changes, e.g., erosion, associated with sea-level rise to examine the effects of these changes for a number of bridges surrounding Freeport in Texas, using already developed fragility models from previous studies.

This study focuses on developing improved fragility models, i.e. parameterized for a range of different bridge configurations, and to examine the effects of climate change on bridge vulnerability using these improved models. Different types of superstructures may exist, even within a single bridge. Therefore, existing models may not fully capture the bridge behavior under coastal hazards. Thus, instead of developing bridge class fragilities or those appropriate for only an individual bridge, this study develops parameterized fragility models that capture the dynamics of the problem and can be applied to a whole portfolio of bridges with varying details and superstructures. Two bridge classes are examined, i.e. MSSS concrete girders and MSSS steel girders, for a portfolio of MSSS bridges located in the Houston-Galveston region of Texas. The bridge superstructure, i.e. deck and girder, is modeled as a grillage, instead of a spine used in the previous studies, and the bridge models are subjected to wave-time histories using OpenSees. A single damage state is considered, i.e. individual deck uplift, and the probability of the deck uplift is conditioned on bridge parameters, e.g. deck width, length, etc., and on two hurricane-related hazards, i.e. surge height and wave height. Given the significant and growing development along the coast in regions subjected to sea level rise (Nicholls et al., 1999, Crosset et al., 2004), an illustration of the application of these parameterized fragility models for alternative sea level rise conditions is shown.

2 BRIDGES MODELING OF HURRICANE RESPONSE

In this study, the response of bridges subjected to hurricane wave and surge loads is assessed using nonlinear dynamic analysis. For this purpose, a general three-dimensional bridge model is created in OpenSees (Mazzoni et al., 2006), which can be used for bridges with different superstructure types. Next, transient analysis is performed to assess the response of the bridge model subjected to wave and storm surge loads. Details on bridge, load, and response modeling are presented in the following sub-sections

2.1 *Bridge modeling*

Deck unseating has been observed to be the most common cause of structural failure in bridges subjected to hurricane wave and surge loads (Padgett et al., 2008, Stearns and Padgett, 2011, Padgett et al., 2012). This type of failure is predominantly observed in simply supported spans, situated at low elevation, wherein several individual deck spans are unseated. Considering this failure mode, bridges can be considered as a series systems of spans where failure of even a single span leads to bridge failure. Therefore, this study models individual spans whose fragilities can be later combined in series to assess the overall fragility of a bridge. The modeling approach adopted herein is further supported by recent analysis of structural layouts and plans of bridges, conducted by the authors, in the Houston-Galveston region. The analysis shows that within a single bridge, superstructure characteristics change from one span to another, such as girder size and girder type. This observation indicates that modeling individual bridge spans with potentially different characteristics and re-combining them as a series system may be more realistic in comparison to modeling an entire bridge with the same superstructure characteristics.

The Opensees model of an individual span consists of a bridge deck, bearings, bridge bents and, foundations. The deck is modeled using a grillage (Hambly, 1976) where the longitudinal element (along the length of the bridge) represent girders and the transverse elements (along the width of the bridge) represent the deck slab. The deck is discretized along the length at a spacing of 1.0 m and the discretization along the transverse direction is governed by the number of girders in the bridge deck. The spacing for longitudinal discretization is determined by evaluating the maximum spacing that leads to convergence

of the total hurricane loads on the bridge deck. Since the deck usually acts as rigid body during deck unseating, the grillage elements are modeled using elastic beam column elements with appropriate section and material properties, which are considered to be variables whose effect on the hurricane response will be studied in the following sections. The bridge deck is placed on top of the bearing assembly situated on the bent cap. The commonly observed elastomeric bearings are modeled using a steel type material to represent the elastomeric pad and a hysteretic material to model the steel dowels in the bearing assembly. Bearing properties such as stiffness of the elastomeric pad and the strength of the dowel bars are considered as variables. The bent cap and the columns are modeled with rectangular and circular beam column elements, respectively, modeled using fiber sections. The fiber section comprises of three different layers that represent the un-confined cover concrete, the confined core concrete, and the longitudinal reinforcement. The effect of transverse reinforcement is incorporated in the properties of the confined concrete following Mander (Mander et al., 1988). Herein, column diameter (D_c), column height (H_c), concrete strength (f_c), yield stress of reinforcing steel (f_y), and reinforcement ratios, longitudinal (ρ_l) and transverse (ρ_t), are also included as variables. The pile foundations are modeled using non-linear springs in translational and rotational directions. The characteristics of the foundation springs are assumed to be uncertain. Since this study primarily focuses on deck unseating failure of simply supported spans, the vertical and torsional degrees of freedom are constrained at the foundation nodes. In order to facilitate modeling deck unseating response, node to node contact elements are used in the finite element model. These contact elements are incorporated between the deck and the bridge bent. The properties of the contact elements are calibrated to ensure that the bridge characteristics are not altered significantly. Additional details on modeling of bridge components can be found in Nielson (2005) and Kameshwar and Padgett (2014).

2.2 *Load modeling*

The OpenSees finite element bridge model described above is subjected to time varying hurricane wave and surge loads. The maximum wave loads on bridge decks are obtained using AASHTO guidelines (AASHTO, 2008). These maximum loads are used along with a modified version of the phenomenological hurricane wave and surge load model proposed by Ataei at al. (2010) to obtain the wave and surge load time history. The load model proposed by Ataei et al. (2010) cannot be directly applied to bridge decks modeled using a grillage because it provides the total horizontal and vertical loads acting on a bridge deck; for a grillage deck model, loads at every girder is required. Therefore, considering the wave velocity and girder spacing, the phenomenological load model is modified to obtain the time history of loads acting on every girder. Using the modified load model, different load time series are obtained for each girder. The magnitude of these loads depends on relative bridge clearance (Z_c) which is the difference between the deck height and the still water level, i.e. Z_c is negative when the deck is submerged; wave period (T) and wave height (H_w), in addition to bridge superstructure type. Herein, Z_c and H_w are considered as variables while T is considered to be uncertain.

2.3 *Response*

Using the finite element bridge span model and the surge and wave load model, dynamic analyses are conducted to evaluate the deck unseating performance. Herein, the bridge deck is subjected to loads from a single wave during the transient analysis. At each time step, the displacements of the deck nodes are recorded to identify unseating failures. The recorded deck node displacements are also used to identify and separate models where transient analysis did not converge due to numerical issues from models where transient analysis fails due to large deck displacements. Finally, the deck response is characterized by using a binary variable which is assigned a value equal to one when unseating is observed and a value equal to zero when unseating is not observed.

3 FRAGILITY MODELING

Using the binary deck unseating response along with the bridge and wave characteristics this study develops logistic regression based fragility models. For this purpose, a machine learning based approach is used. First, key variables that might affect the deck unseating behavior are identified, e.g. deck length (L), deck width (W), slab thickness (h), girder cross-section area (A_{gd}), girder weight (W_{gd}), number of girders (n_{gd}), Z_c, H_w. Next, an experimental design is set up to uniformly span the space of these variables; herein Latin hypercube sampling is used to generate 256 combinations of parameter values. For each combination, a finite element model is developed and the time history of loads is obtained following the procedure described in the previous section. The binary bridge deck unseating response is obtained, for all parameter combinations, by performing non-linear dynamic analysis. Using binary response and the key variables, a logistic regression model is trained to predict the binary response for given values of input variables. Additional information on training logistic regression model can be obtained from Hosmer and Lemeshow (2000). Using the final logistic regression model, the failure probability can be obtained for a given set of bridge and wave load parameters as:

$$p_f\left(uplift \mid X, IM\right) = \frac{\exp\left(g\left(X, IM\right)\right)}{1+\exp\left(g\left(X, IM\right)\right)} \quad (1)$$

where X = bridge parameters; IM = hazard parameters, i.e. H_w and Z_c; and $g(X,IM)$ = polynomial which represents the logarithm of odds in favor of deck unseating. Herein, a stepwise regression method is adopted to ensure that only the most influential parameter combinations are included in $g(X,IM)$.

4 PERFORMANCE ASSESSMENT OF BRIDGES IN HOUSTON-GALVESTON

4.1 *Hurricane scenarios*

In this study, two hurricanes that result in 100-yr and 500-yr surge levels, respectively, are simulated under baseline, i.e. existing sea level conditions, as well as 2050 and 2100 sea level rise (SLR) scenarios. This analysis does not take into account dynamic changes in storm characteristics that may additionally occur due to climate change, which can alter the characteristics (i.e. size and intensity) of the 100-yr and 500-yr storms simulated. Nonetheless, the sea level rise scenarios put into context any increases in surge levels and wave heights that may occur for the simulated storms. The peak surge and wave response for this suite of six storms was determined utilizing the tightly coupled Advanced CIRCulation and Simulating WAves Nearshore (ADCIRC+SWAN) model (Luettich and Westerink, 2004). The two hurricanes were obtained from the Federal Emergency Management Agency's (FEMA's) suite of Upper TX Coast storms utilized for their surge risk analysis (USACE, 2011, FEMA, 2017), and are referred to as Storm 033 and Storm 036. Storm's 033 and 036 result in roughly 100-year and 500-yr surge levels for present day conditions, respectively, based on comparisons against FEMA's most recent surge frequency analysis (Ebersole et al., 2015). The sea level rise conditions for the year's 2050 (0.437 m increase in sea level) and 2100 (1.367 m increase in sea level) are based on mean estimates from the National Oceanic and Atmospheric Administration (NOAA) (Sweet et al., 2017).

4.2 *Bridge inventory*

A set of bridges are selected from the Houston-Galveston region of Texas. This area is located in the Upper Texas Gulf Coast, an area prone to hurricane events and vulnerable to storm surge (Torres et al., 2017). The National Bridge Inventory (NBI, 2017) does not contain enough information regarding parameters required for assessing bridge vulnerability exposed to coastal hazards. Thus, a database was developed through a detailed review of the bridge plans for the area of interest. From this database a subset of bridges with concrete and steel girders was extracted to retrieve structural details, e.g. deck width, deck length, etc., for each bridge class. Table 1 gives an indication of the typical range of these parameters and the bounds for which the LHS for fragility analysis was conducted.

Table 1. Bounds for bridge parameters.

Parameter	Range (concrete girder)	Range (steel girder)
Deck length (L)	6.1-27.4 m	9.1-27.4 m
Deck width (W)	6.6-18.6 m	6.1-18.3 m
Slab thickness (h)	0.11-0.25 m	0.15-0.42 m
Girder c/s area (A_{gd})	0.18-0.51 m^2	0.07-0.49 m^2
Girder weight (W_{gd})	4.18-11.98 kN/m	5.4-37.7 kN/m
Number of girders (n_{gd})	2-17	2-18

4.3 *Risk assessment*

Using logistic regression, the logit function for the uplift of a concrete girder is estimated as:

$$g(X,IM) = 9.78 - 9.24Z_c + 2.31H_w - 80.63h - 0.51n_{gd} + 21.33H_w h \quad (2)$$

Similarly, the logit function for the uplift of a steel girder is estimated as:

$$g(X,IM) = 316.78 - 18.91Z_c + 7.36H_w + 1.77\times10^{-4}W - 4393.7h + 5.19Z_cH_w - 7.96\times10^{-4}Wh - 2.75Z_c^2 + 18{,}826h^2 - 25{,}953h^3 \quad (3)$$

Fragility surfaces are plotted using the derived logit functions for bridges with concrete (Figure 1) and steel (Figure 2) girders, showing the uplift probability conditioned on Z_c and H_w. Fragility analysis indicates that there is a variation in the uplift probability between the two examined bridge classes. For example, there is 33.63% probability for a 0.1 m submerged concrete girder bridge to experience uplift if subjected to a wave height of 1 m, while this probability is 8.26% for a steel girder bridge (Figure 3). This difference can reach up to 30.12% for a wave height of 1.25 m (Figure 4). Thus, considering the same superstructure across a bridge for developing fragility curves may not provide full information on vulnerability.

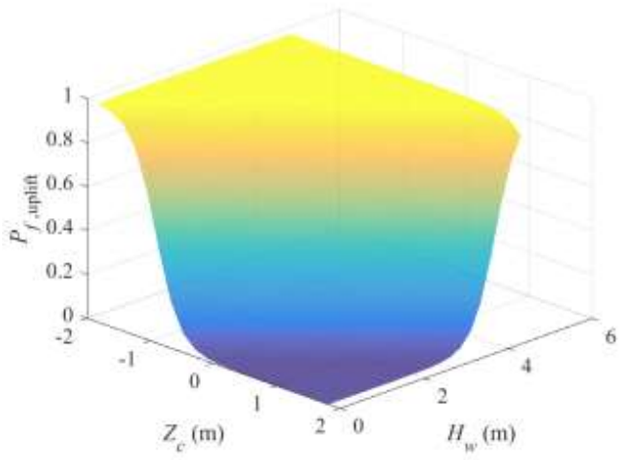

Figure 1. Fragility surface for concrete girder.

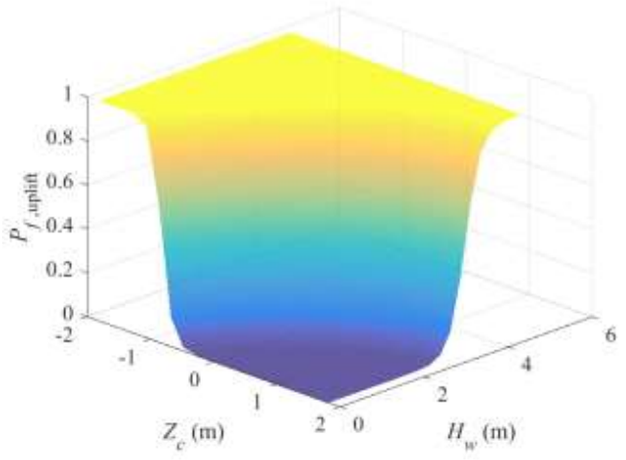

Figure 2. Fragility surface for steel girder.

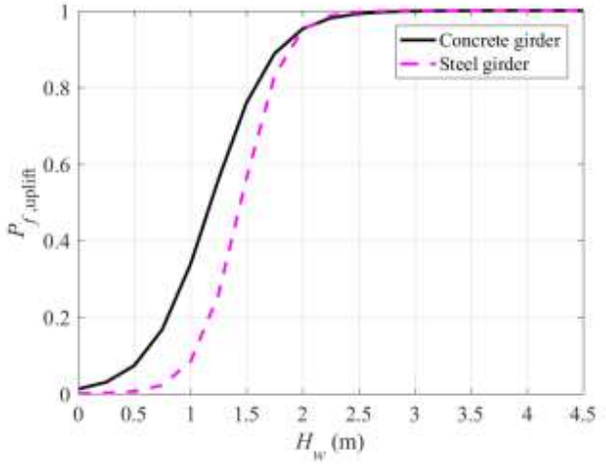

Figure 3. Uplift fragility for Z_c=-0.1 m.

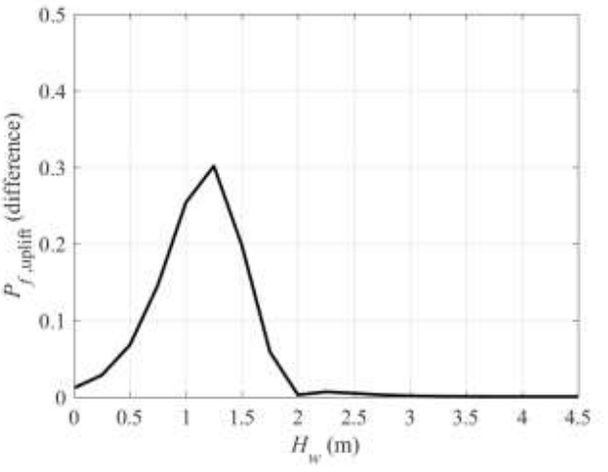

Figure 4. $p_{f,uplift}$ difference between concrete and steel girder for Z_c=-0.1 m.

Then, the conditional probabilities of uplift failure are calculated for the bridges of the examined inventory using the aforementioned logit functions and for current or projected H_w and Z_c. The analysis results indicate that future sea level rise will increase the uplift failure probabilities for both Storm 33 and Storm 36 scenarios. For example, there is a high uplift probability for 35 concrete girder bridges to experience uplift in 2050 if they will be subjected to surge and waves caused by a 100-yr storm, while this number increases to 42 bridges using 2100 sea level projection (Figure 5). In a similar manner, there is an increase in the number of bridges with high uplift probability, i.e. more than 75%, if subjected to storm surge and waves cause by a 500-yr hurricane in 2050 and 2100 (Figure 6). Future storm scenarios indicate an expected increase in the uplift probability for bridges with low current vulnerability. For instance, bridges with failure probability less than 5% (Figure 7), are expected to be more vulnerable in year 2100 (Figure 8) due to storm surge alterations caused by climate change.

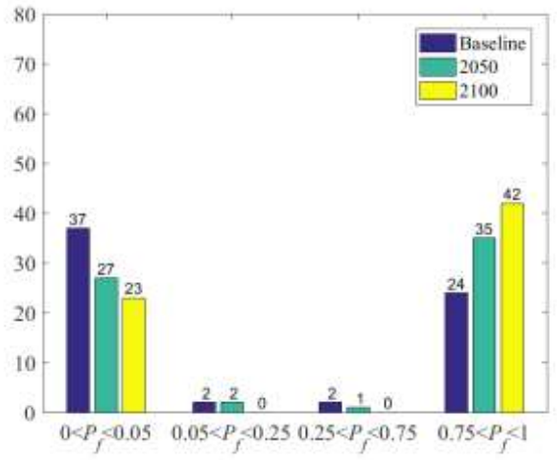

Figure 5. Number of concrete girder bridges within specific bounds of failure probability: Storm 33 scenarios.

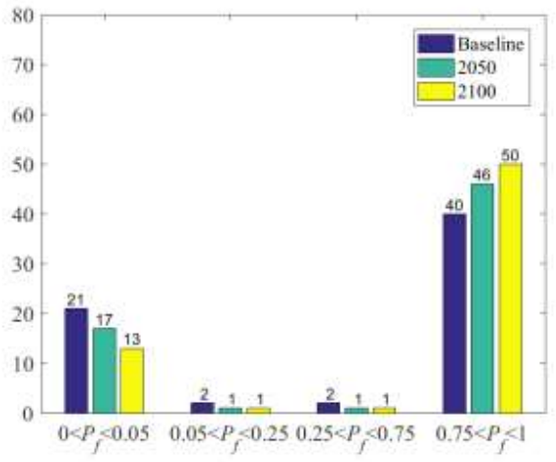

Figure 6. Number of concrete girder bridges within specific bounds of failure probability: Storm 36 scenarios.

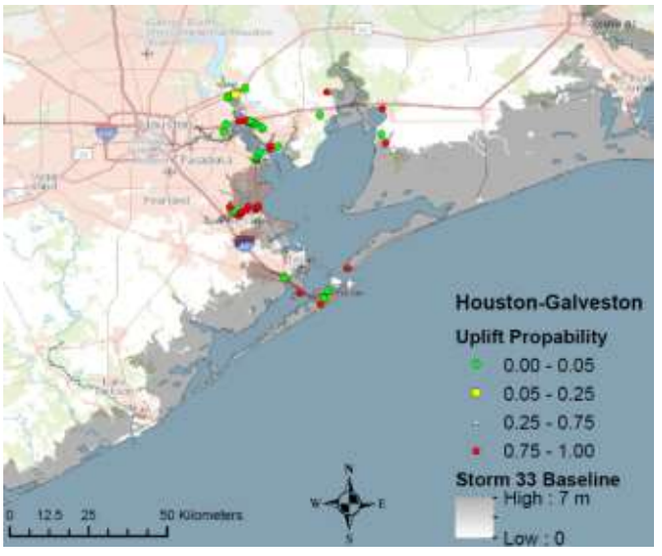

Figure 7. Uplift probability of concrete girder bridges in Houston-Galveston for Storm 33 Baseline scenario.

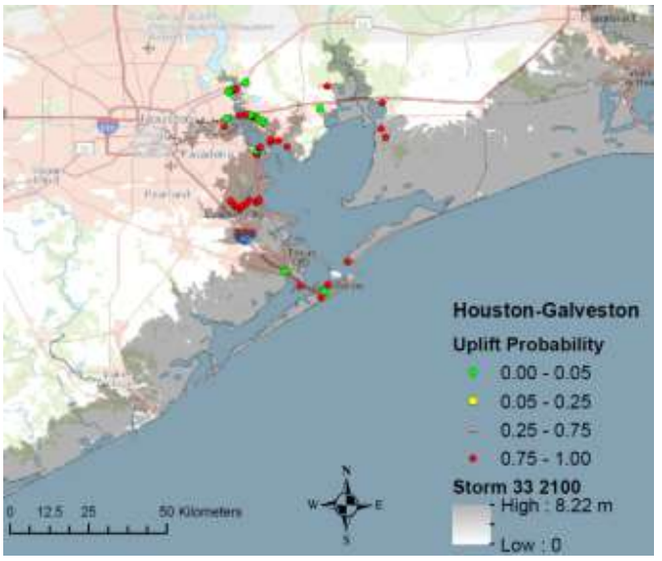

Figure 8. Uplift probability of concrete girder bridges in Houston-Galveston for Storm 33 2100 scenario.

The examined steel girder bridges are in locations not significantly affected by the future sea level rise. Thus, results for this bridge class related to uplift probabilities for current and projected sea level conditions are not reported.

5 CONCLUSIONS

This study examines the vulnerability of bridges exposed to hurricane-induced surge and waves. First, the study addresses a gap in parameterized fragility for a range of different bridge configurations to enable hurricane risk assessment across a region. Thus, a set of bridges are selected from the Houston-Galveston region of Texas and two bridges classes are investigated, i.e. bridges with concrete and steel girder superstructures. Nonlinear dynamic analysis is conducted, i.e. considering wave force time-history, on bridge models from each class generated through Latin hypercube sampling. Then, parameterized fragilities are derived to express the probability of deck unseating given bridge class and hurricane intensity measures. The results indicate that both bridges are prone to uplift damage with the increase of the storm surge although the differences in the uplift probability between the examined bridge classes varies depending on the intensity of the hurricane.

This study further investigates the application of the fragility models for risk assessment of a regional portfolio of bridges in Texas for storm scenarios with and without sea level rise, allowing exploration of climate change effects on bridge damage risks. The results indicate that future sea level rise will further increase the uplift risk of the concrete girder bridges exposed to a hurricane with the same characteristics. Future work will include more superstructure types, e.g. box girder, slab, and will address issues such as system response with spatial variability of wave.

Probabilistic multi-hazard assessment of seismic and scour effects on bridge structures

Z. Chen

X. Guo
College of Civil Science and Engineering, Yangzhou University, Yangzhou, Jiangsu, China

ABSTRACT: This paper proposes a probabilistic framework for assessing seismic and scour effects on existing river-crossing bridge structures. The unique features of this framework include the conjunct use of probabilistic scour and seismic hazard modeling, and the definitions of seismic-scour integrated fragility and demand hazard models. Probabilistic assessment is then performed to evaluate the seismic-scour effects on a representative bridge model. The fragility results for the chosen bridge model reveal that scour tends to be beneficial in reducing structural damage at slight to moderate seismic intensities and to be detrimental in increasing collapse potential at high-level intensities. The demand hazard curves further quantify probabilistically the occurrence of local damage and global collapse, and systematically reveal the complex effects of scour as a hydraulic hazard on bridge structures.

1 INTRODUCTION

There are over 484,500 highway bridges built over river channels in the U.S., among which over 20,904 are regarded scour-critical (Hunt, 2009). A distinct feature of flood-induced scour is that once it starts forming around a foundation, it may accumulate or vary over the bridge's service life. Hence it is intuitive that a potentially more severe risk is that scour is combined with other extreme hazards, such as earthquakes, which may threaten bridges serving in both earthquake and flooding active regions, such as Alaska and California in the U.S.

Towards a multi-hazard approach to assessing the conjunct effects of earthquakes and flooding-induced scour on the vulnerability of bridges, a probabilistic approach to bridge scour analysis is required due to its inherent uncertainties in the first place. In two recent papers, a general approach to probabilistic scour hazard modeling was reported, which is built upon deterministic scour estimation by considering model bias and random errors (Bolduc et al., 2008, Briaud et al., 2013). Furthermore, Briaud et al. (2013) concluded that for shallow foundations supporting bridge structures, the design scour depth needs to be 2.0 ~ 2.5 times of the HEC-18 estimates to ensure that the probability of exceeding the estimated scour depth be less than 0.001, even that both HEC-18 (Sand and Clay) methods are considerably conservative compared with measured bridge scour data. Besides probabilistic scour assessment for bridge foundations, however, these two efforts did not address the multi-hazard effects on a bridge as a system if earthquakes are involved.

For a system-level multi-hazard assessment of seismic and scour effects (termed *seismic-scour effects* hereafter), a number of efforts are found. Wang et al. investigate the vulnerability of scoured pile-foundation supported bridges through probabilistic fragility surface analysis (Wang et al., 2012). However, in their work, scour was treated deterministically. In Dong et al. (2013), a multi-hazard assessment approach was used to study bridge performance considering time-variant structural deterioration; however, scour uncertainty was not considered either (Dong et al., 2013). Prasad and Banerjee investigated the seismic risk of four example bridges considering scour variations (Prasad and Banerjee, 2013, Banerjee and Prasad, 2011). While studying the characteristics of seismic fragility curves, however, only system-level displacement-based demands (i.e. drift demand at the deck level) were used, which led to the conclusion that scour always increases seismic fragility. Several recent efforts are found on probabilistic calibration of load-resistance factors that are used to combine scour condition with seismic and other design forces (Ghosn et al., 2004, Alipour et al., 2012, Wang et al., 2014).

No quantitative and probabilistic framework is found to date that is able to comprehensively assess the conjunct seismic-scour effects on river-crossing bridge's vulnerability. In the following, a probabilistic framework is proposed that aims to output seis-

mic-scour integrated fragility and probabilistic demand hazard. The focus is then on the experimental results and observations based on a simple shallow-foundation supported bridge model, followed by the conclusions in the last section.

2 PROBABILISTIC METHODOLOGY

For assessing performance and vulnerability of structures considering seismic hazards, two probabilistic analysis tools are usually employed, which are probabilistic seismic fragility analysis (PSFA) and probabilistic seismic demand analysis (PSDA). PSFA can been applied to identify the probability of a defined limit-state (e.g. structural damage or collapse) conditional on one or multiple measures of seismic intensity (Karim and Yamazaki, 2003, Shinozuka et al., 2000, Nielson and DesRoches, 2007, Hwang et al., 2001). PSDA is used to assess structural vulnerability by estimating the annual probability of a structural demand exceeding a varying demand parameter without conditioning on the input hazard (Bazzurro and Cornell, 1994, Cornell et al., 2002). The output of PSDA model is a demand hazard curve that is analogous to a seismic hazard curve (from probabilistic seismic hazard analysis, PSHA). Since the demand hazard curve is an essential component of the probabilistic performance-based seismic design framework (Cornell and Krawinkler, 2000), PSDA has been frequently used for assessing building structures (Luco, 2002, Tothong and Luco, 2007) and bridge structures (Tondini and Stojadinovic, 2012, Mackie and Stojadinovic, 2001).

Different from general multi-hazard analysis wherein two or more hazards appear as joint occurrence of two independent events that may be generalized as external forces applied to structures (but independent to structures), earthquake and scour should be treated distinctly. Different from loading-based hazards, scour primarily leads to modification of the geometric boundary condition of the soil-foundation-structure (SFS) bridge system. This boundary modification further results in reduction in foundation stiffness, and nonlinear foundation bearing and lateral capacities as demonstrated previously. To account for such changes, a system-level modeling approach needs to be adopted considering SFSI subjected to dynamic loadings (e.g., earthquakes). This in turn leads to an unfavorable situation, wherein the SFS bridge system is not invariant; rather, it is subject to significant modification in terms of foundation impedance and nonlinear capacities due to the varying scour (treated as a hazard).

2.1 *Mean-Scour Seismic Fragility Modeling*

The seismic fragility or the probability of structural damage given a seismic *IM* can be modeled as a conditional probability, $P(Z>z^* \mid IM)$, where z^* is a specifically defined value of the demand variable. The expression $Z > z^*$ defines a limit state that indicates occurrence of a certain level of damage or even collapse. For measuring the seismic intensity, a sufficient *IM* should be chosen. Peak ground acceleration (PGA) is often used as an objective scalar measure of seismic intensity. When a structure is considered, the spectral displacement (Sd) and spectral acceleration (Sa) defined at the structure's modal period (Tn) are two commonly used measures. In this paper, Sa is adopted; particularly, Sa measured at the fixed-base first-mode period of the bridge model is used

When the sample values of *IM* and *Z* are available, a fitting function in terms of $IM = x$ is usually used to fit the conditional probability $P(Z>z^* \mid IM)$, denoted by $\Psi(x)$. The most popular approach is to enforce a monotonically increasing function bounded by [0, 1], such as the Lognormal cumulative distribution function $\Psi(x)$ (Shinozuka et al., 2000), to fit the data set of $\{(Z>z^*)_i, IM_i \mid i = 1 \ldots N\}$:

$$\Psi(x) = P(Z > z^* \mid IM = x) \approx \Phi\left(\frac{\ln x - \mu}{\beta}\right) \quad (1)$$

where μ and β are the mean and standard deviation parameters of the Lognormal cumulative function, respectively. Based on the sample data, a general approach to parameter estimation is the maximum likelihood estimation (MLE) method (Baker, 2015). This method is adopted in this paper and formulation details are found in Baker (2015).

When scour depth (*SD*) is considered in seismic fragility analysis, an easy treatment is to compute seismic demands using the SFS bridge model that incorporates a designated scour condition in terms of a deterministic *SD* value, y^*:

$$\Psi(x) = P(Z > z^* \mid IM = x, SD = y^*) \approx \Phi_{y^*}\left(\frac{\ln x - \mu}{\beta}\right) \quad (2)$$

The expression in Eq. 2 represents the seismic fragility considering a deterministic scour depth, wherein the uncertainties come from external seismic inputs and possibly from structural materials.

If one considers scour as a type of hazard and then treats scour depth as a random variable, a bivariate fragility model becomes of interest:

$$\Psi(x, y) = P(Z > z^* \mid IM = x, SD = y) \quad (3)$$

If the conditional probability model in Eq. 3 is fitted by a bivariate Lognormal function, a fragility surface model is achieved. A fragility surface model has its merit in expressing the true fragility of a structure when multiple hazards are affecting the structure (Lee and Rosowsky, 2006) or multiple parameters are used to describe one hazardous effect (Seyedi et al., 2010). As implied in Eq. 6, one may consider fitting the conditional probability by a bivariate function in terms of both seismic intensity and scour depth as independent variables and then study the resulting seismic-scour

fragility surface. However, a significant difference of scour effects from seismic effects as illustrated previously is that scour may cause beneficial effects (i.e. reduction of force demands). This implies that the fragility when partially conditional on scour may decrease as the scour depth increases. With the fragility partially depending on seismic measure *IM* (which often designates a monotonic increasing relation), the resulting fragility surface from Eq. 3 may be non-monotonic, which causes difficulty in interpreting such a surface. To retain the traditional simplicity in a fragility curve, it is more straightforward to marginalize out the scour depth as a random variable. Based on the law of total probability, one has

$$P(Z > z^* | IM = x) = \int P(Z > z^* | IM = x, SD = y) f_{SD}(y) \mathrm{d}y = \mathbf{E}_{SD}[\Psi(x, y)] \quad (4)$$

$$P(Z > z^* \mid IM = x) \approx \Phi_{MS}\left(\frac{\ln x - \mu}{\beta}\right) \quad (5)$$

where $f_{SD}(y)$ is the probability density function for the scour depth as a random variable and **E**[] defines the mathematical expectation operator. In Eq. 4, the seismic fragility is defined by integrating out scour depth as a random variable, which is equivalent to the mathematical mean of the bivariate fragility upon the scour depth distribution. Due to this analytical meaning, a notion of *mean-scour* (MS) fragility is proposed in this paper. In the meantime, the analytical expression of the mean-scour fragility $P(Z > z^* \mid IM = x)$ means that the fragility model can be directly estimated by fitting the simulated data set using the Lognormal model in Eq. 5.

2.2 *Seismic-Scour Integrated Demand Modeling*

Traditional PSDA assesses the performance of a structure by probabilistically predicting the seismic response in terms of the probability of exceedance for a limit state defined by $Z > z$, where z is a varying demand value. The resulting function, $H_z(z) = P(Z > z)$, is termed probabilistic demand hazard model. In the original efforts [e.g. (Bazzurro and Cornell, 1994)], a probabilistic demand hazard model (or strictly speaking the mean annual frequency of the exceedance event for a response demand) is evaluated based on the summation over seismic sources described by magnitudes and site distance. In more recent literature, a probabilistic demand hazard model for evaluating the seismic performance of a structure has been defined in a continuous form (Cornell et al., 2002):

$$H_Z(z) = \int P(Z > z \mid IM = x) \mid \mathrm{d}H_{IM}(x) \mid \quad (6)$$

where $P(Z > z \mid IM = x)$ defines the likelihood that the structural demand Z exceeds a post-elastic demand value z, and $\mathrm{d}H_{\mathrm{IM}}(x)$ defines the derivative of the seismic hazard model (the absolute sign is necessary since the derivative is negative).

It is noted that Eq. 6 considers one (seismic) hazard. If flooding-induced scour as a hazardous condition is considered, the integrated seismic-scour demand hazard, denoted by $H_{SS}(z)$, is proposed, which is based on a simple extension of Eq. 6:

$$H_{SS}(z) = \iint P(Z > z \mid IM = x, SD = y) \mathrm{d}H_{IM}(x) \mathrm{d}H_{SD}(y) \quad (7)$$

where $H_{IM}(x)$ and $H_{SD}(y)$ are the probabilistic seismic hazard and scour hazard models, respectively. The demand hazard model in Eq. 7 involves probabilistic models of seismic and scour hazards. The two hazard models are introduced below.

2.3 *Probabilistic Seismic Hazard Analysis*

The probabilistic seismic hazard analysis (PSHA) attempts to define the probability of exceedance (POE) for an IM variable x that is exceeded annually, denoted by $H_{IM}(x)$. In practice, PSHA can be analytically conducted for a given site; for example, analytical formulation was given based on empirical attenuation models and probabilistic calculation was based on a Lognormal distribution assumed for a seismic intensity measure (Field, 2005). In addition, seismic hazard models can be obtained from the web portal of the United States Geological Survey (USGS) for a given site in the United States (USGS, 2015). One key step in PSHA is to select an appropriate seismic *IM* type. Traditionally, peak ground acceleration (PGA) and spectral acceleration (Sa) at a certain natural period (T_n) are commonly used (Kafali and Grigoriu, 2007). In this paper, the USGS' seismic hazard model in terms of SAs is adopted.

2.4 *Probabilistic Scour Hazard Analysis*

For local bridge scour (scour around bridge foundation), two primary estimation methods exist as described in Hydraulic Engineering Circular No. 18 (Arneson et al., 2012), which is termed the HEC-18 Sand and HEC-18 Clay. The HEC-18 Clay method was developed at the Texas A&M University, which was designed to predict scour depths in cohesive fine-grained soils (e.g. clay) and was once termed the SRICOS-EFA method (Briaud et al., 1999). Using the HEC-18 Clay method, the scour depth is the function of time over the period of the hydrograph. First, this method predicts the maximum scour $\hat{y}_{\max}$ as:

$$\hat{y}_{\max} = 0.18R^{0.635} \quad (8)$$

where R is Reynolds number equal to vD_p/υ , v is the upstream velocity, D_p is diameter of the pier, and υ is the water viscosity (10^{-6} s/m^2 at 20^{o}C). The time-dependent scour depth, denoted by $\hat{y}_t$, is defined by linking the maximum scour depth in Eq. 1, the time at

which a given velocity is applied, and the initial rate of scour:

$$\hat{y}_t = \frac{t}{\frac{1}{\dot{y}_i} + \frac{t}{\hat{y}_{\max}}} \quad (9)$$

where t with a unit of year is the time over which a given velocity is applied and $\dot{y}_i$ denotes the initial rate of scour.

Based on the deterministic estimation described in Eq. 8 and 9, multiplicative correction factors are considered to account for the bias and random errors inherent in the deterministic models, which leads to the probabilistic scour modeling (Bolduc et al., 2008) and is termed probabilistic scour hazard analysis in this paper (PScHA to be different from PSHA).

In Bolduc et al (2008), by adopting a Lognormal distribution for scour depth, the probabilistic scour depth is formulated in a Logarithm expression:

$$\mathrm{Log}[y_t] = \mathrm{Log}[\theta_y] + \mathrm{Log}[\hat{y}_t] + \sigma_y \mathbf{N}(0;1) \quad (10)$$

where θ_y is a parameter accounting for the model bias; $\hat{y}_t$ is the deterministic and time-dependent scour estimation from Eq. 9; $\mathbf{N}(0;1)$ represents a Normal random variable with zero mean and unit variance; σ_y is therefore the standard deviation of the Lognormal variable y_t. This implies that when these deterministic parameters, θ_y, $\hat{y}_t$ and σ_y are available, a probability density function for the distribution of the scour depth can be defined using a Lognormal distribution, denoted by $f_{SD}(y_t)$ in this paper. Given $f_{SD}(y)$, the scour hazard can be analytically expressed as $H_{SD}(y_t) = 1 - \int_0^{y_t} f_{SD}(y)\mathrm{d}y$. Similar to the seismic hazard curve, this model when depicted as a curve quantifies the probability of exceeding a scour-depth value at a bridge site; the only distinction is that different from the annual POEs as used in a seismic hazard model, a scour hazard model defined above is calculated at a certain year of service.

3 EXPERIMENTAL RESULTS

3.1 *Simple Bridge Model*

The bridge chosen in this paper has a shallow foundation system with a full embedment depth that is constructed in a hard-soil (e.g. cohesive clay) river bed. The bridge has three spans of concrete decks supported by two concrete columns. Such a bridge is commonly used in practice for short-span river passing when the foundation soil is relatively hard (e.g. clay) (Kimmerling et al., 2002). In addition, by analyzing a shallow foundation-supported bridge model, the probabilistic assessment can be readily conducted. It is noted, nevertheless, the framework developed and demonstrated in this paper can be easily adapted for assessing existing bridges with deep foundation systems (e.g. piles) in soft-soil river bed provided a finite-element (FE) based SFS model is provided. Fig. 1 illustrates the bridge model, which was used in the author's previous work (Guo and Chen, 2015). The bridge is a three-span (27m+36m+27m) continuous structure supported by two piers on two separate shallow foundations. The height of the circular piers is 9.0 m with the diameter of 1.4 m. The steel ratio of the column is about 1.3%. The foundation is constructed on hard clay with a density of 1700 kg/m^3 and with a small-strain shear wave velocity of 260 m/s. The thickness of the foundation is 2.4 m, with the transverse width being 2.8 m and the longitudinal length being 3.3 m, respectively. The original embedment depth of foundations is 4.0 m. The simplified configuration of the bridge is shown in Fig. 1. A three-dimensional finite-element (FE) model for the bridge is developed to simulate the bridge using the OpenSees framework (Mazzoni et al., 2005). The FE modeling and the details about beam-column elements, footing elements, material uncertainties, sampling scheme, and the nonlinear time-history analysis details are found in this work as well. Particularly, we consider a target service period of 50 years among its 75-year design life. The purpose is to mimic the situation of an existing bridge that is subject to progressive scour after 50 years of service.

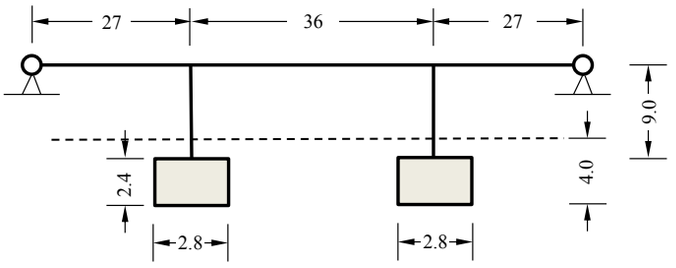

Figure 1. Bridge configuration (unit: m).

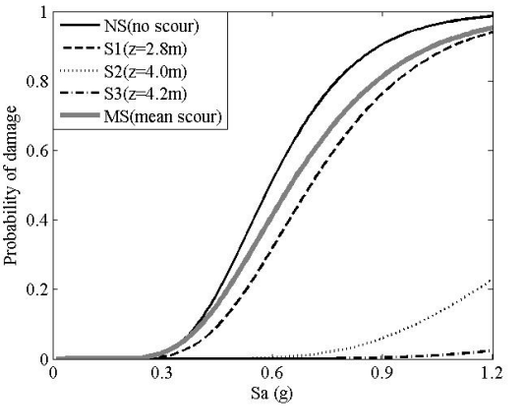
3.2 *Demand Variables*

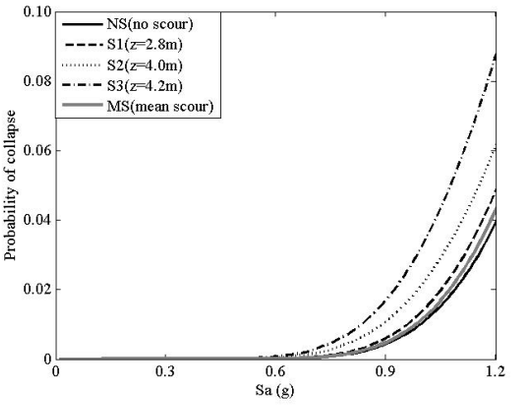
A variety of response demand parameters can be extracted. In this paper two demand variables are considered in the following fragility and demand modeling.

1) Local strain ductility: defined as the ratio of the strain demand ($|\epsilon_{max}|$) at the base of the concrete pier to the compressive yielding strain (ϵ_y) of the concrete, $\mu_s = |\epsilon_{max}| / \epsilon_y$. Since the local strain at the surface is proportional to the curvature, $\epsilon = \rho\, r$, where r is the diameter of the circular column, one can define an equivalent local curvature ductility demand. Hereinafter, local strain ductility demand (μ_s) is used.
2) System drift ductility: defined as the ratio of the transverse system drift demand at the mid-span of the bridge deck ($|u_{max}|$) to the bridge's yielding drift (u_y) at the fixed-end boundary condition, $\mu_d = |u_{max}| / u_y$. For the bridge model



considered herein, the yielding drift is about 6.1 cm.

The local strain ductility demand μ_s reflects the degree of local inelasticity occurred to the bridge's concrete piers. For bridge structures, the ranges for using local strain ductility demand to characterize different damage levels are well defined [e.g. (Choi et al., 2004)]. In general, when given a limit state of $\mu_s > 1$, it implies the onset of local damage or indication of slight damage. Larger threshold may be used to define higher-level structural damage, such as $2 < \mu_s < 4$ for moderate damage or $\mu_s > 4$ for extensive damage. Fragility models resulting from these higher-level damage limit-states are not reported in this paper. The system drift ductility demand indicates the degree of global displacement, which in general consists of structural deformation and foundation-induced rigid-body motion (e.g. sliding and rocking) as a SFS system. In this paper, if μ_d is larger than seven ($\mu_d > 7$), the onset of system collapse limit-state is defined (usually a drift ductility of 5 ~ 10 is used to define bridge collapse in the literature; herein a median value of 7 is used) (Dutta and Mander, 1998, Kim and Feng, 2003). We particularly note that for a scoured SFS bridge, it may be biased to define a limit-state using the system-level ductility demand to indicate structural damage in local members. Especially when considering an extreme scour, a limit-state in the range of $2 < \mu_d < 3$ may be dominated by the rigid-body displacement from the substructure with linear-elastic or insignificant inelastic structural deformation; in this case, structural damage may not reach to the expected level (e.g. $\mu_s < 1$).



3.3 *Fragility Analysis Results*

Based on the limit states defined previously, Fig. 2(a) shows the probability of local damage defined by $\mu_s > 1$ considering four designated scour-depth values (No scour; Scour S1 with z= 2.8 m; S2 with z= 4.0 m; S3 with z= 4.2 m). In addition, the mean-scour (MS) fragility curve according to Eq. 5 is shown as well. Fig. 2(b) uses the same configuration for plotting the fragility curves in terms of the defined collapse limit-state ($\mu_d > 7$). It is noted that material uncertainties are not considered in the two fragility illustrations in Fig. 2.

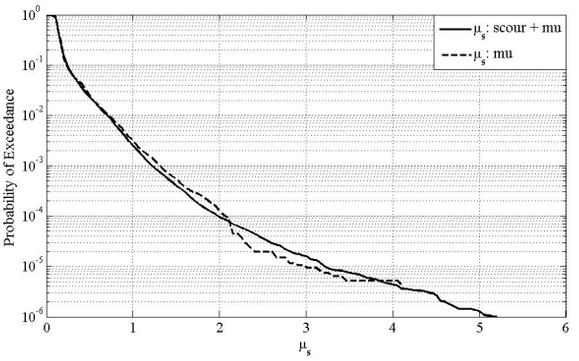
Fig. 2(a) indicates that the probability of damage is insignificant (less than 10%) if Sa (T1) < 0.33 g (equivalently corresponding to an annual POE of 9.2×10^{-3}, which is the Expected Earthquake design level). In addition, at the NS (i.e. z = 0 m) and the S1 level of scour depth (i.e. z = 2.8 m), the probability of damage quickly approaches to a high probability (> 50%) when the spectral acceleration becomes larger than 0.5 g (or an equivalent 0.38% annual POE). The general trend is that if the scour depth increases when the *IM* is greater than 0.33 g, the probability of damage decreases significantly. Especially, when the scour reaches the full-depth of the foundation (S2), the probability of damage dramatically reduces; for example, at Sa (T1) = 1.19 g (about 4.1×10^{-4} annual POE or subject to the MCE-level earthquake), the probability of damage is around 5%, whereas it is 95% compared with the N1 case (z = 2.8 m). This observation is consistent with the aforementioned literature that softened foundations in the context of seismic soil-structure interaction tend to lead to less structural damage or smaller base-shear force demands (Ghosn et al., 2004). However, it should be pointed out that when the bridge is subjected to high-intensity earthquakes and greater scout depths, the potential threat is system collapse. Therefore, it is rational to state that increasing scour depth is only beneficial when subjected to weak to moderate-intensity earthquakes (e.g. in the case of the bridge model herein, Sa(T1) < 0.8 g).

(a)

(b)

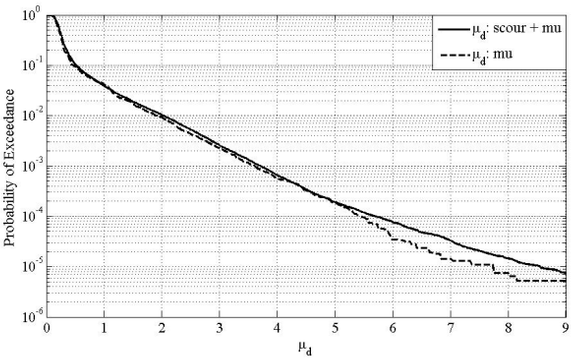
Figure 2. Fragility model at different scour depths without considering material uncertainties: (a) probability of structural damage at the column base; and (b) probability of system collapse.

Fig. 2(b) shows the probability of collapse defined based on the drift ductility demand at the bridge deck. This figure indicates that the probability of collapse increases as the scour depth and the seismic intensity levels increase. Specifically, the conditional probability of collapse is close to zero when Sa (T1) < 0.7g. Nonetheless, the probability of collapse rises for each scour condition when Sa (T1) > 0.7g. For a NS system, the probability of collapse is 4 % if Sa (T1) = 1.19 g or considering a MCE level earthquake. By



contrast, the corresponding probability for a scour system with the scour depth of 4.2m is about 9%, which is about 2.25 times of that for the NS system. Accordingly, scour is detrimental by increasing the probability of collapse at all levels of ground motions, but much significantly when the seismic intensity approaches to the MCE level.

The above fragility curves are constructed at designated scour conditions (NS, S1, S2, and S3). However, for an in-service bridge, its scour depth may be completely unknown; therefore, one may not be able to designate a scour depth. Based on Eq. 5, Fig. 2(a) and (b) also report the resulting MS fragility curves. First, one can observe that the MS fragility curve at either of the limit states lies between the fragility curve at the S1 condition (z = 2.8 m) and the one at the NS condition (no scour or z = 0 m), although it is worthy to mention that this observation depends on the probabilistic scour hazard modeling at a specific site.



Second, similar observations in the trend of the MS curves as *IM* increases are still seen compared with the curves at the designated scour depths. Considering the smaller difference of the MS fragility curves from the curves at the S1 condition yet significant difference from the curves at the S2 and S3 conditions, one may assert that scour survey is critical in terms of the potential high risk resulting from a possibly greater scour depth. Nonetheless, if an accurate scour depth is not available, the proposed probabilistic MS fragility modeling becomes instrumental to quantitatively assess the seismic-scour effects.

3.4 *Demand Analysis Results*

The seismic-scour integrated demand hazard curves can be approximated as expressed in Eq. 7. With the two ductility demand measures, Fig. 3 reports the demand hazard curves, wherein the vertical axis indicates the probability of exceeding a demand variable that is marked in the horizontal axis (which is either μ_s or μ_d). The two illustrations in Fig. 3 provide a comparison between the cases of considering scour vs. not considering scour (in both cases, material uncertainties, denoted by 'mu', are considered). Among them, Fig. 3(a) illustrates the demand hazard curves in terms of the local strain ductility variable; whereas Fig. 3(b) presents the system drift-ductility hazard curves.

(a)

(b)

Figure 3. Probabilistic demand hazard curves considering scour and material uncertainties (denoted by 'mu') vs. considering 'mu' only: (a) strain ductility demand hazard curves; (b) drift ductility demand hazard curves.

First of all, the demand hazard curves in Fig. 3 reveal the effects of scour as a source of hazard on the bridge structure. In terms of the local strain ductility μ_s in Fig. 3(a), the POEs in the range of $\mu_s < 2.1$ indicates that scour lowers the probability of structural damage in bridge piers, which is consistent with the previous fragility study. However, in the range of $2.1 < \mu_s < 4.1$, scour increases the probability of damage, which is not revealed in the fragility study since such limit-state of $2 < \mu_s < 4$ is not defined. It is noted that in both ranges, scour effect is insignificant due to the fact that scour-depth (*SD*) as a random variable has been integrated out numerically; therefore, it should be roughly regarded as a 'mean' effect of the scour. In terms of the system drift ductility μ_d in Fig. 2(b), the overall trend is that the probability of exceeding any specified μ_d increases due to the consideration of scour. This is especially evident when μ_d is greater than 5. This implies that at larger drift ductility levels, wherein the likelihood of system collapse is defined, scour tends to increase the probability of system collapse. Due to these observations, we state that the probabilistic demand hazard modeling provides a more comprehensive approach to evaluating the effects of scour on the seismic response and the vulnerability of bridge structures.

4 CONCLUSIONS

This paper proposes a comprehensive probabilistic framework for assessing the effects of scour on seismic response of existing bridge structures. Through a case-based assessment using a representative bridge model, several important observations are quantitatively revealed. These include:

1. The fragility curves at designated scour depths or the proposed mean-scour seismic fragility curves indicate that scour tends to be beneficial in reducing structural damage at slight to moderate seismic intensities. However, concern should be raised at strong seismic intensities, wherein even with a lowered probability of structural damage, the collapse potential is significantly increased due to scour.
2. The demand hazard curves systematically reveal the complex effects of seismic attacks and scour conditions on exceeding any local structural deformation or system drift demands. These effects include that scour lowers the probability of exceeding a local strain ductility demand at small values compared to the case where scour is not considered; but increases the probability of exceedance at larger demand values. In the meantime, scour systematically increases the probability of exceedance at any system drift ductility level, and more significantly at a larger demand level; or equivalently, scour in general increases the likelihood of system collapse when compared with the case of no consideration of bridge scour.
    1) Material uncertainties can be ignored if solely for evaluating the effects of scour. If ignored, the proposed framework provides a computationally efficient approach to performing integrated seismic-scour assessment for bridge structures. However, if material uncertainties considered, computational cost is much increased since more parametric finite-element models are included, which results in excessive nonlinear static pushover analysis in the framework. To mitigate this, one may choose a small and unique set of ground motions (e.g. only one motion is used in this paper) at different seismic intensity levels.

To this end, we envision that the proposed probabilistic framework and the associated numerical implementation in this paper may provide a rapid means for assessing the conjunct seismic and scour effects on existing river-crossing bridges. We further note that the proposed probabilistic framework can be adopted to assess the effects of flood-induced scour on other bridge types (e.g. deep-foundation supported bridges in soft soils), provided that a finite-element based nonlinear model for the bridge is available.

5 ACKNOWOLGEDGEMENT

The author appreciates the funding from a project supported by the University of Missouri Research Board. The second author gratefully acknowledges the support from the grants from National Natural Science Foundation of China (Grant Number 51708484). In addition, the authors thank for the reviewers for providing constructive comments that greatly help improve the studies in this paper.

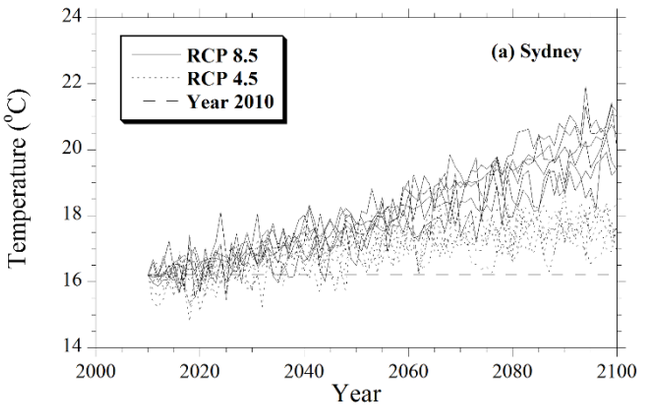
Reliability based corrosion damage assessment for concrete bridge decks under a changing climate

L.I. Peng & M.G. Stewart
Centre for Infrastructure Performance and Reliability, The University of Newcastle, Australia

ABSTRACT: A changing climate may alter the environment during the concrete structures' service life, especially in the longer term. According to the latest Intergovernmental Panel on Climate Change (IPCC) climate projections that temperature and carbon dioxide concentration in the atmosphere are likely to increase significantly by the end of this century. These changes may cause an acceleration of carbonation-induced deterioration processes and consequently a decline of the safety, serviceability and durability of concrete infrastructure. Carbonation-induced deterioration of Reinforced Concrete (RC) bridge decks under a changing climate is investigated in this study. Two latest IPCC climate projection scenarios, i.e. RCP 8.5 and RCP 4.5 emission scenarios, are used here representing possibly high and medium greenhouse gas emission scenarios. The spatial time-dependent reliability analysis is used to include not only the uncertainty of climate projections, deterioration processes and predictive models, but also the spatial variability in material properties and dimensions. The likelihood and extent of corrosion damage is estimated by tracking the evolution of the corrosion process across a bridge deck using Monte Carlo Simulations, and it is more or less affected by the changing climate depending on locations. Case studies of RC bridge decks are presented considering effects of construction methods, climate conditions and design specifications for Australian and Chinese bridges. The findings provide a basis for the development of climate adaptation through the design of concrete bridges, as well as an assessment of the optimal timing and extent of maintenance measures of concrete bridge asset management plans.

1 INSTRUCTIONS

The deterioration rate of RC structures depends on the construction processes employed and the composition of the materials used, as well as the environment. The influences of a changing climate may be potentially important factors for asset management, because it may alter the exposure environment of the structure, and change factors known to affect the corrosion of steel reinforcing bars. The latest Intergovernmental Panel on Climate Change (IPCC) assessment report (2013) indicated a significant increase of CO_2 concentration in the atmosphere which will induce temperature increases to at least 2°C by 2100. Rising temperatures will increase rates of carbonation penetration, as well as the corrosion rate. Changes in relative humidity (RH) will affect corrosion process as well. Peng & Stewart (2016) improved carbonation models by considering the effects of temperature and RH on diffusion coefficient, site-dependent CO_2 levels, and considering RH as a time-dependent variable. Time-dependent RH effects on corrosion rate are also considered (Peng & Stewart 2014). Due to the spatial variability of workmanship, environmental and other factors, it is recognized that the material and dimensional properties of a concrete structures will not be homogeneous. To consider the spatial variability of concrete material properties and concrete cover, and to predict probability and extent of corrosion damage of RC components subject to carbonation induced corrosion, a spatial time-dependent reliability method can be used (Peng & Stewart 2014).



In this paper, two emission scenarios are considered, i.e. RCP 8.5 and RCP 4.5 which represent high and medium greenhouse gas emission scenarios, respectively. RC bridge decks in an Australian city Sydney and a Chinese city Kunming are chosen as a case study to include the effects of construction methods, climate conditions and design specifications. The spatial time-dependent reliability analysis includes the time-dependent climate scenarios and deterioration processes, as well as a large number of random variables and spatial random fields of material properties and dimensions. The surface of concrete structures is discretized into many elements and the likelihood and extent of corrosion damage is calculated by tracking the evolution of the corrosion process of each element using Monte Carlo simula-

tion. Climate adaptation and/or maintenance strategies based on the analysis could provide insights into this problem for policy makers and society (e.g., Stewart & Deng 2015).

2 CLIMATE PROJECTIONS

The IPCC Fifth Assessment Report (2013) uses Representative Concentration Pathways (RCPs) to represent possible CO_2 emission scenarios. The four RCPs, RCP 2.6, RCP 4.5, RCP 6, and RCP 8.5, are named after a possible range of radiative forcing values in the year 2100 (2.6, 4.5, 6.0, and 8.5 W/m^2, respectively). The scenarios RCP 8.5 and RCP 4.5 are used in this study, representing high and medium emission scenarios, respectively. Additionally, an emission scenario based on the Year 2010 CO_2 level of 389 ppm is also considered to provide a reference for other emission scenarios.

To project spatially dependent temperature increases in the future under different emission scenarios, various climate models or Atmosphere-Ocean General Circulation Models (AOGCMs) have been developed based on physical principles at the continental scale. To find the full range of possible values, it is necessary to use multiple models to take into account the uncertainties of models in any impact assessment (Peng & Stewart 2016). Six GCMs are used to project temperature and RH change from 2010 to 2100. Two cities are selected: (a) Sydney, Australia; and (b) Kunming, China. Both cities are major urban centers. The projected annual average temperatures and RH for the six GCM projections, for RCP 8.5 and RCP 4.5 emission scenarios for Sydney and Kunming are shown in Figures 1 and 2. It can be found that there is a large variability between model projections, which makes climate projections particularly challenging. On the other hand, the climate and temperature and RH change trend projections for Sydney and Kunming are similar.

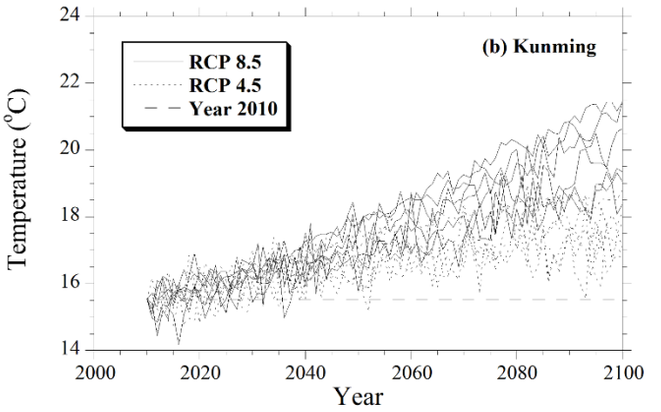


Figure 1. Projected annual average temperatures for the six GCM (BCC-CSM1.1, MIROC5, IPSL-CM5A-LR, CSIRO-MK3.6.0, CNRM-CM5 and ACCESS1.0) projections for RCP 8.5, RCP 4.5 and Year 2010 emission scenarios, for (a) Sydney and (b) Kunming.

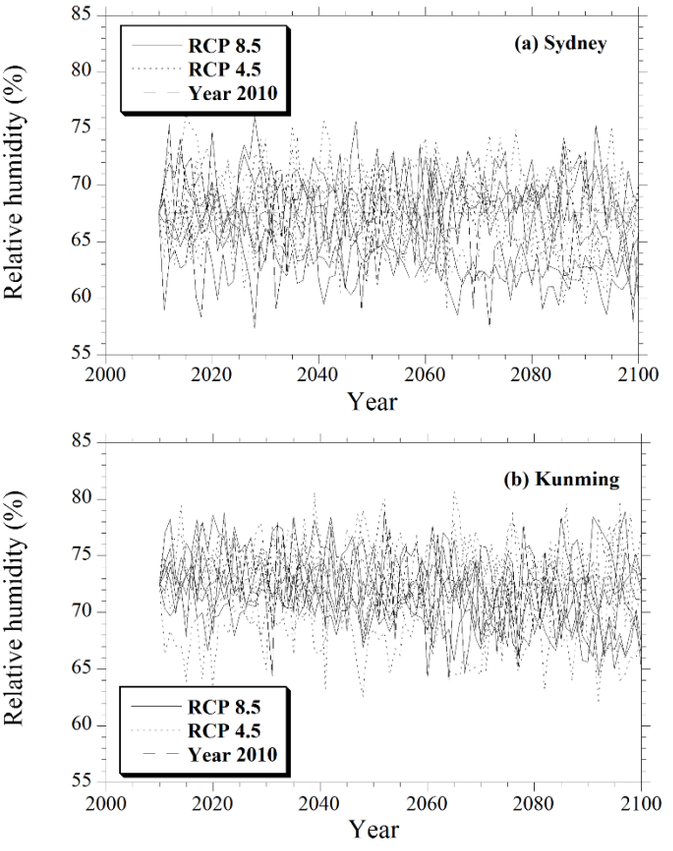

Figure 2. Projected annual average relative humidity for the six GCM (BCC-CSM1.1, MIROC5, IPSL-CM5A-LR, CSIRO-MK3.6.0, CNRM-CM5 and ACCESS1.0) projections for RCP 8.5, RCP 4.5 and Year 2010 emission scenarios, for (a) Sydney and (b) Kunming.

3 CARBONATION INDUCED CORROSION AND DAMAGE

The carbonation induced corrosion process normally consist of three stages: (i) corrosion initiation (T_i, assumed as the time when carbonation depth reaches reinforcement bar); (ii) crack initiation (T_{1st}, time to first cracking-hairline crack of 0.05mm width); (iii) crack propagation (T_{sev}, time for crack to develop

from crack initiation to a limit crack width, w_{lim}). Therefore, the time to corrosion damage (severe cracking or spalling) T_{sp} is the sum of T_i, T_{1st} and T_{sev}.

3.1 *Carbonation induced corrosion*

The carbonation penetration process is simulated as a diffusion process, considering a wide range of influencing parameters including CO_2 concentration, temperature and RH etc. Peng & Stewart (2016) considered the carbonation process as a steady state process modelled by Fick's First Law, and considered time-dependent CO_2 concentration, temperature and RH effects. The carbonation depth model is modified as

$$x_c(t) = \sqrt{\frac{2D(t)}{a}\int_{2010}^{t} f_T(t) f_{RH}(t) k_{site} C_{CO_2}(t) dt}\left(\frac{t_0}{t-2009}\right)^{n_m} \quad t \geq 2010 \quad (1)$$

$$D(t) = D_1 (t-2009)^{-n_d} \quad (2)$$

$$a = 0.75 C_e C_a O \alpha_H \frac{M_{CO_2}}{M_{C_aO}} \quad \alpha_H \approx 1 - e^{-3.38 w/c} \quad (3)$$

where t is defined in calendar years starting from 2010, assuming the bridges goes into service in the year 2010; $x_c(t)$ is the carbonation depth at time t; $C_{CO2}(t)$ is the time-dependent increase in atmospheric CO_2 concentration (10^{-3} kg/m^3); k_{site} is factor to account for increased CO_2 levels in non-remote environments; $f_T(t)$ is time-dependent change in diffusion coefficient due to changes in temperature; $f_{RH}(t)$ is time-dependent change in diffusion coefficient due to changes in RH; D(t) is CO_2 diffusion coefficient in concrete calibrated for time period 2010 to t; D_1 is CO_2 diffusion coefficient at t=2010; n_d is the age factor for the CO_2 diffusion coefficient; t_0 is one year; C_e is cement content (kg/m^3); CaO is CaO content in cement (0.65); α_H is a degree of hydration, the degree of hydration for ordinary Portland cement (OPC) after more than 400 days is estimated as Eq.(3); M_{CaO} is molar mass of CaO and equal to 56 g/mol; and M_{CO2} is molar mass of CO_2 equal to 44 g/mol. The CO_2 diffusion can be hindered by rain with elapsed time because of pore blocking of water in concrete skin, the age factor for microclimatic conditions n_m associated with the frequency of wetting and drying cycles is n_m=0 for sheltered outdoor, and n_m=0.12 for unsheltered outdoor exposures (Yoon et al. 2007). The functions for k_{site}, $f_T(t)$ and $f_{RH}(t)$ are detailed in Peng & Stewart (2016).

3.2 *Corrosion propagation*

When carbonation depth reaches the reinforcing bar, corrosion initiates (T_i) where T_i is the year when the carbonation depth exceeds the concrete cover. The corrosion rate is variable and highly dependent on exposure conditions and atmospheric situations. For instance, the optimum RH for corrosion is 70-80%, and then corrosion rate decreases as RH increases due to reduced diffusion of oxygen through the concrete (Neville 1995). A model that includes RH and temperature effects on corrosion rate proposed by Breysse et al. (2013) shows that a lower RH will decrease corrosion rate when RH is less than the reference RH:

$$i_{corr}(RH,T) = i_{corr\cdot ref}(RH_{ref},T_{ref}) e^{0.0312(RH-RH_{ref})} e^{-4736\left(\frac{1}{273.15+T}-\frac{1}{273.15+T_{ref}}\right)} \quad (4)$$

where a reference state is RH_{ref}=80%, and T_{ref}=20°C.

In the present study, the reference corrosion rate is denoted as $i_{corr-20}$ and is assumed lognormally distributed with statistical parameters given by Duracrete (1998), where a corrosion rate of 1 μA/cm^2 = 0.0116 mm/year. For sheltered moderate humidity exposure environment, the mean carbonation corrosion rate ($i_{corr-20}$) is 0.172 μA/cm^2, and the standard deviation is 0.086 μA/cm^2. These values take into account the concrete grades suggested for the corresponding exposure classes. This is likely to be a conservative assumption as corrosion rate will generally decrease with time due to the build-up of rust products thus impeding the corrosion process (Vu & Stewart 2000).

3.3 *Crack initiation (T_{1st}), severe cracking (T_{sev}) and corrosion damage (T_{sp})*

The time to crack initiation, T_{1st} is estimated by a model proposed by El Maaddawy & Souki (2007). It should be noted, that the accuracy of the time to corrosion damage (T_{sp}, $T_{sp}=T_i+T_{1st}+T_{sev}$) is dominated by the accuracy of time to corrosion initiation (T_i) and the time to crack propagation (T_{sev}, time for crack to develop from crack initiation to a limit crack width), and so damage risk predictions are relatively insensitive to the crack initiation model (Stewart & Mullard 2007).

The definition of how 'excessive' the crack width depends on individual conditions and asset owner policies; in this paper, concrete structures will be regarded as 'severely cracked' when crack width reaches a crack width of 1.0 mm. Mullard and Stewart (2011) have modelled rate of crack propagation which enables the time for a crack to develop from crack initiation to a limit crack width. Since corrosion rate is a time-dependent function of temperature and RH then time to corrosion damage is corrected for a time-variant corrosion rate instead of a time-invariant (constant) corrosion rate, for more details see Peng & Stewart (2016).

4 SPATIAL TIME-DEPENDENT RELIABILITY ANALYSIS

Reinforced concrete construction involves various processes including concrete batching, onsite dimensional set out, reinforcement placement, compaction of the concrete and curing. The nature of these processes introduces the potential for substantial variability of concrete quality due to variations in work practices. The spatial variability of concrete cover, concrete strength, diffusion coefficient and binding capacity are included in the analysis.

Random field theory can be used to model the spatial variability of these parameters. Therefore, a RC bridge deck or a surface can be represented by a 2D random field. In a random field, the surface is discretized into k identical elements of size Δ and the random variables within the random field are statistically correlated based on the corresponding correlation function (Vanmarcke 1983). The midpoint method is used to represent an element by the value at the centroid of that element and this value is assumed to be constant within the element.

The spatial correlation between elements in a random field can be described by the correlation function which defines the exact pattern of decay of the variance. The correlation function $\rho(\tau)$ determines the correlation coefficient between two elements separated by distance (τ) and is representative of the spatial correlation between the elements. As the distance between correlated elements becomes smaller the correlation coefficient approaches unity as defined by the correlation function, and likewise as the distance increases the correlation coefficient reduces.

The Gaussian correlation function has been widely used in engineering applications, including spatial modelling of RC structures, and as such it shall be used herein to model the spatial correlation of elements within a random field (Der Kiureghian & Ke 1988, Sudret 2008, Mullard & Stewart 2009). The Gaussian (or squared exponential) correlation function used herein is

$$\rho(\tau)=\exp\left[-\left(\frac{|\tau_x|^2}{d_x^2}\right)-\left(\frac{|\tau_y|^2}{d_y^2}\right)\right] \quad (5)$$

where $d_x=\theta_x/\sqrt{\pi}$ and $d_y=\theta_y/\sqrt{\pi}$; θ_x and θ_y are the scales of fluctuation for a two-dimensional random field in x and y directions, respectively; and $\tau_x=x_i-x_j$ and $\tau_y=y_i-y_j$ are the distances between centroid of elements i and elements j in the x and y directions, respectively. Once the stochastic random field is defined, Monte Carlo simulation methods are used to generate random variables for each element and the spatially variable parameters of each element are then defined using the correlation function. Monte Carlo simulation can also predict the deteriorated state of each element (T_i, T_{sp}) at every time interval.

4.1 *Proportion of a concrete surface subject to corrosion damage*

Corrosion damage is defined as the time when concrete cover reaches a limit crack width of 1.0 mm. Therefore, the proportion of concrete surface severe corrosion damage at time t (d_{crack}) for each Monte Carlo simulation realization is

$$d_{\text{crack}}(t)=\frac{n\left[t>T_{sp(j)}\right]}{k}\times 100\% \quad (6)$$

where $T_{sp}(j)$ is the time to corrosion damage of element j, and n[] denotes the number of elements for which $t> T_{sp}(j)$.

4.2 *Probability that at least x% of concrete surface has damaged*

The probability that at least x% of concrete surface has damaged at time t is

$$\Pr\left(d_{crack}(t)\geq x\%\right)=\int_{x\%}^{100\%} f_{d_{crack}}(d_{crack},t)\,\mathrm{d}\,d_{crack} \quad (7)$$

where $f_{dcrack}(d_{crack},t)$ is the multi-dimensional probability distribution of $d_{crack}(t)$ obtained from Monte Carlo simulation analysis for each time step t, a value of $d_{crack}(t)$ is calculated and after many simulations the probability distribution $f_{dcrack}(d_{crack},t)$ for every combination of t and $d_{crack}(t)$ will be inferred. As will be shown later $f_{dcrack}(d_{crack},t)$ is highly non-Gaussian and so percentile values of $f_{dcrack}(d_{crack},t)$ can only be predicted from simulation methods (Stewart & Mullard 2007).

5 CASE STUDY: RC BRIDGE DECKS IN SYDNEY AND KUNMING

5.1 *Structural configuration*

According to national code requirements, concrete cover requirements and concrete properties are not constant, generally, depending on the grade of concrete, and the exposure class. Environmental exposure in Australia is classified by the Australian Concrete Structures Code AS5100.5-2004 as three climatic zones (arid, temperate and tropical). Similarly, the environmental exposures in China are also classified for three climatic areas, as severe cold area, cold area and temperate area (JTG.D62-2004). The selected sites of Sydney and Kunming represent temperate climates in both codes. Note that RC structures are assumed to use ordinary Portland cement concrete, and standard formwork and compaction.

Concrete inside buildings in a dry environment, concrete surfaces subject to long-term rain in unsheltered exposures, and RC permanently submerged in water generally have a low carbonation rate. However, concrete inside buildings with moderate air

humidity, and external concrete sheltered from rain have higher likelihood of carbonation (Peng & Stewart 2016). The upper side of bridge deck is usually protected by wearing surface from water ingress and subsequent damage, however, the bottom side of bridge deck should be considered as external concrete sheltered from rain.

The durability design requirements specified in AS5100.5-2004 and JTG.D62-2004 relate to minimum concrete cover and concrete compressive strength, and assume standard formwork and compaction. The exposure classification conditions can be referred from AS5100.5-2004, JTG.D62-2004 and Peng (2015). For RC bridges in Sydney which are 50 km from coast, exposure classification A is appropriate to use. Note that RC structures close to the coast in Sydney have higher cover and are much less susceptible to carbonation induced corrosion. The exposure classification for RC bridge decks in the inland city of Kunming is exposure classification I. The durability requirements for a RC bridge deck in Sydney and Kunming are shown in Table 1. Note that the concrete compressive strengths in Chinese standards are based on cube compressive strengths. The bar diameter is assumed to be 20 mm, in practice, it can be other values of course, but corrosion damage risks are not sensitive to bar diameter (Peng & Stewart 2016).

Table 1. Durability design specifications (AS5100.5-2004, JTG.D62-2004) and deterioration models for bridges.

Class	w/c ratio	C_e (kg/m^3)	Mean D_1	Mean n_d	Cover (mm)	F'_c * (MPa)
A	0.56	320	2.22	0.24	35	25
I	0.55	275	2.22	0.24	30	C25

* C represents cube compressive strength.

5.2 *Spatial and stochastic variables*

A 2D random field is applied to simulate the RC bridge decks considering the spatial variability of concrete cover, concrete strength, and CO_2 diffusion coefficient and binding capacity. In this study, these four parameters are modelled as stationary random fields with respect to space. Random and spatial variables modelled as non-stationary can be included in the analysis if more realistic structural configurations are to be modelled.

Data to characterize the spatial correlation of concrete dimensional, material property and corrosion parameters is limited (Stewart & Mullard 2007, Sudret 2008, Na et al. 2013). The scale of fluctuation, θ, defines the distance over which correlation persists in a random field. Vanmarcke (1983) proposed various methods for the calculation of the scale of fluctuation for stationary random fields. These methods, however, require large amount of spatial data and although this has been collected in some cases, typically the scale of fluctuation is estimated using engineering judgment. However, due to a scarcity of reliable field data of concrete cover, concrete compressive strength, CO_2 diffusion coefficient and binding capacity, the scales of fluctuation in the x and y directions (θ_x, θ_y) are estimated based on previous studies as summarized in Table 2 (Sudret 2008, Na et al. 2013). Because the scales of fluctuation are not identical, the four random fields need to be generated separately. Stewart and Mullard (2007) found that chloride induced corrosion damage probabilities are not overly sensitive if the scale of fluctuation varies from 1.0 to 3.0 m for concrete cover. Nonetheless, more effort is needed to characterize the scale of fluctuation, as well as the shape of the correlation function, with more confidence.

The size of the discretized element is usually defined based on practical and analytical considerations. Sterritt et al. (2001) suggested that the element size should be in the range of 0.1 to 0.75 m. Therefore, element size Δ=0.5 m is chosen herein. The RC slab is 10 m long and 10 m wide, providing a total area of 100 m^2. The deck size, however, can be adjusted to fit needs.

To account for the random variation of basic parameters in structural analysis, the statistical description of the variability of material properties of reinforced concrete slabs is required, see Table 3 (Peng & Stewart 2014). Concrete strength is time-variant, and the time-dependent increase in concrete compressive strength after one year using the ACI method is f_c=1.162f_c(28) where f_c(28) is the 28-day in-situ compressive strength (Stewart 1996). Time-dependent gains in strength beyond one year are not considered in the present analysis. The difference between cast in-situ and precast concrete compressive strength is minor (Wiśniewski et al. 2012). The statistics of concrete cover are based on Australian and Chinese field surveys (McGee 1999, RGRRCSM 1985), and the results are also partly listed in Table 3. Only results for cast in-situ concrete are presented in this paper.

5.3 *Results*

The mean carbonation depths of sheltered and unsheltered RC bridge decks in Sydney and Kunming are shown in Figures 3-4 and are based on the average of six GCM projections. Due to the long-term effects of the wetting and drying cycles, the mean carbonation depths for unsheltered section are reduced significantly compared to sheltered section. Therefore, the analysis to follow will focus on sheltered RC bridge deck section. The RCP 8.5, RCP 4.5 and the Year 2010 emission scenarios have a significant effect on carbonation depths, and carbonation depths for RCP 8.5 and RCP 4.5 emission scenarios can be increased by up to 5.5 mm by 2100. For example, for bridges in Sydney, the RCP 8.5 emission scenario increases carbonation depth by approximately 34% when compared to the reference Year 2010 CO_2 emissions, whereas the RCP 4.5 increases carbonation depths by 13%. The COV of carbonation depth increases from 0.05 in 2010 to 0.08 by 2100. Carbonation depth for RC bridges in Sydney is very close to those in Kunming. Because both cities have similar temperature and RH projections, as well as the similar durability design requirements. The differences of design requirement between RC bridges in Sydney and Kunming are concrete cover and cement content, however, concrete cover thickness will not influence the carbonation process and the results show that the carbonation process is not sensitive to cement content.

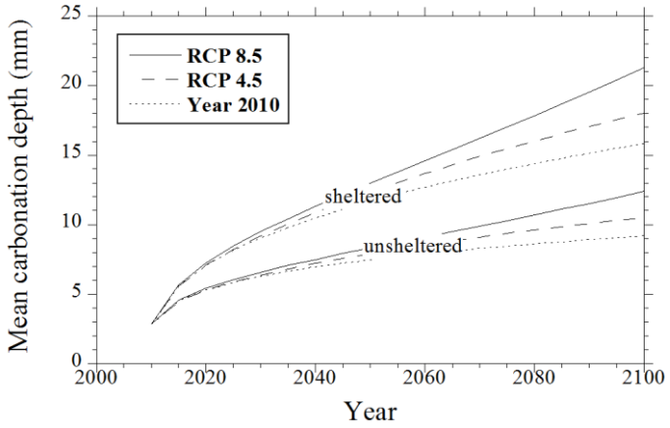

Figure 3. Mean carbonation depth of bridge decks in Sydney under all emission scenarios.

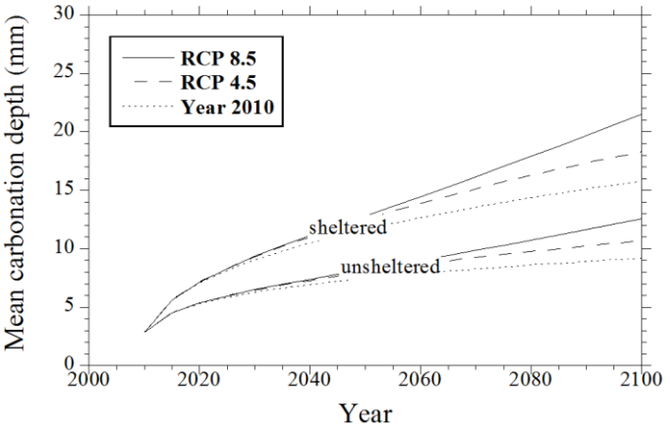

Figure 4. Mean carbonation depth of bridge decks in Kunming under all emission scenarios.

Carbonation depth increases with time. When the carbonation depth reaches the surface of reinforcing bar then corrosion is initiated. Therefore, the extent of corrosion initiation is mainly determined by carbonation depth and concrete cover. Figures 5-6 present the mean extent of corrosion initiation for cast in-situ sheltered RC bridge decks in Sydney and Kunming. The elements that are corrosion initiated for RCP 8.5 emission scenario can be twice as much for the reference Year 2010 emission scenario. In Sydney, less than 5% of the sheltered concrete surface of bridge decks will start corrosion by the end of this century, even under RCP 8.5 emission scenario; while the extent is about 25% for sheltered RC bridge decks in Kunming. As the carbonation depth are predicted to be very similar for bridge decks in both cities, so concrete thickness plays a significant role in initiate corrosion process. The big difference of extent of corrosion initiation for cast in-situ sheltered RC bridge decks are mainly due to higher durability requirements on concrete cover (Table 1) and better construction quality for Australian structures (Table 3).

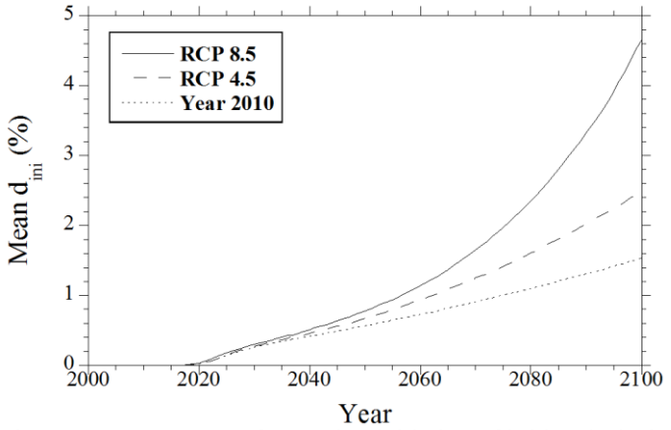

Figure 5. Mean extent of corrosion initiation of bridge decks in Sydney under all emission scenarios.

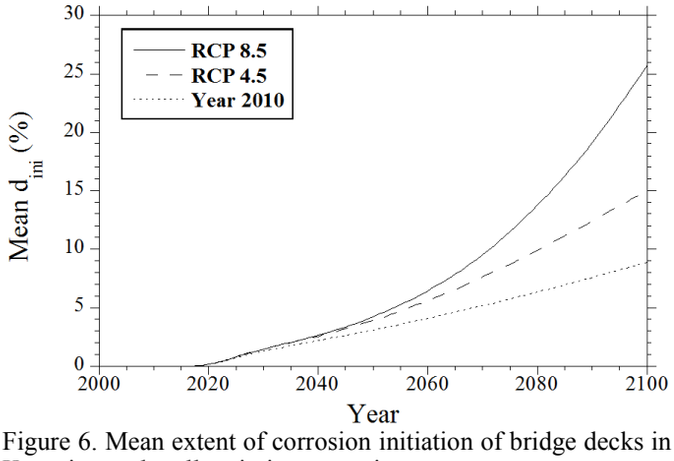

Figure 6. Mean extent of corrosion initiation of bridge decks in Kunming under all emission scenarios.

After corrosion is initiated, the corrosion process is dominated by the corrosion rate. Figures 7-8 present the mean proportion of surface corrosion damage for cast in-situ sheltered RC decks in Sydney and Kunming under all emission scenarios. Less than 0.5% of the concrete surface will be damaged for RC bridge decks in Sydney, for RCP 8.5 emission scenario by 2100. The five times larger corrosion initiation extent for RC bridge decks in Kunming subsequently lead to about ten times larger corrosion damage extent compared to those in Sydney, for RCP 8.5 emission scenario by 2100. Climate change may cause more severe corrosion damage. The RCP 8.5 emission scenario is predicted to cause around twice as much corrosion damage extent in RC bridge decks in Kunming compared to Year 2010 emission scenario. In practical terms, this is equivalent to expecting that up to an additional 2% of all concrete surfaces by 2100 will be damaged and in need of maintenance or repair, because of a changing climate. The differences between results of RCP 8.5 and Year 2010 emission scenario for RC bridge decks in Sydney are relatively lower. Overall, the extents of corrosion initiation and corrosion damage for RC bridge decks in Sydney and Kunming are quite low compared to RC buildings which generally have lower durability requirements (Peng 2015).

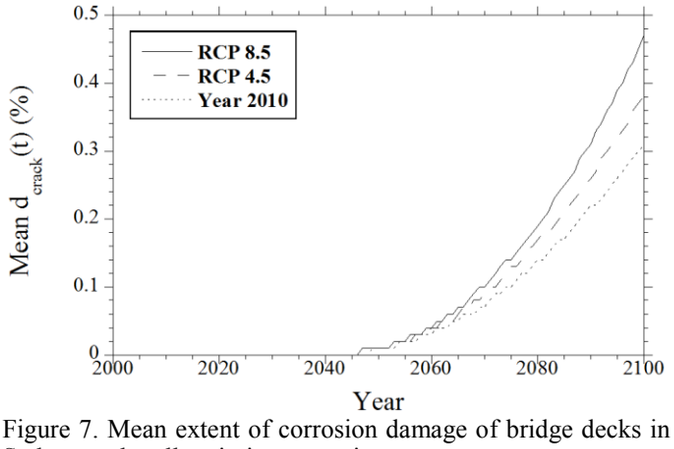

Figure 7. Mean extent of corrosion damage of bridge decks in Sydney under all emission scenarios.

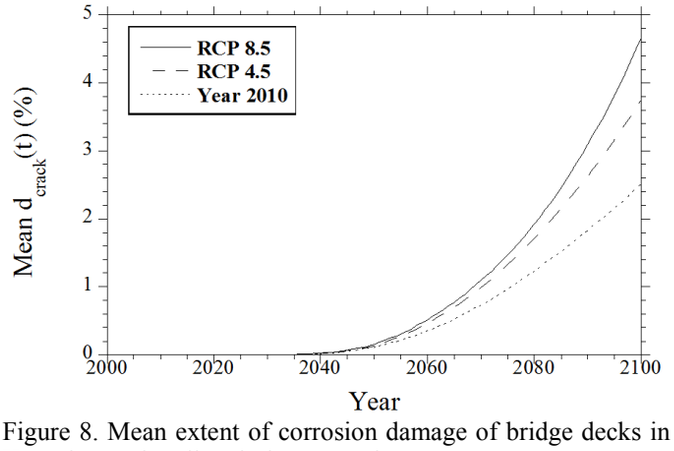

Figure 8. Mean extent of corrosion damage of bridge decks in Kunming under all emission scenarios.

The histograms of proportion of surface corrosion damage for cast in-situ sheltered RC decks $f_{dcrack}(d_{crack},t)$ is highly non-Gaussian (Peng 2015, Peng & Stewart 2014). The likelihood of no or little damage is significantly high, but it will decrease with time. However, even by 2100, the probability of significant damage is still low. Since the extent of corrosion damage can be predicted with time, inspection intervals and repair threshold can be determined to optimize resources to make sure structures to stay at an acceptable safety and service level. On the other hand, the analysis can be used to develop climate adaptation measures in the design stage, considering cost benefit effects of alternative climate adaptation measures to minimize life-cycle costs of structures (e.g., Peng & Stewart 2015).

6 CONCLUSIONS

The paper has described a spatial time-dependent reliability analysis of the carbonation induced corrosion deterioration of RC bridge decks under a changing climate. The spatial random fields of concrete cover, concrete strength, CO_2 diffusion coefficient and binding capacity are included whilst other material and corrosion parameters are treated as dependent spatial or random variables. Time-dependent CO_2, temperature and RH effects on carbonation

depth and corrosion rates are included. The results from the spatial time-dependent reliability analysis were presented in terms of likelihood and extent of surface corrosion damage, for RC bridge decks in an Australian city Sydney and a Chinese city Kunming. It was found that a changing climate can cause the extent of damage to increase by up to 2% for RC bridge decks in Kunming. RC bridge decks in Sydney are under much less risk to carbonation induced corrosion damage mainly due to higher durability requirements and better construction quality on concrete cover. The analysis can be used to optimize investment on maintenance strategies and develop climate adaptation measures in the design stage, which provide insights into this problem for policy makers and community.

7 ACKNOWLEDGEMENTS

The authors acknowledge the World Climate Research Program's Working Group on Coupled Modelling, which is responsible for CMIP, and we thank the climate modelling groups (listed in Figs 1-2 of this paper) for producing and making available their model outputs. For CMIP, the US Department of Energy's Program for Climate Model Diagnosis and Intercomparison provided coordinating support and led the development of software infrastructure in partnership with the Global Organization for Earth System Science Portals. The authors express their appreciation to Xiaoming Wang and Stacey Dravitzki of CSIRO for providing climate data.

Risk-Informed Assessment of Climate Change by Considering Deterioration and Hazards

Y.H. Li[1] and Y. Dong[1]
[1]: Department of Civil and Environmental Engineering, The Hong Kong Polytechnic University, Kowloon, Hong Kong, China

ABSTRACT: Life-cycle probabilistic life-cycle risk assessment of coastal bridges under typhoon hazard is progressively gaining attention. Though damage of coastal bridges during typhoon-induced wave and surge impacts has been widely investigated, probabilistic models are lack of research to characterize the bridge vulnerability and the consequent life-cycle loss. This paper aims to provide a framework of probability-based life-cycle risk assessment of coastal bridges under typhoon hazard and to propose an analytical method to estimate the typhoon-induced life-cycle loss. The proposed methodology can benefit the society to manage risks of coastal bridges during typhoons. The investigations focus on deck unseating failure mode, which is a primary damage pattern for simply supported bridges during typhoons. The proposed methodology is applied to an existing bridge to ensure the feasibility.

1 INTRODUCTION

Highway bridges may be subjected to hazards such as floods, earthquakes, and hurricanes during their service life. Storm surge can cause significant flooding in coastal areas, which could overwhelm infrastructure systems. Overall, hazard risk assessment is of vital importance to ensure structural safety and functionality during the service life of civil infrastructure systems (Frangopol 2011; Dong and Frangopol 2015). Typhoons, also known as hurricanes and tropical cyclones, can cause destructive damage to civil infrastructures and lead to severe casualties and economic losses. Landfalling typhoons become major hazards for coastal regions associated with extreme rainfall, winds and storm surge. Hurricane Katrina is one of the deadliest tropical cyclones in the natural hazard history of the United States, which left over 1,800 deaths with a total loss of more than $125 billion in 2005 (Graumann *et al.* 2005). In China, annual typhoon landfall is up to 7 on average, resulting in significant annual damage loss of $5.6 billion US dollars (Elliott *et al.* 2015). Furthermore, a large number of field observations emphasized the vulnerability of coastal bridges failed during the Typhoon Songda (2004), Hurricane Ivan (2004) and Ike (2008). During typhoon activities, storm surge and the induced inundation destroyed coastal bridges significantly. The subsequent repairs and replacement account for a large proportion of the typhoon hazard financial losses. Hence, research on coastal bridges vulnerable to typhoon hazard is necessarily required to benefit the society in enhancing the preparedness and awareness prior to extreme typhoon events. Additionally, recent research suggested that global climate change may increase the intensity and frequency of typhoons. For instance, warming climate may increase the average intensity of tropical cyclones by 2-11% worldwide by 2100 and the projected global sea level rise may reach 0.21 to 0.82m by the year of 2100 (Webster *et al.* 2005; Emanuel 2008; Knutson *et al.* 2010). Cumulative evidences indicate that the existing coastal bridges are exposed to higher damage risks during future extreme typhoons. All these facts have received an increasing attention from researchers, insurers and policy-makers, which requires a comprehensive probability risk assessment of typhoon hazard damages on coastal bridges.

The impact of typhoons on bridges mainly arises from storm surge and wave-induced loading. The consequent horizontal and vertical uplift forces produce excessive horizontal and vertical displacements at supports. When these displacements surpass the restraint at supports, superstructure becomes unsupported and eventually deck unseating appears. Deck unseating failure is recognized as the most primary damage for simply supported bridges (Kulicki 2010). Although an increasing amount of recent research has been conducted in terms of coastal bridges under typhoon hazard, the investigations of probabilistic risk assessment considering both deck

unseating failure and typhoon wind speed are still lacking. Studies of the corresponding typhoon-induced damage loss for existing bridge are also limited. Recently, Wang *et al*. (2017) suggested a method for hurricane damage loss assessment from the perspective of insurers and proposed a hurricane vulnerability analysis considering the wind speed as well as model uncertainty. Though this work stated hurricane occurrence process can be modeled as Poisson process, this study fails to reflect Poisson process and Poisson distribution clearly in the computation steps. In another typhoon risk investigation, Lin and Shullman (2017) successfully applied the stationary and non-stationary Poisson process model to estimate the hurricane arrivals. However, this research investigated the hurricane induced surge and flooding for New York City and mainly focused the expected annual damage consequences rather than the long-term loss. To overcome these deficiencies, this paper introduces a probabilistic life-cycle assessment framework of coastal bridges vulnerable to typhoons and proposes a new method for typhoon damage loss estimation. A flowchart of the assessment procedures of bridges vulnerable to typhoon hazard is shown in Figure 1.

This probability-based life-cycle framework mainly consists of three stages: hazard analysis of typhoons, structural vulnerability of the given bridge under typhoons and the corresponding typhoon-induced damage loss. The hazard analysis targets the distribution of typhoon arrivals and the distribution of typhoon wind speed. The vulnerability assessment focuses on bridge deck unseating damage because this failure mode is the most predominant for coastal simply supported bridges. The following damage consequence evaluation estimates the total damage loss of the reconstruction of the bridge based on analytical method. A case study of a practical simply supported bridge in New Jersey is conducted to illustrate the proposed approach and to identify the uncertainty on the evaluation consequences.

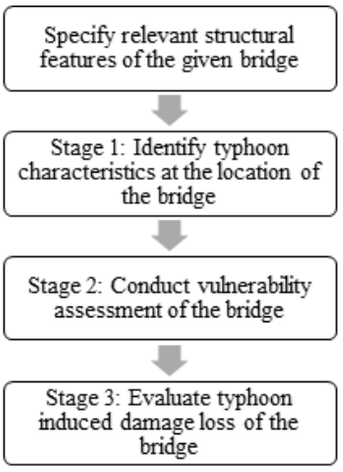

Figure 1. Flowchart of time-variant structural performance assessment process under hazard effects

2 TYPHOON HAZARD EFFECTS

Typhoon hazard analysis is the first stage in the risk assessment process, which provides the probabilistic descriptions of hazard characterization. In this section, typhoon occurrence process and hazard quantification are introduced.

2.1 *Stochastic typhoon process*

For a specific region with given climate environment, storm arrivals can be assumed to be conditionally independent, because the interactions between each typhoon event are comparatively small and require more scientific understanding. Researchers suggested a Poisson process to model the typhoon occurrence process (Onof *et al.* 2000; Elsner and Bossak 2001; Vanem 2011). If the future climate is assumed as stationary, the typhoon arrival process is assumed to be stationary Poisson process. Otherwise, a non-stationary Poisson process is considered instead. These two processes are also named as homogenous and non-homogeneous Poisson process (also known as stationary and non-stationary Poisson process). For a homogenous Poisson process, the typhoon arrival process is with a fixed and constant arrival rate λ. The probability of k (k = 0, 1, 2 …) typhoon events occur within the time interval (0, T) with the mean occurrence rate λ gives

$$\Pr\left(N_T = k\right) = \frac{\left(\lambda T\right)^k}{k!}\exp\left(-\lambda T\right) \qquad (1)$$

The nonhomogeneous Poisson process takes into account the arrival rate varying with time with a notation of $\lambda(t)$. Hence, the probability becomes

$$\Pr\left(N_T = k\right) = \frac{\left(\int_0^T \lambda\left(t\right)dt\right)^k}{k!}\exp\left(-\int_0^T \lambda(t)dt\right) \qquad (2)$$

2.2 *Typhoon wind speed probabilities*

The typhoon hazard can be characterized by the probabilities distribution of the typhoon wind speed. It is usually suggested to adopt the probability information based on a given location, but reference information from adjacent areas or other similar regions can be used if lack of data resources. The research probability distribution of extreme wind speed has been progressively developed in the last two decades (Simiu and Scanlan 1996; Vickery *et al.* 2010; Simiu 2011). A parametric modeling of typhoon wind speed was carried out by Yeo *et al.* (2013), which suggested that typhoon speed can be assumed as Weibull distribution. Accordingly, the cumulative distribution function (CDF) and the corresponding probability density function (PDF) in a nonhomogeneous (parameters are time independent

if for homogeneous situation) process with time-variant parameters $u(t)$ and $\alpha(t)$ gives

$$F_v(v,t) = \Pr(V < v) = 1 - \exp\left[-\left(\frac{v}{u(t)}\right)^{\alpha(t)}\right] \quad (3)$$

$$f_v(v,t) = \frac{\partial F_v(v,t)}{\partial v} = \exp\left[-\left(\frac{v}{u(t)}\right)^{\alpha(t)}\right]\frac{\alpha(t)}{u(t)}\left(\frac{v}{u(t)}\right)^{\alpha(t)-1} \quad (4)$$

3 VULNERABILITY

The following vulnerability analysis is the second stage in the risk assessment, which refers to estimating the probability of failure of coastal bridges against the given typhoon hazard. In structural safety analysis, structural failure typically occurs when the demand exceeds capacity. The limit state is applied to indicate the boundary between desired and undesired performance, at which the capacity equals to the demand. This paper focuses on the predominant deck unseating failure mode for simply supported coastal bridges during typhoons. Deck unseating failure takes place when the capacity of bridge superstructure at supports (capacity C) fails to resist the uplift forces (demand D) caused by storm wave loadings. Therefore, the probability of failure can be written as

$$P_f = P[(C-D) < 0] \quad (5)$$

Deck unseating occurs when the typhoon-induced uplift forces unseat the superstructure vertically and horizontal wave forces dislocate the deck from substructure. These loadings can be determined from both computational modeling and empirical methods. The computational approach refers to the computational fluid dynamic (CFD) method, which gives numerical simulations of three-dimensional hydrodynamic modelling. CFD program can be adopted to analyze the wave structure interactions such as computing the wave-induced forces on bridges decks. Jin and Meng (2011) conducted a study using CFD software Flow-3D to investigate wave forces on the superstructure of coastal bridges but stated that this CFD method was relatively time-consuming. A two-dimensional potential flow modeling was proposed alternatively in their research. Seiffert *et al.* (2014) later suggested a CFD program OpenFOAM calculating solitary wave forces on bridge decks based on the theory of Euler equations. However, for the probabilistic analysis, this numerical method is not computationally efficient to obtain the probability of failure.

Hydrostatic empirical relations were introduced at an early stage by Wang (1970), Overbeek and Klabbers (2001) and McConnell *et al*. (2004). Similar estimations for the vertical uplift and horizontal forces were developed by Douglass *et al.* (2006) depending on the maximum water level elevation and deck clearance height. Americana Association of State Highway and Transportation Officials developed guide specifications for bridges vulnerable to coastal bridges (AASHTO 2008) and this guidance presented a series of equations calculating maximum vertical force, maximum horizontal force and the corresponding overturning moment. This paper adopts AASHTO model to estimate the wave-induced forces upon a bridge.

The vertical loading on bridge superstructure contributes to deck unseating failure. According to AASHTO, the maximum quasi-static vertical force can be computed. The significant wave height and wave period are required values to compute the demand of bridge deck. These two items are characterized by different geographical locations and are replied on fetch length, average water depth and wind stress factor. Experimental studies conducted by AASHTO gives the relationship between the significant wave height and the maximum wave height. Thus, the uplift demand on bridge is the sum of the maximum quasi-static vertical force and vertical slamming force, while the capacity purely equals to the weight of the structure if there are no additional retrofitting measures provided for bridges vulnerable to typhoon loads. The limit state function for the deck unseating failure of coastal bridge is

$$g_{typhoon} = F_w - \left(F_{v-\max} + F_s\right) \quad (6)$$

where F_w is self-weight; $F_{v\text{-}max}$ is maximum quasi-static vertical load; and F_s is vertical slamming force. As stated in the last section, the typhoon wind speed follows a Weibull distribution, which means the demand of bridge varies with the hurricane wind speed and eventually results in the change of probability of failure of the bridge system. This vulnerability model associated with typhoon wind speed aims to characterize the potential of occurrence of bridge deck unseating damage caused by typhoon winds. Monte-Carlo simulation is then applied to this limit state function to obtain the probability of failure

4 LIFE-CYCLE LOSS

The annual risk and life-cycle loss assessment of bridges under hazards is presented in this section. Probability-based evaluation of the typhoon hazard consequences is the last stage of a risk assessment, which is significantly essential for insurers and policy makers to manage the risk loss of coastal communities. Poisson process model is commonly used to model the typhoon arrival process, which consists of homogenous and nonhomogeneous computation

methods. The major difference between these two methods is the definition of occurrence rate (storm arrival frequency in this case, described as intensity function). The homogeneous approach defines a stationary occurrence rate in the Poisson process, while the nonhomogeneous approach gives a time-variant occurrence rate. Details will be provided in formulas with explanation in this section. In both approaches, life-cycle damage loss of bridge under typhoon hazard is considered over the lifespan of the structure. It is assumed that the post-hazard bridges are completely reconstructed to the pre-damage state before the next typhoon event. Since the distribution type of the damage loss is uncertain, expectation, standard deviation (SD) and coefficient of variation (COV) of the total loss are focused to identify the characteristics of this probability distribution. It is defined total time of interest equals to the lifespan of the bridge. Each storm that happens within this time horizon has an index notation. All the future damage loss is transformed into present value through a discount rate. The total annual hazard loss is computed by summing up all the metrics associated with repair, time, fatalities, operating, and environmental losses. Accordingly, the annual total hazard loss can be computed as (Dong *et al.* 2013)

$$L_{tot}(t) = L_{REP}(t) + L_{OL}(t) + L_{TL}(t) + L_{FA}(t) + L_{ENV}(t) \quad (7)$$

where L_{REP} is annual repair loss; L_{OL} is annual operation loss; L_{TL} is annual time loss; L_{FA} is annual fatalities loss; and L_{ENV} is annual environmental loss of a bridge subjected to a hazard. Generally, there are both aleatoric and epistemic uncertainties involved in hazard assessment and consequence evaluation (Ang and Tang 2007). These uncertainties should be considered in this probabilistic total loss assessment framework. Given the distribution parameters, these random variables can be generated using MATLAB (MathWorks 2014). By performing numerical simulation, the expected value and dispersion of the sustainability metrics can be obtained. Considering the time effects on structural performance, the total life-cycle hazard loss can be computed as (Dong and Frangopol 2017a)

$$LCL_T = \sum_{i=1}^{N(T_{\text{int}})} L_{tot}(t_k) \cdot e^{-rt_k} \quad (8)$$

where T_{int} is the investigated time interval (years); $N(T_{int})$ is the random number of events that occur during time interval T_{int} and expected value of $N(T_{int})$ equals λT_{int}; λ is the mean occurrence rate of hazard; $L_{tot}(t_k)$ is the expected total loss at time t_k under hazard; and r is the constant monetary discount rate. The relation between $L_{k,tot}$ and time t can be computed. Subsequently, the total life-cycle loss can be compute.

Given to the homogeneous Poisson process, occurrence of typhoon is modeled with a stationary (time-independent) occurrence rate. The expectation becomes

$$E[TL(t_{\max})] = \frac{\lambda E[L]}{\alpha}[1 - e^{-\alpha t_{\max}}] \quad (9)$$

and the standard deviation gives (Dong and Frangopol 2017b)

$$SD[TL(t_{\max})] = \sqrt{\frac{\lambda E[L^2]}{2\alpha}[1 - e^{-2\alpha t_{\max}}]} \quad (10)$$

The nonhomogeneous Poisson process analysis is applied to model the typhoon arrival when the effect of climate and built environment changes are considered. This approach is with a time-variant occurrence rate. The expectation and standard deviation of the nonhomogeneous case are

$$E[TL(t_{\max})] = \frac{\int_0^{t_{\max}} \lambda(t)dtE[L]}{\alpha t_{\max}}[1 - e^{-\alpha t_{\max}}] \quad (11)$$

and the standard deviation gives

$$SD[TL(t_{\max})] = \sqrt{E[TL({t_{\max}}^2)] - (E[TL(t_{\max})])^2} \quad (12)$$

5 NUMERICAL EXAMPLE

The proposed framework is applied to an existing highway bridge. The time-variant annual hazard loss and life-cycle loss of this two-span concrete simply supported bridge is investigated throughout its service life. The bridge is located at the intersection of Bailey Ave. and US Highway 101. The bridge has two spans of equal length (47.3 *m*) and carries two lanes of traffic in each direction. The schematic layout of the bridge, with the length of 94.6 *m* and the width of 19.2 *m*, is shown in Figure 2. The lifetime is assumed to be 75 years. The failure mode considered in this paper assumes that failure occurs at the deck or/and any two neighboring girders.

According to the proposed risk assessment framework, hazard and vulnerability analysis are conducted based on the introduced methodology. The probability of deck unseating failure of bridge in terms of the given typhoon hazard is computed as 0.005. As for the life-cycle consequences assessment, there are also several preliminaries to be addressed. The deck unseating damage cost equals to the replacement of superstructures with a value of US$ 1,283,200 since deck unseating failure is measured as the only failure mode. In Poisson process model, the item of damage loss is a random variable. Hence, the damage loss equals to the product of deck unseating loss and the probability of deck unseating failure. Another key element in the typhoon-induced bridge loss estimation is the occurrence rate, which refers to the intensity function of the Poisson

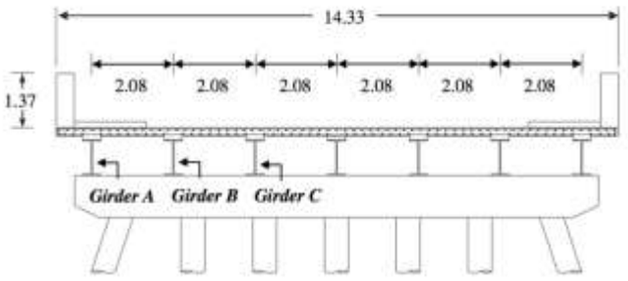

Figure 2. Section view of the bridge under investigation

process. Previous research gave limited evidence to demonstrate the specific correlation between typhoon frequency and time, thus a linear relationship is assumed for the intensity function, with an initial occurrence rate of 0.245/year. This intensity function assumes typhoon frequency increases by 5% over a period of 100 years. A constant discount rate is taken as 3% to transfer the future damage loss to the present. Given the design period of 70 years for the bridge, major characteristics of life-cycle cost in terms of expectation, standard deviation and coefficient of variation are shown in Table 1. In both homogeneous and nonhomogeneous cases, the COV values are larger than 1, which indicates the probability distribution of damage loss is high-variance. In reliability analysis, robustness adaptation is required for further research.

Table 1. Expectation, standard deviation and COV of the proposed life-cycle cost estimation

Occurrence model	Expected US $	Standard deviation US $	Coefficient of variation (COV)
Homogeneous	45,981	49,084	1.06
Nonhomogeneous	126,448	142,788	1.13

6 CONCLUSIONS

This paper proposes a framework to develop costal bridges vulnerable to typhoons based on the probabilistic life-cycle assessment in hazard, vulnerability and consequences evaluation aspects. A typical simply supported bridge was investigated. The proposed analytical approach successfully estimated typhoon-induced consequences by identifying the main distribution characteristics of the damage loss of an existing bridge. This approach could further provide insurers and policy-makers references to manage bridges against typhoon risks in coastal regions. The expected bridge life-cycle cost showed a high-variance distribution, which requires further robustness adaptation investigations to address this issue. Further work can be performed associated with uncertainties of the proposed model by introducing uncertainty indicator to quantifying the distribution type. Additionally, optimization management of bridges can be further conducted after this life-cycle assessment to mitigate the consequence loss during typhoons.

Climate change and potential impact on the seismic vulnerability of highway bridge structures

M. Mortagi & J. Ghosh

Department of Civil Engineering
Indian Institute of Technology Bombay, India

ABSTRACT: The past decade has witnessed significant research progress towards quantifying the seismic vulnerability of aging highway bridges. However, majority of existing literature assumes deterioration rate to be independent of the repercussions stemming from climate change along the bridge service life. In this regard, recent advances on this topic indicate a potential time-dependent shift in average temperature and relative humidity that may influence the degradation mechanism of structural members. Consequently, the influence of climate change on the seismic fragility of bridges need to be evaluated. This study proposes a framework to evaluate the vulnerability of highway bridges under different scenarios considering earthquake hazard, aging and deterioration, and global warming due to climate change. Results reveal that throughout the lifetime of the bridges, the seismic vulnerability consistently increases due to corrosion deterioration and the effect is further pronounced when the influence of potential climate change is incorporated within the fragility assessment methodology.

1 INTRODUCTION

Global warming and climate change are considered as a passive sides of the continued increase in the emissions of greenhouse gases, such as carbon dioxide (CO_2). Recently, soon after the industrial revolution, CO_2 concentration has substantially increased by approximately 0.5% per year (Yoon at el. 2007). Present studies in this area have shown that, increasing level of CO_2 emissions may lead to a rise in temperature (Stewart & Deng 2014). For instance, Peters at al. (2013) shows that by the year 2100 the mean temperature may increase by 4-5°C if the CO_2 emissions continue to record at the high end of emissions scenarios. There are different scenarios to estimate and define the future climate change according to the intergovernmental panel on climate change (IPCC 2007). These scenarios are represented in different categories according to the CO_2 emissions which relate to changes in population growth rate, economy, energy and technology (Stewart et al. 2012). The increase of atmospheric CO_2 concentration has a direct influence on the increase of carbonation depth and temperature that may increase the corrosion rate for carbonation induced corrosion (Stewart et al. 2010). For instance, Zhou et al. (2014) used the CO_2 diffusion as a coefficient in calculating the carbonation depth in their model. On the other hand, the CO_2 emissions and an associated increase of atmospheric temperature may also indirectly influence chloride induced corrosion due to an increase of atmospheric temperature, as elaborated next.

Past research on chloride induced corrosion deterioration of reinforced concrete structures has underlined the sensitivity of chlorides ingress in the concrete matrix to increase in temperature and humidity (Xi et al. 1999, Chen et al. 2006). Accounting for such effects within the climate change context is particularly important since global warming may lead to a time-dependent shift in average temperature and relative humidity (Bastidas-Arteaga et al. 2010, 2013, Stewart et al. 2011, 2012). Until now, a majority of existing literature on chloride induced corrosion assumes a constant or time-dependent deterioration rate that is independent of variations in temperature and humidity along the bridge service life. Recently, Bastidas-Arteaga et al. (2010, 2013) adopted a stochastic approach to demonstrate the impact of global warming and weather effects on chloride ingress in concrete. Using future projections of climate change manifested through alterations in temperature and relative humidity, these studies estimated the increased likelihood of deterioration in aging structures. While these future projections were studied under the "expected" and "pessimistic" climate change scenarios, sub-categories such as seasonal variation effects were also accounted for. Stewart et al. (2011) considered the CO_2 concentration and temperature as the main factors in increasing concrete deterioration and damage risks to different structures. It was found that, due

to climate change and global warming, the damage risks due to chloride induced corrosion increase by approximately 10%.

The primary focus of this paper involves the impact assessment of potential climate change effects on the seismic fragility curves of highway bridge located in moderate to high seismic zones. While recent investigations by Choe et al. (2008 , 2009), Ghosh & Padgett (2010), among others, have underlined the marked increase of seismic fragility due to corrosion deterioration, the individual influence of projected temperature and humidity changes needs further exploration.

To achieve the above objective, the impact of lifetime environmental exposures such as temperature change, humidity and chloride concentration on the corrosion initiation time and corrosion rates is considered first. Next the impact of climate change is demonstrated on the fundamental equations governing corrosion deterioration. Furthermore, based on a future climate change scenario, the influence of aging and climate change is estimated on the column seismic performance of a case-study multi-span continuous steel girder bridge (MSC steel girder bridge) located in the Central and Southeastern United States as illustrated in Section 4. The paper ends with conclusions and recommendations for future work.

2 CHLORID INDUCED DETERIORATION MODELING

Deterioration of reinforced concrete (RC) structures, especially bridges, resulting from chloride induced reinforcement corrosion has been observed as one of the most significant durability problems. Sources of chlorides may stem from application of the deicing salts, particularly in cold regions or proximity to the marine atmosphere. Common manifestations of this deterioration mechanism includes, but are not restricted to, the following:

1. Reduction in steel cross-section area.
2. Cracking and spalling the cover concrete.
3. Degradation of cover strength.
4. Deterioration of steel-concrete interface bond strength.
5. Decreasing the RC structures service life.

This section briefly describes some of the commonly adopted chloride induced deterioration models to estimate corrosion initiation time and corrosion rates.

2.1 *Corrosion initiation time*

Several studies are available in literature that estimate the corrosion initiation time (t_i) of RC structures exposed to a chloride laden environment (Duracrete 2000, Bertolini et al. 2004, Choe et al. 2009). Based on Fick's second law of diffusion and calibration to laboratory test data, t_i can be calculates as shown in Equation (1):

$$t_i = \left\{ \frac{x^2}{4k_c k_e k_t D_0 (t_0)^{n_{cl}}} \cdot\cdot \left[erf^{-1}\left(1 - \frac{C_{cr}}{C_s}\right)\right]^{-2} \right\}^{\frac{1}{(1-n_{cl})}} \quad (1)$$

where k_e is the environmental factor, k_t is the influence of test methods while estimating the chloride diffusion, k_c is the curing factor, t_0 is the age of concrete when the compliance test is implemented, D_0 is chloride diffusion at t_0, n_{cl} is the age factor, C_s and C_{cr} are surface and critical chloride concentration respectively, and *erf* is the Gaussian error function.

2.2 *Rate of corrosion*

In RC structures, following corrosion initiation a reduction in rebar area is typically observed. This rate of reduction can defined in terms of a corrosion current density, i_{corr}, (in $\mu A/cm^2$) or annual metal loss per unit surface area, $r_{corr,}$ (in $\mu m / year$). The rate of corrosion is sensitive to the surrounding relative humidity. In low humidity, the electrical resistivity of concrete controls $r_{corr.}$ On the other hand, when the ambient humidity is high, r_{corr} is primarily affected by the availability of oxygen at the cathode (Tuutti 1982, Yalsyn et al. 1996, Vu & Stewart 2000, Bastidas-Arteaga 2009). For RC structures, it is often observed that the water cement ratio (*w/c*), cover depth (*x*) and environmental conditions (temperature and humidity) directly or indirectly affect the availability of oxygen to corrode the steel rebars. Based on experimental results, Vu & Stewart (2000) investigated a corrosion rate model (Equation 2) that couples the effect of *w/c* and *x* on the corrosion rate at reference environmental conditions. These reference conditions correspond to a temperature of 20 °C and 75% relative humidity.

$$i_{corr,0} = \frac{37.8(1 - w/c)^{-1.64}}{x} (\mu A / cm^2) \quad (2)$$

where *x* is the cover depth (in *cm*).

A number of studies have reported that r_{corr} is a time-dependent parameter and typically reduces with time owing to the following reasons (Tuutti 1982, Yalsyn et al. 1996, Vu & Stewart 2000, Bastidas-Arteaga 2009, Liu & Weyers 1998):

1. The steel surface rust products reduce the diffusion of iron ions away from the steel surface.
2. The reduction of the ratio among the cathode and anode.

According to Liu & Weyers (1998) data, a time dependent model for r_{corr} was developed by Vu & Stewart (2000), as represented in Equation (3).

$$i_{corr}(t_p) = i_{corr,0} \times 0.85 \times t_p^{-0.29} \quad (3)$$

where t_p is time from corrosion initiation and $i_{corr,0}$ can be evaluated by Eq. (2).

2.3 *Time-dependent reduction in embedded steel area*

The reduced diameter of the reinforcement bar at time t after initiation time, can be computed as (Stewart et al. 2010):

$$d(t) = d_0 - 0.0232 \int_{t_i}^{t} i_{corr}(t)dt \quad (4)$$

where d_0 is the initial diameter (in mm). Consequently, the area of reinforcement steel, for equal diameter bars, according to uniform corrosion can be estimated as:

$$A(t) = \begin{cases} n d_0^2 \dfrac{\pi}{4} & for\ t \le t_i \\ n(d(t))^2 \dfrac{\pi}{4} & for\ t_i < t < t_i + (d_o / r_{corr}) \\ 0 & for\ t \ge t_i + (d_o / r_{corr}) \end{cases} \quad (5)$$

3 CHLORIDE INDUCED DETERIORATION MODELING CONSIDERING THE INFLUENCE OF CLIMATE CHANGE

This section of the paper will highlight the likely influence of climate change on the basic corrosion deterioration models elaborated in the previous section.

3.1 *Influence on Initiation time*

Recently, multiple researchers have investigated the effect of environmental conditions, i.e. temperature (T) and relative humidity (RH), on initiation time due to chloride induced corrosion. For instance, a model of initiation time which couples the T and RH effects was reported by Allampallewar et al. (2008), El Hassan et al. (2010). This model is represented as:

$$t_i = \left\{ \frac{x^2}{4D_c(T,RH)(t_0)^{n_{cl}}} \cdot\cdot \left[erf^{-1}\left(1 - \frac{C_{cr}}{C_s}\right)\right]^{-2} \right\}^{\frac{1}{(1-n_{cl})}} \quad (6)$$

where $D_c(T,RH)$ *is expressed as:*

$$D_c(T,RH) = D_{c,ref}\ F_1(T) F_2(RH) \quad (7)$$

where $D_{c,ref}$ is the chloride diffusion at reference condition, reference temperature (20 °C) and humidity (RH=100%) (Allampallewar et al. 2008, Nielsen et al. 2003, El Hassan et al. 2010). The factors $F_1(T)$ and $F_2(RH)$ are represented in Equations (8) and (9).

$$F_1(T) = \exp\left[\frac{U_c}{R}\left(\frac{1}{T_{ref}} - \frac{1}{T}\right)\right] \quad (8)$$

$$F_2(RH) = \exp\left[1 + \frac{(1-RH)^4}{(1-RH_c)^4}\right]^{-1} \quad (9)$$

where U_c and R are the activation energy of chloride diffusion process (in kJ/mol) and the gas constant (8.314 J mol^{-1} K^{-1}) respectively, T_{ref} and RH_c are the reference temperature taken as *296 K* (20 °C*)* and reference humidity at which $D(RH_c)$ = 0.5D(100%) (Nielsen et al. 2003), taken as 0.75, T is the current absolute temperature of concrete (K) and finally, RH is the pore relative humidity.

3.1.1 *Improved corrosion initiation time model*

In this paper, the corrosion initiation time is estimated according to Eq. (7) after accounting for the environmental conditions. So, the initiation time model couples the effect of time, temperature, humidity and the environmental condition as shown in Equation (10).

$$t_i = \left\{ \frac{x^2}{4k_e k_c k_t D_c(T,RH)(t_0)^{n_{cl}}} \cdot\cdot \left[erf^{-1}\left(1 - \frac{C_{cr}}{C_s}\right)\right]^{-2} \right\}^{\frac{1}{(1-n_{cl})}} \quad (10)$$

3.2 *Rate of corrosion*

In the present work, the effects of temperature, relative humidity and chloride concentration on the rate of corrosion are incorporated besides the effect of w/c, cover and time as shown in Equation (11) (Guo 2011)

$$i_{corr}(t) = \frac{37.8(1-w/c)^{-1.64}}{x} \times 0.85 \ldots \ldots \times t_p^{-0.29} \times f_{RH} \times f_T \times f_{Cl} \quad (11)$$

where f_T, f_{RH} and f_{Cl} are the temperature, relative humidity and chloride factor respectively.

The next sections will illustrate the impact of temperature (f_T), relative humidity (f_{RH}) and chloride concentration (f_{Cl}) on the rate of corrosion. One should note that the *w/c* and *x* are assumed to be 0.5 and 38.1 mm, respectively.

3.2.1 *Influence of temperature on corrosion rate*

Past research indicates an increase in corrosion rate at elevated temperatures. For instance, Stewart et al. (2011) note that an increase in temperature by 2 °C may cause an increase in the corrosion rate up to 15%. The relationship between temperature and corrosion rate has also been investigated by Duracrete (2000) as shown in Equations 12 and 13. This model underlines the influence of temperature on corrosion rate at reference test temperature of 20 °C ($i_{corr,20}$)

$$i_{corr} = i_{corr,20}\left[1 + K\left(T(t) - 20\right)\right] \tag{12}$$

where

$$K \begin{cases} 0.025 & if \quad T(t) < 20° \\ 0.073 & if \quad T(t) > 20° \end{cases} \tag{13}$$

Another model describing this relationship was reported by Pour- Ghaz et al. (2009) and Virmani et al. (1983) as:

$$i_{corr} = i_{corr,20} \times f_T \tag{14}$$

where

$$f_T = e^{2283\left(\frac{1}{284} - \frac{1}{T}\right)} \tag{15}$$

where T is the temperature in *Kelvin*.

Figure 1 illustrates the effects of these models on the rate of corrosion. The present work considers he second model for computing the temperature factor.

3.2.2 *Influence of humidity on corrosion rate*

Past experiments by researchers have revealed that when the RH of concrete is less than 50%, the corrosion rate is low and below 35% rust formation halts owing to the high electrical resistance of concrete. On the other hand, corrosion rate is found to be highest between 70% to 90% RH. Additionally, while, there is an exponentially increase in corrosion rate from 50% to 70% RH, there is a rapid drop from 90% to full saturation (Balafas et al. 2010). This primarily occurs because at very high relative humidity, the rate at which oxygen reaches the surface of reinforcement is typically low (Balafas et al. 2010). Based on these observations, the RH factor f_{RH} can be estimated as shown in Equation 16 and demonstrated in Figure 2 (Guo 2011):

$$f_{RH} = e^{-6000\,(RH - 0.75)^6} \tag{16}$$

The relationship between corrosion rate, T and RH, according to Eq. (11), is presented in Figure 3.

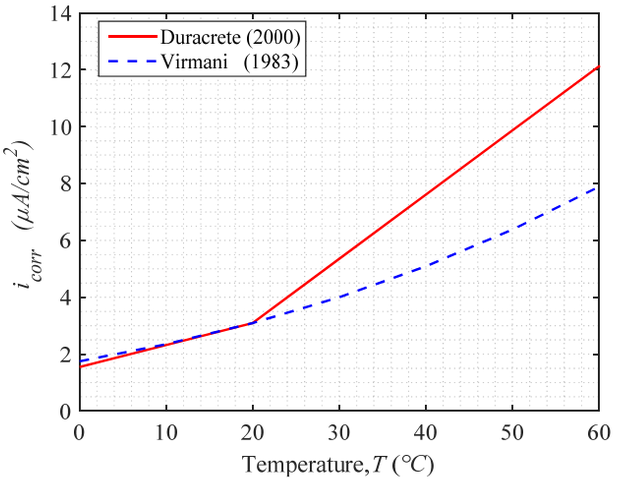

Figure 1. Variation of corrosion rate with temperature.

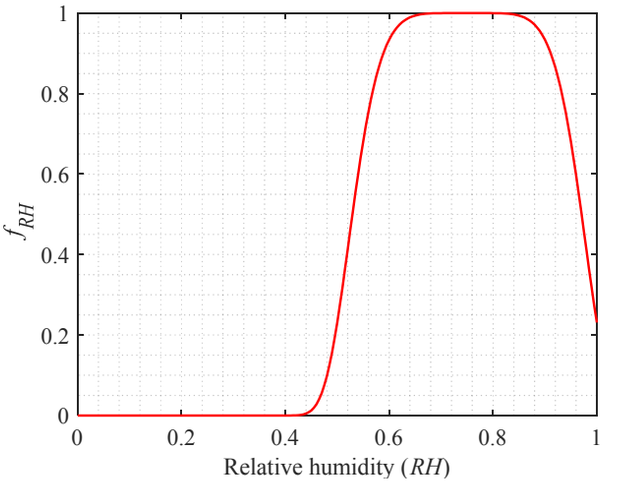

Figure 2. Variation of the relative humidity factor f_{RH} (t) with relative humidity (RH) (Guo 2011).

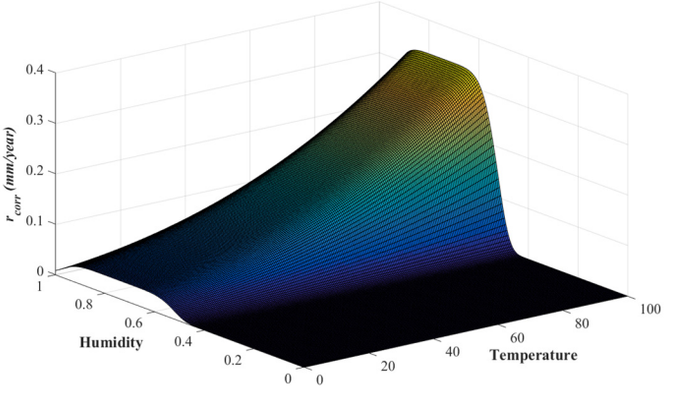

Figure 3. Joint impact of Temperature (T) and Relative Humidity (RH) on corrosion rate (r_{corr})

3.2.3 *Influence of chloride concentration (Cl) on corrosion rate*

Besides assessing the influence of climate change alone, this study also investigates the increase in chloride concentration at the rebar interface along the service life of the structure. The increase in chloride concentration can result in an increase of corrosion rate (Liu & Weyers 1998). This primarily occurs due to the increase in concrete conductivity following an increase in chloride concentration. Besides, in the corrosion process, chlorides accelerate the electrochemical reactions by altering the concrete resistivity when the chloride concentration at the steel surface reaches to the critical chloride concentration. Consequently, the chloride factor, f_{Cl}, can be estimated according to chloride concentration, Cl, and the critical chloride concentration (C_{cr}). The chloride factor can be computed, based on the Liu & Weyers (1998) approach, as follows (Guo 2011):

$$f_{Cl} = \frac{Cl + C_{cr}}{2C_{cr}} \tag{17}$$

Figure 4 shows the estimated chloride factor, f_{Cl}, following initiation time.

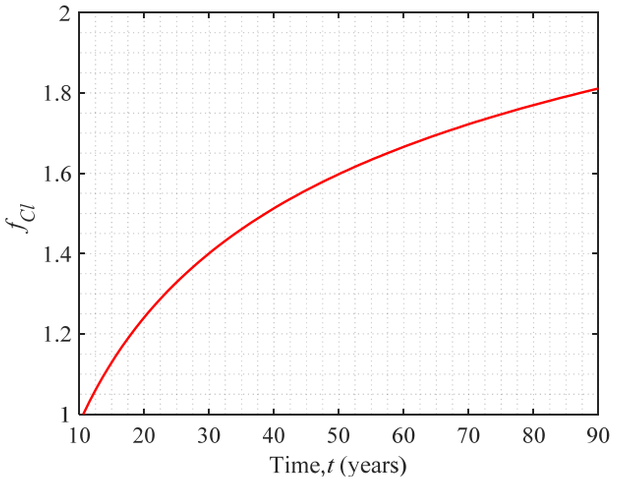

Figure 4. Variation of the chloride factor, f_{Cl} over the time.

4 SEISMIC FRAGILITY UNDER CLIMATE CHANGE

In the past, little attention has been paid to the impact assessment of climate change on the seismic vulnerability of bridge structures. This section investigates the effect of climate change on the seismic behavior of deteriorating multispan continuous steel girder bridge located in South Carolina within Central and Southeastern US (CSUS). This study assumes the corrosion induced deterioration to be localized within the bridge columns, although other studies have underlined potential deterioration of other bridge components, such as bearings (Lindquist 2008).

4.1 *Bridge characteristics and modeling*

The general description of the geometric configuration of the bridge is given in Figure 5. The bridge consists of three spans of 25.10 m length and deck width of 9.53 m. The bridge has two bents, each bent with two columns of 3.93 m height. The column section is 914.4 mm in diameter with 12 #29 (25.58 *mm* diameter) rebars. The finite element modeling of the bridge is developed using OpenSees, following the recommendations by Nielson (2005). The model also considers the uncertainty of the modeling parameter, i.e. yield strength of steel and concrete, bridge component behavior, mass, damping, loading direction. The uncertainty of these parameters and their probability distributions are adopted in this study from Nielson (2005). For nonlinear time history analysis, the two synthetic suites of ground motions developed by Wen & Wu (2001) and Rix & Fernandez (2004) are used to evaluate the bridge seismic performance as adopted by other researchers in the past for bridges in CSUS (Nielson 2005, Padgett 2007).

4.2 *Climate change scenario and environmental conditions*

This study considers three scenarios for vulnerability evaluation: without climate change, expected climate change scenario and pessimistic climate change scenario. Bastidas-Arteaga et al. 2010 defined these scenarios for a period of 100 years as a reference period. For expected scenario, the temperature and relative humidity increases up to 2.5 °C and 5% from reference values, while for the pessimistic scenario, the change in temperature and relative humidity increases up to 6.5 °C and 10 % respectively. For the considered case study bridge location (Charleston, South Carolina, USA), the initial environmental conditions i.e. temperature and relative humidity are assumed to be 19 °C and 73% (see Figure 6) as per past recorded data (U.S. climate data). Figure 7 illustrates the impact of these different conditions on the corrosion rate. The modeling parameters associated with the corrosion initiation time calculated as 10.63 years using Equation 10, can be found in Duracrete (2000) and Choe et al. (2008).

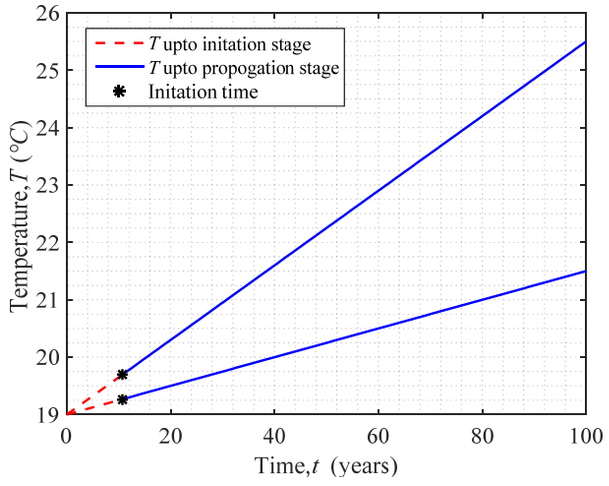

Figure 6. Increase in temperature for two scenarios (expected and pessimistic) along the service life (100 years) of the bridge.

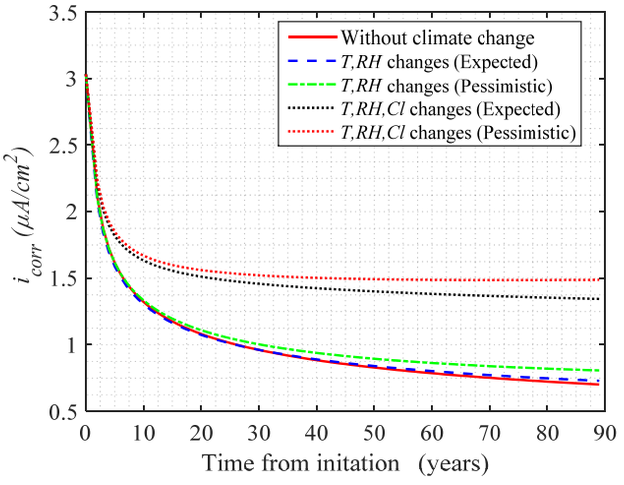

Figure 7. The corrosion rate for the considering case studies.

4.3 *RC bridge column deterioration*

4.3.1 *Loss of reinforcing steel area*

As a consequence of time-dependent corrosion of the RC column, the area of steel bars reduce throughout the lifetime of the bridge. The area loss of reinforcing steel is computed for different climate change cases assuming uniform time-dependent corrosion deterioration model along with a coefficient of variation (COV) of 0.2.

4.3.2 *Reduction in cover concrete strength*

The cracking of concrete cover is caused by the internal tensile forces from the accumulation of expansive rust products. The internal strength is generated as a result of expansive rust products and it leads to various problems. For instance, the formation of cracks leads to an acceleration of corrosion rate and a reduction in the steel cross-section. Furthermore, it may cause a loss in the structure ductility and a reduction in the concrete cross-sectional area (Rao et al. 2016). The model used to estimate the reduction in cover strength is adopted from Rao et al. (2016) and can be expressed as:

$$f_{co}^{*}(t) = \frac{f'_{co}}{1 + \dfrac{0.31416\ \varepsilon_{co} n_{bars}\left[D_{in} - D(t)\right]}{D_{col}}} \tag{18}$$

where f'_{co}, ε_{co} are the peak compressive stress and its corresponding strain respectively, n_{bars} is the number of bars, D_{col} is the undamaged column width, $D(t)$ is the diameter of corroded steel bars and D_{in} is the initial diameter of the steel bars. Details on the reduction in cover strength and the definitions of theses parameters can be found in Rao et al. (2016). The results show a significant decrease in cover concrete strength up to 80% for the time-dependent corrosion model, increasing to 82.7% when temperature and humidity effects are considered and up to about 88% when the influence of chloride concentration is accounted.

4.4 *Seismic fragility of case-study bridge columns under varying case-study conditions*

The seismic fragility curves for bridge columns are developed considering the same approach as mentioned in Nielson & DesRoches (2007). This research focused on estimating the seismic fragility curves for bridge column only, while leaving impact assessment

of climate change on bearings and overall bridge system as future work. To carry out the probabilistic analysis, first nonlinear time history analysis is conducted to develop probabilistic seismic demand models are estimated using linear regression. These demand models are compared with the lognormal limit state capacities of the column for different damage state, i.e. slight, moderate, extensive, and complete, to develop seismic fragility curves as (Nielson & DesRoches 2007):

$$P\left[DS > ds \middle| IM \right] = \Phi\left[\frac{\ln(IM) - \lambda}{\zeta} \right] \quad (19)$$

where $P\left[DS > ds \mid IM \right]$ is the conditional probability of exceeding damage state (DS) for given intensity measure of ground motion (IM) that is taken as peak ground acceleration (PGA), λ and ζ are the natural logarithm of the median IM value and the dispersion parameter for the bridge component fragility, and $\Phi[\cdot]$ is the standard normal probability integral.

Addressing the present purpose, the vulnerability of the bridge under a multi-hazard threat scenario considering earthquake hazard, aging and deterioration, and global warming due to climate change is evaluated. The seismic fragility curves are developed for six different scenarios listed as follows:

1. As-built (no corrosion).
2. Time-dependent (t) corrosion only (No impact of T, RH, Cl concentration)
3. Time, T and RH (Expected scenario).
4. Time, T and RH (Pessimistic scenario).
5. Time, T, RH, Cl concentration (Expected).
6. Time, T, RH, Cl concentration (Pessimistic).

For the above scenarios, Figure 8 shows the seismic fragility curves at 100 years for the case-study bridge column corresponding to the complete damage state. A preliminary review across all cases and damage states reveals similar dispersions for fragility estimates. Consequently, median estimates are used as an indicator to represent the impact of time-dependent aging (t), temperature (T), relative humidity (RH) and Cl concentration on the fragility estimates. For instance, the results reveal that the median PGA decreases by approximately 13.82 % due to aging compared to pristine conditions. This percentage decreases further to 17.08% if the effect of T and RH are considered according to the expected scenario and to 17.52% for the pessimistic scenario. When considering the effect of Cl concentration in conjunction with T and RH, the reduction in the medians emerge as 19.48% and 20.24% for the expected and pessimistic scenarios, respectively. These results underline the criticality of accounting for the impact of climate change and increasing chloride concentration on the seismic fragility of aging bridge structure.

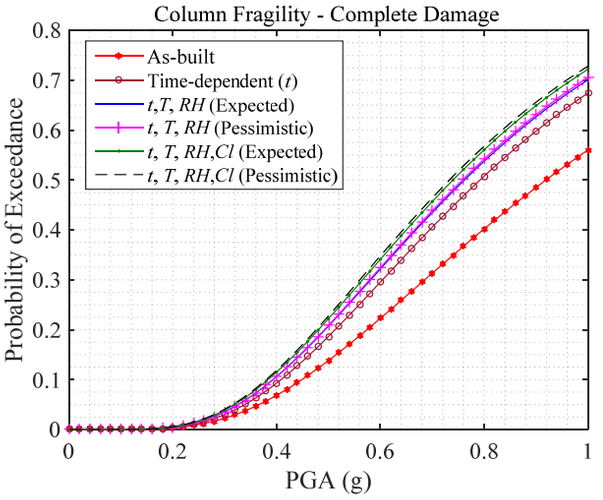

Figure 8. Seismic fragility curves of the bridge columns for different climate change scenarios.

5 CONCLUSIONS

This paper provides a framework to evaluate the vulnerability of highway bridges under a multi-hazard threat scenario considering earthquake hazard, corrosion deterioration, and global warming due to climate change. First, the influence of temperature, relative humidity and the chloride concentration on the rate of corrosion is investigated. Results indicate sensitivity of initial corrosion rate to temperature and relative humidity underlining the need to incorporate these effects within corrosion rate models. Consequently, improved and updated corrosion rate models are used in conjunction with two climate change (expected and pessimistic), to estimate the effect of temperature and humidity on bridge deterioration and subsequent fragility.

For a case-study multispan continuous steel girder bridge located in marine–splash exposure condition within South Carolina, USA a 6.6% reduction in the steel bars diameter is observed for time-dependent aging alone. This percentage further reduces to 8.1% and 12.4% when the effects of climate change (temperature and relative humidity variation), and increasing chloride concentration along with climate change are respectively considered for the pessimistic scenario. One should note that these percentage changes are sensitive to the initial conditions of temperature and relative humidity. In addition to rebar area reduction as a primary manifestation of corrosion deterioration, this study also considers change in cover strength as a secondary effect.

Finally, the impact of aging and climate change on the column seismic performance at the different damage states for the considered case-study is illustrated. For the different climate change scenarios and chloride concentration levels, this study develops seismic fragility curves following a full probabilistic analysis of the case-study bridge that considers uncertainty in ground motions, corrosion parameters, and material and modeling parameters. Results reveal substantial impact of climate change and subsequent increase in chloride concentration across all damage states. For instance, after 100 years of chloride exposure, the median estimates for complete damage state decreases by 13.82% (compared to pristine conditions) due to

time-dependent aging alone. Consideration of temperature and relative humidity effects reveals a further decrease to 17.08% and 17.52% for the expected and pessimistic scenarios respectively. Lastly, considering climate change effects along with increasing chloride concentration leads to a reduction in the median estimates by as large as 19.48% and 20.24% for the expected and pessimistic scenarios, respectively.

ABSTRACT: In this study, using the weigh-in-motion (WIM) data collected from an operational long-span urban highway bridge structural heath monitoring (SHM) system located in Wuhan, China, the statistical characteristics of gross vehicle weight (GVW), axle weights and spacing of axles are obtained, and then a statistical fatigue traffic load model for urban highway bridges is also proposed based on the Miner linear accumulated damage hypothesis and the effective fatigue damage principle. The proposed statistical fatigue traffic model can be used for bridge fatigue design and assessment. On the basis of the types of vehicles, (1) Considering the double or multi-modal distribution characteristics of the traffic GVW, the statistical parameters of the double or multi-modal Gauss distribution are estimated using expectation maximization (EM) algorithm; (2) Considering the single or multi-modal distribution characteristics of the traffic axle weight, the statistical parameters of the single or multi-modal Gauss distribution are estimated using EM algorithm; (3) The expectation and standard deviation of the spacing of axles are directly calculated; (4) Considering the statistical characteristics of the weight and spacing of axle, a statistical fatigue traffic load model for urban highway bridges is proposed based on the Miner linear accumulated damage hypothesis and the effective fatigue damage principle.

1 INTRODUCTION

1.1 *Introduction of WIM and traffic load model*

In the past decades, the structural health monitoring (SHM) techniques have been developed and applied in civil infrastructures such as bridges. As the important part of the bridge SHM systems, the weigh-in-motion (WIM) systems are normally adopted as the tool for surveying the condition of the traffic and for formulating the traffic load model (Jacob 2005, Jacob et al. 2010).

The bridge vehicle load model can be normally divided into two types, i.e., the vehicle load model for calculating the traffic load effect of bridge and the fatigue vehicle load model for fatigue analysis of bridge structures (Getachew and Obrien, 2007, O'Connor and Eichinger, 2007). Furthermore, the vehicle load model can be divided into two categories. The first type of models belong to the static model, which bases on the statistical analysis of the traffic load data. Based on the measured traffic load data, the key parameters of the traffic load model such as the gross vehicle weight (GVW), the axle weight, the speed of vehicle and the spacing of vehicle are theoretically analyzed and studied. The distribution functions of these parameters are obtained, and then the vehicle load models for specific regions are established. The second type of model, which bases on the probability and stochastic theory. By simulating the construction of the corresponding dynamic random traffic flow and the load effect analysis, the vehicle load models, which considers versatile parameters, such as the impact of vehicle lateral position, the random characteristics of the vehicle parameters are established.

In this paper, using the WIM data collected from the Wuhan Junshan Yangtze River Bridge SHM system located in Wuhan, China, the composition of vehicles, the statistical characteristics of the GVW, the axle weights and the axle spacing are obtained. Then the maximum value of the traffic load for the designated reference period are deduced. At last, a statistical fatigue traffic load model for urban highway bridges is also proposed based on the Miner linear accumulated damage hypothesis and the effective fatigue damage principle, which are suitable for the fatigue analysis of the bridge structures.

2 STATISTICAL TRAFFIC LOAD MODEL BASED ON MULTI-MODAL GAUSSIAN DISTRIBUTION

2.1 *Theoretical background: Multi-modal Gaussian distribution*

For any n time moments $t_1, t_2, \cdots, t_n$, the random variables $X(t_1), X(t_2), \cdots, X(t_n)$ obey the joint normal distribution, then the random process $X(t)$ is the Gaussian process with a joint probability density function,

$$f_X = \frac{1}{\sqrt{2\pi} \times \sqrt{|C_X|}} \exp\left[-\frac{(x-\mu_X)^T}{2C_X}(x-\mu_X) \right] \quad (1)$$

where μ_X is the mean matrix, C_X is the covariance matrix. The joint probability density function (PDF) of this Gaussian random process is determined by its mean $\mu_X(t_i), (i=1,2,\cdots,n)$ and covariance $C_X(t_i, t_j), (i, j=1,2,\cdots,n)$.

In cases where each of the underlying random variables $X(t_1), X(t_2), \cdots, X(t_n)$ is continuous, the outcome variable $X(t)$ will also be continuous and its joint PDF is sometimes referred to as a mixture PDF. The cumulative distribution function (CDF) and the PDF if it exists can be expressed as a convex combination (i.e. a weighted sum, with non-negative weights that sum to 1) of all individual CDFs and PDFs. These individual distributions that are combined to form the mixture distribution are called the mixture components, and the weights associated with each component are called the mixture weights. The number of components in mixture distribution is often restricted to being finite.

For a mixture distribution which is composed of n components, the weights of the components are

$$\alpha_1, \alpha_2, \cdots, \alpha_n, \sum_{i=1}^{n} \alpha_i = 1 \quad (2)$$

The PDFs of the components are $f_1(x), \cdots, f_n(x)$ and the joint PDF of the mixture distribution is

$$f(x) = \alpha_1 f_1(x) + \alpha_2 f_2(x) + \cdots + \alpha_n f_n(x) \quad (3)$$

When each of the individual distributions $f_1(x), \cdots, f_n(x)$ is Gaussian distribution,

$$f_i(x) = \frac{1}{\sqrt{2\pi}\sigma_i} \exp\left(-\frac{(x-\mu_i)^2}{2\sigma_i} \right), (i=1,2,\cdots,n) \quad (4)$$

Therefore, the mixture distribution $f(x)$ is also a Gaussian distribution.

2.2 *Data pre-processing*

According to the "Highway Law" and the relevant laws or regulations of China, the axle weight of vehicles travelling on the road should meet the requirements of the road engineering technical standard, i.e., "Limits of dimensions, axle load and masses for road vehicles (GB1589-2004)", and the rules of the Ministry of Communications of China, i.e., "Guidelines for toll collection on toll roads". In addition, considering the overload phenomenon of different vehicles in the actual road operational condition, a few rules have been applied for removing the abnormal WIM data, which are listed as follows,

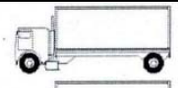
(1) To exclude the vehicles with GVW less than 8kN or greater than 1500kN.

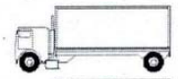
In the provisions of the "Guidelines for toll collection on toll roads", the GVW of six-axle trucks is limited below 490kN. However, the GVW of the actual operational vehicles are normally overloaded 200%, i.e., about 1000kN. On this basis, extra 50% overload is considered. So the limit for the vehicles with GVW greater than 1500kN is made.

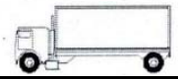
(2) To exclude the vehicles in which the number of axles are not two, three, four, five and six. This is because that the proportion of the other axle number are very scare in China.

(3) To exclude the vehicles with the axle weight less than 3kN or greater than 720kN.

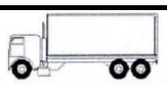
In the provisions of the "Guidelines for toll collection on toll roads", the axle weight of six-axle trucks is limited below 240kN. However, the axle weight of the actual operational vehicles are normally overloaded 200%, i.e., about 48kN. On this basis, extra 50% overload is considered. So the limit for the vehicles with axle weight greater than 720kN is made.

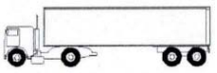


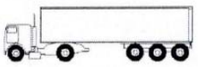




(4) To exclude the vehicles in which the number of axle is not identical with the type of the vehicle.







(5) To exclude the vehicles in which the sum of the axle weight is not identical with the GVW.

2.3 *Statistical analysis of WIM data*

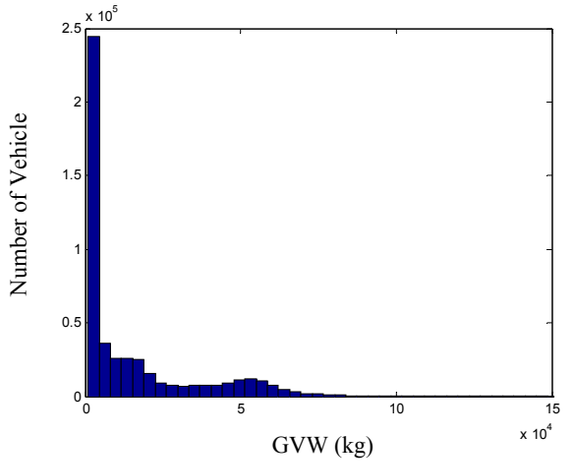
The vehicle WIM data of the Wuhan Junshan Yangtze River Bridge on August 2013 are collected and analyzed. The statistical results of the composition of the vehicles are shown in Table 1.

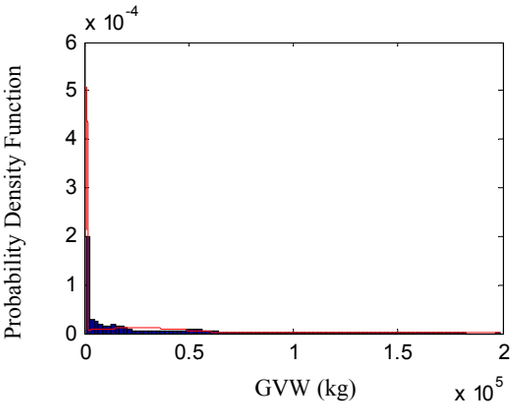
Table 1. The composition of the vehicles.

Models	Illustration	Numbers	Proportion
Two-axle Mini-bus		305481	0.517
Two-axle truck		89942	0.152
Two-axle bus		9758	0.017

Three-axle truck		35331	0.060
Four-axle truck		27826	0.047
Five-axle truck		7023	0.012
Six-axle truck		115120	0.195

The GVW histogram of the vehicles is shown in Figure 1. It can be obviously seen that the distribution of the GVW of vehicles exhibits multi-peak characteristics. The peak values of the vehicle are distributed in the ranges at 2,000 kg - 8,000 kg, 10,000 kg - 24,000 kg, 24,000 kg - 66,000 kg, and three obvious peaks are concentrated in 3,000 kg, 16,000 kg and 54,000 kg. The proportion of the light vehicles less than 6,000 kg are more than 60%.





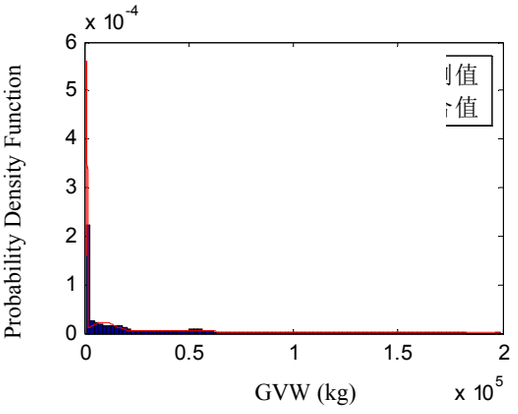


Figure 1. The histogram of GVW.

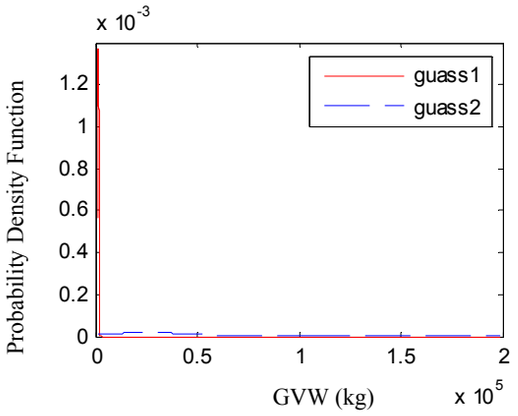
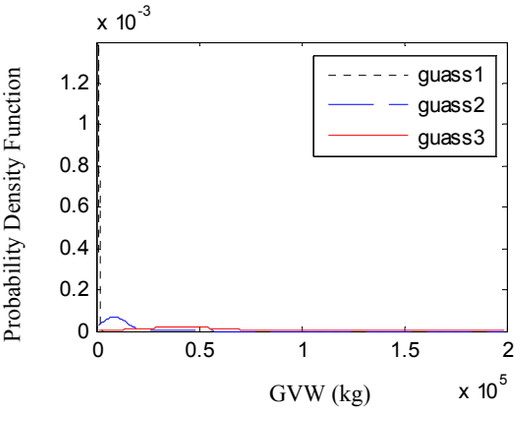
Normally, the mixture Gaussian or Weibull distribution model are used to fit the probability density function of the GVW of vehicles. There are several ways to solve the mixture distribution model parameters, such as the nonlinear least squares fitting method, which solves the model parameters of a multi-modal mixture Gaussian distribution cumulative distribution (Mei et al. 2004, Guo et al. 2011, Lan et al. 2011). In this study, the expectation maximization (EM) algorithm is adopted to fit the PDFs of the double and triple Gaussian distribution for the GVW of the vehicles, as shown in Figure 2. Compared with the double and triple Gaussian distributions, it can be seen that the triple Gaussian distribution is more effective for fitting the PDF of the GVW, and the distribution can be verified by the K-S check with 95% guarantee level.



(a) Double mixture Gaussian distribution



(b) Triple mixture Gaussian distribution

Figure 2. The fitted probability density function (PDF) for the GVW of the vehicles using mixture Gaussian distribution.

(a) Double Gaussian distribution

(b) Triple Gaussian distribution

Figure 3. The components of the double and triple Gaussian distribution.

The components of the double and triple Gaussian distribution are shown in Figure 3 and the corresponding weight, mean and standard deviations are listed in Table 2. As shown in Figure 3, it is clearly seen that the shape of the components of the double and triple Gaussian distribution are different. For the double Gaussian distribution, the means and the standard deviations are 11093 kg, 44026 kg and 5639 kg, 20245 kg, respectively. For the triple Gaussian distribution, the means and standard deviations are: 9852 kg, 31622 kg, 46110 kg and 4767 kg, 16590 kg, 23499 kg, respectively.

Table 2. Fitted parameters of the mixture Gaussian distribution.

Distribution parameter	Weight α	Mean μ	Standard deviation σ
Double	0.5030	11093	5639
	0.4970	44026	20245
Triple	0.3911	9852	4767
	0.3084	31622	16590
	0.3005	46110	23499

The measured cumulative distribution function (CDF) and the fitted CDF by using the triple Gaussian distribution are shown in Figure 4. As shown in Figure 4, the fitted curve is almost the same as the measured curve. It shows that the triple Gaussian distribution can be used to fit the distribution of the GVW of the vehicles.

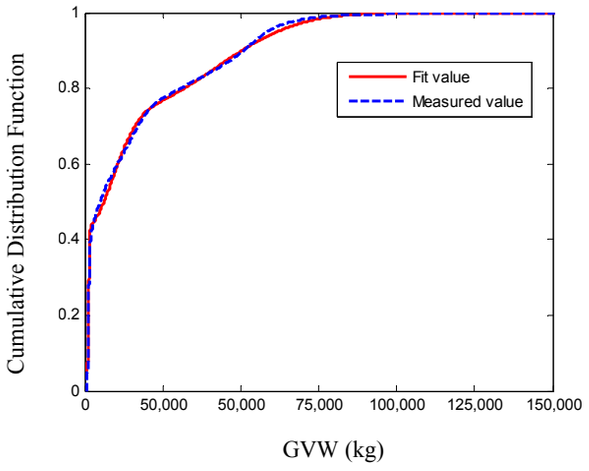


Figure 4. The measured and fitted cumulative distribution function (CDF).

3 ESTIMATION OF THE VEHICLE LOAD EXTREME BASED ON EXTREME VALUE TYPE I DISTRIBUTION

3.1 *Principles of extreme estimation using extreme value type I distribution*

According to the provision of the "General Specification for Design of Highway Bridges and Culverts (JTG D60-2015)", the bridge design reference period is 100 years in China. In this study, it is assumed that the maximum value of the vehicle load in one day can be used to represent the maximum value of the vehicle load in one year. Therefore, a 100-day WIM data are collected and used for the estimation of the vehicle load extreme for bridges in the design reference period. As we known, the composition of the vehicles has very obviously regional characteristics. It is more reasonable to estimate the extreme of the vehicle load based on the measured WIM data for assessing the conditions of bridges.

Many researches have shown that the probability distribution of the vehicle load can be represented by a variety of distributions. The extreme value type I distribution can be a better description.

If the amount of data is big enough and defining X_M as the maximum of a set of random variables X, then X_M can be taken as a new random variable. When $n \to \infty$, it can be proved that the distribution of the random variable X_M is the exponential distribution in the condition that the random variable X obeys the exponential distribution, the normal distribution or the Weibull distribution.

$$F_M(x) = \lim_{n\to\infty}\left[F(x)\right]^n = exp\left\{-exp\left[-\alpha(x-\beta)\right]\right\} \tag{5}$$

where α and β are the distribution parameters of the extreme value type I distribution. The mean and the standard deviation are

$$\begin{aligned} \mu_x &= 0.57722/\alpha + \beta \\ \sigma_x &= 1.28255/\alpha \end{aligned} \tag{6}$$

The corresponding PDF $f(x)$ and the CDF $F(x)$ are

$$f(x) = \alpha e^{-\alpha(x_e-\beta)} e^{-e^{-\alpha(x_e-\beta)}} \tag{7}$$

$$F(x) = \exp(-\exp(-y)),\ y = \alpha(x_e - \mu) \tag{8}$$

Where α and μ are parameters which can be represented as the mean value μ_X and the standard deviation σ_X

$$\mu = \mu_X - 0.5772/\alpha \tag{9}$$

$$\alpha = \pi/(\sqrt{6}\sigma_X) \tag{10}$$

Eqs. (9) - (10) can be changed as the following form,

$$y = -\ln(-\ln(F(x_e))) \tag{11}$$

$$x_e = \mu + (1/\alpha)y \tag{12}$$

3.2 *Estimation of the extreme of the vehicle load*

Based on the Gumbel extreme value theory and the assume that the observed extreme values are independent of each other, it is possible to obtain,

$$F(T = t_0) = F^n(T = t_d) \tag{13}$$

where $F(T = t_0)$ is the extreme distribution of the year, $F(T = t_d)$ is the extreme distribution of the design reference period, $t_d = 100$ years.

Based on the Eq. (7) to Eq. (13), one can obtain,

$$\exp\left\{-\exp\left[-y(T = t_d)\right]\right\} = \left\{\exp\left\{-\exp\left[-y(T = t_0)\right]\right\}\right\}^m \tag{14}$$

Using the Eq. (8) and Eq. (14), one can obtain the following equations,

$$\frac{1}{\alpha(T = t_d)} = \frac{1}{\alpha(T = t_0)} \tag{15}$$

$$\mu(t = t_d) = \mu(t = t_0) + \frac{1}{\alpha(T = t_0)}\ln\left(\frac{t_d}{t_0}\right) \tag{16}$$

As we know $t_0 = 1$, $t_d = 100$, if $\mu_d = \mu(t = t_d)$ and $\alpha_d = \alpha(T = t_d)$ are obtained, the extreme value distribution can be determined as follow,

$$F(x_e) = \exp(-\exp(-y)) \tag{15}$$

The determination of μ_d and α_d can be obtained by using the following steps,

(1) Based on the rules on Section 2.1, to remove the unreasonable WIM data.

(2) To extract the daily extreme value of the processed data and arrange them from small values to large value, then an arrangement of extreme data $\{x_i\}, (i = 1, 2, \cdots, n)$ is obtained,

(3) To calculate the non-exceeding probability of each extreme load $\{P_i\}, (i = 1, 2, \cdots, n)$ and to define a new variable $\{y_i\}, (i = 1, 2, \cdots, n)$

$$P_i = i/(n+1), (i = 1, 2, \cdots, n) \tag{16a}$$

$$y_i = -\ln(-\ln P_i), (i = 1, 2, \cdots, n) \tag{16b}$$

(4) Setting $\{y_i\}, (i = 1, 2, \cdots, n)$ as the horizontal axis and $\{x_i\}, (i = 1, 2, \cdots, n)$ as the vertical axis, a fitted straight line is obtained by using the linear least squares method. The slope of the straight line $1/\alpha_0$ is and the intercept is μ_0 when $y = 0$.

(5) Then the parameters μ_d and α_d can be determined by substituting the values of μ_0 and α_0 into Eqs. (15) - (16).

(6) At last, the extreme distribution of vehicle load in the design reference period can be obtained by substituting the values of μ_d and α_d into Eq. (8).

Following the above steps, the parameters are calculated by using the WIM data, i.e., $\alpha_0 = \alpha_d = 4.7834 \times 10^{-4}$, $\mu_0 = 1.7638 \times 10^5$ and $\mu_d = 1.8601 \times 10^5$. The estimated CDF of vehicle load is shown in Figure 5.

Taking the value at the 0.95 locus of the cumulative distribution function (CDF) curve $F_{X,\max}(X)$, the estimated maximum value of vehicle load in the design reference period is $x_{0.95} = 1922.2$ kN.

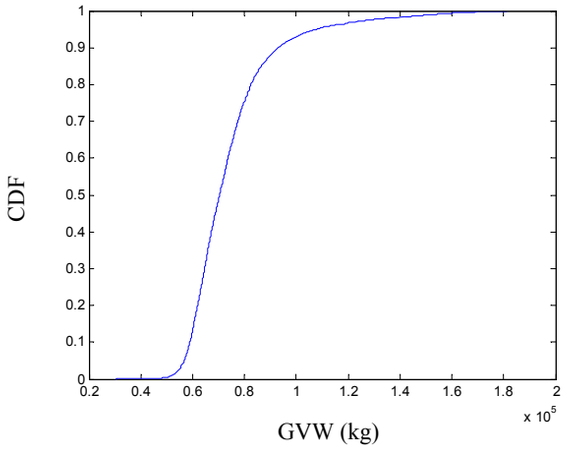

Figure 5. The estimated cumulative distribution function (CDF).

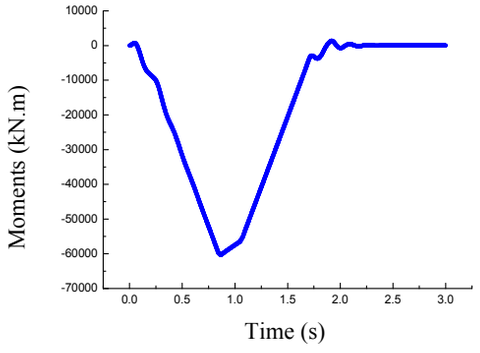
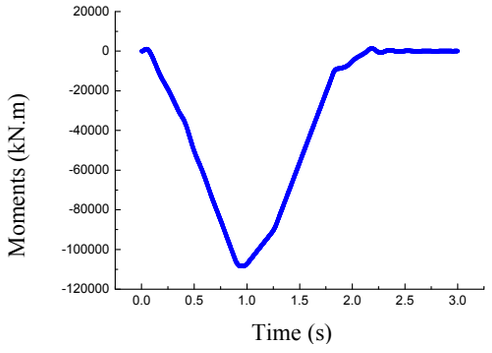


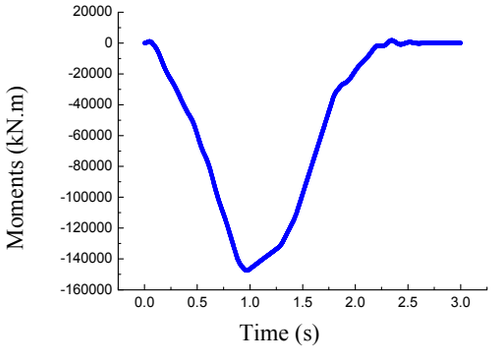
4 FATIGUE VEHICLE LOAD MODEL BASED ON WIM DATA

4.1 *Finite element analysis of the number of stress cycle*

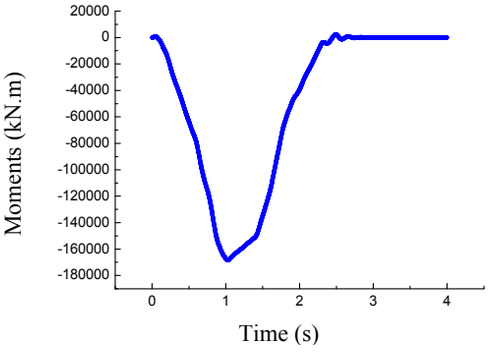


In this study, a finite element (FE) simple support beam bridge model with span of 32 meters is established by using ANSYS software. The vehicle load is simplified as a set of concentrated forces and applied to the simply supported girder bridge model. By adopting the move load method, the moment response time-history curves at the mid cross-section of this simply supported beam are shown in Figure 5. In these calculation, the vehicle speed is measured according to the actual condition. The average vehicle speed of different types of vehicle are shown in Table 3 and the calculation time interval is 0.01s.

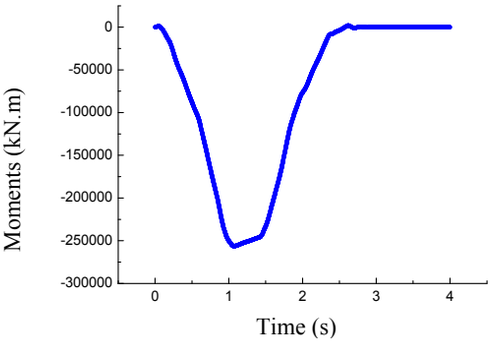
Table 3. The average vehicle speed of different types of vehicle.



Axle type	speed（km/h）
Two axles	69.26
three axles	64.84
Four axles	65.99
Five axles	67.04
Six axles	64.99



(a) Two-axle vehicle



(b) Three-axle vehicle

(c) Four-axle vehicle

(d) Five-axle vehicle

(e) Six-axle vehicle

Figure 5. The mid-span moment response time-history curves of a 32m simply supported beam under different types of vehicle.

As shown in Figure 5, the bending moment time-history curves during the passing of each vehicle have only a big moment cycle and some very small cycles, no matter how many axles the vehicle have. Due to the effect of the dynamic effect, the maximum value of the moment is not generated when the vehicle reaches the mid-span, but is slightly delayed. In addition, for this 32m simple supported beam bridge, when the axles pass, the curve of the bending moment curves are almost the same, but the values are different, which shows that the bending moment curves are not affected by the wheelbase and the axle weight distribution. Therefore, for this 32m simply supported beam bridge, the number of fatigue stress cycles caused by each axle can be simplified to 1, and the maximum bending moment or stress amplitude can be calculated according to a set of concentrated forces acted on the most unfavorable position of the influence line.

4.2 *Fatigue damage analysis of vehicles with different axles*

Only considering the largest moment induced by the six-axle vehicles, the formula of the equivalent stress amplitude is listed as follows,

$$S_{eq}=\left(\sum_{i=1}^{k}n_i S_i^{\ m}\Big/N\right)^{\frac{1}{m}} \tag{17}$$

where S_i is the magnitude of the stress amplitude decomposed by the rain flow counting method; n_i is the magnitude of the actual magnitude of the stress amplitude of S_i; N is the total number of stress amplitude decomposed by rain flow counting method; m is a parameter determined by the S-N curve. For steel structures, m is normally taken as 3.

The equivalent moment is calculated as follows,

$$M_D=\left(\sum f_i \bullet (M_{ri})^3\right)^{1/3} \tag{18}$$

where M_D is the equivalent moment, and f_i is the frequency where the moment M_{ri} appears.

In order to compare the contribution of each axle to structural fatigue damage, the damage ratio D_r can be used to represent the contribution rate of each type of vehicle to structural fatigue damage. Here the damage ratio is the ratio of the damage caused by the axle to all the car to the structure which indicates the cumulative damage caused by fatigue. The calculation formula is listed as follows,

$$D_r=\frac{D_i}{D_{all}}=\frac{n_i S_i^m}{n_{all}S_{all}^m}=\frac{n_i M_i^m}{n_{all}M_{all}^m} \tag{19}$$

where D_i is the cumulative damage caused by the vehicles with i axles, D_{all} is the cumulative damage caused by all vehicles, n_i is the number of cycles caused by the vehicles with i axles, n_{all} is the number of cycles caused by all vehicles, S_{Di} is the stress amplitude caused by the vehicles with i axles, S_{all} is the stress amplitude caused by all vehicles. Based on the rules of the AASSTO specification about the fatigue details, m = 3 is adopted in this article.

The equivalent bending moment of the 32m span simply supported beam and the damage ratio of vehicles with different axles are shown in Table 4.

It should be noted that the composition of the vehicles listed in Table 4 is different with the ones in Table 1. The reason is that all vehicles below 3 tons are not considered for fatigue analysis. As shown in Table 4, although the proportion of vehicles with two-axle is 29.78%, the damage ratio to the bridge is only 10.91%. On the contrary, although the proportion of vehicles with six-axle is 44.53%, the damage ratio to the bridge is 68.89%. It is seen that the six-axle vehicles are the main factor for the fatigue damage to the bridge. Therefore, the six-axle vehicle is adopted as the prototype of standard fatigue vehicle.

Table 4. The equivalent bending moment and the damage ratio of vehicles with different axles.

Number of axles	Proportion	Amplitude of moment (kN•m)	Cycles	Damage ratio
Two	29.78%	61.06	76155	10.91%
Three	12.82%	109.53	32798	8.43%
Four	10.37%	148.49	26523	9.24%
Five	2.50%	169.12	6383	2.53%
Six	44.53%	257.81	113893	68.89%
Total	1		255752	1

4.3 *The standard fatigue vehicle model*

The prototype of standard fatigue vehicle is shown in Figure 6. If the GVW of this vehicle is W, then the axle weights are 0.12W, 0.14W, 0.2W, 0.2W, 0.17W and 0.17W, respectively. The wheelbases are 3.2m, 1.5m, 7.0m, 1.3m and 1.3m, respectively.

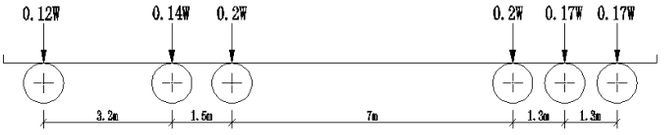


Figure 6. The prototype of standard fatigue vehicle.

The equivalent weight of the standard fatigue vehicle can be calculated through the superposition of each axle weight by using Eq. (20).

$$W_{ej}=\left[\sum\left(f_i W_i^3\right)\right]^{\frac{1}{3}} \tag{20}$$

Where W_{ej} is the equivalent weight of the standard fatigue vehicle; W_i is the equivalent weight of the vehicle with i axles; f_i is the frequency ratio of the vehicle with i axles. Based on the WIM data, the equivalent weight of the standard fatigue vehicle is 36216 kg. Therefore, the axle weight has been allocated by using the ratio of the prototype of standard fatigue vehicle. For convenience of use, the equivalent weight and the axle weight has been slightly adjusted. Then the standard fatigue vehicle model for the urban highway bridges located in Wuhan, China is proposed and shown in Figure 7.

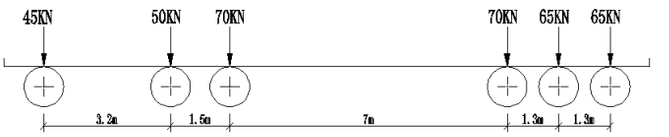

Figure 7. The standard fatigue vehicle model for the urban highway bridges located in Wuhan, China.

5 CONCLUSIONS

In this paper, based on the WIM data collected from the Wuhan Junshan Yangtze Bridge, the mixed Gaussian distribution model is adopted to fit the probability density function of the GVW. The results show that the triple Gaussian distribution is more effective for fitting the PDF of the GVW, and the distribution can be verified by the K-S check with 95% guarantee level. Based on the extreme value type I distribution, the estimated maximum value of vehicle load in the design reference period is 1922.2 kN. Based on the fatigue analysis on a 32m simple supported beam bridge, a six-axle standard fatigue vehicle model for the urban highway bridges located in Wuhan, China is proposed.

Acceleration Response Analysis of a Long-span Steel Arch Bridge Subjected to High-speed Trains Integrating SHM Data

H.L. Li, Y.L. Ding, H.W. Zhao & S.T. Hou
Key Laboratory of C&PC Structures of the Ministry of Education, Southeast University, Nanjing 210096, China

ABSTRACT: In recent years several long-span bridges have been constructed and put into service in China's high-speed railway lines. These bridges usually cross the major rivers of China which serve as vital shipping channels. The long-span structure becomes the superior and sometimes even sole scheme to carry high-speed tracks over the rivers without impacting the water transportation at the bridge site. High-speed trains require stable and smooth geometries of the tracks on long-span bridges to achieve successful and safe passages. Nevertheless, the above mentioned track geometries can be threatened by multiple stressors, e.g., high-speed trains, wind, temperature, among others. Structural health monitoring (SHM) systems have been applied to the long-span bridges, aiming to collect real-time information about both the stressors and structure responses. This information can be used to investigate the performance of bridge structures, and eventually to ensure the running safety of high-speed trains. In this context, the present paper examines the acceleration responses of a long-span steel arch bridge, i.e., the Nanjing Dashengguan Yangtze River Bridge, under operating high-speed train loads. This unique long-span railway bridge and its SHM system are introduced. A coupled dynamic model of the high-speed vehicle and bridge structure system is subsequently developed. Acceleration responses at the typical locations resulting from the coupled dynamic analysis are compared to the SHM data. It is found that at several specific velocity values the maximum accelerations of the bridge produce respective peaks through the parametric study on train speeds. This interesting phenomenon calls for more detailed investigation on the concerned topic in the future.

1 INTRODUCTION

High-speed rails, as a fast, safe, and comfort transportation means, have been constructed more and more in the worldwide. Taking China as an example, a high-speed railway network with the total mileage of about 20,000 km has been completed by the end of 2015. This network connects every city that has a population larger than half million in the middle and eastern China. High-speed rails are currently extending to the western mountainous and eastern coastline areas, where railway lines have to cross some deep valleys and/or broad waterways. Consequently, more and more long-span bridges have been constructed and put into service in high-speed railway lines.

These long-span bridges are required to provide sufficient rigidity to maintain stable and smooth geometries of the tracks, since the high-speed trains are sensitive to the changes of track geometries. Nevertheless, the above mentioned track geometries can be threatened by multiple stressors, including high-speed trains, wind, temperature, and so on. Structural health monitoring (SHM) can serve as an effective tool for collecting real-time information about both the stressors and structure responses (Ko and Ni 2005; Catbas et al. 2008; Feng and Feng 2016). This information can be utilized to evaluate the performance of bridges (Leander et al. 2010; Magalhães et al. 2012). Moreover, online early-warnings may also be realized based on the data obtained from SHM (Ding et al. 2017).

On the other hand, SHM systems can provide reliable calibrations for the theoretical and/or numerical models. Although field measurements are normally considered as real reflections of stressors and load effects, numerical methods play a key role in investigating the scenarios that have not been included in SHM. Dynamic responses of the railway bridges subjected to high-speed trains can be computed by establishing coupled train-bridge model (Li et al. 2015, 2016, 2017). Time histories of displacement and acceleration obtained from the numerical coupling model are subsequently used to assess the performance of bridges (Xia et al. 2012).

In this paper, a preliminary investigation is conducted on a unique long-span steel arch bridge for high-speed railways, i.e., the Nanjing Dashengguan

Yangtze River Bridge, with emphasis on acceleration responses. A coupled high-speed train and bridge system model is established to numerically characterize accelerations of the bridge deck. These computational results are compared with the measurements obtained from SHM. Some discussions are presented along with the acceleration results.

2 DASHENGGUAN YANGTZE RIVER BRIDGE AND SHM SYSTEM

2.1 *Bridge description*

The Dashenguan Yangtze River Bridge (see Fig. 1) is located in the southwest suburb area of Nanjing, crossing the longest river in China, the Yangtze River. The bridge is a continuous steel truss structure with six spans which are, respectively, 108 m, 192 m, 336 m, 336 m, 192 m, and 108 m (see Fig. 2). In particular, two largest spans of 336 m are constructed in terms of steel truss arch, allowing the navigation of huge ships with a 32 m clearance. The Dashenguan Yangtze River Bridge carries six railway tracks on three rail lines. They are, respectively, Beijing-Shanghai (B-S) high-speed railway line, Shanghai-Wuhan-Chengdu (S-W-C) railway line, and Nanjing Metro line S3. The steel arch cross-section and lane arrangement are shown in Fig.3. It is designed that high-speed trains in the Beijing-Shanghai high-speed railway line run through the bridge at the speed up to 300 km/h. The design load of the six tracks is more than 600 kN/m along the longitudinal direction of the bridge, which becomes the largest design load among high-speed railway bridges all over the world.

Figure 1. Photograph of the Dashengguan Yangtze River Bridge.

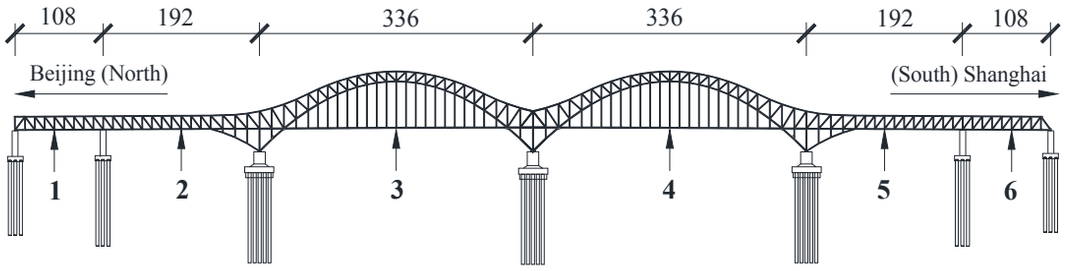

Figure 2. Span arrangement and acceleration monitoring cross-sections (Units: m)

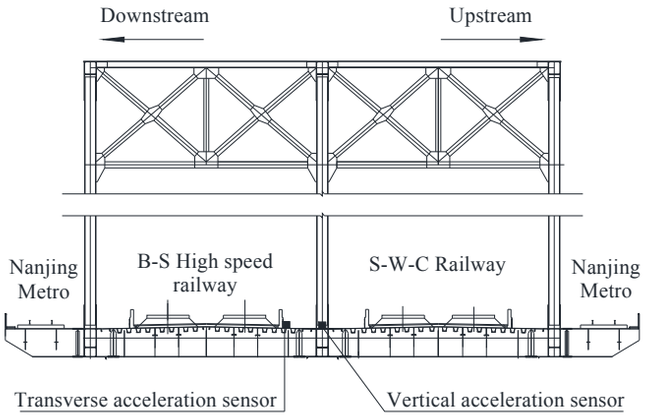

Fig. 3. Locations of the acceleration sensors

2.2 *Acceleration monitoring system*

A long-term SHM system was installed on the Dashengguan Yangtze River Bridge. In this monitoring system, acceleration sensors are employed to measure the dynamic responses of the bridge. The monitoring cross-sections associated with the bridge acceleration responses are shown in Fig. 2. Six cross-sections are instrumented, among which cross-section 1 is on the assisted span on the Beijing side, cross-section 2 is on the side span on the Beijing side, cross-section 3 is on the middle span on the Beijing side, cross-section 4 is on the middle span on the Shanghai side, cross-section 5 is on the side span on the Shanghai side, and cross-section 6 is on the assisted span on the Shanghai side. A vertical acceleration sensor is employed at cross-sections 1 and 6. A vertical acceleration sensor and a transverse one are employed at cross-sections 2, 3, 4 and 5. The locations of acceleration sensors in their monitoring cross-sections are further shown in Fig. 3. The sampling rate of the acceleration sensors is 200 Hz. In addition, Speedometers are also included in the SHM system on the Dashengguan Yangtze River Bridge to monitor the train speeds.

3 COUPLED TRAIN-BRIDGE SYSTEM MODEL

In order to simulate the dynamic acceleration histories of the Dashengguan Yangtze River Bridge under high-speed trains, a coupled train-bridge model is established to conduct numerical analysis. The coupled system model consists of a 3D train model, a 3D bridge model established through the direct stiffness method, and a wheel-rail interaction model.

3.1 *Train model*

High-speed trains running in the China's railway lines are usually composed of eight or sixteen vehicles. Herein, it is assumed that these vehicles are independent from each other. Each vehicle consists of a car body, two bogies, and four wheel-sets. These rigid-body components are connected by the primary and/or secondary suspension systems. The suspension systems are modeled as springs and dashpots. Each car body or bogie has five degrees of freedom (i.e., swaying, rolling, yawing, floating, and pitching); whereas each wheel-set has four degrees of freedom (i.e., swaying, rolling, yawing, and floating) (Li et al. 2016). Using the Lagrange's equation, the dynamic equation of motion of the vehicle can be expressed as

$$\mathbf{M}_v\ddot{\mathbf{X}}_v + \mathbf{C}_v\dot{\mathbf{X}}_v + \mathbf{K}_v\mathbf{X}_v = \mathbf{P}_v \qquad (1)$$

where $\mathbf{M}_v$, $\mathbf{C}_v$, and $\mathbf{K}_v$ are, respectively, the mass, damping, and stiffness matrices of the vehicle model, which are related to the dimensional and mechanical parameters of the vehicle (e.g., spring and damping coefficients of the suspension systems) and usually change with vehicle types; $\mathbf{P}_v$ is the vector of dynamic forces acting on the vehicle model, which is dependent on the adopted wheel-rail interaction model; and $\mathbf{X}_v$, $\dot{\mathbf{X}}_v$, and $\ddot{\mathbf{X}}_v$ represent, respectively, the displacement, velocity, and acceleration vectors.

3.2 *Bridge FE model*

For such a long-span arch bridge, finite elements can be an effective tool to formulate the equation of motion of the bridge. In the present analysis, a 3D FE model of the Dashengguan Yangtze River Bridge is established through the ANSYS software (see Fig. 4). In this model, BEAM188 elements are used to model the arch ribs, hangers, and stiffeners of the box girders. The crossbeams of box girders and floor slab are simulated with SHELL181 elements. There are a total of 59,760 nodes and 112,706 elements in the FE model. Frequencies and shapes of the fundamental modes of shape obtained from the FE model can be found in Zhao et al. (2016). The numerical modal parameters agree with the field test counterparts well.

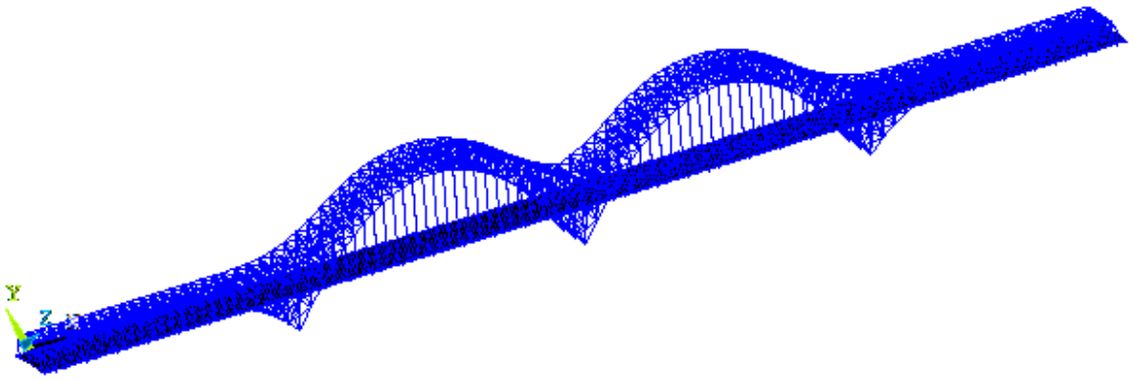

Figure 4. FE model of the Dashengguan Yangtze River Bridge

In this paper, the equation of motion of the Dashengguan Yangtze River Bridge is generated via the direct stiffness method, based on the above men-

tioned FE model. The bridge equation of motion can be written as

$$\mathbf{M}_b\ddot{\mathbf{X}}_b + \mathbf{C}_b\dot{\mathbf{X}}_b + \mathbf{K}_b\mathbf{X}_b = \mathbf{P}_b \quad (2)$$

where $\mathbf{M}_b$, $\mathbf{C}_b$, and $\mathbf{K}_b$ are, respectively, the mass, damping, and stiffness matrices of the bridge, which are obtained from the FE model; $\mathbf{X}_b$, $\dot{\mathbf{X}}_b$, and $\ddot{\mathbf{X}}_b$ are the displacement, velocity, and acceleration vectors of bridge nodes in terms of geometric coordinates, respectively; and $\mathbf{P}_b$ is the vector of dynamic forces acting on the bridge by the running train.

3.3 *System equation of motion*

How to solve $\mathbf{P}_v$ and $\mathbf{P}_b$ on the right-hand side of Equations (1) and (2) is the key issue associated with these equations. $\mathbf{P}_v$ and $\mathbf{P}_b$ are determined by wheel-rail interactions. The interactions can be characterized through assumed wheel-rail contact relationship, i.e., the wheel-rail interaction model. Various models have been proposed in literature (Zhai et al. 2010) to determine $\mathbf{P}_v$ and $\mathbf{P}_b$.

In the present analysis, the linear wheel-rail interaction model proposed in Zhang et al. (2010) is used to establish the vectors $\mathbf{P}_v$ and $\mathbf{P}_b$. Specifically, the vertical wheel-rail forces are related to motions of the bridge deck and track irregularities since wheel-sets are assumed to have the same motion as the bridge deck in the vertical direction. The lateral wheel-rail forces depend on the relative motion of wheel and rail, and track irregularities based on the Kalker's creep theory. Therefore, both $\mathbf{P}_v$ and $\mathbf{P}_b$ are associated with the motion of the vehicle and bridge deck, and track irregularities. If the terms related to the motion of the vehicle and bridge deck in $\mathbf{P}_v$ of Equation (1) and $\mathbf{P}_b$ of Equation (2) are moved to the left-hand side of the equations, the equation of motion of the train-bridge system can be expressed as

$$\begin{bmatrix} \mathbf{M}_v & 0 \\ 0 & \mathbf{M}_b \end{bmatrix} \begin{Bmatrix} \ddot{\mathbf{X}}_v(t) \\ \ddot{\mathbf{X}}_b(t) \end{Bmatrix} + \begin{bmatrix} \mathbf{C}_{vv} & \mathbf{C}_{vb} \\ \mathbf{C}_{bv} & \mathbf{C}_{bb} \end{bmatrix} \begin{Bmatrix} \dot{\mathbf{X}}_v(t) \\ \dot{\mathbf{X}}_b(t) \end{Bmatrix} + \begin{bmatrix} \mathbf{K}_{vv} & \mathbf{K}_{vb} \\ \mathbf{K}_{bv} & \mathbf{K}_{bb} \end{bmatrix} \begin{Bmatrix} \mathbf{X}_v(t) \\ \mathbf{X}_b(t) \end{Bmatrix} = \begin{Bmatrix} \mathbf{F}_v \\ \mathbf{F}_b \end{Bmatrix} \quad (3)$$

where $\mathbf{C}_{vb}$ and $\mathbf{C}_{bv}$, and $\mathbf{K}_{vb}$ and $\mathbf{K}_{bv}$ are, respectively, parts of the system damping and stiffness matrices arising due to the coupling effects of the train and bridge subsystems; and $\mathbf{F}_v$ and $\mathbf{F}_b$ = force vectors associated with track irregularities. Equation (3) can be solved through implicit numerical integration methodology, such as the Newmark-β method. An in-house procedure has been developed on the MATLAB platform to numerically solve the system equation of motion.

4 ACCELERATION RESULTS AND DISCUSSION

4.1 *Track irregularities*

Coupled dynamic analysis is conducted with respected to the high-speed train and Dashengguan Yangtze River Bridge system. Track irregularities adopted in the coupling analysis are generated from the German track irregularity spectra, which can be expressed as (Xia et al. 2012)

$$S_v(\Omega) = \frac{A_v\Omega_c^2}{(\Omega^2+\Omega_r^2)(\Omega^2+\Omega_c^2)} \quad (4a)$$

$$S_a(\Omega) = \frac{A_a\Omega_c^2}{(\Omega^2+\Omega_r^2)(\Omega^2+\Omega_c^2)} \quad (4b)$$

$$S_c(\Omega) = \frac{A_v\cdot b^{-2}\cdot\Omega_c^2\cdot\Omega^2}{(\Omega^2+\Omega_r^2)(\Omega^2+\Omega_c^2)(\Omega^2+\Omega_s^2)} \quad (4c)$$

$$S_g(\Omega) = \frac{A_g\Omega_c^2\Omega^2}{(\Omega^2+\Omega_r^2)(\Omega^2+\Omega_c^2)(\Omega^2+\Omega_s^2)} \quad (4d)$$

where S_v(W), S_a(W), and S_g(W) are respectively the power spectral density (PSD) functions of vertical profile, alignment, and gauge irregularities (m^2/(rad/m)); S_c(W) is the PSD function of cross-level irregularities (1/(rad/m)); A_v=4.032$\times10^{-7}$, A_a=2.119$\times10^{-7}$, and A_g=5.32$\times10^{-8}$ are the roughness coefficients (m^2·rad/m); Ω_c= 0.8246, Ω_r=0.0206 and Ω_s=0.4380 are the cutoff frequencies (rad/m); and b is the half of the distance between the right and left rail centers.

4.2 *Acceleration time histories*

Acceleration time histories of cross-sections 1, 2, and 3 (see Fig. 2) from the health monitoring are extracted. These accelerations were induced by high-speed trains with 245 km/h speed that ran towards Shanghai in the B-S high-speed line. The trains consist of eight vehicles. Acceleration responses at the monitored locations are computed by using the coupled train-bridge system model. The integration time step employed in solving the system dynamic equation of motion is 0.005 s which is equal to the sampling frequency of the monitoring system. Figs. 5-7 show the time histories of vertical accelerations obtained from the monitoring system and numerical simulation.

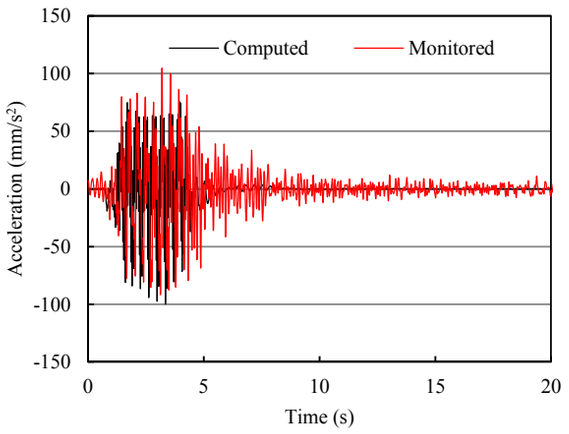

Fig. 5 Comparison of monitored and computed vertical acceleration time histories at cross-section 1

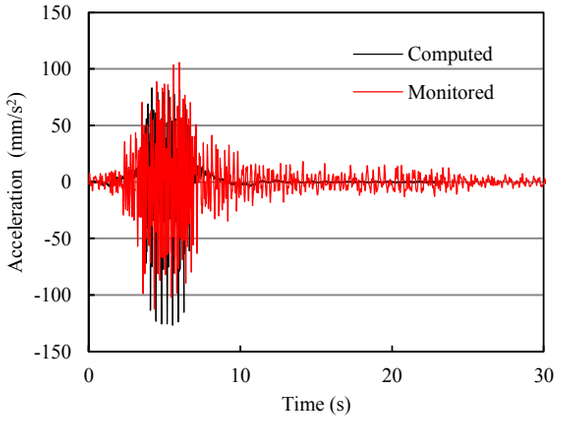

Fig. 6 Comparison of monitored and computed vertical acceleration time histories at cross-section 2

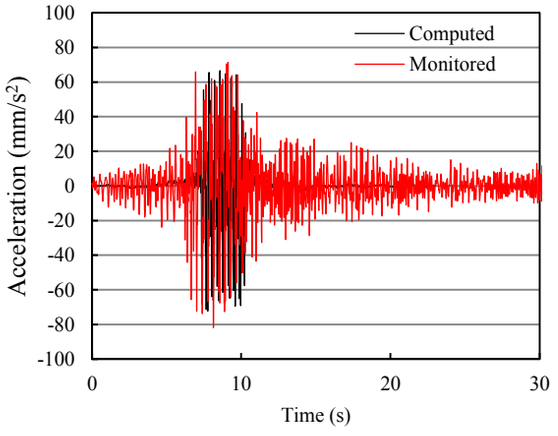

Fig. 7 Comparison of monitored and computed vertical acceleration time histories at cross-section 3

From Fig. 5, it can be seen that the two sets of acceleration time histories are generally close to each other. Amplitudes of the field data above the horizon are larger than the numerical counterparts. Both sets of data show that accelerations are within the prescribed values.

Some differences between the computed and monitored results can be observed in Figs. 6 and 7, mainly since the track irregularities used in the coupled dynamic analysis are numerically generated and do not necessarily reflect the actual smoothness of steel rails on the Dashengguan Yangtze River Bridge. Moreover, track irregularities can cause random vibrations within the high-speed train and bridge system. Consequently, different acceleration time histories will be measured even if a high-speed train running through the Dashengguan Yangtze River Bridge several times under exactly the same conditions (e.g., train speed, environmental temperature, and so on).

4.3 *Acceleration amplitudes*

It is detected in the SHM system that high-speed trains run through the Dashengguan Yangtze River Bridge at various speeds mainly ranging from 200 km/h~300 km/h. Accordingly, acceleration responses at cross-sections 1, 2, and 3 are computed with respect to different train speeds (i.e., 200 km/h ~ 300 km/h). Train composition and track irregularities are identical with those used in section 4.2. Acceleration amplitudes are further displayed in Figs. 8-10, since amplitudes, instead of time histories, can impact the running safety of high-speed trains.

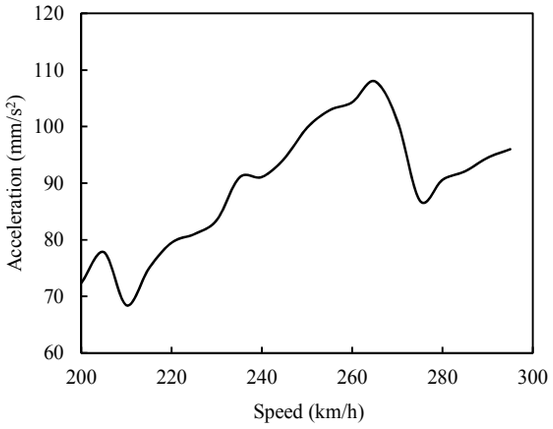

Fig. 8 Variation of amplitude of the vertical acceleration with train speed at cross-section 1

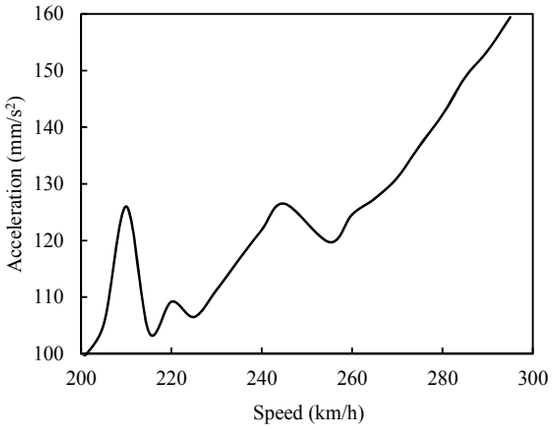

Fig. 9 Variation of amplitude of the vertical acceleration with train speed at cross-section 2

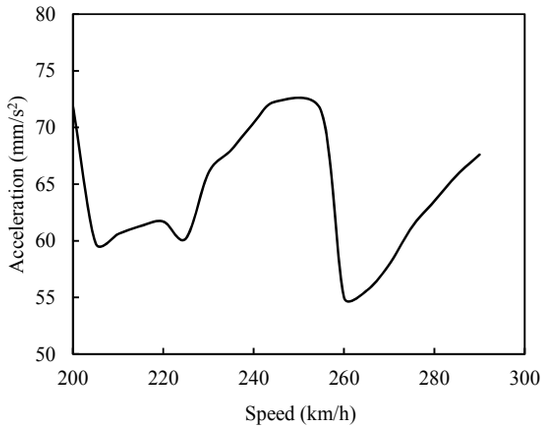

Fig. 10 Variation of amplitude of the vertical acceleration with train speed at cross-section 3

It can be observed in the figures that train speed has significant influence on the bridge acceleration responses. Both peaks and valleys are present in the three acceleration-speed curves. These peaks and valleys may be caused by vibration resonance and cancellation of the train-bridge system (Xia et al. 2014; Yang et al. 2004). In addition, the three acceleration-speed curves are quite different from each other. This implies that all critical cross-sections should be examined to ensure that accelerations of the Dashengguan Yangtze River Bridge are within the prescribed limits under various train speeds.

5 SUMMARY

The high-speed railway network is extending to the western mountainous and eastern coastline areas of China, in which the high-speed railways confront some deep valleys and broad waterways. Long-span bridges provide an effective option to overcome the abovementioned natural barriers. However, high-speed trains are sensitive to the track deformations. How to maintain the geometries of tracks which may be impacted by multiple stressors including high-speed train loads on these unique long-span bridges has been a challenge to researchers and engineers. SHM systems can help obtaining the real-time information about both the stressors and responses of long-span bridges. As an effective alternative, numerical calculations are able to consider loading cases that are not covered by the field monitoring.

As a preliminary study, this paper examines the acceleration responses of a unique long-span railway bridge for high-speed rails, the Dashengguan Yangtze River Bridge, by establishing the coupled train-bridge system model. A 3D train model, 3D bridge FE model, and wheel-rail interaction model considering the effects of track irregularities are incorporated in the system model. Time histories of the bridge accelerations are obtained and compared with the data collected from the SHM system. Acceleration amplitudes are further computed with the help of the coupled system model. Both the time history and amplitude results show that acceleration responses of the examined bridge comply with the code.

Track irregularities are the main cause of random vibrations within the train-bridge system. Time histories shown in Figs.5-7 only represent one sample, and therefore, some differences are observed between the computed sample and the measured sample (see Fig. 6 and 7). It is anticipated that statistical analysis can facilitate reducing the gaps between the numerical and monitoring results. Statistical acceleration-speed curves will provide more useful information, based on which vibration resonance and cancellation phenomena associated with the Dashengguan Yangtze River Bridge can be further investigated.

Optimal weight problem for response sensitivity-based damage identification

Junxian Zhou & Li Wang & Zhong-Rong Lu*
Department of applied mechanics and engineering
Sun Yat-sen University, Guangzhou, P.R.China

ABSTRACT: The response sensitivity approach has been shown to be effective for structural damage identification. The goal function involved is of the form $g(\boldsymbol{\alpha}) = \|\boldsymbol{R}(\boldsymbol{\alpha}) - \hat{\boldsymbol{R}}\|^2_{\boldsymbol{W}}$ with $\boldsymbol{R}(\boldsymbol{\alpha})$ denoting the response function derived via governing equations with given parameters $\boldsymbol{\alpha}$ and $\hat{\boldsymbol{R}}$ the measured data. In many cases of response sensitivity analysis, the weight matrix $\boldsymbol{W}$ is simply set to be de identity matrix and few studies have been presented alone on how to properly choose the weight matrix. This paper tries to present a simple theoretical and numerical investigation on the optimal weight problem for response sensitivity-based damage identification with measurement and model errors. By minimizing the expectation of the squares error in identification results, the optimal weight matrix is found to be $\boldsymbol{W}^{opt} = c\boldsymbol{Q}_R^{-1}, c > 0$ when only measurement errors is involved with covariance $\boldsymbol{Q}_R$. Futher analysis shows that the optimal weight matrix can also make the 'relative error' - square root of expectation of squares relative error in every individual damage parameter minimized. What's more, if model errors, such as errors in the damping and load parameters are additionally considered, the optimal matrix is $\boldsymbol{W}^{opt} = c(\boldsymbol{Q}_R + \boldsymbol{S}_\beta \boldsymbol{Q}_\beta \boldsymbol{S}_\beta^T)^{-1}, c > 0$, where $\boldsymbol{Q}_\beta = E[\boldsymbol{\varepsilon}_\beta \boldsymbol{\varepsilon}_\beta^T]$ and $\boldsymbol{S}_\beta = \nabla_\beta \boldsymbol{R}(\boldsymbol{\alpha}^{ex}, \hat{\boldsymbol{\beta}})$ with $\boldsymbol{\varepsilon}_\beta$ being model errors of the model parameters $\hat{\boldsymbol{\beta}}$. Numerical tests on a plane frame are conducted to see the effect of the proposed optimal weight matrix.

1 INTRODUCTION

Reliable, efficient and non-destructive identification of damage in structures is central to structural health monitoring. Physically damage often arising due to environmental aggressions, possibly unexpected loads and material creep etc, mainly causes a loss of structural stiffness. Therefore, the main task of structural damage identification is to inversely identify the damage locations and intensities from the measured data, e.g. acceleration, displacement responses, eigenfrequencies and/or eigen modes of a structure. Typically, such a procedure belongs to a class of inverse problems and is often modeled as a nonlinear weighted least-squares optimization problem between measurement data and theoretic data. Among the many methods to solve the nonlinear least-squares optimization problem, the sensitivity-based approaches (Chen & Maung 2014, Lu & Law 2007, Lu & Wang 2017) have shown its effectiveness.

In principle, the success of the sensitivity-based approaches is based on the sensitivity analysis and usage of regularization techniques (Lu & Wang 2017). Over the years, considerable work has been focused on the development and application of the sensitivity-based approaches for damage identification in various kinds of structures and with various types of the measured data. Generally speaking, eigenfrequencies and eigen modes is most used for damage identification because they are easily accessed. However, the low-frequency modal data usually obtained in modal tests is insensitive to small or local damage (Link & Weiland 2009). In contrast, as pointed out by Link and Weiland (Link & Weiland 2009), time domain response data from impact tests carries high-frequency information and is sensitive to damage even if the damage is local (Cattarius & Inman 1997); this indicates that time domain response data is beneficial for the detection of local and small damage compared with the modal data. With the time domain data, Lu and Law (Lu & Law 2007) proposed to use response sensitivity analysis for damage identification, and later, Lu and Wang (Lu & Wang 2017) enhanced the response sensitivity approach so that even large damage can be identified. In addition, Link and Weiland(Link & Weiland 2009) conducted an elaborate comparative study for sensitivity-based damage identification using modal data and using time domain response data, for with the latter was shown to be superior in damage identification.

In this paper, the sensitivity-based approaches using the time data (Lu & Wang 2017) is followed up for further investigation. As mentioned above, the objective function is of the weighted least-squares form for which the residual between the measured data and the implicitly derived data and the selection of weighting matrix are concerned. However, limited attention has been paid to the choice and effect of the weight matrix for the weighted nonlinear least-squares optimization problems. It is noteworthy that the weight matrix shall be carefully selected. On the one hand, different kinds of data—displacement, velocity, acceleration or eigenfrequency correspond to different dimensions. Without properly defined weight matrix, equivalent replacement of dimensions, e.g. $1m$ replaced by 10^3mm may lead to quite different objective functions and different identification results thereof. To avoid this, the scaling effect behind the weight matrix should be implicated. On the other hand, when the measured data is at different levels of errors, the weight matrix should be chosen such that large error corresponds to less weight. Primitively, there have already been some reasonable choices of the weight matrix (Friswell & Mottershead 1995, Silva, Maia, Link, & Mottershead 2016, Govers & Link 2010), such as being the reciprocal of the covariance matrix of the measured data. Particularly, in sensitivity-based model updating, proper choice of the weight matrix in each updating step may even pose the equivalent effect of regularization (Friswell & Mottershead 1995, Govers & Link 2010). In this paper, the main aim is to present a thorough view on the optimal choice and the specific effect of the weight matrix for response-sensitivity-based damage identification. Distinct to the work in (Friswell & Mottershead 1995, Govers & Link 2010), the weight matrix herein for the nonlinear least-squares optimization problem does not change during the iterative identification procedure and does not intend to pose the regularization effect; rather, it tries to render the expectation of the squares error of the final identified results minimized. Moreover, in addition to the measurement errors, the model errors such as the external load are also considered and how to properly choose the weight matrix in such cases is also addressed. The remainder of the paper is structured as follows. Section 2 briefly states the underlying damage identification problem. In Section 3, how to choose the optimal weight matrix with measurement and model errors is specifically analyzed. In Section 4, a plane frame numerical example is studied in detail to see the effect of the proposed optimal weight matrix and final conclusions are drawn in Section 5.

2 THEORY

2.1 *Finite element model*

Consider a general finite element model of a linear elastic time-invariant structure, governed by the following dynamic equations,

$$\begin{aligned} &\boldsymbol{M}\ddot{\boldsymbol{d}} + \boldsymbol{C}\dot{\boldsymbol{d}} + \boldsymbol{K}\boldsymbol{d} = \boldsymbol{P}(t) \\ &\boldsymbol{d}(0) = \boldsymbol{d}_0, \dot{\boldsymbol{d}}(0) = \dot{\boldsymbol{d}}_0 \end{aligned} \tag{1}$$

where $\boldsymbol{M}, \boldsymbol{K}, \boldsymbol{C}$ are the system mass, damping and stiffness matrices, respectively. $\boldsymbol{d}$, $\dot{\boldsymbol{d}}$, $\ddot{\boldsymbol{d}}$ represent the displacement, velocity and acceleration responses of the structure and $\boldsymbol{d}_0$, $\dot{\boldsymbol{d}}_0$ are initial displacement and velocity. $\boldsymbol{P}$ denotes the external load vector. Usually, the stiffness matrix $\boldsymbol{K}$ is an affine function of the parameters $\boldsymbol{\alpha} \subset R^m$, i.e., $\boldsymbol{K} = \boldsymbol{K}(\boldsymbol{\alpha}) := \boldsymbol{K}_0 + \sum_{j=1}^{m} \alpha_j \boldsymbol{K}_j$. The damping matrix $\boldsymbol{C}$ is assumed to be the Rayleigh damping, that is, $\boldsymbol{C} = a_1\boldsymbol{M} + a_2\boldsymbol{K}$ with a_1,a_2 being two positive coefficients. In practice, given a set of $\boldsymbol{\alpha}$, the responses (including displacement, velocity and acceleration) of the structure are often obtained by the Newmark method.

2.2 *Sensitivity analysis*

The sensitivity of responses $\boldsymbol{d}, \ddot{\boldsymbol{d}}$ with respect to the parameter α_k can be derived from the following equation

$$\begin{aligned} &\boldsymbol{M}\frac{\partial \ddot{\boldsymbol{d}}}{\partial \alpha_k} + \boldsymbol{C}\frac{\partial \dot{\boldsymbol{d}}}{\partial \alpha_k} + \boldsymbol{K}\frac{\partial \boldsymbol{d}}{\partial \alpha_k} = -\boldsymbol{K}_k(\boldsymbol{d} + a_2\dot{\boldsymbol{d}}), \\ &\frac{\partial \boldsymbol{d}}{\partial \alpha_k}(0) = 0, \frac{\partial \dot{\boldsymbol{d}}}{\partial \alpha_k}(0) = 0 \end{aligned} \tag{2}$$

As is seen, the governing equation for $\frac{\partial \boldsymbol{d}}{\partial \alpha_k}$ is in the same form with the original motion equation (1) except that the force function $\boldsymbol{P}(t)$ is replaced by $-\boldsymbol{K}_k(\boldsymbol{d} + a_2\dot{\boldsymbol{d}})$ and initial conditions are set to zero. Still, the response sensitivity $\frac{\partial \boldsymbol{d}}{\partial \alpha_k}, \frac{\partial \ddot{\boldsymbol{d}}}{\partial \alpha_k}$ can be computed by the Newmark method.

2.3 *Objective function of damage identification*

Now assume that the measured response data $\boldsymbol{R}$ at observed time points $t_j = 1, 2, \cdots, l$ is stored in a vector with the form $\hat{\boldsymbol{R}} = \begin{pmatrix} \hat{\boldsymbol{d}}_i \\ \hat{\ddot{\boldsymbol{d}}}_j \end{pmatrix} = \begin{pmatrix} [\hat{u}_i(t_1), \hat{u}_i(t_2), \cdots, \hat{u}_i(t_l)]^T \\ [\hat{\ddot{u}}_j(t_1), \hat{\ddot{u}}_j(t_2), \cdots, \hat{\ddot{u}}_j(t_l)]^T \end{pmatrix}$, where the displacement and acceleration measurement points can be different and the number of measuring points can

be more than one. Theoretically, given the damage parameters $\boldsymbol{\alpha}$, the measured quantities $\boldsymbol{R}(\boldsymbol{\alpha})$ can be implicitly computed as $\boldsymbol{R} = \begin{pmatrix} \boldsymbol{d}_i(\boldsymbol{\alpha}) \\ \ddot{\boldsymbol{d}}_j(\boldsymbol{\alpha}) \end{pmatrix} = \begin{pmatrix} [u_i(t_1), u_i(t_2), \cdots, u_i(t_l)]^T \\ [\ddot{u}_j(t_1), \ddot{u}_j(t_2), \cdots, \ddot{u}_j(t_l)]^T \end{pmatrix}$.

In damage identification, the aim is to identify $\boldsymbol{\alpha}$ from the measured data which forms a inverse problem and can be formulated as minimization of the following objective function—weighted least-squares of the error in measured quantities,

$$\begin{aligned} \min g(\boldsymbol{\alpha}) &= (\hat{\boldsymbol{R}} - \boldsymbol{R}(\boldsymbol{\alpha}))^T \boldsymbol{W} (\hat{\boldsymbol{R}} - \boldsymbol{R}(\boldsymbol{\alpha})) \\ &= \|\hat{\boldsymbol{R}} - \boldsymbol{R}(\boldsymbol{\alpha})\|^2_{\boldsymbol{W}} \end{aligned} \tag{3}$$

where $\boldsymbol{W}$ is a positive-definite weight matrix. Different weight matrix $\boldsymbol{W}$ could result in different damage identification results and how to properly choose such a weight matrix will be addressed in Section 3. In what follows, how to solve the damage identification problem (3) with response data via the sensitivity analysis is presented.

2.4 *Enhanced response sensitivity approach*

Problem (3) is a typical nonlinear optimization problem and therefore, it should be solved iteratively. A common yet simple manner to cope with such a nonlinear least-squares problem is to linearize $\hat{\boldsymbol{R}} - \boldsymbol{R}(\boldsymbol{\alpha})$ at a given $\bar{\boldsymbol{\alpha}}$, that is

$$\hat{\boldsymbol{R}} - \boldsymbol{R}(\boldsymbol{\alpha}) = \delta \boldsymbol{R}(\bar{\boldsymbol{\alpha}}) - \boldsymbol{S}(\bar{\boldsymbol{\alpha}}) \delta \boldsymbol{\alpha} \tag{4}$$

where $\delta \boldsymbol{\alpha} := \boldsymbol{\alpha} - \bar{\boldsymbol{\alpha}}$ is the *update* of $\boldsymbol{\alpha}$, $\delta \boldsymbol{R}(\bar{\boldsymbol{\alpha}})$ is called the residual between the measured data $\hat{\boldsymbol{R}}$ and the derived data $\boldsymbol{R}(\bar{\boldsymbol{\alpha}})$, and $\boldsymbol{S}(\bar{\boldsymbol{\alpha}})$ is the first-order sensitivity matrix, possessing the following form

$$\boldsymbol{S}(\bar{\boldsymbol{\alpha}}) = \bigtriangledown_{\boldsymbol{\alpha}} \boldsymbol{R}(\bar{\boldsymbol{\alpha}}) := \begin{pmatrix} \frac{\partial \boldsymbol{d}_i}{\partial \alpha_1}, \frac{\partial \boldsymbol{d}_i}{\partial \alpha_2}, \cdots, \frac{\partial \boldsymbol{d}_i}{\partial \alpha_m} \\ \frac{\partial \ddot{\boldsymbol{d}}_j}{\partial \alpha_1}, \frac{\partial \ddot{\boldsymbol{d}}_j}{\partial \alpha_2}, \cdots, \frac{\partial \ddot{\boldsymbol{d}}_j}{\partial \alpha_m} \end{pmatrix} \tag{5}$$

where the sensitivity analysis(2) is involved. Then, a linear least-squares minimization problem for update $\delta \boldsymbol{\alpha}$ can be invoked

$$min\ \hat{g}(\delta \boldsymbol{\alpha}, \bar{\boldsymbol{\alpha}}) := \|\delta \boldsymbol{R}(\bar{\boldsymbol{\alpha}}) - \boldsymbol{S}(\bar{\boldsymbol{\alpha}}) \delta \boldsymbol{\alpha}\|^2_{\boldsymbol{W}} \tag{6}$$

However, problem(6) is often ill-posed and therefore the Tikhonov regularization is utilized where the regularization term $\lambda \|\delta \boldsymbol{\alpha}\|^2$ with $\|\cdot\|$ denoting the usual L^2 norm and λ a small nonnegative regularization parameter is added to (6). Under this circumstance, the update $\delta \boldsymbol{\alpha}_\lambda$ becomes

$$\delta \boldsymbol{\alpha}_\lambda = arg\ min \|\boldsymbol{S}(\bar{\boldsymbol{\alpha}}) \delta \boldsymbol{\alpha} - \delta \boldsymbol{R}(\bar{\boldsymbol{\alpha}})\|^2_{\boldsymbol{W}} + \lambda \|\delta \boldsymbol{\alpha}\|^2 \tag{7}$$

$$\Rightarrow \delta \boldsymbol{\alpha}_\lambda = [\boldsymbol{S}(\bar{\boldsymbol{\alpha}})^T \boldsymbol{W} \boldsymbol{S}(\bar{\boldsymbol{\alpha}}) + \lambda \boldsymbol{I}]^{-1} \boldsymbol{S}(\bar{\boldsymbol{\alpha}})^T \boldsymbol{W} \delta \boldsymbol{R}(\bar{\boldsymbol{\alpha}})$$

The trust-region restriction is additionally enforced by properly determining the regularization parameter λ. For simplicity, the steps of enhanced response sensitivity approach are given in Table 1 and for more details, refer to (Lu & Wang 2017).

3 OPTIMAL WEIGHT MATRIX UNDER MEASUREMENT AND MODEL ERRORS

3.1 *Optimal weight matrix under measurement errors*

Assume that the measured data is subject to normally distributed noise as the following form,

$$\hat{\boldsymbol{R}} = \boldsymbol{R}(\boldsymbol{\alpha}^{ex}) + \boldsymbol{\varepsilon}_R \tag{8}$$

where $\boldsymbol{\alpha}^{ex}$ represent the exact damage parameters and $\boldsymbol{\varepsilon}_R$ is the measured error vector pertaining to the Gaussian distribution subject to zero means and positive definite covariance $E[\boldsymbol{\varepsilon}_R \boldsymbol{\varepsilon}_R^T] = \boldsymbol{Q}_R$. An optimal weight matrix shall render the expectation of squares of the identification errors $E[(\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex})^T (\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex})]$ minimized. To go further, the goal function $g(\boldsymbol{\alpha})$ (3) is further analyzed by linearization,

$$\begin{aligned} g(\boldsymbol{\alpha}) &= \|\boldsymbol{R}(\boldsymbol{\alpha}^{ex}) + \boldsymbol{\varepsilon}_R - \boldsymbol{R}(\boldsymbol{\alpha}))\|^2_{\boldsymbol{W}} \\ &= \|\boldsymbol{\varepsilon}_R - \boldsymbol{S}(\boldsymbol{\alpha}^{ex}) \cdot (\boldsymbol{\alpha} - \boldsymbol{\alpha}^{ex}) + h.o.t\|^2_{\boldsymbol{W}} \end{aligned} \tag{9}$$

where $h.o.t$ represents higher order terms that are negligible with respect to $\boldsymbol{\varepsilon}_R$ when $\boldsymbol{\alpha}$ is in the vicinity of $\boldsymbol{\alpha}^{ex}$. Note that $\boldsymbol{\alpha}^*$ is in the vicinity of $\boldsymbol{\alpha}^{ex}$, this means,

$$\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex} \approx [\boldsymbol{S}^T \boldsymbol{W} \boldsymbol{S}]^{-1} \boldsymbol{S}^T \boldsymbol{W} \boldsymbol{\varepsilon}_R := \boldsymbol{L}_W \boldsymbol{\varepsilon}_R \tag{10}$$

where $\boldsymbol{L}_W = [\boldsymbol{S}^T \boldsymbol{W} \boldsymbol{S}]^{-1} \boldsymbol{S}^T \boldsymbol{W}$. Then, one can has

$$\begin{aligned} E[(\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex})^T (\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex})] &\approx E[\boldsymbol{\varepsilon}_R^T \boldsymbol{L}_W^T \boldsymbol{L}_W \boldsymbol{\varepsilon}_R] \\ &= tr(\boldsymbol{L}_W \boldsymbol{Q}_R \boldsymbol{L}_W^T) \end{aligned} \tag{11}$$

where $tr(\cdot)$ is the trace operator and the last equality arises due to $E[\boldsymbol{\varepsilon}_R \boldsymbol{\varepsilon}_R^T] = \boldsymbol{Q}_R$.

Theorem 1

The optimal choice of $\boldsymbol{W}$ to minimize $F(\boldsymbol{W}) := tr(\boldsymbol{L}_W \boldsymbol{Q}_R \boldsymbol{L}_W^T)$ is

$$\boldsymbol{W}^{opt} = c \boldsymbol{Q}_R^{-1}, c > 0 \tag{12}$$

and then,

$$F(\boldsymbol{W}^{opt}) = tr([\boldsymbol{S}^T \boldsymbol{Q}_R^{-1} \boldsymbol{S}]^{-1}). \tag{13}$$

-end for

Herein, the auxiliary matrix $\boldsymbol{L}_W$ rather than $\boldsymbol{W}$ is used for later derivation. A remarkable feature of $\boldsymbol{L}_W$ is

$$\boldsymbol{L}_W\boldsymbol{S} = \boldsymbol{I}. \tag{14}$$

Then, the problem becomes an equality constrained optimization problem and the Lagrangian multipliers $\boldsymbol{\Theta}$ are introduced to deal with the constraints (14),

$$\ell(\boldsymbol{L}_W, \boldsymbol{\Theta}) = tr(\boldsymbol{L}_W\boldsymbol{Q}_R\boldsymbol{L}_W^T) + tr((\boldsymbol{I} - \boldsymbol{L}_W\boldsymbol{S})\boldsymbol{\Theta}). \tag{15}$$

Optimization of $\ell(\boldsymbol{L}_W, \boldsymbol{\Theta})$ over $\boldsymbol{L}_W$ leads to,

$$\boldsymbol{L}_W = \frac{1}{2}\boldsymbol{\Theta}^T\boldsymbol{S}^T\boldsymbol{Q}_R^{-1}. \tag{16}$$

Then, combination of (14) and (16) yields,

$$\boldsymbol{\Theta} = 2(\boldsymbol{S}^T\boldsymbol{Q}_R^{-1}\boldsymbol{S})^{-1} \tag{17}$$

Along with (16), optimal $\boldsymbol{L}_W$ is found to be

$$\boldsymbol{L}_W^{opt} = (\boldsymbol{S}^T\boldsymbol{Q}_R^{-1}\boldsymbol{S})^{-1}\boldsymbol{S}^T\boldsymbol{Q}_R^{-1}. \tag{18}$$

Further considering, the definitions of $\boldsymbol{L}_W$ and $\boldsymbol{F}(\boldsymbol{W})$, equations (12) and (13) in theorem 1 follows naturally.

Theorem 2

Introduce an order operator $\preceq$ (or inversely $\succeq$) for two symmetric matrix $\boldsymbol{A}, \boldsymbol{B} \in R^{N\times N}$ as follows,

$$\boldsymbol{A} \preceq \boldsymbol{B} \Leftrightarrow \boldsymbol{v}^T\boldsymbol{A}\boldsymbol{v} \leq \boldsymbol{v}^T\boldsymbol{B}\boldsymbol{v}, \forall\boldsymbol{v} \in R^N \tag{19}$$

In the sense of the order operator $\succeq$, covariance of the identification errors $E[(\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex})(\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex})^T] = \boldsymbol{L}_W\boldsymbol{Q}_R\boldsymbol{L}_W^T$ would also arrive at a minimum under the optimal weight matrix $\boldsymbol{W}^{opt} = c\boldsymbol{Q}_R^{-1}$, i.e.,

$$\boldsymbol{L}_W^{opt}\boldsymbol{Q}^R(\boldsymbol{L}_W^{opt})^T = [\boldsymbol{S}^T\boldsymbol{Q}_R^{-1}\boldsymbol{S}]^{-1} \preceq \boldsymbol{L}_W\boldsymbol{Q}_R\boldsymbol{L}_W^T, \tag{20}$$
$$\forall \quad positive\,definite\,\boldsymbol{W}.$$

Proof

For an arbitrary positive definite weight matrix $\boldsymbol{W}$, one can have

$$\boldsymbol{L}_W = \boldsymbol{L}_W^{opt} + \Delta\boldsymbol{L} \tag{21}$$

with $\Delta\boldsymbol{L}$ satisfying $\Delta\boldsymbol{L}\cdot\boldsymbol{S} = 0$. Recalling the Definition of $\boldsymbol{L}_W^{opt}$ in (16), it is also found that

$$\boldsymbol{L}_W^{opt}\boldsymbol{Q}_R\Delta\boldsymbol{L}^T = 0. \tag{22}$$

With equations (21) and (22), there holds

$$\begin{aligned}\boldsymbol{L}_W\boldsymbol{Q}_R\boldsymbol{L}_W^T &= (\boldsymbol{L}_W^{opt} + \Delta\boldsymbol{L})\boldsymbol{Q}_R(\boldsymbol{L}_W^{opt} + \Delta\boldsymbol{L})^T \\ &\succeq \boldsymbol{L}_W^{opt}\boldsymbol{Q}_R(\boldsymbol{L}_W^{opt})^T = [\boldsymbol{S}^T\boldsymbol{Q}_R^{-1}\boldsymbol{S}]^{-1}\end{aligned} \tag{23}$$

3.2 *Additional considerations on model errors*

The model parameters $\boldsymbol{\beta} = [\beta_1, \beta_2, \ldots, \beta_n]^T$ are also taken in account herein in addition to the damage parameter $\boldsymbol{\alpha}$. For structures, the modal parameters $\boldsymbol{\beta}$ may include the mass density in the mass Matrix $\boldsymbol{M}$

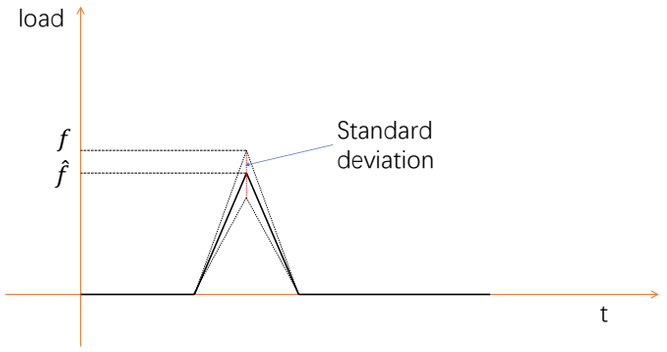

Figure 1: Schematic illustrations for impact load

and the amplitude of an impact load in the load vector $\boldsymbol{P}$, etc. The known values $\hat{\boldsymbol{\beta}}$ pertains to

$$\hat{\boldsymbol{\beta}} = \boldsymbol{\beta}^{ex} + \boldsymbol{\varepsilon}_{\beta} \tag{24}$$

where $\boldsymbol{\beta}^{ex}$ is the unknown exact model parameters and $\boldsymbol{\varepsilon}_{\beta}$ represent the errors subject to Gaussian distribution with zero means and covariance $E[\boldsymbol{\varepsilon}_{\beta}\boldsymbol{\varepsilon}_{\beta}^{T}] = \boldsymbol{Q}_{\beta}$. $\boldsymbol{\varepsilon}_{\beta}$ and $\boldsymbol{\varepsilon}_{R}$ are independent from each other. The derived data under the parameters $\hat{\boldsymbol{\beta}}$ is expressed as $\boldsymbol{R}(\boldsymbol{\alpha}, \hat{\boldsymbol{\beta}})$. In this way, the goal function (3) becomes

$$g(\boldsymbol{\alpha}) = \|\hat{\boldsymbol{R}} - R(\boldsymbol{\alpha}, \hat{\boldsymbol{\beta}})\|^2_{\boldsymbol{W}} \tag{25}$$

To further estimate the covariance of the identification errors $\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex}$, similar to equations(9)-(11). The linear Taylor expansion is applied to the goal function for $\boldsymbol{\alpha}$ in the vicinity of $\boldsymbol{\alpha}^{ex}$,

$$\begin{aligned} g(\boldsymbol{\alpha}) &= \|R(\boldsymbol{\alpha}^{ex}, \boldsymbol{\beta}^{ex}) + \boldsymbol{\varepsilon}_R - \boldsymbol{R}(\boldsymbol{\alpha}, \hat{\boldsymbol{\beta}})\|^2_{\boldsymbol{W}} \\ &\approx \|\boldsymbol{\varepsilon}_R - \boldsymbol{S}_{\beta}\boldsymbol{\varepsilon}_{\beta} - \boldsymbol{S} \cdot (\boldsymbol{\alpha} - \boldsymbol{\alpha}^{ex})\|^2_{\boldsymbol{W}} \end{aligned} \tag{26}$$

where $\boldsymbol{S} = \bigtriangledown_{\alpha}\boldsymbol{R}(\boldsymbol{\alpha}^{ex}, \hat{\boldsymbol{\beta}}), \boldsymbol{S}_{\beta} = \bigtriangledown_{\beta} R(\boldsymbol{\alpha}^{ex}, \hat{\boldsymbol{\beta}}) := [\frac{\partial \boldsymbol{R}(\boldsymbol{\alpha}^{ex}, \hat{\boldsymbol{\beta}})}{\partial \beta_1}, \frac{\partial \boldsymbol{R}(\boldsymbol{\alpha}^{ex}, \hat{\boldsymbol{\beta}})}{\partial \beta_2}, \ldots, \frac{\partial \boldsymbol{R}(\boldsymbol{\alpha}^{ex}, \hat{\boldsymbol{\beta}})}{\partial \beta_n}]$. Minimization of (26) yields,

$$\boldsymbol{\alpha}^* - \boldsymbol{\alpha}^{ex} \approx \boldsymbol{L}_W(\boldsymbol{\varepsilon}_R - \boldsymbol{S}_{\beta}\boldsymbol{\varepsilon}_{\beta}) \tag{27}$$

where L_W is of the same form with that in (10). Note that $\boldsymbol{\varepsilon}_R - \boldsymbol{S}_{\beta}\boldsymbol{\varepsilon}_{\beta}$ are also pertaining to Gaussian distribution with zero means and the follwing covariance,

$$E[(\boldsymbol{\varepsilon}_R - \boldsymbol{S}_{\beta}\boldsymbol{\varepsilon}_{\beta})(\boldsymbol{\varepsilon}_R - \boldsymbol{S}_{\beta}\boldsymbol{\varepsilon}_{\beta})^T] = \boldsymbol{Q}_R + \boldsymbol{S}_{\beta}\boldsymbol{Q}_{\beta}\boldsymbol{S}_{\beta}^T. \tag{28}$$

Refer to the proof of the optimal weight matrix in Section 3.1, the optimal weight matrix herein under both measurement and model errors is found to be

$$\boldsymbol{W}^{opt} = c(\boldsymbol{Q}_R + \boldsymbol{S}_{\beta}\boldsymbol{Q}_{\beta}\boldsymbol{S}_{\beta}^T)^{-1}, c > 0 \tag{29}$$

However, difficulty would arise for sensitivity analysis of $\boldsymbol{S}_{\beta} = \nabla_{\beta}\boldsymbol{R}(\boldsymbol{\alpha}^{ex}, \hat{\boldsymbol{\beta}})$, because the required $\boldsymbol{\alpha}^{ex}$ is unknown. To circumvent this difficulty, the approximate damage parameters $\tilde{\boldsymbol{\alpha}}^*$, that are obtained through damage identification with the weight matrix $\boldsymbol{W} = c\boldsymbol{Q}_R^{-1}$ and are often good approximations of $\boldsymbol{\alpha}^{ex}$, are adopted for computation of the sensitivity matrix $\boldsymbol{S}_{\beta}$ and the optimal weight matrix (29) thereof.

The next section considers the load parameters with model error to investigate the influence of the model error. So here the derivation of sensitivity of time response with respect to load parameters is discuss. Considering an impact load of the triangle form in Figure(1), assume that the real peak value f is of the form $f = \hat{f}(1 + \beta_f)$ where $\hat{f}$ is the known/measured peak value and β_f is the percentage noise and in this way, the load vector shall be parameterized as $\boldsymbol{P} = \hat{\boldsymbol{P}}(1 + \beta_f)$. For the dynamic equations(1), the sensitivity of response with respect to β_f yields

$$\begin{aligned} &\boldsymbol{M}\frac{\partial \ddot{\boldsymbol{d}}}{\partial \beta_f} + \boldsymbol{C}\frac{\partial \dot{\boldsymbol{d}}}{\partial \beta_f} + \boldsymbol{K}\frac{\partial \boldsymbol{d}}{\partial \beta_f} = \frac{\partial \boldsymbol{P}}{\partial \beta_f} = \hat{\boldsymbol{P}}, \\ &\frac{\partial \boldsymbol{d}}{\partial \beta_f}(0) = 0, \frac{\partial \dot{\boldsymbol{d}}}{\partial \beta_f}(0) = 0 \end{aligned} \tag{30}$$

Usually, the initial state of the structure is at rest and then, after comparison between (1) and (30), the sensitivity $\frac{\partial \boldsymbol{R}}{\partial \beta_f}$ is simply obtained as

$$\frac{\partial \boldsymbol{R}}{\partial \beta_f} = \begin{pmatrix} \hat{\boldsymbol{d}}_i \\ \hat{\dot{\boldsymbol{d}}}_j \end{pmatrix} \tag{31}$$

4 NUMERICAL TESTS

A simple plane frame is studied to verify the proposed optimal weight matrix. The algorithm in Table 1 is adopted for damage identification and the algorithmic parameters *RelErr, Nmax,* ρ_{cr}, γ, *Ntr* are taken as the values in the following brackets. For model parameters (only load parameter is considered in here), the known impact load $\hat{\boldsymbol{P}}$ are given and the exact values $\boldsymbol{P}^{ex}$ is obtained as $\boldsymbol{P}^{ex} = \hat{\boldsymbol{P}}(1 + \beta_f)$

A single-span plane frame structure as shown in Figure 2 is studied herein to see the effect of weight matrix. Geometric parameters are: the height and width of the frame $H = 1.2m$ and $L = 0.6m$, and the rectangular cross-section dimensions $b = 0.01m$ and $h = 0.02m$. The properties of the intact frame are: the mass density $\rho = 2.7 \times 10^3 kg/m^3$ and the elastic modulus $E = 6.9 \times 10^{10} N/m^2$. As for the finite element modeling, the frame is uniformly divided into 11 Euler-Bernoulli beam elements with 12 nodes each with three DOFs where x-,y-translational and rotational displacements at the kth node are denoted by u_k, v_k, θ_k. Practically, the fixed nodes 1 and 12 of the frame are modeled with the same large support stiffness $\hat{k}_t = \hat{k}_v = 1.5 \times 10^{10} kN/m$ and $\hat{k}_\theta = 1.5 \times 10^9 kN \cdot m/rad$.

Table 2: Damage identification scenarios for plane frame structure

Damage scenario	Damage location(element no.)	Reduction in elastic modulus	Measurement(with noise)	Model error
1	9,10	20%,25%	$\ddot{u}_2(2\%)$,$u_2(10\%)$,$\ddot{u}_9(10\%)$	———
2	2,4,8	20%,20%,15%	$\ddot{u}_2(2\%), \ddot{u}_4(10\%), \ddot{u}_{11}(10\%)$	$F(t)(2\%)$

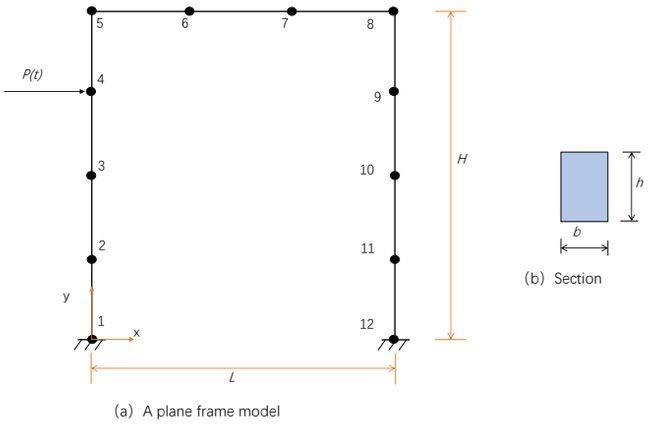

Figure 2: A plane frame model: mesh, load and boundary conditions

In this example, the first two frequencies of the intact frame are found to be 13.095 and 57.308Hz and for simplicity, the first two modal damping ratios are both assumed to be 0.01. Then, the Rayleigh coefficients are $\hat{\alpha}_1 = 1.3395s^{-1}$ and $\hat{\alpha}_2 = 4.52 \times 10^{-5}s$ so that the damping matrix $\boldsymbol{C} = \hat{\alpha}_1\boldsymbol{M} + \hat{\alpha}_2\boldsymbol{K}$ is obtained. As for the external load, the horizontal impact load enforced at 4 node is as follows:

$$\boldsymbol{P}(t) = \begin{cases} 1900 * (t - 0.05) & (0.05s < t < 0.1s) \\ 1900 * (0.15 - t) & (0.1s < t < 0.15s) \end{cases} \tag{32}$$

For this example, the simulated data-displacements or accelerations is obtained from numerical simulation during the time period [0,4s] with a sampling rate of 500Hz. The measured data $\hat{\boldsymbol{d}}_i, \hat{\ddot{\boldsymbol{d}}}_j$ is obtained by addition of measurement errors to simulated data $\boldsymbol{d}_i, \ddot{\boldsymbol{d}}_j$ that is taken from $\boldsymbol{R}(\boldsymbol{\alpha}^{ex}, \boldsymbol{\beta}^{ex})$.

If no model error exists, the optimal weight matrix $\boldsymbol{W}^{opt} = c\boldsymbol{Q}_R^{-1}$ and the identity weight matrix $\boldsymbol{W}^{id} = \boldsymbol{I}$ are used for comparison; while if model errors are considered, the identity weight matrix $\boldsymbol{W}^{id} = \boldsymbol{I}$, the quasi-optimal weight matrix $\boldsymbol{W}^{quasi} = c\boldsymbol{Q}_R^{-1}$ and the optimal weight matrix $\boldsymbol{W}^{opt} = c(\boldsymbol{Q}_R + \boldsymbol{S}_\beta \boldsymbol{Q}_\beta \boldsymbol{S}_\beta^T)^{-1}$ would be adopted for comparative purpose. The identified damage parameters can be obtained by the enhanced response sensitivity approach in Table 1. 20 sets of the measurement data and exact model parameters data when considering model errors will be generated by Monte Carlo sampling. The elastic modulus in the 11 elements are treated as the damage parameters to be identified.

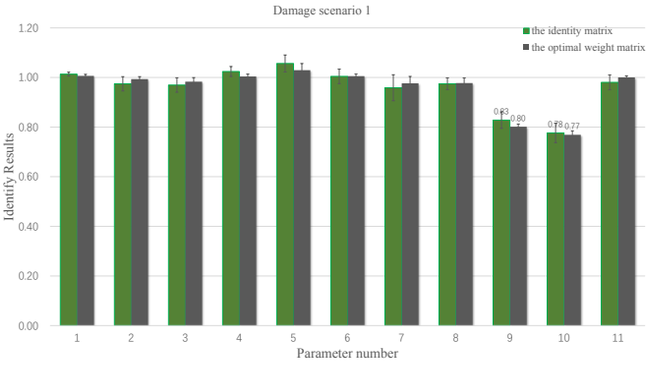

Figure 3: Bar graph with means and standard deviations for damage identification of Scenario 1

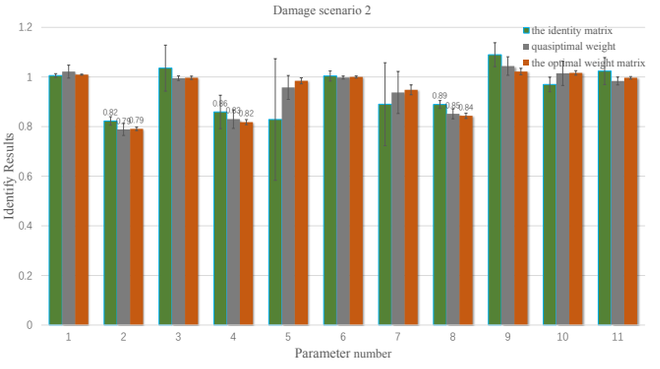

Figure 4: Bar graph with means and standard deviations for damage identification of Scenario 2

Scenario 1 use accelerations and displacements and consider different measurement error levels for accelerations/displacements at different positions (see Table 2). This scenario is assumed to be free from model errors. Based on the Monte Carlo sampling and damage identification algorithm in Table 1, damage parameters can be identified and detailed results on means and standard deviations of individual damage parameters are shown in Figures 3 where ' identified results' refer to $\frac{\alpha_k^*}{\alpha_k^{intact}}$ where α_k^{intact} denotes the parameter before damage. The benefits brought by the optimal weight matrix are obvious since more accurate averages and less standard deviations are obtained under the optimal weight matrix.

Scenario 2 adopts accelerations and additionally take the model errors into account, the Gaussian noise of level 2% is added to the impact load. Along with the Monte Carlo sampling and the enhanced response sensitivity approach, identification results for 20 sampling data sets are obtained with the three specific weight matrices. Statistical bar graphs for the two scenarios are depicted in Figures 4.

For Scenario 2, the result indicates that with the

load error, the identity weight matrix may lead to significant identification errors , while the quasi-optimal weight concerning merely the measurement errors can gain acceptable good identification results and nearly perfect identification results are obtained using the optimal weight matrix where both the measurement and model errors are considered.

5 CONCLUSIONS

In this paper, the selection of the optimal weight matrix has been discussed in case of measurement and model errors. By resorting to the criterion that the optimal weight matrix should minimized the expectation of squares error in identification results, the optimal weight matrix is found to be inversely proportional to the covariance of measurement errors when only measurement errors are considered. In case of model errors, the same criterion shows that the optimal weight matrix depends not only on measurement errors, but also on model errors along with sensitivity to model parameters. Further analysis finds that the optimal weight matrix can also render the 'relative error' of every individual damage parameter minimized. Then, numerical tests on a plane frame is conducted and results show that the optimal choice of the weight matrix can work as expected to improve the accuracy of the damage identification results when different levels of measurement errors(or model errors) or different types of response data are invoked.

A mesoscopic analysis of chloride diffusion with adaptive mesh refinement

Zichao Pan, Dalei Wang, Rujin Ma & Airong Chen
Department of Bridge Engineering
Tongji University, China

ABSTRACT: The chloride induced rebar corrosion is a big thread to reinforced concrete (RC) structures in the ocean, coastal area, and where the deicing salt is used. A mesoscopic numerical analysis of the chloride diffusion process in RC structures can give a full chloride profile in the concrete with the consideration of material heterogeneity, but also requires a lot of computational efforts which is usually unacceptable in a 3D numerical simulation. In this paper, the technique of adaptive mesh refinement (AMR) is integrated into the classic finite element method (FEM) for the chloride diffusion problem. The main idea of the integrated method is to refine the grid based on a predefined refinement criterion step by step during the whole analysis until the required precision of the solution is reached. A computer program is developed to evaluate the efficiency of the novel mesoscopic method for both 2D and 3D chloride diffusion problems. The result shows that the numerical method with AMR can greatly improve the efficiency of the simulation while the precision of the solution in key areas can be ensured as well.

1 INTRODUCTION

The chloride penetration is one of the most significant threads to reinforced concrete (RC) infrastructures in coastal areas and cold regions where the deicing-salt is used. During the chloride penetration process, chloride ions will accumulate at the surface of rebars. When the local chloride content reaches a threshold called "critical chloride content" (Angst, Elsener, Larsen, & ystein Vennesland 2009), rebars will start to corrode with extra prerequisites such as water and oxygen. The safety and service performances of the entire structure will also decrease due to loss of effective cross-sectional area and strength of rebars and bonding strength between rebars and concrete. Thus, the initiation of rebar corrosion is an important signal during service life of RC structures.

To estimate the initiation time of rebar corrosion, numerous efforts have been taken in both experimental and theoretical researches. The latter can be further categorized into the analytical approach where the Fick's law is often used (Zhou 2016, Zhou 2014), and the numerical simulation method which is more flexible and with a wider application. So far, most of early researches were conducted at macro-scale, where the concrete is considered as a homogeneous and isotropic material. With uniform exposure conditions which are often assumed in analysis, the chloride ions will transport into concrete with no spatial variability, which is contrary to some experimental observations (Angst & Polder 2014). The reason is that the concrete is actually a heterogeneity material which is composed of aggregate, cement paste and interfacial transition zone (ITZ) at meso-scale. The transport path of chloride ions will be distorted by the impermeable aggregates, which can result in the spatial variability of chloride penetration due to the random aggregate structure (RAS), i.e., random shape and position.

To investigate the characteristics of chloride penetration at meso-scale, related researches in recent years have been conducted (Pan, Xin, & Chen 2014, Zheng, Zhou, Wu, & Jin 2012, Pan, Chen, & Xin 2015). Some important conclusions are also available, e.g., aggregates with a larger aspect ratio can effectively decrease the chloride diffusivity of concrete (Pan, Xin, & Chen 2014, Zheng, Zhou, Wu, & Jin 2012). But difficulties are also found during these researches. One of the biggest problems is that it is difficult to obtain a mesh with high quality of the meso-scale model for numerical analysis such as finite element analysis (FEA). Due to the geometrical complexity of aggregate shape and tiny spacings between aggregates with a high volume fraction, the free mesh method provided by some commercial softwares will often fail. An alternative approach is to map a prepared mesh with regular element (triangle and square for instance) onto the meso-scale

model, and attribute different material properties to elements according to their positions in the meso-scale model, e.g., completely inside an aggregate or cement paste, partially occupied by an aggregate. This mapping mesh method can always succeed regardless of the geometrical complexity of aggregate shape, but the mesh size should be small enough, and usually smaller than the minimum size of aggregates, which will significantly increase the amount of computational work, especially in a three-dimensional (3D) analysis.

To decrease the computational burden in a mesoscopic analysis of chloride transport problem, the technique of adaptive mesh refinement (AMR) can be introduced. The general philosophy of AMR is to improve the accuracy of numerical solutions by starting the analysis on a coarse initial mesh and then refining the mesh based on the refinement criteria. So far, AMR has been already successfully applied in Calculated Fluid Dynamics (CFD) (Rossi, Cotela, Lafontaine, Dadvand, & Idelsohn 2013, Antepara, Lehmkuhl, Borrell, Chiva, & Oliva 2014) and mechanical behaviors of structures such as fracture (Khoei, Moslemi, Ardakany, Barani, & Azadi 2009, Park, Paulino, Celes, & Espinha 2012, Khoei, Eghbalian, Moslemi, & Azadi 2013) and dynamic response under earthquake (Sun & Li 2016). The overall aim of AMR is to obtain a balance between accuracy and computational efficiency in numerical simulations.

This paper mainly provides an AMR-based finite element method (FEM) to simulate the chloride diffusion in concrete at meso-scale. The detailed implementations of AMR in FEM, e.g., element hierarchy, are described in the first part of the paper. Then, the method is applied into both steady and transient analysis of chloride diffusion problems. The refinement criteria which determines the critical elements to be further refined is proposed and tested. Some benchmarks are also conducted to compare the computational efficiency between AMR-based FEM and normal FEM.

2 MODELS AND METHODS

2.1 *Meso-scale model of concrete*

At meso-scale, concrete is considered as a composite material which can be divided into the cement paste as the homogeneous matrix, the aggregate as the inclusion, and ITZ as the interface between cement paste and aggregate. The ITZ is usually modeled as a soft shell with identical thickness around aggregate. Thus, the meso-scale model of concrete is mainly determined by the characteristics of aggregates, i.e., the shape and position. The shape of real aggregates is so complicated that it is often assumed as some realistic geometries such as sphere, ellipsoid, polyhedron, geometry described by spherical harmonics (Garboczi 2002).

The size of each aggregate in the meso-scale model of concrete should be determined according to the aggregate gradation, e.g., the Fuller's gradation, equal volume fraction (EVF) gradation. For non-spherical shapes, aspect ratios should be also properly decided to realistically model the aggregate shape. Generally, the aspect ratio can be defined based on the sizes of the bounding box of the aggregate. For example, the aspect ratios of an ellipsoid can be simply defined as $\xi_1 = a/b$ and $\xi_2 = b/c$, where a, b and c are the major, medium and minor radii of the ellipsoid. The orientations of each aggregate are usually considered as random variables following a uniform distribution in the range of $[0, 2\pi]$.

When the shapes of all aggregates are determined, the next step is to determine the aggregate position which is often called "aggregate packing". As solid particles, aggregates are not allowed to be overlapped with one another. Thus, separation checks are needed to determine proper position of each aggregate in the meso-scale model. The algorithm of separation check differs for different shapes of aggregates. For example, for spherical shape, it is only needed to calculate the distance between centers of two aggregates and compare it with the radii of these two aggregates. For the other shapes, the algorithms will become much more complicated, e.g., ellipsoid (Wang, Wang, & Kim 2001), spherical harmonics (Qian 2012). The overall packing procedure can follow a classic "take and place" method (Wang, Kwan, & Chan 1999). When an aggregate is to be placed into the meso-scale model, it is checked whether this aggregate is overlapped with any aggregate which is already in the meso-scale model by using the corresponding algorithm of separation check. If so, the aggregate is taken out and dropped into the meso-scale model again until all separation checks are passed. To eliminate the "wall effect" caused by the boundary of meso-scale model on the aggregate packing, the periodic boundary condition can be applied (Qian 2012).

2.2 *AMR scheme*

2.2.1 *Mesh hierarchy*

To decrease the computational efforts, the mesoscopic analysis is usually conducted in a representative volume element (RVE) instead of the entire component or structure. The size of REV (L) should be large enough to fully cover the characteristics of material heterogeneity. In the case of concrete, it is recommended that L should be at least 3 to 5 times larger than the maximum size of aggregates.

The AMR procedure used in this paper can be described by Fig. 1. To start with, an initial coarse mesh which only has one element is given in Fig. 1(a). The initial mesh can be named as level 0 mesh. In Fig. 1, this single element is divided into four elements by generating and connecting new nodes in the middle of

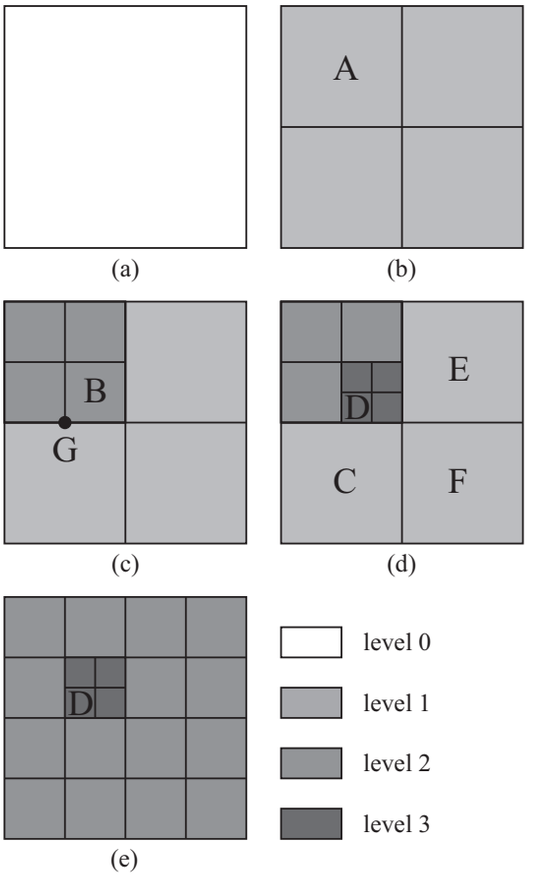

Figure 1: A schematic of 2D AMR and different levels of elements.

each side of the element. The newly created elements result in the mesh of next level, namely level 1. In Fig. 1(c), element A which belongs to level 1 mesh can be further refined to level 2. This procedure can continue to any levels. But it is required that the difference of mesh levels between any two adjacent elements can never exceed one level. Thus, the mesh in Fig. 1(d) is not allowed in AMR, as elements C and D belong to the level 1 and 3 meshes, respectively, with a difference of two levels. If element B in Fig 1(c) needs to be refined, elements C, E and F in Fig. 1(d) should be firstly refined to level 2, as shown in Fig. 1(e).

2.2.2 *Transitional element*

During AMR procedure, new nodes are added in the middle of the side of elements on the mesh of higher level, e.g., node G in Fig. 1(c). These "mid-nodes" can result in the inconsistent nodal solutions of chloride ions in FEA between the adjacent elements. A possible solution of this problem is to apply the multiple-point constraint (MPC) to eliminate the DOFs on mid-nodes from the final matrix solver of linear equations. But this approach requires some additional modifications to the old computer program we developed previously, especially when the sparse matrix is used. Thus, we used another approach, i.e., transitional elements, to solve the problem of inconsistent nodal solutions on mid-nodes. According to the number and positions of mid-nodes, different transitional elements are formed inside the element on the higher

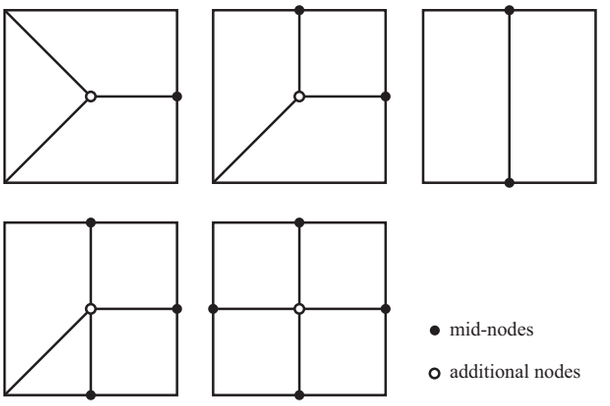

Figure 2: A schematic of additional nodes and transitional elements due to mid-nodes.

level, as shown in Fig. 2. The disadvantage of this approach is that extra nodes should be generated inside the element, which may increases the number of DOFs in the final matrix solver. But these extra nodes can also result in a smooth transition of nodal solutions between elements of different levels.

2.3 *FEM for chloride diffusion problem*

2.3.1 *Transient analysis*

The governing equation of the chloride diffusion can be obtained by the Fick's 2nd law:

$$\frac{\partial \phi}{\partial t} = D_x \frac{\partial^2 \phi}{\partial x^2} + D_y \frac{\partial^2 \phi}{\partial y^2} + D_z \frac{\partial^2 \phi}{\partial z^2} \tag{1}$$

where ϕ is the nodal solution of chloride content, D_x, D_y, D_z are apparent chloride diffusivity in three directions, respectively. For an isotropic material, $D_x = D_y = D_z = D_{\text{app}}$.

In mathematics, Eq. (1) is similar to the governing equation for thermal conductivity. Thus, it can be numerically solved by FEM for thermal conductivity as demonstrated in some textbooks, e.g. (Reddy & Gartling 2000). The final matrix system of linear equations can be expressed as:

$$\boldsymbol{C}\dot{\boldsymbol{\phi}} + \boldsymbol{K}\boldsymbol{\phi} = \boldsymbol{P} \tag{2}$$

where matrices $\boldsymbol{C}$ and $\boldsymbol{K}$ are analogy to the specific heat and conductivity matrices in thermal transfer problem, respectively. This matrix equation can be discretized in time domain and transformed to:

$$\overline{\boldsymbol{K}}\boldsymbol{\phi}_{n+1} = \overline{\boldsymbol{Q}}_{n+1} \qquad (n = 0, 1, 2, ..., M) \tag{3}$$

where $\overline{\boldsymbol{K}}$ and $\overline{\boldsymbol{Q}}_{n+1}$ are:

$$\overline{\boldsymbol{K}} = \boldsymbol{C}/\Delta t + \theta \boldsymbol{K} \tag{4}$$

$$\overline{\boldsymbol{Q}}_{n+1} = [\boldsymbol{C}/\Delta t - (1-\theta)\boldsymbol{K}]\boldsymbol{\phi}_n + (1-\theta)\boldsymbol{P}_n + \theta \boldsymbol{P}_{n+1} \tag{5}$$

where $\theta = 1/2$ is used (the Crank-Nicolson method). By the above equations, the nodal solutions of chloride content can be obtained step by step based on a given initial condition, i.e., $\boldsymbol{\phi} = \boldsymbol{\phi}_0$

2.3.2 *Steady analysis*

In a steady analysis, the nodal solutions of chloride content is irrelevant to time. Thus, Eq. (1) is simplified as:

$$D_x\frac{\partial^2\phi}{\partial x^2}+D_y\frac{\partial^2\phi}{\partial y^2}+D_z\frac{\partial^2\phi}{\partial z^2}=0 \tag{6}$$

and the final matrix equation is simply:

$$\boldsymbol{K\phi}=\boldsymbol{P} \tag{7}$$

2.3.3 *Initial and boundary conditions*

In most cases, it can be assumed that no chloride ions present inside fresh concrete where river sand is used. Thus, the initial condition can be simply:

$$\boldsymbol{\phi}_0=0 \tag{8}$$

The boundary conditions of chloride diffusion problem at meso-scale mainly contain two types, i.e, the Dirichlet (Γ_ϕ) and Neumann (Γ_q) boundary conditions:

$$\phi=\phi_b \quad \text{on} \quad \Gamma_\phi \tag{9}$$

$$\partial\phi/\partial\overrightarrow{n}=q \quad \text{on} \quad \Gamma_q \tag{10}$$

where $\overrightarrow{n}$ is the unit vector normal to the boundary. For the Neumann boundary condition, it is usually assumed that $q=0$. In this case, $\boldsymbol{P}$ in Eqs. (2) and (7) does not exist, i.e., $\boldsymbol{P}=0$.

2.4 *Refinement criterion*

When the nodal solutions of chloride content are obtained on the mesh of level n, for each element , the chloride content inside the element can be calculated based on the nodal solutions and shape functions:

$$\phi(\xi,\eta,\zeta)=\sum_{i=1}^{n}\phi_i\cdot N_i(\xi,\eta,\zeta) \tag{11}$$

where ϕ_i is the nodal solutions, n is the number of nodes in the element ($n=3,4$), (ξ,η,ζ) are the local coordinates of the element, N_i is the shape function. Then, the local field distribution of chloride content in each element is compared with that obtained from the previous level of mesh to calculate the error and define the refinement criterion:

$$\varepsilon=\frac{\int(\phi^{l+1}-\phi^l)\mathrm{d}\Omega}{\Omega}>\varepsilon_0 \tag{12}$$

where Ω is the area (2D) or volume (3D) of the element, ε_0 is the predefined critical value.

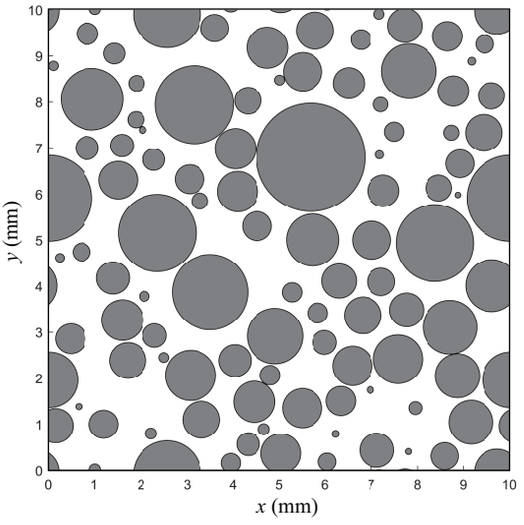

Figure 3: Meso-scale model for benchmarks of steady and transient analysis.

3 BENCHMARKS

Consider the meso-scale model shown in Fig. 3 which is a slice from a 3D model in REV of size $10\times10\times10$ mm^3. Both of steady and transient analysis are conducted in this model to compare the results and efficiency between AMR-based FEM and normal FEM. For the steady analysis, the boundary conditions are:

$$\phi(y=0)=1.0 \quad \phi(y=10)=0.0 \tag{13}$$

$$\partial\phi/\partial\overrightarrow{n}(x=0.0)=\partial\phi/\partial\overrightarrow{n}(x=10.0)=0.0 \tag{14}$$

while for the transient analysis, the boundary conditions are:

$$\phi(y=0)=1.0 \quad \partial\phi/\partial\overrightarrow{n}(y=10.0)=0.0 \tag{15}$$

$$\partial\phi/\partial\overrightarrow{n}(x=0.0)=\partial\phi/\partial\overrightarrow{n}(x=10.0)=0.0 \tag{16}$$

In both of steady and transient analysis, the apparent chloride diffusivity of cement paste is $D_{\text{cp}}=0.0864$ mm^2/d (1.0×10^{-12} m^2/s which represents a small chloride diffusivity of cementitious materials), while the diffusivity of ITZ (D_{ITZ}) is assumed as 5 times larger than D_{cp} (Zheng, Zhou, Wu, & Jin 2012) due to its higher porosity and percolation effect (Winslow, Cohen, Bentz, Snyder, & Garboczi 1994, Bentz, Hwang, Hagwood, Garboczi, Snyder, & Scrivener 1994).

3.1 *Steady analysis at meso-scale*

The results of steady analysis at different mesh levels are shown in Fig. 4. During the AMR procedure, the program can automatically identify the critical elements to be refined based on the refinement criterion in Eq. (12). The results show that most of these critical elements are located at the surface of aggregates.

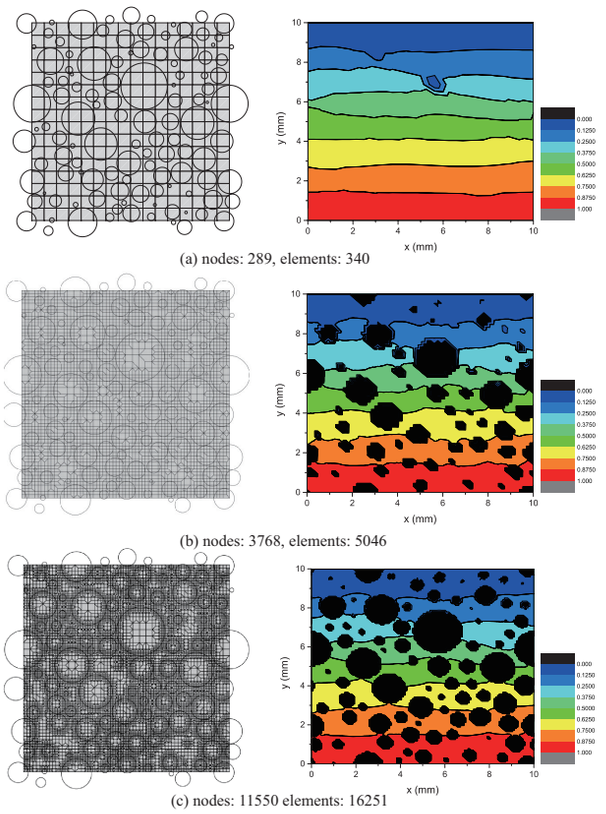

Figure 4: A benchmark of steady analysis of chloride diffusion at meso-scale with AMR.

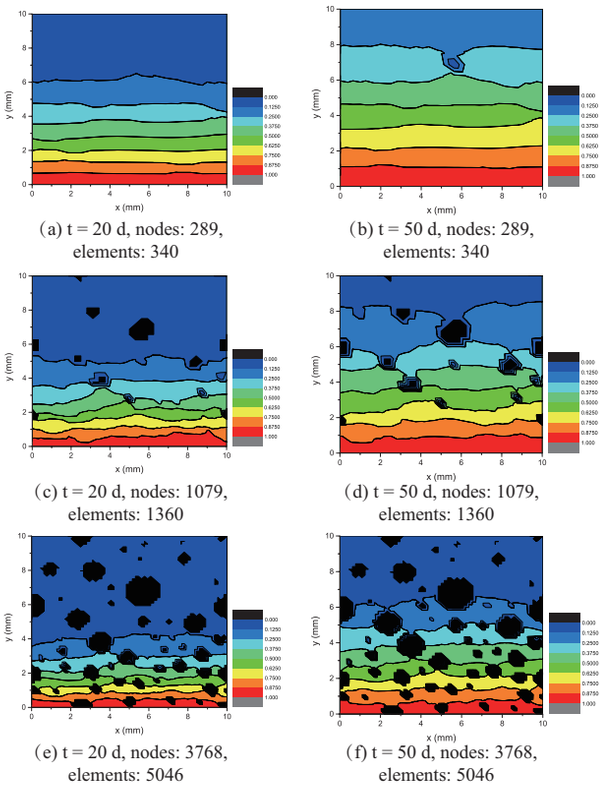

Figure 5: A benchmark of transient analysis of chloride diffusion at meso-scale with AMR.

By refining the critical elements to higher levels of mesh, the effect of aggregates on the field distribution of chloride content, as well as the transport path, becomes more and more significant.

Base on the field distribution of chloride content at meso-scale, we can further calculate the chloride flux in each element and determine the equivalent apparent chloride diffusivity of the REV for structural durability design at macro-scale by following the procedure in (Pan, Xin, & Chen 2014).

3.2 *Transient analysis at meso-scale*

The transient analysis starts from an initial condition $\phi_0 = 0.0$ by assuming that no initial chloride ions, e.g., the chloride ions in sea sand, are mixed in fresh concrete. The whole transient analysis lasts for 50 time steps with $\Delta t = 1$ d. The field distributions of chloride content at time $t = 20$ d and $t = 50$ d obtained at different levels of mesh are plotted in Fig. 5. Similar to the steady analysis, the critical elements are also found at the surface of aggregates, and as mesh level increases, the effect of aggregates on chloride diffusion process becomes more obvious.

3.3 *Efficiency analysis*

To analyze the efficiency of AMR-based FEM, the number of DOFs in AMR-based mesh and uniform mesh in the above benchmarks are compared in Fig. 6. As can be seen, when the mesh level reaches 9, the number of DOFs in uniform mesh will dramatically increase with the mesh level, while the number

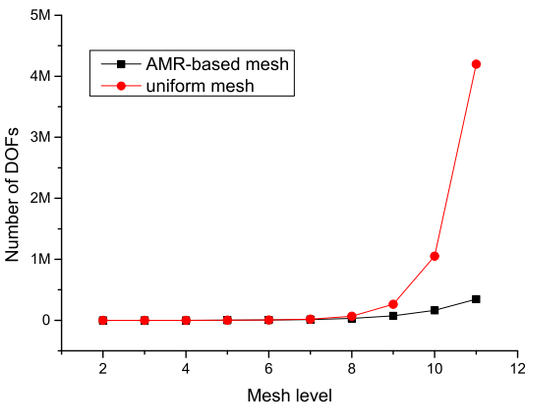

Figure 6: A comparison between number of DOFs of AMR-based mesh and uniform mesh.

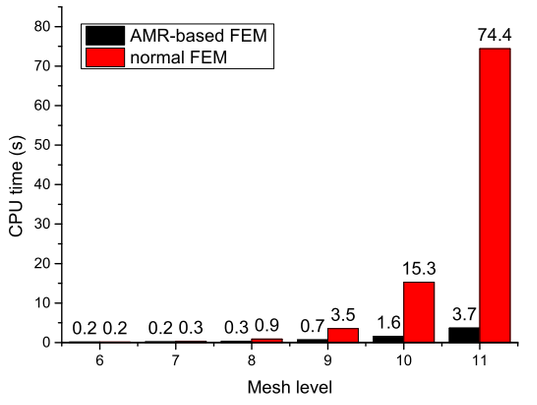

Figure 7: A comparison between CPU time of AMR-based FEM and normal FEM in steady analysis.

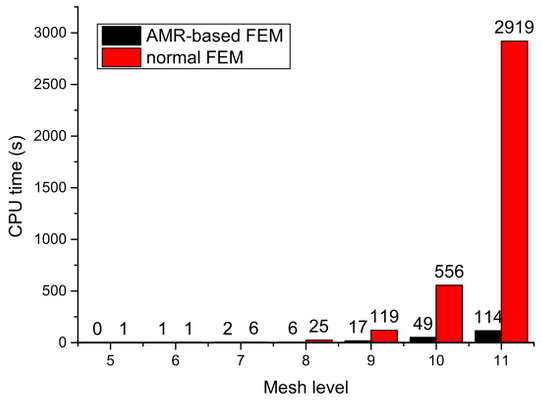

Figure 8: A comparison between CPU time of AMR-based FEM and normal FEM in transient analysis.

of DOFs in AMR-based mesh just shows a slight increase.

The CPU time to conduct the whole numerical simulation, including mesh formation, element refinement, global matrix formation, solver of sparse matrix system, etc., is also compared between AMR-based FEM and normal FEM, as shown in Fig. 7 and Fig. 8 for steady and transient analysis, respectively. Due to the adaptive mesh, the CPU time needed by AMR-based FEM does not change too much with different requirements of the solution precision.

4 DISCUSSIONS

Although the above benchmarks successfully demonstrate the advantages of AMR-based FEM in efficiency of simulation in chloride diffusion at meso-scale, there are still some problems in the current method and developed programs, which will be pointed out and briefly discussed as follows.

4.1 *ITZ modeling*

The ITZ is a special microstructure in cementitious materials in that it has a much higher porosity than bulk cement paste and extremely small thickness, i.e., $10 \sim 50$ μm (Ollivier, Maso, & Bourdette 1996, Scrivener & Nemati 1996). This huge discrepancy between geometrical sizes of ITZ and aggregate makes it difficult to explicitly model ITZ in a numerical simulation. Some researches homogenized the aggregate and its ITZ into an equivalent "aggregate" (Zheng, Zhou, Wu, & Jin 2012), while some researches deliberately increase the thickness of ITZ used in the numerical simulation, e.g., 1.0 mm (Du & Jin 2014), to avoid the difficulty in modeling ITZ.

In the current research, the ITZ is modeled by a classic approach, i.e., assigning ITZ material properties to the interface elements which are partially occupied by aggregates and cement paste. Thus, during the AMR procedure, the ITZ thickness decreases due to the smaller size of elements on the higher level mesh. Furthermore, the geometrical boundaries, as well as the volume fraction, of aggregates in the finite element model is different from that in the original meso-scale model due to the "saw-toothed" effect from the mapping mesh method. Although this effect can be decreased by a refined mesh, it cannot be completely eliminated theoretically.

The above improper modeling of ITZ well explains why the critical elements to be refined in the benchmarks in Section 3 are almost all found at the surface of aggregates. Actually, it is found in the benchmarks that the error calculated by Eq. (12) does not obviously decrease during mesh refinement. Thus, the current program can only terminate the analysis when the mesh level reaches a predefined one or the ITZ thickness (size of interfac elements) meets the requirement of the real thickness observed in experiments. This approach differs from the error control and convergence criterion in classic AMRs. To solve this problem, a better modeling of ITZ in the mass transport issue of cementitious materials by AMR-based FEM should be found.

4.2 *3D AMR-based FEM*

Just as an illustration, the benchmarks in Section 3 are only conducted in 2D. But the proposed method and developed program can be extended to 3D with a more complex data structure and preprocessor. In 3D, the efficiency of AMR-based numerical method can be expected to be further increased compared with a 2D AMR-based method. But a detailed benchmark is not conducted here, as the computation requirements in normal FEM exceed the capacity of computers we used. When the AMR-based method is extended to 3D, the data structure used in the computer program should be carefully optimized. Otherwise, the efficiency of AMR will be slowed down due to the frequent data processing between different levels of mesh.

5 CONCLUSIONS

This paper mainly developed an AMR-based FEM to simulate the chloride diffusion in concrete at meso-scale. The detailed implementations of AMR, FEM in solving chloride diffusion problem and refinement criterion are demonstrated. With the developed program, benchmarks of 2D steady and transient analysis of chloride diffusion at meso-scale were conducted to compare the efficiency between AMR-based FEM and normal FEM. The results showed that AMR could greatly decrease the CPU time needed by FEA, especially in a extremely refined mesh. Furthermore, some problems in the current method and developed program, e.g., improper modeling of ITZ, error control, convergence criterion, data structures, were pointed out and briefly discussed. Through this research, it is

expected to develop a platform for efficient simulation of mass transport process in porosity materials at the scales where the heterogeneity needs to be considered.

Bridge Displacement Monitoring using Acceleration Measurement for Efficient Bridge Management

Y. Umekawa & H. Suganuma
TTES, Inc., Tokyo, Japan

ABSTRACT: In this study, the concept of efficient bridge management system focused on monitoring bridge displacements has been proposed for maintaining numerous middle length bridges in rural government of Japan. In order to monitor displacement easily, a displacement estimation method has been proposed using measured acceleration data. The applicability of the proposed method then has been verified trough the filed measurement using the loading truck. Finally, the management system has been proposed and its application scheme also has been introduced for further actual operations in local districts in the future.

1 INTRODUCTION

1.1 *Background*

Numerous civil infrastructures, which were constructed during the rapid economic growth of Japan, have rapidly been aged or deteriorated and so much attention has been paid to the maintenance of infrastructures. With regards to bridges, there are over 700 thousand bridges in Japan. Therefore, it is necessary to develop efficient maintenance technologies such as Structural Health Monitoring (SHM) systems for satisfactory management of these existing bridges.

Almost 70% of total bridges are managed by local government districts, and these bridges are mainly short or medium length (~50m). In addition, local governments have serious problems such as insufficient financial and human resources, as well as technical shortage. Hence, it is essential to manage as many bridges as possible with minimum cost and effort, leading to the concept of the minimum monitoring system.

In particular, for bridge structures, it is important to measure displacement in relation to loadings such as passing vehicles, as bridge displacement can be used to ensure the application limit of bridges. Moreover, displacement is directly related to stiff nesses of bridges and therefore bridge displacement can be used to understand the tendency of how existing bridges will deteriorate by monitoring change of bridge displacements induced by the known weight of the passing vehicles.

In this study, by considering the implementation cost and applicability in field measurements, an acceleration based displacement monitoring system has been proposed as namely minimum monitoring system. For simple and easy usage, displacement is estimated by numerical integration of acceleration data, which is measured from one acceleration sensor by the proposed method in this study. Next, the field measurement based on loading tests using trucks, have also been conducted for a simple and medium length existing bridge to measure displacements and accelerations from an acceleration sensor attached at the main girder.

From the results of the field measurement, estimated displacements have been compared to directly measured displacements using a contact displacement sensor, and the accuracy of the proposed method has been verified. This study has verified the applicability of the minimum monitoring system for efficient management of bridges. The application scheme of this monitoring system has then been introduced for further actual operation in local government districts.

2 PORPOSAL OF BRIDGE DISPLACEMENT ESTIMATION METHOD

2.1 *Displacement measurement for bridge structures*

As the aforementioned background, bridge displacement is of great importance for monitoring the bridge behavior or for assessing its structural safety, serviceability and integrity, as structural deterioration and damages are mainly caused by dynamic loadings from heavy vehicles passing over bridges.

Direct displacement measurement systems, such as contact displacement sensors and laser displace-

ment sensors, are very expensive and not applicable for bridges as these displacement sensors must require fixed points for reference as well as power supplies. Therefore, although these reference-based sensors are accurate, their practical application for bridge monitoring is not efficient due to implementation costs and limited accessibility. In other measurement system, Global Position System (GPS) or vision-based systems enable reference-free displacement measurements, but their accuracy is not reliable and their installation cost also cannot be considered cost-effective either (Nakamura, 2000, Lee, 2006).

On the contrary, accelerometers are commonly used for SHM of bridges considering they are cost effective and easy to install without the need of any reference points in the recent researches. In addition, recent developments in Micro Electro-Mechanical Systems (MEMS) based sensors have encouraged accelerometers to develop also, by becoming wireless, small, cheaper and more accurate. Therefore, indirect displacement estimation methods, using measured accelerations, have been proposed as an effective method for bridge monitoring systems instead of using direct displacement measurements.

2.2 *Difficulties in bridge displacement estimation from acceleration measurement*

However, double integration of measured acceleration results in not reliable displacement estimation with an unacceptably large drift error due to inherent their sensor noise. Therefore, in order to estimate displacement accurately by using double integration, low frequency noise components must be removed to avoid large estimation errors.

To overcome this difficulty of integrating measured accelerations, Park et al (Park, 2005) proposed an initial velocity estimation method where displacement is estimated using boundary conditions, such as an assumed initial velocity or initial zero displacement, to reduce the effect of large drift. However, this method divides measured acceleration into several segments such as the dynamic and static responses and then integrates each segment to improve the accuracy of the pseudo static displacement estimation. Considering the actual traffic situations on in-service bridges, this estimation method is not applicable for automated displacement determination as the time of passing vehicles remains unknown.

In another study, Richard et al (Richard 2006, Velde 2006, Kandula 2012) estimated bridge deflections by assuming bridge vibrations as the sum of exponentially damped sinusoids. Using this method, noise free acceleration could be obtained and then integrated to displacement. However, this estimation method has to utilize large matrix calculations with Singular Value Decomposition (SVD)-based algorithms, which can cause high calculation cost. Instability also arises when analyzing measured accelerations from MEMS-based sensors because these sensors include much more sensor noise than other sensors.

Lee et al (Lee 2010) developed a Finite Impulse Response (FIR) filter for indirect displacement estimation from measured accelerations, but this integration filter only focuses on the zero-crossing displacement under a passing train and ignored the pseudo static displacement. In parallel, Park et al (Park 2013) proposed an acceleration-based displacement sensor using the smart sensor Imote2 platform. Using this sensor, displacement can be automatically calculated by the proposed FIR filter-based method. The applicability of acceleration-based displacement estimation has great potential to obtain displacement information of even large bridge structures. These recent approaches aim at performing intelligent on-board computing by using wireless monitoring systems with smart sensors and consequently, full-scale bridge monitoring is able to provide more meaningful information.

Umekawa et al (Umekawa 2015) have proposed an integration method using a wavelet transformation and the effectiveness of the proposed method has been verified for analyzing changes of bridge displacement. As the similar approach, and Sekiya et al (Sekiya 2016) have focused on the cause of integration error and represent the importance of selecting acceleration sensors for displacement estimation, and also proposed the method named “free vibration method” using multiple acceleration sensor to detect the entrance and the exit of passing vehicles onto the girder and integrate free vibration and induced displacement by passing vehicles separately.

Even though several displacement estimation methods have been proposed to date, the difficulty of integrating in the lowest frequency regions has yet to be improved, because of high density noise which comes from mechanical and/or thermal effects. This problem is also caused by variety of noise densities in the accelerometer specifications used for analyses. Moreover, the pseudo static displacements induced by passing vehicles are not zero-crossing responses but half-length waves and so it is difficult to evaluate this kind of vibration.

Taking into account the aforementioned integration problems and studies, this paper presents an integration method with auto calculating algorithm from measured acceleration by only one accelerometer. The proposed method is demonstrated using measured acceleration data sets and estimates bridge displacement of an in-service bridge in local government districts. To validate the applicability and accuracy of this integration method, the estimated displacement results are verified by comparing to measured displacements.

2.3 *Proposed method for bridge displacement estimation*

In this study, the target of bridge displacement is basically for only one passing vehicle, as bridge displacement regarding to the known weight should be evaluated to monitor change of the response with time. In addition, bridges in local districts have few amount of traffic and therefore it is not so important to evaluate displacement induced by continuously passing vehicles.

Displacement is induced by a passing vehicle as shown in Figure 1. When the vehicle pass onto a bridge girder, pseudo-static displacement which is a half-length wave and mainly lower frequency based on the passing time, happens to the loading direction and this displacement can be theoretically obtained by double integration of acceleration data.

However, measured acceleration data inherently includes sensor noise and this sensor noise become significant integration error in the process of integration and also this sensor noise cannot be separated by filtering because this sensor noise exist in all frequency domain. Therefore, this estimation error should be removed to estimate displacement accurately. However, this integration error does not linearly increase in the time domain as the density of sensor noise also fluctuate in time because of the mechanical instability of sensors, and therefore it is not possible to estimate simply.

The outline of the proposed method is as shown in Figure 2. Firstly, measured acceleration is theoretically integrated twice to obtain displacement (Figure 2a) following this equation below in time domain.

$$d = \int_0^T \left[\int_0^\tau a(\tau) d\tau \right] dt + v_0 + d_0$$

where d : displacement, a : acceleration, v : velocity, v_0 :initial velocity, d_0 : initial displacement.

Measured acceleration data $a_{measured}$ includes measurement error caused by sensor noise e_i as following the equation.

$$a_{measured} = a_{real} + e_i$$

This integrated displacement includes the estimation error caused by sensor noise as shown in the following equation.

$$d_{estimated} = d_{real} + \sum_0^t \sum_0^t e_i dt^2 + \sum_0^t e_i dt$$

However, this estimation error is basically caused by mechanical behavior of sensors such as temperatures changes and so always not stable. Therefore, it cannot be considered possible to define the model of this estimation error as equation.

Hence, in this proposed method, from the displacement, the entrance and the exit of passing vehicle is detected in time domain, as the displacement induced by passing vehicle can be considered as a local change and distinguished from the estimation error (Figure 2b).

The estimation error can be estimate by using the integrated result by polynomial spline estimation (Figure 2c) and finally the estimated displacement can be estimated be removing the estimated integration error in time domain (Figure 2d)

This applicability and accuracy of this method has been verified by the field measurement using the loading trucks.

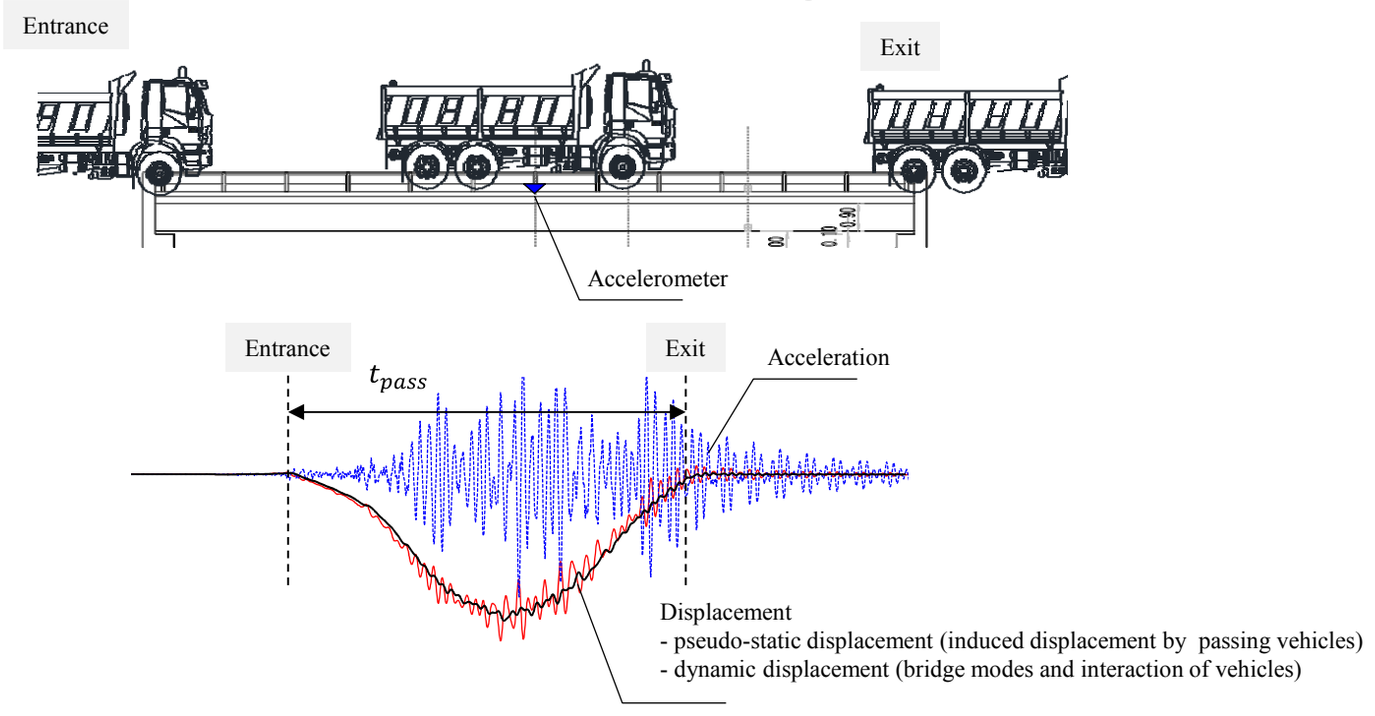

Figure 1. Outline of bridge displacement estimation from measured acceleration

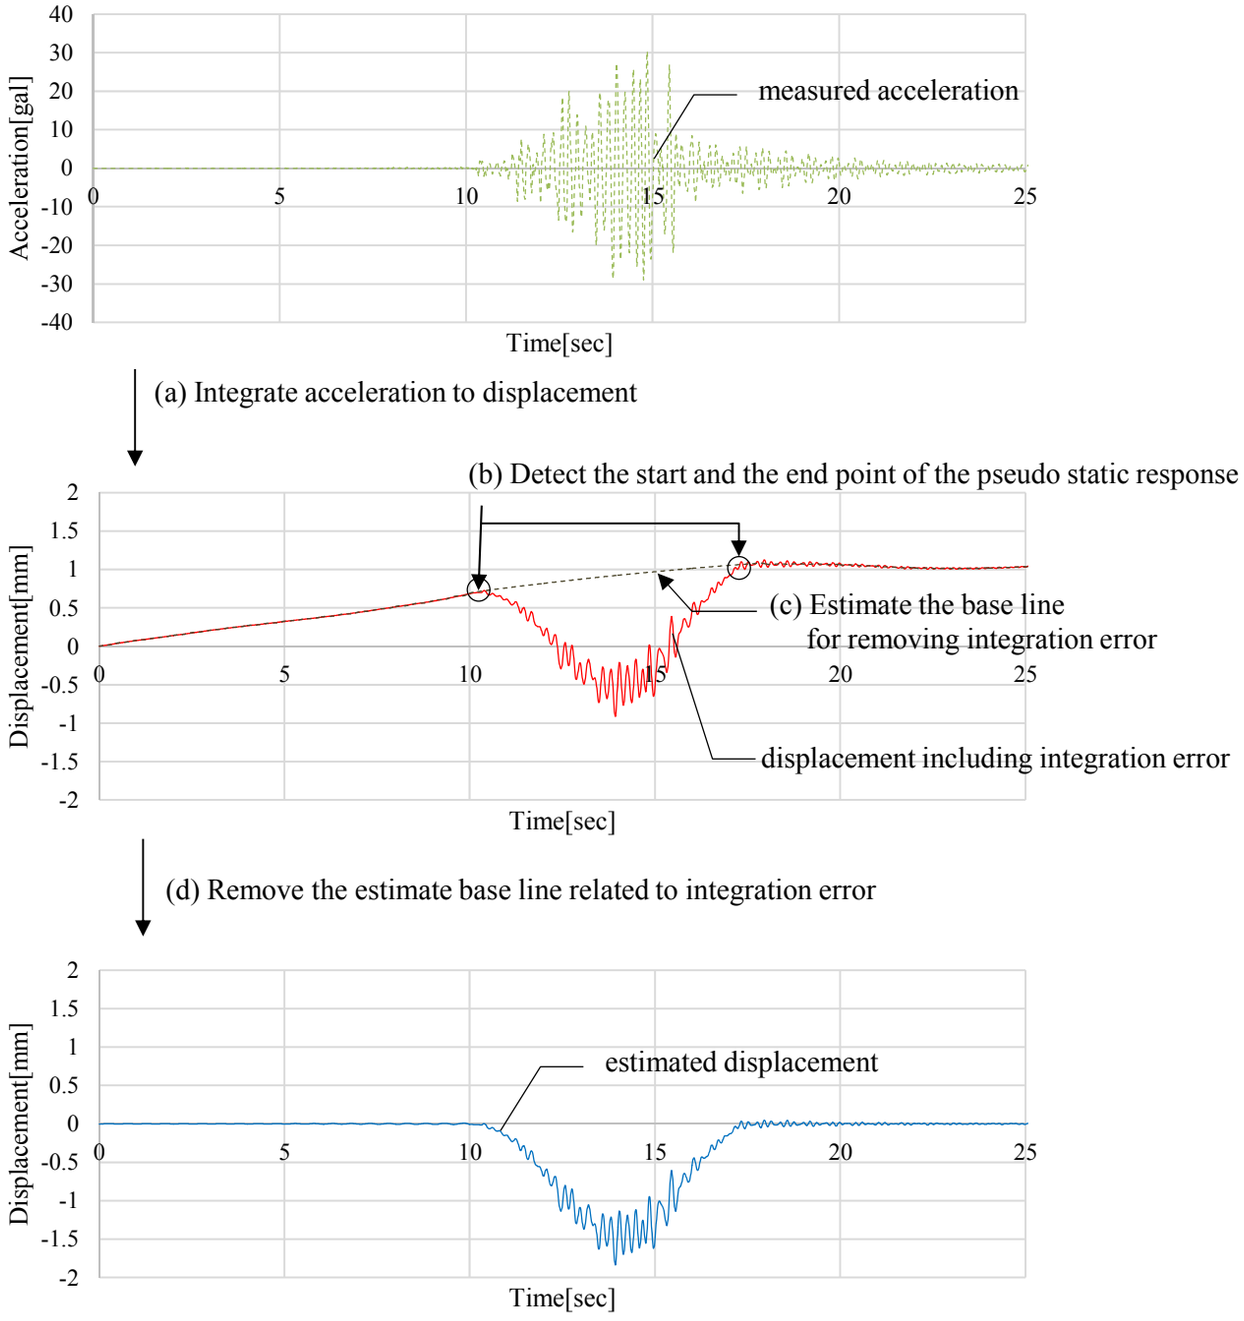

Figure 2. Conceptual outline of the proposed method

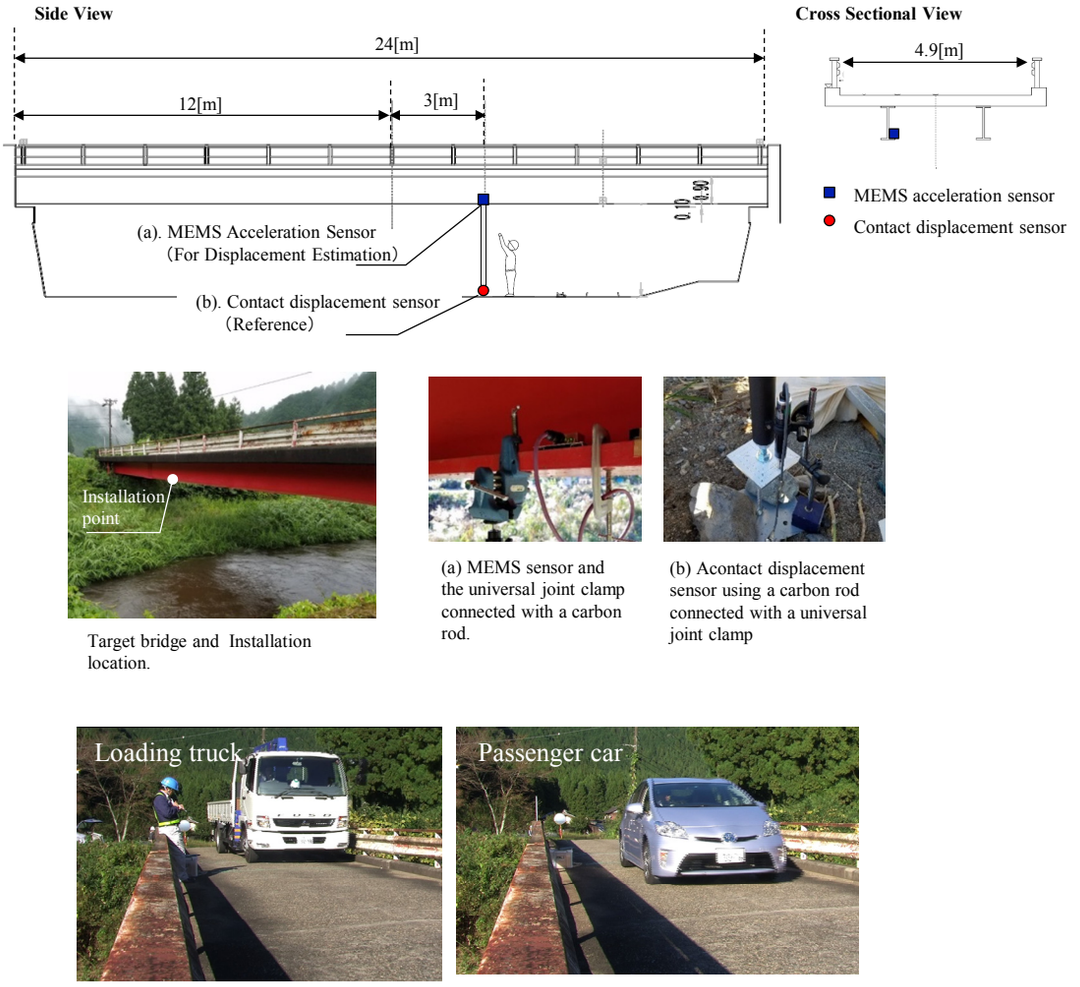
3 FIELD LOADING TEST



3.1 *Target bridge and field measurement*

The target bridge is a steel girder bridge, with one lane as shown in Figure 3. The span length is 24[m] and the effective width is 4.9[m]. This target bridge was selected as local bridges have commonly short or medium length span (~50m) and are located in low-traffic area.

MEMS acceleration sensor was attached at the installation point, lower flange of the girder with magnet sensor base plate. The carbon rod connected with a universal joint, was attached at the same location. The top of this rod has the plate to be measured by a contact displacement sensor attached on the ground. The detailed specification of these sensors is shown in Table 1.

Contact displacement sensor was also installed as reference data to verify estimation results using acceleration data by comparing these data. These sensors were connected to the same data logger with sampling frequency of 100[Hz].

Loading test was conducted using 2axles Truck and a passenger car, which were prepared for inducing enough large displacement to be evaluated. The total weights of these vehicles are 6.2[ton] and 1.5[ton]. The speed of loading test was conducted with around 20[km/h] as there is no space to get faster speed around the target bridge.

Target bridge and Installation location.

Figure 3. Target bridge and the detail of measurement equipment

3.2 *Verification of estimated displacement by using the proposed method*

The displacement induced by the loading vehicles was measured by a contact displacement sensor, and estimated from measured acceleration data by the proposed method. The verification results can be shown in Figure 4. These results show the bridge displacement estimated from the acceleration data by using the proposed method, and the high correlation can be seen between these data. In the case that the loading truck passed through the girder, the maximum displacement was 1.64[mm] and the frequency of this induced pseudo-static displacement was about 0.05[Hz] (passed time = 9[sec]). In this frequency band, it is difficult to obtain the accurate integration results because the larger integration error happens if the frequency of noise is lower than 1[Hz]. In another case that a passenger car passed through the girder, the maximum displacement was around 0.3[mm], and this result shows the high applicability even for small displacement and it is difficult for other displacement sensors to measure accurately this order of small displacement.

The estimation errors were calculated as three times of standard deviation (3σ) of the difference between measured and estimated displacements in each case, and represents that the displacements

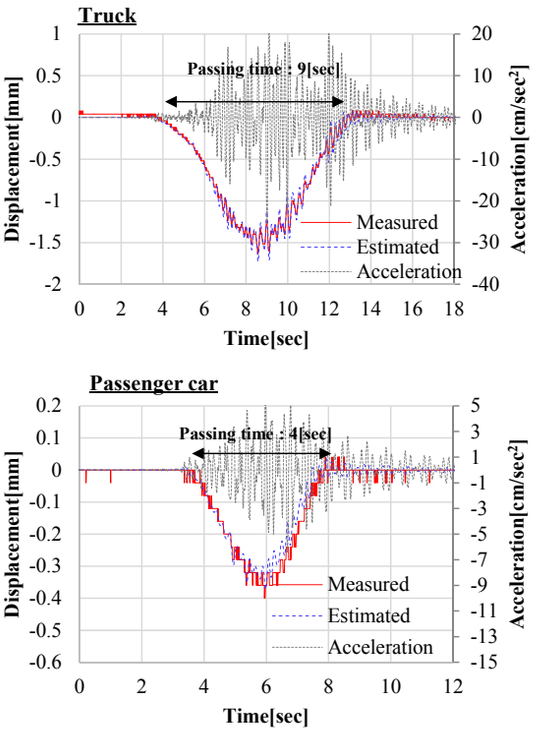

Figure 4. The results of bridge displacement estimation of a loading truck and a passenger's car

could be estimated from a measured acceleration data with high accuracy as shown in Table 2. There are

Table 1. The details of sensor specifications

Type	Range	Frequency band	Resolution
MEMS accelerometer	±5[G]	0.1 – 20[Hz]	0.06[μG]
Contact displacement sensor	±25[mm]	0 – 5[Hz]	0.05[mm]

Table 2. The evaluation of estimated results and its accuracy

Case	Type	Total weight[kg]	Measured displacement [mm]	Estimated displacement [mm]	3σ [mm]

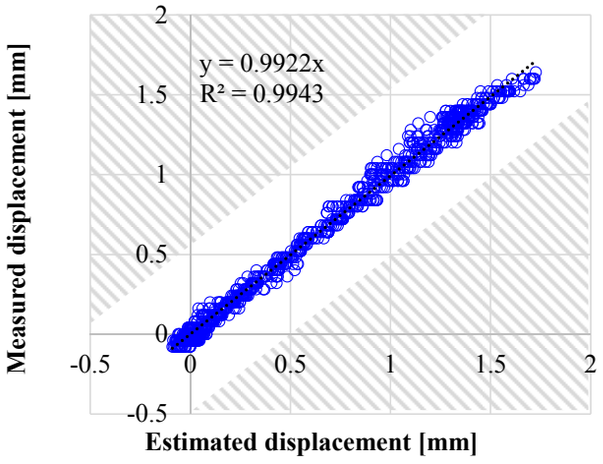

Figure 5. The comparison of measured and estimated results (Case 1: Truck)

still few errors between them, but this difference is caused by differences between each sensor specification of the applicable frequency bandwidth. Also, comparing the estimated and measured displacement in the case 1, these displacements can be seen as a linear relationship as shown in Figure 5. The difference of these displacements are under 0.2[mm] at any sampled time.

Hence, from the measured data by the conducted loading test, the applicability and the accuracy of this proposed method could be verified by comparing to measured displacements as referential data.

Figure 6. The base plate and the sensor plate attached on wheel guard

4 APPLICATION OF THE MINIMUM MONITORING SYSTEM

4.1 *Preparation for the installation of measurement equipment*

The minimum monitoring system requires only one acceleration sensor as acceleration is possible to provide the information of bridge natural frequencies of bridges, and displacements induced by passing vehicles. As acceleration can be installed on the girder by using the base plate, which enables to measure acceleration from on the girder, on wheel guard of bridges as shown in Figure 6. By anchoring this base plate, it is possible to measure acceleration data easily by attaching the sensor plate to this base plate.

4.2 *The development of this proposed system for application*

In order to make this system applicable for local government districts, it is important to design the system which anyone can easily use. According to the recent development of the network infrastructure services such as Cloud services, many things have been connected with the internet, which idea is called by Internet of Thing (IoT). The sensors con-

nected with the internet server to analysis measured data by this proposed method and then these data and results can be stored in data storage by using high secure data transmission. This data is also connected with map location service to efficiently manage the data and the bridge interactively. The prototype device is developed as shown in Figure 7.

4.3 *The actual operation of this proposed system*

The actual application scheme of this proposed system is as shown in Figure 8. The brief outline of actual operations of this proposed method is below.

1) As the initial setup for preparing measurements, the base plate is attached at the center of wheel guards of bridges.
2) Next, when field measurements are conducted, IoT devices including MEMS sensor with the sensor plate, is attached to the base plate.
3) After this preparation, the loading vehicle passes through bridges and then acceleration data are measured at the same time.
4) Measured data is uploaded and stored to Could server through M2M communication with GPS location information, and simultaneously measure data are analyzed by Could computing engine including the proposed analysis algorithm. After measurements are finished, these devices are collected and these base plates are covered until next measurement.

By using the devices temporary and measuring as many bridges as possible at the same time, it is possible to inspect bridge behaviors with reducing maintenance cost of bridges. This system can be considered capable of enabling to support the problems such as cost, human resource and technical shortage in local government districts. In addition, the proposed system has been developed as WEB application (Infra Studio) and this application enables people who have less technical knowledge to manage stored these monitoring data.

5 CONCLUSION

The purpose of this study is to propose a bridge displacement estimation method by using one acceleration data to develop applicable displacement measurement method. A bridge estimation method has been proposed, and has been applied to measured accelerations from an in-service bridge in a local district. The results have then been verified by comparing the estimated displacements to measured displacements measured using a contact displace-

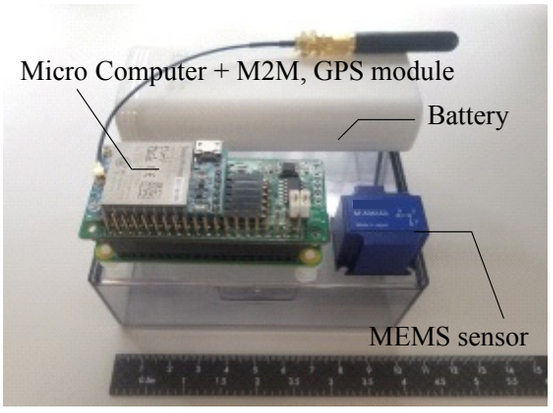

Figure 7. The prototype device for efficient measurement of acceleration data

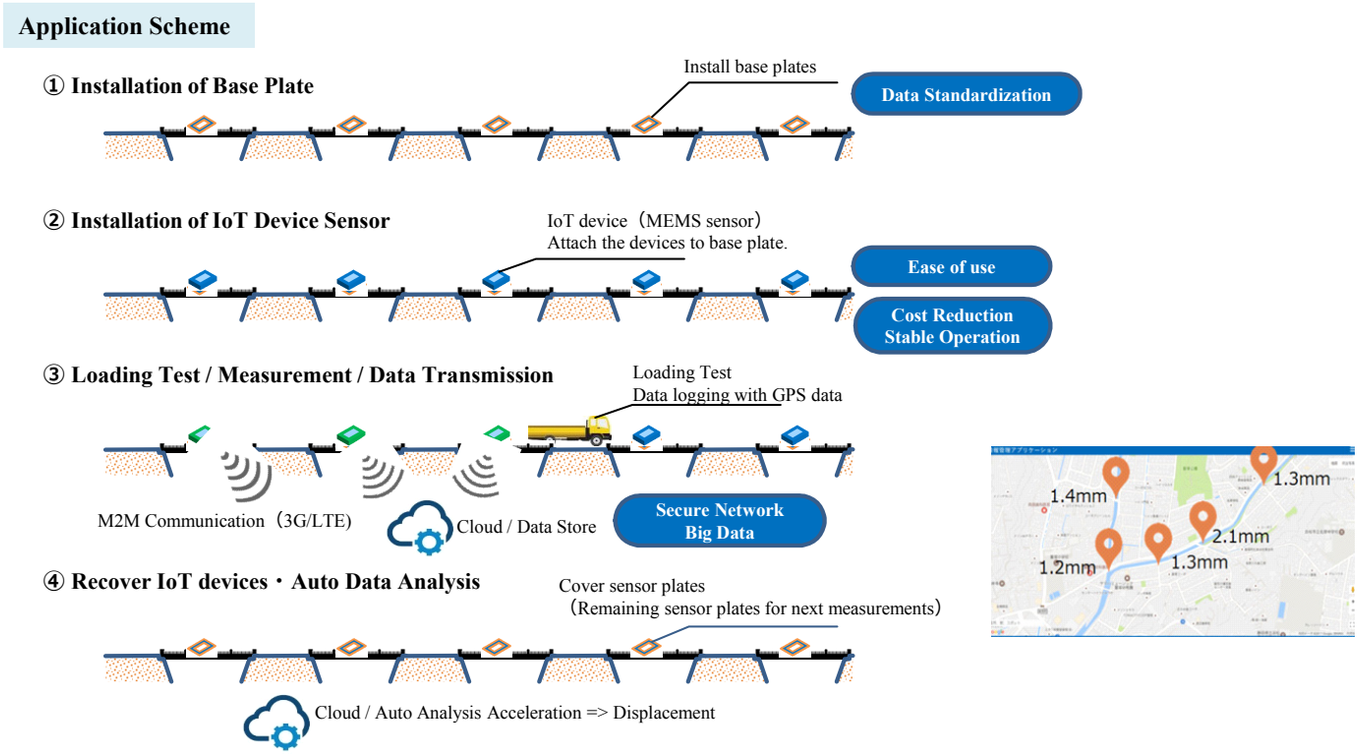

Figure 8. The application scheme of the proposed monitoring system for actual operation

ment sensor. In addition, for applying this proposed method as the minimum monitoring system, the actual operation procedure has been considered and also the bridge monitoring system including data storage and analysis engine has been developed. The results can be summarized as follows.

1) A bridge displacement estimation method has been proposed, and its applicability has been verified trough field measurement regarding to the light amount of the traffic amount such as the prepared loading trucks.
2) The accuracy of the proposed method has been verified by comparing estimated displacements to measured displacements. The estimation error has been validated as three times of standard deviation of difference between their data.
3) The concept of the minimum monitoring system has been introduced and then the actual operation procedures have been considered. The applicability of this system has been developed by using the Cloud network system.

The applicability of this proposed method has been verified. However, this proposed method has been developed for measuring bridge displacement basically when a single passing vehicle pass through short or medium span length bridges and therefore the proposed method should be developed for continuous and complex traffic situations for applying to many kinds of bridge structures. By developing the IoT device, more efficient measurement and maintenance of bridge could be possible. Considering efficient bridge management system, the knowledge of civil engineering and the application of ICT technologies should be connected.

Guide for a Successful Monitoring Project from Finland

J. Wuorenjuuri
VR Track Oy, Helsinki, Finland

Monitoring structures is one of the main fields of structural engineering in the future. Monitoring project have many challenges. It requires more skills and more knowledge from all partners involved in the monitoring project. In the past, it has been difficult to see monitoring as a project. The roles have been unclear in monitoring process, results have not been so clear for decision makers. The purchaser of monitoring has not been able to get the information he thought he would get. And the monitoring costs have been a surprise. But the fact is that monitoring costs are reducing all the time and the results are greatly just as good as the purchaser himself knows how to buy these services. In Finland to help purchasers to build a successful project a Bridge Monitoring Guide was introduced in 2016.

1 NEED FOR MONITORING GUIDE

1.1 *Background*

The Bridge Monitoring Guide is drawn up to assist purchasers in monitoring of bridges and to form engineering problems into monitoring projects. The guide presents the contents and the process of the monitoring project and how to run a successful project through. At the same time, a separate Bridge Monitoring Handbook is introduced to assist designers, consultants, and expert companies to plan the monitoring projects as service providers.

As more monitoring companies and service providers come to the field of monitoring, also purchasers must be able to meet the requirements of procurement of effective monitoring results.

Information generated by bridge monitoring projects must serve effectively the decision making relating to bridge management and usability issues. Unified methods of purchasing and quality assurance activities improve these goals and help achieving cost-effectiveness of monitoring objectives and reduce unnecessary monitoring.

This Bridge Monitoring Guide can be used for monitor projects to road, rail, light traffic, and street bridges. The guide may also be used, as applicable, for other engineering structures. The Guide serves as help for procurement procedures and quality assurance. The Guide describes the monitoring methods, the monitoring project process, the quality control, and safety issues of the monitoring project, and can be used to monitor both new and existing bridges. The Guide also includes general guidelines for test loading of bridges.

1.2 *Terminology*

It was also very important in the Bridge Monitoring Guide to define the words, roles, and documents in a Monitoring project.

One of the main challenges has been, that when purchaser buys a monitoring service, he expects results from the monitoring report. But often comes up to be disappointed, when the monitoring project only gives raw data as a report. Of course, the purchaser needs to also buy the analyzing service from an expert.

Also, there has been problems, that the known problem has been monitored using unsuitable monitoring method. It is like getting answers to different questions that originally the purchaser had in mind. It is up to the purchaser to know what he is buying and what should be included into a Monitoring Project to get the right results.

1.3 *Basis for monitoring*

Monitoring is a method of structural engineering that produces numerical information about the actual behavior of the structure. Monitoring supplements the conventional inspections of the bridge by pro-

ducing information that can be utilized and compared later in determining bridge loads, service life, comfort and damages, and the assessment of design solutions. Monitoring is not a substitute for bridge inspections, but can be incorporated into the inspection system. The monitoring of the bridge condition aims to give the information needed for most cost-effective repair or construction measure.

The repair and construction measures are usually based on solutions, which are very dependent on good quality data. By improving this data for example by monitoring, a more cost-effective outcome is possible. Monitoring can be also executed several times if needed.

The monitoring projects to solve bridge capacity issues is mainly related to situations where the axle and total weights of heavy traffic and the stresses they cause are to be determined in advance. In these monitoring projects, mainly known loads are used and the goal is to find a connection between the actual behavior of the structure and the calculated model. The focus of capacity related monitoring is in the final phase of the monitoring project, which is the analysis of the results. Monitoring can be used to produce bridge behavior information about normal permissible weights and special transports.

Bridge monitoring can provide information to determine bridge life. In the analysis phase of the monitoring project, the relationship between the original design life and a more accurate estimate of the current lifetime can be specified, based on the measured conditions and the deterioration issues of the bridge. This information can be used either for the choice of the repair principles or for the safe end of the bridge for use.

In addition to the capacity and deteriorations analysis, monitoring can be used other purposes such as to provide information on the usability, comfort levels or vibrations of the bridge or the general development of bridge standards. In addition, monitoring can provide information on new innovative design or construction solutions if needed to verify special structures.

Mostly, monitoring is related to the use of the bridge, but monitoring can also be executed during the construction phase for quality management purposes of construction works. The duration of monitoring can vary from one-time monitoring to continuous monitoring of the entire bridge lifespan. Monitoring can also be restricted to specific structural parts or it may be localized to damaged points.

Monitoring can consist of one project called a Monitoring Project and a monitoring program consists of several Monitor Projects. The monitoring project consists of three components: monitoring planning, monitoring implementation and analysis of monitoring results. The implementation part of the monitoring is the inspection activity at the bridge site.

2 MONITORING NEEDS AND GOALS

The decision to monitor a bridge must be based on monitoring needs. Monitoring is an option when the available information of a bridge cannot achieve the desired target state. Monitoring needs can be related to bridge damages, bearing capacity, lifetime, comfort, and development. There may be a need for monitoring may already before the bridge is built, but often the monitoring need arises after the construction phase when the bridge is in use. The need to monitor the condition of a bridge often comes up after special inspections or known failures and the need for monitoring of the bearing capacity is linked to capacity calculations.

Bridge monitoring must be a systematic activity that is performed according to the instructions given. The results should be stored in a database or a bridge register and in a unified mode, so the data can be used later without special programs.

The monitoring need must be a starting point for a monitoring plan. The monitoring plan defines the monitoring project and the form of implementation. The Monitor Project should produce enough new information so that the target state of a bridge can be achieved cost-effectively. To collect the right information, monitoring must include goals for the implementation and the analysis phases, so that the original target is reached. These goals must be defined in the monitoring plan. The purpose of goals for monitoring is also to reduce unnecessary monitoring.

The goals of the monitoring implementation and analysis phases must be defined at the beginning of the monitoring plan. Since setting of goals has a significant impact on the costs of monitoring, they can be specified during the monitoring plan phase, with more accurate information about the more exact monitoring methods and their costs. Setting targets for monitoring is most effective when it is done in co-operation between the purchaser and the main monitoring consultant of a Monitoring Project. The goals of Monitoring must be set so that they are achievable. Also, multiple simultaneous goals can be set for monitoring.

A Monitoring Project does not include the actual bridge repairs or modifications. The Monitoring Project only produces more measurement data,

which is supplemented by information on the load bearing capacity and damage analysis models of a bridge. The design for bridge repairs or modifications is part of the post-monitoring activities that can be taken to reach the target state of a bridge. A Monitoring Project gives information to the decision maker on the investment needs

3 MONITORING METHODS

3.1 *General*

The monitoring method describes the continuity and duration of the monitoring performed in the Monitoring project. There are three monitoring methods: continuous, periodic and single monitoring projects. The monitoring method does not directly describe the scope of monitoring.

The selection of the monitoring method influences the most to the duration of the monitoring. In addition, it affects the installation of measuring devices and sensors, the implementation of monitoring and the cost of monitoring. As a basic rule, continuous monitoring has the highest cost and single monitors have the lowest costs.

3.2 *Continuous monitoring*

Continuous monitoring is a continuous measurement of the bridge without interruption. The continuous monitoring may take several years and often it will permanently install the sensors in the structure. Continuous monitoring is the most productive and often cost-effective monitoring.

In continuous monitoring, attention should be paid to the early stages of the Monitoring Project and, if necessary, monitoring, especially for long-term operation, maintenance and calibration capabilities of sensors and measuring devices. Continuous monitoring can track time-dependent quantities. Moving the measurement data from the subject to the monitoring results analyzer can happen continuously and automatically or intermittently for example once a day.

3.3 *Periodic monitoring*

In periodic monitoring, the bridge is monitored in sequences. The length of the period to be measured and the length of the period can be short or long for up to several years. The spacing between periods may be regular or irregular, and repairs or modification to the bridge can be made between the periods. Periodic monitoring is particularly suited to ensuring the success of repairs to the bridge. Periodic monitoring can be used to monitor time-dependent variables.

In the early stages of the Monitoring Project, in the periodic monitoring phase, attention should be paid especially to the calibration of sensors and measuring devices.

3.4 *Single monitoring*

In single monitoring, the bridge is monitored for only one period. Single monitoring will change into periodic monitoring if it is renewed later, for example, after bridge repairs. The possibility of periodic monitoring should already be identified in the monitoring plan to consider the repeatability of the measurement arrangements and possible re-installation of the sensors. The duration of a single monitoring may be some weeks. For example, information about continuous heavy traffic and its effects on the bridge can be obtained. However, during single monitoring, the condition of the bridge is not expected to change, so it is not possible to generate data on time-dependent quantities.

3.5 *Selection of monitoring method*

Selection of the monitoring method is the responsibility of the purchaser of the Monitoring Project. The monitoring method generates a significant part of the cost of monitoring and substantially affects the information produced by monitoring. The choice of monitoring method depends on the need for monitoring, the target state of a bridge, the cost of monitoring and the usefulness of the results obtained. Different monitoring methods can often be used to achieve the goals. Selecting a monitoring method is always bridge-specific and case-specific.

In case of a damaged bridge all monitoring methods can be used. Continuous monitoring and periodic monitoring techniques can be used to distinguish time-dependent factors from monitoring results. In single monitoring, it is important to use a sufficiently large load of normal traffic if the test load is not used. The monitoring of the development of a damage requires continuous or periodic monitoring. In assessing the significance of damage, the monitoring method should be chosen based on possible new information that can be produced and monitoring costs.

In the case of the determination of axle loads (= permissible axle and total weights), periodic and single monitoring can be used to monitor the bridge. Changing the permissible axial and total weights is often subjected to test loads, and single monitoring can be used to verify the load carrying capacity. Continuous monitoring is often not cost-effective in the estimation of bearing capacity, but it can be used to monitor the performance of a bridge repairs or increasing permissible loads on bridge.

Information related to estimate the remaining lifetime of a bridge, can be generated by all monitoring methods. Single monitoring cannot produce information about factors that change over time. In single monitoring the lifetime review is only related to the information produced by the test loading. Periodic or continuous monitoring can be used to produce accurate continuous information for estimating service life.

The most appropriate monitoring method and the cost of monitoring is usually made more accurate during monitoring planning. When the information and goals are defined, the main monitoring consultant of the monitoring must specify the various monitoring options for the purchaser so, that the target status defined by the purchaser can be achieved after the Monitoring Project. Selection of the monitoring method should also consider the available Monitoring Project implementation scenarios.

4 SCOPE OF MONITORING

4.1 *General*

The scope of the monitoring describes the resources used to plan, implementation and analyzing the results of the Monitoring Project. The scope of the monitoring involves the use of the monitoring technology, the number of measuring devices used and the analysis of the monitoring results. The monitoring project has three different scopes: limited, extensive, and extra extensive. Selecting the scope of monitoring is part of the task of the purchaser.

The scope can be selected during the monitoring project or can be refined when the monitoring plan is completed and the purchaser has more information about the monitoring. The scope of monitoring affects the number of measuring points and measurement techniques.

4.2 *Extra-extensive monitoring*

In addition to the phenomenon under examination, the extra-extensive monitoring provides detailed information on the actual behavior of the entire bridge. More than one measurement technique and very many measurement channels is used to monitor the same phenomenon in an extra-extensive monitoring to model the actual behavior of the bridge.

4.3 *Extensive monitoring*

In extensive monitoring, information is provided in addition to the item under consideration, and the overall real behavior of the bridge. There may be several measurement techniques and several measurement channels is used.

4.4 *Limited monitoring*

In limited monitoring, information is provided only on the phenomenon under review. In a limited monitoring, only one measurement technique is used to generate information. The measurement channels are usually up to 20, but a simple method can be used to analyze the monitoring results.

4.5 *Selecting the Scope of Monitoring*

The scope of monitoring plays a major role in the cost of monitoring the project. The scope of the monitoring is always based on the most cost-effective scope option. In selecting the scope, the purchaser must estimate the amount and reliability of the data generated by the monitoring in relation to the cost of monitoring. The scope of monitoring should always be chosen so that the information can be used reliably to achieve the target state with an analytical model.

The importance of the bridge should be evaluated when selecting the scope of the monitoring. Significance means the importance of a bridge or bridge type on the transport network. In addition, it is necessary to evaluate the possible replacement of the bridge. With a large replacement cost, extensive monitoring can help achieve cost savings if the renewal of the bridge can be postponed to the future or even demolished after use.

5 MONITORING PROJECT

5.1 *General*

The Monitoring Project is a set of monitoring issues and processes. The Monitoring Project includes all three aspects of the monitoring (planning, implementation, and analysis of results), the documents of each sub-area and the contracts between the parties involved. The whole monitoring project is designed to provide the necessary additional information to achieve the defined target state.

The monitoring project has three main forms of implementation (divided monitoring, centralized monitoring, and shared monitoring). Implementation forms determine the roles and tasks of the parties involved in the monitoring project. The suitability of the implementation forms for the monitoring project depends on the monitoring method, the duration of the monitoring and the resources available.

Choosing the right choice for the implementation method is intended to ensure the quality and cost-effectiveness of Monitoring Project. A Monitoring Program consists of several Monitoring Projects. It is important that the measurement and analysis results are stored in a systematic database.

5.2 *Roles of the monitoring project*

The Monitoring Project includes different roles for the various parties involved, which include responsibilities in the areas of the monitoring project. Responsibility is defined as a set of issues, the role of which being the same. In one project, the same company or person can have more roles. For example, in centralized monitoring, in addition to its role of the main monitoring consultant can have roles as the main monitor planner and monitoring results analyzer.

Each project must have at least the following roles:
- Purchaser
- The main monitor consultant or planner
- The monitoring implementer
- The monitoring results analyzer
- The monitor expert of Purchaser
- Safety Coordinator

The Project options for Monitoring can be as in the following 5.3 – 5.5.

5.3 *Project option 1: Divided Monitoring Project*

Divided monitoring is the most common form of monitoring. There are three parties involved in divided monitoring during the entire monitoring project: the purchaser, the main consultant of monitoring and the monitoring implementer. In addition to these parties, the project may include sub-consultants. In the divided monitoring, the monitoring results are analyzed for the main consultant of monitoring. There may be more monitoring implementers if the Monitoring Project is periodic and lasts for a long time.

Divided monitoring can be applied to conventional Monitoring Projects, which can be both short and long. From the purchasers point of view, divided monitoring usually requires less contract documents because the monitoring process can be purchased mainly with the plan main monitoring consultant. For the purchaser, the greatest risk is that the implementation of the monitoring must be realized as planned.

5.4 *Project option 2: Centralized Monitoring Project*

Centralized monitoring is a lightweight Monitoring Project for the Purchaser. In addition to the purchaser, there is only one company in a Centralized Monitoring Project. One company is involved in the planning, implementation and analyzing of the monitoring results. In a Centralized Monitoring Project, the information link between the contract partners is more straight forward, and the risks caused by the communication between the partners are small.

A Centralized Monitoring Project is suitable for monitoring cases where the role of the purchaser in the monitoring project is kept to a minimum and where the monitoring content is clear. A Centralized Monitoring Project requires extensive contract documents from the Purchaser because the entire monitoring project is usually purchased at the beginning of the project. Additionally, the purchaser must have expertise in monitoring to evaluate the measurement techniques proposed and the suitability of the monitoring implementer.

5.5 *Project option 3: Shared monitoring Project*

A Shared Monitoring Contract is a purchaser-oriented mode for a Monitoring Project. In a Shared Monitoring Project, a different partner performs each aspect of monitoring. In addition to the purchaser, the Monitoring Project, the main monitoring consultant, the monitoring implementer, and the monitoring results analyst participate in the monitoring project. Long-term monitoring projects may have more monitoring implementers.

A Shared Monitoring Project is recommended to be used only in long-term monitoring projects where other Monitoring Project forms cannot be used due to the length of the Monitoring Project. It is recommended for the purchaser to use a monitoring expert consultant in a Shared Monitoring Project.

The major risks of a Shared Monitoring Project are the flow of information between the partners and complexity of project management. The separation of the Monitor Planner and the Monitoring Results Analyzer according to a Shared Monitoring Project raises the risk that the analysis of the monitoring results does not correspond to the monitoring plan. In Shared Monitoring Projects, the quality and content of plans and design documents is an important factor in successful Monitoring Project.

5.6 *The risks of a monitoring project*

The monitoring project involves risks that depend on the complexity of monitoring and its implementation. Risks occur in all three areas of monitoring. Risks can be divided into risks associated with management, planning and implementation. Risk analyzes are part of the risk management. Risks can be controlled by selecting the most appropriate monitoring method and form of project.

The risks associated with planning and implementation of monitoring depend mainly on the objectives of monitoring and on the complexity of the monitoring target. The risks of planning and implementation are mainly managed through monitoring plans that the purchaser accepts and the partners have sufficient professional skills. The risks of a Monitoring Project vary from one project to another. A general risk may also be lack of experience or lack of skills of chosen partners.

6 CONTENTS OF THE MONITORING DOCUMENTATION

6.1 *General*

The main monitor planner of the monitoring is responsible for determining the points to be examined by professional judgment so that reliable data are obtained from the condition and operation of the structures. The implementer of the monitoring is responsible for the reliability of measurement results and the long-term performance of sensors and other instruments. To ensure the reliability of the results, calibrations and related measurements must be made in continuous monitoring. The planner of the monitoring determines the level of accuracy for which measurements to be achieved.

The monitoring project includes the following documents:

- Contracts
- Monitoring Plan
- Safety plan
- Implementation plan
- Measurement Report from implementer
- Monitoring Report from Analyzer of results

In some cases, these requirements can be lowered if the project is small in scope or does not include structural monitoring. In a Centralized Monitoring Project, the Monitoring plan, Safety plan and Implementation plan can be combined into a single document.

Devices used for monitoring must be serviced and calibrated in accordance with their manufacturer's instructions. The documentation of the calibration data must be up-to-date.

Monitoring projects usually change during the way, so it is important to agree on the unit prices to possible modifications by the purchaser. The relevant structural drawings should also be available at the bridge site. It is also necessary to agree that the information is available for purchaser, project partners and possibly the maintenance partners during and after the project.

In case of continuous Monitoring Projects, different partners have different practices regarding the ownership of measuring instruments. The contract documents must specify whether the buyer is purchasing the measuring equipment and who owns them after the monitoring project. In principle, measuring instruments are part of the monitoring provider and their rental price should be included the implementation of the monitoring.

7 QUALITY MANAGEMENT

7.1 *Organization and staff*

The various partners involved in the monitoring must announce in their tenders the structure and organization of the monitoring service, as well as the duties and powers of those responsible for the implementation of the work. Persons participating in monitoring projects must meet requirements of purchaser for skills and safety levels. Continuity of competence must be ensured.

The quality assurance must be a part of the Monitoring Project. Usually the main monitoring consultant has the role of to ensure the quality of the Monitoring Project unless otherwise agreed.

7.2 *Subcontractors*

The subcontractor must meet the same organizational and personnel requirements as what is required from the main monitoring contract partners. The subcontractor must comply with the quality assurance procedure of the monitoring contract partners. Also, safety requirements must be met.

7.3 *Quality assurance*

The purchaser requires a quality assurance procedure documented by the monitoring partners. The quality assurance procedure will be reviewed at the first meeting. The partners implementing the monitoring system will make its own quality control in accordance with its quality assurance process.

Quality interim reporting during the audit period is done as agreed in the first meeting. A summary of the supplier's internal quality assurance and its results are presented to the purchaser in the final monitoring report. In small assignments communication and reporting can be agreed separately.

8 WORK SAFETY

8.1 *General*

All safety and performance issues in monitoring must comply with the requirements and instructions the purchaser as well as of laws and regulations and other governmental regulations. The laws set out the responsibilities and obligations of the employer, as well as the rights and obligations of the employee.

Monitoring is a form of structural inspections and the execution must be based on the safety regulations, procedural instructions, and safety instructions of the Finnish Transport Agency's guidelines. Monitoring is not construction work that has additional safety requirements. The Monitoring Project must have a Safety Coordinator appointed by the purchaser, who is responsible for the safety and health measures during the preparation, design and implementation phase of the project. The Safety Coordinator may be a from organization of purchaser or a consultant. A Safety plan that manages occupational safety must be always drafted.

There are also requirements for safety equipment and tools that can be used on a bridge site. Bridges in road environments have safety qualification requirements for all workers. Railway bridges require also Safety qualification for all workers. At bridge site that cross both road and railways, workers must have both qualifications.

8.2 *Transport arrangements*

Traffic arrangements are included in the monitoring order unless otherwise stated in the contract of the Monitoring Project. The safety document prepared by the purchaser also presents issues and requirements regarding traffic safety and traffic arrangements.

The monitoring implementer can either buy traffic arrangements as a comprehensive service for specialized companies or implements arrangements with their own resources. The organizer of the traffic arrangements must be named in the monitoring implementation plan.

The organizer of the traffic arrangements must always draw up a written traffic control plan. The traffic control plan is part of the monitoring implementation plan that must be approved by the purchaser. A notice of work that influence traffic must be made to the responsible Traffic Center in advance.

9 CONCLUSIONS

The main message to Monitoring Projects is that they should be well organized, management of the project has to be effective to get exact and useful information from monitoring. Monitoring is too expensive and time consuming, that it is waste of resources if the project does not produce enough information or it produces a lot of additional information that no one can use.

The purchaser has to have enough information and vision to make a good Monitoring project. he must know what to demand even if he does not understand the technical aspects of monitoring. The Bridge Monitoring Guide, that has been introduced in Finland to help purchasers to put together a monitoring project after a problem of capacity, damages or service life deficiencies has been detected. It is very important to understand, that monitoring is a helpful tool in decision making, especially when costs of aging infrastructure is getting higher every year.

The key issues are:
- clear project plan
- the choice of monitoring method
- the choice of scope of monitoring
- the scope of monitoring project type
- risk management
- quality management
- safety management
- the choice of skilled people

The cost of monitoring has reduced to a good level, and it will continue to do so. In Finland, there are many successful Monitoring Projects that have met the needs of wise decision making. Some projects are to understand the behavior of a bridge with special details or with damaged parts. Or to help decide to renew or repair methods. This is economical solution for a good infrastructure.

Bending-Shear Fatigue Behavior of Concrete Girder Bridges

Ming Yuan & Donghuang Yan & Yun Liu
Changsha University of Science & Technology, Changsha, China

ABSTRACT: Under the bending-shear condition, the diagonal crack of web will appear in concrete box-girder bridge when principal tensile stress of tensile-shear zone concrete exceeds principal stress limit value. The overall objective of this study is to develop a calculated method for the fatigue behavior of web under bending-shear of concrete box-girder bridge. First, some basic conceptions and calculation methods of concrete fatigue theory are introduced. Next, the time-history curves of bending moment, shear force and principal tensile stress in typical section have been achieved. Then the effects of vehicle speed and heavy vehicles for the equivalent principal tensile stress on web of box-girder are discussed. Finally, the reliability index is established to assess the fatigue life for existing concrete box-girder bridge. Some conclusions are drawn on the basis of the current research.

1 INTRODUCTION

The vehicle speed and overloading vehicles increase with the development of traffic. For service bridges, concrete microscopic cracks may occur and propagate by cyclic load. Under the bending-shear condition, the diagonal crack of web will appear in concrete box-girder bridge when principal tensile stress of tensile-shear zone concrete exceeds principal stress limit value (AASHTO 2002, JTG D64-2004 2004). Especially for the concrete box-girder bridge with small-medium span, the compressive stress value of principal tensile stress reserve generally small under dead load condition. Considered the effect of live load, the changes of principal tensile stress amplitude are more significant. Therefore, calculating principal tensile stress accurately under vehicles cyclic load is a challenging problem for fatigue life assessment and prediction.

Several studies have been proposed for concrete flexural fatigue (Shi & Yao 1990, Zhu 2011,Gaspar & Stucchi 2013, Sousa et al. 2013). These methods do not directly associate the bending-shear fatigue behavior. The overall objective of this study is to develop a calculated method for the fatigue behavior of web under bending-shear of concrete box-girder bridge. First, some basic conceptions and calculation methods of concrete fatigue theory are introduced. In combination with actual traffic volume of two typical highways, five typical kinds of vehicles are chosen as vehicle load spectrum of concrete box-girder bridges. Next, the time-history curves of moment, shear force and principal tensile stress in typical section have been achieved. The principal tensile stress spectrum at the web of box-girder is acquired by Rain-flow counting method. According to Miner linear fatigue damage rule, the equivalent principal tensile stress spectrum is proposed for fatigue life assessment and prediction. Then the effects of vehicle speed and heavy vehicles for the equivalent principal tensile stress on web of box-girder are discussed. Finally, the reliability index is established to assess and predict fatigue life for existing concrete box-girder bridge.

2 CALCULATED METHOD

2.1 *Vehicle load spectrum*

Many vehicle load spectrum for fatigue of the steel bridge have been obtained. Especially in Britain, the United States and other European countries, steel bridge fatigue load spectrums have been developed successfully and widely used. Combined with the actual traffic volume of highway bridge (Ju & Fan 1994). The following characteristics of vehicle load can be analysed by a certain method. The vehicle has various types, because the axle load, wheelbase, track width and total weight are different.The vehicle loads are processed according to the following principles:

1) According to the statistics of actual traffic, the same amount of axle is classified according to the vehicle load (the original load spectrum).
2) In each kind of vehicle load, according to the fre-

quency of the axle and axle load, and the equivalent axle load of each type of each axis can be found. Based on Miner equivalent fatigue accumulation rule (Gaspar & Stucchi 2013, Sousa et al. 2013), an equivalent conversion on the axle load is conducted, and then equivalent total weight has been obtained. The jth axis load of the equivalent vehicle is shown as

$$W_{ej} = (\sum f_i W_{ij}{}^m)^{1/m} \quad (1)$$

Where, f_i is the relative frequency from the same kind of vehicle, W_{ij} is the axle load, m is the slope of material S-N curve.

3) Wheelbase is generally be calculated by weighted method. C_j is the jth wheelbase of the vehicle load, it is shown as

$$C_j = \sum f_i \, C_{ij} \quad (2)$$

Where C_{ij} is the jth wheelbase of the ith vehicle load.

2.2 *Principle tensile stress spectrum*

The principle tensile stress spectrum of prestressed concrete box-girder bridge is calculated by vehicle-bridge coupling vibration model. The specific steps are list as follows:

1) According to the circumstance of bridges in roads, statistics of various models of axle load, the vehicle weight and traffic are surveyed.

2) Fatigue vehicle model is defined according to the statistics and classification of different models. Then the simulation models are computed.

3) Through the program of vehicle-bridge coupling vibration model, the time history for bending moment and shear force of bridge is concluded, and then the time history for principle tensile stress is achieved.

4) According to the drain sump method or the rain-flow counting method, the load effects $\Delta\sigma_e$ are acquired.

2.3 *Equivalent principle stress amplitude*

Because the internal force or stress course is discrete under axle load, the required stress amplitude cannot be directly applied in the analysis of fatigue performance and fatigue life prediction. It needs to simplify according to the Miner linear fatigue damage rule equivalent simplification. The formulas of the equivalent stress amplitude are shown as Eq. 3 ~Eq. 8.

The variable amplitude stress of bridge under vehicle load is divided into k parts S_{r1}, S_{r2},..., S_{rk}, its corresponding cycles n_1, n_2, n_3,..., n_k, assuming that the bridge structure or component under constant stress level S_{r1}, S_{r2},..., S_{rk}, the corresponding fatigue life N_1, N_2,..., N_k, under the effect of amplitude stress S_{ri}, the bridge structure or component have fatigue damage after cycles. According to the Miner linear cumulative damage rule,

$$D = \sum_{i=1}^{k} \frac{n_i}{n_k} = \frac{n_1}{N_1} + \frac{n_2}{N_2} + \cdots + \frac{n_k}{N_k} = 1 \quad (3)$$

According to the formula of constant amplitude fatigue $N(\Delta\sigma)^m = C$, m is the slope of S-N curve.

$$\sum n_i (S_{re})^m = C \quad (4)$$

$$N_i (S_{ri})^m = C \quad (5)$$

According to Eq. 3 and Eq. 4

$$\sum n_i / N_i = (S_{ri})^m / (S_{re})^m \quad (6)$$

According to Eq. 6 and Eq. 3

$$\sum \frac{n_i}{N_i} = \sum \frac{n_i}{\sum n_i} \bullet \frac{(S_{ri})^m}{(S_{re})^m} = \sum \alpha_i \bullet \frac{(S_{ri})^m}{(S_{re})^m} = 1 \quad (7)$$

Then, the equivalent stress amplitude is represented as

$$S_{re} = [\sum_{i=1}^{n} \alpha_i S_{ri}^m]^{1/m} \quad (8)$$

Where,

S_{re} -- the equivalent stress amplitude (MPa);

α_i -- the frequency of stress amplitude S_{ri};

S_{ri} -- stress amplitude (MPa);

m -- Material constant, generally value 3.0.

2.4 *Evaluation of fatigue life*

In view of the fatigue life evaluation and prediction, there are generally two kinds of methods to evaluate the fatigue life of bridge in the practical application. One method is using fatigue test data to evaluate the fatigue life by analysing fatigue curve. Another method is using the theory of fatigue crack propagation to evaluate the fatigue life.

Structural fatigue reliability index can be calculated as

$$\beta = \frac{\lg \Delta\sigma_R + 2S_R - \lg \Delta\sigma_e}{\sqrt{S_R^2 + S_e^2}} = \frac{\lg \Delta\sigma_R + 2S_R - \lg(k_1 k_2 k_3 \sqrt[m]{100/T\Delta\sigma})}{\sqrt{S_R^2 + S_e^2}} \quad (9)$$

$$= \beta_0 + \frac{(\lg T - \lg 100)/m}{\sqrt{S_R^2 + S_e^2}}$$

$$T = 10^{[2 - m(\beta_0 - \beta)\sqrt{S_R^2 + S_e^2}]}$$

Where, β_0 is the goal of fatigue reliability index, S_R, S_e is the standard deviation.

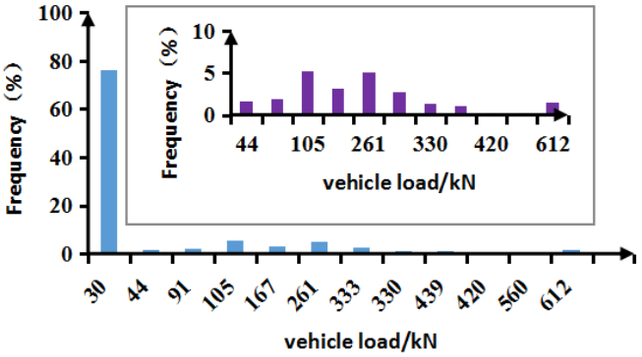
3 DEMONSTRATION EXAMPLE

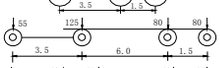
3.1 *Example of vehicle load spectrum*

Traffic volume survey is a statistics on a road of various kinds of vehicles and vehicle weight, through the investigation of road traffic. It can be used for study the change of the traffic volume (vehicle type, such as the distribution of the van), and provide ref-

erence for bridge design.

Actual traffic volume of two typical highways are combined and discussed. According to the statistics of actual traffic volume, vehicle load was classified by the same number of axles, the equivalent axle load and average wheelbase was calculated according to the Eq. (1) and Eq. (2). In order to simplify the load parameters of the vehicle model, the average equivalent axle load and average wheelbase are made following adjustments: 1) the equivalent axle load take multiples of 5 kN. 2) the average wheelbase take multiple of 0.5 m, as shown in Table 2.





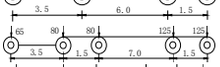


Figure 1. A bridge vehicle load distribution histogram in 2008

Table 1. The calculation results of the equivalent axle load, average wheelbase

Vehicle model number	Axle number	Equivalent axle load (kN)	Average wheelbase (m)
M1	2	42 83	4.42
M2	3	61 100 100	3.55 1.32
M3	4	53 123 82 82	3.35 5.92 1.24

Table 2. A bridge load spectrum in 2008

Vehicle model number	Graphic (The axle load: kN, wheelbase: m)	Total weight (kN)	The ratio of the total traffic volume(%)
M1		130	11.89
M2		260	5.03
M3		340	4.08
M4		475	1.24
M5		610	1.43
	Total		23.67

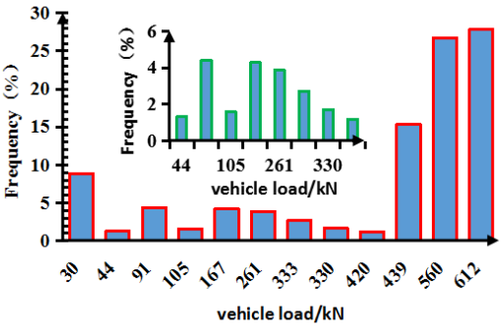

Figure 2. A highway bridge vehicle load distribution histogram in 2010

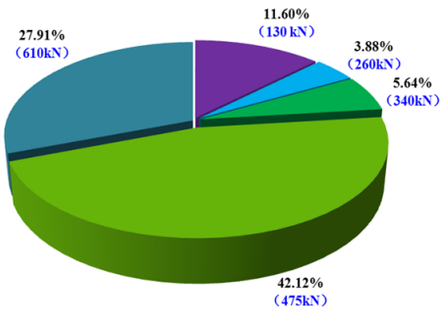

Figure 3. A highway bridge load distribution histogram in 2010

3.2 *Example of PC box-girder bridge*

The proposed methodology is demonstrated in this section for the fatigue analysis of a PC box-girder bridge. The bridge cross section under consideration is given subsequently in Figure. 4. The cross section form is single box section, span L=40 m, beam height H=2.2 m, top plate width B=13.0 m, bottom plate width D=9.0 m. The chamfer size of top plate is 20×60 cm, the chamfer size of bottom plate is 20×40 cm, the cantilever length of box girder is 2.0 m, web plate thickness is 0.4 m, the thickness of top plate is 0.25 m and bottom plate is 0.22 m.

C50 concrete is applied in the upper main bearing structure of bridge, the axial compressive strength standard value f_{ck}=32.4MPa, the axial compressive strength design value f_{cd}=22.4MPa. The prestressed steel strand with high strength and low relaxation is applied, the tensile strength standard values f_{pk}=1860MPa, diameter d=15.20mm, area S=139.0mm^2, modulus of elasticity E_p=1.95×105MPa.

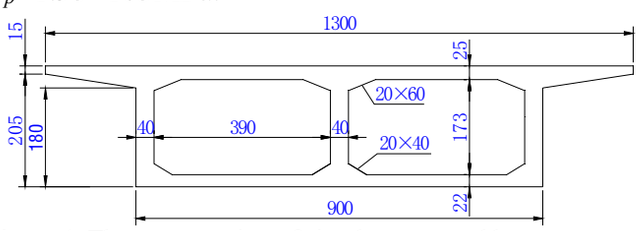

Figure 4. The cross section of simply supported beam

A program of vehicle-bridge coupling vibration model is applied to calculate the mid-span bending moment and shear force time history. Combined with the rain-flow counting method, then the princi-

pal tensile stress spectrum of control points on the box girder web is obtained, as shown in Fig.5 and Fig. 6. It is descried that: (1) The small stress amplitude of load spectrum 1 is taken relatively major proportion, and the high stress amplitude of load spectrum 2 is taken relatively major proportion; (2) Compared load spectrum 1 with load spectrum 2, its principal tensile stress is changed with the speed variation, and principal tensile stress amplitude also increased.

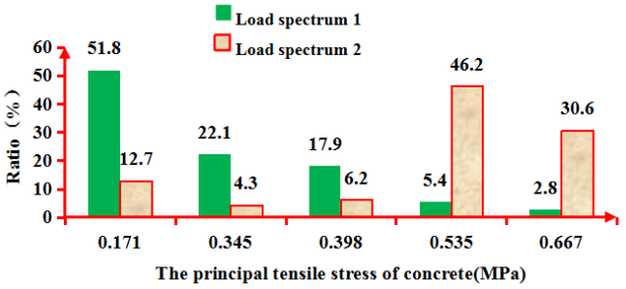

Figure 5. The position 3# of principal tensile stress spectrum on box girder web plate (vehicle speed is 10 m/s)

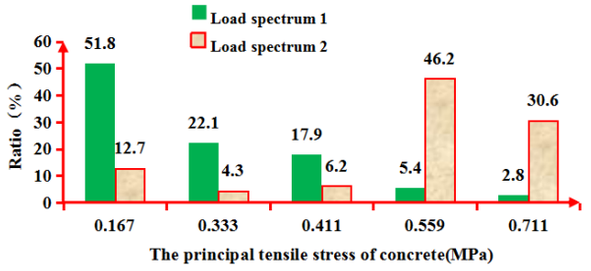

Figure 6. The position 3# of principal tensile stress spectrum on box girder web plate (vehicle speed is 50 m/s)

The equivalent principal tensile stress amplitude of 3# position on the box girder web is studied under different vehicle speed and heavy traffic volume, based on load spectrum 1and load spectrum 2. It is represented as follows as Figure 7~Figure 10. It can be descried that the equivalent principal tensile stress amplitude increases with vehicle speed and traffic volume growth. The heavy traffic volume affects the change of equivalent principal tensile stress amplitude obviously.

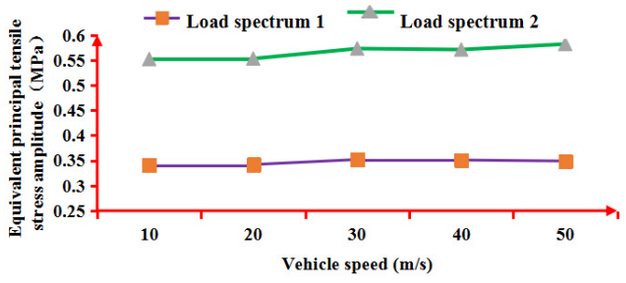

Figure 7. The equivalent principal tensile stress amplitude of 3# position on the box girder web under different vehicle speed

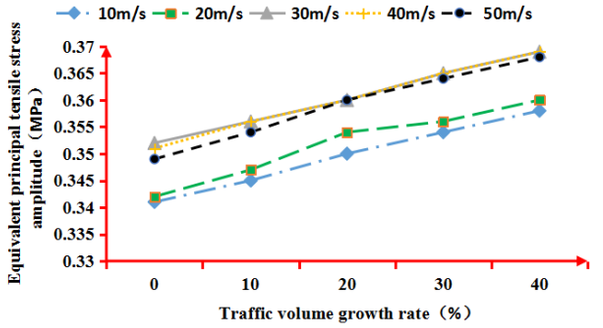

Figure 8. The equivalent principal tensile stress amplitude of box girder web under increased heavy traffic volume

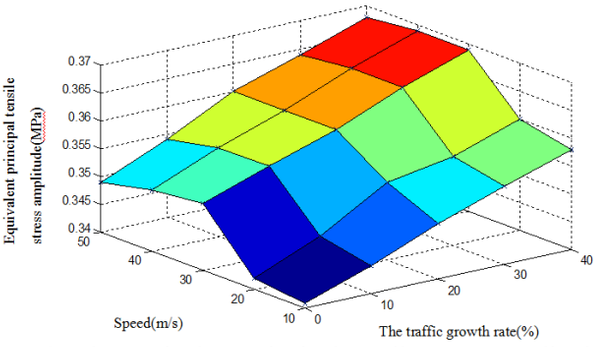

Figure 9. The equivalent principal tensile stress amplitude of 3# position on the box girder web plate under different vehicle speed and heavy traffic volume (load spectrum 1)

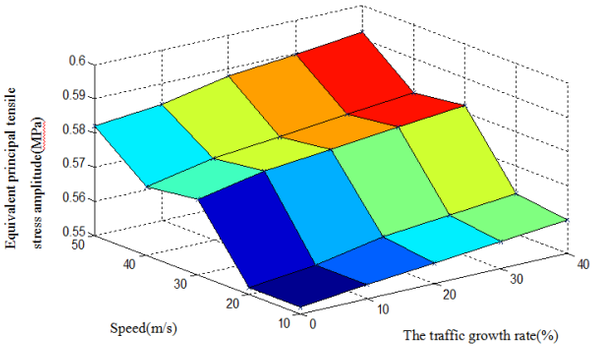

Figure 10. The equivalent principal tensile stress amplitude of 3# position on the box girder web plate under different vehicle speed and heavy traffic volume (load spectrum 2)

The reliability index under two load spectrums considering vehicle speed and heavy traffic volume are discussed. The parameters of reliability index are list as S_R=0.12MPa, S_e=0.066 (load spectrum 1), S_e=0.082 (load spectrum 2), $\Delta\sigma_R$=1.06MPa. The calculation values of reliability index and fatigue life are shown as Figure 7~Figure 10. The reliability index of bridge decreases according to the increase of vehicle speed and heavy traffic volume.

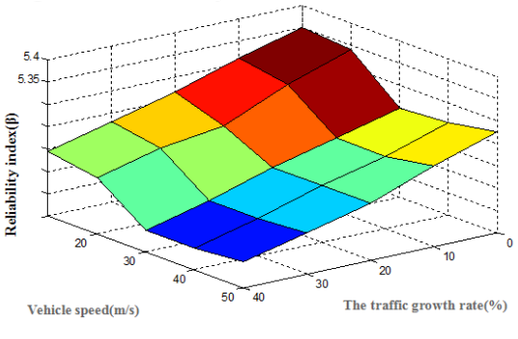

Figure 11. The reliability indexes considering the different vehicle speed and increased heavy traffic volume (load spectrum 1)

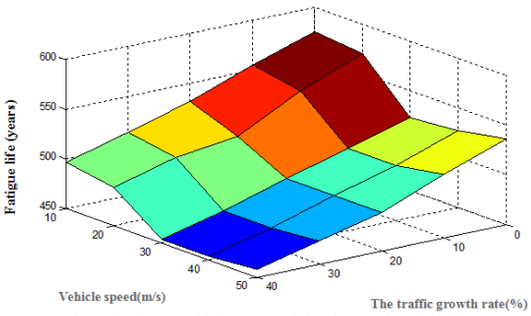

Figure 12. The fatigue life considering the different vehicle speed and increased heavy traffic volume (years) (load spectrum 1)

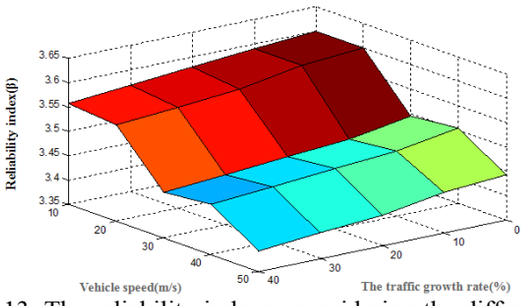

Figure 13. The reliability indexes considering the different vehicle speed and increased heavy traffic volume (load spectrum 2)

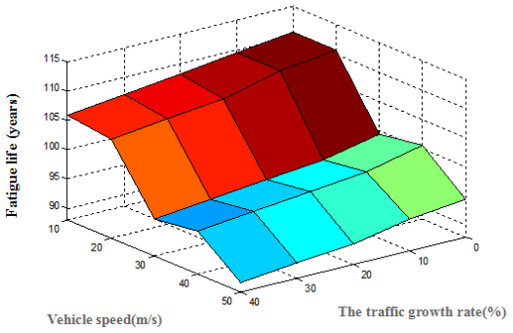

Figure 14. The fatigue life considering the different vehicle speed and increased heavy traffic volume (years) (load spectrum 2)

4 CONCLUSIONS

In this study, a calculated method for the fatigue behaviour of web under bending-shear of concrete box-girder bridge is proposed. Several conclusions are drawn on the basis of this study:

(1）Considering the growth of vehicle speed and heavy vehicle traffic volume, the principle tensile stress and equivalent principal tensile stress increase with the vehicle speed. The heavy vehicle traffic volume effect on principal tensile stress and equivalent principal tensile stress obviously, which increase with heavy vehicle traffic volume. The varieties of equivalent principal tensile stress amplitude are affected extremely when considering the vehicle speed and heavy traffic volume at the same time.

(2) Based on the equivalent principal tensile stress amplitude on the web of box girder, the fatigue life of PC simply supported box-girder bridge is evaluated under vehicle load. The growths of vehicle speed and heavy vehicle traffic volume affect the reliability index and fatigue life. The heavy vehicle traffic volume has significant influence on reliability index under bending-shear of box-girder bridge.

ABSTRACT: The uncertainties of the design, execution and maintenance are clearly revealed in the increase of the dynamic impact on the structures. In the maintenance of the bridges we can observe that each factors are relevance on the total value impact dynamic projected or expected. Knowing each percentage of importance, facilitates the process of maintenance of each responsible area, this was initially done intuitively to be able to locate where the trigger of the problem was. Theoretically we lack parameters to obtain the variables that allow us to use an adequate analysis of reliability. However, it was necessary to approach the problem experimentally, by assembling a known vehicle, on a bridge, track and instrumented vehicle, isolating known defect patterns, to be able to measure the relevance of each variable within the dynamic amplification. This global instrumentation project is certainly the first instrumentation in Brazil, isolating defects of the vehicle, track and bridge, more interestingly, the whole company managed to work together with a common purpose that was the efficient maintenance of bridges. We obtained the importance of each parameter, final coefficient of experimental dynamic impact measured for each bridge, with the transmissibility levels of each transition zone of the system. It was also obtained the reduction that each parameter is responsibility in the total residual life of the structure, being able to convert this into monetary numbers and a more real decision making.

1 INTRODUCTION

Dynamic impact management has parameter importance in the management of bridges following prioritization. We can verify the importance of each parameter in isolation to be able to reduce risks and levels of uncertainty so we can be able to maintain a more efficient maintenance input (Figure 1).

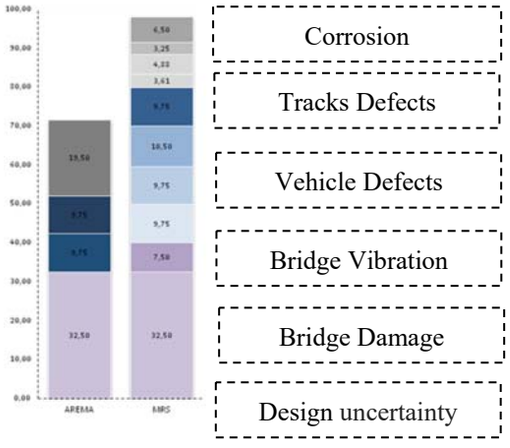

Figure 1 – Dynamic Impact Variable

We observed that we have different parameters that participate in this dynamic impact and each of them has relevance in maintenance. The main ones are listed below:

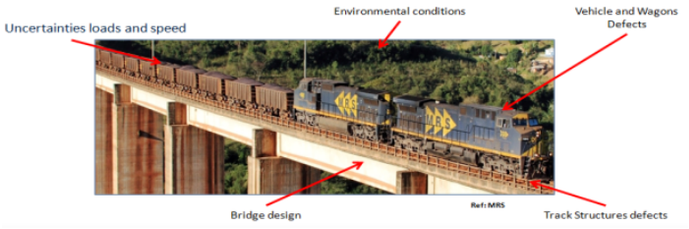

Figure 2 – Uncertainties Railway Bridges

2 DYNAMIC IMPACT MANAGING

2.1 *Loading Deviation*

The loading deviation brings a reduction in the capacity over the structural life of the bridge, which does not mean that the structure can collapse, but that it will reduce the useful fatigue life of the bridge because of the differences of each axis applied in the structures, which increases the stress response peaks for unbalanced loading, so the structure response is at higher cycles (Figure 3).

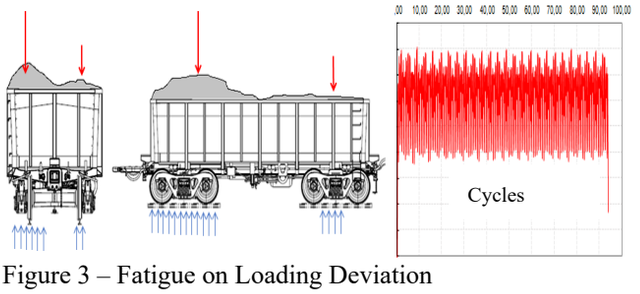

Figure 3 – Fatigue on Loading Deviation

In order to verify the importance of a vehicle passing with loading deviation, different bridges were numerically modelled and a vehicle with different deviations travelled noticing that there are some deviations loading configurations that do not affect the bridges in a certain span. Thus, we can determine a maximum load deviation for each bridge with a certain configuration as shown in Figure 4.

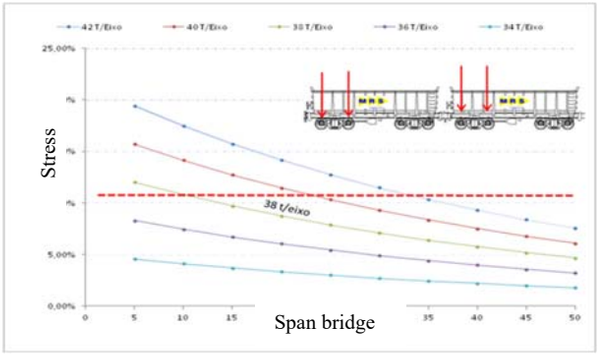

Figure 4 – Different Span to Loading Deviation Analysis

2.2 *Uncertainties of Execution, design and quality control*

The uncertainties of execution, design and quality control are the most difficult ones to control because in every project there are security factors that depend very much on the experience of the designer. In execution we often have changes to reduce costs. The worst is that these changes still often decrease the quality of the work (Figure 5).

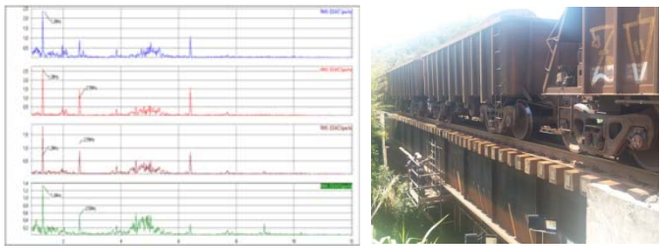

Figure 5 – Instrumentation Bridge to calibrate models

The way to mitigate these uncertainties is to raise the actual dimensions of the structure and to instrument it in order to know how it is actually behaving and what its utilization factor is.

2.3 *Track and Vehicle Defects*

Track and Vehicle Defects greatly amplify the dynamic impact on the structure, measure instrumentation, and achieve an impact factor of 2,00 times the static value (Merheb, 2017). Spring faults in vehicles have high importance for the future maintenance of the bridge as well as road
defects (Figure 6).

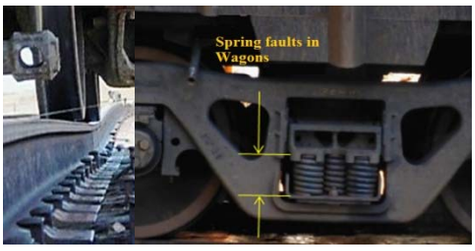

Figure 6 – Defect Vehicle and Tracks

2.4 *Vehicle Speed*

The velocity of the vehicle influences the response of the structure directly. It is known that the greater the speed the greater the dynamic impact, and the smaller the bridge span the greater the dynamic impact. We can observe that in certain structural configurations it is more efficient to increase velocity than to decrease velocity because there is a correct relationship between velocity and structure response. However, as a standard, we find that, for railroad trains, velocities that lead to resonance when there is damage in the structure floats between 30 and 50 km/h (Figure 7).

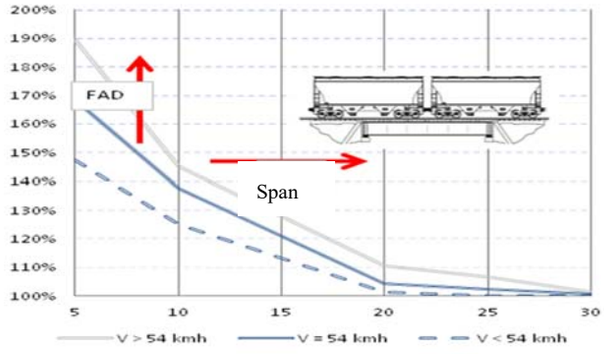

Figure 7 – Impact of speed on Span Bridge

2.5 *Damage Structure and Dynamic Response*

Damage to the structure will lead to less inertia, hence a different structural response; this can be observed in the vibration modes of the structure.

Figure 8 – Damage Bridge Inspection to New Plan Bridge

Local damage change can lead to dynamic impact amplification by up to 30% of global risk in the structure, (Figure 8).

All these values were guided separately, based on the experience and research in the different railway companies.

It is very relative and qualitative, so we can observe that initially after a benchmarking with different railroads and areas we get the values.

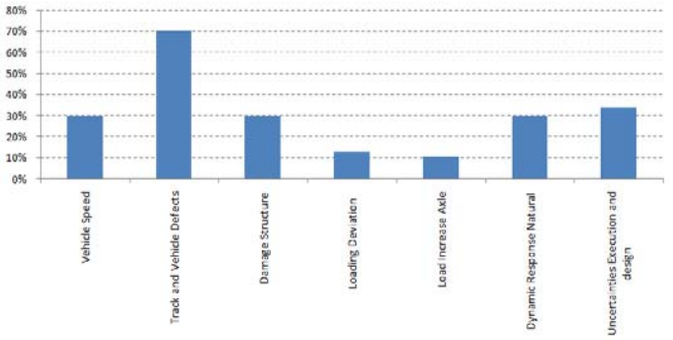

Figure 9 – Initial Model Dynamic Propose

In our management of maintenance, these values were used as parameters and maintenance indicators, allowing managing our budgets and responsibilities of each area, this development also leveraged a need to calibrate each parameter, thus increasing the need to experimentally implement bridges, vehicles and tracks. A model was thus created to instrument all variables controlled and to quantify each parameter.

3 GLOBAL INSTRUMENTATION PROCEEDS

As a part of the PhD thesis of the Principal Author, global vehicle, bridge and bridge instrumentation will be performed to obtain calibrated information of each parameter enabling to have a calibrated model. This is also important for verifying each vehicle defect or pathway as it influences the dynamic response of the structure. Different damages will be planned for the track and for the vehicle in order to seek the most unfavourable case and trying to isolate every request to calibrate the numerical model of the bridges and obtaining a greater reliability. Figure 22 shows, finally, the instrumentation global planning.

The influence of the accumulated damages, load deviation of each wagon, road defects, as well as pathologies in the structures and dynamic response of the vehicle are studied. These parameters influence the dynamic factor, such as fatigue, speed, mass, stiffness and damping of the vehicle. the same, etc.

Two bridges of different characteristics are being instrumented to evaluate each defect and influence of each parameter on the dynamic impact, this will be possible by performing an overall instrumentation, of all these parameters isolating each defect and evaluating them separately, in order to obtain a matrix of damage and defect that allows to be introduced later in the matrix of decision and prioritization.

The instrumentation model is presented below, where the steps of vehicle, track and bridge instrumentation are shown.

Considering the mobile load associated with the passage of vehicles at different speeds, the damage obtained and, where necessary, local damage will be used to evaluate the fatigue and the remnant service life, exhaustion of the connections and consequent redistribution of efforts, proposing a method hybrid that takes advantage of the best characteristics of each method studied.
The configuration of the vehicle will be carried out in the following manner, following isolation assumptions of each variable that influences the dynamical impact amplification process.

The first block formed by the locomotive and 4 wagons, will be composed of GDU type wagons, in perfect conditions, in this block will be instrumented the trick near the locomotive, where the vertical movement of the springs and dynamic response of the same will be observed.

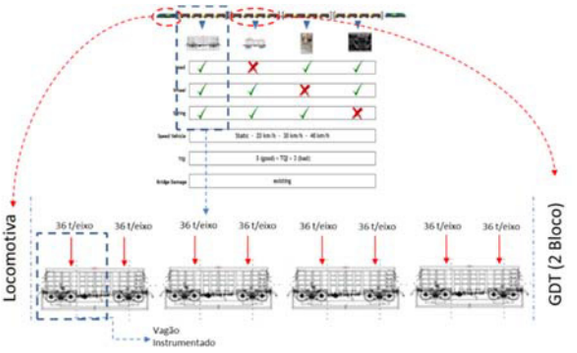

Figure 10 – First Block Vehicle Instrumentation

The instrumentation proposed in the spring was configured with two accelerometers, two extensometers and one LDVT, to visualize the vertical displacements and the internal tensions of the spring. The second block is formed to isolate the deviation in the load, so a deviation with a maximum of 11% difference between imbalance tricks will be performed so that it does not cause danger in the operation of the vehicle.

The values were obtained from historical load logs obtained by the company, so a composition was created that allows simulating the maximum deviation found and verifying the voltage increases in the track and in the bridge.

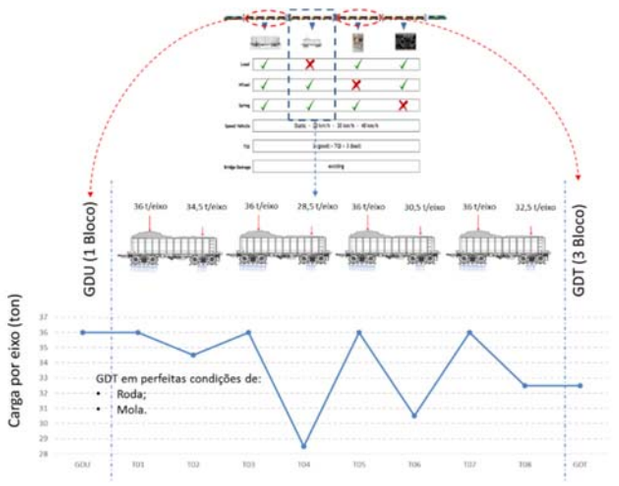

Figure 11 – Second Block Vehicle Instrumentation

In the third block we isolated the problems found in the wheels, these defects are classified by impact rates, being the same:

- Take up to 225 KN;
- Media up to 330 KN;
- Record up to 450 KN;
- Very high up to 550KN.

In the railroad it is very difficult to find the last case, because when a wheel fault generates 450 KN is immediately removed from the service. In this case, the highest value found before the test will be placed.

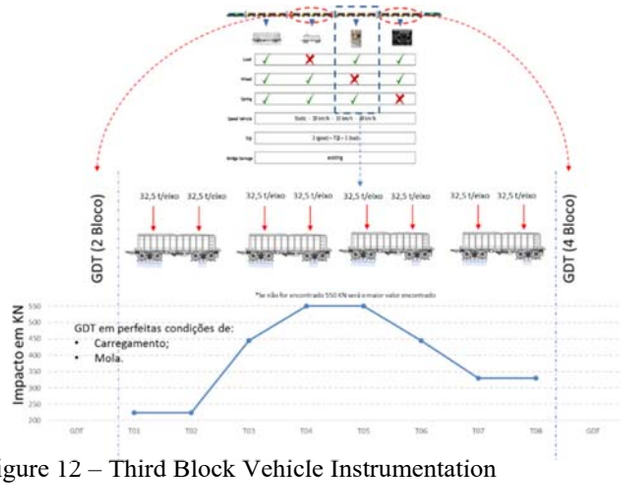

Figure 12 – Third Block Vehicle Instrumentation

Finally, the last block will be where we have demade spring insulated in the vehicle, it was configured by the residual capacity of use, so were divided into solid spring (0% capacity), spring with 10%, 15% and 20% capacity.

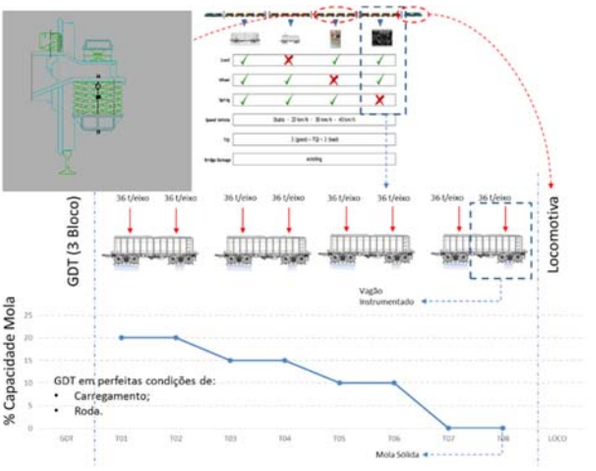

Figure 13 – Last Block Vehicle Instrumentation

4 BRIDGES, VEHICLES AND TRACKS INSTRUMENTATION CHARACTERISTICS

The different effects of wheel, spring and loading were placed in each block of the instrumented vehicle in order to isolate the defects and the impact that each of them generates on the structure. Thus we can observe the configuration of the vehicles for the test.

The vehicle was loaded in the configuration presented in the previous chapter and different passages with different speeds were made to calibrate the whole numerical model;

Figure 14 – Loading deviation

The springs were calibrated by withdrawing or including springs lacking the ability to absorb the dynamic impingement on the bridge.

Figure 15 – Different types of damage spring

The wheel defects are defects obtained from the maintenance, produced by the use of them over time, obtained a maximum value of 330 KN, it is not exceeded for reasons of operational safety.

Figure 16 – Different types of damage wheel

4.1 *Bridge Instrumentation*

The Bridge analyzed, studied and evaluated is the Bridge Belizário River, located at km 097+327 Km of the Center Line, in the municipality of Mendes/ RJ, It has a span of 26,30 meters with a metal beam with full welded profile. The Bridge analyzed, studied and evaluated is the Bridge Itinguçu located at km 019+795 Km, in Mangaratiba, it has a span of 39.34 meters of inverted beam metal.

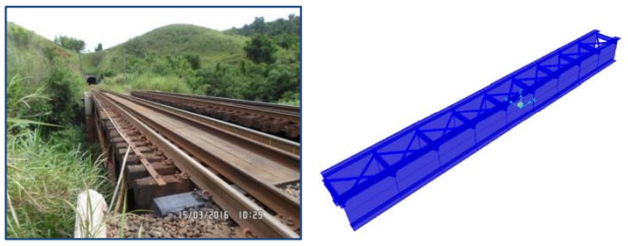

Figure 17 – Bridge Belizario Instrumentation

In the case of the Belizario bridge it was instrumented with road defects on the bridge and transitions, later maintenance was carried out on the track and again instrumented with the same test vehicle in order to isolate the effects of the defects of the permanent track.

Figure 18 – Bridge Itigunçu Instrumentation

The instrumentation of the bridge was with extensometry and accelerometry, locating the sensors in places that have the highest displacement, vibration and stress indexes, so we can obtain data to calibrate our numerical models. The instrumentation project is also aligned with the instrumentation tracks, to be able to stay in the same instrumentation points and then make comparisons to obtain the dynamic coefficients.

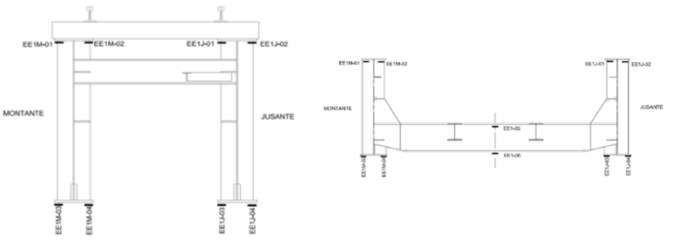

Figure 19 – Instrumentation Project

The instrumentation was also acquiring the real trains that travel on the bridge, thus performing a continuous instrumentation for approximately 2 weeks.

Figure 20 – Sensors Installation on Bridge

4.2 *Vehicle and Spring Instrumentation*

The instrumentation of the vehicle was carried out in order to observe the load deviation, wheel and spring defects, as these variables influence the dynamic impact of the structure.

Figure 21 – Spring Model Instrumentation

4.3 *Track Defects Instrumentation*

The track was instrumented exactly in the places where the bridge was also instrumented, so as not to lose information, as well as in the transition, the sensors in this case are pressure sensor specific, being able to obtain real values of dynamic loading.

Figure 22 – Damage on track and instrumentation

5 RESULTS

The frequency of inspections will largely depend on the expertise and experiences of the technician, for it was recommended to conduct a brief survey on the different standards and railways. Each railway will have the frequency that best suits the scene, conditions and economic partners interests. Figure 20

Finally, with this instrumentation and analyzing the results, we can visualize the importance of each defect on the amplification of the dynamical impact on the tensions of the main elements of the bridges, and we can even simulate the loss of life of the fatigue produced by each variable.

Thus obtaining a management tool for each variable and consequently each area responsible for it.

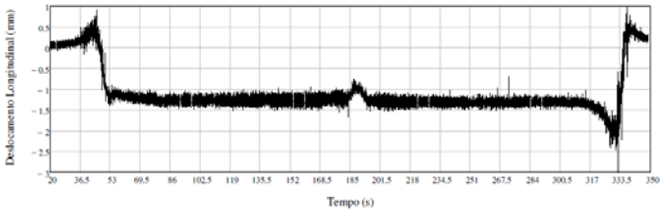

Figure 23 – Resultsxxxx

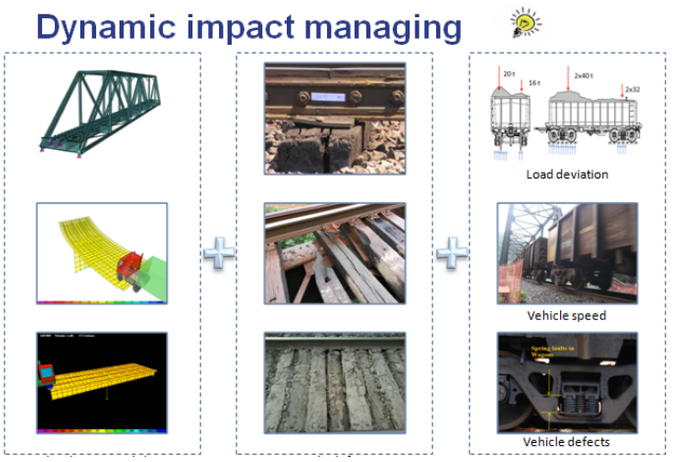

Figure 24 – Results xxxx

6 CONCLUSIONS

The frequency of inspections will largely depend on the expertise and experiences of the technician, for it was recommended to conduct a brief survey on the different standards and railways. Each railway will have the frequency that best suits the scene, conditions and economic partners interests. Figure 20 shows a new vision of all bridge railways. Later to, the fatigue analysis and visual inspection damage, we can see different defects and solutions for each railway.

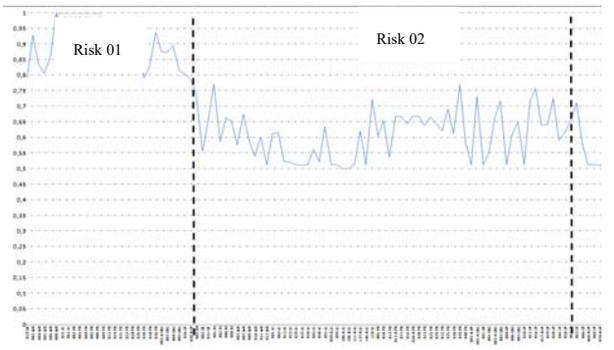

Figure 25 – Map of Risk railway

The results of prioritization are easy to manipulate by Excel, allowing the calculation of annual budget. Using the prioritization techniques was considered more effective to achieve management of railway assets, minimizing risks and planning resources properly.

The fatigue analysis and visual inspection damage, we can see different defects and solutions for each railway and allow to create a maintenance planning;

The visibility to dynamic impact managing and uncertain, we allow minimizes the effect of the dynamic impact and us to have an adequate control of all the operation and maintenance on the bridge;

Using the prioritization and reliability techniques was considered more effective to achieve management of railway assets, minimizing risks and planning resources to time of rehabilitation.

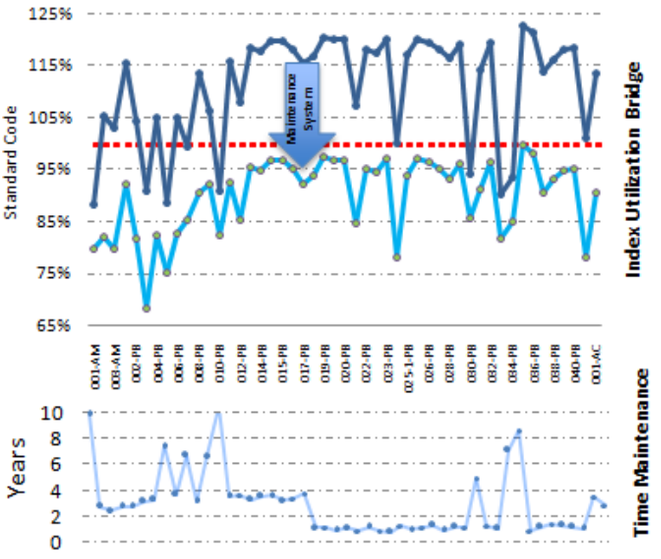

Figure 26 – Influence of Impact Dynamic

Having the visualization of the variables that influence the dynamic impact, we can observe and act in a targeted and precise way for each section, which minimizes the effect of the dynamic impact and allows us to have an adequate control of all the operation on the bridge. Figure 21 shows a diagram of the railroad with the percentages of use for each bridge, being able to understand accurately what the main

problems in the bridge are, either concerning maintenance, road or vehicle.

ABSTRACT: Integrating fibre-optic sensor networks in a newly-constructed infrastructure assets enables data-driven performance assessment during its construction and throughout its operational life. As part of a multi-million pound railway infrastructure redevelopment project, two new railway bridges were instrumented with an extensive network of both discrete (fibre Bragg gratings or FBGs) and distributed (based on Brillouin optical time domain reflectometry or BOTDR) fibre optic sensors to measure both strain and temperature throughout construction and in-service. Completed in 2016 in Staffordshire UK, both 'self-sensing' bridges contain more than 500 fibre Bragg grating sensors and over 600 metres of distributed fibre optic sensor cabling. This paper describes the sensing technologies employed, installation techniques for improving sensing robustness, the monitoring programme and objectives, data processing methods and assumptions, and the primary monitoring findings of this project. Results related to measurements of prestress losses in prestressed concrete girders, estimates of steel girder deflection using FBGs and videogrammetry, and assessments of percentage utilisation of critical superstructure elements are presented. In terms of future directions, BIM-based environments which incorporate sensor elements and an emerging field of research known as *Data-Centric Engineering* are introduced as tools to better manage, maintain and learn from the information generated from self-sensing infrastructure.

1 INTRODUCTION AND BACKGROUND

Smart infrastructure results from the combination of physical (i.e. bridges, tunnels, roads, etc.) and digital (i.e. sensors, internet of things, GIM, etc.) infrastructure, leading to more reliable information to enable better, cheaper and faster decision making (CSIC 2016).

From a U.K. perspective, there are a number of challenges facing the infrastructure management sector. In particular, these challenges include, pressures to maintain adequate levels of asset performance under shrinking financial budgets; aging assets which require ever-increasing maintenance and upgrading; tighter government regulations requiring greater accountability and risk assessment; and the unknown future effects of climate change (ICE 2017). To combat these challenges, smarter infrastructure is required. It has been estimated that the smart infrastructure sector has the potential to create opportunities worth anywhere between £2.4 and £4.8 trillion ($3.2 and $6.3 trillion) globally (CSIC 2016).

Within the envelope of smart infrastructure systems is the concept of 'self-sensing' (or 'sensory') structures. These structures use measurements from embedded sensing systems to provide information on their internal state (Measures 1992). Any structure can be converted into a 'self-sensing' structure whether the sensor system is installed during construction or long after the structure has been in operation. Bridges are good candidates for implementing a sensing system as they represent critical assets within road and rail networks and their long-term in-situ performance, particularly how they deteriorate, has not been well categorized. Therefore, sensing systems, at a minimum, should be designed to function reliably in the long-term. Most importantly, sensor and monitoring systems in general should not be implemented before defining the purpose of monitoring for a particular asset or application. Further guidance on structural health monitoring (SHM) system selection for bridges is provided in Vardenega et al. (2016), Webb et al. (2015) and Middleton et al. (2016).

First appearing in the early 1990s, fibre optic based sensor systems have been installed to monitor a variety of bridge types around the world. In Australia, fibre optic sensors (fibre Bragg gratings) installed externally in combination with digital image correlation techniques were used to measure strain during load testing of a prestressed concrete girder bridge (Gowripalan et al. 2016). Similar bridge

monitoring studies which incorporate the use of fibre optic sensing have been undertaken in Canada (Tennyson et al. 2001; Regier and Hoult 2014), the United States (Cardini and DeWolf 2009; Glisic 2012), Sweden (Jemli et al. 2003), Portugal (Costa and Figueiras 2012), China (Chan et al. 2006) and India (Scott et al. 2013). Compared with electrical-based sensors, FOS have several advantages including being corrosion resistant, having higher accuracy, good long-term stability and requiring less cabling (and therefore reduced interrogator channel requirements).

In the U.K., while traditional SHM systems have been deployed across various large-scale bridge projects, the use of fibre optic sensing has been very limited (Webb et al. 2017; Lydon et al. 2017). This paper presents a new fibre-optic-based bridge sensing case study. Completed in April 2016, the Stafford Area Improvements Programme (SAIP) involved a major upgrade and redevelopment on the West Coast Main Line near Crewe including the construction of 11 new bridges.

An Innovate UK and EPSRC-funded research project in collaboration with the Staffordshire Alliance (Network Rail, Laing O'Rourke, Atkins, and VolkerRail) and the University of Cambridge's Centre for Smart Infrastructure and Construction (CSIC) constructed, to the authors' current knowledge, the most densely-instrumented 'self-sensing' railway bridges in the U.K. Two of the 11 new bridges (one steel composite and one prestressed concrete) constructed as part of the SAIP were extensively instrumented as prototypes containing durable, permanent, fibre-optic based strain monitoring systems.

This paper provides an overview of the monitoring system and sensing technologies, innovative techniques for improving sensing system robustness, data processing and analysis assumptions, and the primary monitoring findings. Additional insight is provided into new tools related to self-sensing infrastructure and the emerging research area known as data-centric engineering.

2 SELF-SENSING BRIDGE PROTOTYPES

2.1 *Description of bridge structural systems*

Intersection Bridge 5 is a steel half-through skewed (22.6º) railway bridge formed by two 2.2 metre deep main I-girders with composite concrete deck supported on transverse steel cross beams. It carries two new lines of ballasted track and forms the primary structure in the SAIP as it crosses the existing West Coast Main railway line. It has a single skew span of 26.8 metres and is simply-supported on piled abutments. To provide lateral buckling restraint of the top I-girder flanges, U-frames consisting of vertical stiffeners at corresponding moment-connected steel cross beam locations are provided at every three metres. This bridge type was selected for this application to achieve construction depth requirements.

Underbridge 11 is a prestressed concrete girder bridge with infill concrete deck simply-supported on elastomeric bearings on piled abutments. The 11.2 metre span carries one line of ballasted track over a minor watercourse. Seven prestressed concrete (PC) TY7 internal beams and two PC TYE7 edge beams form the main superstructure. The 0.7 metre deep PC beams were precast offsite 6 months prior to being erected on the abutments. A 200 mm thick reinforced concrete deck slab and solid concrete infill in between the PC beams were cast in-situ. Transverse tie bars were installed across the deck through web opening holes in the PC beams. An additional concrete slab bridge was constructed adjacent to Underbridge 11 which forms part of a pedestrian footpath. This bridge type was selected for this particular application because it promoted offsite manufacture and led to reduced erection times and construction costs. Figure 1 depicts the completed self-sensing bridges.

2.2 *Sensing system technology*

Fibre optic sensors (FOS) are typically grouped within two main categories: discrete and distributed.

This research study involved the combined use of both types of FOS, discrete FOS known as fibre Bragg gratings and distributed FOS based on optical time domain reflectometry (OTDR).

Bragg gratings are written into the core of an optical fibre typically using an excimer laser. The refractive index at the grating locations are altered compared with the adjacent fibre. This creates a dielectric mirror which reflects laser (ultraviolet) light at a specific frequency. Typically, several (up to 20 or greater) FBGs can be written each with different Bragg wavelengths along a single fibre. When an FBG is stretched, the grating period shifts which results in a change in wavelength of the reflected ultraviolet light (Kreuzer 2006). This change in wavelength is then converted to an equivalent change in strain. The FBGs used as part of this study were formed using a draw tower process and were coated with glass fibre reinforced polymer coating for added robustness during installation. Sensor arrays with up to 20 FBGs at one metre spacing were produced. Using an optical fibre interrogator combined with an optical fibre multiplexer, both produced by Micron Optics, it was possible to record strain changes at 250 Hz of up to 320 individual FBG sensors simultaneously.

Distributed FOS sensors, on the other hand, have the ability to measure strain changes along the entire length of a fibre optic cable. Based on the optical time domain reflectometry (OTDR) technique, an optical pulse (laser light) is shone down an optical fibre where a photodetector measures the amount of backscattered light in the fibre. Knowing the speed of light, the time information is converted to distance. One particular backscattered light component known as Brillouin scattering, carries information about the temperature and amount of strain in the fibre based on its wavelength shift; this is known as Brillouin Optical Time Domain Reflectometry (BOTDR) (Glišić and Inaudi 2007). The BOTDR cable used as part of this study was a steel-reinforced single-mode low bend loss fibre. Strain values are averaged over a 50 cm length are taken at steps of 5 cm along the entire cable. Unlike FBG sensors, BOTDR based sensing is not suitable for capturing dynamic strain changes as measurement times of 5 minutes or greater are typical depending on the length of cable.

FOS are particularly sensitive to temperature changes (i.e. index of refraction is altered and the glass fibre expands or contracts) and therefore, various compensation techniques are required in order to isolate temperature effects and obtain mechanical strains. Separate temperature-compensation FO sensors for both the FBG and BOTDR FOS were implemented on this project to account for these effects.

2.3 *Sensor topologies and installation*

On Underbridge 11, a combination of FBG and BOTDR sensors were employed. Figure 2 depicts an overview of the sensor topology for Underbridge 11. A primary objective of the monitoring programme was to assess and compare the strain measurements provided by both systems.

In total, six of the nine prestressed concrete (PC) beams were instrumented along the top and bottom prestressing strands with 10 strain FBGs, 6 temperature FBGs and both strain and temperature BOTDR sensing cables. All PC beam instrumentation was completed at the pre-casting facility following prestressing of the strands before pouring of the concrete. The early-age behaviour of the beams was then assessed prior to their erection on the bridge abutments (refer to Butler et al. 2016 for further details). Additional sensors were then installed along the top layer of reinforcing in the concrete deck (6 FBGs) and along the transverse ties (4 FBGs) at both midspan and quarterspan locations (refer to Figure 2). Sensors were secured to the prestressing strands and reinforcing steel using plastic ties spaced at approximately 300 mm.

Only FBG sensors were installed on Intersection Bridge 5 as depicted in Figure 3. The main west and east girders were instrumented with 20 strain and temperature compensating FBGs along both the top and bottom flanges. Two cross beams, one at midspan and one near the end (skew) span were also instrumented with 7 strain and temperature FBGs along the top and bottom flanges. At the instrumented cross beam locations, 7 strain and temperature FBGs were installed within the transverse concrete deck along the top layer of reinforcing steel. One of the web stiffeners forming part of the midspan U-frame was also instrumented with 6 vertically oriented FBGs (4 strain and 2 temperature). Following cleaning and abrasion of the surface of the steel superstructure, the FBG sensors were attached using a structural adhesive. The final surface painting system was then applied by the bridge contractor following sensor installation. FBGs installed within the concrete deck were attached to the reinforcing steel using plastic cable ties spaced at approximately 300 mm.

The most vulnerable component of the installed fibre optic sensor networks are the splices between both the primary sensor array and the routing cables and optical connectors. For this reason, a series of special splice protector designs were devised in the laboratory prior to sensor deployment. Combined with the ruggedized coatings applied to the sensor cabling, the final installed sensor network has so far

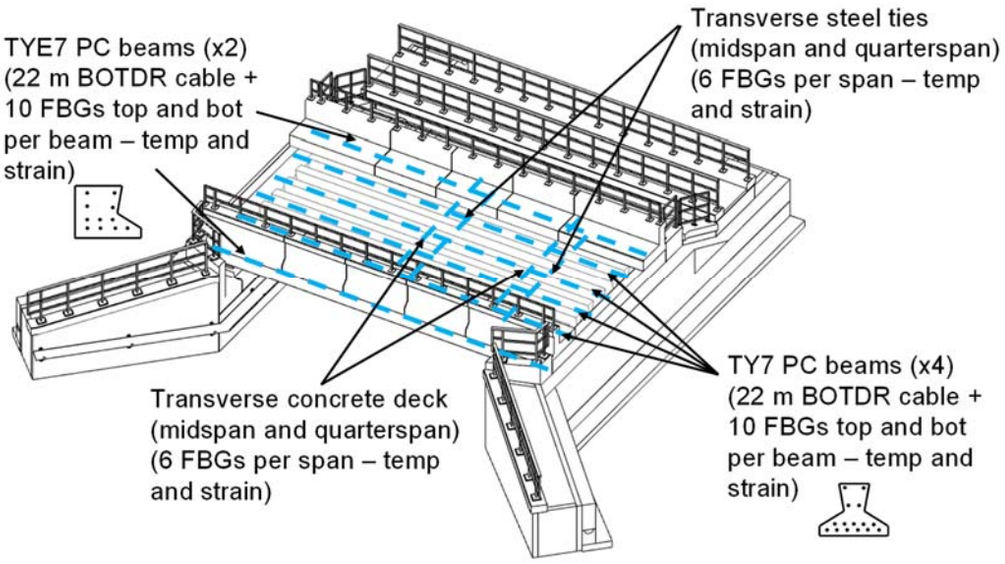

Figure 2. Sensor topology for Underbridge 11

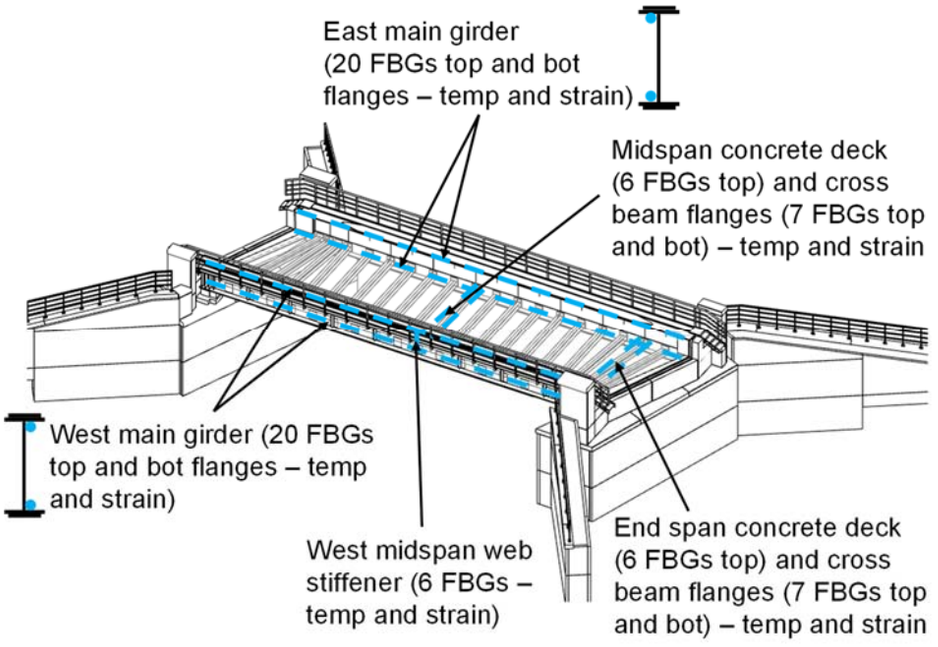

Figure 3. Sensor topology for Intersection Bridge 5

proven to be highly resilient during its first two years in operation.

3 MONITORING RESULTS AND DISCUSSION

The installation of the monitoring systems for both bridges was completed by the fall of 2015 and both bridges were opened to rail traffic by March 2016. Since their opening, two additional monitoring visits occurred in July 2016 and one year later in July 2017. The following section presents an overview and discussion of some of the key findings to date.

3.1 *Prestress losses in PC beams (Underbridge 11)*

A primary focus of monitoring Underbridge 11 was to assess the early age and long-term prestress losses within the PC beams. In particular, the strain changes measured from the FBG sensors were used to estimate the change in prestress during the first two years of the internal TY7 (average of two) and external TYE7 (average of two) PC beams as presented in Figure 4.

Changes in prestress were calculated based on the interpolated strains acting through the centroid of the prestressing steel. Note that baseline stress values were taken from a time immediately prior to detensioning of the prestressing strands. The total measured change in prestress for the TY7 and TYE7 PC beams between January 2015 and July 2017 were 211 MPa and 165 MPa, respectively. The values of long-term prestress losses calculated using Eurocode 2 (according to EN 1992-2, BSI 2004) are presented in Butler et al. (2016). The total (120 year) estimated

prestress losses for the TY7 and TYE7 PC beams were 275 MPa and 267 MPa, respectively. Therefore, the measured prestress changes for the TY7 and TYE7 PC beams were 77% and 62% of the Eurocode 2 estimated ultimate losses, respectively. Based on the estimated change in prestress from the FBG strain measurements, it appears that the loss of prestress in the TYE7 beams (average of two beams) is greater than the loss in the TY7 beams (average of two beams).

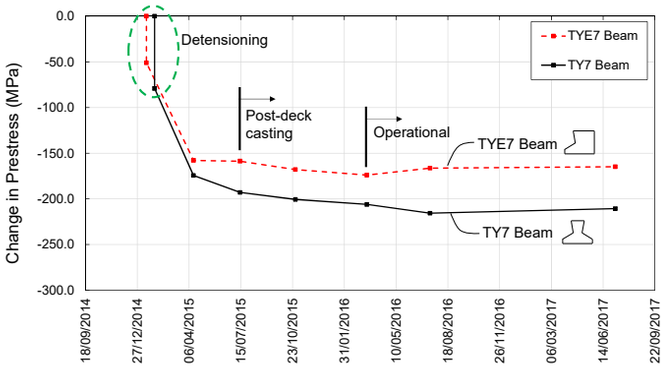

Figure 4. Estimated change in prestress in PC beams from FBG strain measurements

This difference in prestress losses appears to stem from greater elastic shortening losses during the detensioning process. Based on Figure 4 it appears that the value of the prestress losses increase slightly after the bridges become operational. It is suspected that ambient effects (i.e. temperature, relative humidity, wind, etc.) may account for these anomalies however, further research is required to better understand this effect.

In comparing discrete versus distributed fibre optic sensor technology, a previous study by the authors reported that the FBG and BOTDR measured strains during the first six months following beam casting were similar (Butler et al. 2016).

3.2 *Steel girder deflections under live loading (Intersection Bridge 5)*

Strain measurements taken from the FBG sensors (ε_{FBG}) installed along the top and bottom flanges of the two main girders were used to estimate the midspan deflections under passing trains. Based on the assumption of Euler-Bernoulli beam bending and using linear regression to fit a set of polynomial basis functions ($a_i\varphi_i$) to the curvature calculated from the strain data, double integration was performed numerically to obtain estimates of the girder's vertical deflection at a given time t_i, $w(x,t_i)$, along the total length L, of the girder. The midspan deflection ($w_{midspan}(t_i)$) at a given time t_i, is then reported as $W(L/2,t_i)$. This procedure is repeated for each time step (in this instance at 250 times per second which is equivalent to the FBG sensor acquisition rate) and for each FBG top and bottom pair (20 in total per girder). A summary of the algorithm was implemented using Matlab and is outlined below:

For t_j = 0 to t_{final} (based on size of data file)
  For i = 1 to n (= number of FBGs)

$$\frac{|\varepsilon(x)_{top}| + |\varepsilon(x)_{bot}|}{z} = k(x)_{FBG} \rightarrow k(x)_{POLY} = \sum_{i=1}^{n-1} a_i\varphi_i(x)$$ Linear regression

$$\frac{\partial^2 w(x)}{\partial x^2} = -\left(\frac{1}{z}\right)\varepsilon(x) = k(x) = -\sum_{i=1}^{n-1} a_i\varphi_i(x)$$ Equate to Euler-Bernoulli beam formulation

$$w(x) = -\sum_{i=0}^{n-1} a_i\psi_i(x) + Ax + B$$ Numerical double integration

$$A = \left(\frac{1}{zL}\right)\sum_{i=1}^{n-1} a_i[\psi_i(L) - \psi_i(0)]$$ Calculate integration constants from beam boundary conditions

$$B = \left(\frac{1}{z}\right)\sum_{i=1}^{n-1} a_i\psi_i(0)$$

  End i

$$w_{midspan}(t_i) = w(L/2, t_i)$$ Calculate midspan deflection

End t_j

This methodology is similar to methods reported by Vurpillot et al. (1996) and Todd et al. (2000). It was assumed that the girder was simply-supported implying a vertical deflection of zero at both ends. A third-order polynomial was chosen as a basis function and was found to provide an adequate fit to the calculated curvature data. To validate the FBG-calculated deflection results, an advanced videogrammetry system produced by Imetrum was used to measure the midspan deflection of the east main girder when a 4-car passenger train passed over the bridge (refer to Figure 5 and Figure 6).

Figure 5. Videogrammetry system setup for measuring midspan deflection of east main girder

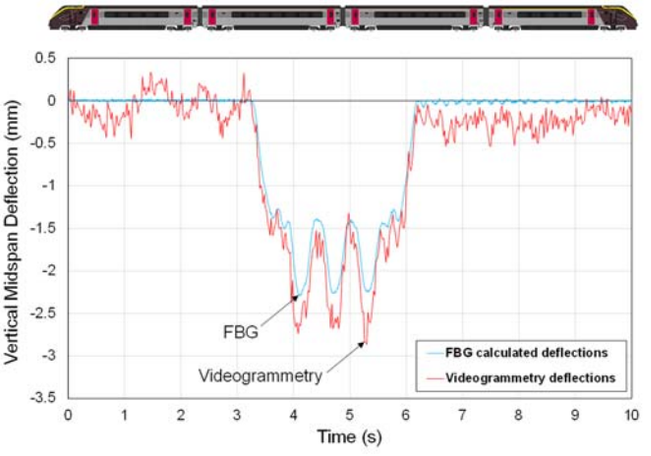

Figure 6. Midspan deflection of east main girder versus time using FBG back-estimated and videogrammetry measurements

The FBG-estimated midspan deflection results followed a very similar deflection profile as compared to the videogrammetry based results. On average, the maximum (corresponding to the peak deflection values in Figure 6) midspan deflections measured using the videogrammetry system were 18% higher than those estimated from the FBG strain measurements. This difference may be due to inherent errors in measurement of the videogrammetry system and also due to errors which arise within the back-calculation of deflection via double integration of the FBG-strain measurements. While additional monitoring data from both the FBGs and videogrammetry are required, the initial results of these two deflection estimation methods seem promising.

3.3 *Percentage utilisation assessment*

A primary benefit of integrating sensing within a structure is the ability to estimate and assess levels of performance in-service. In particular, the FBG sensors installed within Intersection Bridge 5 along the top and bottom flanges of the main girder can be used to estimate the curvature and moment demand under average daily rail loading. Calculated moment demand envelopes can then be generated and updated as more data is collected. As an example, Figure 7 presents the moment demand envelopes for both main girders based on FBG strain data collected from 12 trains passing over the bridge over a period of 8 hours. During this period, only two passenger train types, Class 350 'Desiro' and a Class 221 'Super Voyager' passed over the bridge. Note that the measurement results seem to indicate a sensor malfunction on the east main girder possibly due to localized debonding.

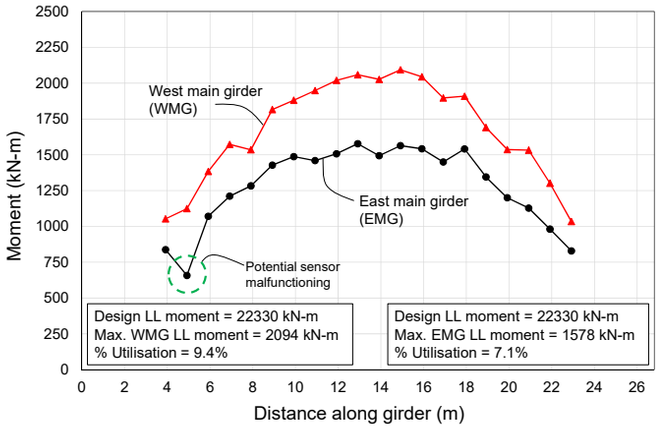

Figure 7. FBG estimated moment demand envelopes for the main girders on Intersection Bridge 5

To provide an estimate of the percentage utilisation of each girder considering the data collected from the 12 trains, the (ultimate) design live load moment capacity of the girder section must be calculated. Using Eurocode design equations (BSI 2005, 2006) for calculating the capacity of the main I-girders and based on previous studies by the authors (Delgado et al. 2017) the design moment capacity under live loading ($M_{DES,LL}$) is 22.3 MN-m. Therefore, based on the sensor data-generated moment envelopes, the west main girder and east main girder have percentage utilizations of 9.4% and 7.1%, respectively. Note that the west main girder appears to be consistently supporting a higher proportion of the live loading compared with the east main girder. This may be due to additional vertical loads induced from the track curvature which creates slightly unbalanced loading on the west track. Another potential explanation for this difference may stem from the dominant rail traffic patterns on the bridge in which more heavily-loaded (e.g. Class 221 versus Class 350 train types) passenger trains tend to travel on the west line (in this case southbound). This would have the effect of skewing the moment demand envelopes. Therefore, future research will include collecting and processing data from a larger number of trains. Daily, weekly, monthly and seasonal effects will also be considered when revising and interpreting the percentage utilisation estimates.

4 FUTURE TOOLS FOR LONG-TERM MONITORING OF SELF-SENSING BRIDGES

This monitoring project has highlighted the variety of information that can be captured for assessing bridges when they are constructed with an integrated sensing system. It has also revealed that if self-sensing structures are to be widely adopted across all levels of infrastructure then consideration of the long term management, analysis and interpretation of the information generated is critical. The following sections introduce two new areas of research currently being explored for increasing the value of monitoring data.

4.1 *Sensing-integrated BIM models*

Building information models (BIM), are digital representations of physical assets which are typically employed during the design and construction phases. However, there is growing interest to leverage BIM in facilities and asset management (Burcerik-Gerber 2012). Preliminary work has been completed in developing BIM elements for sensors which can store continuous strain and temperature data from FBGs, BOTDR or other sensor types and provide a visualization directly within the BIM model (Delgado et al. 2017). This proposed approach will enable engineers and asset managers to use a common interface in which they can use the information generated during an asset's operation. In terms of long-term inspections, this approach can help to avoid subjectivity, increase reliability, and provide an integrated long-term data management system.

4.2 *Data-centric engineering*

Through a collaboration between the Lloyds Register Foundation funded program on Data Centric Engineering (DCE) at the Alan Turing Institute and the Cambridge Centre for Smart Infrastructure and Construction (CSIC) at the University of Cambridge, a multi-disciplinary team of engineers and data scientists are working to characterize and analyse the vast quantities of dynamic strain data gathered from the self-sensing bridges and other structures.

DCE may be viewed as an approach for learning about engineering structures which leverages physics-based (e.g. finite element) models which are updated based on sensor data and statistical (data-driven) models that incorporate prior knowledge of the physical asset. This combined model would provide the self-sensing structure with a 'digital twin' which would exist alongside the asset and be updated and refined throughout its service life (Lau et al. 2018a).

This collaboration has thus far developed streaming statistical models and temporal de-trending techniques which have been successfully applied to large, continuously recorded strain data sets collected from Intersection Bridge 5 (Lau et al. 2018b).

It is envisioned that merging concepts such as sensing-integrated BIM models and 'digital twins' will provide powerful future platforms on which to build additional value into the data generated from condition monitoring systems.

5 CONCLUSIONS

This paper has discussed the creation of two fibre-optic based self-sensing railway bridge prototypes. The bridges included Underbridge 11, an 11.2 metre prestressed concrete girder bridge with a cast in-situ concrete deck, and Intersection Bridge 5, a 26.8 metre steel half-through skewed I-girder bridge with a composite concrete deck. Discussions of the sensor technologies employed along with the installation techniques and sensor topologies are presented. Based on two years of collected monitoring data, the primary findings of this study include:

1. Pertaining to the prestressed concrete girder Underbridge 11, a comparison of the measured prestress losses in the internal (TY7) beams and the external (TYE7) edge beams indicated a higher prestress loss for the TYE7 beams in their first 2 years in-service. Based on the change in prestress, the TY7 and TYE7 beams had reached 77% and 62%, respectively of the Eurocode 2 predicted long-term losses.

2. Two methods for estimating the midspan deflection of the Intersection Bridge 5 east main girder under live loading were investigated as part of this study. The first method involved applying an algorithm which considered Euler-Bernoulli beam theory and moment-curvature relationships to calculate vertical deflection using FBG-measured horizontal strains. In addition, a videogrammetry system was also deployed to measure deflections of the east main girder. It was found that both methods produced similar time-deflection profiles however, the videogrammetry deflections were on average 18% greater than those estimated from the FBG strain measurements. While additional monitoring data is required, these initial results were found to be promising.

3. Based on the monitoring data collected from 12 passenger trains passing over Intersection Bridge 5, moment demand envelopes for both main girders were derived in order to compare with the design live load moment capacity. Based on their moment envelopes, the west and east main girders' structural utilization percentages under live load were 9.4% and 7.1%, respectively. It was noted however, that further monitoring is planned to develop a larger moment demand envelope data set that will also consider the effect of environmental factors such as temperature on the measure moment demand.

This paper concludes with a discussion of current advances in BIM models which are capable of storing, managing and visualizing data obtained from sensor systems. A new area of research referred to as data-centric engineering is introduced where research efforts are currently underway to integrate finite element models with advanced statistical models for data generated from self-sensing bridges.

ACKNOWLEDGEMENTS

The authors would like to acknowledge EPSRC, Innovate UK and the Lloyd's Register Foundation for funding this research through the Centre for Smart Infrastructure and Construction (CSIC) Innovation and Knowledge Centre and the Alan Turing Institute. Research related to installation of the sensor system was carried out under EPSRC grant no. EP/L010917/1. Data related to this publication is available at the University of Cambridge data repository.

ABSTRACT: Bridge weigh-in-motion (BWIM) system uses the bridge as a scale to estimate vehicle weights. For BWIM systems, reliable axle detection is a prerequisite for the accurate identification of axle weights and GVW. The existing nothing-on-road (NOR) BWIM systems typically use additional sensors, such as the free-of-axle-detector (FAD) sensors, for axle detection. However, these NOR axle detection strategies were reported to be only suitable for certain types of bridges and susceptible to wheel transverse positions. In this study, a equivalent shear force (ESF) method is proposed to identify vehicle speed and axle spacing by using the flexural strain signal recorded from the weighing sensors. Compared to the existing NOR BWIM systems, the proposed method does not require additional sensors for axle detection, which reduces the cost and facilitate the installation of BWIM systems. The effectiveness and accuracy of the proposed method are demonstrated through numerical simulations using three-dimensional vehicle-bridge coupled analysis.

1 INSTRUCTION

The Bridge weigh-in-motion (BWIM) offers an efficient way for vehicle overweight enforcement and traffic monitoring using an instrumented bridge (Moses 1979; Zolghadri et al. 2016). The obtained traffic in-formation is valuable for the management of transportation networks and safety assessment of bridges (Lydon et al. 2016; Jacob & O'Brien 2005). In the past several decades, great efforts have been spent on developing new BWIM algorithms and improving the identification accuracy of BWIM systems (Peters 1984; Jacob & O'Brien 1998; WAVE 2001; O'Brien et al 2009; Žnidarič et al. 2015). A comprehensive state-of-the-art review of existing BWIM algorithms and instrumentation was presented by Yu et al. (2016).

In order to identify the axle weights and gross vehicle weight (GVW), accurate axle detection is required by most BWIM systems. Typically, a BWIM system includes weighing sensors and axle detecting devices (Moses 1979). Axle detection can be pavement based using sensors installed on the road sur-face such as tape switches, pneumatic tubes, and piezoceramic sensors. Although pavement-based axle detection can usually achieve good accuracy, they are not ideal for BWIM applications as they are not durable and can cause interruption of traffic (WAVE 2001; Chatterjee et al. 2006; Zhao et al. 2014). In order to eliminate the use of axle detectors on the road surface, the concept of nothing-on-the-road (NOR) systems and the free-of-axle detector (FAD) algorithms were introduced in the Weighing-in-Motion of Axles and Vehicles for Europe (WAVE) project (WAVE 2001). The FAD method uses FAD sensors in addition to weighing sensors to measure the local bridge responses which contain the information of vehicle axles. However, the FAD methods are only suitable for certain types of bridges and are susceptible to the transverse position of wheels (O'Brien et al. 2012; Ieng SS et al. 2012; Kalin et al. 2006). Aiming to overcome these disadvantages, alternative axle detection strategies have been developed for NOR BWIM systems. For example, O'Brien et al. (2012) and Bao et al. (2016) used shear strains to identify vehicle axles. Lydon et al. (2017) developed a NOR BWIM system based on advanced fiber optical sensors. Ojio et al. (2016) proposed a contactless BWIM system using roadside vision systems to monitor and identify vehicle speed and axle spacing.

For bending moment-based BWIM systems, it is beneficial to directly extract axle information from the global strain signals. Kalhori et al. (2017) identified vehicle axles using the peak-to-peak approach which utilizes flexural strains, though some axles might be missed under some circumstances. Yu et al. (2015) used wavelet transformation of the bridge global response for axle detection. Nevertheless, it is usually difficult to directly identify vehicle axles from the global strain signal of bridges because the global bridge response is less sensitive to individual

vehicle axles compared with local bridge responses. In addition, signal processing techniques were adopted by some researchers to improve the accuracy of axle detection. Kalin et al. (2006) utilized a band-pass filter to isolate individual axles. Wall et al. (2009) calculated the second derivative of bending moments for vehicle speed and axle spacing identification. However, this method is susceptible to measurement noises. Wavelet analysis, as a powerful pat-tern recognition technique, has also been applied for axle detection by some researchers (Chatterjee et al. 2006; Yu et al. 2015; Dunne et al. 2005; Lechner et al. 2010). Nevertheless, this technique is susceptible to the errors in the original signal (Lydon et al. 2016).

In this study, a novel equivalent shear force (ESF) method was proposed to estimate vehicle speed and axle spacing. This method directly uses the flexural strain signals acquired from weighing sensors to de-tect the vehicle axles. In order to demonstrate the effectiveness and accuracy of the proposed ESF meth-od, extensive numerical simulations based on a three-dimensional (3D) vehicle-bridge coupled analysis are conducted. The impacts of various factors on the ac-curacy of the proposed method are also examined.

2 BRIDGE-VEHICLE COUPLED SYSTEM

2.1 *Dynamic Equation of Bridge and Vehicle*

The dynamic equations of motion of bridge and vehicle can be expressed as following:

$$M_b \ddot{d}_b + C_b \dot{d}_b + K_b d_b = F_{bv} \tag{1}$$

$$M_v \ddot{d}_v + C_v \dot{d}_v + K_v d_v = F_{vb} + F_{vg} \tag{2}$$

where M_b, M_v, C_b, C_v, K_b, and K_v are the mass, damping, and stiffness matrices of the bridge and the vehicle, respectively; d_b and d_v are the displacement vectors (in the vertical direction) of the bridge and the vehicle, respectively; F_{bv} and F_{vb} are the vectors of the wheel-road contact forces acting on the bridge and the vehicle, respectively; and F_{vg} is the gravity force vector of the vehicle.

Utilizing the force and displacement compatibility at the contacting points between the bridge and the vehicle, the motion equations of the bridge and the vehicle can be coupled as follows:

$$\begin{bmatrix} M_b & \\ & M_v \end{bmatrix} \begin{Bmatrix} \ddot{d}_b \\ \ddot{d}_v \end{Bmatrix} + \begin{bmatrix} C_b & C_{bv} \\ C_{vb} & C_v \end{bmatrix} \begin{Bmatrix} \dot{d}_b \\ \dot{d}_v \end{Bmatrix} + \begin{bmatrix} K_b & K_{bv} \\ K_{vb} & K_v \end{bmatrix} \begin{Bmatrix} d_b \\ d_v \end{Bmatrix} = \begin{Bmatrix} F_{br} \\ F_{vr} + F_{vg} \end{Bmatrix} \tag{3}$$

where C_{bv}, C_{vb}, K_{bv} and K_{vb} are time dependent terms related to the tire-road contact forces; and the subscript r denotes road surface roughness which will be introduced in the following section. The details of deriving the above equations can be found in (Deng & Cai 2010a) and (Deng & Cai 2010b) and are not introduced here for the sake of brevity.

2.2 *Road Surface Condition*

Road surface roughness is a main source of excitation for the vibration of bridge-vehicle system. It can be described by a zero-mean stationary Gaussian stochastic process which can be generated through its power spectral density function. The International Organization for Standardization (ISO 1995) classified the road surface condition (RSC) based on different roughness coefficients. Based on the ISO classification, a total of four different road surface conditions, namely, smooth, very good, good, and average, were considered in the present study, with corresponding roughness coefficients of 0, 5×10^{-6}, 20×10^{-6}, and 80×10^{-6} m^3/cycle, respectively.

2.3 *Solving the BVI problem*

Eq. (3) can be solved using numerical integration algorithms. A Matlab program was developed to solve the BVI problem using the Newmark-β method in the time domain. The BVI model has also been validated using field measurements by Cai et al. (2007) and Deng and Cai (2011). The strain of the bridge can be calculated based on the bridge dynamic displacement responses by:

$$\varepsilon = B \cdot d_b \tag{4}$$

where B is the strain-displacement relationship matrix assembled with the derivatives of the element shape functions with respect to x, y, and z, and can be derived following a standard finite element formulation process.

3 METHODOLOGY FOR DETECTING VEHICLE SPEED AND AXLES

3.1 *Equivalent Shear Force Method*

Figure 1 (a) shows a linear-elastic beam AB with arbitrary support conditions. P, Q, and O are three consecutive points on beam AB while point O is located at the middle of points P and Q. l_A, l, and l_B are the length of segments AP, PQ and QB, respectively. The reaction forces of the beam AB are represented by M_A, M_B, F_A, and F_B, which are functions of x, as shown in Figure 1(a).

When the beam AB is subjected to a concentrated force F applied at a distance of x from point A, the

bending moment at positions P and Q of the beam AB can be expressed as:

$$M_P = M_A(x) + M_P^F, \quad M_Q = M_A(x) + M_Q^F$$
$$M_P^F = \begin{cases} F_A(x)l_A - F(l_A - x), & 0 \le x < l_A \\ F_A(x)l_A, & l_A \le x < l_A + l + l_B \end{cases} \quad (5)$$
$$M_Q^F = \begin{cases} F_A(x)(l_A + l) - F(l_A + l - x), & 0 \le x < l_A + l \\ F_A(x)(l_A + l), & l_A + l \le x < l_A + l + l_B \end{cases}$$

From Eq. (5), the following two variables can be defined and derived:

$$V^E(x) \triangleq \frac{M_Q - M_P}{l} = G(x) + F_A(x)$$
$$G(x) = \begin{cases} -F, & 0 \le x < l_A \\ -F(1 - \frac{x}{l}), & l_A \le x < l_A + l \\ 0, & l_A + l \le x \le l_A + l + l_B \end{cases} \quad (6)$$

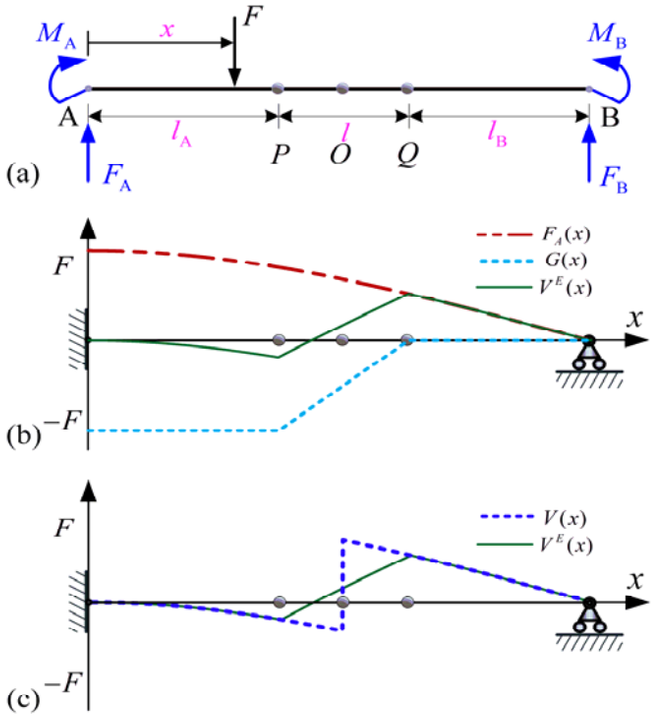

Figure 1. Schematic of the ESF method: (a) beam AB with arbitrary boundary conditions; (b) the influence lines of $F_A(x)$, $G(x)$, and $V^E(x)$; (c) the influence line for the shear force at point O and the ESF of segment PQ.

For the purpose of illustration, the influence lines for $F_A(x)$, $G(x)$, and $V^E(x)$ for a beam with a fixed support on the left end and a roller support on the right end are obtained based on Eq. (6) by assuming F=1, and the results are plotted in Figure 1 (b). It can be seen that $V^E(x)$ has two sudden changes of slope corresponding to a valley and a peak on its influence line.

In fact, based on the theory of mechanics of materials, V^E, which is derived by the moments at points P and Q as shown in Eq.(6), is an approximation of the shear force at point O:

$$V^E \approx V = \frac{dM}{dx} \quad (7)$$

Therefore, V^E is called the equivalent shear force of PQ hereafter. The influence line of the shear force V at point O and the influence line of the ESF of PQ are plotted in Figure 1 (c). When points P and Q approach point O, the ESF curve shown in Figure 1 (c) will converge to the shear force at point O.

3.2 *Axle Detection*

The sudden changes of the slope of V^E can be used to identify axle passing. Firstly, two segments P_1Q_1 and P_2Q_2 were selected as shown in Figure 2. The lengths of the two segments are denoted as l_1 and l_2, respectively. The distance between the centers of the two segments is L, as shown in Figure 2. Then, the ESF of the two segments can be obtained using Eq. (6). Based on the characteristic of the ESF, if a N-axle vehicle passes the bridge, there will be N groups of valleys and peaks on the ESF of a segment. Thus, the axles can be identified as the number of valleys or peaks on the ESF curve. The vehicle speed can be predicted using the time lag between the ESFs of the two segments and the known distance L. It should be noted that, theoretically, the vehicle speed can be identified using the time lag between the valley and the peak. However, in reality, the dynamic effect and measurement noises tend to shift the peaks and valleys away from their theoretical locations, making it difficult to accurately identify the vehicle speed using only one segment. Therefore, two segments with a center spacing of L were used for identification.

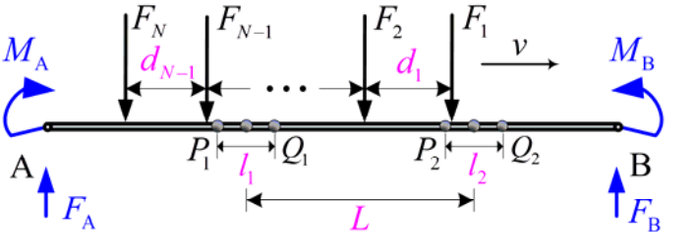

Figure 2. Two beam segments for axle detection.

Figure 3 shows the static bending moment and the ESF of two segments of a simply-supported beam AB subjected to two moving loads with a spacing of d. The x axis represents the location of the first axle and the y axis represents the bending moments or the ESF. From Figure 3, the number of axles can be identified by counting the number of valleys (t_{11}^1 and t_{21}^1 relative to P_1 on V_1^E, or t_{11}^2 and t_{21}^2 relative to P_2 on V_2^E) or peaks (t_{12}^1 and t_{22}^1 relative to Q_1 on V_1^E, or t_{12}^2 and t_{22}^2 relative to Q_2

on V_2^E). Then, the vehicle speed can be predicted as:

$$v = \frac{L}{\Delta T} = \frac{L}{\frac{t_{s1}^2 + t_{s2}^2}{2} - \frac{t_{s1}^1 + t_{s2}^1}{2}}, \quad s = 1 \text{ or } 2 \tag{8}$$

where ΔT is the time lag between ESF1 and ESF2 and it can be automatically determined by using an alternatively cross-correlation algorithm proposed by Kalin et al. (2006). After the vehicle speed is obtained, the axle spacing can be easily calculated as:

$$d = v\left(\frac{t_{21}^s + t_{22}^s}{2} - \frac{t_{11}^s + t_{12}^s}{2}\right), \quad s = 1 \text{ or } 2 \tag{9}$$

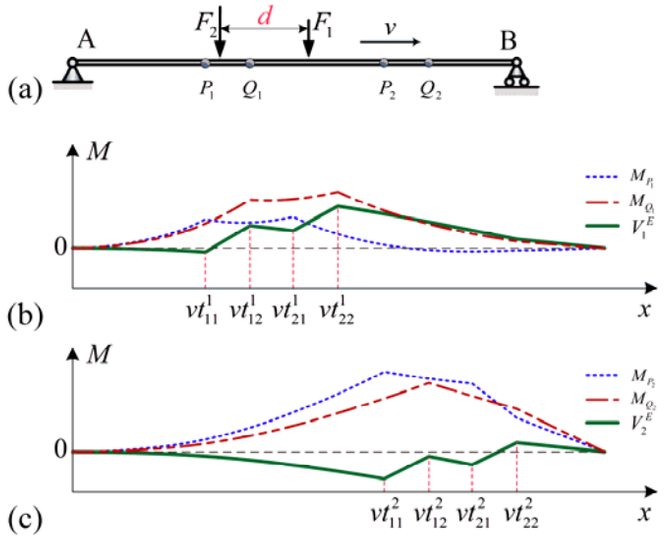

Figure 3. Bending moment and ESFs of a beam: (a) a simply-supported beam AB subject to two moving loads; (b) the static moments at P_1 and Q_1, and ESF of P_1Q_1 (V^E_1); (c) the static moments at P_2 and Q_2, and ESF of P_2Q_2 (V^E_2).

Based on the above discussion, it can be seen that two groups of measurement points, with two points in each group, are needed to identify the vehicle speed and axle spacing. Nevertheless, in practice, only three measurement points are needed since the two segments can share one measurement point located in the middle. In addition, it should be mentioned that the ESF method can only be used to identify axles whose spacing is larger than the spacing of the two adjacent measurement points. For those closely-spaced axles (for example, an axle group), the proposed method may automatically treat them as one single axle in the identification process.

In-service bridges under routine traffic loads can normally be considered as linear-elastic systems. Namely, the global bending moment is linearly related to the flexural strain. Taking a multi-girder bridge for example, the total global bending moment of the bridge at a cross section can be calculated based upon the recorded normal strain as follows:

$$M_s = \sum_{i=1}^{n} EW_i \varepsilon_{s,i}, \; s = \{P_1, Q_1, P_2, Q_2\} \tag{10}$$

where E is the modulus of elasticity of the bridge material, Wi is the section modulus of the ith girder, and $\varepsilon_{s,i}$ is the normal strain of the ith girder at section s. However, it was found in this study that using the strain information from all girders is not necessary since the strain from one particular girder that bears a significant portion of vehicle loads can fulfill the requirement of identifying the vehicle speed and axle spacing, even under different transverse locations of the moving vehicle. Therefore, there is no need to install sensors on all girders in the lateral direction, and the strain information from the girder that bears the largest amount of vehicle loads was selected in the present study, namely:

$$V_j^E = \frac{M_{Q_j} - M_{P_j}}{l_j} = \frac{EW}{l_j}\left(\varepsilon_{Q_j} - \varepsilon_{P_j}\right) \tag{11}$$

Since $\frac{EW}{l_j}$ is a constant scalar, for the sake of convenience, ESF is redefined by ignoring the constant using Eq. (12) in the following analysis:

$$\text{ESF}_j = V_j^E \Big/ \frac{EW}{l_j} = \varepsilon_{Q_j} - \varepsilon_{P_j} \tag{12}$$

4 NUMERICAL SIMULATIONS

4.1 *Case Description*

4.1.1 *4.1.1. Bridge model*

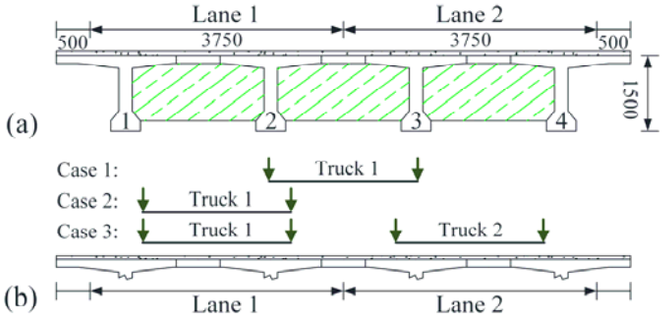

Figure 4. (a) Bridge cross section (unit: mm); (b) Considered loading cases.

In the present study, a multi-girder bridge with four identical T-beams was used in the numerical simulations. The bridge's cross section and the selected loading positions are plotted in Figure 4. The bridge was modeled using solid elements in ANSYS. The finite element model of the bridge is shown in Figure 5. In the simulation study, three measurement stations with an equal spacing of 2m are selected on the soffit of Girder 2 which bears the largest proportion of vehicle loads. As shown in Figure 5, the three

measurement stations are denoted by A, B, and C where station B is located at the mid-span. The ESFs of AB and BC were then calculated using the longitudinal strains collected from those stations.

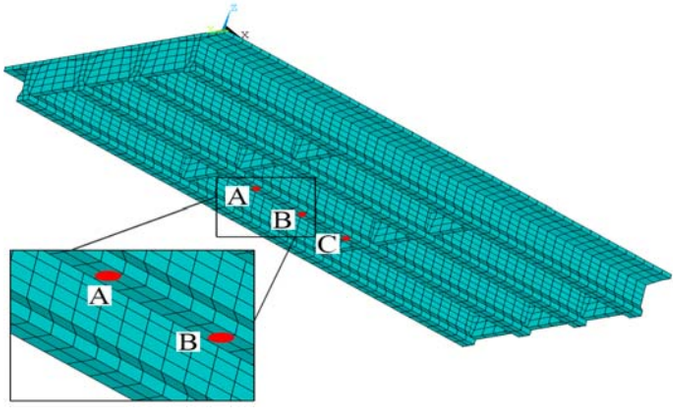

Figure 5. FE model of the bridge and locations of the measurement stations.

4.1.2 *Vehicle Model*

In the numerical study, three typical highway trucks were adopted. Figure 6 shows the axle configuration of the three trucks. Each truck was modeled by mass-spring-dashpot systems. Detail properties of the three vehicles can be found in (Harris 2007; Shi and Cai 2009; Wang and Liu 2000; Zhang et al. 2006; Zhou and Chen 2015). In the simulation, five vehicle speeds from 10 m/s to 30 m/s with an increment of 5 m/s, four different road surface conditions including smooth, very good, good, and average, and three loading cases including both single vehicle cases and cases with multiple vehicle presence were considered to simulate different scenarios of truck passing. Table 1 summarizes the parameters considered in the numerical simulation.

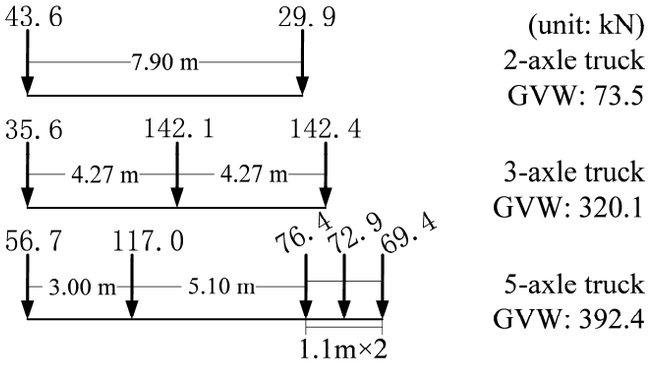

Figure 6. Axle weight distribution of the three trucks (Note: GVW=gross vehicle weight).

Table 1. Values of Parameters Considered in the Numerical Simulation

Parameter	Value
Speed (m/s)	10, 15, 20, 25, 30
Roughness	Smooth, very good, good, average
Truck type	2-axle truck, 3-axle truck, 5-axle truck
Loading case	1: one truck along the centerline of the bridge
	2: one truck along the centerline of Lane 1
	3: two trucks in both traffic lanes

4.2 *Identification Results for Single-Vehicle Cases*

For the single-vehicle cases, the truck either travelled along the centerline of the bridge or along the center of the left lane. Figure 7 shows the typical longitudinal strain responses and the calculated ESFs under the passage of the 2-axle truck. Figure 8 shows the ESFs of Girder 2 and the detected peaks and valleys under the passage of each truck at the speed of 20 m/s. For the purpose of demonstration, only a few typical cases were plotted. From Figure 8, it can be seen that clear peaks and valleys are observed and that the number of peaks and valleys is the same as the number of vehicle axles except for the case of the 5-axle truck where only three peaks or valleys are found. For the 5-axle truck, the three rear axles are closely spaced, which resulted in only one identifiable peak and valley. It should be mentioned that the difficulty in identifying closely-spaced axles has been reported by many researchers. Usually, the closely-spaced axles, such as a tandem or tridem axle group, are identified as a single axle by most BWIM systems. In the present study, the three rear axles of the 5-axle truck are treated as a single axle with a weight of 218.7 kN. The equivalent axle spacing between the second axle and the rear axle group is calculated as:

$$\mathrm{AS}_2' = \sum_{i=3}^{5} \mathrm{AW}_i \left(\sum_{j=2}^{i-1} \mathrm{AS}_j \right) \Bigg/ \sum_{i=3}^{5} \mathrm{AW}_i \tag{13}$$

where AW_i is the weight of the ith axle and AS_j is the spacing between the (i-1)th axle and the ith axle. Using the proposed method, the vehicle speed and axle spacing were calculated. For each RSC, five vehicle speeds were considered and for each set of RSC and each vehicle speed, ten runs with ten randomly generated road surface profiles were performed using the BVI simulation. Then, the root mean square (RMS) of the ten results is calculated for the error analysis. Table 2 gives the RMSs of the relative errors (%) in the identification results. For the sake of brevity, the results of 3-Axle truck are omitted.

From Table 2, it can be seen that: (1) the proposed method can effectively identify the vehicle speed and axle spacing. The RMSs of the identification errors are all within five percent for the vehicle speed and axle spacing; (2) vehicle speed does not seem to have a significant impact on the identification accuracy; (3) RSC affects the identification accuracy as rough surface tends to induce more vibrations and decrease the identification accuracy. Nevertheless, the identification results still show a satisfactory degree of accuracy under the average RSC.

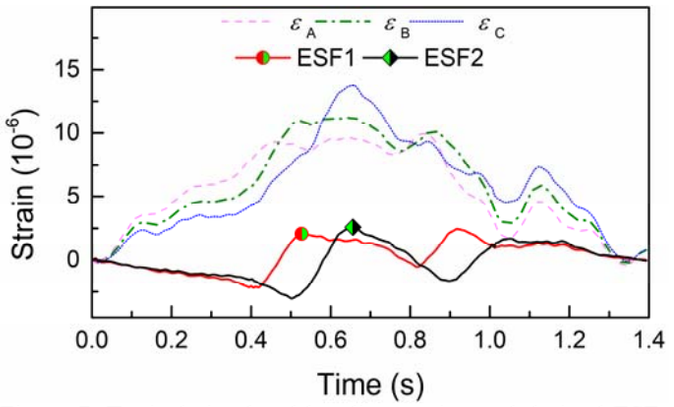

Figure 7. Typical simulated bending strains and derived ESFs (Loading case 1, 2-axle truck, v = 20 m/s, average RSC).

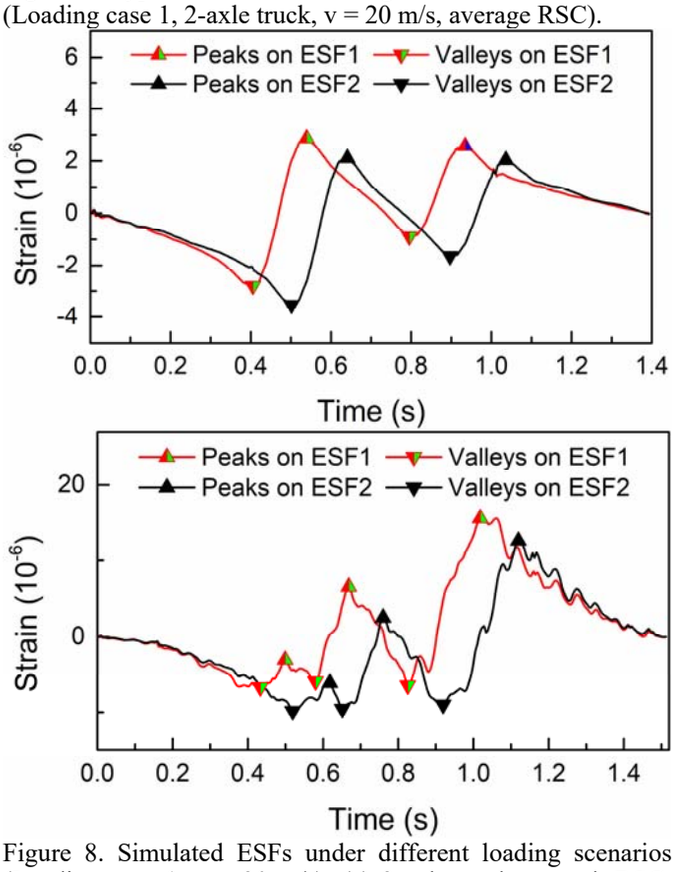

Figure 8. Simulated ESFs under different loading scenarios (Loading case 1, v = 20 m/s): (a) 2-axle truck, smooth RSC; (b) 5-axle truck, average RSC.

In addition, the identification results for loading case 2 are very similar to those for loading case 1 when measurement stations are selected on Girder 2 and thus they are not presented here for the sake of brevity. Meanwhile, in order to investigate the effect of the transverse location of the measurement stations, three measurement stations with the same longitudinal location as those on Girder 2 were selected on Girder 3 and Figure 9 shows the bending strain time histories and the ESFs for the 5-axle truck passing at a speed of 20 m/s under loading case 2. It can be seen that the ESFs of Girder 3 do not show clear peaks or valleys, making it infeasible to identify the vehicle axles. This is because when the vehicle was positioned in Lane 1, the shear forces induced on Girder 3 is so small that the peaks and valleys are not easily identifiable. This also indicates that two groups of measurement stations are required for each traffic lane in order to capture the information of all vehicles passing over the bridge. Also, the ESF signal under different traffic lanes can potentially be used to determine the traveling lane of the vehicle.

Table 2. The RMS of the Relative Identification Errors (%) of the Three Trucks (Loading case 1)

RSC	True speed (m/s)	RMS of identification error (%)				
		2-Axle truck		5-Axle truck		
		Speed	AS	Speed	AS_1	AS_2

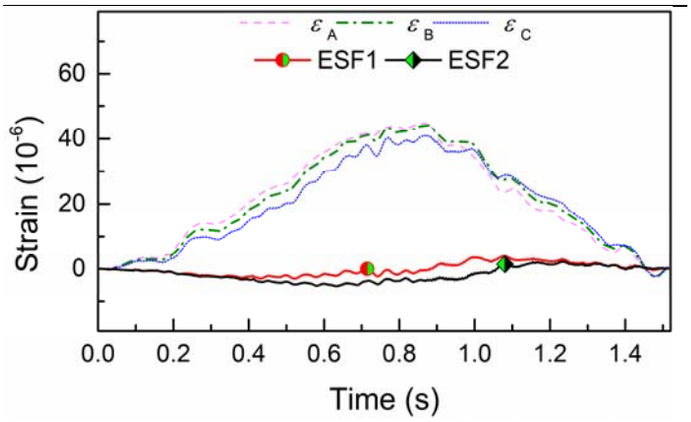

Figure 9. Simulated bending strain and ESF of Girder 3 (Loading case 2, 5-axle truck, v = 20 m/s, average RSC).

4.3 *Identification Results for Cases with Multiple Truck Presence*

In this study, a loading case with a 2-axle truck traveling in Lane 1 and a 3-axle truck traveling in Lane 2 were considered, as presented in Figure 4 (c). In order to represent the real traffic, three driving plans were developed and summarized in Table 3.

Figure 10 shows the time history of the simulated strain response and the ESFs for Girder 2 and Girder 3 following the first driving plan. The two trucks were set to travel at 20 m/s with a headway distance of 5 m and average RSC was used. From Figure 10, it can be seen that the peaks and valleys on the ESF time histories for both girders can still be clearly identified when the two trucks passed over the bridge simultaneously. For Girder 2, the ESF shows two groups of peaks and valleys corresponding to

the 2-axle truck while for Girder 3, the ESF shows three groups of peaks and valleys corresponding to the 3-axle truck. The RMS of relative identification errors (%) for two trucks traveling at the same and different speeds are summarized in Table 4 and Table 5, respectively. It can be seen that good accuracy was achieved in the identified vehicle speed and axles for both trucks, suggesting that the proposed method is able to deal with cases with multiple vehicle presence.

Table 3. Driving Plans of Two Trucks in Different Lanes (Loading Case 3).

Driving plan	Description
1	Two trucks enter bridge at the same time at the same speed (from 10 to 30 m/s)
2	Two trucks travel at the same speed (from 10 to 30 m/s) with headway distance of either 5m or 10m.
3	Two trucks enter bridge at the same time while the speed of the 2-axle truck was kept at 20 m/s but the 3-axle truck's speed varies from10 to 30 m/s.

5 SUMMARY AND CONCLUSIONS

In this study, a novel axle detection strategy, i.e., the equivalent shear force method, was proposed to identify the speed and the axle spacing of moving vehicles on bridges. The proposed ESF method utilizes the global bending strains of bridges to achieve axle detection and thus can be used for the NOR BWIM systems. Numerical study was conducted to demonstrate the performance of the proposed ESF method. The identification results showed that the proposed ESF method can provide accurate and reliable axle detection for the NOR BWIM systems. The effects of measurement location, vehicle speed, vehicle's lateral position, road surface condition, and multiple vehicle presence on the identification accuracy were investigated. Based on the results obtained, the following conclusions can be drawn: (1) in order to identify vehicles traveling in a particular lane, strain sensors need to be installed underneath that lane; (2) the vehicle's speed and lateral position do not affect the identification accuracy; (3) the identification accuracy decreases as the RSC worsens. Nevertheless, the identification accuracy is still acceptable under the average RSC; (4) the ESF method is able to identify vehicle speed and axle spacing under the cases with multiple vehicle presence.

Compared with traditional NOR axle detection methods such as the FAD methods, the ESF method uses the global bending response of bridges and is thus applicable to most bridges whose dominant internal force is bending moment under vehicle loading. Furthermore, the ESF is not susceptible to the lateral position of the vehicles and can also be used to identify multiple vehicle presence. These advantages make the ESF method a reliable strategy of axle detection for commercial NOR BWIM systems. Future studies will focus on developing algorithms for automatic identification of vehicle axles using

the ESF method and testing the performance of the ESF method in full-scale experiments.

ABSTRACT: Currently, new processes are being developed for the model-driven design of structures which make use of the upcoming means of digitalization, such as object-oriented-modeling (OOM), interconnecting Web-based Server-Architecture, Machine-Algorithms for design and fabrication procedures. Relevant Building Information is modeled over the lifecycle which means that data is available and disposable and no longer "hidden" in documents (i.e. design is no longer document driven). New processes focus on the optimization of engineering tasks in the design of structures, such as definition of initial requirements, construction and simulation (optimize geometry and material consumption), time scheduling and cost estimation. BIM principle: Information should be assigned and used without any redundancies in all phases and processes of the product life-cycle. This contribution picks up the idea of comprehensive parametric product templates in combination with an implicit design technology as it is widely used in the production industry for an automated but still strongly adaptive design. These techniques are very helpful especially in the preliminary design of road bridge structures.

1 INTRODUCTION

With the ongoing digitalization and automation of construction processes, the thought arises, that the same can be done for the planning process of bridge models. By creating template models, the earlier stages of the planning process can be automated. Creating and using templates offers various advantages compared to current planning methods. The main one is that they can be used repeatedly, reducing planning costs and time drastically. Draft designs of bridges can be created within hours. Including the correct placement, dimensions and alignment, as well as related documents such as drafts, bill of material, and sustainability evaluations. At the draft design stage objects of the model are accurately represented, whilst lacking details such as screws, welds and reinforcement. Details like that are only available as annotations (LOD300).

This paper explains the core concept behind a parametric, adaptive road bridge model that is created project unspecific and can hence be used as a template for multiple projects featuring a similar bridge design. It can adapt to local requirements and different gradients by allowing alterations to the corresponding parameters.
After using the template, the draft design becomes available straight away. It contains documents such as tables, text files and drawings. All of which are connected to the main model and automatically update on changes. Giving the user live feedback, on how alterations may affect the bridges' sustainability, appearance and cost.

The thought behind a parametric, adaptive design is to create a BIM-model that can be used multiple times, instead of creating a new bridge model for every construction project. This approach is especially viable for standardized bridge designs, since their layout only varies in detail and thus requiring less changes to the parameter. The currently underutilized functionality of creating such a model with associativity will become increasingly important in the future. In other branches, such as the aviation and automobile industry, this modeling technique is already used a lot with highly beneficial results.

2 METHODOLOGY

This paper focuses on using new BIM-processes in early design and including them into a composite bridge model template. An example is used to study the effects in a relevant application in practice, see Figure 1. The goal is to have a parametric, adaptive bridge model with a maximum grade of automation in bridge design. This model can be used for multiple projects as a template. It provides an instant adjustment to local requirements. It also includes the preparation of the structural analysis of the bridge as well as other documents (drafts, tables etc.). All documents related to the model automatically adapt to changes of the parameters. This model can be used repeatedly for different projects, since the parameters can be easily modified to fit local requirements and thus making the initial design process cheaper, quicker and less error-prone.

At first, the basic structure of the model is shown and compared to the use of a parametric, adaptive bridge design to current designing methods, pointing out the advantages and disadvantages of using a parametric, adaptive bridge design with an implicit geometry description. An implicit geometry description saves all methods of an object in a hierarchical construction history. This is contrary to most BIM-systems working with an explicit or hybrid geometry description that only saves the final geometric attributes. The implicit geometry description offered by sophisticated CAD software is a necessity for the creation of a bridge template and subsequent individual modification and detailing, see Section 2.

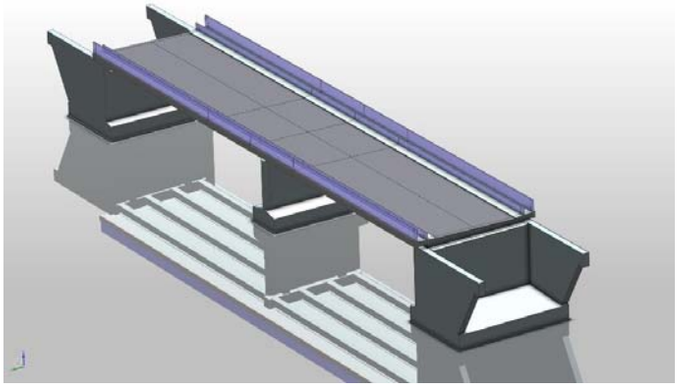

Figure 1: Composite Road-Bridge Type developed as a parametric, adaptive template Building Information Model

In Section 3, the challenges and advantages of the new approach are described. The creation of a model that can be used as template, results in a higher work load at first sight. However, the use of parametric adaptive, bridge models proofs to offer great potential in multiple reuse cases. It can greatly cut early project planning times. This makes its use a valid option for standardized bridge structures, but not for the creation of individual bridge designs. Overall it proves to be the next step for designing standardized bridge models satisfying today´s demands for faster and cheaper design processes.
In this Section the technical background of a template driven parametric top-down modeling based in a history-based CAD-process is explained in detail.

Section 4 presents how an adaptive building information model can reduce the planning times of a bridge, taking away the time intensive process of creating a draft design as well as preparing further planning processes. Therefore, it allows a less labor-intensive planning process. In addition, a quality improvement comes with the use of the template. Functions such as pre-dimensioning cost estimation and sustainability rating can be easily integrated into the template.

2.1 *Requirements for a parametric adaptive template driven modeling of road bridges*

For route-bound infrastructures such as bridges it seems to be clearly advantageous to choose a top-down modeling strategy as most components are dependent on the alignment and fixed by outer constraints such as crossing routes or as-built-infrastructures.
In preliminary design, a rather less detailed model (Level of Detail (LoD) 300) is needed which can easily (and ideally automated) adapt to different positions and shapes to several variants of alignments. Hence there is a strong need of flexibility in positioning and form fitting.
At the same time adjacent information such as technical documentation, drawings, structural analysis, bill of material and costs, time-sheets and sustainability values directly result from the model properties.

2.2 *Parametric Top-Down Modeling Technique*

The most common method to describe an object oriented 3D model is the Boundary Representation Method. This method only saves information on the geometric attributes, leaving out any information on the creation process so that there is no adaptivity given.
Sophisticated CAD software allow for a more flexible Procedural Method. As the name already suggests, this method saves the procedure of the creation process in a timeline.
With the procedural method the engineer has a tool to create and individually modify all individual parameters and features in design in pre- and post-processing. It allows for the manipulation of every step that was involved in the creation of the model. This is imperative for the use as a template, since it requires alterations of the modeling history. The modeling history can be edited at any given point

before and after applying the template which is a strong benefit in the preliminary design phase of a road bridge.
In a so-called "control" part file the guiding geometrical information such as the alignments, planes of main axes and master sketches are created and stored. From this control part file the necessary information is referenced to other work part files where the 3D-object modeling of individual components (superstructure, pillars etc) is finally generated. The advantages of such a top-down master-model strategy are a good overview and central adaptivity of all important parameters, such as the alignment and the cross-section which might be changed several times in early project phases. In addition, the assembly allows for the potential to install a centralized template.
Furthermore, simultaneous engineering of bridge components is possible as all major information may be linked from the master-part and then processed individually in separate work part files while the master-model can be protected by read-only.

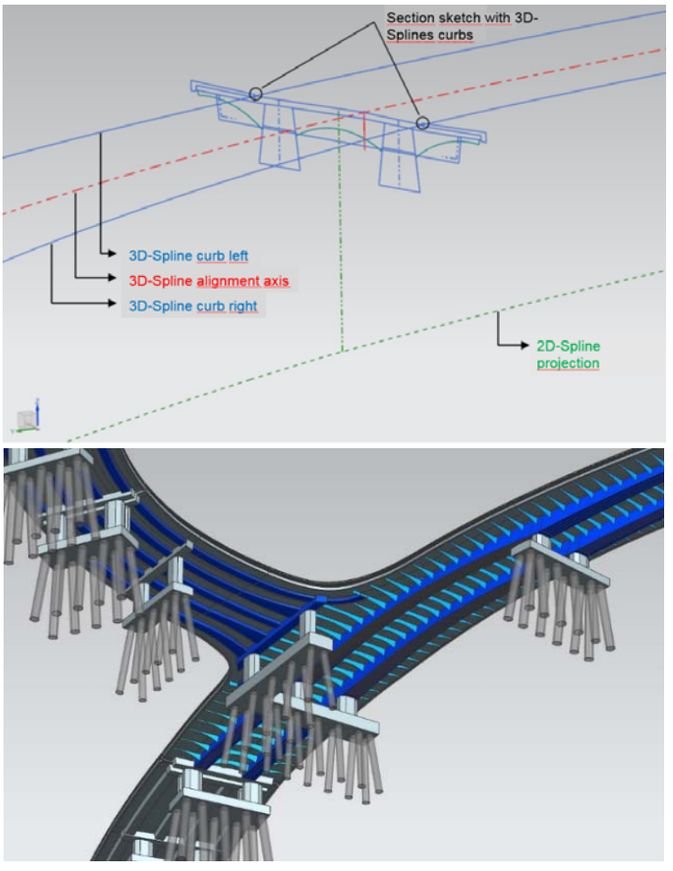

Figure 2: upper: "Control" part-file: Three Alignments which define the widening road surface and a parametric cross section guided by the alignments; lower: completed 3D-model of the bridge structure based on referenced control objects and parameters [6]

Figure 2 (upper) shows the three spatial alignments which were integrated in this project to define the widening road surface in 3D. The three alignments are "cut" into the cross-sectional space in order to guide the variable composite cross-section of the bridge which is set up by additional structural parameters. The main alignment ("3D-Gradiente") is projected in the x-y-space for the definition of main axes and planes.

2.3 *Adaptivity in implicit CAD*

Changes to the model are mostly applied to the control assembly which shall contain all relevant parameters and features to be adapted in a preliminary design. The other reloaded objects automatically adapt to the changes due to the associations. Associations between two objects are not allowed to be bi-directional, exchanging information back and forth to keep the content consistent.

However, a successful adaption to individual boundary conditions affords a high flexibility also in modification and detailing of the related geometry in all work parts. For this purpose, sophisticated implicit modeling techniques are needed which have the full set of parameters and features even after the preliminary template modeling has been finished.

2.4 *Template Driven Design*

The template collects a set of relevant parameters and features to be modified during the modeling process which are located in the model control part-file. The studies show that the template has to be worked out thoroughly in advance by the designing engineer to avoid conflicts in design.
In the presented study the following parameters were chosen:

- Coordinates for alignment-curves
- Crossing-angle of alignments
- Main-Spans for each field individually
- Type of cross-section
- Structural height (Steel-girder)

Those parameters can be adapted within a template by inserting individual values, given values, functions or automated rules. Obviously, upper and lower boundary conditions should be given to ensure reasonable solutions and quality.
Once updated the template allows for the automated adaption of the instant creation of drafts, cost estimates, bill of material and sustainability ratings (See also section 4). To obtain the required data most elements were created with a level of development of 300 according to the description made by the American Association of Architects [2]. This means that 'the quantity, size, shape, location, and orientation of the element as designed can be measured directly from the model without referring to non-modeled information such as notes or dimension call-outs.' Unlike regular execution planning, the model can be used as groundwork for the further planning.

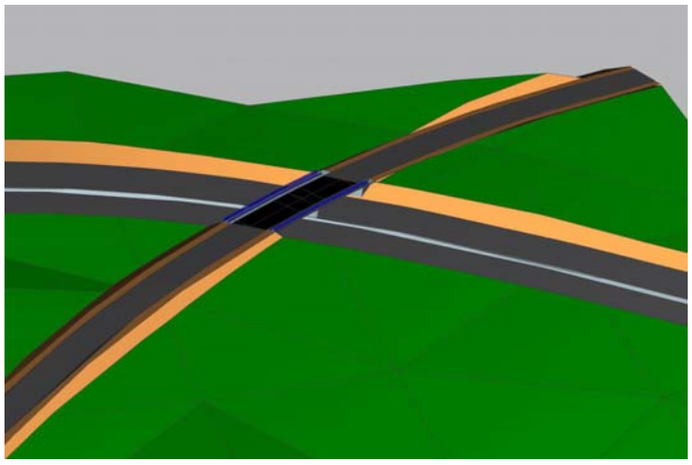

Figure 3. Parametric Two-Span Bridge adapted to a crossing regular Highway in terrain

The model can easily be applied to any given requirements. The integrated product template studio offers a fast and simple way to change the bridges' parameters. It gives live feedback on the status of the parameters requirements, assuring that all values are correct and recommending possible corrections.
There are, however, a few issues which would require an intense preparatory work to be automated. One of those is the adaption to the digital terrain model. The number of variations possible in this adaption of abutment and DEM seems to make automation ineffective. It is recommended to adapt this manually within the implicit post-processing and detailing, for example for the construction pit that should interact with the terrain. Furthermore, depending on the client´s demands, the gradient might be manually inserted as well. Alternatively, the bridge can also be aligned using coordinates that can be inserted in the product template studio.

3 RESULTS AND FINDINGS

3.1 *Issues*

The automation in model design does not come without issues. As it is always the case when switching to a new method of planning, getting used to it can take a while. Using the procedural method requires an intense preparatory work before starting modeling in the beginning. Unlike the regular Boundary-Representation-Method, with the sole purpose of creating objects with the correct attributes, the creation of a parametric, adaptive design requires the user to consider in what sequence the features work and interact in advance.
Since changes to the bridges parameter force the software to recalculate all objects which get affected by these changes, it must be assured that the changes get applied in the correct sequence. Using a hierarchical order helps to keep the sequence consistent.
Furthermore, the model history should be clearly structured to assure that the used features can be easily manipulated. This requires clear conventions every planner must follow.
It becomes evident that the initial creation of the template is much slower than creating a non- associative model. But the increased effort is well worth it as it becomes evident in the next section.
Finally, current software independent data exchange formats do not allow the exchange of method information. Thus, the template is solemnly usable with one software product ('closed BIM').

3.2 *Advantages*

There are many advantages using a model template. First and foremost, the enormous time savings, since creating a model only requires modifications to the initial template parameters. The conceptual and draft design phase in a regular BIM phase usually require a lot of effort compared to the conventional planning process. Using the template allows reducing the effort for the first planning stages to a minimum.
Later stages take similar time as in a regular BIM process. The draft and concept design in a regular BIM process usually take more time then in a conventional planning process, moving the planning expenses to the earlier stages. Unlike the conventional planning process, where the draft design is not further used, BIM processes utilize the draft design without any breaks in the information flow. This saves time in the execution planning.
Additionally, to the reduction of planning errors generally coming with the application of BIM, this method reduces the amount of errors even further. Since, errors that occur due to issues with the template can be corrected to prevent them in future projects.
Current fee structures often do not distinguish between draft designs created in a BIM process and designs in conventional planning. It is thereby favoring the conventional planning process, since it is less time intensive and therefore cheaper. The template fixes this imbalance since it takes away plenty of the effort from the early planning stages, see Fig. 4.
Most objects are created without any associativity between each other, except the one to the control assembly, which means they can be easily separated. This can be utilized by distributing objects among several employees and companies at the same time without worrying about clashes (concurrent engineering). This reduces the time for the execution-planning as well, assuring an even quicker model creation and subsequent process.

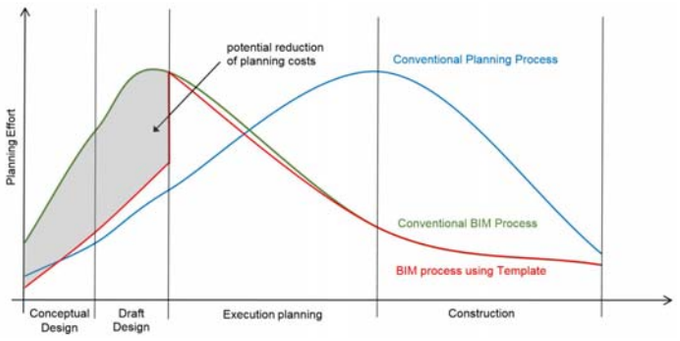

Figure 4. Difference of template driven parametric bridge design to other planning procedures

4 AUTOMATION WITH PARAMETRIC, ADAPTIVE BIM TEMPLATES

4.1 *Drawings as derivatives*

The geometry is stored and maintained in a "work" part file, the so-called the master-model (master part). Simulations, 2D/3D-Derivatives (e.g. as drawings or 3D-visualizations) and even the adjacent structure, the assembly of all bridge components, reference to the master-model. The decisive advantage: Any changes conducted in the master-part will update via associations as long as they were defined consistently.

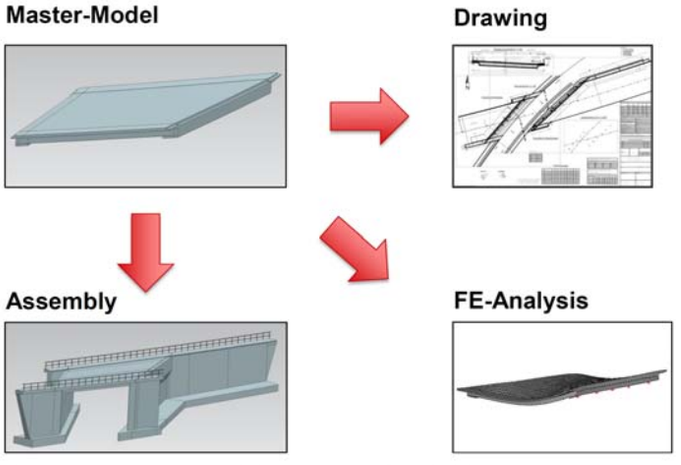

Figure 5. Master-model-concept of a bridge superstructure, drawings, FEA and assemblies receive all geometrical information from the master-part [7]

In 3D-Design, drawings are no longer main products but derivatives of the 3D-Model. Drawings are derived by defining a section plane in the model which is subsequently placed on a 2D-plan. The drawing part files are fully associative to the model as they are positioned upwards to the hierarchical structure. The associativity is unidirectional from master to slave so that changes have to be performed in the master-model.

As the 3D-Model follows the alignment sections have to be defined on curved surfaces.
The authors strongly recommend to modify these current regulations for 2D-drawings with respect to the potential and capability of 3D-models [8]. As a clear advantage compared to 2D-drawings, 2D-derivatives of 3D-models represent real sections and can be positioned everywhere in the 3D-model. This evidently leads to a better understanding, consistency and accuracy.
Hence the authors recommend to increase the number of 3D-sections. Sections which are modified or coupled with others lose associativity to the 3D-model! An example is shown in the next figure 6.

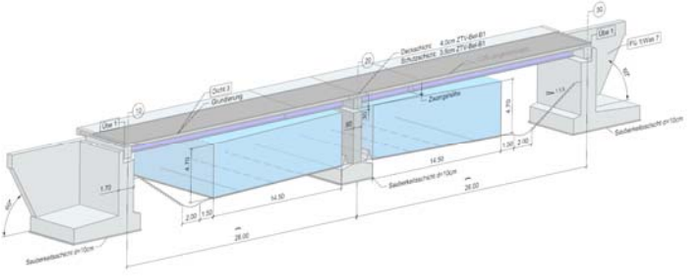

Figure 6. Curved longitudinal section in the 3D-Model, guided by the spatially curved alignment projected in vertical direction. Product Manufacturing Information illustrate the regulatory information (Attributes) [8]

For a further automation, manufacturing drawings can be extracted from the model whilst not only geometrical but also manufacturing information can be integrated in the model and supplied for the following production processes, logistics and erection. Figure 7 shows an example of prefabricated concrete elements automated in construction order and driven by the model. The attributes were assigned to the individual master-parts and visualized by so-called Product-Manufacturing-Information (PMI) in NX.

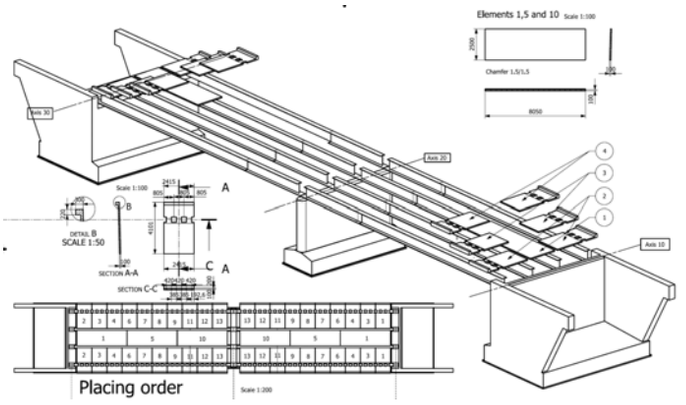

Figure 7. Manufacturing drawing for the logistic and erection of prefabricated R/C bridge deck elements

Current software independent data exchange formats allow for the exchange of such manufacturing

information. Thus, the template is generally usable with any BIM software product (‘open BIM’).

4.2 *BIM2FEM Embedded Structural Analysis*

The technical background of Building Information Modelling (BIM) is a relational database where objects such as 3D-parts, semantic data, drawings and simulations are linked. BIM is a model-driven process, so that a master-model-concept is a common technique in CAD/CAM software applications [4, 5].

The geometry is stored and maintained in the master-part. Simulations, 2D-Derivatives (Drawings) and even the adjacent structure, the assembly of all bridge components, reference to the master-model. The decisive advantage: Any changes conducted in the master-part will update via the references.

Based on the master-model-concept, the first and most important engineering task in the proposed method is to enrich the geometry of a structural component by well-chosen geometrical and statical constraints for the subsequent Finite-Element-Analysis (FEA), see Figure 8.

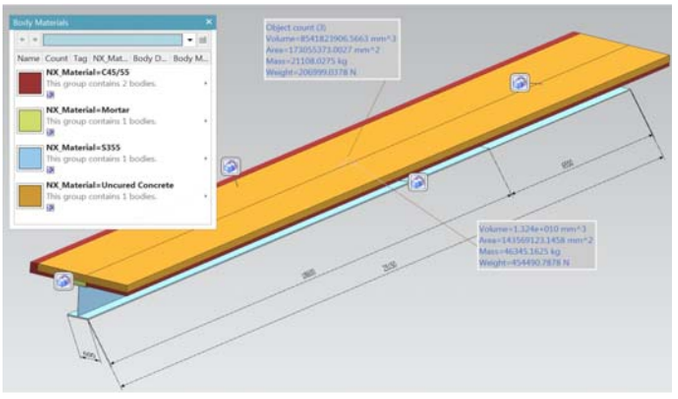

Figure 8. 3D-CAD Model enriched with geometric and static boundary conditions and Attributes for the subsequent simulation

Apart from the automatic generation of the finite element mesh, the calculation of the necessary cambering of the steel girder was integrated into the model as well. The resulting deflection graph as seen in Figure 1 is loaded back into the main model to create the optimal precamber for the steel girder. As the rest of the model, the calculation automatically adapts to changes of the parameter. It can also be considered to add the pre-dimensioning to the process using iteration steps. This can reduce the time effort since the geometry of the elements do not require modifications later. It also improves the sustainability, since a geometry optimization is often not done to the full extend.

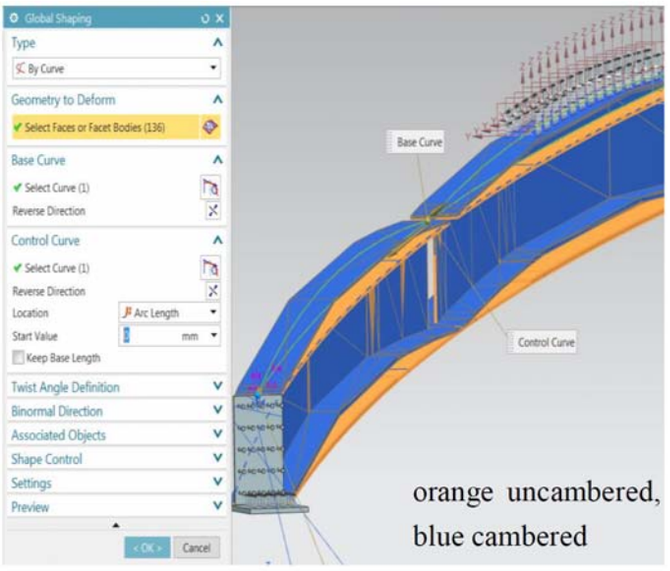

Figure 9. Cambering calculated in CAE updated in 3D-CAD-Geometry for the further production process

The system was meshed using a tetrahedral mesh, since it is the most versatile mesh and more importantly the only one not necessarily requiring mesh dependent boundary conditions. This comes as great advantage, since boundary conditions bear the risk of getting lost upon geometry changes. The forces for the dead loads were included by measuring them in the master model and afterwards linking them as parameter into the calculation. All forces and boundary conditions were applied to the geometry itself instead of the mesh to keep the adaptivity.

4.3 *Sustainability*

The Building Information Model can be used to rapidly evaluate different concepts. With the linked sustainability and estimation results there is an instant feedback. For this study, the sustainability of two different girder types (bridge type 3 (BT3): open, welded profile vs. bridge type (4) open, rolled profile) were compared.

It can be pointed out, that the different girder shapes had little impact on the environmental impact, even though the steel beams make up for ~10% of the carbon dioxide emissions of the super structure. The welded steel beam performed slightly better due to its optimized shape.
For the evaluation of the bridges sustainability reference bridges were used. The evaluation was done in consideration of the span width. The bridge was compared to other composite bridges, since they generally have an inferior environmental impact compared to concrete bridges. The environmental impact of the materials was determined using aggregated cause-effect data from ‘eco balance of bridges’

[3]. Overall the bridge had slightly lower CO_2 emissions than the average reference bridges.

Table 1. Sustainability life-cycle inventory

SP*	GE	EC	RMC	W	SW
Unit/m² bridge surface	tCO_2	GJ	t	t	t

* GE Greenhouse Effect
EC Energy Consumption
RMC Raw Material consumption
W Waste
SW Special Waste
BT Bridge Type No. Length
SP Sustainability Parameter

5 CONCLUSION

It can be assumed that it will become increasingly important in the future to create automated building information models of standardized structures. Such models can be used repeatedly and optimized along the way. The planning method minimizes errors and maximizes the speed in which a construction is planned. It allows to compensate the disadvantages typical for the early planning stages of BIM models. It must be emphasized that the major requirements for a successful application of 3D-CAD in road-bridge design are

- Template concept according to BIM-Use-Cases
- An implicit (procedural) CAD-tool based on Constructive Solid Geometry
- Top-Down modeling and control part files
- Timeline history for parameters and features
- Well sorted Associations and part-structures
- Template for Human-Machine-Interaction

The presented study already shows the great potential of having a parametric, adaptive bridge model template. Whereas this model only includes elements for the draft design it can be expected that more and more planning elements such as drawings, manufacturing data, structural simulations or reporting files such as the bill of material and sustainability records may be included into the template, dependent on how often the bridge design is used. Currently implicit modeling structures are not completely supported by Open BIM concepts, this might change in the future, making it possible to automate the entire life-cycle process.

The report shows only the beginning of an adaptive, parametric model. More and more planning elements can be added to the model. Including not only the execution planning, but also product lifecycle management, information on the required maintenance. The post construction 3D-model can be marked with 3D- annotations, giving information on the condition of each element. By using hyperlinks, various kinds of information (photos, protocols, processes) can be included to the model as well, it thereby becomes easier to find the problematic areas on subsequent inspections. Damages can be directly evaluated with regards to construction information included in the model and even the demolition planning can be simplified.

ABSTRACT: The performance of four methods in establishing whether a bridge has experienced damage or not from the response to the crossing of a vehicle, is assessed within the Marie Skłodowska-Curie Innovative Training Network titled TRUSS (Training in Reducing Uncertainty of Structural Safety, http://trussitn.eu, 2015-2019). The first and second methods extract vibration based damage sensitive features and apply a Bayesian Belief network respectively from/to bridge accelerations to determine the occurrence of damage. A third method based on bridge rotations applies bridge weigh-in-motion concepts to detect damage from estimated vehicle's weights. Finally, a fourth method derives bridge curvature and damage from the vehicle response. A blind test based on the responses of a complex vehicle-bridge interaction theoretical model is carried out to assess performance. The estimations of damage by each method are collected independently and compared to the exact solution.

1 INTRODUCTION

1.1 *TRUSS innovative training network*

TRUSS (Training in Reducing Uncertainty in Structural Safety) is a Marie Skłodowska-Curie Innovative Training Network (ITN) funded by the European Union under the Horizon 2020 Programme aiming to address some of the needs by operators managing infrastructure. The overall approach of TRUSS ITN is to integrate 14 Individual Research Projects (IRPs) into the overall network collaboration, which is encompassed by two thematic research clusters: (i) buildings, energy and marine infrastructure and (ii) rail and road infrastructure. At the most basic level, there is a number of bilateral collaborations, centred around each IRP. An Early Stage Researcher (ESR) is recruited for each IRP and assigned a doctoral studies panel composed by experts from at least two European countries, including both academic and industrial participation. Structural safety and Structural Health Monitoring (SHM) is a broad area of investigation and while training within TRUSS provide ESRs with an overall understanding and advanced skills, IRPs respond to specific needs for a particular infrastructure type. Detailed info about TRUSS can be found in González (2017).

1.2 *Damage detection for bridges*

Within the rail and road infrastructure cluster, there are four IRPs focused on the development of methods for detecting damage in a bridge from the response to traffic. The inputs for three of these methods are the response of sensors directly attached to the bridge when crossed by a vehicle: bridge accelerations for both an approach based on vibration parameters (VIB) and a Bayesian Belief Network (BBN), and bridge rotations for a Bridge Weigh-In-Motion (B-WIM) – based approach. The input for the fourth method is the response of displacement sensors mounted on the vehicle (i.e., drive-by) traversing the bridge. Therefore, blind test comparisons based on a vehicle-bridge interaction (VBI) theoretical model are carried out to assess performance. Section 2 defines the simulation model employed to gather input responses as required by each method. Section 3 describes the background of each damage detection method. Each method is tested at a different research institution. Damage is identified, located and quantified for scenarios that are unknown a priori. The solutions to these scenarios, distinguished by location and severity of damage, road roughness, and vehicle weight and speed, are discussed in Section 4. Finally, Section 5 provides conclusions.

2 VEHICLE-BRIDGE INTERACTION MODEL

2.1 *Bridge model*

The bridge is modelled as a beam-and-slab with 0.9 m deep precast concrete beams and a 0.16 m thick continuous structural slab on top of them. The struc-

ture is 20 m long and 10 m wide (Figure 1), allowing to accommodate two traffic lanes. There are a total of 10 longitudinal beams spaced by 1 meter and placed symmetrically with respect to the bridge centerline. The slab is discretized into 1 m x 1 m plate Finite Elements (FEs), with the exception of the rows of plate elements closest to the edge that have a size of 1 m (long.) x 0.5 m (trans.). Each of the 10 longitudinal beams is discretized into 1 m long 20 elementary beams. I.e., the bridge model has a total of 220 plate elements and 200 beam elements. The bridge is simply supported in all beams at both ends.

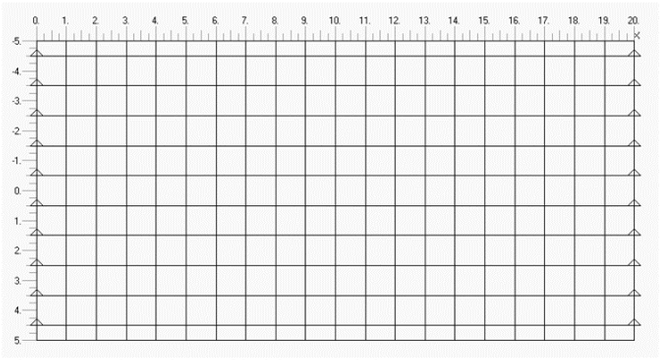

Figure 1. Plan view of bridge model.

The section of the longitudinal beams has a second moment of area of 0.108 m^4 for those beam elements closest to the supports (i.e., longitudinal coordinate x between 0 m and 1 m, and between 19 m and 20 m), and of 0.0685 m^4 for the rest of beam elements (i.e., x between 1 m and 19 m). All bridge material has been assumed to have a density of 2500 kg/m^3 and Poisson's ratio of 0.15. The slab has longitudinal and shear moduli of $31x10^9$ and $13.48x10^9$ N/m^2 respectively. The beams have a modulus of elasticity of $34x10^9$ N/m^2 and shear modulus of $14.78x10^9$ N/m^2. Regarding global dynamic properties, a 3% modal damping is adopted and the first natural frequencies of the bridge model are 6.13 (longitudinal), 7.14 (torsional), 9.27 (torsional) and 12.34 (torsional) Hz.

2.2 *Vehicle model, road profile and interaction*

The configuration of the vehicle is a typical European 5-axle articulated truck with rear tridem. The overall length of the truck, including front and rear frame overhangs, is 14.9 m. The distances between the 1st axle and the remaining four axles are 3.6 m, 9.93 m, 11.24 m, and 12.55 m, i.e., spacings between consecutive axles of 3.6, 6.33, 1.31 and 1.31 m. The transverse distance between two wheels of an axle is 2 m. In all scenarios, the vehicle travels from left to right, with inner and outer wheels located along the path at 0.5 m and 2.5 m respectively from bridge centerline in Figure 1.

The truck is modelled using vertical elements that consist of stiffness springs and damping elements whereas horizontal elements are made of bars and/or rigid elements. Mass elements are used to model the body masses of the tractor and the trailer which are rigidly connected to the frame. More details on the truck model can be found in González et al (2015). Table 1 provides dynamic properties for stiffness and damping of the tire and suspension corresponding to each individual wheel of an axle. A single tire is assumed for the 1st axle while two tires are considered for other axles. Two different Gross Vehicle Weights (GVWs) are tested. For the first truck model, namely vehicle A (fully-loaded), GVW adds up to 40 tons while for the second truck model B (half-loaded), the GVW is 25 tons. The distribution of GVW to individual wheel weights can be found in Table 1. Body frequencies of the truck oscillate between 1.4 and 4.1 Hz and axle roll and hop frequencies between 10.5 and 15.6 Hz.

Table 1. Wheel properties

Wheel	Static		Dynamic			
	A	B	Tire		Suspension	
	kN	kN	kN/m	kNs/m	kN/m	kNs/m
1st axle	31.87	28.83	1000	3	1800	5
2nd axle	53.94	35.10	2000	3	500*	0*
3rd axle	36.77	19.55	2000	3	1800	5
4th axle	36.77	19.55	2000	3	1800	5
5th axle	36.77	19.55	2000	3	1800	5

* Air suspension in 2nd axle. All other axles have steel susp.

The interaction between vehicle and bridge is implemented using a Lagrange multiplier technique (González 2010). A 'very good' road profile according to ISO standards is added to the bridge surface and to a 50 m approach length. The profile consists of 101 spatial waves between 0.01 cycles/m and 4 cycles/m with a geometric spatial mean of $0.5x10^{-6}$ m^3/cycle and phases randomly generated for each wave. The road profile remains the same in all runs, except for three test scenarios.

2.3 *Calibration data*

The response of the bridge to 4 simulated runs is provided for calibrating each damage detection algorithm. The same vehicle is driven at 20 and 30 m/s with two different gross vehicle weights (25 and 40 tons) as a result of altering the body mass of the trailer (Table 1). Algorithms 1 (VIB) and 2 (BBN) are provided with accelerations at nine bridge locations with coordinates (5,-2.5), (10,-2.5), (15,-2.5), (5,-0.5), (10,-0.5), (15,-0.5), (5,2.5), (10,2.5) and (15,2.5) related to Figure 1, where the first coordinate refers to the longitudinal direction (i.e., three simulated sensor locations in longitudinal sections at ¼, ½ and ¾ of the bridge span). Algorithm 3 (B-WIM) is provided with rotations at six bridge locations with coordinates (0,-2.5), (20,-2.5), (0,-0.5), (20,-0.5), (0,2.5) and (20,2.5) (i.e., three simulated sensor locations at both support ends). Finally, algorithm 4 (drive-by) is provided with displacements of the vehicle for the contact wheel point and immedi-

ately above the wheel for each of the 10 wheels. The difference between these two points aims to simulate the profile measurements by a Traffic Speed Deflectometer (TSD) (Rasmussen et al 2002). For the calibration runs, the bridge is assumed to be healthy, i.e., all elements maintain the properties given in Section 2.1.

2.4 *Test data*

A total of 16 different simulations are conducted in order to test the ability of the algorithms to detect, locate and quantify damage (Table 2). Damage is modelled as % stiffness loss at selected beam elements. The location given in the table corresponds to the central part of the damage in the affected beams (in m from the first support), which extends 1.5 m at both sides. All damages have a total width as specified in Table 2 and a total length of 3 m with the maximum % stiffness loss taking place along the meter in the middle of the affected length and then, decreasing gradually until becoming zero. The percental values in Table 2 are calculated with respect to the stiffness (modulus of elasticity multiplied by second moment of area) of the entire cross-section.

Table 2. Test data

Test	Vehicle		road	Damage scenario (L = 20 m)			
No.	Speed m/s	truck type		location m	width m	stiffness-loss percentage	lane*
1	20	A	2	3L/4	5	8.0%	2
2	30	B	3	Healthy			
3	30	A**	1	L/4	5	6.0%	2
4	20	B **	2	Healthy			
5	20	A	1	5L/8	5	8.0%	1
6	30	B	1	L/8	5	12.1%	1
7	30	A	1	L/2	5	10.0%	2
8	20	B	1	L/2	5	6.0%	2
9	20	A	1	3L/8	5	12.1%	1
10	30	B	1	2L/3	10	16%	1-2
11	22.5	A	1	L/3	10	20.1%	1-2
12	27.5	B	1	L/3	5	10.0%	1
13	30	A	1	5L/8	5	8.0%	2
14	20	B	1	5L/8	10	16.0%	1-2
15	20	A	1	L/3,3L/4	10,5	11.9%,12.1%	1-2,1
16	30	B	1	3L/8,2L/3	10,5	24.2%,8%	1-2,2

* While lane 1 corresponds to the half of the bridge where the vehicle is travelling, lane 2 corresponds to the opposite half. Lane 1-2 corresponds to the full width of the bridge.
** Twice the value of suspension stiffness given in Table 1.

It is important to keep in mind that variations in the test data with respect to calibration data can be attributed not only to damage but also to one or a combination of the following sources: (i) location and severity of damage, (ii) change in road roughness, (iii) change in vehicle dynamic properties, (iv) change in vehicle gross mass, and (v) change in vehicle speed. Other than these causes of change, parameters of the VBI model remain the same as in calibration runs. All road profiles have a 'very good' road class, but those labelled with different numbers correspond to different amplitude and distribution of the road irregularities. Calibration data has been obtained with the road labelled '1' in Table 2. Road labels '2' and '3' correspond to geometric spatial means of $2\text{x}10^{-6}$ and $8\text{x}10^{-6}$ m^3/cycle respectively. The parameters in Table 2 remain hidden to the contributors, except for those algorithms requiring speed and GVW to operate. The latter could be obtained on site, i.e., via a Pavement-based WIM (P-WIM) system or nothing-on-the-road B-WIM system.

3 DESCRIPTION OF ALGORITHMS

3.1 *Using vibration parameters*

The damage identification method proposed in this section is based on the logical utilization of vibration data to obtain parameters that can discern structural changes without prior knowledge of structural properties. The use of vibration parameters as damage sensitive features provides an alternative to standard modal-based damage sensitive features which can suffer under changing environmental and operational conditions and are generally further limited in accuracy when applied to short non-stationary signals, such as those assessed herein, as their methodology assumes linear structural behaviour and signal stationarity (Moughty & Casas, 2017a). A number of vibration parameters have been shown to demonstrate damage sensitivity when assessed under ambient conditions (Mougty & Casas, 2017b), such as Cumulative Absolute Velocity, i.e., the summed integral of all absolute acceleration values of the response history, generally used to determine site specific earthquake energy.

$$CAV = \int_0^t |\ddot{x}(t)|dt \tag{1}$$

Destructive Potential Factor is another earthquake energy based feature that also accounts for frequency characteristics by including the variable ν_0 - number of zero crossings per unit of time.

$$P_D = \frac{\frac{\pi}{2g}.\int_0^\infty \ddot{x}(t)^2\ dt}{{\nu_0}^2} \tag{2}$$

Vibration Intensity is also a vibration energy based feature, but utilizes a Fourier based frequency.

$$I = \frac{\int_0^t |\ddot{x}(t)|dt}{f} \tag{3}$$

All of the above vibration parameters utilize energy, while two also incorporated a frequency denominator, the premise of which is that given constant conditions and loading, a structure will exhibit an increase in vibration energy when damaged and a reduction in vibration frequency, resulting in a synergistic damage detection relationship. The application of the aforementioned vibration parameters to the current case study first requires some regression procedures to establish the various ancillary varia-

bles in the 16 test runs such as vehicle velocity, weight and road profile. Beginning with *vehicle velocity*, one can take advantage of the three sensors located along the vehicle path to obtain the times of impact of the front wheel through the use of a high pass filter that is sufficiently designed to suppress all structural and vehicle dynamic behavioral frequency signatures (> 200 Hz), leaving only high frequency noise and impacts at sensor locations, as Figure 2 demonstrates for a 20 m/s case, with first wheel impact times labeled.

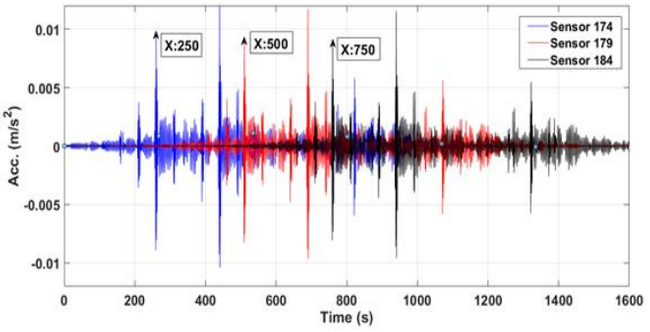

Figure 2. First wheel impact times for sensors along vehicle path (20 m/s case).

Vehicle weight is assumed to be either 25 tonnes or 40 tonnes and classification is conducted using Peak Ground Displacement Values. Road profile condition is determined by isolating the frequency content associated with the vehicle/road profile interaction in the three sensors along the vehicle path by obtaining their Cross Spectral Density (CSD) and comparing it to the CSD for the three sensors on the opposite side of the bridge where the vehicle/road profile interaction is less evident. Figure 3 presents the CSD comparison for a 20 m/s vehicle velocity case, where it can be seen that a distinct deviation in frequency content exists above 40 Hz, indicating that the vehicle/road profile induced vibration for the 20 m/s cases is predominantly associated with, but not limited to, frequencies > 40 Hz. The same can be said of frequencies > 60 Hz for vehicle velocity of 30 m/s. A change in road profile can be assessed by comparing the CAV of the filtered data of the calibration case and test case.

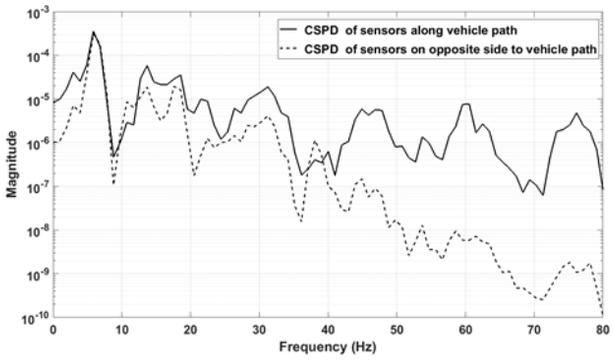

Figure 3. CSD of sensors along vehicle path and opposite side of bridge (20 m/s case).

Once all ancillary variables have been established in all test cases, the presence of damage can be assessed by first normalizing the calibration vibration parameters before obtaining the percentage difference at each sensor location for each test case. This will provide an estimate of both damage presence and location. The determination of stiffness loss is not feasible through energy based parameters, however the degree of damage severity can be determined in a relative sense, i.e. from no damage to greatest damage.

3.2 *Using a Bayesian belief network*

A BBN approach is proposed for condition monitoring and fault detection of bridges. In fact, the adoption of BBN for SHM purpose is limited. However, a BBN-based approach can provide an assessment of the bridge health state every time when new evidence of the bridge behavior becomes available, and consequently the health state of the bridge can be monitored continuously by taking account of all kind of uncertainties, which are not accounted for by FE model updating and machine learning methods. Conversely, BBN are able to manage different sources of uncertainties, such as incomplete knowledge of the actual health state of the bridge (i.e. epistemic uncertainties) and such as the degradation mechanism of the bridge, which is initiated at unknown time (i.e. aleatory uncertainties). At the same time, interdependencies between different bridge elements can be evaluated by a BBN approach (Franchin et al. 2016, Vagnoli et al. 2017).

A BBN method is developed by defining two parts: i) a graphical visualization part, which is composed of nodes and arcs; ii) a quantitative part, which is composed of Conditional Probabilities Tables (CPT). The nodes represent the elements of the bridge of which the bridge manager would like to monitor the health state, whereas the arcs are directed links between different nodes and they represent the influence of the parent node (i.e. the node from which the arc departs) on the health state of its child (the node to which the arc is directed) (Vileiniskis et al. 2016). It is worth noting that the accuracy of a BBN approach strongly depends on the definition of the CPTs, which quantify the conditional probabilistic relationship between connected nodes, i.e., the influences between different elements of the bridge.

A reliable BBN is developed by performing a detailed analysis of the bridge structure, in order to describe the bridge elements of interest, the measurement system on the bridge, and the possible influences between different bridge elements. Therefore, the BBN approach aims to monitor continuously the health state of the bridge during a long period of time, rather than in a short period. Indeed, the CPTs, which can be defined initially by using historical datasets, visual inspection reports, simulation of

an FE model of the bridge under study or relying on expert judgement, can be updated every time when new evidence of the bridge behaviour is available. Finally, it should be noted that the BBN can assess the health state of the whole bridge, by monitoring the health state of its elements, and, at the same time, assess the health state of each bridge element by monitoring the health state of the whole bridge (Siraj et al. 2015).

The BBN of the beam-and-slab bridge is developed by assuming that each beam of the bridge can be divided into five smaller elements of 4 m length. For example, Figure 4 shows only the BBN part for the beams of the bridge at 4.5 m and 3.5 m for clarity. The five parent nodes (B_*i*_E_*j*, where *I* =1, 2, …, 10, and *j* = 1, 2, …, 5), which are shown within the dashed box, represent the five elements of each beam. The health state of each beam element is influenced by the condition of its neighbour elements, as shown by the B_*i*_E_*j*_1 nodes within the dotted box in Figure 4. In a similar way, the health state of a beam is influenced by the health state of its 5 smaller elements (Beam_*i* nodes), and the health state of the neighbour beams, as shown by the beam_*i*_1 nodes in Figure 4. Finally the health state of the whole bridge is assessed by considering the health state of each beam and their smaller elements.

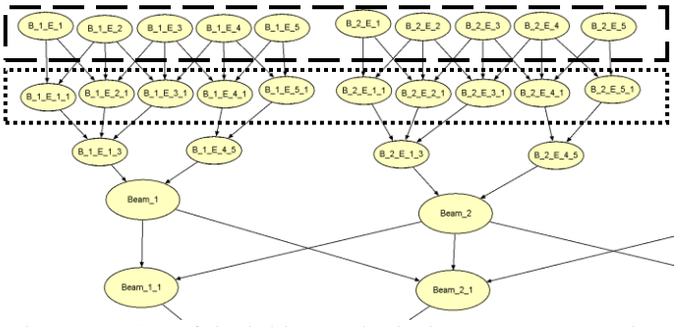

Figure 4. BBN of the bridge. Only the beams at 4.5 m and 3.5 m of the bridge are shown for clarity.

The CPTs of the BBN are evaluated by defining three possible health states for each node, and developing an expert elicitation process, due to the fact that datasets and information about the bridge behaviour are not available. If measurements of the bridge behaviour, historical datasets and visual inspection reports were available, the CPTs would have been defined by merging these different sources of information, and a more reliable BBN would be developed. The BBN monitors the health state of the bridge by providing a probability for each health state of each bridge element, and thus of the whole bridge. Indeed, when new evidence of the bridge behaviour is provided by the measurement system, it is compared with the reference behaviour of the bridge, i.e. the behaviour of the healthy bridge, and then the health state of the parent nodes is updated accordingly. Simultaneously, the updated state of the root parent nodes is propagated through the BBN, and the health state of each longitudinal beam, and of the whole bridge, is updated. In this way, the health state of the bridge is monitored by observing the evolution of the probabilities of the bridge health state over time, and the causes of the changes of the bridge health state are identified.

3.3 *Using Rotations for Bridge Weigh-in-Motion*

It is well known that the change in rotation between two points along the length of a bridge structure is equal to the area under that part of the curvature diagram, i.e., the area under the *M/EI* diagram where *M* is moment and *EI* is flexural stiffness. Hence any reduction in flexural stiffness due to damage should result in an increase in the area under the curvature diagram. This area can be measured using inclinometers installed on the bridge.

Broadly speaking, damage can be identified by an increase in rotation. However, rather than looking directly at rotation values, which are influenced by the applied load or moment, the method proposes to process those rotation values with a B-WIM algorithm to estimate the weight of each passing vehicle. B-WIM is a system that uses the response of a structure under a traversing vehicle to back-calculate its axle weights. The algorithm is based on the bridge's influence line. During installation, the influence line of the structure is obtained by back-calculating the influence ordinates from the response to a vehicle of known weights and axle configuration using a process described by OBrien et al (2006). If damage had occurred, it is expected that the B-WIM algorithm will suggest an increase in the predicted weights.

A P-WIM system can be installed at the bridge site to determine the actual weights of vehicles crossing the bridge. Then the ratio of GVW predicted by P-WIM and B-WIM systems will be used as damage indicator. This approach is similar to that proposed by Cantero & González (2014), except that the B-WIM system used in their study is based on strain measurements, which is sensitive only to damage near the vicinity of the sensors, and as result, it is only applicable to structurally indeterminate bridges (i.e., integral bridges). As rotations are affected by stiffness at points remote from the sensors, the concept proposed here is also applicable to determinate bridges.

The influence lines of rotation are calculated at each sensor location using responses due to a 5-axle calibration truck (Section 2.2). Figure 5 shows a typical rotation time history. The response of the bridge consists of dynamic and static components. Moving average filtering is applied on the raw data to smooth out the dynamic response. Figure 5 shows the raw data (in solid blue line) for a sensor placed at the left-hand support, on the south side of the bridge, 2.5 m away from the bridge centerline in the transverse direction (sensor coordinates: (0,2.5)). The filtered rotation data is shown in red. The dashed black

curve represents the predicted static response of the bridge, obtained as a linear combination of the influence line and the axle weights. It can be seen that the static response due to the estimated weights fit the 'measurements' with a high degree of accuracy. The contributions of the individual axles are shown in dashed pink lines.

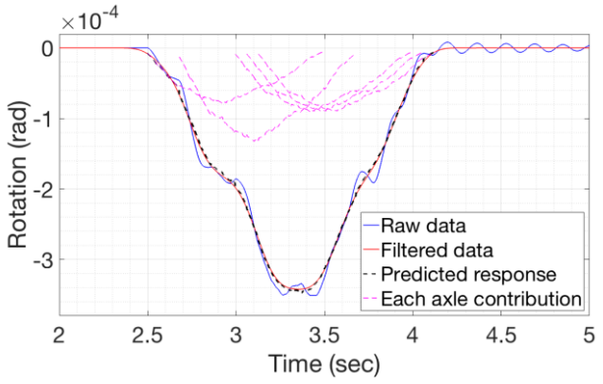

Figure 5. Recorded and predicted rotation time histories for calibration run with truck A travelling at 20 m/s.

Table 3 gives the calculated changes in GVW found using the rotation data recorded at each sensor location for four calibration runs. It can be seen that the proposed method accurately calculates the GVW with no more than 0.7% variation.

Table 3. % change in predicted GVW for the calibration runs.

Run No	(Actual – Predicted)/Actual GVW (%)					
	Sensor coordinates: x(m),y(m)					
	0,-2.5	20,-2.5	0,-0.5	20,-0.5	0,2.5	20,2.5
1	0.3	0.2	0.3	0.2	0.3	0.2
2	0.2	0.2	0.2	0.2	0.3	0.2
3	0.0	0.0	0.0	0.3	0.2	0.5
4	0.6	0.6	0.6	0.7	0.6	0.7

Table 4 gives the changes in inferred GVW for the 16 blind test response histories. Test nos. 5-10 and 13-16, indicated in bold text in Table 4, are damaged test scenarios according to the algorithm. The damaged location is identified by analyzing the magnitude of change in GVW obtained from each sensor. It was found out that sensors placed closer to a damage location are more sensitive to detect damage than the sensors placed further away. Further analyses were carried out where it was concluded that variations in GVW for test nos. 1-4 and 11-12 are either due to the change in road profile or vehicle dynamic properties.

3.4 *Using curvatures from vehicle deflections*

Flexural stiffness or curvature (2nd derivative of deflection) is increasing in popularity for damage detection and location purposes (Catbas et al. 2008). Curvature can be calculated by the ratio of bending moment to stiffness or by the second derivative of deflection measurements.

Table 4. % change in predicted GVW for the blind test runs.

Test No	(Actual – Predicted)/Actual GVW (%)					
	Sensor coordinates: x(m),y(m)					
	0,-2.5	20,-2.5	0,-0.5	20,-0.5	0,2.5	20,2.5

OBrien et al (2017) use Instantaneous Curvature (*IC*) to locate damage in noisy conditions. In this paper, *IC* is calculated from the relative deflections obtained by subtracting the deflection under the tyre contact point and the displacement of the point of the wheel just above the tyre measured from a stiff bar representing an axle of the vehicle model defined in Section 2.2. Damage is estimated using both the healthy (i.e., calibration) and the potentially damaged (i.e., test) signal using curvatures. The inputs to the algorithm in this paper are vehicle displacements. In practise, a TSD is a vehicle that could be used to take vertical velocity readings on pavements that would facilitate to determine their deflection (Rasmussen et al. 2002). However, the application of TSD for damage detection on bridges is still at an early stage of development.

IC is based on deflection measured at three locations on the bridge at any given time. For the vehicle under investigation, data under each axle of the vehicle can have unequal distances between axles. The central difference method is used to estimate curvature (Singh & Bhadauria 2009). In ideal circumstances, *IC* is calculated using absolute deflections relative to a global reference. A more realistic alternative is to measure the relative deflections of the bridge relative to the vehicle. *IC* is dependent on the position *x* of the vehicle on the bridge and the time *t*. These parameters are related through the velocity of the vehicle. Traditional definition of curvature considers calculation at a time instant and *IC* was prepared according to this procedure. In order to locate damage in this test, the absolute value of the difference in *IC* between the healthy and the damaged cases denoted by *AD* is used:

$$AD = |IC_{Dam} - IC_{Hea}| \quad (4)$$

where IC_{Dam} = damaged instantaneous curvature; and IC_{Hea} = corresponding healthy curvature. A val-

ue of *AD* higher than $1x10^{-6}$ is a clear indicative of damage as shown by Figure 6.

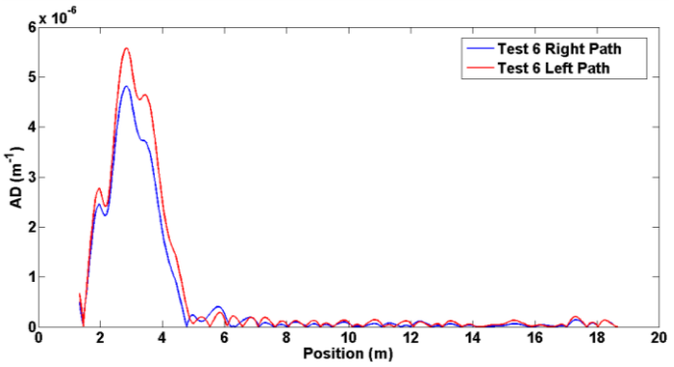

Figure 6. *AD* results for test no. 6 (Table 2).

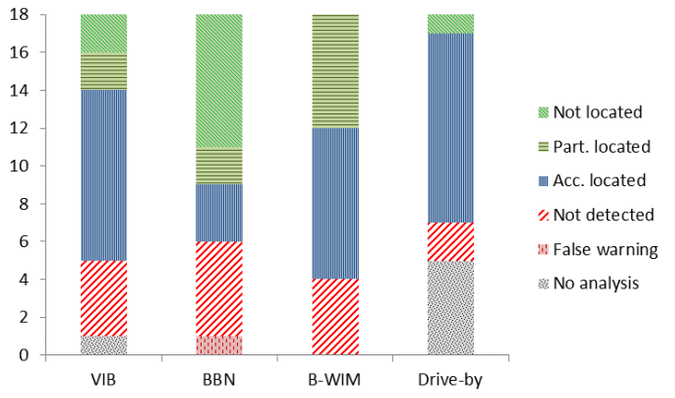

Figure 7. Comparison of performance by each algorithm.

Damage can easily be located around 3 m from the left support in this figure. The magnitude of *AD* provides information about how close is the damage to the wheel path and the intensity of the damage. *AD* can oscillate between 10^{-7} to 10^{-4}, but damage detection cannot be guaranteed if values are too low.

4 TESTING

Generally speaking, all algorithms achieve location of damage along the longitudinal direction *x*, while VIB, BBN and B-WIM -based methods try to locate damage transversally too. Therefore, they meet requirements for level II damage detection techniques that are able not only to stablish if damage has occurred, but to also simultaneously determine the location of damage. Figure 7 shows the outcomes of the algorithms classified into the following categories: damaged being 'not located', 'partially detected', 'accurately detected', 'not detected', 'false warning' (or misidentified), and 'no analysis'. The latter category addresses those instances in which an algorithm cannot evaluate the data due to changes in road roughness, vehicle properties or speed that do not match the conditions in the calibration run. 'False warning' refers to the case when the bridge is deemed to be damaged when, in reality, changes in the response are due to causes other than damage. 'Not detected' are situations when damage goes unnoticed to the algorithm. The first three categories in the legend of Figure 7 refer to tests in which it is successfully established that damage has occurred but: (i) the location of the identified damage differs completely from the actual location damage ('Not located'), (ii) the proposed range of damage intersects partially with the actual damage or it is significantly wider, thus including several non-damaged elements ('Part. located'), and (iii) damage is located within 1 m of its true position ('Acc. located'). In Figure 7, location refers always and exclusively to the longitudinal position of the damage along the bridge. It must be noted that a total of 18 instances are identified in the figure, since both test nos. 15 and 16 (Table 2) include two damage locations.

VIB locates damage both longitudinal and transversally with high rate of success. It can be seen from Figure 7 that damage is detected longitudinally in 13 of 18 cases (72%). Among those 13 cases, damage is partially or accurately located 85% of times. In contrast to other algorithms, identification of the half of the bridge affected by damage is always successful. On the downside, in the case of multiple damages, the algorithm is only able to detect one of them.

The BBN stablishes prior probabilities of damage using the four calibration runs and then, following an analysis of the variation of those probabilities, evaluates whether damage has occurred in the bridge or not. The BBN is able to analyze all the proposed tests (damage detected in 12 of 18 cases, i.e., 67% success); however, successful location of the damage is scarce. The algorithm tends to place the damage in the central elements of the bridge, which may indicate that, while it is capable of detecting damage, it has more difficulties on locating it. Nonetheless, one strength of this method is its probabilistic approach towards the solution, which could allow for further improvements if a larger calibration sample was available for defining CPTs.

The B-WIM algorithm is able to detect damage both transversally and longitudinally, although it sometimes identifies as damage a wider area than in reality. In addition, when damage affects all the width of the bridge, the method tends to concentrate the damage exclusively on the half of the bridge opposite to the vehicle path. Nonetheless, as shown in Figure 7, the algorithm shows a 78% rate of success, with 14 out of 18 cases where damage is accurately or partially located.

Drive-by detects damage in 11 cases (61%). This is somewhat expected as there are 5 test scenarios (nos. 1, 2, 4, 11 and 12) where the algorithm is unable to analyze and assess the data. However, damage is accurately predicted in 77% of those 11 cases where an analysis is feasible. It must be highlighted that when damage is located on the vehicle path, the algorithm is always able to accurately locate it. The cases where the algorithm is not able to detect damage correspond to the damage being located on the

other side of the bridge (i.e., test no. 8). However, if this damage was large enough (test no. 7), the method is still able to warn of the presence of the damage. Location of damage is however limited to its longitudinal position due to the conditions of the test. In this regard, it is necessary to note that the other three algorithms based on sensors placed on the bridge are provided with data concerning several transversal locations across the deck section, while the drive-by algorithm only uses data from the vehicle driving along a fixed path in one half of the bridge. If the vehicle was driven in the other half of the bridge, there could be potential for the drive-by system to also estimate the transverse location of damage.

5 CONCLUSIONS

This paper has presented four novel damage detection algorithms, developed within the Marie Skłodowska-Curie TRUSS ITN, which can be used either for SHM or routine bridge inspections. Given that accelerometers are relatively common, economical and easy to install, accelerations have been used as input to two algorithms. An alternative algorithm has used bridge rotations that can be obtained via inclinometers. Unlike strain sensors, which are mainly attached at bridge midspan, inclinometers can be installed on the soffit of the deck at abutment locations without bridge or lane closures. Ultimately, drive-by does not require placing any sensor in the bridge at all. However, a hi-tech instrumented vehicle must be used in order to obtain the curvature of the road surface through vertical velocity readings with sufficiently high resolution.

Overall, the B-WIM algorithm has appeared to be the most successful in establishing if damage has occurred (14 damages); followed by VIB (13), BBN (12) and drive-by (11). B-WIM has also been able to locate those identified 14 damages (i.e., adding predictions labelled partially and accurately), while VBI (11 located) and drive-by (10 located) show a slightly smaller rate of success. There have been aspects where B-WIM is outperformed by other algorithms, i.e., VIB has given the best performance in providing the transverse location of damage. In addition, the longitudinal range of damage predicted by B-WIM has often been on the safe side. Interestingly enough, drive-by has provided the best results in precisely locating the longitudinal position of damage, i.e., 10 times compared to 9 and 8 times using VIB and B-WIM respectively.

ABSTRACT: The functional safety of steel bridges is of great importance for governments and infrastructure managers. This functionality is, however, affected by natural aging and environmental threads such as corrosion. Corrosion can play major role in steel bridge failure; mainly by reducing the thickness of bridge girders or by forming pits on the steel surface which consequently affects the structural integrity of the bridge. In this study, an innovative technique for representation of corrosion has been used when applying a multi-failure reliability analysis method. To this aim, the distribution of corrosion pits is modelled by a 2D random field and then, the generated surface is incorporated with a Monte-Carlo reliability analysis method to predict the service life of in-service steel bridge girders.

Keywords: Steel bridge, random field, non-linear corrosion, serviceability prediction, Monte-Carlo simulation

1 INTRODUCTION

Bridges are among the most important transportation infrastructures which play an important role in transporting people and goods worldwide. Reliability of in-service bridges dropped over years, affected by external factors such as corrosion and loading. The combination of corrosion and loading can cause failure of bridges which costs millions of dollars for asset owners. According to a report by NACE [2], corrosion cost of highway bridges to US economy has been estimated at $8.3 billion, which forms 37% of overall corrosion costs to US infrastructures. These costs can be reduced by implementing a proper maintenance strategy that is based upon the results of an accurate reliability analysis.

Most of the determining factors in a reliability analysis, such as corrosion factors, load parameters, mechanical properties, etc., show high degrees of randomness which needs to be addressed in accordance. Such randomness limits applicability of deterministic methods for reliability assessment of structures. The issue indicates the necessity of applying the probabilistic methods when running a reliability analysis. Throughout the literature, service life prediction of corrosion affected steel bridges has been done by considering the impact of cross-section loss due to corrosion on overall operation of the bridge. Sharifi and Paik [3] studied the effect of corrosion on ultimate strength of steel girders. The corrosion loss was modelled using power-law formula and First Order Reliability Method (FORM) was employed to evaluate the reliability analysis of a steel-box girder over time. The study showed that, simultaneous impact of dead-load, live-load and corrosion cause a drastic reduction in safety and reliability of steel bridge girders. This approach, except for the reliability analysis method and also the selected limit-states, has been widely used by other researchers [4-6] for the structural assessment and service-life prediction of steel and reinforced concrete bridges and buried pipelines. The researches, however, fell short in accurate representation of the geometrical characteristics of corrosion, where the authors ignored the spatial variability of corrosion over the steel surface.

It has been proved that, considering the spatial variations of corrosion instead of its uniform representation can highly affect the result of a reliability analysis [7,8]. Random field theory, has been demonstrated to be able to model a corroded surface considering its correlation structure. This method has been successfully used for modelling spatial distribution of pits in reinforced concrete bridges [7], in cast-iron pipeline corrosion modelling [8] and also in naval engineering for modelling corrosion in ship's hull [9].

The first step in implementation of a reliability analysis is to select proper limit-states which represent the common failure modes in the studied infra-

structure. Several failure modes are suggested to be examined when studying reliability of steel bridge girders, among them the deflection, shear and flexural failure are of greater importance [1,5]. In regards with the reliability analysis methods, Since FORM and Second Order Reliability Method (SORM) methods require linearization of limit-state functions and also are unable to deal with lognormal random variables, Monte-Carlo simulation can be a good alternative. This method is, however, computationally demanding even for today's computers.

Once the reliability assessment technique has been determined, engineers are often encountered with the task of identifying the component that has the most effect on the system's overall performance. I shape steel girders of utmost importance when studying the reliability of steel bridges, since many catastrophic bridge failures were reported to be subjected to failure of these components [10,11]. In this research, corrosion depth on a steel bridge girder is modelled by 2D random field that is discretised based on Karhunen–Loève (K-L) series expansion. A Monte-Carlo simulation is then used for evaluation of three limit-states (flexural, shear and deflection) and also for generation of random fields and random variables. The final goal is to find the service life of an in-service corrosion affected girder as the critical component of the steel bridge. A parametric sensitivity analysis is also performed to compare the importance of involved parameters in service-life prediction of the steel girder.

2 PROBLEM FORMULATION

Corrosion of steel girders is a time-variant process. The power law formula (Equation (1)) can be used for measuring corrosion depth over time in which the constants 'a' and 'b' are obtained from regression analysis of inspection data. In this paper, corrosion factors (i.e., a and b in Equation (1)) are selected based on assumption.

$$\Delta = at^b \tag{1}$$

As discussed in the introduction section, deflection, shear and flexural are the critical failure modes Therefore, the limit-states for deflection, shear and flexure are selected to be evaluated in this study. A limit state is a condition of a structure beyond which the relevant design criteria is violated. The following equation shows the general form of the limit state for a structure subject to a time-variant deteriorating process such as corrosion:

$$G(R,S,t) = R(t) - S(t) \tag{2}$$

In equation 2, $G(R,S,t)$ is a limit state function, $S(t)$ is the stress affecting the limit state requirement at time t, and $R(t)$ is the resistance of the structure at time t. When the stress becomes greater than the resistance of the structure, the failure occurs. The failure criteria are selected so that; deflection failure occurs when the deflection at the middle of the span excesses the allowable deflection. Moreover, flexural failure occurs if the flexural moment becomes more than the flexural resistance. As for the shear failure, shear force excesses the shear resistance of the steel section. Formulations of the stresses and resistances can be found in Table 1.

Limit states	Stress	Resistance
Flexural	M_S	$M_\sigma = f_y Z_P$
Shear	τ_S	$\tau_R = 0.6 f_y A_P$
Deflection	$\Delta_S = \frac{P\left(l^3 + l/2 - 6.5\right) \times \left(3l^2 - l^2/4 - 42.25 + 6.5l\right)}{48EI}$	Δ_R

Table 1. Stress and resistance formulations for the three failure modes [1].

The combined effect of the aforementioned failure modes is also considered as a system failure, which is obtained by considering the failure modes as the serviceability failure modes and by applying the following formulation, in which P_{f1}, P_{f2} and P_{f3} are probabilities of deflection, flexural and shear failure respectively:

$$P_f(t) = 1 - \left[\left(1 - P_{f1}P_{f2}P_{f3}\right)\right] \tag{3}$$

To deal with uncertainty associated with the random parameters involved in this research, a Monte-Carlo Simulation is used. The Monte-Carlo method uses random sampling for simulating a large number of experiments. In this method value of each random variable (x) and also the generated random fields for each time step are selected and then the limit state function (G (x)) is evaluated. Failure is defined so that the limit state function is violated (i.e. for the negative values of G (x)). This process is repeated continuously; dividing the number of failures by the total number of iteration, *N*, obtains the estimated probability of failure:

$$P_f \sim \frac{1}{N}\sum_{j=1}^{N} I'\left(G(x_j) < 0\right) \tag{4}$$

In equation 4, *I'* is 1 if $G(x_j) < 0$ or is 0 if $G(x_j) \geq 0$ and $j = 1 \ldots, N$ is the indicator of samples. The generated sample size is a determining fac-

tor in the accuracy of the Monte Carlo Simulation. The smaller probability of failures requires larger sample size to obtain an accurate simulation result.

The geometry of a corroded surface can be modelled mathematically using random field theory. Based on K-L expansion method, a random field $X(x)$, can be represented with a sequence of uncorrelated random variables $\xi_i,\ i, r_o \in \mathbb{N}$ [12]

$$\hat{X}(x) = \mu(x) + \sum_{i=1}^{r} \sqrt{\lambda_i}\xi_i\phi_i(x). \quad (5)$$

Where $\mu(x)$ is mean function, r_0 is number of terms in the series with largest eigenvalues, ξ is a set of uncorrelated standard normal random variables and, λ and $\phi(x)$ are eigenvalues and eigenfunctions of covariance kernel. The correlation between random variables of the random field is captured using the autocorrelation function which is a function of the distance between points in the domain and the correlation length. In this research, a typical exponential squared autocorrelation function has been used.

3 WORKED EXAMPLE

In this paper, a 20m span of a typical railway steel bridge with concrete filled deck, has been selected as a worked example. Each span is consisted of five steel girders with yield strength of 250 MPA, and dimensions as described in Figure 1 and Table 2. It has been assumed that, the girder is under the effect of both dead load and live load. The load due to the weight of concrete deck, overhead structure and the weight of steel girder itself are considered as the dead loads. On the other hand, axle loads of trains crossing the bridge is treated as the random live load. To represent the most extreme scenario, two trains are considered to cross the bridge at the same time and the placement of axle forces on the studied girder is chosen so that to create the maximum bending M_S and maximum shear τ_S. The statistical characteristics of the dead and live loads have been listed in table 2.

In the current research, the distribution types of the involved random variables are selected based on assumptions, so that the parameters for which no information is available are considered as normal, and the parameters for which the negative values of mean and coefficient of variation are not physically admissible are chosen Lognormal. In addition, the corrosion depth is presented by random field. Table 2 represents the values of the involved parameters in the failure criteria.

Symbol	Definition	Value	Mean	COV (%)	Distribution
E	Modulus of elasticity of girder, kPa	---	213.74×10^6	1.0	Normal
a	Multiplying constant	---	0.4	0.25	Normal
b	Exponential constant	---	0.5	0.30	Normal
l	Length of span, m	---	20	0.1	Normal
Δ_R	Allowable deflection, m	---	0.031	0.1	Normal

Table 2. Definition, values and type of variables involved in the research

The probability of failure is calculated for each nodes of the discretised random field and the failure is counted as soon as the failure occurs in the first node of the field. The following section provides the results of the analysis.

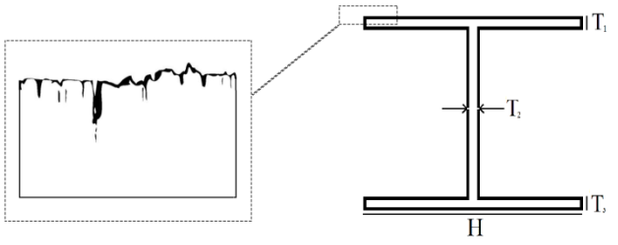

Figure 1. Dimensions of the steel grid; the values of T_1 to T_3 are reduced by equation 1 over time.

RESULTS AND DISCUSSION

Figures 2 to 5 present the results of the proposed methodology with an algorithm developed in MATLAB® R2017a environment. Considering the failure threshold to be 0.002, it can be seen from figure 2 that, the system failure is likely to occur after 90 years, while shear failure, the first failure mode that reaches the threshold, is occurred 10 years later. Flexural and shear failure contribute more to the failure of the girder as a whole. Moreover, the deflection failure is unlikely to occur before 400 years, which shows the importance of consideration of the first two failure mode in design code of steel girders.

To study the impact of steel grade and the corrosion factors on reliability of the girder, a sensitivity analysis has been conducted by changing the values of three parameters; steel grade, multiplying and exponential constants while keeping the rest of variables constant. Results of the sensitivity analysis of steel grade, and the corrosion factors can be found in figures 3 to 5. The figures reveal the significance of the impact of the corrosion exponential constant on overall failure condition of the girder, so that adding one unit to its numerical value can extend the service-life by 400 years (Figure 5). To a lesser extent, the multiplying factor should be taken care of by the analyst, since for the same scenario, the service-life is extended by 90 years. Among all of the studied

parameters in this research, steel grade shows the least impact on the reliability of the steel girder.

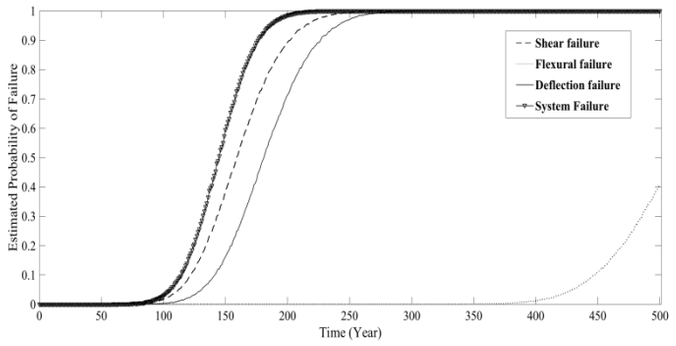

Figure 2. Estimated probability of failure over time for shear, flexural, deflection and system failure.

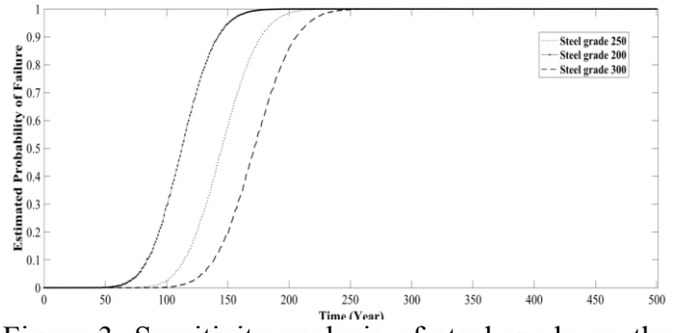

Figure 3. Sensitivity analysis of steel grade on the system probability of failure.

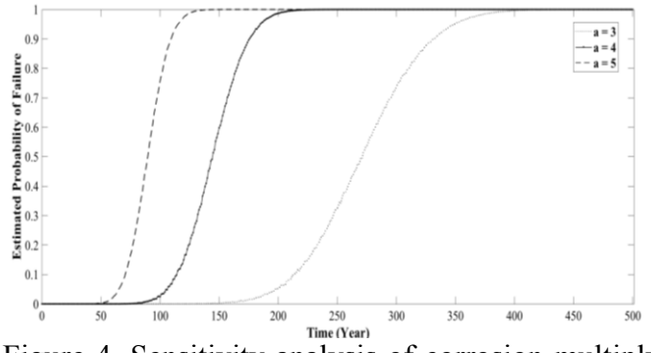

Figure 4. Sensitivity analysis of corrosion multiplying constant on the system probability of failure.

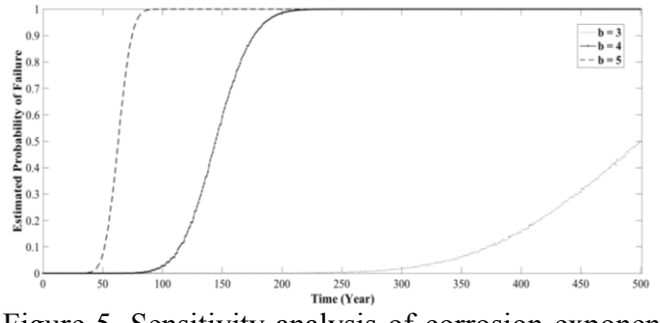

Figure 5. Sensitivity analysis of corrosion exponential constant on the system probability of failure.

Generally speaking, this study shows the importance of random variables on the system failure of steel girders, as well as the significant impact that the corrosion process can have over time. Although the proposed methodology is an applicable service life prediction method, there is still research required to improve it. An issue that needs to be addressed in the future research is that, the method ignored the correlation among limit-states when utilizing equation 3. On the other hand, the method assumed that the correlation structure of the random fields remains constant over time, while, it has been proved that the correlation structure of a corroding surface changes with time [8]. This issue can be solved by developing a time-dependent correlation length model. That, however, requires field data consisted of 3D scanned geometry of a corroding steel girder over time, which is a challenging task to obtain.

CONCLUSION

In this paper, a time-dependent reliability analysis method that considers the spatial variability of corrosion has been applied for service-life prediction of an in-service steel bridge girder. The method incorporated random field theory into an existing time-dependent Monte-Carlo reliability analysis method to make it more realistic yet simplistic. It was shown by a worked example that; the method is applicable on steel bridge elements. A parametric sensitivity analysis also performed to measure the importance of three selected parameters on overall failure of the girders. The results indicated that a greater care should be taken when selecting the values of corrosion factors for a reliability analysis. The proposed methodology enables asset managers to plan more efficient maintenance strategy for the bridge girders. Since maintenance strategies are mainly involved in finding a balance between probability of failure and the cost of reducing the risk, an optimal maintenance strategy can be achieved using the probability of failure estimation from the presented method and determining failure cost by stakeholders.

Corrosion risks: assessment of enclosed spaces, monitoring real bridges

M. W. K. Bowers
Arup, London, United Kingdom

ABSTRACT: Enclosed spaces created by box sections in long (and short) span steel deck bridges are often perceived as high risk spaces for corrosion requiring design mitigation. This risk is often poorly defined and leads to onerous requirements for mitigation and corrosion protection. Anecdotal evidence and prior research suggests the real corrosion risk in such spaces is much less than anticipated.

Accepted practice around the world for long span structures of this type is to use de-humidification systems to control the environment to less than a critical relative humidity. It is assumed these systems offer a life cycle cost benefit compared to painted steelwork which is assumed to require relatively frequent maintenance.

This paper presents results, over eighteen to twenty-four months, the environment within this type of enclosed space (one structure with a de-humidification system and two without) by means of monitoring temperature, relative humidity and surface wetness. Where possible this data was correlated with external weather data to understand how the internal environment reacts to the external conditions.

1 INTRODUCTION

Corrosion in spaces created by long and short span bridge decks and other high volume enclosed spaces in bridges or other structures, is often perceived as a risk requiring design mitigation. The risk is often poorly and conservatively defined leading to onerous requirements for mitigation and corrosion protection.

Anecdotal evidence and prior research experience suggest real corrosion risks and maintenance in such spaces is much less than anticipated. Arup investigated the environments within enclosed bridge spaces and based on this work we now have a better understanding of environmental conditions within enclosed spaces and can recommend appropriate corrosion mitigation.

2 ACCEPTED PRACTICE

2.1 *Long-span structures*

For long-span bridge decks, accepted practice in many parts of the world is to use dehumidification plant to condition the space to a relative humidity (RH) below which corrosion cannot occur. The value of RH can vary but is often relatively low; around 45%. The use of dehumidification adds complexity to the original construction and leaves the bridge owner with additional costs associated with running and maintaining the plant. These costs can be significant and the usual RH limits mean the plant runs for long periods of time to ensure the limit is not exceeded in all parts of a structure.

It is often assumed that dehumidification offers a life cycle cost benefit over painting the steel because of a perceived need to maintain the paint system. It is also assumed that the life to maintenance of paints within decks is comparable to that of external surfaces and that complete repainting is required approximately every 20 years; this is expensive given the very large areas and often difficult with access in confined spaces

2.2 *Short-span structures*

For short span bridges the preferred options for control of corrosion within decks and boxes is the provision of a corrosion allowance (additional thickness

to the steel that can corrode over the life of the structure without affecting integrity) and a paint system. Often the assumed corrosion risk and mitigation is overstated by assuming more severe service environments than occur in practice.

3 STRUCTURES INVESTIGATED

Arup have undertaken research at 3 existing long span structures in the United Kingdom to assess the performance, service environments and corrosion risks within these spaces.

At each structure an initial survey was carried out to understand the overall condition and note any evidence of corrosion, standing water or water ingress.

3.1 *Tay Road bridge*

The Tay Road bridge is a twin box long spanning bridge that has 42 piers with a total length of 2.25 kilometers in Dundee, Scotland. The Tay Bridge has no dehumidification system in the spans.

The internal box sections show no signs of wetting or corrosion at any point along either span, even in the end spans which are more open to the environment. The steel shows no sign of corrosion.

Figure 1. Tay Road Bridge

3.2 *Cleddau Bridge*

The Cleddau Bridge is a single box long spanning bridge that has 5 piers with a total length of 0.8km in Pembroke Dock, Wales. The Cleddau Bridge has no dehumidification system in the spans.

The internal box sections show signs of localized surface corrosion. This localized corrosion is not of structural significance, and is located at areas where there appears to have been water ingress, such as around external vents, service penetrations and bulkheads. There is no evidence of condensation or corrosion from condensation on surfaces.

The bridge has not been fully repainted since it was built in 1975. Areas of localized repainting have occurred where new steel has been added. At the time of inspection, there were plans to work through the bridge to maintain the limited areas of corrosion and coating deterioration.

Figure 2. Cleddau Bridge

3.3 *Humber Bridge*

The Humber Bridge is a single box suspension bridge spanning 2.2km across the Humber, just outside of Kingston upon Hull. The Humber Bridge has a dehumidification system.

During the walkthrough of the bridge deck, locations of standing water were noted around penetrations in the deck. This water is regularly cleaned out and the dehumidification system prevents it becoming surface condensation. No areas of corrosion were observed.

The entry sections to the span are not included in the dehumidification system. Monitoring on this structure included both the dehumidified and open sections of the deck. This allowed a direct comparison of the environments and the conditions achieved by the dehumidification system.

Figure 3. Humber Bridge

4 MONITORING

The study looked to monitor relative humidity (RH), temperature and surface wetness. During the planning of the project there was a discussion as to whether wireless loggers should be used. It was decided that manual retrieval of data was better as it allowed for visual inspection of the spaces at roughly six month intervals.

In each bridge, RH and temperature were monitored for a period of 18 to 24 months starting in 2012. The period originally was to be 12 months to capture all seasons and the perceived wettest times of the year. It became possible to continue the monitoring to capture the spring and autumns seasons twice and therefore giving a more complete data set.

Each structure had 3 or 4 monitoring locations over the complete span, located to take account of possible different environments due to the bridge orientation (N-S or E-W), structural features, or in the case of the Humber Bridge, humid and dehumidified zones.

A photograph of the typical monitoring set up can be found in figure 4.

4.1 *Relative humidity and temperature equipment*

Relative humidity and temperature were logged using a *Testo 174H Mini Data Logger*. These loggers took readings every 30 minutes regardless of condition and had no trigger levels. The time between visits was set by the battery life and number of measurements recordable by the internal logger.

4.2 *Time of wetness equipment*

Time of wetness (ToW) was logged using a *Madge-Tech LF101A Data Logger*. This device activate when moisture is present on the leaf and creates a potential across the dielectric sensor. These loggers had trigger values that were calibrated on various wetness levels to ensure they triggered and began recording when surface wetness was present (+-0.2mV). When placing these loggers around the bridge decks, in general they were placed in locations that appeared to have water ingress or areas of surface corrosion.

4.3 *External conditions*

External weather data, where available was taken from the closest weather station or obtained from the bridge management.

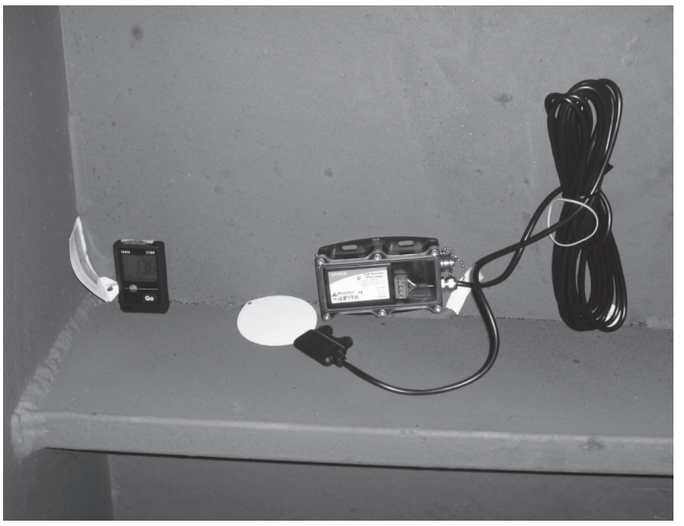

Figure 4. Equipment in place at the Humber Bridge

5 RESULTS OF INTERNAL ENIRONMENT MONITORING

The following is a summary of the results observed on site at the three bridges.

5.1 *Relative Humidity*

The relative humidity levels observed at the bridges is detailed in table 1. Along with the minimum, maximum and mean information from each bridge, the time above various levels of relative humidity are also an important metric when considering corrosion and can be found in table 2.

Table 1. Minimum, maximum, and mean relative humidity at the three bridges.

	Relative Humidity [%]		
Bridge	Min	Max	Mean
Cleddau	36	97.1	74.9
Humber (dehumidified)	13.4	82.2	37.6
Humber (open section)	27.2	94.3	67.7
Tay	30.9	98	75.7

Table 2. Time above 40, 60 and 80% RH in the three bridges.

	Time above RH level [%]		
Bridge	>40%	>60%	>80%
Cleddau	99.2	89	37.8
Humber (dehumidified)	44.7	1.4	0
Humber (open section)	97.8	72.5	19.4
Tay	99.7	93.9	33.9

5.2 *Temperature*

The temperatures observed at the bridges is detailed in table 3.

Table 3. Minimum, maximum, and mean temperature at the three bridges.

	Temperature [°C]		
Bridge	Min	Max	Mean
Cleddau	-1.9	22.9	11.8
Humber (dehumidified)	-4.4	37.7	12
Humber (open section)	-5.5	32.1	11.2
Tay	-2.2	27.8	9.4

5.3 *Surface Wetness*

No periods of wetness were recorded at the locations observed during the project.

6 COMPARISON WITH EXTERNAL DATA

For this paper, it is important to understand the relationships between internal and external conditions of the bridges. Figure 5 and 6 show a comparison of temperature and relative humidity for the month of April 2013 and figures 7 and 8 a single day from the period of May 2013.

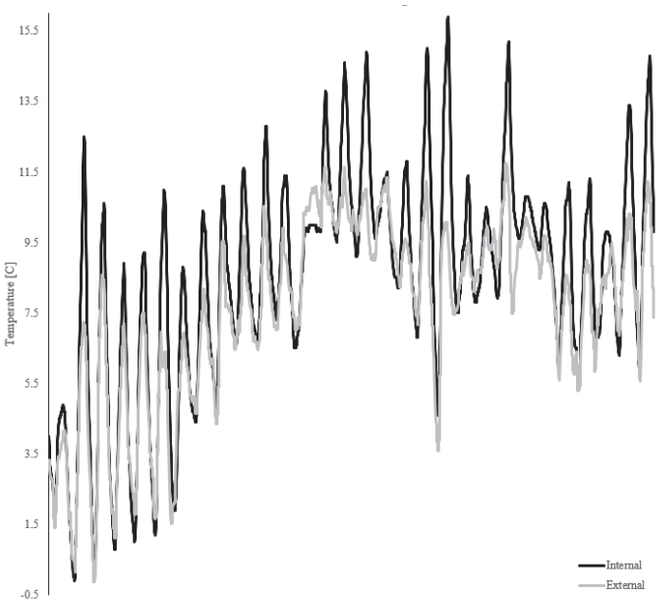

Figure 5. Comparison of internal and external temperature at Cleddau Bridge (April 2013)

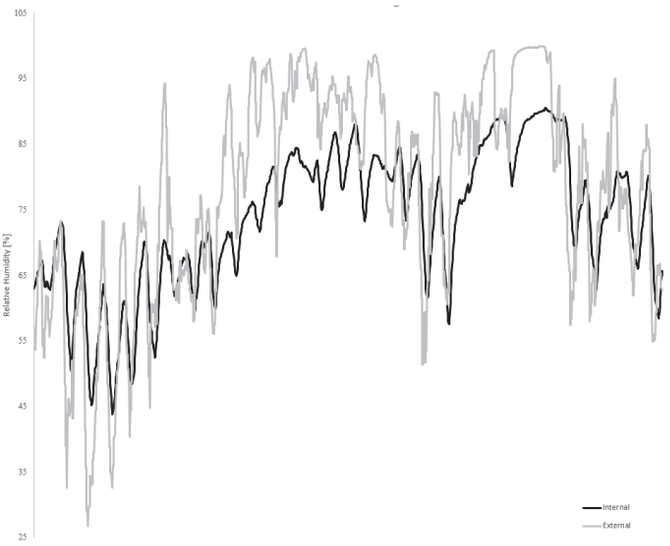

Figure 6. Comparison of internal and external relative humidity at Cleddau Bridge (April 2013)

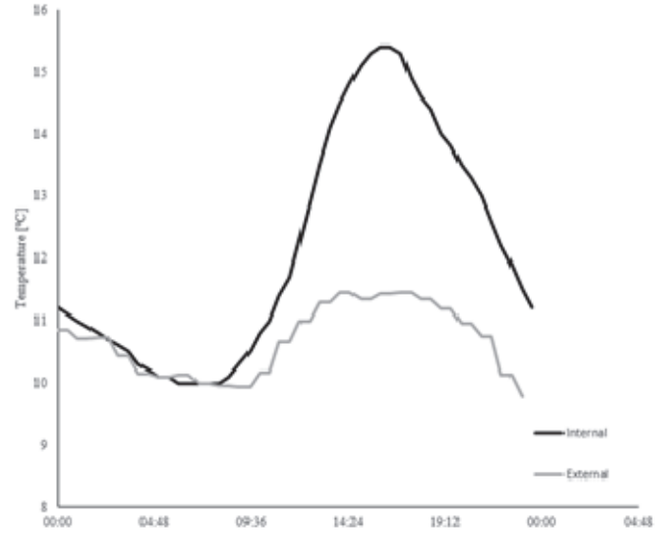

Figure 7. Comparison of internal and external temperature at Cleddau Bridge (5-May-2013)

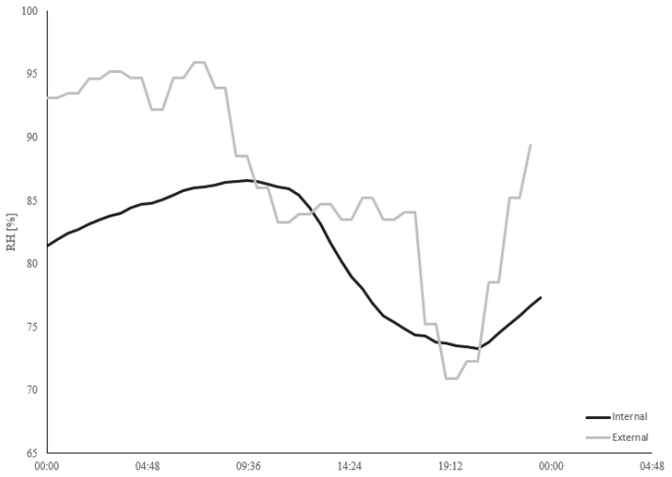

Figure 8. Comparison of internal and external relative humidity at Cleddau Bridge (5-May-2013)

7 DISCUSSION: OBSERVED EVIRONMENT

The inspections of all structures show that corrosion within deck spaces is not a significant risk. Both the Tay and Cleddau Bridges are protected with a primer which has received only partial maintenance during the 40-year service life. This information is consistent with anecdotal, based on the experiences of the current bridge managers. Where corrosion was found in the inspected structures it was at isolated locations and had not resulted in significant loss of section. Corrosion was found where water could pond and often this was associated with ingress through poorly sealed or maintained details such as penetrations into the deck space that allowed water ingress rather than the formation of condensation.

All three structures are typical of modern bridge fabrication, at least in respect of the environments created within the decks. The decks may be 'nominally sealed' and prevent direct ingress of the weather (sun, rain and wind) none were airtight or hermetically sealed. It is assumed that in all cases the bridges could 'breathe' and allow some exchange of air between the internal and external environment.

The observations of low incidence and significance of corrosion was consistent with environmental monitoring. ToW sensors did not record any significant water formation on any surfaces within any of the three structures. It was found that the RH and temperature within the bridge deck changes slowly compared to the external conditions. The relatively slow changes in internal environment with significant lag relative to external changes suggests conditions are close to equilibrium. The risk of condensation within such spaces is low and that the conditions required for condensation are different to those in an external environment, or on the external surface of the structure.

During the monitoring period, there was only one instance, based on the external conditions when condensate could have formed on the internal surface but none was recorded on the ToW sensor. This occurred in November 2013 and indicates that water deposition did not occur, or it did not occur in a location where sensors were present.

It is often assumed the critical RH below which corrosion will not occur is in the range of 40 to 70%; the relatively low RH to cause corrosion is due to the deposition of the air borne pollutants on the surface, particularly chlorides, sulfur dioxide and dust particles. These pollutants are hydroscopic and absorb moisture from the atmosphere at RH values well below saturation. It is clear from this research and previous studies undertaken at the Transport Research Laboratory(TRL)[1][2] that this range of 40 – 70% is likely inappropriate for internal spaces. The critical RH is probably very close to saturation and those conditions occur rarely in closed spaces on bridges in temperate climates. The TRL work and this research is also consistent with other research in related environments such as those found in modern vented cavity wall construction[3][4].

Internal spaces of bridge decks are not exposed to the weather nor wind borne contaminants that could settle on the internal surfaces. This accounts for the high RH required to cause corrosion and why no ToW was measured within the three structures during the monitoring period, even with the RH exceeded the assumed limits.

The absence of pollutants and relatively stable environments within bridge decks and other large volume spaces show that corrosion risks are much lower than often assumed in design. The design assumption is that condensate can form for long periods and that conditions within the structure (in terms of RH and temperature) will be very similar to the external conditions due to a free exchange of air. The monitoring has shown this is not the case. Condensation may and probably does at time form in these spaces, but the frequency and duration of both are low. This results in low ToW (measured in hours per year) and low annual corrosion rates.

8 DISCUSSION: CORROSION RISKS

The internal RH and temperature values (annual mean) allow an estimation of corrosion risk using the method given in *ISO 9223:2012*. To do so requires an estimation of deposition rates of pollutants, sulfur dioxide and chloride. Given these pollutants are essentially wind borne and the internal surfaces of bridge decks are protected from the wind, these deposition rates are likely low. Again, this is consistent with observations regarding time ToW and previous research. Therefore, one can assume a low

deposition rate for both pollutants, of lower bound S and P classes of *ISO 9223:2012.*

The results of the calculation are shown in table 4. The values for corrosion rate would put all the boxes (except the dehumidified Humber box) in the mid-range of the C2 class (corrosion rate 1.3 to 25 microns per year). This being said, the method of calculation has potential errors which are listed as -33% to +50%; allowing for this error, the boxes still fall in the C2 class.

It should be noted that even with a dehumidification system the bridge falls into this C2 category, all be it at the lower end.

The calculation gives the rate for the first year and it is highly likely that the rate over subsequent years would gradually decrease and eventually stabilize after 20 to 25 years.

The calculation has used the data from a single monitoring point which would give the most conservative corrosion rate and not the fully averaged values given in tables 1 and 3.

Table 4. Calculation to ISO 9224 to determine corrosion loss per year from measured conditions.

Bridge	RH [%]	Temp [°C]	Corrosion rate per yr. [microns]	
Cleddau	76.1	10.1	10	(+50% 15)
Humber (dehumidified)	38.7	12.1	3.8	(+50% 5.8)
Humber (open section)	67.7	11.2	8	(+50% 12)
Tay	76.9	9.82	10.1	(+50% 15)

9 DISCUSSION: CORROSION PROTECTION

If the corrosion risk within large volume spaces is low, the risk requires relatively modest measures to mitigate it. The options for protection are:

- Use of a paint specification
- Use of a corrosion allowance
- Use of dehumidification
- A combination approach

9.1 *Paint specifications*

Experience shows that primer only paint specifications provide effective and very long term protection (at least 40 years) with minimum requirements for maintenance of the paint. This performance is understandable given that steel within these spaces is not exposed to damaging UV light from the sun or exposed to long periods of wetness.

Where maintenance has been observed to any coatings in the deck spaces it has been to relatively small areas and has not required a complete removal or replacement of paint on the steel surface.

It follows that a modern paint specification would provide long term protection to internal spaces and would have very low maintenance requirements.

9.2 *Corrosion allowance*

The low risk of corrosion within bridge spaces means that effective protection could be provided with almost a nominal corrosion allowance of, say, 1mm on the section thickness. However, design standards may take a more conservative view. For example, the UK National Annex to *EN 1993-2* suggests, in the best case, a 2mm allowance to be added which could be significant when added to all internal surfaces. The assumption appears to be that condensation (and therefore surface wetness) is a more regular occurrence than is found in practice.

9.3 *Dehumidification*

This research has shown there is little justification for dehumidification of internal bridge spaces in temperate climates. The corrosion risks do not warrant the use of this method and the assumptions on which it has been based look doubtful. The cost argument largely relates to an assumption on the long term performance, and therefore maintenance of paint coatings within the deck space. Those assumptions are directly contradicted by this research and anecdotal evidence from other structures. The assumed RH limit below which corrosion will not occur is also questionable. This research is consistent with the previous research of others and indicates the RH limit is much closer to saturation than the assumed range of 40 – 70%.

9.4 *A combined approach*

Arguably the most effective protection to the internal parts of a structure can be provided by combinations of a paint specification, with an assumed practical life (not life to first maintenance) of 50 years and a nominal corrosion allowance of 1mm. This would assume minor maintenance of the coating but no complete replacement over the life of the structure.

An alternative for longer span structures, that provides a degree of redundancy is the use of a paint specification backed up with a dehumidification system. In this case it would be the recommendation that the trigger value for this system to turn on be set to a value of 90% or higher. This would limit the period for which the plant operated but would provide redundancy if conditions within the structure differed significantly from those assumed. The critical RH could, in the future, be reduced.

10 CONCLUSIONS

This research has shown:

That environments found in long span bridge decks are relatively stable and change much more slowly (with respect to RH and temperature) than the external environments.

That the risk of condensation and long periods of surface wetness in bridge decks is much lower than anticipated.

That corrosion risks within bridge decks and other large volume spaces is much lower than usually assumed in design.

That modest paints specifications (essentially a primer only specification) provide very effective and long term protection within bridge spaces and do not require significant maintenance.

That the use of dehumidification of decks and other large volume spaces is not the preferred option for corrosion control.

The preferred option for corrosion control in decks and other spaces is the use of a primer only paint specification and a nominal corrosion allowance.

ABSTRACT: Corrosion of steel is a worldwide issue which potentially affects structural integrity of bridges. This research presents the results of comprehensive lab tests on the stress effect on corrosion and the combined effect of stress and corrosion on the mechanical properties of steel bridge elements. G250 mild steel specimens, commonly used for bridge construction, are used for analysis. Both stressed and non-stressed specimens are immersed in acid solutions to simulate corrosion progress. The stress effect on corrosion rate (mass loss) is studied. The combined effect of stress and corrosion on mechanical properties is also studied. Hydrogen concentration is monitored for stressed and non-stressed steel during corrosion to find the mechanism of the degradation of mechanical properties. The outcome of this research can help bridge engineers and asset managers to better model corrosion and more accurately assess the structural integrity of corrosion affected steel bridges.

1 INTRODUCTION

Corrosion is a major concern for steel bridge structures. Corrosion can lead to losses of cross sections and reduction of mechanical properties, including yield strength, ultimate strength, and ductility (Garbatov et al. 2014). It reduces service life of bridges and makes the bridges vulnerable to failure (Chen 2007, Li et al. 2017). In most of the cases, bridge steel is simultaneously stressed under loading and is subjected to corrosion (Wang et al. 2014). Therefore, it is vital to model and quantify the corrosion behavior and corrosion impact of steel under stress and corrosion combined environment, in order to optimize maintenance, repair, and rehabilitation of steel bridges.

Stress leads to the decrease of corrosion resistance of steel (Javaherdashti et al. 2006, Ren et al. 2012, Xu & Cheng 2012). In details, Revie (2008) and Li & Cheng (2008) pointed out that passive oxide films are formed before and during corrosion which provides a protective layer for steel against corrosion. The applied stress ruptures the passive oxide films and enhances the dissolution rate at steel surface. In addition, stress also causes deformation on steel surface, which increases the surface energy and makes corrosive solution easier to cover the steel surface (Ren et al. 2012)

The interaction of stress and corrosion also results in the reduction of mechanical properties of steel (Revie 2008, Marcus 2011). On one hand, as mentioned earlier, stress plays a key role in the rupture of the passive oxygen films and the initiation of the micro plastic deformation at grain boundaries. They are directly related to initiation and propagation of stress corrosion cracking (Li & Cheng 2008). On the other hand, hydrogen embrittlement becomes more serious when steel is stressed (Revie 2008, Eggum 2013). This is because stress causes more cracks and voids within steel that favors the diffusion and residence of hydrogen atoms.

Despite the previous researches on the effect of stress on the corrosion rate of steel, the review of the literature highlights the limitations in the current knowledge. To begin with, literature mainly focuses on the acceleration effect of plastic stress on corrosion. However, in most of the real cases, steel is subjected to elastic stress (70% to 80% of the yield strength) under serviceability load, and there is lacking knowledge on the effect of elastic stress on corrosion. Ren et al. (2012) and Wang et al. (2014) indicated that elastic stress attributes to the surface energy increment, which subsequently increases the corrosion rate of steel. However, Xu & Cheng (2012) pointed out that the application of elastic stress has no effect on the corrosion rate of steel. To examine these conflicting views, the current research carries out a comprehensive experiment to investigate the effect of elastic stress on corrosion rate.

Next, as mentioned above, stressed steel is more susceptible to stress corrosion cracking and hydrogen embrittlement than non-stressed steel (Revie

2008, Marcus 2011). It is expected that the reduction of mechanical properties is more significant for stressed steel than non-stressed steel under similar corrosion environment. However, very limited literature compared the level of degradation of mechanical properties between stressed and non-stressed steel. In addition, the combined effect of corrosion and stress on mechanical properties has been studied mainly for pipeline steel, high tensile stress, and stainless steel (Li & Mahmoodian 2013, Mahmoodian & Li 2017a, b), as the case in Cheng (2007) and Liu et al. (2008), there is almost no relevant research focusing on the corrosion of mild steel under the stress and corrosion combined environment. The mild steel, however, has been widely used for bridge construction (Yakel & Azizinamini 2005).

In addition, according to literature, it is reasonable to assume that there are more hydrogen atoms penetrating into steel when steel is stressed at the same corrosion time. Nonetheless, the hydrogen concentration between stressed and non-stressed steel has not been compared at the same corrosion environment in the previous literature.

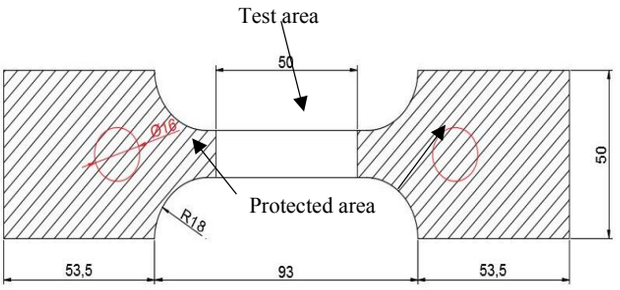
This paper presents a comprehensive experimental program to achieve three objectives: (1) to investigate effect of elastic stress on corrosion of mild steel, (2) to quantify the degradation of mechanical properties under stress and corrosion combined environment, and (3) to measure the increase of hydrogen concentration during corrosion to determine the mechanism of degradation of mechanical properties.

G250 mild steel, a steel used commonly for bridge construction, is used in this study. Simulated corrosion tests are conducted by immersing both stressed and non-stressed steel specimens in acidic solutions. Mass loss and mechanical properties of specimens after each stage of immersion are measured. In addition, hydrogen concentration has been measured for both stressed and non-stressed steel after each stage of corrosion.

2 EXPERIMENTAL SET UP

2.1 *Sample Preparation*

The test specimens were taken from Grade 250 mild steel. This type of steel is commonly used for the construction of bridges and other common steel structures. All the specimens were fabricated according to ASTM E8 (2016), shown in Figure 1. The specimens were wrapped with acid resistant tapes at both ends, so that corrosion only takes place in the tested area (i.e., 50mm gauge length in the middle)



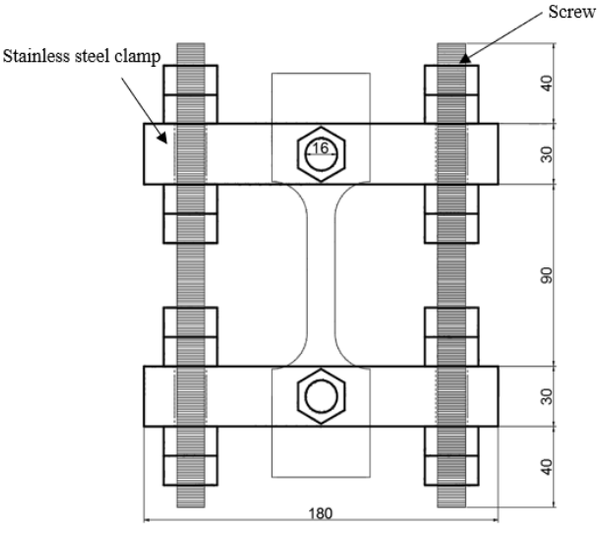


Figure 1. Specimen for tensile test (Units: mm)

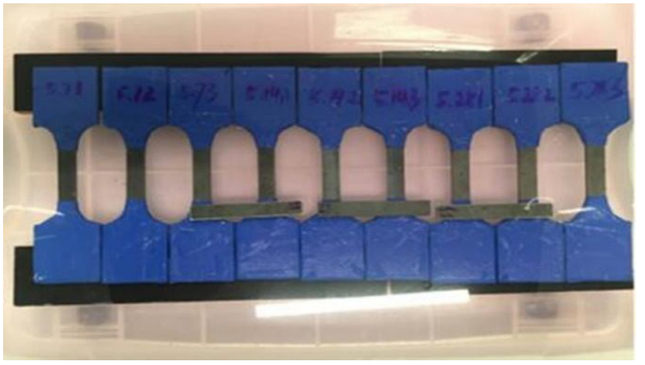
2.2 *Design of stress system*

The steel specimens were stressed up to 70% of yield strength (220Mpa). This percentage was determined based on the ratio between serviceability load and ultimate load referring to AS5100.2 (2017). Specimens were stressed through clamp and jig system designed as Figure 2a. The system is composed of two 1800mm×30mm×26mm grade 904 stainless steel plates and four M16 high tensile steel screws. Specimens were stretched by tensile test machine and then screws were fixed to maintain the stress (Fig. 2b). The clamp and jig systems were wrapped with acid resistant tape and then coated with Vaseline (Fig. 3b). This is to prevent the corrosion of clamp and jig system. In addition, the distance between the stainless-steel clamps was measured constantly during corrosion to control the releasing of stress.

(a) Design of clamp and jig system (Units: mm)

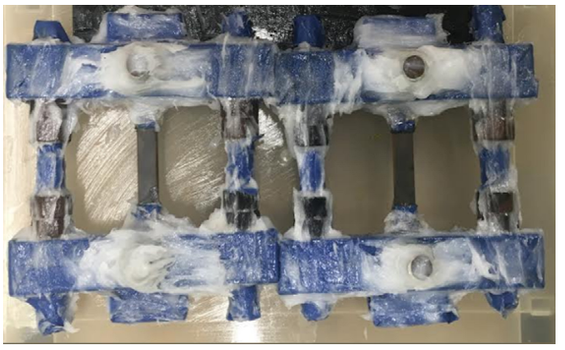
(b) Stress process of the specimen

Figure 2. Details of clamp and jig system



2.3 *Immersion test*

Corrosion simulation was carried out through acid immersion test following ASTM G31-72 (2004). Hydrochloride acid (HCl) was selected as the immersion solution, consistent with the literature (Revie 2008, Eggum 2013). Two HCl solutions at different pHs were chosen for the corrosion simulation, namely HCl with pH=2.5 and HCl with pH=5. In particular, the solution with pH=5 well simulates the natural corrosion of bridge steel according to Liu et al. (2014). The solutions with pH=2.5 were chosen to accelerate corrosion within the given time frame of the project.



The immersion duration was set as 7, 14, and 28 days. For stressed and non-stressed cases, there were 4 specimens for each immersion time, where 3 specimens went through tensile test and 1 specimen was taken for hydrogen concentration measurement. Specimens were weighed before and after corrosion to determine mass loss as an indication of corrosion rate. The test plan is shown in Table 1 and the immersion test set up is shown in Figure 3.

Table 1. Test plan for tensile test and hydrogen measurement test

Solution	Stress (Mpa)	Immersion duration (days)	Number of specimens	
			Tensile test	Hydrogen measurement
Before immersion	0	0	3	1
pH=5	0/220	7	3	1
		14	3	1
		28	3	1
pH=2.5		7	3	1
		14	3	1
		28	3	1

(a) Non-stressed specimen

(b) Stressed specimen ready to immerse in acid

Figure 3. Set up of immersion test

2.4 *Hydrogen measurement*

Hydrogen concentration was measured for stressed and non-stressed steel specimens after each stages of corrosion. Hydrogen concentration tests were performed using Barnacle cell according to ASTM F 1113-87 (2017). The set up for hydrogen measurement is shown in Figure 4. In theory, Barnacle cell takes hydrogen containing steel as the anode, and uses a nickel/nickel oxide electrode as the cathode.

Figure 4. Set up of hydrogen concentration test

For the measurement, steel specimens were exposed to 0.2 Molar sodium hydroxide (NaOH) so-

lutions restored in Teflon cell. Hydrogen gas and atoms within steel reacted within hydroxide (NaOH) solutions and the current of reaction was recorded after 30 minutes to calculate hydrogen concentration, following Equation 1.

$$I_p = FC_0(D/\pi t)^{1/2} \quad (1)$$

where I_p is the current density, F is the Faraday constant (96485.3 C/mol), C_0 is the hydrogen concentration, t is the recording time (30mins by standard), D is the diffusion coefficient for mild steel (2.5×10^{-8} cm/s^2).

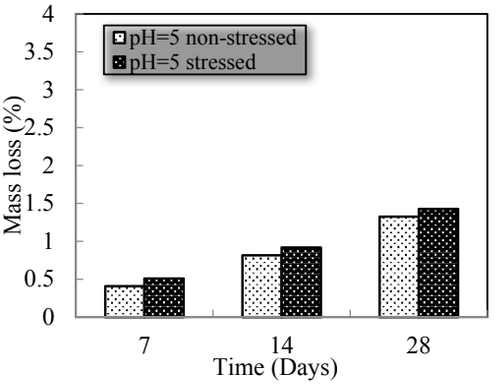
2.5 *Tensile test*

Tensile test was conducted according to ASTM E8 (2016). The cross-head speed was set as 1.1 mm/s for entire specimens. Yield strength, ultimate strength and failure strain were measured through tensile test.

3 RESULTS AND DISCUSSION

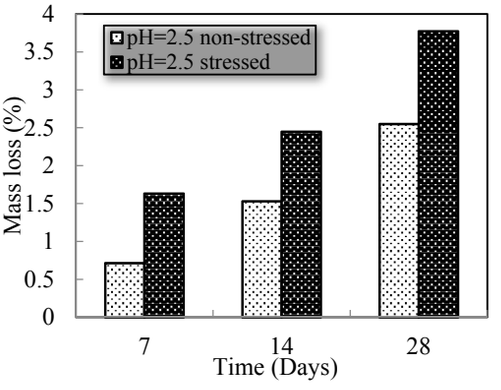
3.1 *Mass loss versus time*

The mass losses of steel specimens as a function of time for both stressed and non-stressed specimen are shown in Figure 5. From Figure 5, for non-stressed specimens, mass loss is 1.42% in pH=5 HCl and 3.77% in pH=2.5 HCl, whist for stressed specimens, mass loss is 1.33% in pH=5 HCl and 2.55% pH=2.5 HCl after 28 days' immersion. The results indicate that a higher concentration of acid favors the corrosion process, and there is an acceleration in corrosion rate when specimens are stressed. The findings are in agreement of the previous literature (Ren et al. 2012).



The result indicates the applied elastic stress can increase the corrosion rate of steel. Corrosion is an electrochemical process and corrosion rate increases with the decreases of electrochemical potential (Ren et al. 2012). Electrochemical potential can be reduced by the applied stress due the following reasons: (1) Passive oxide films are formed before and during corrosion and the reactions are shown from Equation 2 to Equation 5. Stress ruptures the passive oxide films. At the film rupture site, galvanic corrosion occurs between the exposed steel and the surrounding oxide films (Revie 2008, Marcus 2011). This leads to the decrease of the electrochemical potential. (2) With the presence of stress, the surface energy of steel increases and this reduces electrochemical potential by making the acid solution easier to attach and cover the steel surface (Ren et al. 2012). (3) When the presence of stress, local stress concentration leads to the plastic deformation at grain boundaries. The plastic deformation decreases the activation energy of anodic dissolution and subsequently decreases the electrochemical potential. In addition, plastic deformation at grain boundaries can further rupture the passive oxide films and reduce the corrosion resistance (Revie 2008, Marcus 2011).

$$Fe + 4H_2O \leftrightarrow Fe_3O_4 + 8H^+ + 8e^- \quad (2)$$



$$2Fe_3O_4 + H_2O \leftrightarrow 3Fe_2O_3 + 2H^+ + 2e^- \quad (3)$$

$$3Fe^{2+} + 4H_2O \leftrightarrow Fe_3O_4 + 8H^+ + 2e^- \quad (4)$$

$$2Fe^{2+} + 3H_2O \leftrightarrow Fe_2O_3 + 6H^+ + 2e^- \quad (5)$$

(a) pH 5

(b) pH 2.5

Figure 5. Mass loss versus time

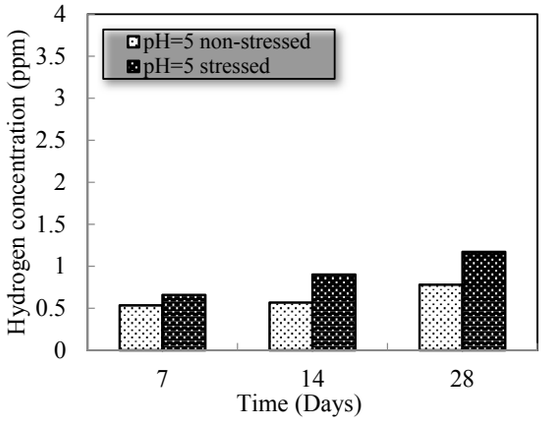
3.2 *Hydrogen concentration versus time*

Figure 6 shows hydrogen concentration grows during corrosion, and the concentration is higher for stressed specimens than none-stressed samples at the same immersion time. In details, after 28 days' immersion, hydrogen concentration increases from 0 to 0.78ppm in pH=5 HCl and to 1.97 ppm in pH=2.5 HCl for none-stressed specimens. For stressed specimens, the concentration increases to 1.17ppm and 2.58ppm in these two solutions respectively.

The hydrogen concentration grows more rapidly for stressed specimens than none-stressed samples at the same immersion time. There are two explanations: On one hand, corrosion is a combination of oxygen reduction (Eq .6 and Eq.7) and hydrogen evolution reaction (Eq. 8 and Eq.9) (Revie 2008, Marcus 2011). Hydrogen gas (H_2) is released in hydrogen evolution reaction, which can diffuse in steel and cause the increase of hydrogen concentration. Stress accelerated corrosion and makes more hydrogen gas release at steel surface (Eggum 2013). In addition, hydrogen evolution reaction plays a more dominant role on the corrosion reaction at pits and cracks. Stress ruptures the passive oxide films, favors localized corrosion, and makes more pits and cracks formed on the surface. This subsequently enhances hydrogen evolution reaction and makes more hydrogen release and diffusion into steel (Eggum 2013).

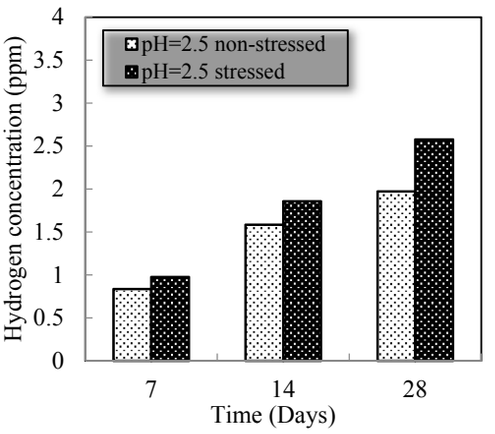
Oxygen Reduction Reaction (ORR):

$$1/2O_2 + 2H_3O^+ + 2e \rightarrow 3H_2O \text{ Acid} \quad (6)$$



$$1/2O_2 + H_2O + 2e \rightarrow 2OH^- \text{ Neutral alkaline} \quad (7)$$

Hydrogen Evolution Reaction (HER):



$$H_3O^+ + e \rightarrow 1/2H_2 + H_2O \text{ Acid} \quad (8)$$

$$H_2O + e \rightarrow 1/2H_2 + OH^- \text{ Neutral, alkaline} \quad (9)$$

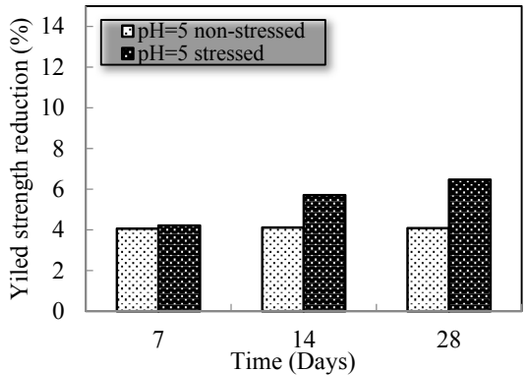
On the other hand, hydrogen atoms in the acid solutions can be absorbed by steel and this also increases hydrogen concentration. Stress favors the absorption of hydrogen atoms by increasing the surface energy on the steel surface. Stress also creates more dislocations and voids inside steel that traps hydrogen atoms (Eggum 2013).

(a) pH= 5

(b) pH= 2.5

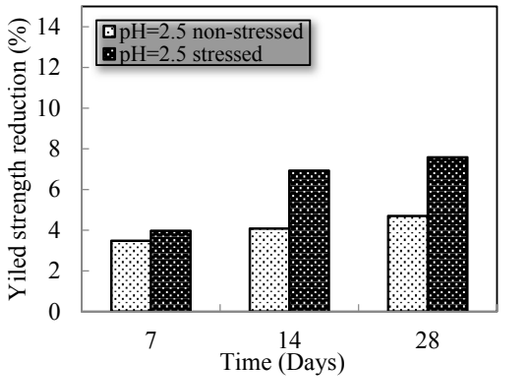
Figure 6. Hydrogen concentration versus time

3.3 *Mechanical properties versus time*



The stress effect on yield strength and ultimate strength is determined in two ways according to Seica & Packer (2004), one emphasized the importance of section loss, surface roughness and corrosion products (rust) on the degradation of mechanical properties. Original cross-section area is used to determine the yield strength and ultimate strength of corroded specimens (Fig. 7 and Fig. 8). This is referred to "as original" condition. The other one focused on the corrosion effect on metallic mechanical properties only. The area of reduced cross-section by corrosion is used to determine yield strength and ultimate strength of corroded specimens (Fig. 9 and Fig. 10). This is referred to "as is" condition.

As shown from Figure 7 and Figure 8, there is a significant reduction in yield strength and ultimate strength for "as original" condition. The reduction is more significant for stressed specimens than non-stressed specimens at the same immersion time. To be specific, in pH=5 HCl, yield strength reduces by 4.08% for non-stressed steel and 6.47% for stressed steel after 28 days' immersion. In pH=2.5 HCl, the yield strength reduces by 4.70% for non-stressed steel and 7.58% for stressed steel after 28 days' immersion. In addition, the ultimate strength for non-stressed and stressed specimens reduces by 3.72% and 12.33% in pH=5 HCl, and 4.12% and 13.63% in pH=2.5 HCl after 28 days' immersion.



There is no notable change in yield strength and ultimate strength for "as is" condition (Fig. 9 and Fig. 10). This is because corrosion only affects 0.2mm below the steel surface for the 6mm thickness specimens (Revie 2008). In this way, the reduction of the resistance (flexure and shear resistance) of steel after corrosion is mainly caused by the loss of cross section, the increase of surface roughness, and the formation of corrosion products of the steel surface (Revie 2008).

However, there is a significant reduction in steel ductility. From Figure 11, failure strain (ductility) reduces by 14.4% and 36.6% in pH=5 HCl and pH=2.5 HCl respectively for non-stressed condition and reduces by 29.0% and 40.9% for stressed conditions. The reduction of failure strain is a combined effect of hydrogen embrittlement, element composition changes, grain size changes, and residual stress concentration caused by pitting corrosion.

Since the concentration of hydrogen within steel is increased more rapidly with the presence of stress, the reduction of failure strain is more serious for stressed steel than non-stressed steel at the same corrosion time. In addition, stress plays a key role in the rupture of the passive oxygen films and the initiation of the microplastic deformation at grain boundaries. This can also lead to more serious reduction of the ductility of steel during corrosion. Due to the reduction in ductility, failure of bridge may occur suddenly without any signs, and the bridge steel can be more vulnerable to fatigue failure (Revie 2008)

4 CONCLUSION

The results of a comprehensive corrosion study on bridge steel (mild steel) have been presented in this paper. The stress effect on corrosion rate and hydrogen concentration is quantified. The degradation of mechanical properties is quantified both for stressed and non-stressed steel after corrosion. Two different solutions of hydrochloride acid (HCl), namely pH=5 HCl and pH=2.5 HCl, are used for corrosion simulation test. The tests found that there is acceleration in corrosion rate when steel is stressed. The stressed steel specimens also have higher hydrogen concentration than non-stressed steel at the same immersion time. This indicates that stressed steel is more vulnerable to hydrogen embrittlement during corrosion. In addition, considering the corrosion effect on metallic mechanical properties of steel, corrosion has limited effect on yield strength and ultimate strength, but it can lead to significant reduction on the ductility of steel. The reduction of ductility is al-

so more serious for stressed steel than non-stressed steel at the same immersion time since it has higher hydrogen concentration. The outcome of this research can help bridge engineers and asset managers to understand the corrosion process of steel bridges under stress, and understand the effect of corrosion on the mechanical properties of steel elements of aging bridges.

3D cellular automata based numerical simulation of atmospheric corrosion process on weathering steel

J.S. Zhu, X.Y. Guo & J.F. Kang
School of Civil Engineering, Tianjin University, Tianjin, P.R. China

ABSTRACT: In order to reproduce the atmospheric corrosion process of weathering steel (WS), a three-dimensional (3D) cellular automata (CA) based method was proposed. Firstly, the basic assumptions were made with the purpose of simplifying the complicated corrosion process. Then the evolution rules of atmospheric corrosion were proposed and the MATLAB program was developed. Secondly, the results obtained from the CA model were compared with the basic corrosion laws verified by experiments. Results show that the basic hypotheses and evolution rules are reasonable and the model is reliable, which can be used to describe and to identify the corrosion kinetics, corrosion morphology and distribution characteristics of pits for WS in atmosphere. Finally, the parameter analysis was performed. The CA model can be used to continuously predict the corrosion behaviors of WS in the long-term atmospheric corrosion process.

1 NTRODUCTION

Weathering steels (WS) are increasingly used as engineering materials owing to environmental and economic advantages. The main applications of WS include bridges and other load-bearing structures, such as electricity posts, utility towers, guide rails and roofing, etc (Morcillo et al. 2013 & 2014). Protective rusts which form on the surface of WS at early stages can reduce further rusting. Therefore, WS can be used without painting or after rust stabilizing surface treatment. Being applicable to relatively mild environments such as rural and urban setting, these steels encounter difficulties in coastal areas because airborne salt deposits may generate porous and non-adhesive rusts on their surface (Nishikata et al. 2014). And when the steel structures are subjected to loads, such as bridges under vehicle loads, the protective rust layers may crack or even fall off. In these cases, the rust layers tend to lose protection, resulting in further corrosion of WS, especially pitting corrosion.

In previous studies, the atmospheric corrosion models of WS were established by fitting the long-term corrosion data. The models were mainly based on the empirical formulas (Bohnenkamp et al. 1974, Pourbaix 1982, Wang et al. 2013 & Miura et al. 2017). However, due to the fact that the corrosion data obtained from atmospheric exposure tests are discontinuous, the models cannot dynamically and continuously describe the evolution of corrosion damage of WS over time. Computational simulation technology can be used to achieve the continuous corrosion process of WS. A promising approach for simulating the corrosion evolution process is cellular automata method (Malki et al. 2005). Cellular automaton (CA), originally proposed by Von Neumann (Von Neumann & Burks, 1966), is a discrete dynamical system. It not only exhibits various properties of continuous dynamical systems but also facilitates implementation. These properties make it to be an efficient method to model complex physical and chemical systems (Chopard & Droz, 2005). Recently, extensive works from corrosion science aiming to establish the cellular automata (CA) models of metal corrosion have been done (Lishchuk et al. 2011 & Van der Weeën et al. 2014). However, an in-depth research on the corrosion process and a rigorous analysis of pit development of weathering steel (WS) by cellular automata (CA) method are lacking in civil engineering. The present study seeks to fill this gap.

The main objective of this research is to develop an approach based on 3D CA to simulate atmospheric corrosion evolution of WS by specific rules governing the electrochemical reactions and diffusion. This research consisted in the 3D CA model development, with the purpose of reproducing the actual atmospheric corrosion process of WS. To achieve this goal, the MATLAB program of corrosion evolution was developed. In order to validate the hypotheses made in the model, the results of corrosion damage growth obtained from the CA model were compared with the basic corrosion laws verified by experiments. At last, the parameter analysis was performed.

2 CELLULAR AUTOMATA METHOD

Cellular automata are described as discrete space-time dynamical systems evolving according to certain local rules. And the systems are defined in a discrete space composed of cells with finite states. Basically, the CA represent simple mathematical idealizations of physical systems. In fact, any physical system satisfying differential equations may be approximated as a CA by introducing discrete coordinates and variables, as well as discrete time steps. CA provides a simple framework to describe, simu-

late, and understand the behaviors of complex physical systems. The CA method was developed by researchers in many fields of science (Chopard & Droz, 2005), such as sociology, computer, biology, ecology, geography and physical chemistry, etc. The application of CA in civil engineering was mainly focused on the durability analysis of concrete structures in aggressive environments, such as the diffusion of carbon dioxide and chlorine ion in the concrete (Biondini et al. 2004 & Cao et al. 2012). However, the CA method was barely applied to study the damage evolution of atmospheric corrosion of steel, which could be of practical importance in quantifying corrosion damage and predicting structural integrity in engineering structures. A complete CA system is composed of cells with finite states, cell space, cell neighbors and evolution rules.

3 3D CELLULAR AUTOMATA MODEL OF CORROSION EVOLUTION

3.1 *Basic hypotheses*

In view of the complexities of atmospheric corrosion, some necessary simplifications need to be made. Based on the characteristics of CA model the basic assumptions are made as follows:

1) The corrosion kinetics is governed by the O_2 diffusion. Compared with the diffusion, the rate of chemical reaction is extremely rapid. Once Fe contacted with O_2, they react immediately.

2) The electrolyte film attached to the steel surface remains neutral during the corrosion process. The anode and cathode regions are not distinguished in the electrochemical reaction. And $Fe + 1/2O_2 + H_2O \rightarrow Fe(OH)_2$ is considered as the only chemical reaction equation in which a single corrosion product is produced. The harmful ions and pollutants in the atmosphere, such as chloride ion, sulfur dioxide and carbon dioxide, are not considered to participate in the chemical reactions.

3) It is assumed that the electrolyte film exists on the surface of steel during the whole corrosion process. The O_2 concentration in the electrolyte film remains constant in certain atmospheric environment during the corrosion process. And the H_2O is sufficient which is not consumed during the chemical reactions.

4) A cell represents a set of molecules or atoms. In order to ensure the chemical equilibrium, it is assumed that the number of atoms represented by one Fe cell is twice as many as that of molecules represented by one O_2 cell or H_2O cell.

5) The corrosion products attached to the steel surface can slow down the corrosion rate of WS. Simultaneously, the corrosion products can be dissolved with a certain probability, which will result in the continued corrosion process.

3.2 *Evolution rules of atmospheric corrosion*

3.2.1 *Configuration of cell space*

The CA model describing the atmospheric corrosion mechanisms is defined in a three dimensional cubic lattice with Von Neumann 6-connectivity. The model is composed of a 100×100×100 mesh with constant boundary conditions (on the top and bottom) and periodic boundary conditions (on the front, back, left and right). There are four different kinds of sites involved in the lattice, which are solution site W, oxygen site O, metal site M and product site P. The solution sites occupied by H_2O cells provide the neutral environment for the electrochemical reactions. The oxygen sites, metal sites and product sites are occupied by O_2 cells, Fe cells and $Fe(OH)_2$ cells, respectively. One site is only occupied by one substance based on the exclusion rules. The 3D model and profile are shown in Fig. 1. The upper half of model is the electrolyte in which the O_2 cells are distributed randomly, and the lower half corresponds to the steel substrate. The electrolyte concentration can be defined by the ratio of the sites number O/(O+W), which keeps constant during the evolution process.

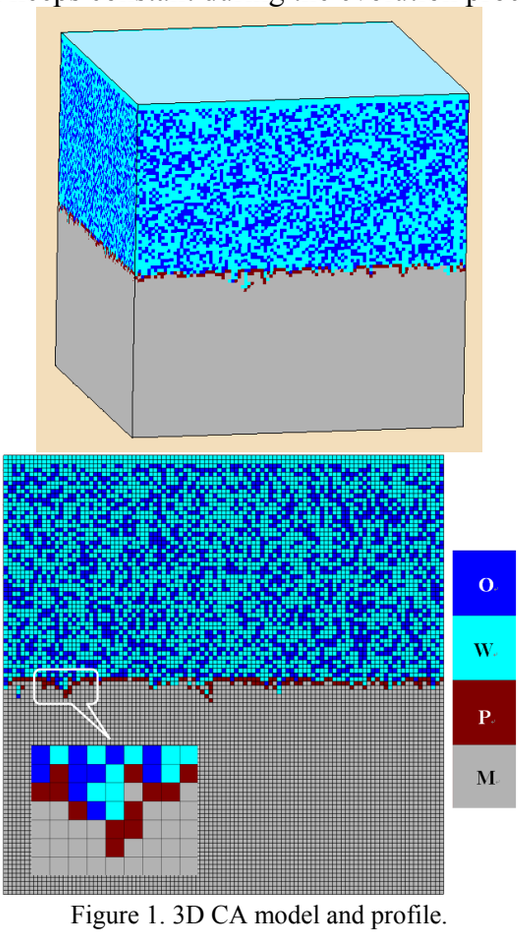

Figure 1. 3D CA model and profile.

3.2.2 *Rules of electrochemical reactions*

According to the previous definition, $Fe + 1/2O_2 + H_2O \rightarrow Fe(OH)_2$ can be expressed by M+O+W→P and P→W. P can be dissolved with probability p, by which the cracking or dissolution of protective rust layers resulting from external factors is simulated.

Based on the basic hypotheses in section 2.1, the reactions can be simplified as M+O→P+O and M+O→O+W, which occur with probability (1-*p*) and *p* respectively. The following rules of reactions are defined.

When M is faced by O, it is dissolved with a fixed probability *p*, causing that M site turns into O and that original O site is occupied by W. Otherwise, P is produced with a fixed probability (1-*p*), causing that M site turns into P and O stays put. However, when M is in contact with any other site, its site keeps unchanged. W site can be occupied by O or P, and P is deposited on the top of M site under gravity and is not affected by any other cell.

3.2.3 *Rules of oxygen diffusion*

Only the oxygen diffusion is considered in this model. A random walk method is used to simulate the diffusion process in the CA model. The rules based on the random walk method conform to the Fick's second law, which had been confirmed by Chopard and Droz (Chopard & Droz, 2005). All the O in the electrolyte simultaneously attempt to jump to the adjacent sites at each time step during the diffusion process. There are three possible outcomes when an O attempts to move to the nearest neighbor site. Firstly, if the adjacent site is occupied by another O, the O stays in place and randomly chooses a direction to face. Secondly, if the adjacent site is W faced by another O or more, the O stays in place and randomly chooses a direction to face. Finally, if the adjacent site is W and no other O face it, the O abandons its current site and swaps with the W and randomly chooses a direction to face.

In summary, during a transition, all the O_2 cells move towards the six directions randomly according to the rules of diffusion. When O_2 cells meet Fe cells, their states will change according to the rules of electrochemical reactions, and the produced $Fe(OH)_2$ cells are deposited under gravity. The MATLAB program is developed to implement the process.

4 MODEL ANALYSIS AND VERIFICATION

The developed model aims at simulating the evolution of atmospheric corrosion of WS, permitting to describe and identify the corrosion kinetics, corrosion morphology and distribution characteristics of pits for WS in atmosphere. For the initial conditions, the lower dissolution probability can be used to describe the formation of a dense and well-adhering rust layer on the surface of WS and the O_2 concentration is mainly related to the environmental parameters. When WS is located in the high relative humidity regions, the electrolyte film on the steel surface can last for a longer time. So the quantity of O_2 reacting with Fe is larger than that in dry environment. As an example, the O_2 concentration *c* and dissolution probability *p* are set as 60% and 0.3 in following analysis, respectively.

4.1 *Corrosion kinetics*

Fig. 2 and Fig. 3 show the variation of average depth and corrosion rate with time steps, respectively. The corrosion rate is equivalent to the variation of average depth per unit time step. In Figs. 2 and 3, the points *A*, *B*, *C* and *D* in curves correspond to the time step 10, 100, 200 and 400, respectively. It is observed that the evolution process of atmospheric corrosion of WS can be divided into four phases: initial phase (before point *A*), rapid growth phase (point *A* to *B*), slow growth phase (point *B* to *C*) and steady phase (after point *C*). In initial phase, the average depth increases linearly with time steps, and the corrosion rate is at a high level. In this phase, the rust layers formed on the surface of WS are porous which cannot provide good protections. Subsequently, the corrosion process proceeds to rapid growth phase, where a great increase in corrosion degree appears. For the WS exposed in atmosphere, the rust layers gradually thicken and the inner rust layers close to substrate begin to become dense. Furthermore, the growing rust layers hinder the O_2 penetration and slow down the diffusion, resulting in the decrease of corrosion rate, as described in Fig. 3. Then the corrosion rate is reduced to point *B*, and the slow growth phase begins. In this phase, the dense protective layers continue to develop and the average depth grows slowly to point *C*. After point *C*, the corrosion rate is close to zero and the average depth keeps virtually unchanged. In steady phase, it is considered that the stable protective layers have formed on WS.

As Bohnenkamp et al. noted in 1974, the corrosion curves of WS obey power function and most of the experimental atmospheric corrosion data has been found to adhere to the following kinetic relationship (Morcillo et al. 2013):

$$C = At^{n} \tag{1}$$

where *C* is the corrosion depth after time *t*, *A* and *n* are constants. *A* is equivalent to the corrosion after the first year of exposure, which is considered as a measure of the initial corrosion resistance of WS. *n* is the time exponent, reflecting the change in average corrosion depth with exposure time and the corrosion evolution of WS. The value of *n* does not affect the corrosion in first year but corrosion in successive years.

In order to determine the relationship between corrosion rate and exposure time, an exponential decrease equation was proposed by M. Morcillo et al. based on a large number of experimental data, as follows:

$$y = A_1 \exp(\frac{-x}{t_1}) + y_o \quad (2)$$

where y is the corrosion rate, x is the exposure time, A_1, t_1 and y_o are constants. In general, the Eqs. (1) and (2) are obtained by fitting the short-term experimental data, and the longest time for WS specimens exposed in atmosphere is about 20 years.

As shown in Figs. 2 and 3, the Eqs. (1) and (2) are used to fit the curve segments which are from point A to C, respectively. The correlation coefficients are 0.9657 and 0.9924, respectively. It is proved that the simulation results agree well with the corrosion laws presented by the experimental results.

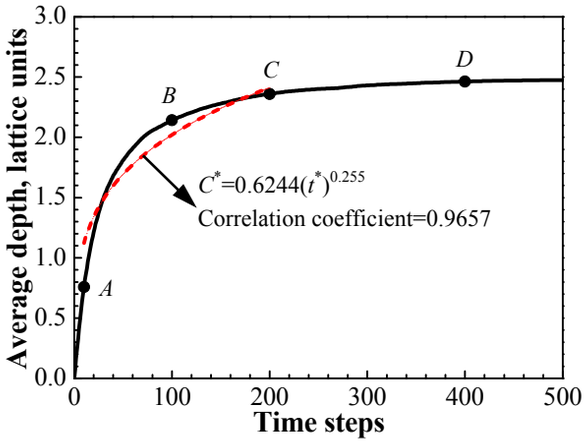

Figure 2. Average depth as function of time steps.

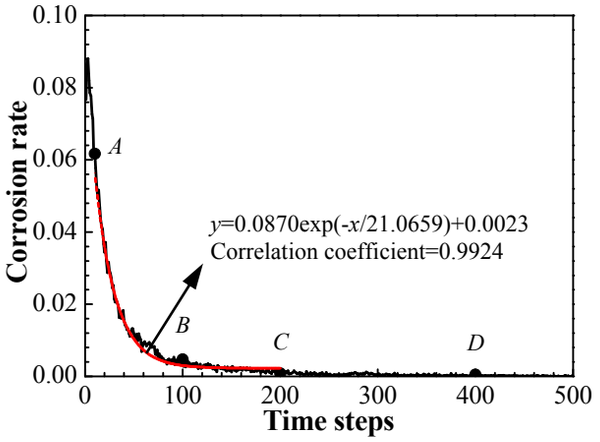

Figure 3. Corrosion rate as function of time steps.

4.2 *Corrosion morphology*

Fig. 4 shows the overall corrosion morphologies of WS at different time steps. At time step 10, the pits initiation is observed and a few of pits with a maximum depth of 4 lattice units appear. With the increase of time steps, the initiated pits grow in size and new pits also begin to initiate. At time step 100, the top layer of entire area is corroded. The pit depth is mainly 1 to 3 lattice units, while only one pit with the depth of 8 lattice units is found. Then more pits reach the 8 lattice units depth. More wide and shallow pits appear at time step 200. Subsequently, the pits area increases with time steps but the average depth for whole sample basically remains constant owing to the increasing protections of rust layers.

Fig. 5 shows the variations in the cross-sectional shape of pits at different time steps. It can be seen that the variations of corrosion depth are consistent with the law described in Figs. 2 and 4. As observed in Fig. 5, the cross-sectional shapes of pits primarily contain: vertical, wide and shallow, elliptical, narrow and deep, subsurface, horizontal and undercutting, etc. These shapes are similar to those presented in ISO 11463. In steady phase, the cross-sectional shapes of pits are mainly wide and shallow, and elliptical.

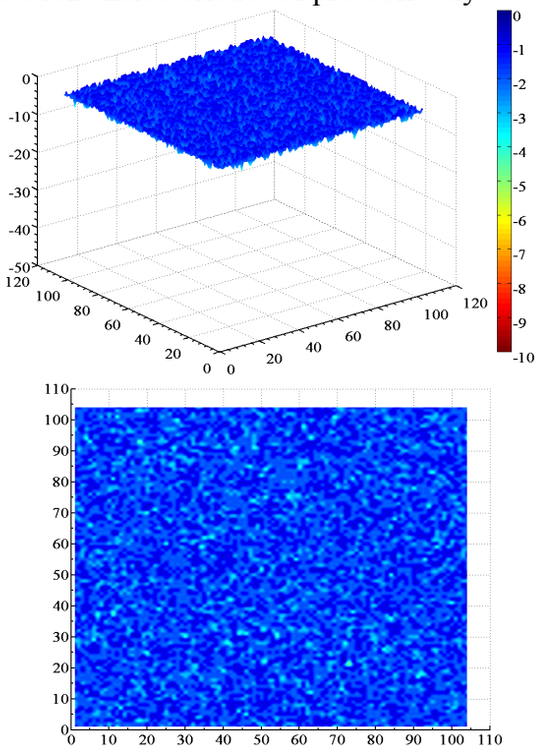
4.3 *Distribution characteristics of pits*

Fig. 6 shows the distribution characteristics of pits. According to statistical analysis, at time step 10, 62.5 percent of the entire area is corroded, and pits with the depth of 1 to 2 lattice units account for 98.7 percent of all the pits. Subsequently, as time steps increase, the proportion of pits with the depth of one lattice unit begins to decline while the proportion of pits with the depth of 2 to 4 lattice units starts to raise. After 200 time steps, the frequencies of different depth pits tend to be stable. Generally, in terms of time step 100, 200 and 400, the pits with the depth of 1 to 3 lattice units account for 91.7, 85.6 and 84.0 percent, respctively. Based on the previous studies, the pit depth conforms to the Weibull distribution preferentially (Xu et al. 2012). Weibull statistical analysis is based on the weakest link theory about chain, and its cumulative distribution function is as follow (Weibull, 1951):

$$F(x) = 1 - \exp[-(\frac{x-\sigma_u}{\gamma})^m] \quad (3)$$

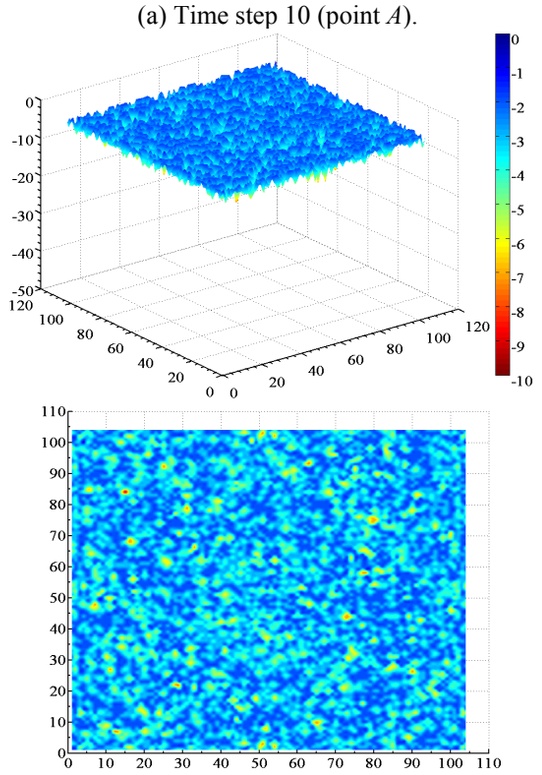
where x is the pit depth, σ_u is the location parameter, γ is the scale parameter, and m is the shape parameter. σ_u is usually taken as 0 in practical application and the Eq. (3) can be simplified as a function with two parameters. Therefore, the probability density function can be expressed by:

$$f(x) = \frac{m}{\gamma^m} x^{m-1} \exp[-(\frac{x}{\gamma})^m] \quad (4)$$



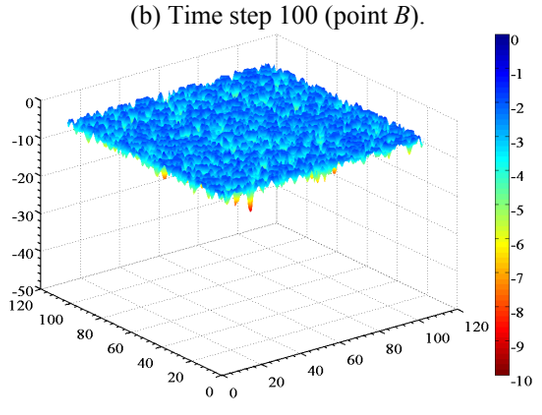
$$\mu = \gamma \cdot \Gamma(1 + \frac{1}{m}) \quad (5)$$

$$\sigma^2 = \gamma^2 \cdot \Gamma(1 + \frac{2}{m}) - \mu^2 \quad (6)$$

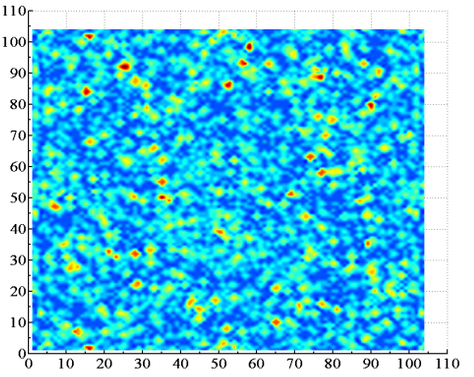


where μ and σ are the mean and standard deviation of pit depth, respectively. Γ corresponds to the gamma function.

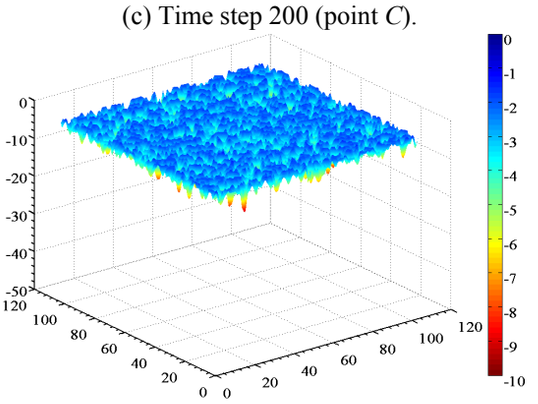
In the present study, Eq. (4) is used to fit the distribution of pit depth, as described in Fig. 6. According to m and γ obtained by fitting, Eqs. (5) and (6) are used to calculate μ and σ, respectively. In addition, a comparison between calculation and simulation results is presented in Table 1. It can be observed that Eq. (4) produce good agreement with the distribution of pit depth which is acquired from the CA model, and the mean and standard deviation calculated by equations get close to the simulation re-

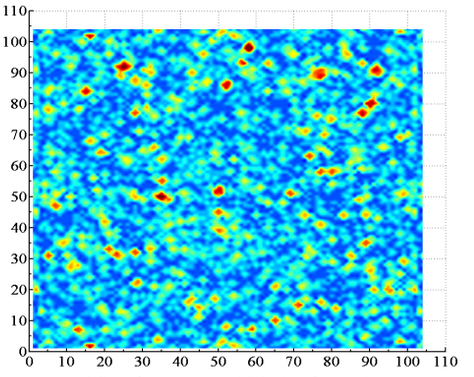


sults. It is proved that the CA model can reflect the distribution characteristics of pits correctly.



(a) Time step 10 (point *A*).





(b) Time step 100 (point *B*).

(c) Time step 200 (point *C*).

(d) Time step 400 (point *D*).

Figure 4. Corrosion morphologies of WS at different time steps.

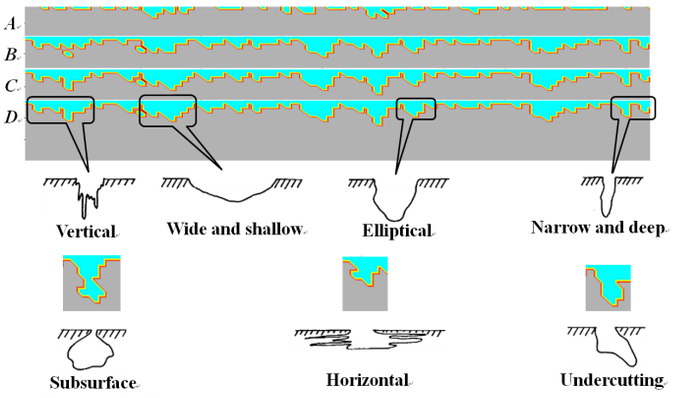


Figure 5. Variations in the cross-sectional shape of pits.

To sum up, the simulation results including the corrosion kinetics, corrosion morphology and distribution characteristics of pits accord with the general atmospheric corrosion laws of WS. It is indicated that the basic hypotheses made in section 3.1 are reasonable and the model is reliable. The 3D CA model can be used to simulate the evolution of atmospheric corrosion for WS effectively.

Table 1 Comparison between calculation and simulation results for statistical characteristics.

Corrosion process	m	γ	Correlation coefficient	Mean μ (Weibull)	Mean μ^* (CA)	μ^*/μ	Standard deviation σ (Weibull)	Standard deviation σ^* (CA)	σ^*/σ
A (time step 10)	2.668	1.269	0.9999	1.1280	1.1813	1.05	0.4555	0.4202	0.92

5 PARAMETER ANALYSIS

The atmospheric corrosion of WS is not a continuous process. Electrochemical corrosion occurs only when the electrolyte film is formed on the surface of steel. It has been proved by experiments that relative humidity is the key parameter influencing the long-term atmospheric corrosion of WS (Gong et al. 2009). The relative humidity can influence the thickness and existence time of electrolyte film, thus further affect the quantity of O_2 reacting with steel. Moreover, temperature can affect the O_2 diffusion through electrolyte film. Hence the influence of relative humidity and temperature on the atmospheric corrosion can be attributed to that of O_2 concentration. The behaviors of rust layers are affected by the chemical compositions of WS, concentration of erosive ions and external loads. The influence of these factors can be attributed to that of dissolution probability. Therefore, the parameters including dissolution probability and O_2 concentration are analyzed in this section.

The effect of dissolution probability and O_2 concentration upon the corrosion kinetics is presented in Fig.7 and Fig.8, respectively. It can be seen that the dissolution probability has a significant impact on the corrosion rate. The corrosion rate increases with the dissolution probability, which leads to the differences of average depth for different dissolution probabilities. And with the increase in time steps, the differences get larger and larger. In addition, it requires more time steps to reach the steady phase in terms of the larger dissolution probability. As observed in Fig.8, the O_2 concentration has an effect on the early stage corrosion rate but has no effect on

the final corrosion state. With the increase of O_2 concentration, the time steps that it takes to reach the steady phase decreases. In general, the final corrosion damage of WS is determined by the dissolution probability, while the O_2 concentration only affects the time steps required to reach the final corrosion state.

6 CONCLUSIONS

The objectives of this study were to reproduce the atmospheric corrosion process of WS at the mesoscopic scale and obtain the macroscopic expression of cumulative corrosion damage. The following conclusions are obtained by the intensive analysis:

(1) The simulation results conform to the general atmospheric corrosion laws of WS. Therefore, the basic hypotheses and evolution rules of corrosion are reasonable and the model is reliable. 3D CA method is presented as a useful tool with the application of simulation of atmospheric corrosion process. It can permit to describe and identify the corrosion kinetics, corrosion morphology and distribution characteristics of pits for WS in atmosphere.

(2) The evolution process of atmospheric corrosion of WS can be divided into four phases: initial phase, rapid growth phase, slow growth phase and steady phase. In initial phase, the average depth increases linearly with time steps. In second phase, the growing rust layers hinder the oxygen penetration, which results in the decrease of corrosion rate. Subsequently, the dense protective layers continue to develop. In steady phase, as the corrosion rate is close to zero, it is considered that the stable protective layers have formed on WS.

(3) During the evolution process, many metastable pits cannot grow into stable pits because of the protections of rust layers. The surface morphologies of stable pits develop from ellipse to diamond with the increase of time steps. In general, the simulated morphology can be seen as a realistic representation of multi-pit corrosion damage and the CA model can reflect the distribution characteristics of pits correctly.

(4) The final corrosion damage of WS is determined by the dissolution probability, while the oxygen concentration only affects the time required to reach the final corrosion state.

Structural performance of bridges under deterioration processes: Bicentenario Bridge

J.D. González & F.A. Cerda
University of Concepción, Concepción, Chile

ABSTRACT: Over time, bridges reduce their expected performance levels to environmental and mechanical effects under service loads or extreme events. This research presents a methodology to include corrosion and fatigue deterioration processes in the bridge analysis. In addition, performance and reliability assessments of the structure over time are conducted based on current design standards: strength, fatigue and serviceability. Uncertainties related to estimation of vehicle load, properties of the materials and parameters associated with corrosion are included by means of a probabilistic distribution.

These techniques are applied to a real case study, the Bicentenario Oriente Bridge, currently under construction in Concepción, Chile. The steel girders of a particular span are studied and by means of a fault tree analysis the reliability of the system is calculated by reliability at element level. This analysis allows an evaluation of the proposed methodology and verification of the expected diagnoses for bridges with similar structure.

1 INTRODUCTION

In Chile, there are around 12,000 bridges, which require a periodic evaluation of their structural condition. Due to the earthquake of 2010, of the 100 bridges that suffered damage, 20 collapsed. Currently, the integrity of all structures and their possible performance in face of future events are not known (Tang 2010).

Structural health monitoring (SHM) aims to predict and reduce the risks associated with different levels of structural damage by studying its structural condition with periodic reviews, sensor implementation, and subsequent analysis and interpretation of data.

In civil engineering, the application of SHM arises from the need of private and governmental industries to detect damage to their infrastructure early in order to generate an increase in safety of human lives and to decrease the economic impact associated with structures out of operation (Farrar & Worden 2006).

Civil structures, due to their inherent vulnerability are prone to deterioration through corrosion, fatigue and physical damage over their life-cycle. This can lead to unsatisfactory performance under service loads, natural disaster or extreme events.

The study of the condition of the structure over time allows the prediction of the remaining useful life and the incorporation of maintenance strategies to ensure that the structure operates over a range of minimum performance.

2 PERFORMANCE MODEL

One way to study the structural condition is by applying a performance model that includes the effects of degradation over time. Similarly, one way of assessing structural performance is through the reliability index associated with the limit states of the current design standard.

Throughout structures life-cycle, their initial performance level decrease reaching unsatisfactory levels due to environmental and mechanical factors over time under service loads or extreme events.

It is necessary to have maintenance that corrects the problems presented in the structure in order to increase the lifetime and reduce the costs associated with maintaining operating structure, which increases the values of the performance indicator.

Because the condition of the structure decreases over time, the accumulated deterioration until time t can be defined as $D(t)$. The rate of degradation can change drastically over time due to variations in environmental conditions, material properties, use loads, among other. For a case where there is no maintenance, the performance indicator can be written as:

$$V(t) = \max\{V_o - D(t), 0\} \quad (1)$$

where $V(t)$ is the performance indicator; V_o is the remaining life of the system at time t equal 0; and $D(t)$ is the accumulated deterioration at time t.

In Figure 1, a performance curve is presented with the application of a corrective maintenance at time t_f. It is observed that $V(t)$ is the performance indicator; $D(t)$ is the accumulated deterioration at time t; t_f is the time at witch limit performance is reached; k^* is the limit performance. It is observed that when the performance indicator reaches the acceptable limit value, a corrective maintenance is performed (Sánchez-Silva et al. 2016).

According to Sánchez-Silva & Klutke (2016), continuous degradation models can be divided into progressive and shock-based. The progressive degradation consists in that the capacity of the structure decreases continuously linearly or non-linear in time. The expression is presented below:

$$V(t) = V_o - \int_0^t \delta(\tau) d\tau \quad (2)$$

where V_o corresponds to the remaining life of the system at time t equal 0; $\delta(t)$ is the rate of deterioration; t is the domain of integration.

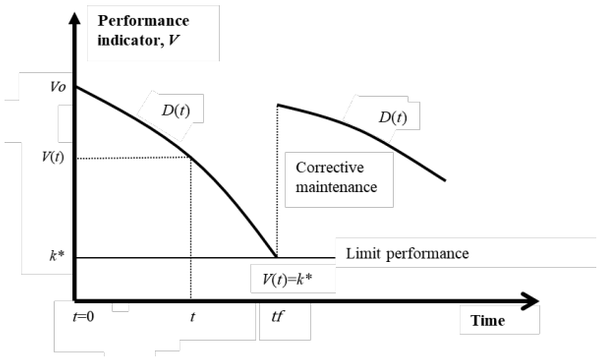

Figure 1. Description of system performance over time (Sánchez-Silva et al. 2016).

On the other hand, shock-based degradation is caused by extreme events such as earthquakes, tsunamis, fires, etc. These events cause a significant change in the physical properties of the system over a short period of time. The expression representing it is shown below:

$$V(t) = V_o - \sum_{i=1}^{Ni} Y_i \quad (3)$$

where Y_i corresponds to the random variable that describes the deterioration caused by event i; N_i is the ith event.

Frequently, both degradation processes occur simultaneously throughout the structure life-cycle. The expression is presented below:

$$V(t) = V_o - \int_0^t \delta(\tau) d\tau - \sum_{i=1}^{Ni} Y_i \quad (4)$$

2.1 *Reliability index and probability of failure*

The structural condition can be presented by reliability or probability of failure associated with a limit state. The latter consists of an event whose occurrence must be avoided to ensure proper behavior of the structure. Due to the uncertainties present in the lifetime of the structure, resistance and demand should be considered as random variables.

For a structural element, the resistance is represented over time by $R=R(t)$, the demand by $S=S(t)$ and the performance function by $g=g(t)$ with $g(t)=R(t)-S(t)$. Considering r_k y s_k as the results of the variables $R_k=R(t_k)$ y $S_k=S(t_k)$, respectively, the probability of failure at time $t=t_k$ can be evaluated by integrating the density function in the fault domain. The expression is presented below:

$$P_f(t_k) = P[R_k < S_k] = P[g \le 0] = \int_{\tau_k} f^k_{R,S}(r,s) dr ds \quad (5)$$

As an alternative way, the structural safety can be evaluated by the reliability index $\beta_k=\beta(t_k)$.

$$\beta(t_k) = \frac{\mu_{R,k} - \mu_{S,k}}{\sqrt{\sigma^2_{R,k} + \sigma^2_{S,k} - 2\rho_k \sigma_{R,k} \sigma_{R,k}}} \quad (6)$$

where μ and σ correspond to the mean and standard deviation, respectively; and ρ_k corresponds to the correlation between R and S.

If resistance and demand are normal variables, the probability of failure and the reliability index are related by the following expression:

$$P_f(t_k) = \phi(-\beta_k) \quad (7)$$

where $\phi(\cdot)$ corresponds to standard normal cumulative probability function.

Figure 2 presents the probabilistic distribution of resistance and demand of the structure (Soliman 2015).

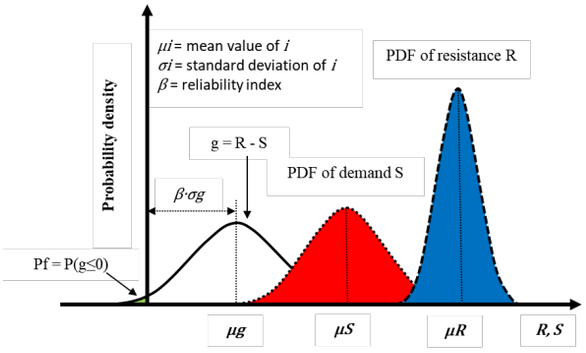

Figure 2. Concept of probability of failure and reliability index (Soliman 2015).

Soliman (2015) presents the resistance and demand values as probabilistic distributions with a mean and standard deviation. In the same way, the probability of failure is represented as the area where $g \leq 0$.

2.2 *Corrosion model*

The corrosion models mainly present the effect of uniform corrosion on the structural elements, being the main cause of this phenomenon the accumulation of water and salt on the steel surfaces (Kayser & Nowak 1989a). These models consist of the representation of the loss of surface at the cross-sectional and longitudinal level of the element that generates a loss of area, inertial and stiffness.

Corrosion severity depends on the properties of the material (material alloys), local atmosphere (temperature and relative humidity) and exposure conditions such as initial climate, exposure duration, orientation, exposure angle, time of wetness, atmospheric pollutants, de-icing salt.

Klinesmith et al. (2007) developed a model of atmospheric corrosion taking into account four environmental variables (wetness, sulfur dioxide, salinity and temperature). The expression is presented below:

$$Y(t) = A\, t^{B} \left(\frac{TOW}{C}\right)^{D} \left(1 + \frac{[SO_2]}{E}\right)^{F} \left(1 + \frac{[Cl]}{G}\right)^{H} e^{J(T + T_O)} \tag{8}$$

where Y is the corrosion loss in μm; t is the exposure time in years; TOW is the time of wetness in h/year; SO_2 is the concentration of sulfur dioxide in μg/m^3; Cl is the chloride deposition rate in mg/m^2/day; T is the environmental temperature in °C; and A, B, C, D, E, F, G, H, J, T_o are empirical coefficients.

Figure 3 shows dark areas where corrosion patterns usually occurs in steel girder bridges (Kayser & Nowak 1989b). It can be seen that the surface with corrosion near the supports occurs throughout the web height. In the middle zone, corrosion occurs in the lower quarter web height.

Kayser & Nowak (1989b) identified the areas where the highest values of corrosion were produced due to the presence and accumulation of surface water, temperature, salinity, among others.

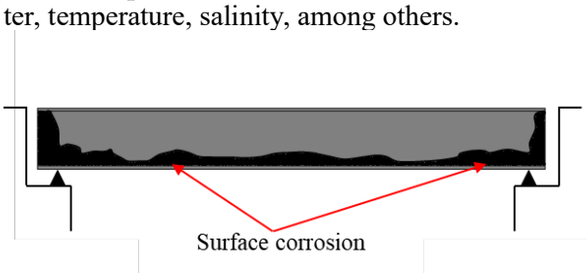

Figure 3. Corrosion pattern of a steel girder bridge (Kayser & Nowak 1989b).

By combining information on location and corrosion ratio together with the structural analysis of the elements for the calculation of stresses, a structural condition degradation model can be generated which indicates performance over the structure life-cycle.

2.3 *Limit states and loads*

All structures have basic requirements: safety against collapse and satisfactory performance over its lifetime. Likewise, stability, strength, functionality and durability requirements must be met. Limit states usually define the various ways in which a structure does not meet these basic requirements. If the structure does not exceed one of the limit states, it is considered that it no longer fulfills the functions for which it was designed.

AASHTO LRFD Bridge Design Specifications consider factors for each load and for each nominal resistance. The vehicle loads can be represented in three types: design truck, design tandem and design lane load.

For the evaluation of the structural performance, the reliability index was calculated by means of the limit states of Strength I, Fatigue and Service II (ASSHTO LRFD).

3 STRUCTURAL MODELING

A structural model is generated that allows the analysis of a composite steel beam, where input data correspond to the initial dimensions and cross-section of the element, corrosion values, distribution of corrosion on the elements and the permanent and transient loads, among others. Corrosion penetration was represented on a yearly time scale.

After applying the respective factors, the effects of service loads are compared with the values of limit states presented in AASHTO LRFD and reliability index of the elements is calculated.

The structural model of the composite beam is performed using the OpenSees (Open System for Earthquake Engineering Simulation) software that incorporates within its commands and library the representation of structural elements through the use of finite elements.

The finite element model generates structural behavior data through different corrosion scenarios for the beam elements. The model consists on the representation of a composite element (steel beam and concrete slab). This consists of the representation of the cross-section with rectangular and linear elements in order to give them different material properties. The first elements are called patch quad and represents the steel beam and the concrete of the reinforced concrete slab; the second elements are called layer straight and are used to represent the re-

inforced steel of a section of a reinforced concrete slab.

The behavior of the beam is represented discreetly; each level of corrosion corresponds to one year of use of the structure. The AASHTO LRFD standard indicates that design life of a bridge should be at least 75 years. However, Feyermuth (2009) indicates that bridges must have a minimum service life of 100 years under appropriate maintenance actions but without large repairs. For each of the year of study, iteration is generated to the model that includes corrosion, cross-sections and previous results.

The input data of the model correspond to: properties of the materials, length of the elements, types of support, cross-sections, corrosion values and loads with their respective factors depending on the limit state.

The applied load on the model correspond to dead loads due to structural components and wearing surfaces; to vehicle loads by design lane load and design truck, represented as distributed and punctual load, respectively.

The output data of the model are stresses, deformations, displacements and forces at the points of interest.

Figure 4 presents a flowchart of the structural modeling process and calculation of reliability index by means of the limit states of Strength I, Fatigue and Service II. It is possible to observe the case of deterioration considered and the factors involved in the calculation of the penetration of corrosion.

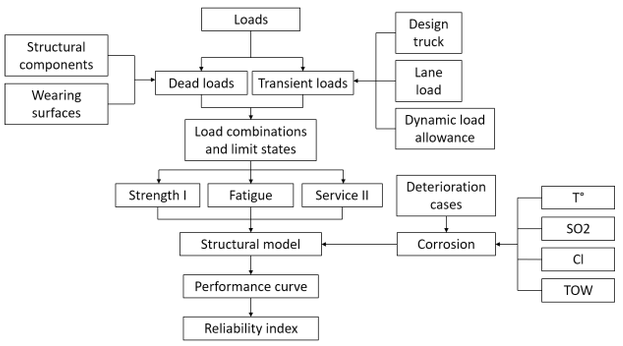

Figure 4. Flowchart of the modeling process and obtaining results.

As mentioned, the behavior of an element under the effects of corrosion is represented by a loss of thickness in the different elements of steel girder cross-section (flange and web).

The formulation of the corrosion pattern presented by Kayser & Nowak (1989b) with the corrosion values extracted from Klinesmith et al. (2007) is carried out by using the finite element tool by means of cross-sections of the fiber type for the representation of the beam and slab elements.

In this study, the corrosion representation is made by removing the affected zones of the steel section for each level of corrosion, both in the web and in the bottom flange along the beam. Figure 5 shows modeling of the cases without corrosion and with corrosion in middle sector and the supports. It can be observed that the painted areas represent the corrosion in the steel element, according to the patterns presented by Kayser & Nowak (1989b).

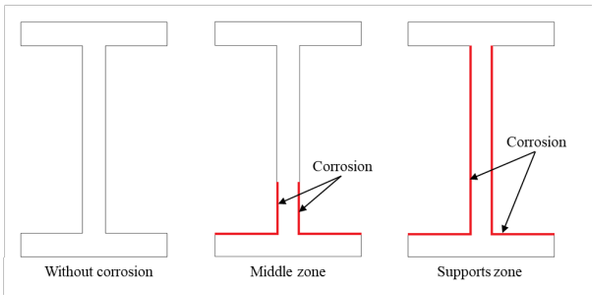

Figure 5. Corrosion scenarios for the steel beam represented in the model.

4 CASE STUDY

The methodology was applied to the Bicentenario Oriente Bridge in its structure located to the east side, currently under construction in Concepción, Chile. The objective of the road project is to increase connectivity between Concepción and San Pedro de la Paz. The bridge is represented by a simply supported span.

The structure is represented by the model previously explained in OpenSees software. The inputs are the dimension and materials of the elements; the permanent and transient loads given by the weight of the elements and the vehicular loads; and corrosion values for each damage scenario.

The distribution coefficient that represents the effect of the loads in the structure is incorporated in OpenSees by means of a 3D model.

4.1 Characteristics of the structure

The total length of the bridge is 1490m between north and south abutments. These points are connected to the main streets through access structures. The bridge has two traffic lanes 3.5 m wide each. Figure 6 presents the location of the Bicentenario Oriente Bridge over the Biobío river.

The structure is composed of 3 girder spans with lengths ranging between 39.60 m and 40.66 m. The span to be studied has a length of 39.72 m and is supported by piers C10 and C11. The spacing between longitudinal girders is 3.5 m. The length of each girder is 39.52.

The steel girders vary their cross-section longitudinally. The thickness of the flange increases as the center of the span is reached. Four zones are generated with different cross-section for each half girder. The three elements that compose the span have the

same characteristics. Figure 7 shows the four zones representing half of each girder. It is possible to emphasize that the girders are symmetrical with respect to their middle point. They are made of A573 Gr 50 steel with yield strength of 345 MPa.

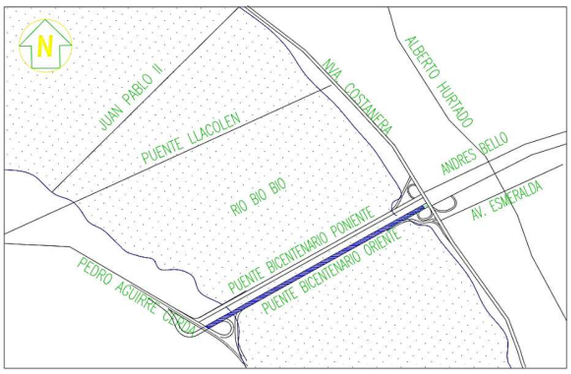

Figure 6. Location of Bicentenario Oriente Bridge, Chile (Public Works Ministry, Chile).

Table 1 shows the dimensions of the four zones representing half of the element.

Table 1. Dimensions of each cross-section of the girder.

Dimension	Zone 1	Zone 2	Zone 3	Zone 4
	mm	mm	mm	mm
Length	8760	1000	4000	6000
Top flange width	400	400	400	400
Top flange thickness	20	20	30	30
Web depth	2000	2000	2000	2000
Web thickness	12	12	12	12
Bottom flange width	500	500	500	500
Bottom flange thickness	30	38	38	50

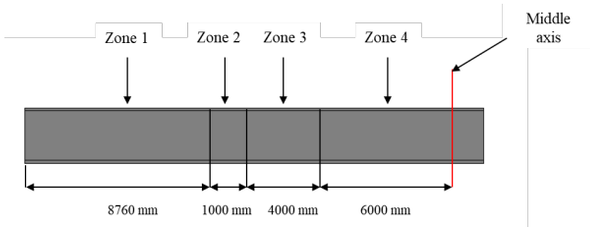

Figure 7. Cross-sections of the girder (Public Works Ministry, Chile).

4.2 *Corrosion values*

The mean penetration values are given by expression presented by Klinesmith et al. (2007). The values of temperature, time of wetness, sulfur dioxide concentration and chloride deposition rate correspond to data representative of Concepción.

Figure 8 shows the increase in penetration of the element surface as the years of exposure increase.

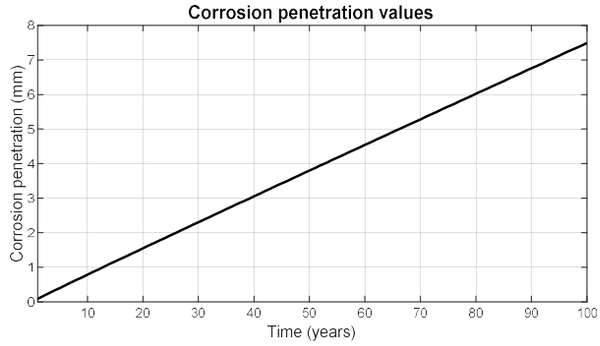

Figure 8. Penetration of corrosion on the surface of the element.

4.3 *Variability in loads*

Due to the consideration of design loads as operation loads in the bridge lifetime, it is necessary to add stochastic characteristics that consider the variability of them in the operation of the structure.

The average values considered in the study are those extracted from the software by means of the analysis with input of the properties and loads presented in the previous sections with their respective load and distribution factors.

In the same way for the values of resistance, it is considered variability associated to the properties of the materials, corrosion parameters, atmospheric conditions, construction of the structure, among others.

Table 2 shows the values of the coefficients of variation considered in the reliability index calculations.

Table 2. Coefficient of variation values for permanent loads, transient loads and strength.

Load	CV
Permanent	0.10
Transient	0.20
Resistance	0.05

5 RESULTS

In the next section it is presented the results obtained from the analysis of the elements of the study case structure for interior and exterior girder.

5.1 *Limit state Strength I*

The strength limit state compares the ultimate moment acting on element with nominal moment that is a function of the plastic moment and corresponds to resistance.

Figure 9 shows the nominal moment values for the largest cross-section of the element corresponding to the middle zone (zone 4) for interior and exterior girder. The degradation of the resistance in rela-

tion to the time of exposure to the effects of corrosion can be observed. The slope difference is produced by the location of the neutral axis in each girder member due to the different concrete areas in each composite section. In the same way, the latter justifies the higher values for the interior girder.

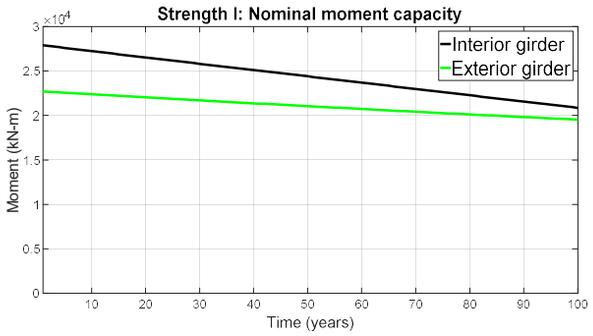

Figure 9. Nominal moment, cross-section zone 4, Strength I.

The reliability index is presented in Figure 10. It is observed that due to the expressions present in the calculations of the limit states, the reliability index curves for each element have the same characteristics as the nominal moment curves. Limits are not reached with the study period. However, a much higher rate of decrease for the interior girder can be noted.

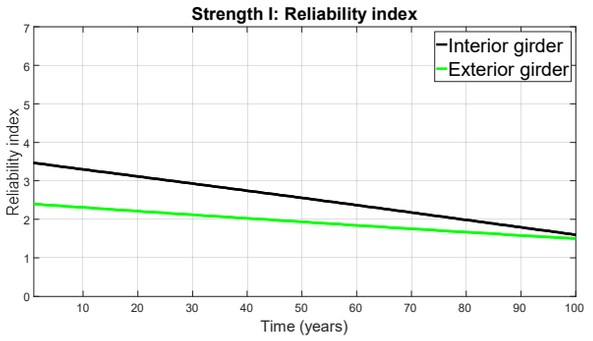

Figure 10. Reliability index, Strength I.

5.2 *Limit state Fatigue*

The fatigue limit state compares the stress range with the stress limits for each number of cycles.

Figure 11 (logarithmic scale) shows the stress range limit curve for the detail studied on the bridge girder. This curve includes finite and infinite load-induced fatigue life.

The reliability index is presented in Figure 12. It is observed that due corrosion the stress in the elements increases and the reliability index decreases for each load cycle. The first zone of the curve correspond to finite life fatigue (logarithmic) and the second to infinite life fatigue (linear). The exterior girder has lower values due to the greater demand generated by the fatigue truck.

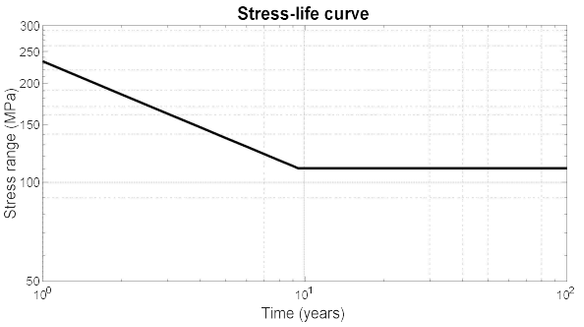

Figure 11. Stress-life curve, Fatigue.

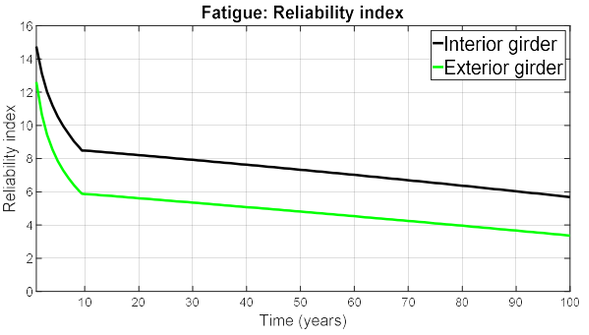

Figure 12. Reliability index, Fatigue.

5.3 *Limit state Service II, permanent deformations*

If loads are applied above the elastic limit, the material acquires permanent deformations and the element does not recover its original shape when removing the loads.

In the limit state of Service II, the calculation of permanent deformations is made by the tensions in the steel sections.

Figure 13 shows the maximum stress values within the life of the bridge. An increase in values is observed due to loss of cross-section of elements. Also, it is observed that the values of stresses are close enough to the yield strength of the steel of 345 MPa. The values are higher in the interior girder due to the transverse distribution of the vehicle load.

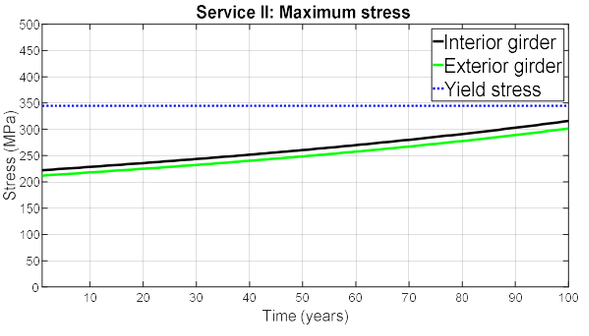

Figure 13. Maximum stress, Service II, Permanent deformations.

Figure 14 shows the reliability index values. It is observed that the values approach zero. The exterior

girder has higher values due to its lower stress demands.

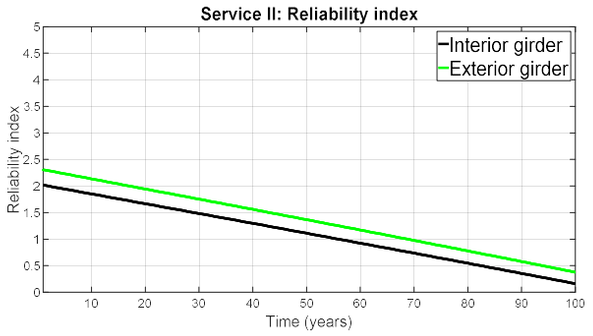

Figure 14. Reliability index, Service II, Permanent deformations.

5.4 *Limit state Service II, elastic deformations*

It consists of the deformation of the elements produced by the loads of use: design truck and lane load. The vehicle load must include the dynamic impact load.

From Figure 15 it can be seen that the interior girder has major deformations. On the other hand, the maximum deformation limit is not reached.

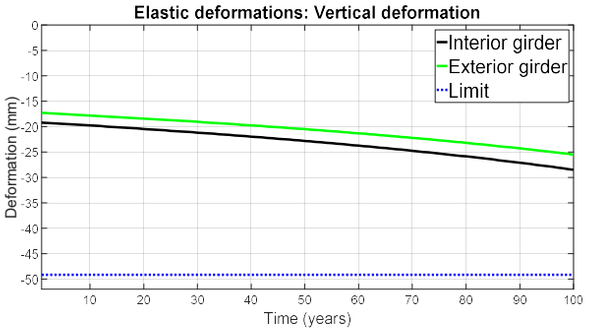

Figure 15. Vertical deformations, Service II, elastic deformations.

Figure 16 shows the reliability index values. It is concluded that the reliability index reaches values above the limit and, therefore, the probability of failure is low throughout the lifetime of the structure.

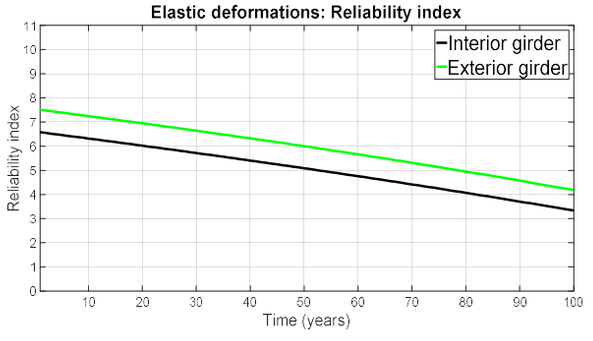

Figure 16. Reliability index, Service II, Elastic deformations.

5.5 *Overall limit state*

The overall reliability index of the structure corresponds to the graph of all limit states studied. Its purpose is to present a reliability value at the structure level that corresponds to the lowest value according to the possible failure scenarios. In this case, the system is series so if any of the girders fails, the system will fail.

From Figure 17, it can be seen that Service II limit state presents the lowest reliability values and controls the structure condition. In more detail, the interior girder is the one that has a high probability of surpassing the limit stress in the bottom flange and not fulfilling the conditions of service.

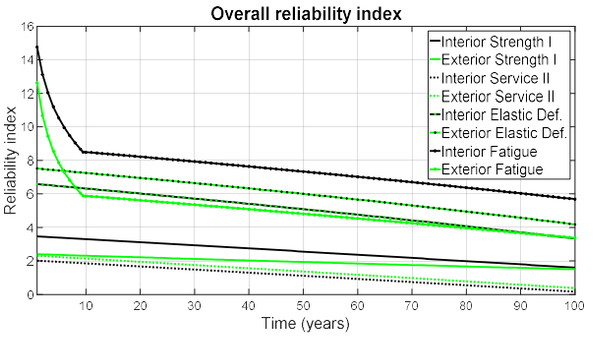

Figure 17. Overall reliability index.

6 CONCLUSIONS

Through the present research, it is proposed a methodology for the evaluation of the structural performance under process of corrosion degradation through the use of a finite element model for a steel girder and concrete slab bridge. For this purpose, software was used to generate different damage scenarios that represented the time of exposure to corrosion degradation agents. A period of 100 years was considered as service life of the structure and by means of the reliability index the structural condition was analyzed over time under current design standards.

When applying the methodology to the case study, a span of the Bicentenario Oriente Bridge, it was obtained that the evaluated limit states corresponding to strength, fatigue and serviceability were not exceeded within the operational life of the structure.

It was possible to corroborate that the properties of the elements are affected in relation to the time of exposure to corrosion degradation agents. The values of cross-section and resistance of the elements decreased and the values of stress and deformations increased.

The limit state of Service II is the one that controls the performance of the structure because it presented the lowest values in lifetime. In the same

way, the interior girder evidenced the greater solicitations because it supports the greater proportion of the traffic lanes.

The limit states of Strength I and Fatigue were not reached with the studied period, being the probability of failure low in the analysis. Despite this, the exterior girder showed the lowest values of reliability.

In relation to the above, it was concluded that the effects of corrosion degradation did not reduce the structure design life. However, these effects acting in conjunction with other degradation agents such as reinforced concrete corrosion or extreme events such as earthquakes, tsunamis, fires, can generate performance values below the expected limits.

The generated model can be updated with observations generated with visual inspections related to the advance of corrosion and other damage conditions. Also the parameters of the corrosion model must be calibrated for local conditions.

The predictive capacity of the model can be improved by calibrating the load and data models of the structure based on data measured in the field with the installation of sensors.

Predictive modelling of the deterioration of Australian state bridge network

H.D. Tran & S. Setunge
RMIT University, Melbourne, Australia
Y-C. Koay & H. Luczak
VicRoads, Melbourne, Australia

ABSTRACT: Road bridges are life line structures essential to ensure community mobility. Management of an aging bridge network on limited resources can be a challenge for the state authorities. Prediction of future condition states of bridges at component level is essential to optimise maintenance actions and ensure the safety and serviceability of the network. This is the first step in developing an advanced management strategy. A research project funded by the Australian Research Council in partnership with the Roads Corporation of Victoria (VicRoads) and conducted at RMIT University in Melbourne examined the level 2 visual inspection data collected by over 4-5 inspection cycles with the objective of predicting deterioration of bridge components. The quality and quantity of the data were analyzed and observed to be adequate for developing component level deterioration prediction models. A range of deterioration prediction methods including the deterministic models and stochastic models were examined to understand the validity of the different methods in predicting the deterioration of bridge components using visual inspection data. A case study with a demonstration on concrete open girder is investigated for the well-known linear models and the commonly used Markov deterioration model. The results show that the Markov model can produce more reasonable prediction than the linear model when presented with short time inspection data. Furthermore, preparation of valid data is also important to ensuring accurate and sensible prediction from deterioration models. This study also shows that the issue of first inspection has significant impact on predictive outcomes and thus should be carefully considered in preparation of valid data.

1 INTRODUCTION

1.1 *Background*

Bridges are important infrastructure assets because they have intensive capital investment, and play a crucial role in transportation network for ensuring well being of population. After many years of service, bridge structures are aging and deteriorating, which become hazard to traffic users in the event of structure failures or falling apart. Because bridge structures are public assets, the asset management of bridge structures requires not only ensuring safe and serviceability throughout their service life but also cost-effective maintenance, rehabilitation and replacement program (MRR).

It has been a common practice that bridge structures are routinely inspected to detect damages and defects before repair, rehabilitation and replacement can be carried out. The inspection intervals and detail levels of inspections are varied among bridge management agencies. The norms are 3 levels of inspection with level 1 of screening with interval 3-6 months, level 2 of visual detail with interval 2-3 years and level 3 of in-depth for specific cases.

It has been increasingly recognized that deterioration models of bridge structures provide useful information of deterioration rate and prediction of future condition of bridge structures. Such information is important for asset management of bridges structures in terms of timely and cost-effective inspection and maintenance program, and reliability analysis for prioritization and long-term management.

Intensive industry surveys (Ryan T. W. et al, 2012, Principal Bridge Engineers, 2014) and research works (Moomen, 2016, Goyal, 2015, Jamali et al., 2013) have been carried out to understand the cause of deterioration, contributing factors and to model the deterioration process for current and future prediction. In brief, summary points are as follows:

The cause of deterioration is specific to material of bridge structures. For example, fatigue is often with steel and creep is often with concrete.

Contributing factors to deterioration include traffic volume, exposure to corrosive soil and air and so on.

Deterioration process can be single or combined processes such as stress corrosion cracking in steel

and coupled with random damage events such as flooding and earthquake.

Deterioration models are divided into knowledge-based, data-driven and mechanism-based models. Few bridge management agencies use knowledge and experience to determine future deterioration from inspected defects (Safia et al., 2013). The data-driven models use the inspection data to predict the future deterioration (Agrawal et al., 2010, Bu, 2013, Edirisinghe et al., 2013). The mechanism-based model is based on deterioration mechanisms such as corrosion of reinforcing steels (Jamali et al., 2013, Lu et al., 2011).

1.2 *Aims and Objectives*

This study aims to compare the predictive deterioration between the deterministic linear and the stochastic Markov models, which are data-driven deterioration models. The deterministic linear model is well known for its ease of use and implementation. However, it is criticized for failure to capture the uncertainty of deterioration process, which can be addressed by the stochastic Markov model. The data-drive model is chosen over the physical model because it is attempted to utilize the level 2 inspection data, which are available and supplied by VicRoads, a bridge management agency in Australia through a collaborative research project on bridge deterioration modelling. The physical models are considered more advanced and accurate but they require intensive and detailed data that are costly and difficult to obtain. Therefore, they are not selected in this study.

The objectives of this study are:

i. To describe the level 2 inspection data of the case study with VicRoads, that are used for the deterioration models
ii. To present how valid data are compiled for deterioration models
iii. To compare the predictive deterioration between the linear and Markov models.

2 DESCRIPTION OF CASE STUDY

2.1 *Overview*

VicRoads is the registered business name of the Roads Corporation in Victoria State of Australia (www.vicroads.com.au). It is a Victorian statutory authority established under the Transport Act 1983 and continued in the Transport Integration Act 2010. One of VicRoads' core services is to plan, develop and manage the arterial road network, including roads, bridges, culverts, traffic signs and so on.

The bridge management of VicRoads is supported through its RAS, which is a computerized and web-based 2D database. RAS contains basic data of 6207 structures including bridges, culverts and tunnel with their attributes such as number of spans, length and width. The oldest structure was built in 1899. RAS also stores 261324 records of level 2 inspections as of 2017. The first recorded inspection was 1995.

The VicRoads's inspection practice is published in open-access inspection manual (Principal Bridge Engineers, 2014), which basically has 3 levels of inspection. Level 1 inspection is considered a screening inspection with maximum interval of 6 months. The level 2 inspection is a routine inspection with typical interval of 2 years and level 3 is an in-depth inspection for special cases.

A 2-year collaborative research project between VicRoads and RMIT University has been established to develop deterioration models using level 2 inspection data for bridge structures. The outcomes of this project could provide justifying for future state funding of bridge management and also provide support for more effective and efficient asset management program.

2.2 *Level 2 Inspection data*

The VicRoads' inspection manual describes the breakdown of bridge structures into superstructures and substructures and into structure elements such as piles, decks and bearings. Each bridge element is coded by their function and one of 5 types of material (i.e. timber, steel, prestressed, concrete and others). For example, the 2C mean open girder/stringer with concrete material.

The level 2 inspection provides condition rating for individual elements based on their inspected defects as per inspection guidelines. The condition rating is a 1-4 scale with one being good and 4 being worst. The condition state percentage distribution is used to provide inspection reports. For example, an inspection report of [90% 10% 0% 0%] of 2C means 90% of the open girders is in condition 1, 10% in condition 2 and 0% in condition 3 and 4. Some key notes of inspection are:

Widening section of structure is treated as a separate structure. This means the same structure ID will have separate structures known as N (original), L (left widening) or R (right widening) with corresponding inspection records.

The inspection report also indicates location of defects and quantity but not in a consistent and standardized format.

3 COMPILATION OF VALID DATA

3.1 *Missing data*

For bridge structures, 639 out of 6207 structures have missing built year, which are then removed from valid pool of data for deterioration model.

For inspection records, 6827 out of 261324 inspection records have missing widening data (i.e. N, L or R are not specified), which then removed from the valid pool of data.

The valid pool of data then contains 5568 structures and 246997 inspection records.

3.2 *Bridge widening*

It has been found that the widening of bridge was carried out for many bridges, noting that additional new structures are often added to support the widening section but the material of new structures need not be the same with the existing structures. Therefore, the widening sections are treated as separate structures to the original bridge structures but both are operated in the same working environments. However, the construction year of widening is not recorded in RAS and thus the result of first inspection cannot be used to compare with the constructed year but can be used to compare with the subsequent inspections.

3.3 *Inspection twice*

It has been found that 2 inspection records by different inspectors are reported for the same year. For example, the 2C open girder was found to have 87 inspection-twice out of 757 inspection records. It is decided to remove one of two inspections from the valid pool of data.

3.4 *Condition improvement*

It has been found that condition of elements is improved at the second or else inspections after the first inspection. Some improvements are [60% 40% 0% 0%] at 1999 became [90% 0% 10% 0%] in 2002. This is unacceptable because percentage in condition 1 cannot be increased unless maintenance was conducted. There are 160 condition improvement out of 757 inspections.

It is decided to remove inspections with condition improvement from the valid pool of data. However, the subsequent inspection is still kept and the inspection with condition improvement becomes the new reference year.

3.5 *Abnormal condition distribution*

It has been found that a small portion of inspection records show abnormal condition distribution. One abnormal example is [90% 0% 0% 10%] because for the same structure elements under the same working environments, it seems abnormal to have such a significance difference in the deterioration. However, there are only 8 such cases out of 757 inspection records of 2C (for example).

It is decided to remove such abnormal cases of inspections from the valid pool of data.

3.6 *First inspection*

The average built year is 1972 with standard deviation of 21 years. However, the first recorded inspection year was 1995. It is not sure whether any maintenance action had been conducted from built year until first inspection record. Taking example of the 2C open girder, it has been found that there are 239 first inspections out of 757 inspections and 144 out of 239 cases shows 100% in condition 1.

Another study (Ackah 2016) has found the similar issue. One solution is to use a 5-10 years difference form the first inspection records as acceptable built year. To ensure reliable data, the effect of first inspection records on the outcome of deterioration modeling will be investigated in this study.

3.7 *Repeat inspection*

It has been found that repeat inspections occur from the first inspection until 2017. However, the inspection intervals are not consistent even for the same structure. To utilize the repeat inspection, the following assumptions are used:

i. Deterioration is treated over unit time of 1 year and therefore different inspection intervals are not an issue.
ii. Repeat inspections that show unchanged condition 1 are treated as one inspection record from the start of inspection until the last inspection. This would increase the time stay in condition 1, a critical concern that was found in a published study and will be explained later in this study. For example, a series of repeat inspection at 1999, 2001, 2003 and 2005 showing unchanged condition 1. This series would become one inspection record between 1999 and 2005 showing time of 6 years staying in condition 1 instead of 3 inspection records with 2 years staying in condition 1.

3.8 *Unchanged condition*

It has been found that unchanged condition occurs at inspection and mostly at condition 1. For example, the condition is still 1 at inspection in 1999 and then 2002. From deterioration process point of view, if the rate of deterioration is very slow, it can be assumed to be constant because visual inspection could not identify such small changes. The unchanged condition is not suitable for deterioration models such as linear regression and Gamm process models that require strictly increasing deterioration. This issue is investigated in this study.

4 DETERIORATION MODELS

4.1 *Linear regression model*

Equation 1 shows the linear relation between bridge condition (output) with age (input factors) (Agrawal et al., 2010). More input factors can be added into Equation 1 in a similar manner.

$$Y=a_0 + a_1 * age + \varepsilon \quad (1)$$

where a_0 is constant coefficient, a_1 is slope coefficients of age (year) and ε is measurement error assumed to have zero mean and independent constant variance.

The interpretation of Equation 1 is that a) for the case of one input and one output, the relation is a straight line; b) for the case of two and more inputs, the relation is a plane and hyper-plane; c) the linear relation means constant deterioration rate over time; d) measurement error means that for the same values of inputs, every time the output is measured or assessed, the output value might not be the same due to equipment sensitivity or human subjectivity; e) deterioration is increasing with age, meaning unchanged condition is not valid.

For calibrating or estimating the model coefficients, the least square method is often used to minimize the error term between the observed output and model output.

The predictive performance of the linear model is often assessed using the coefficient of determination R^2 between observed values and model outputs.

4.2 *Markov model*

The Markov model is based on the stochastic theory of Markov chain (Madanat et al., 1995), which describes a system that can be in one of several condition states at any time, and it can stay still or move to another state at each time step with some transition probabilities. This theory is well suited for observation of level 2 condition data of bridge elements because the snapshot inspection reveals the condition state at the time of inspection and the unchanged and changed condition states over time can be captured with the transition probabilities.

The most important property of the Markov chain is that the probability of movement depends only on the current condition regardless of the history of movement, called memoryless property. This means that a) the currently known condition can represent for the accumulated deterioration up to the current time and b) the future condition does not depend on how long it stays in previous conditions. This property is well suited for long life assets such as concrete. In the opposite is usage-based assets such as light bulbs and machineries in which their future condition depends on how long they have been used in the past.

The Markov model is mathematically expressed as a matrix M of transition probabilities:

$$M = \begin{bmatrix} P_{11} & P_{12} & P_{13} & P_{14} \\ P_{21} & P_{22} & P_{23} & P_{24} \\ P_{31} & P_{32} & P_{33} & P_{34} \\ P_{41} & P_{42} & P_{43} & P_{44} \end{bmatrix} \quad (2)$$

where P_{ij} is the probability of moving from a condition state i to a condition state j over a unit time step. In this study, P_{ij} is assumed zero if i>j meaning improved condition is not modeled due to lack of maintenance data.

The memoryless property and the theory of total probability can be used to predict the probability vector $[P_1\ P_2\ P_3\ P_4]$ at any future time T, given the known current condition with certainty or probabilities $[C_1\ C_2\ C_3\ C_4]$ as shown in the Chapman-Kolmogorov Equation:

$$[P_1\ P_2\ P_3\ P_4] = [C_1\ C_2\ C_3\ C_4] * M^T \quad (3)$$

Equation 3 is a matrix multiplication of current condition with the transition matrix powered to future time T. To utilize Equation 3, the transition matrix M of Equation 2 needs to be estimated. Among several calibration/estimation techniques, this study uses the proven Bayesian Markov chain Monte Carlo simulation technique (Micevski et al., 2002) to estimate the transition matrix M of the Markov model. In brief, the Bayesian technique transforms the unknown elements Pij of the transition matrix M into a multivariate distribution by using observed data, Equation 3 and the Bayesian theory. The Markov chain Monte Carlo simulation is then used to generate sampling data of the elements, which become the estimator of the unknown elements. The details can be referred to Micevski et al. (2002).

The predictive performance of the Markov model is commonly validated using the Chi-square test on a separate dataset that is not used in the calibration of the Markov model (Micevski et al., 2002). The validation dataset is often randomly selected from 15-20% of the entire dataset.

5 RESULTS

The deterioration models in Section 4 are applied to the case study and the results are demonstrated for the concrete open girder 2C.

5.1 *Effect of first inspection*

To investigate the effect of first inspection, the dataset of all inspection is compared against the dataset of second up inspection (i.e. first inspection data is removed) in both linear and Markov models.

Table 1 show that the Markov model passes the fitness test for both datasets. The negative values for R^2 of the linear model on both datasets indicate the poor fitness of linear model and the linear model should not be used.

Table 1. Results of fitness test for Markov and linear models for percentage prediction on condition 1.

Data	Markov model	Linear model
	Chi-Square test	R^2 Value
All Inspection data	55.8<85.9	-0.544
Second up inspection data	7.8<67.5	-0.247

The calibrated transition matrix for old bridge is shown as a demonstration in equation 4 and 5 for all-inspection and second-up inspection.

$$M(all) = \begin{bmatrix} 0.9934 & 0.0052 & 0.0008 & 0.0006 \\ 0 & 0.9984 & 0.0009 & 0.0007 \\ 0 & 0 & 0.9972 & 0.0028 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (4)$$

$$M(second) = \begin{bmatrix} 0.9894 & 0.0082 & 0.0018 & 0.0006 \\ 0 & 0.9889 & 0.0104 & 0.0007 \\ 0 & 0 & 0.9991 & 0.0009 \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (5)$$

Despite the unacceptable fitness of linear models, Figures 1 and 2 can still be used to illustrate the significant effect of first inspection. This effect shows that linear model is sensitive to the range of calibration data. In Figure 1, the observed data cover a wide range of age up to 100 years and thus the prediction make more reasonable sense as compared to Figure 2.

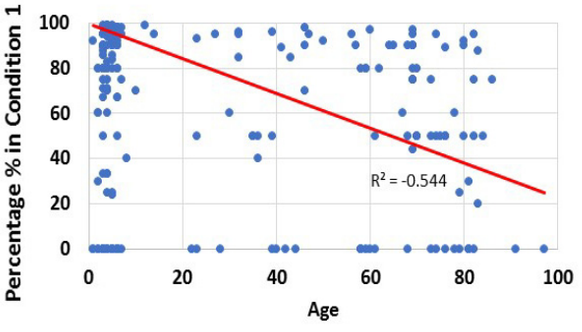

Figure 1. Linear model fitted with all inspection data for percentage in condition 1

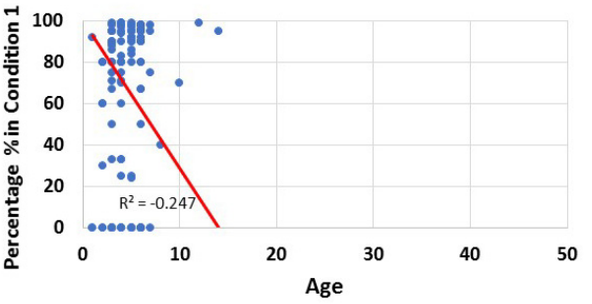

Figure 2. Linear model fitted with second up inspection data (first inspection removed) for percentage in condition 1.

Figures 3 and 4 show the effect of first inspection on Markov model. It appears that the removal of first inspection makes the deterioration faster. For example, at the age of 100 years, the percentages in condition 1are 45% and 18% and 20% and 30% in condition 4 for all-inspection and second-up inspection respectively,

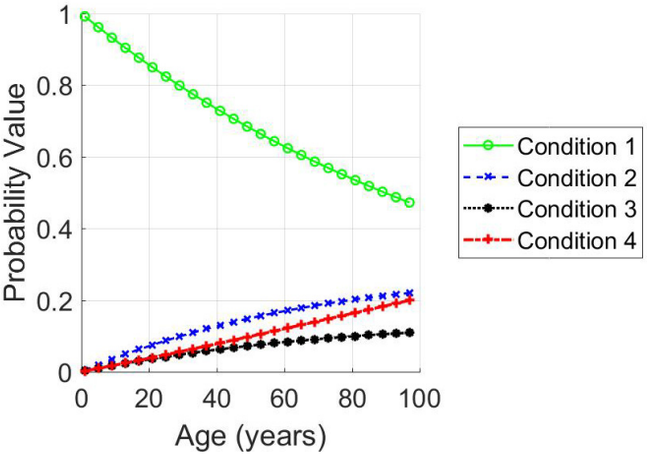

Figure 3. Markov model on all inspection data.

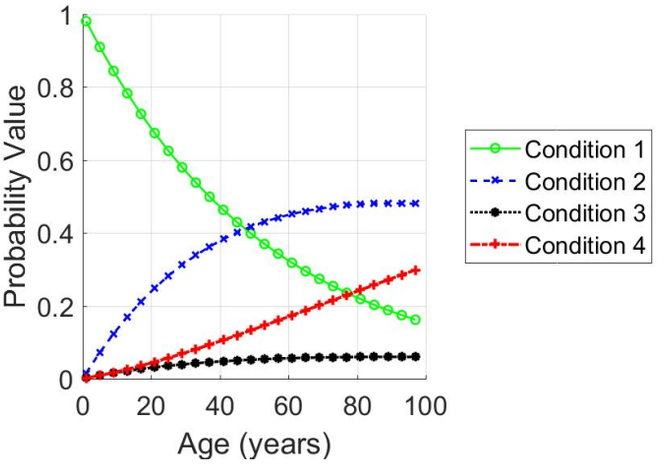

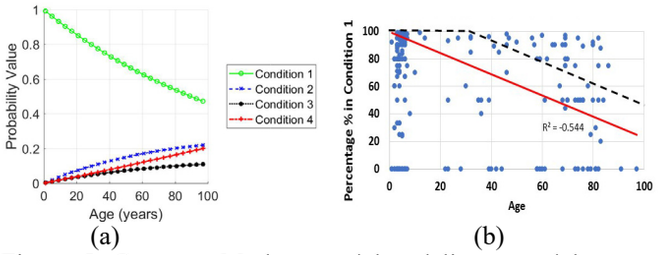

Figure 4. Markov model on second up inspection (i.e. first inspection removed)

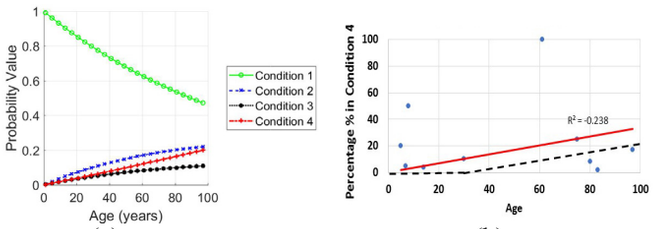
5.2 *Effect of unchanged condition one*



To study the effect of unchanged condition 1 on linear model, the unchanged condition 1, which is removed from the calibration dataset of the linear model, is used to calculate the average time staying in condition 1. The revised linear model as shown with dash line of Figure 5b has 2 segments. The first segment is horizontal line, representing for the time staying in condition 1, which is calculated as 31 years. The second segment is the deterioration line, which is similar to the calibrated shown in Figure 1. Figure 5a is the replot of Figure 3 for ease of comparison.

It can be seen from Figure 5a and 5b that the revised linear model is quite similar to the condition 1 of the Markov model. The concept of 2-segment linear model is further applied to condition 4 as shown in Figure 6, which also shows the similarity between Markov model and 2-segment linear model.

(a) (b)

Figure 5. Compare Markov model and linear model on percentage in condition 1 for all inspection data

(a) (b)

Figure 6. Compare Markov model and linear model on percentage in condition 4 for all inspection data

5.3 *Model comparison*

The Markov model passes the fitness test while the linear model fails as shown in Table 1. The poor fitness of the linear model can be seen in Figure 1 where observed data have high uncertainty as shown with the un-patterned scattering. Instead of trying to fit an impossible line through the observed percentage in condition 1 with age, the Markov model takes a different approach by capturing the percentage changes between condition states. Furthermore, the Markov model and the 2-segment linear model have similar rate of deterioration as shown in Figures 5 and 6. However, for the case of removing first inspection, the linear model shows much faster rate of deterioration than that of the Markov model. This highlights another shortfall of linear model when range of observed data is unable to cover the range of prediction. This also shows the good generality of Markov model in such cases.

6 DISCUSSION

This study is limited to the case of concrete material with a demonstration on open girder 2C. However, the methodology can be extended to all bridge elements with different material.

The effect of contributing factors such as traffic volume and exposure condition will be investigated in further studies.

This study shows the weakness of the linear model and thereby supports the use of stochastic Markov model in modelling deterioration of bridge elements.

Despite the advantage, the Markov model still shows deterioration in the first few years. This is considered unrealistic as found in a previous study (Sobanjo and Thompson, 2011). The previous study claimed that the new structures are expected to stay in condition 1 for the first 10-30 years before transitioning into deteriorated conditions. If all structures follow this pattern then Markov model should be applied to the data after transition start. If some new structures start to move to condition 2 after few years due to unknown causes such as uncertainty of material batch, inconsistent construction practice or damage event, then the Markov model can reflect that. Therefore, it is not the shortfall of the Markov model but how valid data is compiled for the deterioration models.

The comparison between Markov model and other stochastic models such as Gamma process model (Edirisinghe et al., 2013) will be conducted in further works.

7 CONCLUSION

Deterioration models can significantly improve the efficiency of asset management of bridge networks. This study presents a methodology of preparing valid data for deterioration model. This is an important step that is often overlooked and results in poor prediction.

This study also compares the deterministic linear model against the stochastic Markov model. The demonstration on a concrete open girder shows that the Markov model is more suited than the linear model.

Further investigations will be conducted to study the effect of contributing factors, and to compare against other stochastic models.

Quality Specifications for Roadway Bridges in Europe

Joan R. Casas
UPC-BarcelonaTech, Barcelona, Spain

Jose C. Matos
ISISE, University of Minho, Guimaraes, Portugal

ABSTRACT: In Europe, there is a large disparity from country to country regarding the way performance indicators are quantified and goals and quality controls specified. The main objective of COST Action TU-1406 is to establish quality specifications for roadway bridges that could be accepted on a European basis. The application of these common specifications will be highly dependent on the changes in philosophy and operational methods (inspection, testing,…) that the new specifications will require in the future as a result of their implementation. Therefore, to reduce to a minimum the possible reluctance of operators to change the actual performance indicators and the methods to obtain them and also to take advantage of the existing background and knowledge and the data-bases available after a lot of years of use, it is mandatory that the new homogenized quality specifications proposed as result of the Action are based on the actual practice.

1 INTRODUCTION

In the past few years, significant worldwide research has been done regarding condition assessment of roadway bridges. Obtained values from visual inspection or non-destructive testing, which provide information regarding the assessed bridge condition state, are compared with previously established goals. As a result, there are currently several methodologies to assess the bridge condition. More recently, the concept of performance indicators (PI) was introduced, simplifying the communication between consultants, operators and owners. However, large deviations continue to exist on how these indicators are defined and obtained and, therefore specificactions are required for a standardization of this procedure. For a standardized procedure, for example, quality control plans (QCP) are further important instruments which are based on the previously mentioned PIs and pre- specified PI-goals. However, these performance goals are difficult to obtain, as they are highly subjective as they reflect the user and societal requirements. Recently, COST Action TU1406 emerged with the main ambition of developing a guideline for the establishment of QCPs in roadway bridges in Europe, by integrating the most recent knowledge on performance assessment procedures with the adoption of specific goals (Casas, 2016a,b, Matos, Casas, & Fernandes, 2016). This guideline will focus on bridge maintenance and life-cycle performance at two levels: (i) performance indicators (PIs), (ii) performance goals (PG). The primary goal is, among others, to update and adapt existing PI tables to guarantee a state-of-the-art PI based bridge assessment technology in Europe. Performance indicators related to sustainability will also find place in such new assessment standards. By developing new approaches to quantify and assess bridge performance, as well as quality specifications to assure expected performance levels, it is expected that bridge management strategies will be significantly improved and homogeneized all across Europe, enhancing asset management of aging structures in Europe.

The main challenges in the development of a quality control plan for highway bridges are the following:

- Quality assurance and control is important in all industrial fields and construction industry is no exception. Bridge management is a part of construction industry activities that ensures that the bridge attains the desired service life and quality level.

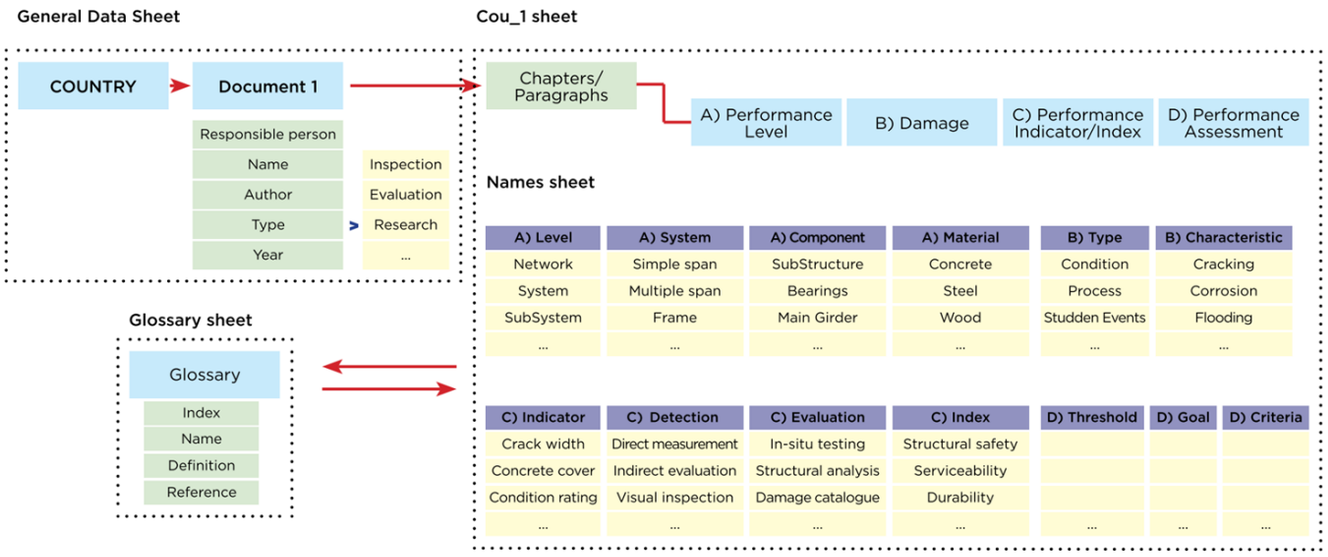

Figure 1. Structure of the Performance indicators database for the survey process

- Important parts of any BMS are quality assurance and control plans that must provide the basis for quality data acquisition and processing. Reliable data related to the condition of the structures is essential for all further processes, however ensuring continuously the quality of this data is a demanding task, as the data acquisition is mainly based on periodic visual inspections. Data processing and decision models, on the other hand, are dependent on preselected criteria and decision methods. A well-designed decision model will yield reliable result through the lifetime of its use.
- The third component of quality assurance and control in bridge management is maintenance planning. Bridges differ in size, condition, structural design, materials used etc., therefore these specific features need to be acknowledged in the maintenance plans. Designing unique plan for every bridge is irrational and designing a general plan for all bridges impossible. Additionally, optimizing maintenance for individual bridge may worsen optimization on the network level and viceversa. A compromise has to be made in order to implement a quality plan successfully into practice.

2 COST ACTION-TU1406

Infrastructure managers are facing now conflicting requirements to improve the availability and serviceability of aging infrastructure, while the maintenance planning is constrained by budget restrictions.

Many research efforts are ongoing, for the last few decades, ranging from development of bridge management system, optimization models, life cycle cost analysis, to big data analysis and implementation of artificial intelligence models into decision support tools. Since transport infrastructure is presenting crucial factor for the economy and societal development, it is not only subject to technical requirements,
but it is also required to keep up with societal and economic requirements.

Therefore, bridge maintenance planning should accommodate multiple performance goals (PGs) which need to be quantified by various performance indicators (PIs) and key performance indicators (KPIs)

Through WG1 activities, the development of a PIs database had been defined as an essential component of COST TU1406. The preliminary works developed into the working group indicated that an extended systematic screening on practical national inspection and evaluation documents was necessary in order to obtain a consistent and conclusive information associated with PIs, PGs and performance thresholds (PTs) from each COST partner country.

The core of the survey process for obtaining PIs and corresponding key performance indicators (KPI) is given in Figure 1. The two COST nominated persons per country, together with the infrastructure operators and owners chose beforehand the relevant documents (e.g. inspection, evaluation, research etc.) from which the PIs, and related information were extracted. A user interface (UI) served for a systemized data collection and it also allowed a relative flexible treatment of the number of data sets and PIs (unrestricted data input), which of course varies a lot from one to the other document.

The results of the screening process that involved a total of 36 countries, were partly heterogeneous and with a number of overlapping terms. This mainly results from a free interpretation leeway and different know-how of experts in visual inspections, performance evaluation, performance assessment and decision making in the participating countries. The previously sketched data collection process resulted in a list of more than 700 terms that were considered as related to performance indicators according to the inspection and assessment documents, which was later clustered and homogenized. The screening results were used for a homogenization process by the WG1 core group and the nominated persons from each country were asked again to verify their performance and damage specific inputs, by comparing them with the homogenized and categorized terms. These homogenized data were the baseline for all further studies and quantifications and provide also the basis for an effective comparison of performance quantities between countries.

From this process resulted a shorter list of 385 terms, grouped in 11 clusters from defects to rating and loads. The list was considered, not as a final list of PIs, but as a list of terms that can be related with PIs (PI related terms as addressed in WG1 Report). Assuming that not all the 385 terms can be considered as PIs as this high number will make the objective of the Action unpractical, a new practical based categorization of the terms had been performed. The following four categories of terms were considered: performance indicators (PIs), damage processes (DPs), observations (OBS) and other data (OD). A fifth category was considered, related with non-interceptable processes, once they are out of the scope of this group. The sixth category considered was labelled as Combined Performance Indicator, trying to cluster terms that reflect general properties of a structure and may be derived, among other ways, from the combination of several PIs. As an example, the term bridge condition was considered in this category since one can assume that it can be derived from all the other PIs. (Amado & Hajdin, 2017; Strauss et al., 2016). The distribution of the 385 PIs related terms through the 8 categories above defined is shown in Table 1 (Amado & Hajdin, 2017). The complete categorization of terms can be found in the COST TU1406 WG1 report.

In order to move on with the reduction of the list of PIs, an expert group was asked to specify PIs according to the following points: Measurable? Quantifiable? Target value available? Valid for ranking? Allow decision with economic implications?. These questions are based on the definition of performance indicator that was agreed within the COST Action: performance indicator is a measurable and quantifiable parameter, related to the bridge performance, that can be directly compared with a target measure of a performance goal (absolute measure of performance) or can be used for ranking purposes, among a bridge population (relative measure of performance), in the framework of a Quality Control Plan or life-cycle management (decisions and actions involving economic resources)

Table 1. Distribution of the 385 PI related terms through 8 different categories

Categories	Number of PI related Terms
Performance Indicator	17
Performance Indicator-Redundant	7
Damage Process	27
Damage Process - Redundant	13
Observation	245
Other Data	33
Non-Interceptable Processes	16
Combined PI	27
Total	385

In order to assess performance goals, Key Performance Indicators (KPIs) need to be defined, at strategic and tactical level. Those KPIs are determined from a number of PIs collected at an operational level. For the purpose of this Action, the PIs are determined at at the bridge element level.

At the end, approximately 100 extricated PIs are further related with one or more of the key performance indicators (KPIs) defined in Working Group 2 (WG2): reliability (R), availability (A), maintainability (M), safety (S), security (Se), environment (E), costs (C), health (H), politics (P), rating/inspection (I). A further process is required for categorization of PIs in relation to PGs and PTs at different levels: component (CL), system (SL), network (NL); taking into account different aspects: technical (Tech), sustainability (Sust) and socio-economic (SoEc).

The screening process and the expert questionnaire made it possible to assign the performance indicators to component (CL), system (SL) and network level (NL), and to assign the PIs to the spider tails or KPIs, as presented in Figure 2. The assignment shown in the figure refers to five selected countries (Austria, Chile, Croatia, Portugal and Spain). This information is available in a similar form for the other countries in the WG1 Report. Figure 2 shows the spider diagram indicating the KPIs and the country specific assigned PIs obtained from the expert analyses as presented above. The green areas in Figure 2 represent the most favorable rate and the red areas should alarm the bridge operator and require immediate intervention.

As some times they could be contradictory (increasing of safety also derives in increase of cost, for instance), bridge performance goals should be set as a multi-objective system, taking into account different

aspects of bridge and network performance. The basis of the approach is the work developed so far in the Netherlands. Netherlands' Rijkswaterstaat (RWS) has developed RAMS SHEEP concept, which additionally to RAMS (Reliability, Availability, Maintainability and Safety) defines the following aspects: Security, Health, Environment, Economics and Politics [7], where each criterion is defined as follows:

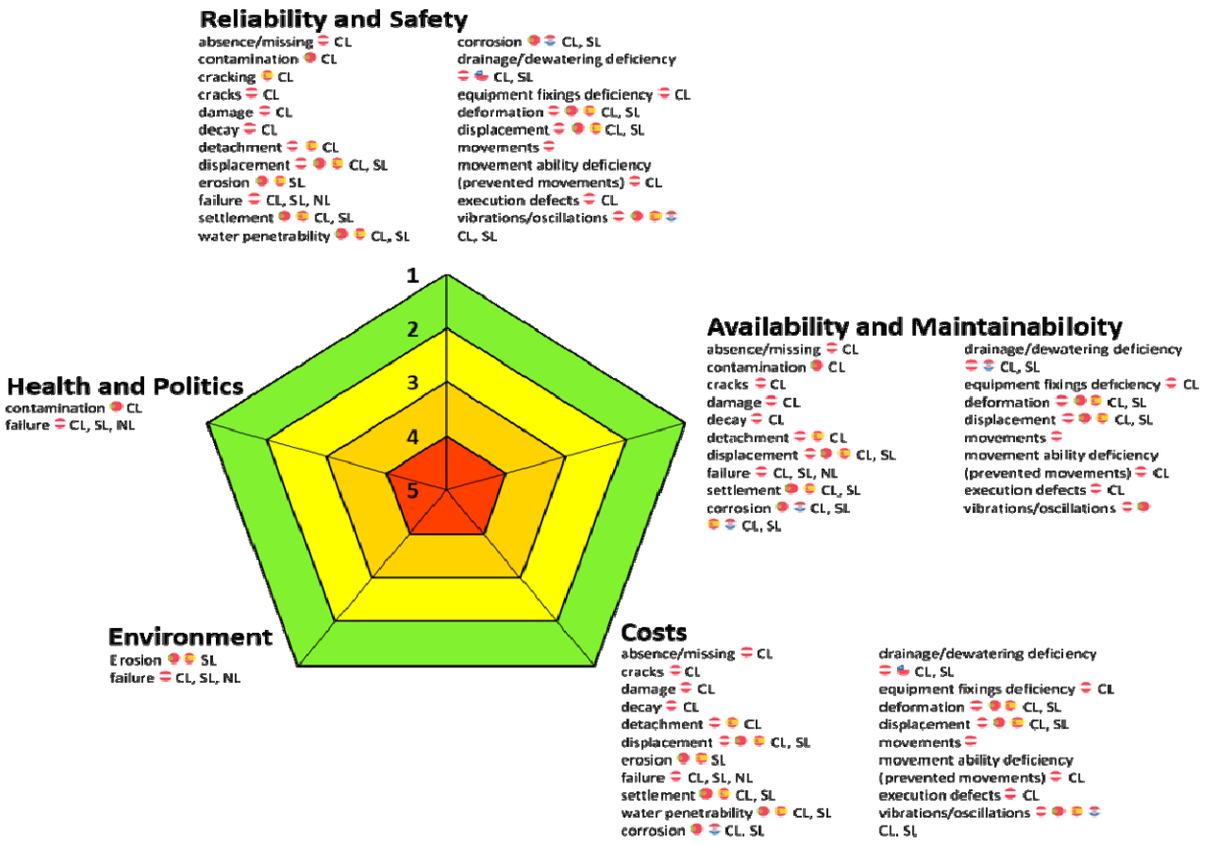

Figure 2. The spider diagram indicating the KPIs and the country specific assigned PIs and/or observations and damages.

- Security: related to the safety of a system regarding to vandalism and unreasonable human behavior.
- Health: being related to physically, mentally and socially defined aspects.
- Environment: concerns the physical environment requirements
- Economics: regarding the relationship between cost and value.
- Politics: concerning political-administrative and social requirements.

In Figure 3, the process of the multiple performance goals assessment is presented, also showing the transition from a system to the network level.

In order to get the optimum quality control plan, Multi-criteria decision-making (MCDM) provides a systematic approach to combine these inputs with benefit/ cost information and decision-maker or stakeholder views to rank the alternatives. MCDM is used to identify and quantify decision-maker and stakeholder considerations about various (mostly) non-monetary factors in order to compare alternative courses of action. Hierarchy structure for linking multi-objective bridge performance goals, covering most of the previously mentioned aspects with performance indicators is required. Possible result of multi-criteria assessment of different bridge maintenance alternatives represented in a spider diagram as in Figure 2 can be finally used for a decision making about the optimal maintenance or design solution.

Alternatively, the multiple performance criteria can be combined into a so-called utility function, in which all the criteria are brought into a single scale. In order to transform the various out into a single (mostly monetary) scale it is necessary to establish weight factor for the individual types of criteria.

Some of the weight factors are available in some countries (for example weight factor for traffic delays, noise, injuries etc.), depending on the selection of criteria, some weight factor may still need to be developed. In the development of the weight factors the starting point can be taken in the qualitative approach mentioned above, from which the apparent relative weight can be deducted

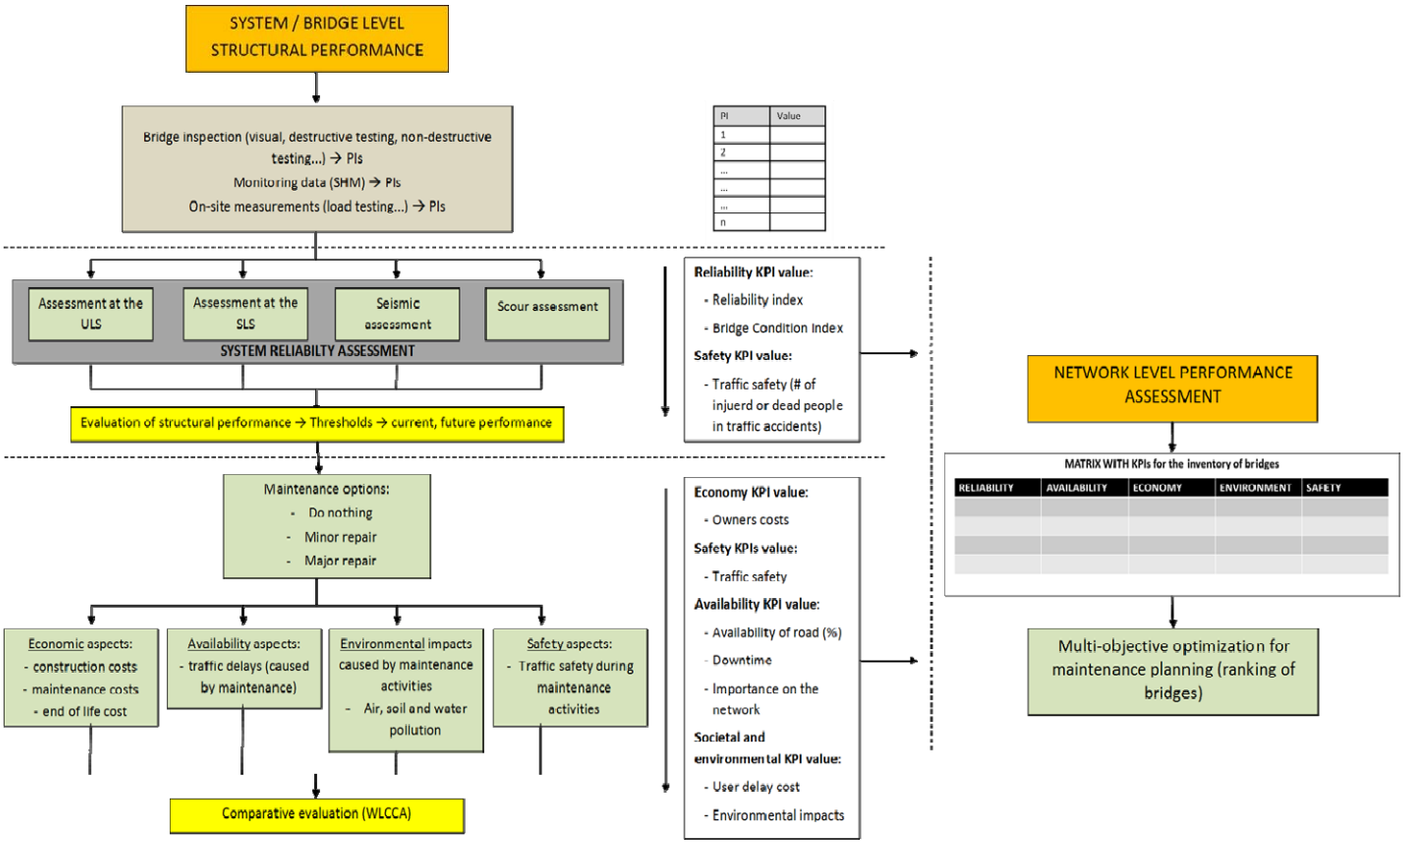

Figure 3. Overview of the process for performance goals assessment and transition from system to network level

Once the possible outcomes have been brought to a single scale, the best decision can be found as a formal optimized decision process, in which option with the maximum "utility" shall be selected as the recommended decision.

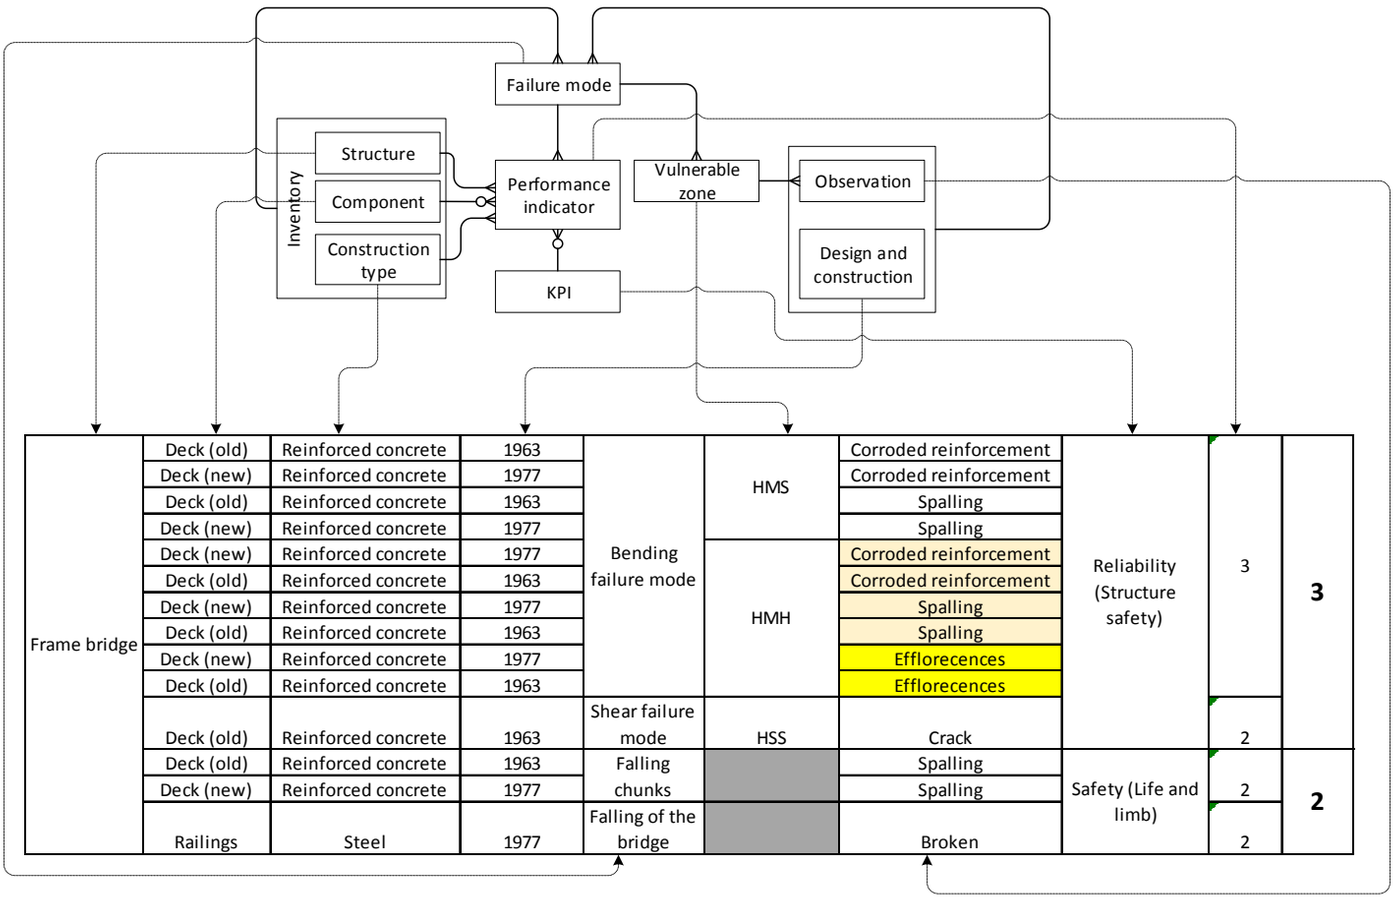
Utility theory provides a measure of preferences of a decision maker over a group of alternatives (Ishizaka, Nemery 2013). Based on the six axioms of utility theory, Multi-attribute utility theory (MAUT) is introduced by (Keeney, Raifa 1993). MAUT provides a systematic approach to reduce the qualitative values of various attributes (i.e. performance indicators) into utility functions. The obtained utility scores are then aggregated based on the relative importance of attributes. The final score assign a ranking to each alternative based on either minimization or maximization function. In other words, MAUT assigns the relative importance of performance indicators (e.g. condition, cost, etc.), while comparing number of bridges. These bridges are often referred as alternatives in MAUT.

MAUT involves the single decision maker who is willing to make certain trade-off among the performance goals while exposed with uncertainty and risk (Keeney, Raiffa 1993). The uncertainty is usually originated because of unavailable and dynamic nature of data, and involvement of number of stakeholders. For instance, in the bridge planning the exact estimation on number of users affected due to maintenance activity is difficult to define. MAUT integrates a body of mathematical utility models and a range of decision assessment methods in order to assist in decision ranking problem (Thevenot et al. 2006). The single attribute utility function is calculated for each performance aspect, which reflects the risk attitude of the decision maker.

In WG2 of TU1406 COST Action, a web-based tool was developed to apply the multi-objective optimization. The developed tool have implemented one of the method of MCDA namely Multi-Attribute Utility Theory (MAUT) by using the R Utility package (Reichert, Schuwirth, & Langhans, 2013). The tool as well as further information on the treatment of performance goals within the Action can be found in Stipanovic et al. 2017.

Finally, quality specifications or quality controls should be defined in WG3. The quality control framework includes the following goals:

- Reliability: including the probability of structural failure (structural safety) or operational failure (serviceability)
- Availability: the proportion of time a system is in a functioning condition. In our case is the additional travel time due to imposed traffic regime on the bridge
- Safety (not structural safety): minimize or eliminate the harm people during the service life of the bridge
- Economy: minimize life-cycle cost
- Sustainability: environmental friendliness



The quality control plan is divided in 2 groups:

- Static (snap shot) control: to inspect and investigate the bridge and determine whether the reliability (structural safety and serviceability) and the safety are met. This is the basis for the decision making on actions.
- Dynamic control: Based on the static control and including the plan and actions to execute in order to ensure the long term fulfillment of safety and serviceability goals. The goals to achieve are related to availability, economy and sustainability as it includes the feasible maintenance scenarios that define costs and availability over certain time frame by using reliability and safety forecasts.

Because the reliability goal should be checked against feasible failures, the practical application of the method has divided global group of bridges into the following bridge types: frame, arch, continuous beam, so for each type the most vulnerable zones can be identified and the corresponding performance indicators related to reliability observed and/or quantified. For instance, regarding a frame type bridge, the regions close to mid-span and supports will be those selected for a reliability analysis. This division also helps in the process of selecting the best maintenance policy. For instance, for the frame bridge shown in Figure 4, the corresponding flowchart and assigned values of reliability and safety based on the visual inspection is presented in Figure 5. The maximum value for both KPIs is 5. In this case, the values obtained are 3 for reliability and 2 for safety. The goals of availability, economics and sustainability are governed by maintenance scenarios. In fact, the snapshot assessment of availability and costs are of none or little interest. Therefore, the feasible maintenance scenarios (do nothing, preventive and corrective) are defined. Regarding availability indicator, each maintenance intervention requires certain traffic regime, which may include closure for certain type of vehicles or lane closure or narrower lanes. The normal traffic regime can be assigned with the maximum performance value. The other traffic regimes can be ranked by the additional travel time they cause for the road users. This additional travel time can be also monetized according to the guidelines given in the WG2 report. The selected intervention scenario is obtained based on the MAUT approach as previously explained. In WG2 report a case study showing a practical application to define the best maintenance scenario for a group of bridge (network level) is presented.

3 CONCLUSIONS

After an exhaustive analysis of the data obtained in the research carried out, it was concluded that different countries have different definitions of PIs and how they are obtained. Due to the existence of different interpretations, an additional clustering and homogenization process was required. From this procedure it was possible to verify that all countries have a PI, named condition index, condition rating or deterioration index, mainly obtained through visual inspections. Although in some cases this is the only existing PI used, there are countries, like Denmark or The Netherlands, in which operators and bridge owners are currently using other relevant indicators. In Denmark, concepts like remaining service life, robustness, safety index-reliability and vulnerability are addressed. On the other hand, in The Netherlands, the performance is evaluated by the RAMSSHEEP (reliability, availability, maintainability, safety, security, health, environment, economics and politics) approach, where risk is used to obtain
social, environmental, economic and political indicators.

How collecting PIs used across Europe was presented. The aim was to establish good practices on the definition of QCPs for roadway bridges. This should be the basis for the future proposal of the definition of PIs that could be adopted and used all over Europe.

The methodology is based on a deep analysis of the existing bridge management policies and available documents for inspection and evaluation existing in European countries and the main PIs used, with the objective to define a common group of quality specifications and control plans that can be assumed by all these countries. The gathered data from European countries was further analyzed and systematized.

As the focus on an efficient delivery of network performance increases, so does the interest in the relations between societal goals, performance indicators for both the road network and bridges or bridge elements. The implementation of asset management should increase the integration of network and bridge performance requirements. Network or even societal goals tend to be rather broad in their defini-

tion. Furthermore, there is often no exclusive relationship between performance indicators set at a lower level and goals at a higher level. An important notion is that in many countries, the main focus of bridge management is still the condition assessment of the particular objects or elements thereof.

The objective of the COST TU 1406 Action is to investigate the way bridge PIs and KPIs are collected and quantified, how performance goals are specified across Europe, and finally to produce guideline documents linking collection and quantification of PIs, KPIs, performance goals, standards, and practices to decision making processes. This paper shows an overview of performance goals at different levels, from high-level strategic decisions to low-level, system-specific requirements developed within the Action. The paper also explains how other performance aspects, like traffic safety, availability, economy, environmental and societal impacts could be quantified and used for the multi-objective bridge performance goals assessment. At the end, 5 performance goals and corresponding KPI´s were defined: Reliability, Availability, Safety, Economy and Sustainability and based on them, the Quality Control plans are defined. These, in turn, are divided into static (point in time) and dynamic (maintenance plans) control. In the current practice, in most countries, the condition state or the condition index is used as an unique KPI, instead of reliability and safety.

4 ACKNOWLEDGEMENTS

This article is based upon the work from COST Action TU-1406, Quality specifications for roadway bridges, standardization at a European level (BridgeSpec), supported by COST (European Cooperation in Science and Technology).

ABSTRACT: Across Europe, multiple management systems were developed with the aim of managing roadway bridges in an efficient manner. Although being generically similar, the condition assessment process, based in the assessment of performance indicators which are compared with performance goals in order to evaluate the accomplishment of established quality control plans, can be identified as one difference among them. This leads to the existence of multiple different methodologies for assessing the bridge condition, and consequently to a considerable variation in roadway bridges quality. COST Action TU1406 aims to achieve the European economic and societal needs by standardizing the condition assessment and maintenance level of roadway bridges. For such purpose it would be required to establish the specific recommendations for the quantification of performance indicators, the definition of standardized performance goals and, finally, a guideline for quality control plans.

Keywords: *performance indicator, performance goal, quality control plan, roadway bridge, asset management*

1 INTRODUCTION

In the past few years, significant worldwide research has been done regarding condition assessment of roadway bridges, specifically through the use of non-destructive tests, monitoring systems and visual inspection techniques. Obtained values, which provide information regarding the assessed bridge condition state, are then compared with previously established goals. As a result, there are currently several methodologies to assess the bridge condition. A similar problem was addressed with roadway pavements in the past. Although this was a worldwide problem, in Europe it was solved through COST Action 354 "Performance indicators for pavements' (COST 354, 2004). More recently, the concept of performance indicators (PI) was introduced, simplifying the communication between consultants, operators and owners. However, large deviations continue to exist on how these indicators are obtained and, therefore specific actions are required for a standardization of this procedure. For a standardized procedure, for example, quality control plans (QCP) are further important in-

struments which are based on the previously mentioned PIs and pre-specified PI-goals. However, these PI-goals are difficult to obtain, as they are highly subjective. A first very good generalized overview of the current methodologies to assess the bridge condition is given in the report by Hooks and Frangopol, (2013). In addition, bridge performance measures in relation to the goals of bridge projects is available in Adams and Kang (2009). As can be seen in Table 1 the authors listed a set of PIs, including a classification depending on the level of analysis: cross section (CS), component (CO) or/and system (SY). It should be mentioned, that the operators are already using some of these PIs intensively, while others are still in a conceptual phase. It is, however, endeavored that road authorities can collect experience as soon as possible with these indicators. An assistance to this process is provided by the publication of Ghosn et al. (2016), where he presents a complete and comprehensive description of available reliability-based PIs.

Recently, COST Action TU1406 emerged with the main ambition of developing a guideline for the establishment of QCPs in roadway bridges, by integrating the most recent knowledge on performance assessment procedures with the adoption of specific goals (Matos, 2016; Matos, Casas, & Fernandes, 2016). This guideline will focus on bridge maintenance and life-cycle performance at two levels: (i) performance indicators (PIs), (ii) performance goals (PG). The primary goal is, among others, to update and adapt existing PI tables to guarantee a state-of-the-art PI based bridge assessment technology in Europe. Performance indicators related to sustainability will also find place in such new assessment standards. By developing new approaches to quantify and assess bridge performance, as well as quality specifications to assure expected performance levels, it is expected that bridge management strategies will be significantly improved, enhancing asset management of aging structures in Europe. The target groups and end users who will exploit the outcome of the COST TU1406 action are: (i) public/private owners, as their assets will be maintained in an upscale level; (ii) operators, as standardized procedures for reducing maintenance costs, guaranteeing the same quality-level, will be introduced; (iii) design and consultant engineers, as the assessment of roadway bridges performance will be established in a uniform way, according to the developed guideline; (iv) equipment and software companies, as a new perspective will be given, regarding the most suitable equipment and software for the assessment of roadway bridges; (iv) academics, and researchers and engineers, as they will take an advantage of their involvement in the guideline preparation; (v) students, as they will benefit from COST tools (e.g. training schools) and from the contact with different stakeholders involved in this Action; (vi) relevant European, international and national associations, with which the main outcomes of this Action will be shared; and (vii) standardization bodies and code writers, which will benefit from the developed guideline. More details and backgrounds are discussed in Matos (2016) and Matos et al. (2016).

2 OBJECTIVES

Based on the previously outlined specifications to assure expected performance levels and to assure a significant improvement in bridge management strategies, the following objectives have been defined in the COST TU1406 action:

(1) to develop, for the first time in Europe, a guideline for the establishment of QC plans (QCPs) for roadway bridges at a European level. The Action aims to achieve the European economic and societal needs by standardizing the condition assessment and maintenance level of roadway bridges;

(2) to examine the possibility of incorporating new indicators related to sustainable performance of roadway bridges as well as research performance indicators PIs which are still in the process of definition.

(3) to establish detailed recommendations for assessing PIs, technical as well as sustainable, and for characterizing associated specific goals.

(4) the claim of a European PI database, which is associated with the following sub-tasks: (a) the systematization of available knowledge associated with existing QC plans for bridges at an European level and the characterization of associated PIs and PGs; (b) the exploration of the up-to-date knowledge on PIs, including technical, environmental, economic and social indicators; (c) the definition of quality specifications through the definition of performance goals PGs, quarantine a required performance level; (d) the development of detailed examples for practicing engineers on the assessment of PIs as well as

in the definition of PGs - these are to be integrated into a guideline; (e) the flexibility of the DB to incorporate present and future operational and research based PIs and PGs of the COST countries

For an efficient achievement of the above-defined objectives, a linear work process was defined, which is divided into the following work packages as presented by Casas (2016) and Matos et al. (2016): *WG1: "Performance indicators"*. The goal was to explore those PIs of bridge structures, in the course of international research cooperation, which capture the mechanical and technical properties and its degradation behavior, already partly covered by code specifications. Considerations also include: natural aging, quality of the material; service life design methods; sustainable indicators; environmental, economic and social based indicators, performance profiles. The final result is the implementation of a PI database for

Europe with flexibility to accommodate country-specific requirements. Further information on this WG can be found in Strauss and Ivanković (2016). Objectives of WG1 are therefore, among others, the characterization of bridge PIs, which can address: (a) the safety: the load factor, and the reliability index to ultimate limit state (ULS); (b) the serviceability: the condition index, and the reliability index to serviceability limit state (SLS); (c) the availability, and robustness; (d) the costs: the total life cycle costs (LCC), and values related to durability aspects; and (e) aspects of environmental efficiency: CO2 footprint; *WG2: "Performance goals"*. The objective was to provide an overview of existing PGs for the indicators previously identified in WG1, and to develop technical recommendations which will specify the PGs. These goals will vary according to technical, environmental, economic and social factors. Further information on this WG can be found in Stipanovic and Klanker (2016); *WG3: "Quality Control Plans"*. Bridge quality control (QC) is actually restricted to the design and construction phases and are achieved by complying with existing design code requirements. When it comes to existing bridges, despite the age, location or even the current condition state, QC is performed according to existing design codes or the owner/operator expertise. There is no uniform procedure to assess existing bridge state condition. Therefore, there is a real need to establish a guideline for performing the QCPs for existing bridges. This plan should be based on multilevel procedures, from simple visual inspections to in-depth investigations, and on the level of doubts with regard to bridge performance. It should also define at which time intervals QC is necessary, and which condition the more detailed investigations or corrective actions are necessary. Based on the results of WG1 and WG2, as well as on survey of existing approaches in practice, the objective of WG3 is to provide a methodology with detailed step-by-step explanations for the establishment of QCPs for different bridge types. The QCP has to establish PGs, which are user/society related, e.g.: traveling time; traffic allowance; safety level; comfort/serviceability; Further information on this WG can be found in Hajdin (2016).

3 SYSTEMATIZATION OF AVAILABLE KNOWLEDGE ABOUT PIS

3.1 *General*

In a first step, associated with the targets of WG1 to WG3, a technical survey among the COST TU1406 participating countries was carried out in order to clarify: (a) what is already being done around Europe in the field of bridge management strategies and performance based concepts; and b) what is considered necessary for enhancement. These surveys focused on guidelines, inspection documents, evaluation and assessment documents already in use by the infrastructure operators and documents from the research area.

Thus, the extracted PIs could already been categorized in PIs already in use, PIs on the way to be in use, and research based PIs. The surveys were made possible with the help of the networks created in the course of COST TU1406. These networks include people from different stakeholders (such as infrastructure operators, consultants and owners of infrastructure facilities, universities, institutions in the field of infrastructure facilities) and from various scientific disciplines (e.g. on-site testing, visual inspection, monitoring, structural engineering, structural analyses sustainability, etc.). The motivation for this first process step was based on the following very important findings: (a) The bridges performance is very good in most European countries and the infrastructure owners or operators are doing a very good work; (b) It is important to learn the stakeholders strategies in order to improve and enhance (if required) their procedures and rules; (c) The implementation of a common methodology across Europe, with flexibility to accommodate country-specific requirements, needs to know what is being done now. Too many changes will reluctance make bridge owners and operators reluctant to process the harmonized methodology in their daily work. In addition, the new harmonized methodology cannot be disregarded.

3.2 *First phase of the process of data collection*

As can be seen from Figure 1, a kind of closed questionnaire concerning predefined performance indicators PIs based on former characteristics and the country-specific situations was carried out in the first round. The following widely agreed PGs were used to define those PIs that where of interest for the survey and with respect to bridge management strategies: PIs in connection with (a) the safety, (b) the functionality (serviceable), (c) the availability (to the user), (d) the total life-cycle cost of bridges, and (e) the environmental impact. In particular following PIs where stressed: (I) Concerning the safety: the load factor, the safety factor, and the reliability index to ULS; (II) Concerning the serviceability: the condition index, and the reliability index to SLS; (III) Concerning the availability goal: robustness (the bridge should be minimally affected by external conditions not specifically foreseen during design), and resilience (the bridge should be quickly recovered from any undesired disruption); (IV) Concerning of being economically viable: the total life-cycle cost, and the durability aspects values (a more durable bridge will be an inexpensive bridge to maintain), such as the diffusivity coefficient of chlorides in concrete, and the permeability of concrete cover; (V) Concerning the goal of being environmentally friendly: CO2 footprint.

The first survey phase provides the following findings among others, which are also discussed in a more comprehensive way in Casas (2016) and Strauss et al. (2016). It was of high importance in this first survey phase (a) that the original documents were also made available (important passages marked in color) since different translations led to a very high number of e.g. management strategies or assessment methods, which proved to be not correct when inquiring and considering the original documents, and (b) to differentiate between the operational and the research-based documents in order to allow objective proposals for enhancements.

3.3 *Second phase of the process of data collection*

The COST TU1406 Geneva Workshop was held in September of 2015 to define further essential steps of the WG1 group. The goal was the clearer differentiation between the already applied concepts and documents and the research-based approach. Each WG member was asked to participate in the workshop, and (b) to prepare a poster or oral presentations with the following objectives: (1) Extract from the available documents in each country the most important (> 8) PIs; (2) show the formulation and the procedure on how to obtain the PI; (3) show the thresholds with respect to each PI, if available; (4) show the goals with respect to each PI, if available; (5) characterize, based on their experience, if the indicated or proposed PI are already applied by owners, operators, experts, …, and in which project phases; (6) characterize those groups that are important PI, but not applied now, or not applied now and needing further research in order to become fully implementable.

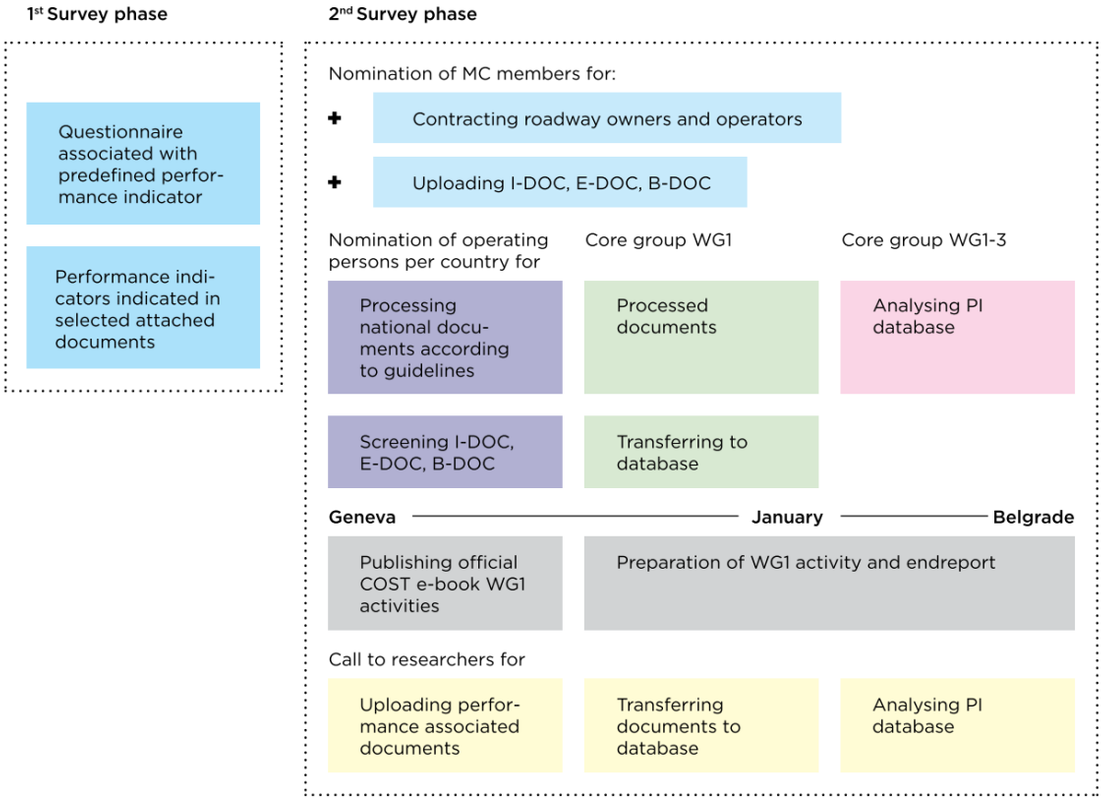

Figure 1. Technical survey on performance indicators

The workshop in Geneva indicated that an extended systematic screening on practical national inspection and evaluation documents is necessary in order to obtain a consistent and conclusive information associated with PIs, PGs and performance thresholds (PTs) from each COST partner country. Two responsible persons were nominated for each COST partner country, whereas the management committee (MC) member (1st person) had the responsibility to build up the contact to the infrastructure operators and owners in order to determine with them the afore mentioned relevant documents, and the 2nd nominated national expert (2nd person) had the responsibility to process the screening of the documents of its country and to fill up the PI-database, which is described in more detail in the next section.

3.4 *Performance indicators database for the survey process*

Through WG1 activities, the development of a PIs database had been defined as an essential component of COST TU1406. The core of the survey process for

obtaining PIs and corresponding key performance indicators (KPI) is given in Figure 2. As mentioned previously the two COST nominated persons together with the infrastructure operators and owners chose beforehand the relevant documents (e.g. inspection, evaluation, research etc.) from which the PIs, and related information were extracted. A user interface (UI) served for a systemized data collection and it also allowed a relative flexible treatment of the number of data sets and PIs (unrestricted data input), which of course varies from one to the other document very much.

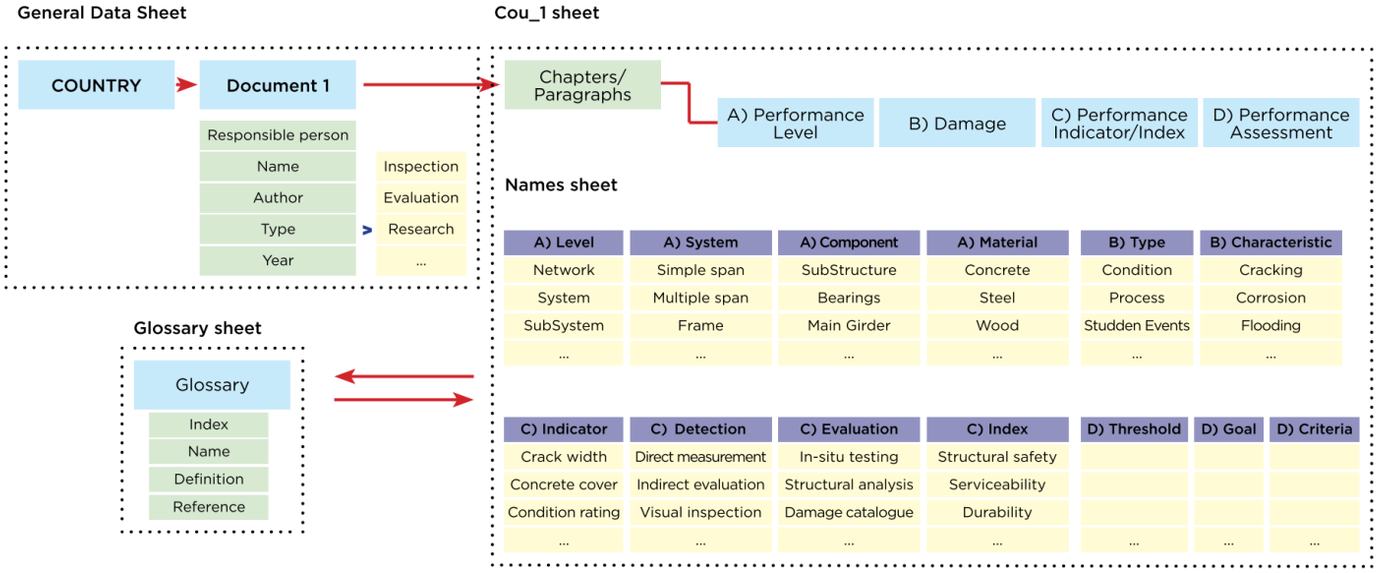

Figure 2. Structure of the Performance indicators database for the survey process

The UI for the survey is structured in MS Excel (see Figure 4), where the information may be stored in four groups: (i) Performance Level; (ii) Damage Processes (DP); (iii) PI/Index; and (iv) Performance Assessment. Besides this data, there is an opportunity to add additional references and specific information about a group element (e.g. evaluation process, formula, Figure, etc.). The background for this structure comes from screening of the Austrian national document (Bundesministerium für Verkher, Innovation und Technologie, 2011) and two documents from United Kingdom (County Surveyors Society CSS, 2004). The performance indicators database for the survey process is divided into several documents as shown in Figure 4. In order to support on the interface in the screening process, a Glossary of key terms is required to store the information and terminology related to PI, PG, PT and PM. Such Glossary has been prepared on the basis of the information from German and Austrian documents (BASt, 2015, Bundesministerium für Verkehr, Innovation und Technologie, 2011). During the screening process it was updated by national specific information on the one side in their own language, and on the other side in English. The Glossary is acting as a background document, whose definitions are used to support the filling of the data base.

In a "Damages Sheet" the nominated persons were able to fill in the national damages which are not comprised in the Glossary. All prepared interfaces for the screening of national relevant documents were prepared with the aim of being user friendly and allowing the free input. In the Glossary this was made possible by adding the sheet "New terms". Here, the users were free to add additional concepts, definitions, explanations and keywords in relation to PIs, goals, thresholds, criteria and methods (Figure 4). At present in the data surveying process, 36 countries are included.

3.5 *Homogenization Process*

The results of the screening process were partly heterogeneous and with a number of overlapping terms. This mainly results from a free interpretation leeway and different know-how of experts in visual inspections, performance evaluation, performance assessment and decision making. The screening results were used for a homogenization process by the WG1 core group and the nominated persons from each country, were asked again to verify their performance and damage specific inputs, by comparing them with the homogenized and categorized terms. These homogenized data were the baseline for all further studies and quantifications and provides also the basis for an effective comparison of performance quantities between countries.

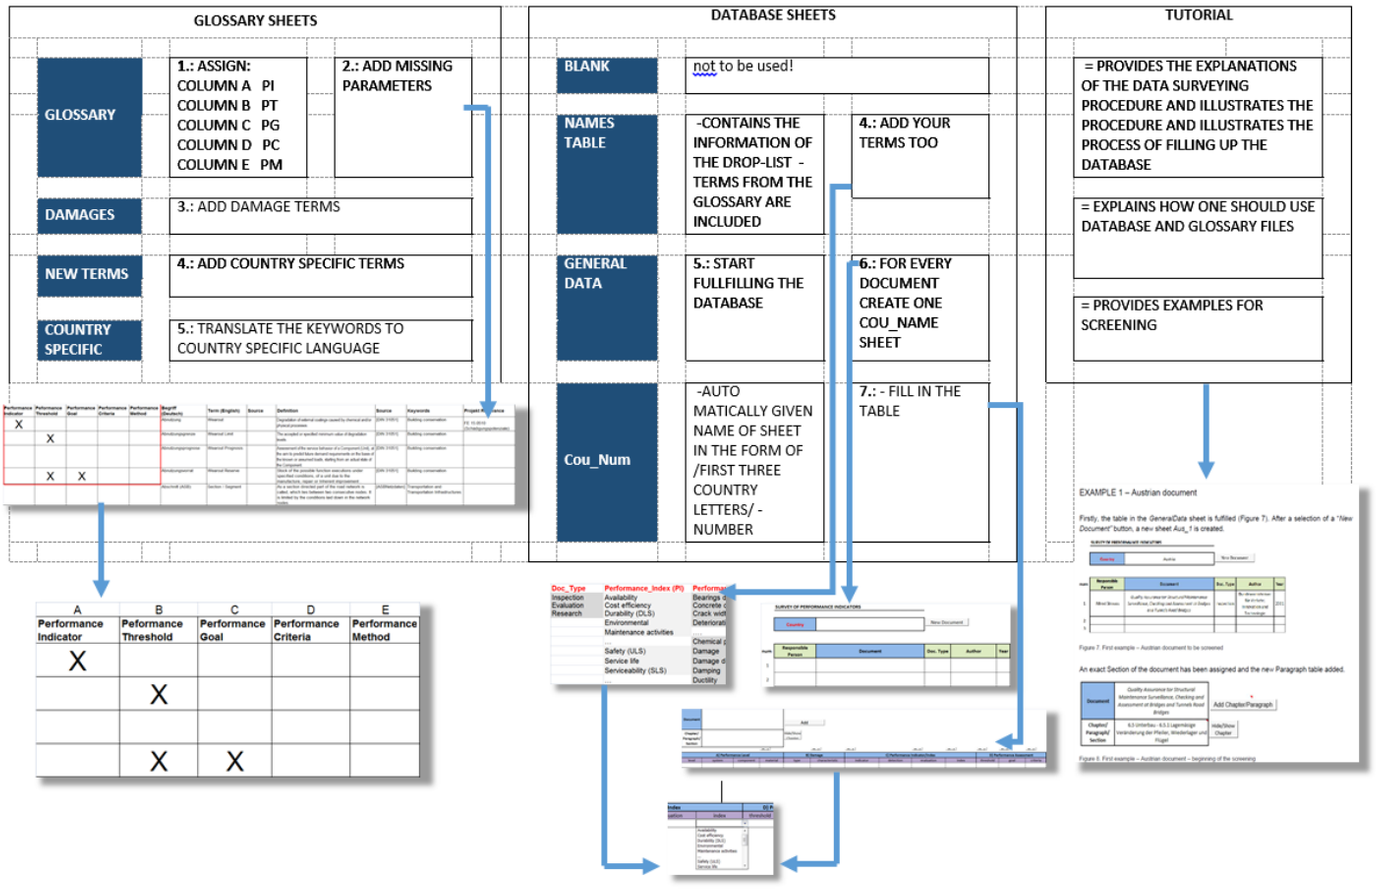

Figure 3. Performance indicators database for the survey process and its associated documents-B

3.6 *Findings from the process of data collection*

The previously sketched data collection process resulted in a list of more than 700 terms, which was later clustered and homogenized. From this process resulted a shorter list of 385 terms, grouped in 11 clusters from defects to rating and loads. The list was considered, not as a final list of PIs, but as a list of terms that can be related with PIs (PI related terms as addressed in WG1 Report). Assuming that not all the 385 terms can be considered as PIs a new practical based categorization of the terms had been performed. The following four categories of terms were considered: performance indicators (PIs), damage processes (DPs), observations (OBS) and other data (OD). A fifth category was considered, related with non-interceptable processes, once they are out of the scope of this group. The sixth category considered was labelled as Combined Performance Indicator, trying to cluster terms that reflect general properties of a structure and may be derived, among other ways, from the combination of several PIs. As an example, the term bridge condition was considered in this category once one can assume that it can be derived from all the other PIs. (Amado & Hajdin, 2017; Strauss & Ivanković, 2016). The distribution of the 385 PIs related terms through the 8 categories above defined is shown in Table 2 (Amado & Hajdin, 2017). The complete categorization of terms can be found in the COST TU1406 WG1 report.

Regarding DPs, Bień and Gładysz-Bień (2016) proposed three main groups of degradation mechanisms (DM) in arch bridges, related with physical, chemical and biological phenomena. In Table 4 the list of DMs considered by these authors was compared with the list of DPs resulted from the categorization of terms proposed in the WG1 report. A correlation could also be found for most of the terms. One single term referred in the bibliography could not find a synonym in the present proposal, which was the term Leaching. It's also important to note that, in some cases, several Damages Processes related terms could be found for the same DMs.

3.7 *Assessment of Performance Indicators*

As shown in the framework for the establishment of QCPs (Hajdin, 2016), its intended to translate the assessment made for each PI through a performance value (PV), based in a qualitative approach that can

be applicable also in a quantitative manner. Independently from the tool used to achieve this goal, event trees, fault trees, Bayesian Networks or others, it was understood that each PI is related with certain DPs and that this latter category is related with certain observations. The conjugation of these relations with other information such as the level of assessment, structure type, element, time and other data (comprising measurements, material properties, etc.) will allow to determine a certain PV.

4 PERFORMANCE INDICATORS VS. KEY PERFORMANCE INDICATORS

4.1 *General*

It was agreed, among the TU1406 community, that PI is a measurable and quantifiable parameter related to the bridge performance that can be compared with a target measure of a PG or can be used for ranking purposes among a bridge population in the framework of a QCP or life-cycle management (which includes decisions and actions involving economic resources). To evaluate certain performance indicator, performance thresholds (PT) or criteria must be set. A threshold value constitutes a boundary for purposes such as: a) monitoring (e.g. an effect is observed or not), b) assessing (e.g. an effect is low or high), and c) decision-making (e.g. an effect is critical or not). A criterion is a characteristic that is relevant for the choice between processes e.g. such as maintenance actions or others. Although the interaction of different PIs is inevitable, their categorization into technical, sustainable and socio-economic indicators through component, system and network level is proposed in order to more easily identify the level of their influence to a certain KPI related to PG.

In order to move on with the reduction of the list of PIs, an expert group was asked to specify PIs according to the following points: Measurable? Quantifiable? Target value available? Valid for ranking? Allow decision with economic implications?.

At the end, approximately 100 extricated PIs are further related with one or more of the key performance indicators (KPIs) defined in WG2: reliability (R), availability (A), maintainability (M), safety (S), security (Se), environment (E), costs (C), health (H), politics (P), rating/inspection (I). A further process is required for categorization of PIs in relation to PGs and PTs at different levels: component (CL), system (SL), network (NL); taking into account different aspects: technical (Tech), sustainability (Sust) and socio-economic (SoEc).

Figure 4. Terms obtained from the entire screening process of the operational documents in connection with performance assessment of bridge structures

Figures 5 show the terms obtained from the entire screening process of the operational documents in connection with performance assessment of bridge structures. From these figures it can be seen which of the overall terms are documented and also used in bridge engineering in five selected countries: Austria,

Chile, Croatia, Portugal and Spain. In addition a separation of the terms in "2º Level PIs, 2ºPI; Damage Process, DP_; Non-interceptable processes, NIP; Observation, OBS; Other data, OD; Performance Indicator, PI" was defined in cooperation with WG2 and WG3 as can be seen from the superscript next to the terms in order to allow the setup of an efficiently manageable QC. More details are discussed in the report of WG3. The PIs are considered as elements that are related to the KPIs of the "RAMSSHEEP" spider, as presented in the next paragraph. The coloring of the terms as can be seen in Figures 5 and 6, refers to the local or object classification. Finally, the remaining country-specific consideration, in addition to the 5 countries shown in Figures 5 and 6, can be found in the WG1 report.

Figure 5 and 6 shows the terms extracted from the inspection and evaluation documents for the respective category defined previously. It is striking that the number of actually characterized PIs is only 29 of the 385 terms.

The screening process and the expert questionnaire made it possible to assign the performance indicators to component (CL), system (SL) and network level (NL), as shown in Table 6 and to assign the PIs to the spider tails or KPIs. The assignment shown here for the five selected countries is available in a similar form for the other countries in the WG1 Report. Figure 7 shows the "RAMSSHEEP" spider indicating the KPIs and the country specific assigned PIs obtained from the expert analyses as presented above.

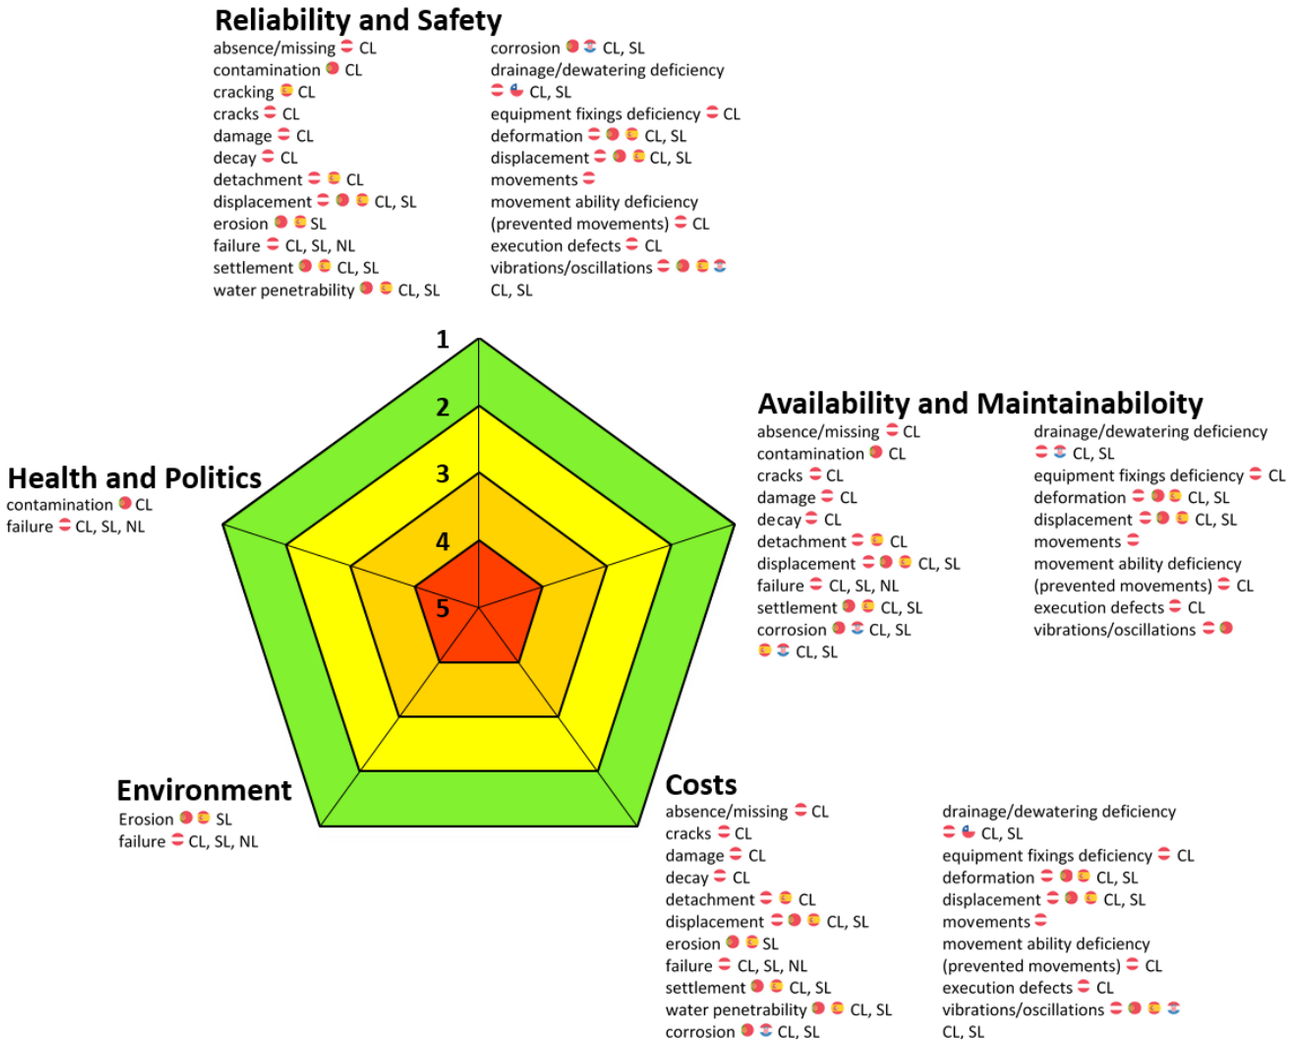

Figure 5. The "RAMSSHEEP" spider indicating the KPIs and the country specific assigned PIs

Further process will require allocation of rating value (1-5, as in table 1) and weighting factor (whose values are still to be defined) to each PIs related to five main groups of KPIs which are established in relation to requirements of the WG2 and WG3. The final rating and weighting will reveal overall rating (with rating factors r_{SRS}, r_{AM}, r_C, r_E and r_{HP}) of each of the five most important KPIs groups. The green areas in Fig. 7 represent the most favorable rate and the red areas should alarm the bridge operator and require immediate intervention.

5 PERFORMANCE INDICATORS DATABASE FOR THE ASSESSMENT PROCESS

5.1 *Relational Database Structure*

A relational database is a set of tables containing unique instances of data fitted in predefined categories, which, due to the established relations, allows users to view information as needed. A considerable amount of information was provided from the screening process. Although this data was gathered in a structured manner, it is dispersed through multiple files, becoming rather difficult to manage, analyze or compare. Therefore, in order to overcome such restrictions, a relational database with an organization structure represented in Figure 8 was developed.

The information included in the "GeneralData" sheets, concerning the documents titles from where the data was retrieved, was introduced in the "srv_op_doc" table. This data is related to its respective country through the foreign key "country_id". The "Cou_num" sheets from the Excel workbooks contains the screened data, organized per document chapter. In the relational database, this information was inserted in the "srv_op_chapter" table, concerning the documents chapters, and in the "srv_op_record", that contains all the findings. The homogenization data was inserted in the "srv_hmg" table. All the remaining tables concern the data given in the "Names_Table" sheet which feed the dropdown lists included in the "Cou_num" sheets and are linked to the main tables through foreign keys.

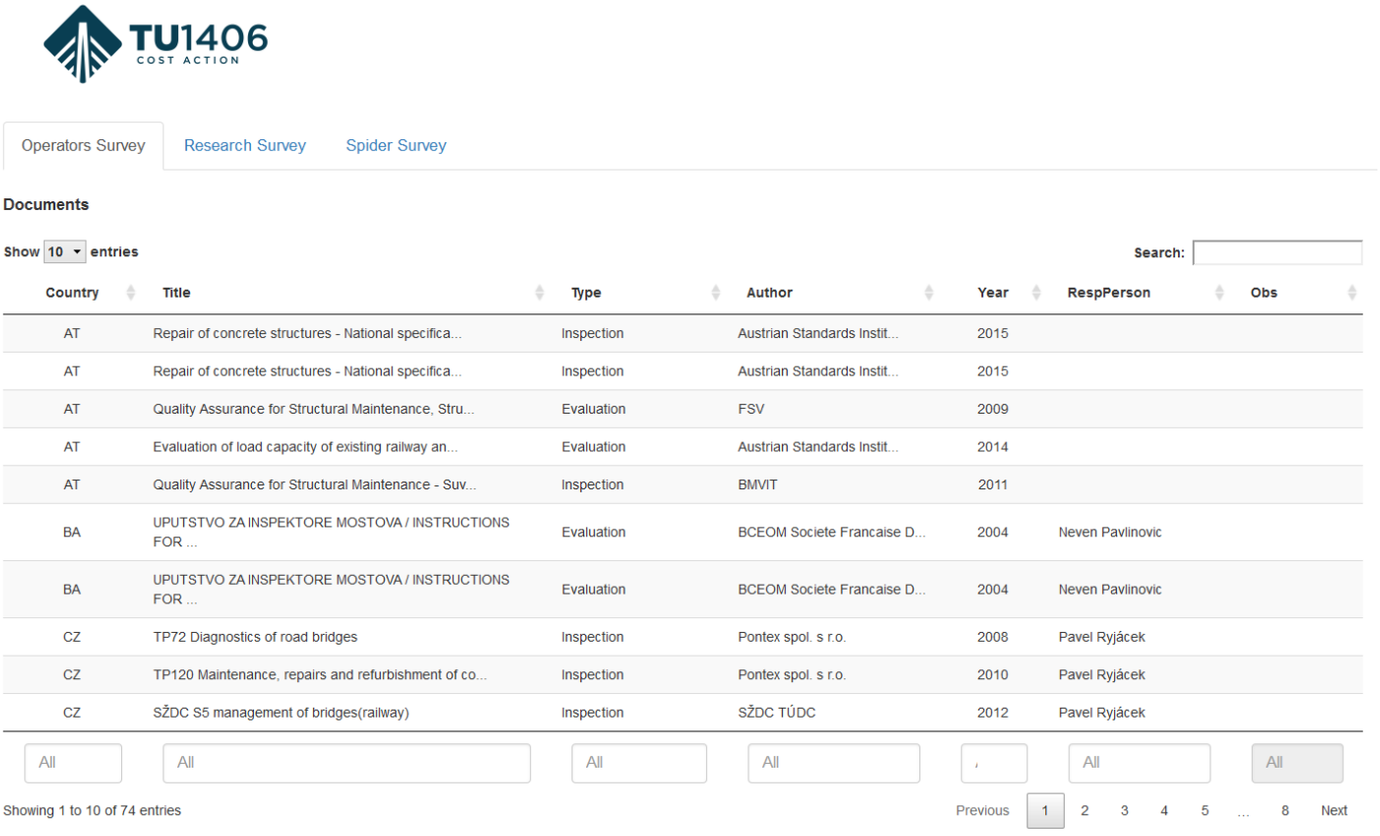

Figure 6. User interface

In addition to the database development, and due to the high number of documents provided by the countries involved, several routines were developed. They allow to read the information from the Excel files and insert it in the database in a systematic way.

5.2 *User Interface*

The development of a database by itself brings many advantages to all organizations. However, given that the management of such tool is not very user friendly to those with no experience in such field, a visual interface is required. From this perspective, a UI capable of displaying the information contained in the database was also developed. Given all technologies available, and considering those currently in use by COST Action TU1406 (see Figure 9).

6 CONCLUSIONS

In this paper, an overview of COST Action TU1406 with incidence in the work and the methodology adopted within WG1 to achieve the purpose of collecting PIs used across Europe was presented. The aim was to establish good practices on the definition

of QCPs for roadway bridges. This should be the basis for the future proposal of the definition of PIs that could be adopted and used all over Europe.

The methodology is based on a deep analysis of the existing bridge management policies existing in European countries and the main PIs used with the objective to define a common group of quality specifications and control plans that can be assumed by all these countries. The gathered data from European countries was further analyzed and systematized. Thereby, the existing roadway bridges in EU member countries are managed not only country-specific but also in a consolidative manner.. Although showing an European initiative, the proposed methods in this paper can be also applied to other countries in the world, where homogeneity in QC of existing roadway bridge stock is needed, in order to facilitate the existence of a roadway network that allows the communication and transportation from one region to another in a safe, reliable and cost-effective way.

Although it was possible to reach a high level of satisfaction with the obtained results, more work is still needed. It will be necessary to have a selection of the most relevant PIs for achieving KPIs for an optimal QCP within the bridge management and also to allocate them with appropriate weights to set different levels of importance between them. The next step is the definition of the technical recommendations for the specification of PGs based on existing ones for the indicators discussed in this study.

Quality control plan for RC bridges exposed to flooding events

N. Tanasic
University of Belgrade, Faculty of Civil Engineering, Serbia
R. Hajdin
Infrastructure Management Consultants, Zurich, Switzerland

ABSTRACT: The state-of-the-art bridge management practice do not adequately account for flooding and related local scour, thus fail to provide crucial information to viably mitigate consequences of bridge failures. The current policies in practice, which are solely based on visual inspections, need to be updated with efficient, preferably quantitative methodologies for a comprehensive and timely screening of vulnerable bridges. The research is aimed at application of key performance indicators which consider relevant data for assessment of vulnerability to local scour. Herein, particularly bridge exposure and bridge resistance are assessed. The latter involves failure modes, an essential ingredient for evaluation of a probability of failure, which is related to the indicator of reliability. The guidelines are necessary for inspection of bridge vulnerable zones i.e. segments that have the key role in resistance to failure. The practical evaluation of the reliability class is presented for RC girder bridges, which support elaboration of adequate quality control plans.

1 INTRODUCTION

The current bridge management (BM) practice in planning of adequate maintenance actions for bridges endangered by flooding hazards cannot provide satisfactory results, as it mostly relies on the lessons learned in the aftermath of failures. In Europe, related BM procedures are qualitative and not comprehensive. In most cases, they are based solely on visual inspections (Tanasic & Hajdin, 2017a), which was confirmed within ongoing research project COST TU1406 (Matos et al., 2016). In the U.S., the consideration of flooding hazard in decision-making is based on qualitative ratings of specific National Bridge Inventory (NBI) items. Still, some U.S. states additionally apply own methodologies, which take into consideration more thorough inspection procedures and involve vulnerability assessments (e.g. New York State Department of Transportation, 2003).

In the last two decades, the risk-based approaches are being developed to address the flooding impact on bridges and transportation infrastructure. In the HYRISK approach (Pearson et al., 2002), the total consequences of a bridge failure are thoroughly elaborated. This methodology accounts for a bridge foundation type and static system, but uses the information on past failures as the basis for estimation of the probabilities of failure. Recently, this approach is suggested to be updated to account for soil erodibility at bridge sites, as a major determinant of a scour related failures (Bones et al., 2017). In Khelifa et al. (2013) the risk-based approach is presented, where the NBI items are used to account for climate change effect on the frequent occurrences of flood and related rising of the probability of failures.

There is not many software that account for risk analysis of bridges exposed to flooding events. In HAZUS-MH (Federal Emergency Management Agency, 2007) and Road Risk (Swiss Federal Road Office, 2011) a coincidence analysis between the geographic extents of flooding and infrastructure location is performed. Although, different flooding scenarios may be considered, the structure resistance and indirect of consequences of failure are not elaborated.

Currently, the main research need in assessment of flooding impact on inadequate bridge performance, are investigation and application of performance indicators (PI) that may timely identify scour-susceptible bridges (Brown et al., 2014). In Tanasic & Hajdin (2017c), the threat of flooding hazard in the Serbian road network was assessed in the light of a flooding event in May 2014. The motivation was to provide the principal steps for an upgrade of current BM procedures, and the novel, vulnerability-based approach was suggested to identify endangered bridges that to be examined in more detail.

The ongoing European research project COST TU1406, elaborates quality control (QC) plans for roadway bridges, by accounting for uncertainties of

interceptable and non-interceptable (i.e. sudden) processes that can significantly affect a bridge performance. The adopted approach involves application of key performance indicators (KPIs), based on RAMSSH€EP approach (Rijkswaterstaat, 2012). The first task within the COST project comprised survey of relevant PIs used by national road agencies (Strauss et al., 2016). In the second task, performance goals were investigated (Stipanovic et al., 2017), while in the third task, the report on the quality control plan is being prepared (Hajdin et al., 2017 and Linneberg et al., 2017).

In the scope of this paper are the relevant findings of the COST project related to failures due to flooding hazard and related local scour which is regarded as a sudden process. The influence of possible failure modes of girder bridges on the probability of a failure, and their relation to the KPI of Reliability is elaborated.

2 THE RELEVANT DATA SET FOR ASSESSMENT OF A THREAT OF LOCAL SCOUR

All bridge types regardless of age, static system or materials may be affected by a flooding hazard, where foundations of bridge substructures and bridge embankments may be exposed to the process of local scouring. Eventually, there is removal of supporting soil at foundations, while the soil and the bridge structure jointly resist this adverse action until the bridge fails under its own dead load (Tanasic, 2015). This bridge resistance still waits to be adequately accounted in the current BM practice, in order to avoid an overestimation of vulnerability.

The observations that are commonly used in the assessment of local scour are related to the visual appearance of foundations, embankments and an area beneath a bridge. These are not by themselves an effective PI and only have significant value if noticed timely, as they can relate to a probability of failure. There are direct observations, which can point out a problem with local scour, such as substructure settlement/rotation and resulting localized damage (e.g. cracks) at joints, bearings and other bridge elements. These indicate that a failure has already occurred, thus an immediate attention i.e. adequate repairs are necessary. For a BM practice, these types of observations can trigger inspection of yet undamaged bridges, with a similar hydrology data, but still cannot be used as a reliable indicator for estimation of failure rate.

Any type of damage on structural elements, which is not a result of a foundation displacement/rotation, are of interest as it may decrease bridge resistance to an oncoming flooding event. Here, the importance of two parameters: damage location and its severity (e.g. area/depth affected) must be determined for diverse bridge types and their elements in order to conduct a comprehensive analysis on possible bridge failure modes, which is elaborated in section 4.

The scour depth is an observation/indicator that may be directly measured, monitored or indirectly evaluated by empirical formulas. The choice of the right approach is based on available resources (e.g. budget, available data and equipment, etc.) and engineering judgement which mostly relies on experience. In practice, visual inspection can trigger either monitoring/measuring of scour depth or a countermeasure instalment, but this cannot be regarded as a reliable diagnostic method since scour can be a sudden process. Also, indirect evaluations of scour depth are applied to complement the decision-making process, but this require additional effort and resources. In the related empirical formulas, customary practice is to model uncertainties of the relevant parameters with probability distributions (Johnson & Dock, 1998).

Although the information on the scour depth entangles the data on flooding magnitude, channel properties, soil properties and substructure geometry, it must be coupled with relevant data on bridge type and demand (e.g. traffic volume) for reliable decision making. It is evident that a risk-based methodology is a feasible approach to adequately consider a flooding hazard in BM. The emphasis is on a simple, yet comprehensive approach, which relies on existing information and inexpensive, but reliable inspection procedures. It should include the most relevant data, and these may be structured in three groups:

1. Exposure to a local scour at substructures
   - Flood magnitude & duration
   - Water channel geometry & properties
   - Debris/ice potential
   - Soil erodibility
   - Piers & abutments type/geometry, position and alignment in respect to a water flow
2. Resistance to failure modes induced by local scour at substructures
   - Soil cover
   - Geotechnics properties of soil
   - Type/detailing of sub/superstructures
   - Location & severity of a damage on relevant bridge elements
3. Consequences related to failure modes
   - Loss of life & limb
   - Costs of repairs or replacement
   - Down time
   - Network & traffic data to include indirect costs of failure

A major drawback for a practice-ready approach are diverse types & levels of uncertainties related to this data. Although most of this information are not usually stored in a bridge database, it exists up to an extent in a bridge design documentation or in other databases (e.g. hazard and traffic related data). Even-

tually, some data may be inferred based on an experience (e.g. reinforcement detailing) or surveyed in a one-time inspection. For a full risk-based approach, an estimation of the flood magnitudes that will affect a bridge is required, which is an overkill for BM practice. It is far more convenient to adopt a certain flooding magnitude (e.g. 100-year flood), a related scenario, e.g. local scour at a pier, and apply a vulnerability approach (Tanasic & Hajdin, 2017c), which is briefly presented in following section.

3 VULNERABILITY ASSESSMENT AND KEY PERFORMACE INDICATORS

From a BM perspective, the vulnerability may be defined as the expected total consequences of inadequate bridge performance caused by a hazard (e.g. flooding) of a certain magnitude (Birdsall). Here, the formula which defines this relationship is given as:

$$V_n^s = P_n^s \cdot (DC_n + IC_n) \quad (1)$$

where: $V_n^s =$ the vulnerability of a bridge with respect to a flooding event of a specific magnitude *s* and a chosen failure mode *n*; $P_n^s =$ the conditional probability of a bridge failure in the chosen failure mode *n*, with the respect to a flooding event of a specific magnitude *s*; $DC_n =$ direct consequences with respect to the chosen bridge failure mode *n*; and $IC_n =$ indirect, mostly traffic related consequences with respect to the chosen bridge failure mode *n*.

The vulnerability is a comprehensive PI for decision-making, with respect to a failure due to a hazard, that identifies and ranks the bridges that need to be investigated in more detail. It considers the resistance of a bridge to local scour action related to the flooding of a certain magnitude. The essential ingredient for its evaluation are the failure modes, which account for partial damage or a collapse. However, the adequate vulnerability approaches are beyond the scope of the COST project.

In the approach of the COST action, the focus is on evaluation of KPIs: Reliability, Availability, Safety, Economics as the most viable for the elaboration of QC plans. The failure modes are required for evaluation of the probability of a bridge failure, which is in a direct relationship with the KPI of Reliability. The direct consequences of a failure, related to loss of life and limb, are required to assess the KPI of Safety, while the KPIs of Availability and Economy are dependent on the chosen mitigation actions. The indirect consequences of a failure and direct costs of bridge repair/replacement due to a failure, are not accounted for in the evaluation of the KPIs within the COST.

4 BRIDGE FAILURE MODES AND VULNERABLE ZONES

In the analysis of failure modes (FMs), the influence of specific bridge elements on the bridge resistance needs to be addressed. The FMs are usually discussed in the light of observed damage (e.g. May et al., 2002, Briaud et al., 2010 and Ettema et al., 2011), but the differentiation between diverse bridge types and specific damages, and an explanation how the related failures occur, have not been provided.

The resistance of a bridge to a flooding event is primarily dependent on analysed scenarios (e.g. a local scour at a middle pier). For each scenario, the possible FMs are governed by the soil cover at an affected substructure and the combined resistance of a soil-bridge system. Here the foundation soil geotechnical properties have a key role, due to large safety factors in the design. Secondary, but not unimportant is the engaged superstructure resistance governed by the type/properties of bearings/joints and main girder (Tanasic & Hajdin, 2015). The main FM types and the key elements of girder bridges, which reflect on how much bridge resistance can be engaged, are listed in Table 1., while the related examples are given in Figure 1.

The failure mode type 1 (FM1) is the most dangerous since it may cause progressive collapse (Figure 1.a), provided that the design of the main girder is not failure/collapse safe to a damage to one of the supports (e.g. FM4 in Figure 1.d). The FM2 may occur if the top of the pier of an affected foundation is not restrained to a movement in the horizontal plane, by design or due to a poor condition state of bearings. This FM is common for multiple-single span bridges e.g. in Figure 1.b. The FM3 is "the most desired" case, since the requirement for failure is that the foundation soil and the structure need to deplete their joint resistance to a partial loss of the support at the affected substructure foundation (Figure 1.c).

Regarding Table 1., the clear and concise guidelines are necessary for inspection of bridges and in particular, their vulnerable zones. The vulnerable zones comprise bridge segments, which have a crucial role in resistance to a failure due to local scour at substructure foundation/s (Figure 2.). Here, the soil cover at substructures is included. Any type and severity of a damage at vulnerable zones is of interest, as it may decrease the overall bridge resistance to an oncoming flooding event i.e. increase the probability of a failure.

Table 1. Key bridge elements for girder bridge resistance to local scour and failure modes (FMs)

Bridge element	Attention	Resistance to a failure mode	Failure Mode
Affected substructure	Inadequate detailing or condition	Structure governed	1
Bearing/joint at the top of the affected substructure	Inadequate detailing or condition	Soil governed (low superstructure effect)	2
Bearings/joints at other substructures	Horizontal displacement free or restrained	Combined soil-bridge resistance	3
Main girder	Detailing	Combined soil-bridge resistance	3
Main girder	Detailing	Failure safe	4

5 THE ASSESSMENT OF RELIABILITY

The semi-quantitative approach is presented, where the Reliability class with associated matrix (Figure 4.) is defined via Exposure class and Resistance class. The Exposure class aims to grade the threat of a certain flooding scenario and related local scour. The Reliability class aims to account for diverse bridge types, their characteristic FMs and a temporal aspect i.e. information update on the condition in the vulnerable zones. For the case were there are several substructures affected, the assessments of Exposure and Resistance classes are performed for each substructure separately, to estimate which is the case that has the highest Reliability class.

5.1 *Assessment of Exposure class*

There are four exposure classes on the vertical axis of the matrix in Figure 4.b, where one denotes the lowest, and four the highest exposure of a bridge. The main data for this assessment comprise an extreme flood hydrograph, river channel properties/geometry and information on foundation soil type/erodibility.

The first class denotes bridges with substructures that are not in a floodplain for the adopted extreme flood (e.g. return period of 100 years), whereas the second class implies that a substructure is going to be in a contact with water. Still, this does not necessarily involve local scour. Thus, an assessment of the soil erodibility should be performed on site or in a laboratory in a one-time inspection, or assessed indirectly, which is further elaborated.

Two parameters are commonly used to describe threshold value for soil erosion rate of 0.1mm/hr – the critical shear stress at the soil interface (τ_c) or the critical velocity for initiation of erosion (V_c). Their application depends on the methodology for indirect evaluation of local scour, and here the two approaches, given in (Florida Department of Transportation, 2010) and (Briaud et al., 2011), are suggested to use for coarse-grained and fine-grained soil, respectively. Any other approach may be used, but preferably it should account for temporal aspect of local scour i.e. evolution of its magnitude over flood duration, to provide a more realistic values of possible scour depths.

The transition from the second to the third Exposure class implies that the mean approach velocity of flow upstream V, for the adopted extreme flood, can induce soil erosion. To evaluate V, the information on river channel geometry (cross section and slope) and the Manning coefficient are necessary. In the absence of reliable data for an investigated location, these may be verified easily in one-time inspection. The V_c may be either evaluated based on the median soil particle diameter (D_{50} > 0.01mm) and critical soil particle shear velocity (Melville & Coleman, 2000) or conser-

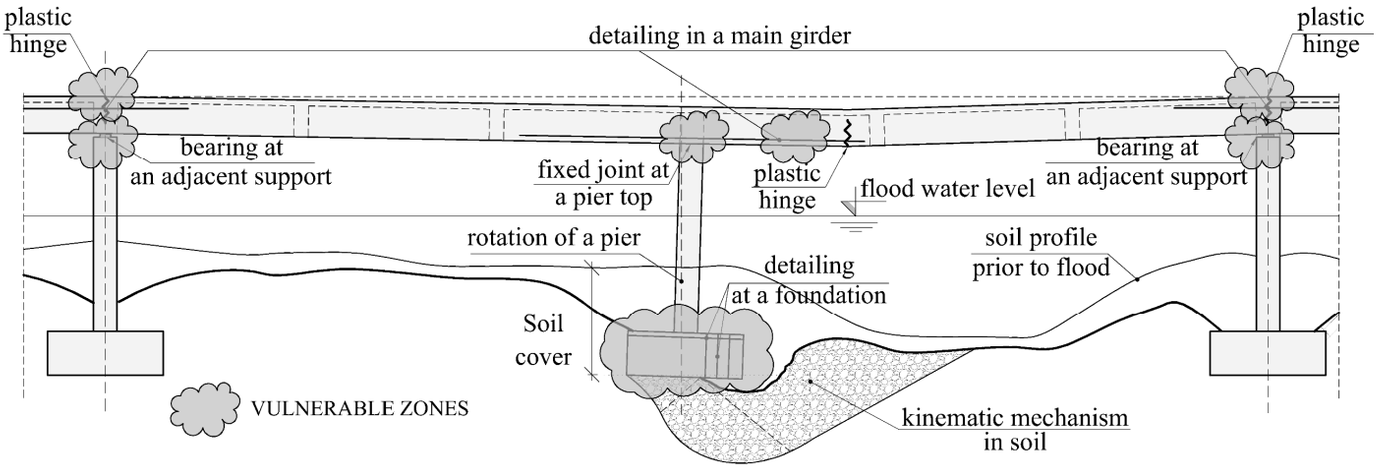

Figure 2. Multiple-span girder bridge and its vulnerable zones and an example of a failure mode due to local scour at a pier - adapted from (Tanasic & Hajdin, 2017b)

vatively accounted for the recognized soil type by using erosion function charts (Briaud et al., 2011), that can be also used for estimation of the τ_c.

If a bridge is in the class three and have a history of flooding events, it should be classified in the fourth class. Also, the fourth class of exposure may be selected if there are conditions on site, which may exacerbate local scour (e.g. debris/ice, flow constriction, etc.), but cannot be readily accounted in the indirect evaluation of local scour.

5.2 *Assessment of the Resistance class*

The resistance of a bridge to local scour is graded in five classes (horizontal axis of matrix in Figure 4.), where one denotes the highest and five the lowest resistance. The main data for this assessment comprise possible FMs and condition of bridge elements in vulnerable zones, including the height of a soil cover.

A bridge is initially categorized in a class based on a relevant failure mode and foundation type (Figure 3.). By design, the bridges with deep foundations are clearly more resistant to a failure, but here FMs which involve pile buckling should be considered (Ramey & Brown, 2004). For shallow foundations, the ultimate extent of scour cavity beneath the foundation level govern the probability of failure (Tanasic, 2015), which is accounted for in FMs in Table 1.

The bridges with countermeasures are categorized in the first class, if the condition of these protective measures is good. Otherwise, their presence is ignored. Transition to a higher class (a lower resistance) is possible in a case where a condition of a segment, which is in a vulnerable zone (Figure 2.), becomes worse, i.e. may affect the possible FMs.

When the Exposure class is equal three or higher, the update of resistance class is possible when the soil cover at a substructure reaches a predefined threshold. For this assessment, a potential local scour depth at an affected substructure may be indirectly evaluated via well-established scour evaluation formulas (Arneson et al., 2012). An example of thresholds for the soil cover is given in Figure 4.a, which is based on the adopted extreme event magnitude. The update of resistance class is considered conservative, as the related evaluation formulas tend to overestimate local scour depths observed on-site. Nevertheless, it is regarded as sufficiently accurate and comprehensive for practice, provided that the failure modes are adequately considered.

The common situation in practice is that the data on foundation type/geometry is unknown and it cannot be reliably obtained from the available project documentation, date of construction, design code, etc. The bridges with unknown foundations are to be treated as bridges with shallow foundations i.e. can be initially categorized in a class three, four or five (provided the main girder is not failure safe).

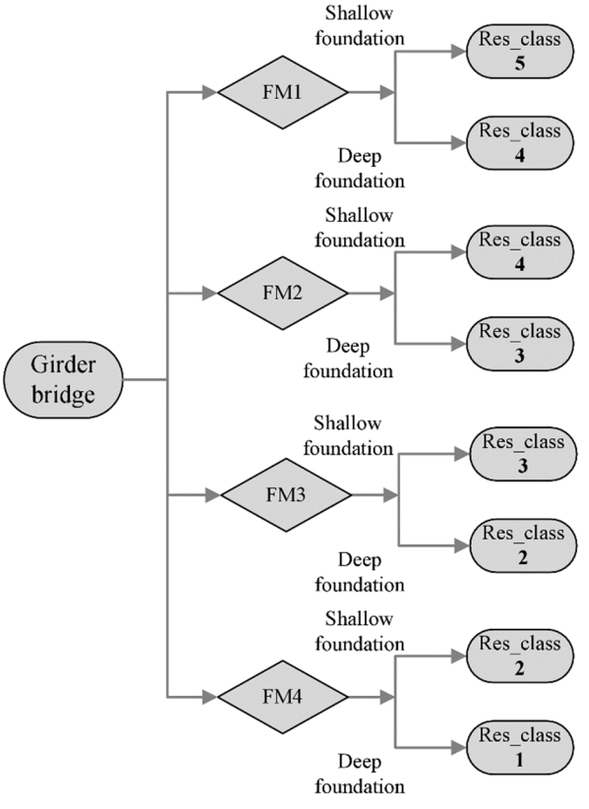

Figure 3. Relationship between failure mode (FM) types (Table 1.) for girder bridges and their initial resistance classes.

Another issue is the soil cover at bridge substructures, and here both foundation depth and the actual soil cover at the affected foundation can be unknown. If the Exposure class for these bridge substructures is equal or higher than three, their initial Resistance class should be increased by one (five is the max. value).

5.3 *Assessment of Reliability class*

The given matrix (Figure 4.b) provides a practical solution for the semi-quantitative assessment of reliability, where all relevant information on a bridge exposed to a local scour event is considered. The main advantage of the presented approach over the current practice is a possibility to account for the resistance of specific bridge types via failure modes. This provides a more realistic assessment of a threat of failures and thus lead to elaboration of adequate QC plans.

The presented reliability assessment has a potential to be upgraded in a full quantitative approach, which would provide a more detailed differentiation between the given reliability class thresholds.

a) **Update of the Resistance class**

3	$L_s < 0.5\ S_c$	three and more consecutive flooding events
4	$0.5\ S_c > L_s > S_c$	two consecutive flooding events
5	$L_s > S_c$	one flooding event

*L_s = Indirectly evaluated local scour depth

*S_c = Soil cover; (for deep foundations = max. allowed for a pile buckling failure mode

b) **Reliability class**

high	medium	low	very low	critical

6 CONCLUSION

The current decision-making in bridge management related to flooding hazards, relies mostly on visual inspection and assessment of a substructure exposure to local scour, while the bridge resistance is usually ignored. The ongoing research is oriented towards application of comprehensive performance indicators in practice to reliably anticipate bridge failures in oncoming flooding events and aid in adequate mitigation of the related threat.

Here, the research within COST TU1406 action aims to account for both the interceptable and non-interceptable processes in elaboration of quality control plans, by application of the RAMSSH€EP methodology. The key performance indicators (KPI), which are selected to be further elaborated in a practice ready approach are: Reliability, Safety, Availability, and Economics. For a flooding hazard, it is evident that risk-based assessments are necessary. There is a need to set a basis for application of these approaches in the future. It is suggested to account for a vulnerability assessment as it considers all relevant data: exposure to the hazard magnitudes, related bridge's resistance and total consequences.

The essential ingredient in a vulnerability assessment is probability of a bridge failure due to local scour. It is directly related to the KPI of Reliability, and governed by the bridge exposure to a local scour and the bridge resistance which is accounted with relevant failure modes. The relationship of a bridge type to a failure mode is based both on the inherent and time dependent properties (e.g. condition) of key bridge elements which are in vulnerable zones.

The semi-quantitative approach was suggested to assess the Reliability, where a Reliability class is obtained via Exposure class and the Resistance class. The main parameters that Exposure class accounts are: extreme flooding magnitude, information on soil erodibility and complications on a bridge site which can exacerbate scour. The Resistance class considers failure modes and general foundation type, which govern the initial classification, and the height of soil cover at an affected substructure. The latter may additionally update the resistance class when compared to indirectly evaluated local scour depth.

The presented approach is going to be extended within a COST action to account for frame and arch bridges and their characteristic failure modes.

7 ACKNOWLEDGEMENTS

The research presented in this paper is based on a COST TU1406 research project - "Quality specifications for roadway bridges, standardization at a European level", and the work of its Work Group 3. The information on bridge in the example is obtained with the courtesy of Serbian Road Directory – Sector for maintenance of state roads and Sector for informatics systems in transportation. The authors would like to thank Tamara Komarica and Momčilo Veljović for their cooperation.

Monitoring in management of roadway bridges

J. Bień, T. Kamiński & M. Kużawa
Wrocław University of Science and Technology, Poland

ABSTRACT: The paper presents review of monitoring methods applied in bridge engineering as well as proposal of a unified classification of the monitoring procedures − based on suggested standardized criteria. Implementation of the monitoring tools in Bridge Management Systems is also presented. State of the art related to practical applications of such systems is illustrated and expected development trends in this area are discussed. Proposed solutions are based on results of the European international research projects as well as on long-term experience in design and implementation of the Bridge Management Systems in Poland.

1 INTRODUCTION

Road asset management is a task of great responsibility, since it involves vital assets to the community. Roadway bridge structures are complex physical systems consisting of many heterogeneous components.

Management of operation and maintenance of bridges requires efficient system of structure condition monitoring. Generally, monitoring system can be defined as arrangement of all activities that are performed with the goal to collect data for bridge condition assessment as a background for competent management.

Monitoring of bridge structures is an interdisciplinary activity that requires expert knowledge from different disciplines: structure inspection, non-destructive testing, structural and electronic engineering, modelling and simulation techniques, data processing, communication and archiving techniques, software design and implementation techniques. Since all these disciplines can hardly be covered by a single expert, monitoring is an activity that is essentially based on cooperation of a group of experts in very different engineering fields and backgrounds. A common detailed analysis and planning as well as communication between the experts is required for a successful monitoring activity.

Creation and development of effective bridge monitoring systems is a subject of research in many countries as well as was a topic of a number of the international research projects, e.g.:

- Bridge Management in Europe (BRIME 97-2220), Deliverable D8, Bridge Management and Condition Monitoring, 1999,
- Bridge Management in Europe (BRIME 97-2220), Deliverable D11, Modelling of deterioration, 1999,
- Integrated Monitoring Systems for Durability Assessment of Concrete Structures – SMART STRUCTURES, Final Report, European Commission, Brite EuRam III Programme, 2002,
- Smart Structures. Integrated Monitoring Systems for Durability Assessment of Concrete Structures, Project Report, 2002.
- Corrosion of Steel in Reinforced Concrete Structures – COST 521. Final Report, Eds. Cigna R. et al., European Commission, Directorate-General for Research, 2003,
- Improving Assessment, Optimisation of Maintenance, and Development of Database for Masonry Arch Bridges, Research Project, UIC, 2007.

At the moment one of the largest international research projects focused on roadway bridge monitoring and management is COST Action TU1406 "Quality specifications for roadway bridges, standardization at a European level" (www.tu1406.eu).

The main objective of the Action is to develop a guideline for the establishment of quality control plans in roadway bridges, based on specific performance indicators. These indicators can be qualitative or quantitative based, and they can be obtained by means of the monitoring systems.

By developing new approaches to quantify and assess the bridge performance, as well as quality specifications to assure an expected performance level, bridge management strategies based on efficient monitoring systems will be significantly improved, enhancing asset management of ageing structures.

2 MONITORING STRATEGIES

Monitoring can be generally defined as an act of acquiring, processing, communicating and archiving information about the actions on structure and/or the action effects on a structure over a given period of time (Bień et al. 2004, Watanabe E. 2010). Forms of bridge condition monitoring can be divided into two main categories (Fig. 1). The first category of monitoring procedures comprises regular as well as irregular (special) inspections based on visual examination and results of the non-destructive testing (NDT) and/or semi-destructive testing (SDT). The inspections are performed regardless of the structure loads by means of various types of NDT & SDT techniques (Bray D.E. & McBride D. 1992, Cartz L. 1999, Hellier Ch.J. 2001, Helmerich R. 2007, Malhorta V.M. & Carino N.J. 2003, Wenzel H. 2005). In majority of existing Bridge Management Systems the regular inspections are performed on basic level (every year) and on advanced level (every 5 years). This category of load-independent monitoring is usually applied to all bridge structures. Detailed procedures and requirements are defined in national regulations (Bień et al. 2016, Helmerich R. et al. 2012).

The second category of monitoring actions includes observation of bridge structure response to loads by means of installed technical measuring equipment. A technical monitoring system is a data acquisition and processing unit which continuously and autonomously provides real-time information about a structure or a structural component. This type of monitoring should contribute to an exact estimation of the bridge condition, which is impossible to achieve with inspections only.

In this category static and dynamic controlled proof loads can be distinguished (Bień et al. 2015) as well as short- and long-time technical monitoring under normal road traffic and natural environmental conditions. Predefined proof load tests are usually applied before opening a new bridge structure to traffic or after completing major rehabilitation works. Short- and long-term monitoring are based on application of transducers for sensing physical or chemical quantities along with programmable electronic equipment for acquiring, processing and communicating data as well as utilization of algorithms that define how data acquisition, processing and communication is performed. Short-term monitoring (usually 24 hours to few days) is executed by means of temporally installed sensors, while the long-term monitoring requires permanently mounted system.

The overall objective of technical monitoring is to improve the knowledge on the real behaviour of structures, supporting inspections and recognizing of unapproachable areas. The information obtained by monitoring can be used for very different purposes:

- identification of bridge loads and environmental impacts,
- monitoring of bridge reactions on loads and other influences,
- recognition of bridge degradation processes and structural performance,
- documentation of bridge history and prediction of a remaining life-time.

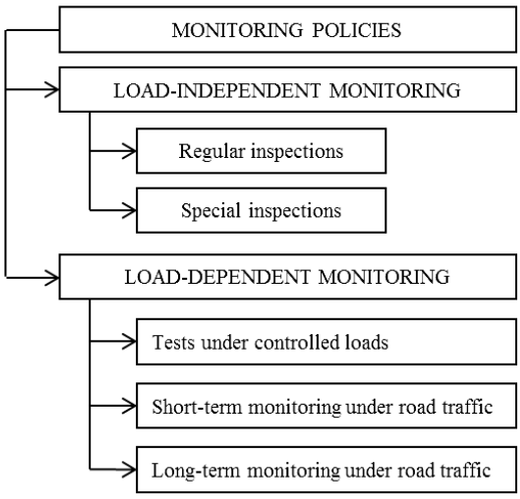

Figure 1. Basic forms of monitoring applied in bridge management.

Depending on the goal of analysis the following types of technical monitoring systems can be distinguished (Table 1):

- Action monitoring – allowing assessment of the magnitude as well as the spatial and temporal distribution of specific forces acting on a structure or a structural component, including traffic loads and environmental impacts (Hildebrand M. et al. 2008).
- Reaction monitoring – allowing assessment of the state of displacement, stress/strain level and distribution in a structure as well as vibration parameters: frequency, velocity, amplifications, damping caused by traffic loads and other influences (Cunha A. et al. 2007, Doebling et al. 1996).
- Performance monitoring – allowing to evaluate whether a structure or a structural component meets the performance requirements under specific or any actions, defined by the performance indicators (Enright M.P. & Frangopol D.M. 2000).
- Health monitoring – monitoring allowing the real-time assessment and prediction of the health condition of a structure or a structural component by means of their safety and serviceability indicators (Wenzel H. 2009).

Each monitoring system has to be designed individually, taking into account specific problems of the observed bridge structure. In practice each specific implementation is usually a mixture of categories listed in Table 1.

Table 1. Types of technical monitoring systems and expected effects.

Type of monitoring system	Monitoring effects
Action monitoring	Characteristics of all loads acting on a bridge structure Geometry and speed of vehicles Changes of traffic structure on the bridge Environmental influences (temperature, wind, humidity, earthquakes, etc.) Monitoring of overloaded transports Monitoring of accidents on the structure and in the neighbourhood
Reaction monitoring	Displacements, strains, stresses, vibration frequency, velocity and amplifications, etc. of structural elements Verification of theoretical analyses Modal parameters of the structure Dynamic amplification factors Material effort level
Performance monitoring	Identification of critical values of measured quantities Detection of bridge defects based on modal parameters changes Monitoring of parameters of defects (location, extent, intensity) Assessment of bridge technical condition and serviceability
Health monitoring	Changes of bridge technical condition and serviceability History of loads and environmental influences (temperature, wind, humidity, earthquakes, etc.) Observation of degradation processes progress (e.g. depth of concrete carbonation, corrosion advancement, etc.) Determination of input values for degradation models Remaining life-time prediction

Application of advanced monitoring systems to all bridge structures is not technically needed and would be economically not feasible. The technical monitoring is usually limited to the following situations:

- record-breaking long-span structures,
- bridges with innovative structural and/or material solutions,
- very important bridge structures, strategic components of transportation system,
- damaged structures awaiting rehabilitation or replacement,
- selected reference bridge structures, representative for the national bridge asset, monitored for creation and verification of degradation models.

In each case a monitoring of all bridge components with sensors is not necessary. Therefore, the technical monitoring process has to be restricted to a limited number of components which could affect the safety, durability and resistance of the bridge. In the scope of the investigation especially defects previously identified should be monitored and changes should be analysed.

3 MONITORING TECHNOLOGIES

Diverse purposes of monitoring procedures require application of problem specific technologies which differ substantially from each other. Classification of the technologies can be based on:

- frequency of inspections/measurements including:
  - continuous observation with defined frequency of measurements,
  - periodical observations with predefined schedule and program,
  - irregular observations/measurements dependent on specified conditions;
- type of monitored occurrences:
  - physical parameters,
  - chemical processes,
  - biological phenomena.

In the case of the load-independent monitoring based on inspections a wide range of the non-destructive testing methods and semi-destructive testing methods can be used. Classifications of the most popular NDT methods and techniques, which do not in any way breach the integrity of the tested structures (Hoła J. et al. 2015, Kühn B. et al. 2008) are presented in Table 2.

Table 2. Classification of NDT methods and techniques.

Testing methods	Measuring techniques
Optical methods	Visual inspection Endoscopy Microscopy Geodesy CCTV
Acoustic methods	Acoustic emission Impulse response Impact-echo Parallel seismic Ultrasonic techniques Ultrasonic tomography
Radiological methods	Radiographic techniques Computer tomography
Electromagnetic methods	Electromagnetic induction Radar techniques Magnetic techniques Electric potential/resistance techniques
Laser methods	Laser static techniques Laser dynamic techniques
Sclerometric methods	Static techniques Dynamic techniques
Thermographic methods	Passive techniques Active techniques

In Table 3 classification of the semi-destructive testing (SDT) methods, requiring material samples to be taken or any other minor breach of structural integrity, is shown. In this classification physical, chemical and biological methods applied during field and laboratory tests are distinguished.

Table 3. Classification of SDT methods and techniques.

Testing methods	Measuring techniques
Field tests	
Physical methods	Pull-out/pull-off tests
	Penetration tests
	Water resistance test
	Pressure techniques(flat-jack test, water penetration test, etc.)
Chemical methods	Rainbow/pH tests
	Chloride test
	Alkali test
	Electroanalytical tests
Biological methods	Macroscopic techniques
	Microscopic techniques
Laboratory tests	
Physical methods	Physical parameters of materials based on tests of specimens
	Computer tomography techniques
Chemical methods	Quantitative analytical techniques
	Electroanalytical techniques
	Spectral analyses
	Chromatography analyses
Biological methods	Advanced microscopic analyses
	"In vitro" culture techniques

In monitoring of bridge structures by means of installed technical measuring equipment wide range of measuring techniques and sensors can be engaged (Bischoff R. et al. 2007, Maia N.M.M. et al. 2003, Wenzel H. 2005). Typical tools applied for monitoring of forces acting on a structure are presented in Table 4.

Table 4. Monitoring of loads and environmental impacts.

Physical quantity	Measuring techniques and sensors
Live loads	Wheel pressure sensors
	TV/video cameras
Temperature	Thermocouples
	Thermistors
	Electrical resistance thermometers
	MEMS sensors
Humidity	Hygrometers
	MEMS sensors
Wind	Anemometers
Water flow	Water level sensors
	Water velocity sensors

For observation of bridge structure reactions to traffic loads and other influences as well as for bridge performance and health monitoring the following physical and chemical quantities are taken into account (Cunha A. et al. 2007, Doebling S.W. et al. 1996, Hildebrand M. et al. 2008, Watanabe E. et al. 2010, Wenzel H 2005, Wenzel H. 2009):

- linear and angular displacements,
- strain and stress level,
- vibration velocity, acceleration, frequency,
- crack opening changes,
- forces in bearing, cables, etc.,
- quantities specific for degradation processes.

The most popular measuring techniques and types of sensors used in bridge monitoring technical systems are presented in Table 5.

Table 5. Measuring techniques and types of sensors used in monitoring of bridge structure performance.

Physical or chemical quantity	Measuring techniques and sensors
Linear displacement	Geodetic techniques
	Mechanical sensors
	Inductive sensors
	Vibrating wire sensors
	Capacitive sensors
	Eddy current sensors
	Fibre optics sensors
	Laser techniques
	Radar techniques
	Hydraulic sensors
Angular displacement	Inclinometers
	Fibre optics sensors
	MEMS sensors
Strain/stress	Electrical resistance gauges
	Fibre optics sensors
	Vibrating wire sensors
	MEMS sensors
Vibration velocity and acceleration	Piezoelectric sensors
	Capacitive sensors
	Inertia sensors
	Inductive sensors
	Radar techniques
	Laser techniques
	MEMS sensors
Crack opening	Mechanical sensors
	Inductive sensors
	Fibre optics sensors
	Vibrating wire sensors
Bearing/cables reactions	Electrical resistance gauges
	Piezoelectric sensors
	Vibrating wire sensors
Degradation processes	Acoustic emission sensors
	Chloride level sensors
	Sensors of pH level
	Corrosion sensors

4 MONITORING IMPLEMENTATION AND OPERATION

General scheme of implementation procedure of long-term monitoring system based on sensors is presented in Figure 2. In the first step the goals of the monitoring system should be defined as a basis for the system architecture design. After detailed designing of all components and installation of the whole system on the bridge the testing procedure should be performed. Experimental values should be compared to results achieved by means of theoretical model of the structure (Bień J. 2011). Testing process should also confirm that bridge performance indicators can be observed using the monitoring system.

In the case of positive results of the testing the monitoring system can be accepted for operation. During long-term action of the system some maintenance activities are often necessary, including modifications of the system elements and improvements of the bridge theoretical model engaged in analysis of monitoring results.

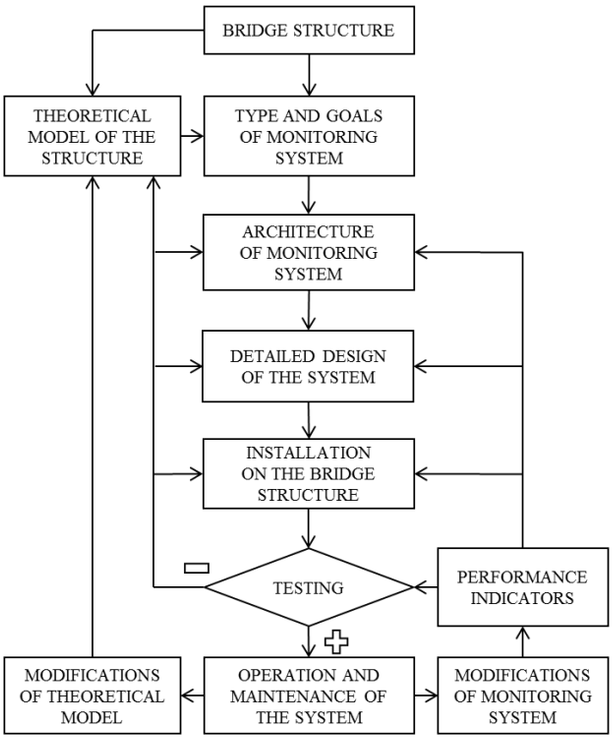

Figure 2. General scheme of monitoring system implementation.

Contemporary bridge monitoring systems are often equipped with knowledge-based expert tools supporting processing and analysis of experimental data as well as supporting decisions in management of bridge operation and maintenance (Bień J. & Rawa P. 2004). Taking into account fast development of the Information Technology (IT) we can expect that in the near future the bridge monitoring systems will be a part of the unified Building Information Management (BIM) process (Chang-su Shim et al. 2017).

Operation scheme of an advanced monitoring system is presented in Figure 3. The basic components of the systems are:

- measuring system with equipment transmitting data to acquisition module,
- data processing module using theoretical model of the structure for analysis and interpretation of measurements,
- module responsible for presentation of output data, often equipped with visualization tools,
- expert system supporting decisions in management of bridge operation and maintenance by means of information collected in data and knowledge base (Bień J. et al. 2010, Kamiński T. et al. 2013).

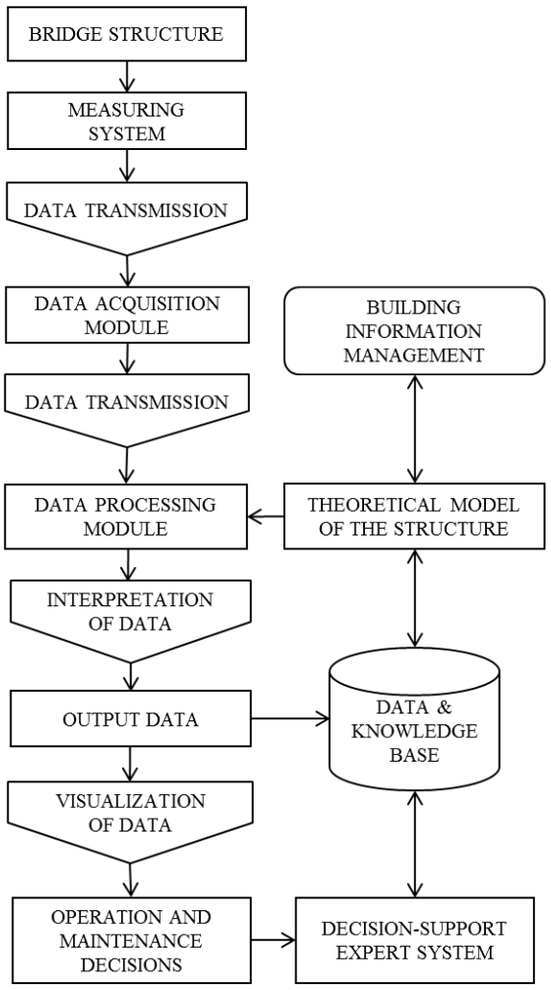

Figure 3. Operation scheme of monitoring system supported by knowledge-based expert system.

5 CONCLUDING REMARKS

Monitoring of bridge structures' condition plays more and more important role in management of roadway bridge infrastructure. Structural health monitoring is one of the diagnostic tools evaluated within the COST Action TU1406 "Quality specifica-

tions for roadway bridges, standardization at a European level" as a significant instrument in bridge quality control. It may be carried out both in a permanent way by means of built-in gauges mounted on a structure as well as within systematic inspections and arranged tests of a limited duration with application of external measuring devices.

The main objectives of monitoring processes in bridge management can be formulated as follows:

- on-line observation of bridge technical condition and serviceability based on predefined performance indicators,
- analysis of changes in structure response to loads focused on detection and identification of defects,
- acquiring of input values for individual lifetime model for monitored bridge helpful in operation and maintenance planning,
- cognitive analysis of bridge structures behaviour for improvement methods of designing, modelling and analysis, maintenance, optimization of costs, etc.

Proposed terminology with definitions of basic terms as well as classifications of types of monitoring systems with measuring methods and techniques create an approach to unification of this bridge engineering area on an international level as a part of the COST Action TU1406.

Bridge Management in Australia and New Zealand: Current Approaches and Future Needs

M.M. Melhem & C. Caprani
Department of Civil Engineering, Monash University, Clayton, Victoria, Australia

A. Ng
VicRoads Asset Services, Kew, Victoria, Australia

ABSTRACT: This article presents a review of the management of existing road bridges within Australia and New Zealand. Currently, the approaches to bridge management vary between the nine regional road jurisdictions. Different performance measures are applied, and different road bridge management systems are used. A uniform approach and agreement of the performance goals is desirable. Hence, the future needs required for these jurisdictions will also be discussed. Achievement of a uniform system not only provides an efficient way for bridge management of road bridges, but also allows quality assurance for their design life of 100 years and beyond.

1 INTRODUCTION

1.1 *Importance of Bridge Management*

Bridges are a fundamental component of the road transport infrastructure, linking communities and enhancing network productivity. But with aging infrastructure, increasing traffic demand, larger heavy vehicles, funding constraints, and other problem hazards, there is increasing need for quality assurance for the existing road bridges during their design life (Geiger *et al.,* 2005). For Australian and New Zealand bridges, the design life is 100 years (AS5100.1, 2017), one of the longest design lives internationally. Therefore, it is a significant task for both countries to assure performance goals are met to provide an efficient and effective transport network.

Performance goals can be on three different levels (Stipanovic *et al.*, 2017). At the operational level, performance goals for the individual road bridges and their components are considered. The tactical level includes part of the road network, such as series of bridges forming a major highway. And the strategic level considers the entire road bridge network and connectivity. For each of these levels, a range of performance goals can be present. Cost Action TU1406 indicate performance goals are that a road bridge or road bridge network should be safe, functional (serviceable), available, cheap and environmentally friendly (Straus & Mandic Ivankovic, 2016). Netherlands' Rijkswaterstaat (RWS) have considered a RAMS-SHEEP approach for road bridges; reliability, availability, maintainability, safety, security, health, environment, economical, political (Casas & Matos, 2017).

To measure whether these performance goals are being met, key performance indicators are compared to performance targets. The performance indicators are described through performance measures. Examples of performance measures at the operational level include condition rating, and at the strategic level include level of service. The process of measuring performance indicators to compare with targets to assess performances is best facilitated by road bridge management systems (BMSs).

A BMS assists with information collection, storage and analysis of bridges in a road network and is designed to support decision-making about funding quality assurance works that ensure road bridges met performance goals (Austroads, 2009). Database modules provide information on the performance of the bridge network and interact with predictive models to output results that assist in the planning of any future works program. Examples around the world include "AASHTOWare" Bridge Management (formally PONTIS), BRIDGIT, and OBMS (Austroads, 2013). The road bridge management process is an ongoing cyclic process. That is, after the works program is completed, the relevant database modules are updated, and the predictive models interact with the modules once again.

1.2 *Australian and New Zealand Context*

In Australia and New Zealand, more than 50,000 road bridges are currently in service (Rummey & Dowling, 2004). The road bridge stock is aging,

with the majority of existing road bridges in Australia built immediately after World War II when the country underwent a significant construction boom (Ng *et al.*, 2017).

In addition to the aging problem, Australia is heavily dependent on road freight. Out of the total freight task, 95% is carried by vehicles weighing 4.5 tonnes or more (Department of Infrastructure and Regional Development, 2014) and this road freight task is projected to double after 2030 (Bureau of Infrastructure Transport and Regional Economics, 2013), putting increasing pressure to allow a higher volume, and even heavier, vehicles on Australian road networks.

Over 800 agencies and jurisdictions are responsible for managing road bridges in Australia and New Zealand (Rummey & Dowling, 2004). These include a combination of private and public sectors, local councils, and nine regional road jurisdictions (State Road Authorities or SRAs) (Table 1). The three largest of these road jurisdictions, measured by number of structures managed, are located in the most populous states of Australia; Queensland (Department of Transport and Main Roads – TMR), Victoria (Roads Corporation – VicRoads), and New South Wales (Roads and Maritime Service – RMS)

Table 1. Nine regional road jurisdictions (SRAs) ranked by number of bridges and culverted managed (Sonnenberg, 2014)

Road Jurisdiction (SRA)	Abbreviation
Department of Transport and Main Roads Queensland	TMR
Roads Corporation Victoria	VicRoads
Roads and Maritime Service New South Wales	RMS
Department of Planning, Transport and Infrastructure South Australia	DPTI SA
Department of Infrastructure, Energy and Resources Tasmania	DIERT
Main Roads Western Australia	MRWA
Department of Urban Services Australian Capital Territory	DUS
Department of Infrastructure, Planning and Environment Northern Territory	DIPE NT
New Zealand Transport Agency	NZTA

This article presents a review of the management of existing road bridges within Australia and New Zealand. Currently, the approaches to bridge management vary between the SRAs. Different performance measures are applied and different BMSs are used. Indeed, a uniform approach and agreement of performance goals is desirable, especially with the advent of the national Performance Based Standards for Australia. Hence, the future needs required for these jurisdictions will also be discussed. Achieving a uniform system across these regions not only provides an efficient way for bridge management of road bridges, but also allows quality assurance for their design life of 100 years.

2 CURRENT PRACTICE

2.1 *Approaches to Management*

Since the 1990s, in both Australia and New Zealand, SRAs have been individually adapting bridge management approaches used overseas (Michael, 1994).

Generally, there are two bridge management approaches used in practice: top-down and bottom-up. The top-down approach begins at the strategic level. Quality assurance projects are commissioned for the entire road bridge network based on the needs of stakeholders such as road users, government, and the environment. From the bottom-up, quality assurance is managed by collecting inventory data, such as condition and capacity, from individual road bridges. It is this data that then drives the policies to ensure the bridge network continues to perform in a manner fit for purpose (Austroads, 2013).

When reviewing overseas practice, most SRAs considered the American BMS. In New Zealand, it was found that such a system was too "data hungry", and that given the small number of road bridges managed by NZTA, a simpler system could be applied (Austroads, 2002). Hence, New Zealand adopts a top-down approach to road bridge management. On the other hand, Australia mainly considers a bottom-up approach (Figure 1)

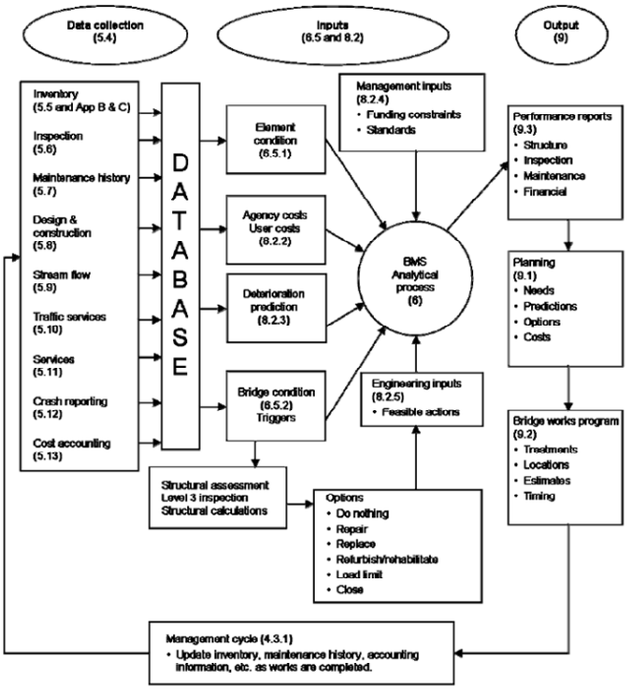

Figure 1. Road bridge management system cyclic approach across Australia and New Zealand (Austroads, 2009)

2.2 *Bridge Management Systems in Australia*

Most of the road jurisdictions in Australia have some form of a database system to capture information about bridge inventory, inspection data, condition reports, and capacity assessments. These systems have slight differences, but all have the same ultimate objective; to assist in planning for commissioning of future performance assurance works.

The earliest reported road bridge management system is that of Main Roads Western Australia (MRWA), operating in the late 1980s. Moreover, the system in the Department of Planning, Transport and Infrastructure South Australia (DPTI SA) is said to be operating for more than 30 years (Austroads, 2002). In 1995, a strategy for managing the performance of bridges in Victoria was introduced by VicRoads (Austroads, 2013). It concluded that a system was required to capture bridge inspections, condition, load capacity, and setting of realistic budget need. As such, the VicRoads bridge management system was developed. It comprises basic modules of inventory with inspection and maintenance recording. Other bridge management systems similarly developed includes those by Roads and Maritime Services, New South Wales (RMS NSW), Transport and Mainroads (TMR), Queensland, and Department of Infrastructure, Planning and Environment, Northern Territory (DIPE NT).

Over the years, these bridge management systems have undergone a series of revisions. One notable change is the move towards coverage of all road structures, and not just bridges. For example, in Victoria the current system is the Road Asset System (RAS), and in Queensland, it is the Structural Assets Management System (SAMS).

2.3 *Inspection Manuals*

As shown in Figure 1, inspections are necessary in the road BMS. They provide an up-to-date inventory for the structure, including its condition and capacity. Indeed, each SRA have developed inspection manuals as part of their road BMS. Often, these documents form part of the relevant laws for the region (for example, the *Road Management Act 2004* in Victoria). Additionally, local government road agencies within the state are likely to use their regional road jurisdictions inspection manual for the management for their local road bridges.

A tiered approach to inspections is outlined in the manuals for the largest three regional road jurisdictions; VicRoads, RMS and TMR (Sonnenberg, 2014). There are minor differences between these three road jurisdictions. Notably, VicRoads and TMR follow three levels of inspections, whereas RMS follows four levels.

Level 1 inspections are practically a drive-by inspection of the structure to ensure it is still functioning with no obvious gross defects. This simply updates the road bridge inventory. This occurs once every 6 months in Victoria, between 6 to 12 months in Queensland, and according to road maintenance in New South Wales.

Level 2 inspections are condition assessments based on close visual inspection conducted by an inspector. Some road jurisdictions conduct accreditation program for their inspectors. Based on the individual element condition ratings, the bridge condition is quantified, using an approach discussed later. The frequency of these inspections depends on the structure type, condition, and location.

Level 3 investigations are detailed engineering studies performed by structural engineers, which may include material testing to quantify structural integrity issues. For Victoria and Queensland, Level 3 includes structural analysis to quantify the load-carrying capacity of the road bridge. Whereas, Level 4 assessments in New South Wales quantify the load-carrying capacity of the road bridge, including proof loading tests. They are conducted when deemed required.

At first, these inspection manuals considered bridge structures only, but nowadays inspection manuals also provide guidance for all road asset structures. Other changes include guidance for higher level inspections, and clarity for condition inspection of structural elements that were not made of steel or concrete (VicRoads, 2014).

2.4 *National Standard*

When a national code for the design for new bridges was drafted in the early 2000s, the need for a section covering the assessment of existing bridges was vital. Indeed, the first edition of the Australian Standard AS5100 (2004) included *Part 7: Rating of Existing Bridges* to achieve this aim. The standard outlines how rating for a bridge is calculated for load-capacity estimation. It became the basis for Level 3 (or Level 4 for RMS) investigations.

The 2004 AS5100 code had some limitations, including limited information about the methods of assessment for different materials, such as masonry, for example. Often road agencies would refer to international standards to perform the higher-level investigation (Shoghi & Giufre, 2017). The code recently (2017) underwent an update to provide a clear methodology on how bridge assessments are to be conducted. In particular, the order in which condition assessments and capacity assessment are performed is clarified (Figure 2). Additionally, the methods for testing of different material types are detailed in *Part 8* of the Standards.

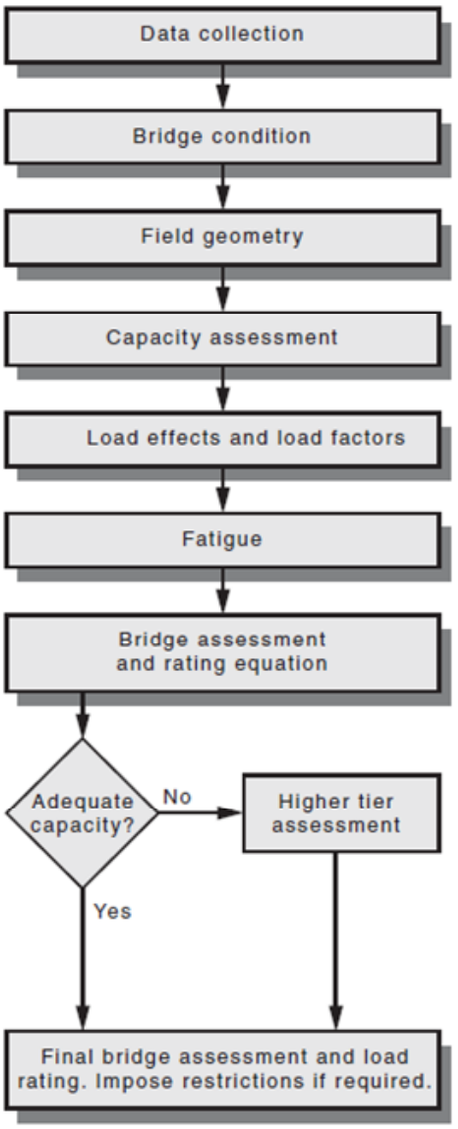

Figure 2. Australian and New Zealand Bridge Capacity Assessment Flowchat (AS 5100.7, 2017).

3 PERFORMANCE MEASURES

3.1 *Performance Goals to Indicators*

The performance goals for the individual road jurisdictions in Australia/New Zealand are not explicitly documented. This is different to other international bodies such as Netherlands' Rijkswaterstaat . However, Austroads (2009), the association of Australian and New Zealand road jurisdictions, have concluded the main performance goals for road bridge networks are:

- Functionality: minimum traffic delays;
- Safety: safe for intended use;
- Aesthetics: maintenance of an acceptable appearance;
- Sustainability: no backlog of repairs, and;
- Economic: keeping costs to a minimum.

The suggested key performance indicators by Austroads (2009) for measuring these goals are:

- Condition;
- Reliability;
- Remaining life;
- Risk;
- Socio-economic, and;
- Sufficiency indicators.

The extent to which the suggested indicators are applied as performance measures varies across the nine regional jurisdictions. As alluded to earlier, the bridge management practises across the jurisdictions are often at the operation level (bottom-up), which would suggest strong usage of the above performance measures. Nevertheless, the quantitative targets for these indicators is limited: it appears that subjective rankings are instead used for decision-making about future maintenance works.

3.2 *Condition Ratings*

Condition ratings are visual inspections of the elements that make up the road bridge to provide a measure of the condition for the structure. This in turn advises whether the performance goals of functionally and aesthetics are being met. Across all jurisdictions, condition ratings are performed as part of Level 2 inspections. The individual components of the bridge are visually inspected and then quantified based on a scaled rating system.

Most states in Australia use a 1 to 4 condition state rating for individual elements on a bridge, with 1 being as-built and 4 being poor (Austroads, 2013). NZTA uses five condition states, where the last state is complete failure of the component. Similarly, TMR has a condition state 5, but used for when the entire structure is rated as unsafe – it is not used at the component level. Only DPTI SA has a more significant difference to the other authorities: eight element conditions ratings are used, 0 to 6, and 9 (Not Applicable, Very Good, Good, Adequate, Poor, Very Poor, No rating, Unsafe).

After assessment of individual components, the overall bridge rating is then quantified. However, this step is conducted differently by the road agencies. For example, VicRoads applies a weighted average method, the Bridge Condition Number (BCN). It is an average rating for the clustered group of elements that are weighted based on the perceived importance in the structure. This results in a bridge condition index from 100 to 0, with 0 being as-built (Austroads, 2013). Figure 3 shows the BCN publically available for road bridges in Victoria. Alternative methods for bridge conditions include the RMS Bridge Health Indicators (BHI): it is qualitative method, reporting the bridge as either "Poor", "Fair" or "Good" based on the condition state and importance of the element under consideration.

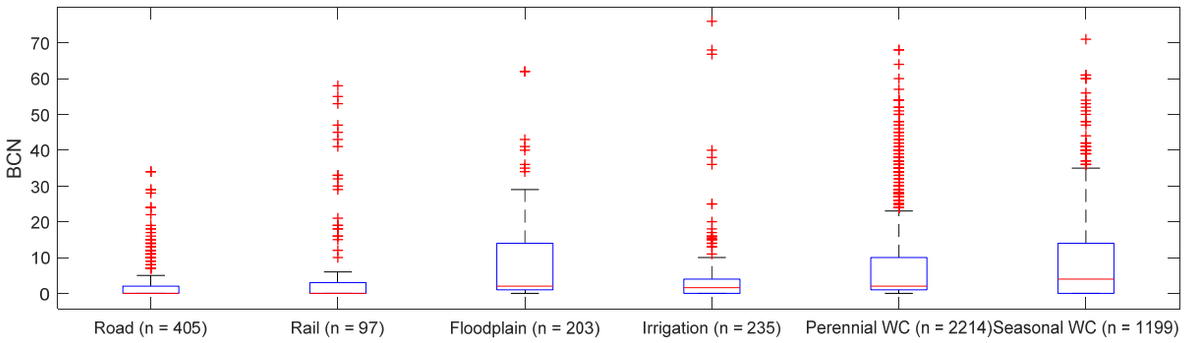

Figure 3. Published Bridge Condition Number (BCN) for "Road Over" Bridges in Victoria indicating current bridge conditions. (WC = Watercourse) ('n' = sample size) (Reference: VicRoads Data).

It is important to note that element condition ratings are a subjective process. However, authorities have in recent years enacted approaches to reduce this subjectivity, namely: (1) training and certification of bridge inspectors; (2) inspection manual guidance, such as photographic examples of different condition ratings for elements. Ultimately though, there are no quantitative measurements at Level 2 inspections – with the minor exception of crack widths.

3.3 *Sufficiency Indicators*

Aside from condition, there are other bridge sufficiency measures. Austroads (2004) suggested bridge width, bridge vertical clearance, and bridge load capacity. These parameters indicate the level of functionality for the road network.

Bridge width in the road network context refers to the percentage of bridges not providing the target trafficable carriageway width for the location. These targets vary between each road jurisdictions and depend on the local circumstances and route strategy. Additionally, each road authority specifies their target clearance for road bridges depending on local circumstances and route strategy.

Bridge load capacity for the network is the number of bridges with live load capacity less than the legal requirement. AS5100.7 (2017) presents a multi-tiered approach for capacity assessment (Figure 2). The load rating factor (*RF*) is nationally recognised as the first-basis for measuring load capacity. The rating factor is expressed as:

$$RF = \frac{\text{Available capacity for traffic load effects}}{\text{Load effects of nominated rating vehicle}} \quad (1)$$

where the structural capacity of the existing bridge is determined using the relevant contemporary design standards. However, alternative measures are used by the regional road jurisdictions for heavy vehicle access considerations. For example, as a proxy for capacity estimation, the live load model used for the bridge design is used in some cases. As an example of this approach, VicRoads applies the Critical Ratio algorithm when determining if a heavy vehicle is approved for restricted travel (Caprani & Ng, 2017);

$$CR = \frac{\text{Proposed vehicle load effects}}{\text{Reference load effects}} \quad (2)$$

The standard also allows load capacity measures using results of field investigation, and test loading in the field. The extent of these vary depending on the regional road jurisdictions.

3.4 *Strategic Measures*

Condition ratings and sufficient indicators are example of bottom-up performance measures. Data from individual bridges are combined to provide an indicator of the state of network. Bottom-up bridge management is common in Australia, but top-down performance measures are also used.

Life-cycle cost analysis can help identify the most economical action from a series of possible alternatives. Austroads (2013) presents the following model for the life-cycle cost for bridges:

$$LCC = DC + CC + MC + RC + UC + SC \quad (3)$$

where DC is the design cost, CC is the construction costs, MC is the maintenance cost, RC is the rehabilitation cost, UC is the user cost, and SC is the salvage cost.

Risk-based analyses have recently been introduced into the road BMS for particular SRAs. The risk is calculated as the product of the probability of failure and consequence of failure, which in turn comprised of tabulated factors that depend on the bridge properties. The probability of component failure (PCF) is expressed as:

$$PCF = LF \times RF \times CF \times IF \times EF \quad (4)$$

where LF is the loading factor (the type and number of vehicles), RF is the resistance factor (material type of different components), CF is the condition

factor, IF is the inspection factor and EF is exposure factor. The probability of system failure is calculated as follows:

$$PSF = \frac{\sum PCF}{n} \quad (5)$$

where n is the number of components in a system. Moreover, the consequence of failure is expressed as:

$$COF = HC + EC + TC + NC + RC \quad (6)$$

where HC is the human consequence (based on annual daily traffic), EC is the environmental consequence, TC is the traffic access consequence (detour distance), NC is economic consequence for replacement, and RC is the road class.

Other indicators, include the level of service for the network, and political motivators such as improving higher productivity freight vehicle (HPFV) access on the network.

4 FUTURE NEEDS

4.1 *Towards Unification*

As has been seen, there are many different approaches in road bridge management and variations in the performance measures across the regional road jurisdictions in Australia and New Zealand. While the latest edition of AS5100.7 provides clear definition on what is to be conducted for a bridge assessment, there is clearly still much room for the individual agencies to adopt their own method. Nevertheless, it is increasingly recognized that a unified approach would be beneficial. This comes on the back of other developments, such as the advent of the National Heavy Vehicle Regulator in Australia, who sets nationally applicable Performance Based Standards (PBS) for trucks.

A unified approach requires agreement of all road agencies and jurisdictions on whether three level or four levels of inspections are required, the scaling for the condition rating system, and the approach for measuring the overall bridge condition. Clear performance goals and prescribed performance targets are also required to achieve unification. Currently, a ranking approach is used for allocation of funds for future works.

Agreement on a unified approach would lead to the development of a single inspection and management manual applicable for all road bridges in Australia and New Zealand. Such harmonization would facilitate ready understanding of needs across all jurisdictions, and would reduce barriers for consultants to operate across jurisdictional lines.

Austroads Project BS.B.C.008 was initiated to develop a consistent approach and methodology for Australia (Rummey & Dowling, 2004). It concluded that the RMS approach to bridge management is most suitable. That is, a four-tiered level of inspection and modified version of the BHI to be used for bridge condition. In addition, the Austroads Bridge Task Force is currently proposing an investigation into the best approach to implement harmonisation.

4.2 *Improved Performance Measures*

Visual inspections for condition measures are prone to subjectivity, and can be particularly redundant if the process is sub-contracted outside the road jurisdictions. Therefore, SRAs should consider adopting structural health monitoring (SHM), weigh-in motion (WIM), and other recent technologies to quantitatively measure bridge performances. Such approaches are already adopted internationally. However, the use of such technologies have only been recently applied locally, with the latest version of AS5100.7 promoting the use of SHM in one clause.

A key point, not clearly addressed, is how condition measures can be used to determine the effective reduction in load-carrying capacity. Some international codes have developed different rules for assessment of existing structures to those used for the design of new structures. AS5100 does not follow this approach and states the structural capacity of existing components is to be determined using the relevant design standards. Thus, future revisions of the national standard should consider adopting different methods for the assessment of existing structures.

4.3 *Alternative Performance Indicators*

Deterministic bridge ratings provide a quick, efficient, and thus economical measure of bridge performance. However, ratings contain uncertainty as input parameters are subject to randomness and so may not reveal the true performance level. The use of a probabilistic approach can consider these uncertainties. Nowadays, bridge standards such as the American, Canadian, Danish, Swiss and British codes have moved away from traditional deterministic load rating processes and allow the use of reliability analysis for bridge performance assessments (Wisniewski *et al.*, 2012). The reliability index (β) as performance indicator for a limit state is commonly used internationally. AS5100 is yet to adopt this change. The reliability index can be considered for both safety and serviceability limit states, and at the element, or structure level. Ongoing work at Monash University and other international universities is attempting to extend this to the road network level as well.

A key hurdle to the adoption of an overarching safety-based framework is that the use of probabilistic methods for bridge assessment in Australia is not facilitated in AS5100:2017. While the 2004 edition

simply focused on the use of rating factors for performance assessment, the 2017 edition encourages the use of higher-tier assessments (Figure 2). However, details on what constitutes higher-tier assessments is limited. The Austroads Project TP1952 is currently investigating current SRA's methods that go beyond the current AS5100.7 and what international methods may be appropriate in an Australian context (Ng *et al.,* 2017). The early stages of this project have suggested that probabilistic methods and reliability indices are the basis of a framework to ensure safety whilst moving beyond deterministic evaluation.

4.4 *Updated Bridge Management Systems*

Deterioration models are an important aspect of BMS for maintenance optimisation. Based on the inspection data, deterioration models can provide an estimate of the deterioration rates. Typically, the probability of a structure or element moving from one state (condition rating) to another are estimated using Markov chains. This approach uses a matrix encapsulating transition probabilities which must be calibrated based on historical data. The problem with this approach is that by the time sufficient historical data is available to properly calibrate the transition matrix, the moment to take benefit of preventative maintenance has passed.

A survey conducted by Austroads (2002) concludes that none of the nine regional road jurisdictions use such models in their BMS. Research between universities and these jurisdictions are presently underway (Austroads, 2013). Hence, there are ambitions for inclusion of these models in their bridge management systems. It is important that the adoption of this approach is carefully calibrated using a combined laboratory data and field data approach to avoid the problem of timing mentioned above.

5 SUMMARY

Approaches to bridge management vary across the different road jurisdictions in Australia and New Zealand. While they all aim to achieve the same outcome, different performance measures are used for the different performance indicators to determine whether adequate performance exists across the bridge network. While the process towards unification has begun, clear performance goals with set targets, improved performance measures, alternative performance indicators such as the reliability index, and improvements to the existing bridge management systems are required. This will not only provide an efficient way for bridge management of road bridges locally, but also allows improved quality assurance for the remaining useful life of a bridge.

Repair and Retrofitting of Bridges under IBMS protocol

Sitarama Sagi Raju
Managing Director, IBMS, IDDC Engineers Pvt. Ltd.

Tumati Kiran kumar
Junior Bridge Engineer, IBMS, IDDC Engineers Pvt. Ltd

ABSTRACT: At present there are 169758 structures in Indian Bridge Management System (IBMS) on total 2.5% of national road network. Out of 169758 structures 36673 bridges which include minor, Major bridges. Based on the IBMS Rating system, we have identified 6551 bridges which are under distress condition (either structurally or functionally) and require either immediate attention or planned inspection.

Many a times even after taking all the due precautions and all quality control measures, bridge structures deteriorate. Generally the causes of distress on bridges are classified into three categories, such as Aggression by Mechanical elements, Aggression by Physical elements and Aggression by Chemical elements. From the above mentioned reasons, structure may be predominantly affected by Aggression by Chemical element from the day one it is constructed. Within the IBMS rating system, we prepare the probability matrix which will give us the Deterioration Time (Δt).

Based on the above mentioned cause of deterioration, we find out Primary cause of deterioration and Secondary cause of deterioration. Based on this cause of distress an appropriate principle is applied in order to suggest or recommend the repair/rehabilitation methodology.

1 INTRODUCTION

Bridges form one of the most important infrastructure facilities in the world. As a component asset management program, the Indian bridge management system (IBMS) facilitates performance-based and data-driven project planning by storing historical bridge data, including bridge characteristics, inspection data, rating information, uses deterioration models and economic models to predict future needs when optimizing network-level and project-level decisions. In world-wide phenomena the cause of deterioration is due to inadequate design & construction, overloading, lack of adequate maintenance, atmospheric effect and unseen abnormal floods, earthquakes etc. Effectiveness in detection and characterization of major deterioration types: delamination, concrete degradation, reinforcement corrosion, and cracking.

Bridge Management system are used to monitor and making a decision‟s regarding maintenance, preservation, and repair, subject to budget constraints. Defining general processes and addressing distress, diagnosis of the cause, proposing remedial measures and the corresponding principles and methods. It generates detailed inventory data and condition ratings of assets, ensuring the dynamics of deterioration process are captured.

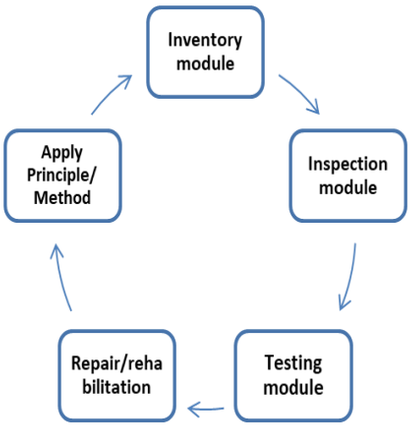

Figure 1. IBMS Life Cycle

IBMS use the principle of "FRWD" (First repair the worst damage) to ensure the entire bridge inventory is rendered in safe in a phased manner. IBMS applies a technical logic to manage the bridge assets during its life cycle.

2 FRAMEWORK FOR CONSIDERING IBMS PARAMETERS

Bridge has a unique identity number which is link with state code, RTO Zone, highway number, chainage and bridge number that gives national identity for every National highway bridges in India. To deep findings, picking precise location details in the form of latitude and longitude is being collected in auto mode using Ground Positioning System that accurate location of bridge. Engineering properties of bridge design, materials and other technical details of the bridge are being collected. In data collection Structural data, functional data and socio-economic data is collected on basis of rating system. Rating is between 0-9 conditions which are deciding the importance of bridge.

3 APPROCH FOR RATING SYSTEM

For Structural data, we consider Integral-Non Integral Deck, Super structure, Sub-structure and Scour. For functional data Bank & channel, waterway adequacy & deck geometry etc., are taken into account. For Socio- Economic, daily traffic, economic growth, environmental impact etc., are collected. For every component rating „0" is worst condition and „9" is excellent condition each rating has descriptive details is presented. In every rating system is accumulating with alpha numeric string. Based on performance of rating will decide bridge condition either bad or good in technically. Deep finding for inventory data apply classified filter to view data by as structural form, material of construction, type of bridge, loading as per IRC, age of bridge, traffic lane on bridge, crossing feature, length of bridge, width of carriage way.

Over viewing bridge inspection report details that gives all the details with component wise such as structural data, approach details, protection works, foundation, superstructure, substructure details, bearing & pedestals, expansion joints, drainage system & wearing coat, etc.,

Based on this inventory rating codes, IBMS analyse the data and indicates the bridge which needs further investigation which is in depth or detailed study using various Non- Destructive test procedures. A detailed remedial plan is defined for each bridge tested.

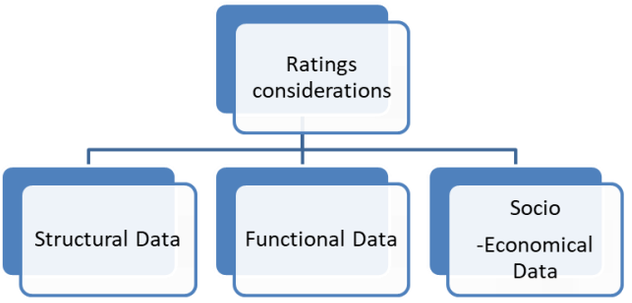

Figure 2. Rating Module

4 EVALUATING DISTRESS BRIDGES BASED ON RATINGS

In the first task, inventory data and rating is completed, the same is required to be validated during the inspection stage.

The second task during Bridge Inspection, the Bridge Inspection Engineer has to ascertain the ratings provided during inventory. This provides for in built validation of data collected during inventory. Based on the observations of the bridge parameters and the environment and traffic condition existing at bridge location, it is essential for the bridge Inspection engineer to reassess the rating provided by the Inventory engineer. This procedure fulfils the need for self-validation of all data that ensures that data used by IBMS in processing is correct and validated. Inventory compiles Structural rating (SR), Functional rating (FR) & Socio-Economical rating (SER). If structural rating (SR), are below 5 then either of the three conditions (C1, C2, and C3) are applied.

1. Where C1 applies if SPi $\leq$2, where i=1 to 4 then immediate attention
2. Where C2 applies if SPi $\leq$5 and $\geq$2 where i=1 to 4 Planned inspection within 6 months
3. Where C3 applies if SPi $\geq$6, where i=1 to 4 Inspection only as per schedule

From out of 35504 bridges, 6764 bridges are distressed condition. As below given table no of distressed bridges which have structural rating is below 5. For Immediate attention bridges which are responding for repair immediately because bridges are totally deteriorated, it may cause to economic loss. Planned Inspection which rating is 3, 4 & 5 is needed to test and if any distress identified then repair to notified. Inspection as per schedule is need to Re-inspected again next year to evaluate if it deteriorates testing proposed if not again inspection.

S.no	Type of bridge	No.of Bridges	No of distressed Bridges	Planned Inspec-tion	Immediate atten-tion
1	Extra-Long Bridge	1744	296	11	285
2	Major Bridge	3395	664	24	640
3	Minor Bridge	31534	5591	113	5478

Table 1. List of Distress Bridge

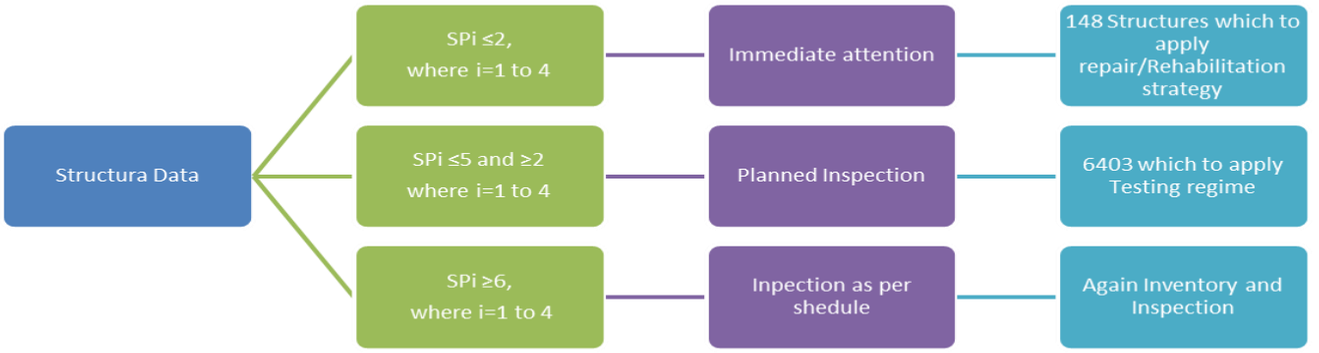

Figure 3. Flow chart shows decision making to identify distress bridges based on ratings

5 RENDERING BRIDGE SAFE

1. Cause Identification
2. Deterioration time identity
3. Applicability of MRSR

5.1 *Data Processing and Identification of cause*

The third task during the inspection process is to complete the prognosis of distress in bridge if any distress is observed. To be able to do this, it is critical that the Bridge Inspection Engineer to understand the various deterioration processes and what type of distress causes this deterioration process to happen.

The Distress in bridge is any situation; that is not designed and has occurred. Deterioration is the manifestation or propagation of this distress in a continuous manner to cause alarm. Bridge Inspection Engineer based on his expertise and knowledge will judge the reason for the distress to have occurred and this form the prognosis of distress. The main cause of distress which sometimes results in manifestation of other type of distress or is severe is called the primary cause of distress. The subsequent distress that gets manifested or resultant due to primary distress is called secondary distress. Distress can occurs in specific and localized manner as much as it can occur in the overall structure. The final distress map of the bridge may be a result of multiple causes (primary cause and secondary cause) and combined effect of both primary and secondary causes. This could at times make it difficult to determine the correct primary cause. Primary cause can be defined as the cause that is seen to the maximum and has resulted in most extensive distress from among the all the other causes.

Ideally it is better to eliminate the causes rather than identify the cause. This could result in a matrix of causes. From among these identified causes, the primary cause can be confirmed if not properly identified initially.

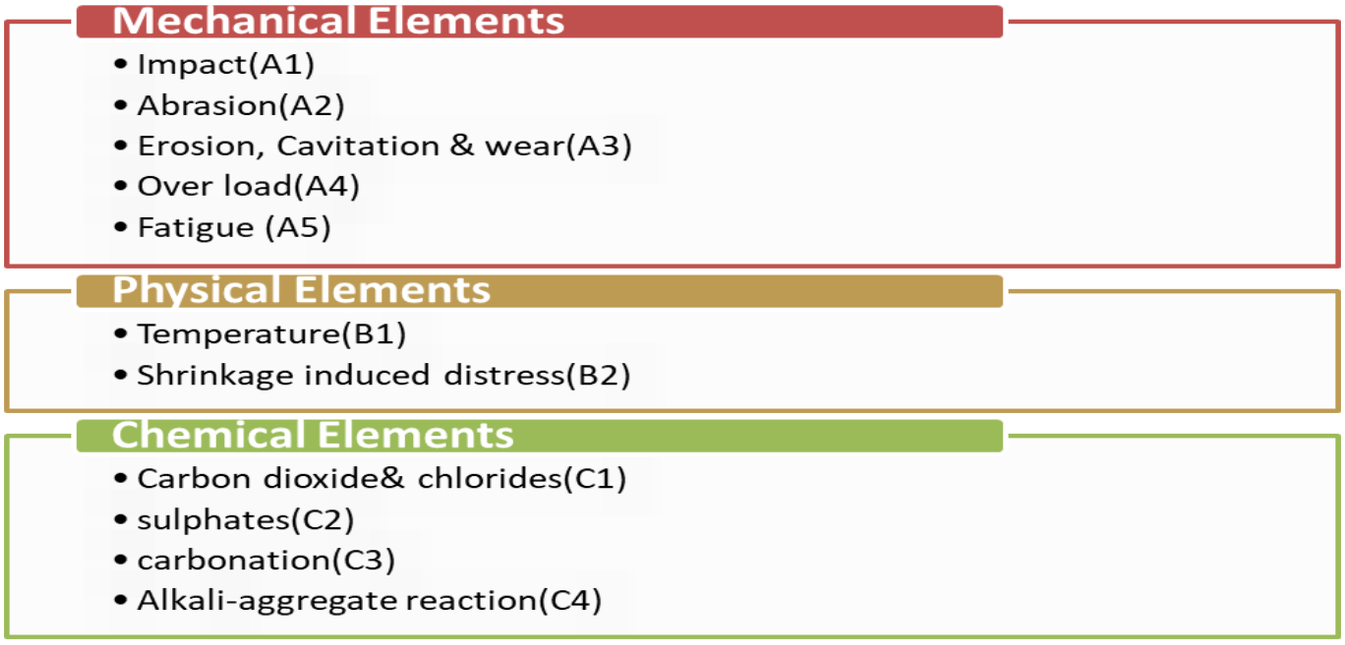

Figure 4. Causes Identification

5.2 *Identification of deterioration time*

By above defined causes is to be able to capture the combined effect of each of the process, based on site condition testing engineer will assign the rating number to each of the process and then combine these rating in the form of a **Deterioration Matrix P.**

$$\mathbf{P}= [\textit{Mechanical} \quad \textit{Physical} \quad \textit{Chemical}]$$

$$P=\begin{pmatrix} A1 & B1 & C1 \\ A2 & B2 & C2 \\ A3 & 0 & C3 \\ A4 & 0 & C4 \\ A5 & 0 & 0 \end{pmatrix}$$

This deterioration matrix is then converted to deterioration probability matrix. As per Rating system for every cause ratings are to be consider from "1" to "9" which stand 1 stands for worst and 9 is good [X1,X2,X3… X9) for each rating has description details. Rating 9 is good condition, so there is no possibility of deterioration X= [X9-1, X9-2, X9-3….X9-9]. Once the probability matrix is formed, the vertical column summation yields the impact probability of one particular process on the deterioration of the bridge. Input data is essential which is based on ratings allotted to the bridge based on site condition. Summation of all matrixes rating to get probability of deterioration in each clause of matrix P = [X9-1/X, X9-2/x….. X9-9/x]

The summation of Mechanical, Physical and Chemical process is should equal to 1

Year of deterioration T = Chemical Probability * Δt + Physical Probability * Δt + Mechanical Probability * Δt

$\therefore$ Δt is the deterioration time. It is based on the total impact such as overloading, environmentally effect.

5.3 *Applicability of MRSR*

5.3.1 Maintenance:

Maintenance is needed to preserve the intended load carrying capacity of the bridge to ensure correct functioning, aesthetic appearance and continued safety. It excludes any work leading to improvement of the structure by strengthening or by widening to carry heavier loads or wider gauge. It consists of the prevention of deterioration by normal causes, wear, and damage through accidents, vandalism and built-in imperfections. Maintenance deserves great attention. Maintenance is to be performed in a systematically way because it has been proved to be the most economical. All structures should be designed and constructed with consideration of both capital expenditure and predictable maintenance cost.

IBMS has in place over 150+ routine maintenance procedures (RMM), over 100+ detailed maintenance procedures (DMM) and frequently maintenance procedure (FMM)

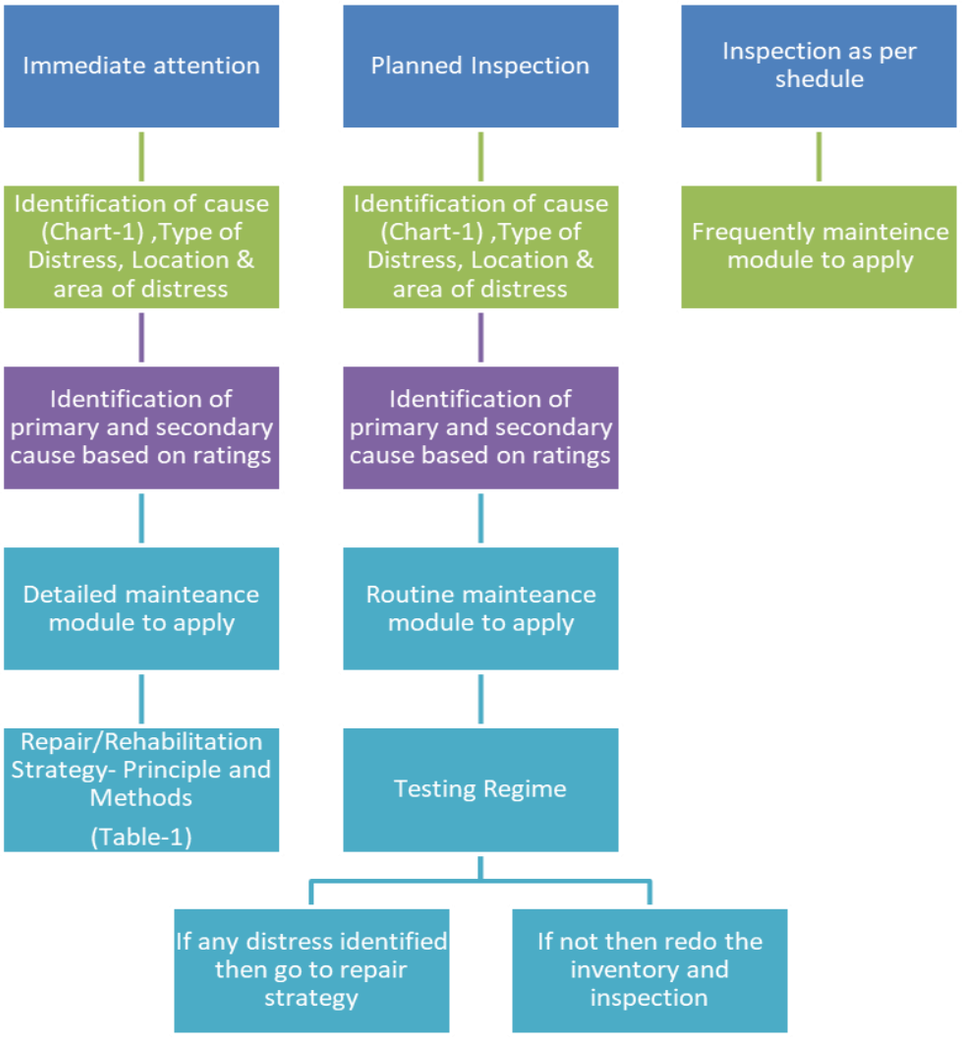

Figure 4. Protocol for MRSR

5.3.2 Repair/Rehabilitation:

IBMS has its immediate goal (2015-2020) to render all bridges safe and during subsequent period of time to increase the efficiency of bridge management. With this as the goal and focus, it is important that the choice of repair strategy is adopted. Based on the cause of defect/ distress, the primary and secondary cause of distress is identified. There are 24 tests that have a proper testing procedure and test results should adequately confirm the cause of distress. Similarly other contributory causes for distress are identified and the overall deterioration process is defined.

During identification of the cause of distress, laminar behaviour of the bridge is to be accounted for most the distress affects the lamina of the bridge component. Such effect could cause the surface lamina of the component to deteriorate faster than the section. Such effects are to be recorded and accordingly the repair strategy is to be selected.

Once the principle cause is identified, certain principles only can be adopted to address that cause. However as the bridge structure is massive, contributory factors and principle factor could be affecting the bridge in certain specific areas/ locations. In such cases the locations and cause will dictate the repair principle. Certain principle of repair need to applied to the whole bridge structure to enhance the performance of the bridge and such principles have to be applied post all other repair principles are applied.

Certain principle of repair need to applied to the whole bridge structure to enhance the performance of the bridge and such principles have to be applied post all other repair principles are applied In such cases the locations and cause will dictate the repair principle. Certain principle of repair need to applied to the whole bridge structure to enhance the perfor-

mance of the bridge and such principles have to be applied post all other repair principles are applied. Appropriate method of repair is very critical in the longevity in the performance of the repair section. IBMS follows a protocol which defines first the principle of repair for each of the cause of distress.

While detailed specification of each of the suggested method needs to be evolved, the basic principle followed is described herein under.

The specification which is product / system specific shall include the performance requirements for the product and the system to be used. Most of the product/ system fall under the generic of Chemical.

Based on ratings, cause of distress and nature of distress identification proper remedial principle will be adopted.

Sl. No.	Cause of Distress	Nature of Distress	Principal Possible Measures for Remedy
		(I) Distress in Concrete	
1	**(A) Mechanical** Impact, Overloading, Movement, Settlement, Explosion, Vibration, Seismic	Cracking Delamination Spalling Disintegration	1. **Crack Filling:** By Injection of suitable grouting and/or filler material after sealing them, Active cracks due to corrosion, ASR or foundation settlement etc. Should not be injection grouted. 2. **Concrete Restoration:** By Hand applied mortar, Spraying of mortar (Guniting), Spraying of concrete (Shotcreting), Recasting of concrete, Replacement of old element by new one 3. **Structural Strengthening:** By Addition of new reinforcement externally, Bonding of steel plates, Wrapping/Bonding by Fibre Reinforced Plastic (FRP), Encasing the member partly or wholly either by concrete or by mortar or ultra-high performance concrete reinforced or non-reinforced, Addition of new reinforcement by drilling holes & embedding in concrete, Pre-stressing by external cables.
2	**(B) Chemical** Alkali Aggregate Reaction, Aggressive Agents (Acids, Salts (sulphates, phosphates, etc.), Biological Activities		1. **Protection against Ingress:** By Sealing & Injection of cracks (for dormant / dead cracks only), of cracks, Impregnation of surface, Application of membranes, Surface coating, providing external panels. **2. Moisture Control:** By Coating of the exposed surface, Cladding over the surface, Impregnation of hydrophobic material. **3. Increasing Resistance to Chemicals:** By Overlays, Coatings, Impregnation
3	**(C) Physical** Shrinkage, Erosion, Wear and Tear, Fire		1.Protection against ingress 2.Moisture control 3.Structural strengthening 4.Increasing Physical Resistance: By Overlays, Coatings, Impregnation

(II) Distress in Reinforcement and Pre-stressing		
Carbonation of Concrete	Uniform Corrosion: Cracking & Delamination	1. Preserving or restoring passivity 2. Control of Anodic areas.
Corrosive contaminants: Sodium chloride, Calcium chloride & Others	Pitting & Stress corrosion: Spalling & Cracking	1.Cathodic control 2.Cathodic protection 3.Chloride of anodic areas 4.Restoring passivity
Severe progress of corrosion due to above effects	Scaling of steel: severe loss of surface area	Local replacement of steel reinforcement or part or full replacement of the member

Table 2. Remedial Principles based on causes

5.3.3 Strengthening

Strengthening operations aim at restoring the bridge to its original service level it once had and has now lost. In some cases this consists of giving the bridge the service level which was intended, but could not be attained because of deficiencies in the original design and/or construction. The procedures require design inputs and cannot be generalised. The design of these remedial measures needs in-depth analysis of the present status of the bridge component that needs to be strengthening and details of its original condition. Various techniques are available for strengthening of bridges and some of them are recent advances like use of FRP and similar materials.

5.3.4 Replacement

Replacement is to be carried out when the whole structure or at least its major components are required to be replaced, Replacement are essential at times when the age of the bridge has advanced and the bridge show distress where the cost effectiveness of the rehabilitation or strengthening is not economically feasible.

6 CONCLUSION

IBMS has attempted to adopt a logical flow of process to be used to define the various maintenance, rehabilitation, strengthening or replacement procedures. The basis of such decision making rests on the dynamics of the bridge and its condition defined just before the decision is required to be taken. At time, the decision is triggered due to deterioration process and in such case the logical sequence would be try and prevent the bridge from further deterioration.
IBMS aims to render all bridges safe by application of MRSR modules to the bridges few at a time (presently using the FRWD protocol to bridges whose rating is below 3) and once all bridges are rendered safe (rating above 5), the efforts would be directed to improve on the efficiency of the management of bridges by ensuring all bridges have repeat rating above 6 and would only require timely maintenance.
The quantification can also be automated once the as built drawings of the bridges are available and then on this drawing we superimpose the distress. The future of IBMS shall involve application of BIM (Bridge Information Modeling) to IBMS.

Technology exploitation is the motto of our IBMS and hence we are looking for future trends that can be applied to this process.

The construction of the new Tappan Zee Bridge

R.D. Csogi, PE
Greenman-Pedersen, Inc., Babylon, New York

ABSTRACT: Construction for the original Tappan Zee Bridge started in March 1952 and the bridge opened to traffic on December 15, 1955. The original bridge was designed to last only 50 years due to material shortages during the Korean War at the time of its construction. The aging bridge bears an average of 138,000 vehicles per day, substantially more traffic than its designed capacity. The new Tappan Zee Bridge is being constructed just to the north of the original structure. It is a 3.1 mile twin crossing comprised of low marine viaduct Approaches, and features twin cable-stayed bridges over the shipping channel. The new bridge has a fully integrated Health Monitoring system designed to monitor the structure for its full 100 year service life. The construction cost is valued at $3.98 billion.

1 INTRODUCTION

The new Tappan Zee Bridge is being constructed over the Hudson River literally yards to the north of the existing bridge … for a specific reason. First the location of the original Bridge has to be explained. The site of the original bridge is at the Hudson River's second-widest point at 3.1 miles wide.

The reason the site was chosen was to have it be as close as possible to New York City, while staying out of the 25-mile range of the Port Authority's influence, thus ensuring that revenue from collected tolls would go to the then newly created New York State Thruway Authority, and not the Port Authority. In order to maintain jurisdiction over the new Bridge, The Thruway Authority had no choice to build to the north.

With the location determined, next was the size, capacity and use of the replacement structure. The new crossing consists of two parallel structures built 32 feet apart from one another. This space and the parallel structures are designed to accommodate a rapid transit system in the future.

The South Bridge contains 4 lanes of vehicular traffic with adjoining emergency breakdown lanes, and carries eastbound traffic. The North Bridge also contains 4 vehicular lanes with adjoining emergency lanes. In addition, there is a shared pedestrian and bicycle pathway which is behind barriers and protected from the vehicle lanes. Also contained within the pedestrian/bikeway area are viewing "bump out" overlook pods at 6 location along the length of the Bridge.

The centerpiece of the new parallel crossings are the cable-stayed Main Span Bridges. Each cable-stayed bridge spans 1,200 feet over the Hudson River shipping channels. Each bridge has 4 concrete Towers that reach a height of 419 feet. Each bridge has 96 stay cables ranging in length from 190 to 623 feet (See Figure 1).

The new Tappan Zee Bridge is being designed and constructed under a Design/Build Agreement between the New York State Thruway Authority and Tappan Zee Constructors, LLC (TZC).

Figure 1. Artist Rendering of the New Tappan Zee Bridge

This consortium consists of Fluor Enterprises, American Bridge Company, Granite Construction Northeast, Traylor Brothers, and the major subcontractor, HDR serving as the Designer. Their winning bid was $3.1 billion, construction began in the Spring of 2013, and the proposed contract completion date is currently August 15, 2018.

2 THE DESIGN

In the traditional Design-Bid Build (DBB) arena, a design is developed to allow numerous Contractors to bid on a singular design. It incorporates common foundation, span length, deck systems elements that are common to most Constructors. Utilizing the Design-Build (DB) model, Contractors and designers are free to entertain designs that suit the Contractor's means and methods without the constraints of the DBB model.

The secret to Tappan Zee Constructor's winning bid was ultimately tied to their unique means and methods, or namely their one of a kind floating crane, the Left Coast Lifter. The Left Coast Lifter was built for the American Bridge/Fluor joint venture, which was the lead contractor on the new Oakland Bay Bridge in San Francisco, California.

The Left Coast Lifter is built on a barge hull. The barge was built in Portland, Oregon by U.S. Barge, LLC and ferried to Shanghai, where it was fitted with a shear-leg crane manufactured by Shanghai Zhenhua Port Machinery Co. Ltd. The completed sheerleg was ferried back to the United States on a semi-submersible heavy-lift ship. The shear-leg crane on Left Coast Lifter has a 328-foot long boom, weighing 900 tons with a 1,900 lift capacity. It is the largest barge crane ever used on the U.S. West Coast (See Figure 2).

Figure 2. The Left Coast Lifter erecting an Approach Span tri-girder segment.

With its lifting capacity of 1,900 tons, it allowed the designer to design bridge elements such as girders to unusually long lengths. On the Approaches, the typical span length is 350 feet from pier to pier. The superstructure girder design was driven by the capacity of the Left Coast Lifter. Each span consists of five 12 foot deep welded plate girders. The girders are fabricated in either 3 or 2 girder sets at a fabrication facility on the Hudson River just outside of Albany, New York. The girder sets are fabricated complete with all cross bracing, scuppers, and utility conduits. They are barged downstream to the work site and lifted onto the piers in either 2 or 3 girder units (See Figure 2).

The design of the foundations and substructure also relied on large modular units that also could be lifted with the Lifter. Due to the large amount of muck and soft soils that comprise the Hudson River bottom, the pile lengths were typically 360 feet in length, and 4 to 6 feet in diameter, with 1" thick steel walls. While not unusual for these soil types and large pier to pier span lengths, what was unusual was that these piles were fabricated in 180 foot segments and required only 1 welded splice.

In keeping with the use of modular components, the Pier Caps were precast off-site, barged to the pier stem locations on the Hudson River, and lifted with the Lifter. These Pier Caps were massive and most weighed in at 200 tons. Being of a trapezoidal shape, this saved a lot of intricate onsite forming on the river, and eliminated weather dependencies for the foundation work.

From the beginning, Tappan Zee Constructors decided to begin the design effort with Building Information Modeling (BIM) technology, and utilize this model throughout the fabrication and construction process. BIM enabled designers to visualize the structure in three dimensions and from infinite vantage points. This visualization can identify potential design conflicts early in the process and allow designers to discover efficiencies that can help reduce cost and improve construction scheduling. The BIM design model also helped to quantify and organize the materials needed for this project.

The open structure of the BIM model allows all project participants to coordinate their specific aspect of the design or construction. This includes the Prime designer, HDR, and all of its sub-consultants, as well as the Prime contractor, TZC, and all of their sub-contractors, and the Owner, the Thruway Authority. For example, Welsbach Electric Corp. used the BIM model to configure the installation of the bridge's electrical conduits and wiring. This was coordinated with the production of the crossing's steel girders.

Once the bridge is complete and operational, the BIM model will be utilized by future maintenance

crews. Each of the approximately 500,000 bridge elements can be viewed with links to pertinent design and maintenance information. Maintenance crews will be able to view the model from mobile devices, laptops or desktop computers. This will allow the crews to see every piece of the bridge at every possible angle.

3 MOBILIZATION

Before a single pile was driven or a single cubic yard of concrete was placed, an enormous amount of mobilization and preparatory work was required for this one of a kind bridge project. Multiple staging areas and equipment yards were constructed on both sides of the River. Field Offices and crew changing facilities were either built or reconfigured from existing buildings that were leased for the project. In all, these facilities were expected to support over 5,000 workers, engineers and other support staff for the duration of the project.

One such building that was procured after the Contract Execution between TZC and the NYSTA, was an on-site building to house the Designer's design staff and Contractor's procurement and management staff. These two entities were co-located under one roof to facilitate the numerous meetings that were required to ensure the speedy completion of the new bridge's design.

Other mobilization efforts that were being accomplished were the pre-construction geotechnical investigations both on land, and on several barge-based operations for additional engineering analysis of the river bottom. Dredging began in the shallow areas adjoining the riverbanks to support the staging of barge-mounted cranes and equipment. Over 800,000 cubic yards of material was removed from these areas. To compliment riverbank staging areas and to minimize the dredging efforts, two temporary construction trestles were built. Each totaling 1,000 feet in length and extended out into the Hudson River parallel to the alignment of the new Approaches.

The Left Coast Lifter was on its way from San Francisco via the Panama Canal to a shipyard downstream from the Tappan Zee near Jersey City. It spent several months moored there where it was modified for the specific needs of the project. This work included rigorous lift testing, precise tuning, careful inspections and installation of a new state of-the-art computer operating system complete with touch screen controls.

In addition, perimeter environmental monitoring stations were installed near both the Rockland and Westchester County shorelines as part of the New Tappan Zee Bridge Project's Environmental Performance Commitments (EPC). These commitments are intended to monitor, minimize and mitigate potential adverse effects related to construction noise, vibration and air quality associated with the project.

Noise was monitored very closely during construction. Highly sophisticated monitoring devices were installed at locations near the project site to ensure that construction activities are performed without exceeding allowable sound levels. The monitoring devices record the level of sound and automatically report back to the engineers should noise levels even approach a level not to be exceeded and then display the results online.

Finally, survey work was proceeding both on land and on the Hudson River for both control and foundation layout. Much of this work utilized the existing bridge structure as control and had to be accurately surveyed to verify as-built coordinates.

4 FOUNDATION WORK

Foundation work began with the development of an acceptable work plan that incorporated environmental considerations, a test pile program, and a quality assurance/control verification process. There are two basic components for the Approach Span Pier and Main Tower foundations … the concrete-filled steel piles, and a pile cap which consists of a precast slab unit which serves as the bottom form and steel modular forms to create a "tub" for each pile cap. These tubs are lifted and positioned atop each pile cluster at a pier location, fitted with reinforcement cages and filled with concrete (See Figure 3).

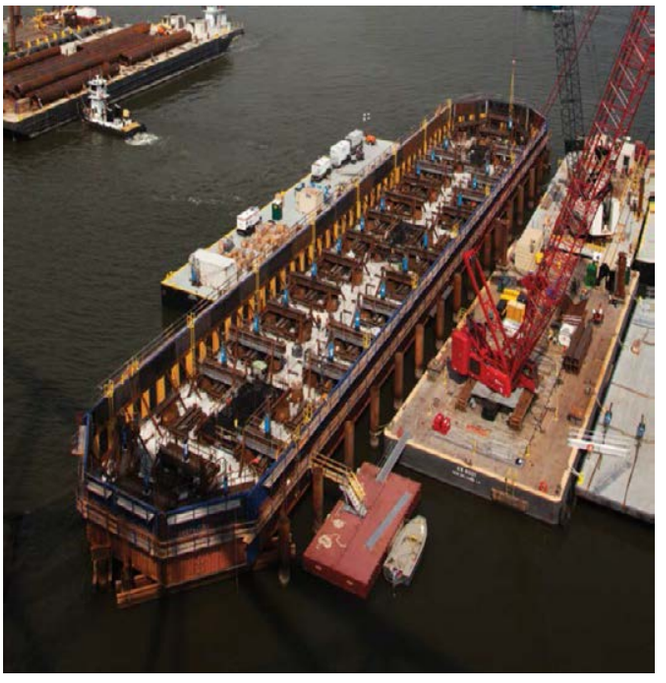

Figure 3. Main Tower Pile Cap Formwork

There are 1,000 piles that are utilized for the new Tappan Zee Bridge. In total, there are 41 Approach Span Piers and 2 Main Tower Piers. The Main Tower piles are 6 feet in diameter and the Approach Span Piers rest on 4 foot diameter Piles.

Some are driven to bedrock where it was located high enough to be reached. This occurred on the Westchester side of the Hudson River where the bedrock was approximately 150 feet below the river surface. On the Rockland side, it was approximately 700 feet below the river surface. These piles were designed as friction piles, some reaching 360 feet in length.

The largest cluster of piles were for the four Main Tower structures which are the major support structures for the twin cable-stayed bridges. The two Main Tower Piers were built large enough so the two side by side Towers share the singular pile cap. Each Tower foundation pile cap sits on 64 six foot diameter piles. Each Tower foundation pile cap measures 320 long by 60 feet wide, and is 14 feet thick.

The Main Tower piles were driven using a template, a 4600 barge-mounted Ringer crane, both a vibratory and impact hammers, and bubble curtain units for environment compliance. The Main Tower piles were installed in halves with the lower segment being 170 feet in length and weighing 70 tons. The upper segment was 110 feet and weighed 52 tons. The two halves were joined with a full penetration weld.

Each pile segment was lifted into the template guide and allowed to sink under its own weight approximately 40 feet into the mucky river bottom. The pile was tapped several times with the hammer to displace any fish in the vicinity, and the bubble curtain activated to deaden the driving noise for the aquatic life. The piles were conventionally driven to the required blow count.

The pile cap "tubs" (previously described) were lowered over the protruding piles with strand jacks, and rested on collars installed at the appropriate elevation. The rebar was set into position and the tubs were filled with 20,000 CY of concrete.

A unique feature to these operations were the use of floating concrete batch plants. Utilizing three floating concrete plants during the peak of construction was also a key aspect to TZC's competitive low bid. These plants were highly mobile and allowed TZC to deliver 125 cubic yards of concrete per hour (per plant) at any location on the Hudson River.

Imagine the logistics of having to move traditional concrete trucks to points on the river. Also imagine the number of these trucks that were removed from the Thruway and local roads by utilizing these floating batch plants.

In addition, these plants also included several environmentally-conscious features. An advanced air quality system reduced dust from escaping the plants during production and highly efficient, clean engines reduced emissions. All systems on the plant and its accompanying support barge were be painstakingly contained to prevent spillage into the river.

5 SUBSTRUCTURE WORK

The second year of the project saw substructure begin in earnest. Working with 130 barges fitted with cranes and various types of equipment and materials, work progressed on the Approach Span Piers and Main Towers.

Building atop the completed pile caps each of the Approach Span Pier stems were conventional formed with modular forms. These forms were completed to the required height and lowered around pre-tied and stacked reinforcement cages. The taller piers were constructed in segments by filling the lower segments with concrete, curing, and restacking to form the upper segment.

Once these stems were complete, the Lifter would erect the precast Pier Caps onto the stems. These Pier Caps were prefabricated by Coastal Precast Systems in Chesapeake, VA and were barged to the project site. These caps were trapezoidal shaped and weighed approximately 200 tons.

By far the most noticeable substructure elements for the new Tappan Zee Bridge crossing are the Main Towers for the twin cable-stayed bridges. Each Tower leg cants outward from the base until it reaches its final height of 419 feet. Each pair of legs are tied together at the final roadway elevation with a massive, precast concrete crossbeam weighing 700 tons (See Figure 4).

Figure 4 – Main Tower Construction with Precast Concrete Crossbeam in Position

Tower leg construction begins with the use of modular steel "jump forms". The jump forms, were positioned on the Main Tower pile caps, and enabled construction of the open concrete towers to take their shape. Crews used a series of climbing tower cranes and catwalks to install steel reinforcement and to cast the concrete. As each segment is completed, the forms "jump" to the next level via a screw jacking system, allowing the next segment to be built on top of the preceding one.

Each jump form is composed of two different forms, one internal form and one external. The external form moves upward ahead of the internal form, providing a safe area for workers to install rebar cages. While the rebar is installed, the internal form remains with the previous segment of the tower until the next segment is ready to be filled with concrete. The internal form is moved upward and both forms are then joined together, acting as casting chamber (See Figure 4).

6 SUPERSTRUCTURE WORK

Once the pier construction advances to a point where there are a substantial number completed, the erection of the steel superstructure begins. The steel superstructure actually begins at a fabrication facilities located in Pennsylvania, North Carolina and Virginia. They are welded steel plate girders that range in length from 350 to 410 feet, and are typically 12 feet deep.

They are shipped to a TZC assembly yard located at the Port of Coeymans on the Hudson River in Albany County. At the assembly yard, the girders are connected in either 3 or 2 girder units, or assemblies. Each girder assembly is bolted together with cross frames and all appurtenances including electrical, communication, etc. conduits. In all, 100,000 tons of steel were used to create 134 girder assemblies.

Each assembly is barged 95 miles from Coeymans to the bridge site. The first 410 foot, 850 ton assembly was set on June 17, 2015 using the Lifter. The Lifter utilizes a custom designed lifting frame which employs 4 hydraulic rams located at the 4 corners of the frame (See Figure 2). This allows the girder assemblies to be "pitched and yawed" to precise elevations to accurately set the assemblies on the bearings (See Figure 5).

The erection of the girder assemblies using the Lifter was a very unique operation. The Lifter does not have the ability to rotate its derrick type boom. It can only raise and lower the boom to change the pick radius, raise and lower the lifting frame and attached load. The Lifter's positioning system is comprised of four anchors positioned off each of the four corners of the barge hull, and connected with winch lines. By reeving in and bailing out via these winch lines, the Lifter can be accurately turned and positioned to pick up or position its load. All of the positioning capability for the Lifter is carefully controlled by its pilot, and assisted by way of GPS and computer enhanced controls.

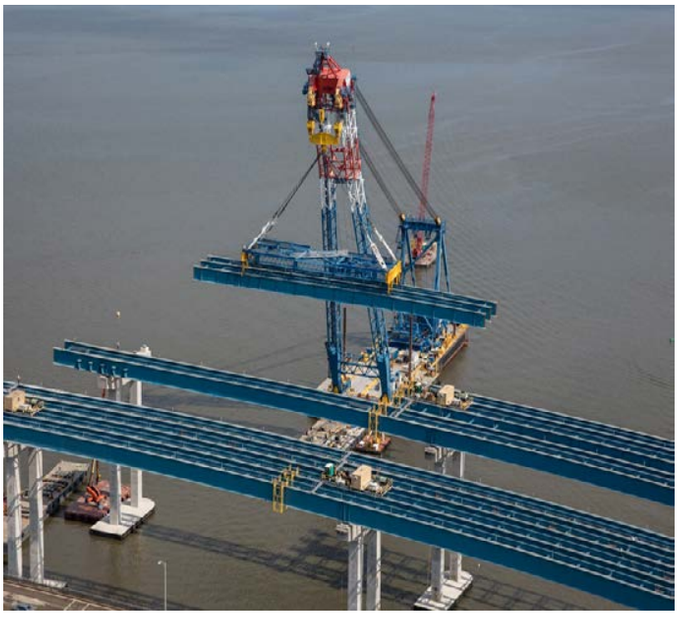

Figure 5 – Girder Assembly Erection Using the Lifter and the Hydraulically Controlled Lifting Frame

Most, but not all of the girder assemblies could be erected using the Lifter, and were traditionally erected on land by crawler cranes in smaller assemblies … except for one. On the Westchester side of the Hudson River is the first river pier, a land pier and the Westchester Abutment. Between the land pier and the first river pier lies the Metro-North Hudson Line railroad tracks. Running along the Hudson River banks, this extremely busy commuter line serves as a major transportation link between Westchester and New York City.

Land based cranes could not be positioned within the Metro-North right of way and effectively erect the Approach girders without fouling the track areas. Track shut downs would be limited and only allowed during minimal off-peak, nighttime periods. TZC developed an alternative girder installation method, they launched the girder assemblies over the Metro-North track areas.

The process began by erecting individual beams into a girder assembly on land and rolling it on a specially-designed track system just east of the Westchester Abutment, These assemblies were pushed west over the railroad tracks toward the first pier in the river. As the operation progressed, additional girders were connected and pushed westward until the assembly reached the first river pier. The entire operation took approximately three months, and work over the Metro-North tracks occurred during three Friday overnights. This approach maxim-

ized safety for both workers and the public and minimizes any potential impact to Metro-North Railroad and its passengers. Construction activities were suspended when trains passed through the area, and resumed when given the "all clear" instruction by Metro-North.

Following the girder assembly erection were the precast deck installation. In keeping with the modular approach to building the new Tappan Zee Bridge, over 6,600 precast deck panels were cast at off-site facilities and trucked to the Port of Coeymans fabrication facility and then barged to the work site.

Weighing as much as 74,000 pounds each, the approach span deck panels are 12 feet long, range between 22 and 45 feet wide and nearly 11 inches thick. When fully assembled, the deck panels for both the approach and main spans will comprise a surface area of more than 65 acres. The individual panels are joined together by pouring concrete around the galvanized steel reinforcement that extends out from each panel. The final driving surface will consist of a 1-inch Rosphalt overlay which will ensure durability and a safe, even ride for drivers (See Figure 6).

Figure 6 – Precast Deck Unit Installation on the Approach Spans

The final superstructure type is the twin cable-stayed structures. Work began with the installation of four large pre-assembled sections of steel, weighing nearly 340,000 pounds each, atop the main span crossbeams. These steel segments allowed the Main Span team to build out from the towers one section at a time, attaching stay cables to the structure along the way.

The new bridge utilized 192 stay cables to support the eastbound and westbound roadways on the main span. Crews first installed the casing with a single steel strand in place. Once the material is secured to anchor points in the main span towers and the steel girders of the road deck, workers installed additional strands through the casing, parallel to one another. The process continued until the casing is filled with strands.

Figure 7 – Erection of the Main Span Cable-Stayed Superstructure

Each side of the eight towers has 12 pairs of stay cables, ranging in length from 190 to 623 feet. The completed 2,230-foot main span supports a total of 74 million pounds of steel and concrete (See Figure 7).

7 CONCLUSIONS

Besides the construction of the actual bridge crossing, there are many more aspects to this project. For example, there are 36 existing buildings that are associated with the existing Tappan Zee Bridge. They range in function from NY State Police facilities to maintenance buildings. Some of these facilities will be maintained or replaced by TZC during the life of the project.

The facility component for the new Tappan Zee Bridge includes a new NYSTA consolidated maintenance and administration facility, a new facility for the New York State Police, and several electrical, communications and storage facilities. In addition, a temporary joint NYSTA/State Police facility will be established until construction of the new facilities are completed.

On August 25, 2017, 4 lanes of traffic from the existing Tappan Zee Bridge were shifted to the northernmost new bridge. This allowed a portion of the existing crossing to be demolished and the remaining tie in areas to be completed on the north-

ernmost new bridge. On October 6, 2017 when these areas were complete, the remaining 4 lanes of traffic were shifted to the new northernmost bridge. In this configuration, the new bridge carried all traffic from the original Tappan Zee Bridge.

Using the Lifter, demolition began on the existing bridge Approaches to allow the final tie in construction for the southerly new bridge to be completed. Demolition of the existing Tappan Zee Bridge will continue throughout 2018, and the second new bridge will be completed by June 2018.

Once complete, the 4 eastbound lanes will be shifted onto the newly completed bridge. This will be the final configuration with the eastbound and westbound traffic situated and separated on the two independent bridge crossings. The 100 year lifespan of the new Tappan Zee Bridge will begin.

A case study of early cracks of a concrete pylon

J.Song & X.F.Shi
Department of Bridge Engineering, Tongji University, Shanghai, China

ABSTRACT: The durability of concrete pylon is one of the key issues in the maintenance of cable-stayed bridges. However, a lot of wide cracks were produced at construction stage of many pylons, which may lead to a decrease in durability. The causes of cracks of a concrete pylon were studied in this paper. Firstly, the thermal parameters are identified by temperature test, and FEA method are adopted for simulation. It is proved that the hydration heat has a significant effect on cracking. The cracks are divided into two kinds: surface cracks and internal cracks. The surface cracks are caused by the sudden cooling during the formwork removal stage. The internal cracks are caused by the excessive temperature difference between segments. The analysis can provide reference for the prevention, treatment and maintenance of such structural.

1 INSTRUCTIONS

Pylon is a key component of the bridge with cable bearing system. Generally, it is built with segmental pouring method. According to the survey, the pylon is prone to produce a large number of cracks (Ma and Wang, 2002, Jing and Li, 2000, Gan, 2004) in construction stage, which seriously affects the appearance quality of structure. Part of the cracks has significant width, which may lead to a decline in structural durability.

The exorbitant hydration temperature in one of the main causes of cracks(Liu and Hu, 2017, Honorio et al., 2015). The control technology has been established in mass concrete, (ACI, 2007). However, crack control is not carried out much in the construction of pylon.

This paper mainly discusses the crack causes of a concrete pylon. After the construction of a segment, a large number of cracks were detected. The finite element model is established, which parameters are obtained by fitting the measured temperature, to verify the causes of cracks. The result of FEA simulation demonstrate that the main causes are the high temperature and lack of preventive measures.

The surface cracks are caused by the sudden cooling during the formwork removal stage. The internal cracks are caused by the excessive temperature difference between segments.

The deep cracks have adverse effects on structural durability and should be concerned in such structures. The case study in this paper can provide a reference for the prevention, analysis and maintenance of cracks.

2 DETAILS OF PYLON AND CRACKS

2.1 *Details of pylon*

This paper studies the lower part of the pylon. The total height of the lower part is 151.48m, horizontally divided into two limbs. The size of one limb is shown in Fig. 1. Longitudinal and horizontal dimensional proportion is 7:2. The middle of the section is hollowed. The solid area on both sides is 3×4m, and the thin wall is 8×1.5m.

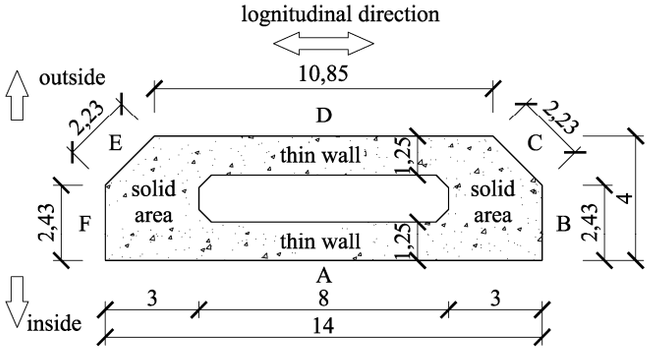

Figure 1. Size of section (unit: m)

The pylon used C50 grade concrete. Material consumption for one square: cement 336kg, fly ash 96kg, mineral powder 48kg, sand 714kg, gravel 1072kg, water 154kg. The adiabatic temperature rise is 58.3℃. The pylon is built segmentally. The height of one segment is between 4 to 6m. The outer surface is formed with WISA formwork (the material is wood), and the inner cavity is formed with steel formwork.

2.2 *Details of cracks*

This segments did not take any temperature control measures. The pouring height is 4.5m. The formwork were removed 4 days after pouring, and cracks are detected 10 days after pouring. The crack distribution are shown in Fig. 2.

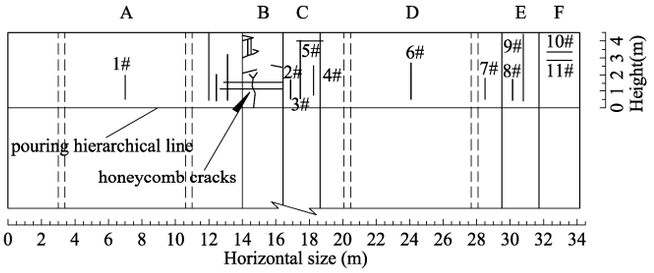

Figure 2. Unfolded surface of crack distribution

A and D are the outer surfaces of the thin wall. Vertical crack 1# and 6# are distributed in the center of these surfaces. The cracks rise from the interface of two layers of concrete with the height 2~3m and the width 0.1mm.

There are lots of cracks distributed on the surfaces of the solid area, such as B, C, E, F and sides of A and D. The side B is full of cracks, and most of the cracks are short with the width 0.05mm. There are 4 cracks in side C, 3 in longitudinal direction with crack length 1 to 4m and the crack width varies from 0.04 to 0.12mm. Another crack is distributed horizontally with crack length 1.4m and crack width 0.01mm. There are two longitudinal cracks distributed in side E, the crack length varies from 1.3～4m and the crack width is about 0.04mm. There are two horizontal cracks distributed in side F, its crack length is 1.5m and the crack width is about 0.09mm.

The detection shows that the cracks are characterized by large number and random distribution. The number of cracks in the solid area are more than that of the thin wall. The cracks on the solid area tend to be random, with different directions like horizontal, vertical and oblique, also the distribution is uneven. The cracks on the thin wall are more regularity, but the crack width is wider than solid areas.

3 CAUSE ANALYSIS OF CRACKS

3.1 *Finite element model*

Adopt ANSYS to establish finite element model of three segments of pylon. Single segment height is 4.5m. Considering the symmetry of the structure, half model is established. Element type of thermal analysis is Solid70. When stress analysis is conducted, the element is converted to Solid45. See the features of model and element in Fig.3.

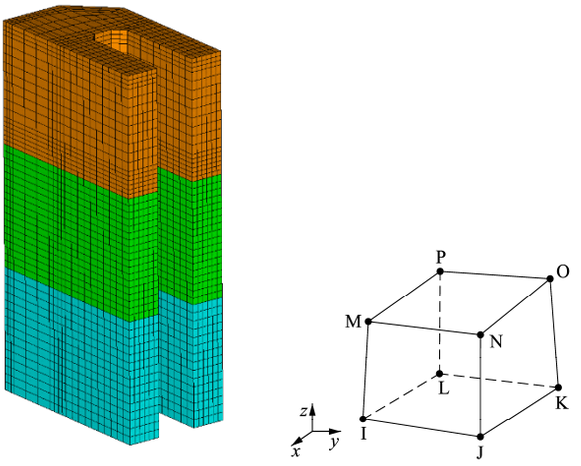

Figure 3. Finite element model and element characteristics

3.2 *Identification of parameters*

The basic formula of temperature calculation are as follow (Zhu, 2012, Kaviany, 2002):

$$\rho c\frac{\partial T}{\partial t}=k\nabla^2 T+\frac{dQ}{dt} \tag{1}$$

$$Q=Q_0\left(1-e^{-\gamma t}\right)=c\rho T_{abs}\left(1-e^{-\gamma t}\right) \tag{2}$$

where, T =temperature, t =time, ρ = density, c = specific heat capacity, λ = heat conductivity coefficient, Q = quantity of heat, Q_0 = total heat of concrete hydration reaction, γ = hydration reaction rate, and T_{abs} = increase in adiabatic temperature.

The concrete heat conduction equation requires a limit to the first and third boundary conditions. The first boundary condition is used to describe the initial temperature field of concrete pouring. The third boundary condition is used to describe the surface heat loss when the concrete makes contact with the fluid.

$$T\left(0\right)=T_0\left(x,y,z\right) \tag{3}$$

$$q=-\lambda\frac{\partial T}{\partial n}=\beta\left(T-T_f\right) \tag{4}$$

where, q = heat loss on a concrete surface, $\boldsymbol{n}$ =the outer normal direction on the surface, T_f = the fluid temperature, and β = convective heat transfer coefficient.

Table 1. Value of parameters

Para.	Value*	Para.	Value*	Para.	Value*
c	960	$T_{0,\ \text{pylon}}$	25	$\beta_{\text{wood formwork}}$	2
λ	2.33	T_{water}	22	$\beta_{\text{steel formwork}}$	5
γ	1.5	T_{air}	25	$\beta_{\text{top surface}}$	10
T_{abs}	58.3	β_{pipe}	380	β_{surface}	10

* In addition to temperature in degrees Celsius, the other parameters are used in international units.

The parameters are fitted by temperature monitoring. The final parameters are shown in Table 1. The

water temperature of the pipe and the air temperature are using the average value.

The measured data and simulation results are compared in Fig. 4.

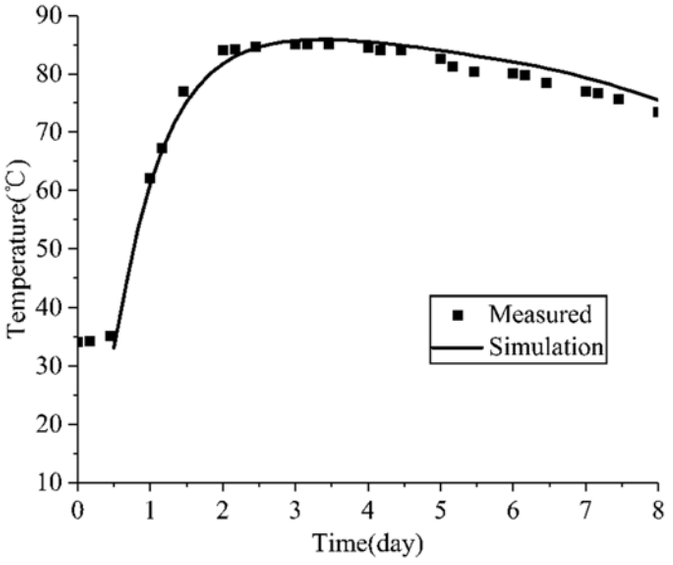

Figure 4. Actual measured data and simulation results

The heat transfer coefficient of the exposed surface (under shade) is calculated by using the following formula (Liu, 2006):

$$\beta_{surface} = 3.46v + 6.02 \tag{5}$$

where, v = the wind speed, here adopt 1m/s.

The coupling effect of temperature and material characteristics should be considered in early age concrete, and the relevant model of CEP-FIP is used to calculate.

$$t_T = \sum_{i=1}^{n} \Delta t_i \exp\left[13.65 - \frac{4000}{273 + T(\Delta t_i)/T_0}\right] \tag{6}$$

where, t_T = the temperature adjusted concrete age which replaces t in the corresponding equations, Δt_i is the number of days where a temperature T prevails, $T(\Delta t_i)$ is the temperature during the time period Δt_i, T_0=1℃.

Creep is calculated by relaxation coefficient. The relaxation coefficient is used to describe the phenomenon that the stress decreases gradually with the extension of time when the concrete is subjected to the forced strain.

$$\varepsilon(t) = \frac{\sigma(\tau_0)}{E(\tau_0)} + \sigma(\tau_0)C(t,\tau_0) + \int_{\tau_0}^{t} J(t,\tau)\frac{d\sigma(\tau)}{d\tau}d\tau \tag{7}$$

When the strain in formula 7 remains constant, the formula can be written as follows:

$$\sigma(\tau_0)C(t,\tau_0) + \int_{\tau_0}^{t} J(t,\tau)\frac{d\sigma(\tau)}{d\tau}d\tau = 0 \tag{8}$$

When $\sigma(\tau_0)$=1, the relaxation coefficient can be solved by formula 8. The relaxation coefficient provided by the literature is adopted here (Zhu 2012):

$$\begin{aligned} K(t,\tau) = 1 &- \left(0.25 + 0.25\tau^{-0.4}\right)\left[1 - e^{-0.2(t-\tau)}\right] \\ &- \left(0.15 + 0.3\tau^{-0.4}\right)\left[1 - e^{-0.006(t-\tau)}\right] \end{aligned} \tag{9}$$

where, $K(t,\tau)$ = relaxation coefficient when moment τ is loaded into moment t. $\sigma(t)$ = residual stress at t moment. $\sigma(\tau)$ = transient stress at τ moment.

The relaxation coefficient curve is shown in Fig.5.

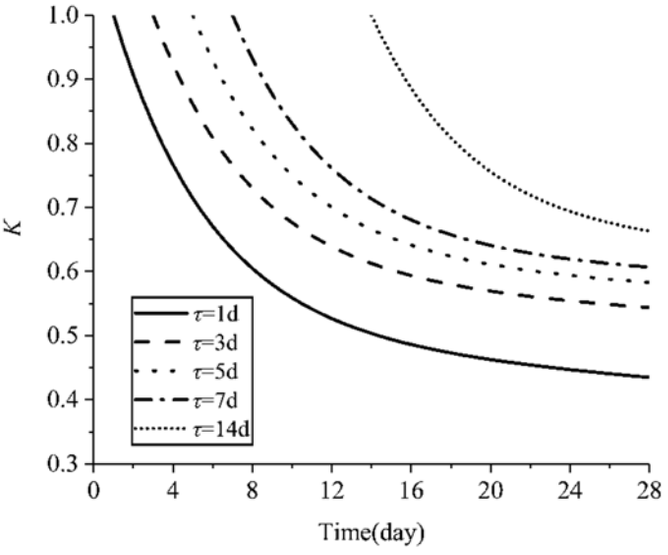

Figure 5. The relaxation coefficient

Time effects are also considered. The relative strength and the modulus of elasticity of concrete at various ages can be estimated form formula 10 to 13 (CEB-FIP, 2010).

$$f_{tk}(t) = \beta_{cc}(t) f_{tk} \tag{10}$$

$$\beta_{cc}(t) = \exp\left\{0.25\left[1 - \left(\frac{28}{t}\right)^{1/2}\right]\right\} \tag{11}$$

$$E_{ci}(t) = \beta_E(t) E_{ci} \tag{12}$$

$$\beta_E(t) = \left[\beta_{cc}(t)\right]^{0.5} \tag{13}$$

where, $f_{tk}(t)$ = the mean concrete strength at age of t days, f_{tk} = the mean strength after 28 days, $E_{ci}(t)$ = the modulus of elasticity at an age of t days, E_{ci} = the modulus of elasticity at an age of 28 days, $\beta_{cc}(t)$ and $\beta_E(t)$ are coefficients which depends on the age of concrete t, t = the age of concrete adjusted according to formula 6.

In addition, the stress calculation takes into account the gravity and the construction step. The value of elastic modulus and tensile strength of 28 days are obtained by experiment. E_{ci} =5.36×10^{4}MPa, f_{tk} =3.9MPa.

3.3 *Causes of cracks*

The temperature of the internal of the solid, the surface of the solid and internal of the thin wall are shown in Fig. 6.

The internal of the solid and internal of the thin wall are affected by high hydration heat, and the temperature rose up to 70~78 ℃ within 2 days. Then under the influence of natural cooling, the solid area cools slowly, thin wall cools faster simultaneously.

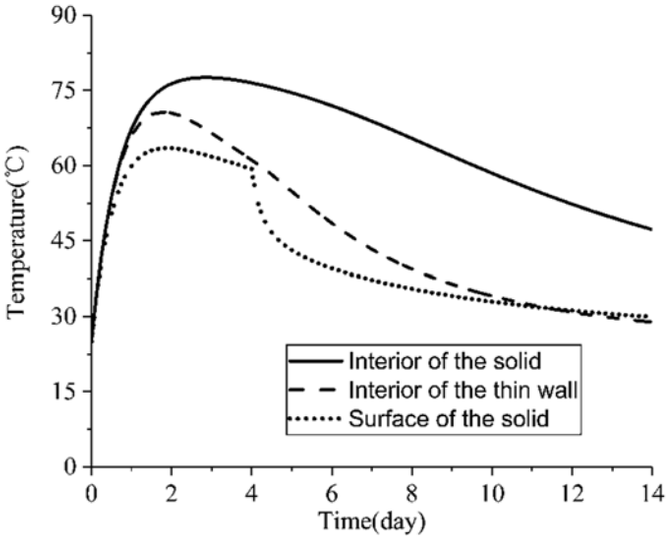

Figure 6. Temperature variation curve of typical position

The maximum temperature of surface is 64 ℃. After the formwork is removed in the fourth day, the temperature decreases sharply to 15℃ within 1 day.

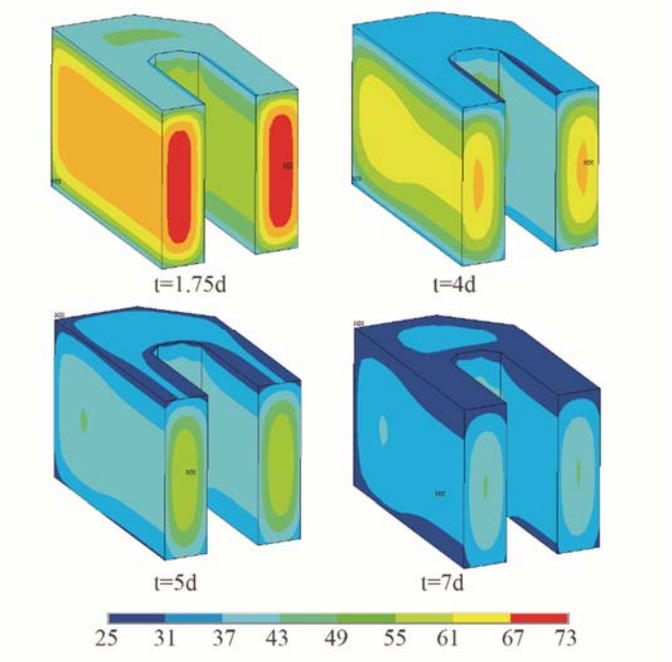

Figure 7. The change of temperature field (Unit:℃)

In fact, the structure is affected by non-uniform temperature field which changes with time. There are mainly 4 stages, as shown in Fig.7. The first stage is the temperature rising stage, when the internal is generally in high temperature state, and the temperature of the surface is much lower. The second stage is cooling stage, the heat is emitted from the surface, and the internal and surface temperature are gradually cooled. The third stage is rapid cooling stage, after the removal of formwork, the temperature of surface decreases sharply. The last stage is chill stage, the surface and interior temperature approach the ambient temperature gradually.

There are two kinds of temperature difference for pylon, one is the temperature difference between the current segment and base segment, and the another is the temperature difference between the internal and the surface. Due to the inhomogeneity of temperature field distribution, the temperature effect is complex. Only the solid finite element method can reflect the specific influences of these two kinds of effects. The stress results are shown in Fig.8.

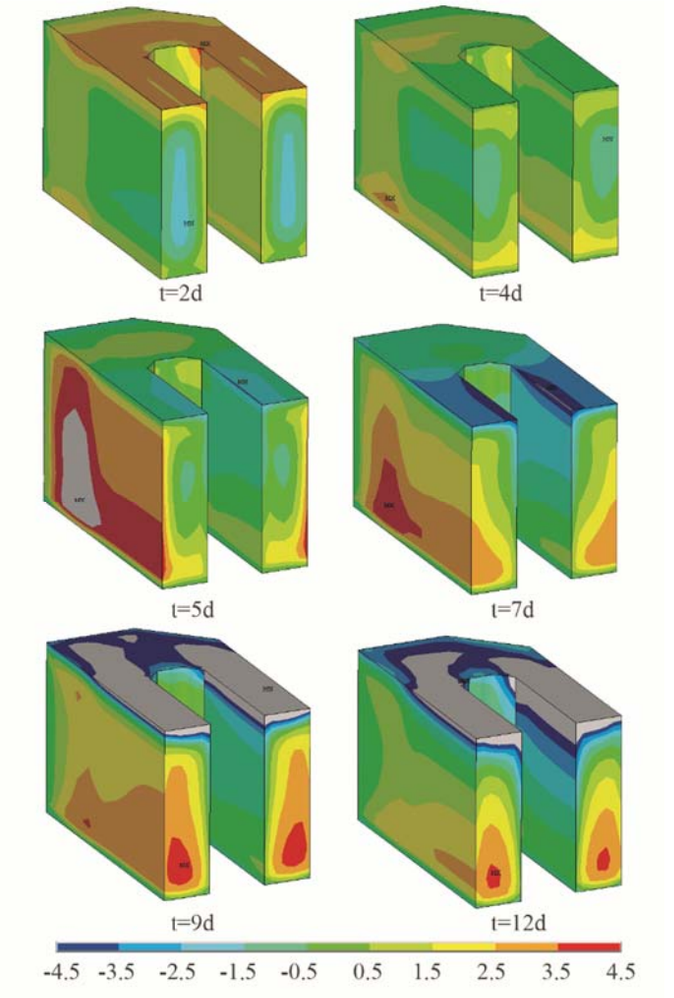

Figure 8. The horizontal stress distribution (Unit: MPa)

Temperature rise stage (0~2d): The internal of the thin wall is compressed, and the temperature gradient of surface produces small tensile stress.

Cooling stage (2~4d): The internal compressive stress gradually decreases, and tension occurs in the joint surface.

Rapid cooling stage (5d): The surface temperature decreases rapidly, the tensile stress exceeds 4.5MPa, and the tensile effect of solid is larger than that of thin wall.

Chill stage (5~10d): The temperature continues to decrease, when the temperature of the upper segment rises. The temperature difference causes the gradual expanding internal tensile.

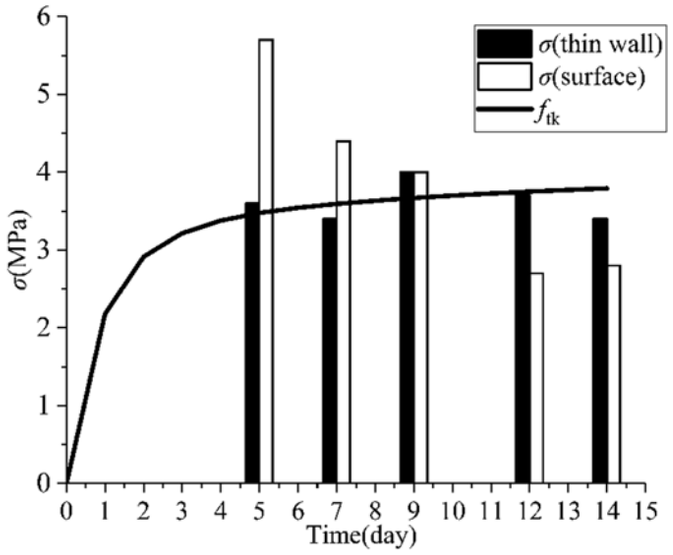

Figure 9. Tensile stress and tensile strength

The stress results are consistent with the crack detection results. The assumed crack development process is: after the formwork removes (5~7d), the cracks appear on the surface of the solid area, and the vertical cracking occurs on the surface of the thin wall. There are only 1 vertical crack on the thin wall, which may be caused by the stress releasing after the cracking. As the temperature continues to decrease (9d), cracks extend to the interior. The tensile stress and tensile strength are summarized in Fig. 9.

3.4 *Discussion*

As can be seen from the analysis, the crack is mainly produced in the form removal stage. However, insulation measures are adopted in some pylons, which may inhibit the creation of cracks.

Adopt the same finite element model to calculate the stress under the condition of heat preservation.

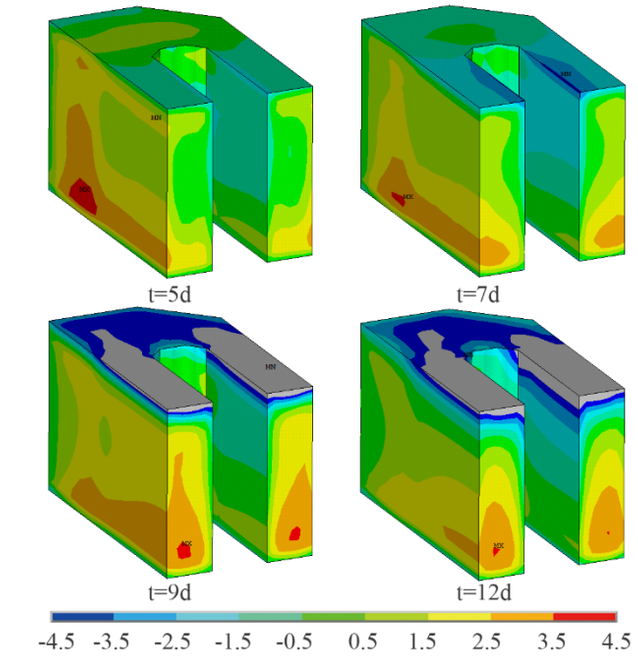

Figure 10. The stress under thermal insulation condition

After the template was removed on day 5, the surface stress was significantly reduced compared to the uninsulated condition. The surface stress of the solid is reduced to 3.5MPa, and the surface stress of the thin wall is reduced to 2.6MPa.

With the cooling process, the internal tensile stress of the thin wall increases gradually. And the stress reached a peak of 3.6MPa on the 9th day, as shown in Fig.10.

The insulation measures can only reduce the number of cracks, but may not avoid the cracks. Moreover, the risk of internal cracks is not reduced for the thin wall.

Reduce the temperature rise of the pylon could be an effective method to control thermal cracks. Fig.11 shows the stress when the adiabatic temperature rise is adjusted to 40℃. The surface stress is reduced to below 4MPa, and the internal stress of the thin wall is reduced to less than 3MPa.

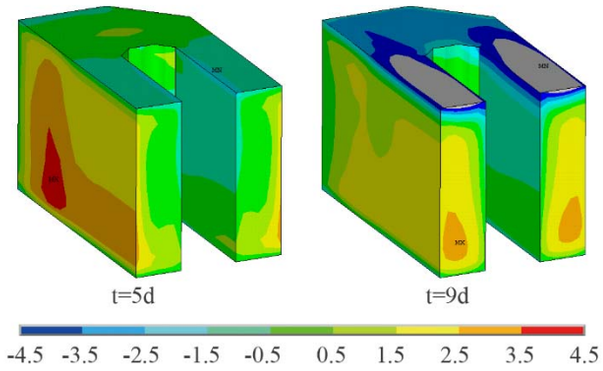

Figure 11. The stress after reducing temperature rise

A series of control measures have been adopted: (1) 0 to 2 days: using pipe cooling to decrease the temperature rise. (2) 4 day: remove the formwork and wrap the segments with oilcloth. (3) 4-14 days: keep the oilcloth sealed to make the temperature drop slowly. (4)14 day: end the protection. No cracking occurs in subsequent sections, and the early cracks in the bridge pylon can be avoided.

4 CONCLUSION

The causes of cracks of a concrete pylon are mainly discussed in this paper, and the conclusion is as follows:

1) The pylon is characterized with quick temperature rise and higher temperature, which are the main causes of the surface cracking and the internal cracking.

2) The surface cracks are generated in the formwork removal stage, resulting from sudden temperature decrease. The internal cracks of the thin wall are generated in chill stage, caused by inter-segment constraints.

3) The control measures are applied in the subsequent segments, and no cracks are occurred.

Hydration heat is one of the main causes of cracks. Some cracks may develop deep and have adverse effects on structural durability. The analysis of this paper can provide reference for the prevention, treatment and maintenance of such structural.

Yiliguoqi
Mechanical and Civil Engineering Division of Gifu University, Gifu City, Gifu Prefecture, Japan

ABSTRACT: In Japan, regional governments manage 70% of all road bridges (over 700,000 road bridges), and half of these bridges will be in their service life in the near future. However, regional governments lack the resources (in finances, specialists, and technologies) that are needed to maintain this many bridges. Therefore, it is necessary to develop a practical method of bridge integrity evaluation to assess the degree of a bridge superstructure's structural health. This paper proposes a bridge integrity evaluation method by applying support vector machines (SVMs) of artificial intelligence (AI) techniques. This paper proposes that bridge integrity evaluation methods provide bridge inspectors and engineers with a more reliable and efficient bridge structural health assessment approach.

1 INTRODUCTION

1.1 *Background*

Japan has over 700,000 road bridges; 70% of these bridges are situated on the regional roads and are managed by regional governments. Many of these regional bridges were constructed during the high economic growth period (from the mid-1950s to the early 1970s), and about 40% of these bridges will be over 50 years old in 10 years (The Road Committee of the Panel on Infrastructure Development 2014). Furthermore, regional governments' maintenance budgets are limited. Regional governments usually have a shortage of financial resources, specialists, and technologies. Thus, developing practical bridge maintenance programs for regional governments is an important issue. To address this issue, this paper proposes using artificial intelligence (AI) techniques to analyses a priority assessment of structure's inspection items; this will assist bridge engineers when they assess a bridge's integrity. This would be a great approach for regional governments.

1.2 *Overview and scope of the study*

For a bridge management system (BMS), there are three modules: management, assessment, and maintenance. Management always controls inspection data. Assessment is used to analyse the condition of quality, life cycle cost, cost benefits, and the priority of a bridge's maintenance. The maintenance module is the result of management and assessment when conducting efficient site works. Each BMS depends on their efficient bridge inspections. Bridge inspectors use their judgment to evaluate and appraise maintenance problems and critical deterioration on site. This responsibility is based on the assumption that the individual bridge inspector has a sound understanding of bridge inspection, maintenance, and rehabilitation requirements (Arong et al. 2014).

Additionally, in 2007, the Minister of Land, Infrastructure, Transport and Tourism (MLIT) started a subsidy program for regional governments to establish long-term bridge maintenance programs. In this program, prefectures conduct bridge inspection programs that follow the MLIT's protocol; bridges on arterial routes that carry large volumes of traffic are inspected periodically for every five years. However, some regions still do not inspect their bridges; others conduct inspections, but inspection protocol and quality are not standardized (Masahiro et al. 2013). According to the Regular Inspection Procedure for Road Bridge (2014), which is regulated by the MLIT, the Gifu Prefecture conducts regular inspections (every five years) of all bridges that span longer than 2 meters once.

Over the past few years, several experimental studies on the evaluation of bridge integrity with AI techniques have been carried out by researchers. Reviewing the techniques in Japan, Oishi H analysed slope data using the support vector machine (SVM) of an AI technique; this was done to evaluate a risk of dangerous spots for sediment related disaster by learning the data of each slope. The results showed that an SVM can evaluate a risk with higher precision than a conventional rating method (Oishi et al. 2007).

Chikata Y compared an SVM with learning vector quantization (LVQ) to examine the evaluation of bridge integrity with pattern recognition (Chikata et al. 2007). Sugimoto H proposed estimating the synthetic safety of infrastructures by using an SVM (Sugimoto et al. 2009). The Yuki K research group analysed the inspection and repair records of bridges' expansion joints with an SVM; this was done to evaluate judgement criteria for repairing civil engineering structures. Due to the Yuki K study, the setting method using an SVM is an effective tool for the maintenance management plan of civil engineering structures; this is because the method has high integrity due to the structure's evaluation by a professional engineer (Yuki et al. 2012). In the above studies, the SVM was introduced; it can be an effective tool for the maintenance management plan of civil engineering structures. Regional governments face a lack of economic resources and bridge maintenance engineers; as a result, researchers are focusing on numerical simulations using an SVM to estimate bridges' integrity and the priority of their maintenance repairs. However, it is almost impossible to replace bridge experts with AI techniques when estimating bridge integrity in the current situation regarding technical. Therefore, studying the weight of inspection items' priority, which uses the SVM to estimate bridge integrity to assist regional governments, is vital for the maintenance of bridge infrastructure.

In this study, we propose the efficient health integrity evaluation method for bridge structure members. We applied an SVM to determine the weight priority of inspection items; this was done to assist regional governments in assessing bridges' integrity. The SVM was used to classify bridge structure members' health. The input data were the deterioration degrees of items in the detailed site inspection on structure member; the output data were the bridge structural members' degree of health. As a numerical example, 124 pieces of inspection data of the steel composite girder bridge in the Gifu prefecture were used. Keeping a balance between correctly classified accuracy and Receiver Operating Characteristic (ROC) curves enabled the weight assessment of the bridge structure members' inspection items to combine. It was found that the combined weight of bridge structure members' inspection items provides bridge inspectors and maintenance engineers with a more reliable and efficient bridge structural health assessment approach.

2 THEORETICAL BACKGROUND

2.1 *Introduction to SVMs*

An SVM is a type of binary supervised machine learning. It is also a type of AI algorithm. Recently, SVMs have received a great deal of attention, and they demonstrated excellent performance in terms of pattern classification. SVMs are based on the induction principle of structural risk minimization, which aims to minimize a test error by controlling two contradictory factors: a functional risk from empirical data and a capacity for the set of real-valued functions (Cortes et al. 1995; Vapnik et al. 1998).

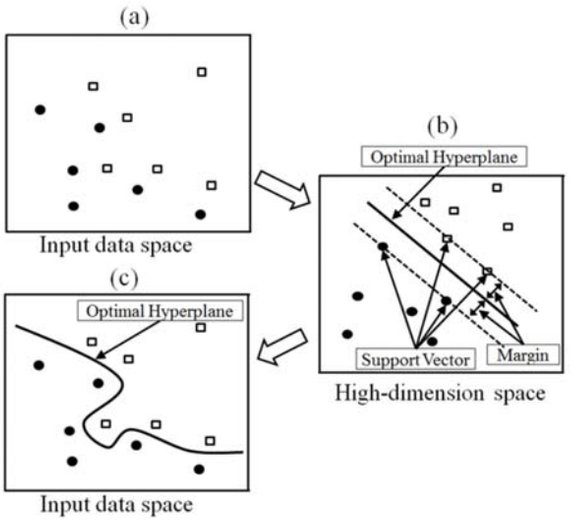

Figure 1. SVM concept diagram

An SVM algorithm aims to find the optimal separating hyperplane that effectively separates the data points into the labelled classes (see Fig. 1). Let us consider that we have a binary classification problem. Fig.1-(a) shows a mapping input space of non-separable data points. For convenience, we can assume the labels are +1 (positive examples) or –1 (negative examples). What follows χ denotes a vector with a component x_i. The notation x_i will denote the i^{th} vector in a dataset $\{(x_i y_i)\}_{i=1}^{n}$, where y_i is the label associated with x_i. The naive way of making a non-linear classifier out of a linear classifier is to map our data from the input space χ to a feature space F using a non-linear function $\Phi: \chi \rightarrow F$ (see Fig.1-(b)). SVMs operate by finding a linear hyperplane that separates the positive and negative examples with a maximum interclass distance or margin. The discriminant function in the feature space F can be considered as follows (Ben-Hur et al. 2010):

$$f(x) = \sum_{i=1}^{n} \alpha_i \kappa(x, x_i) + b \tag{1}$$

where b is the model bias. Note that only those points that lie closest to the hyper-plane have α_i and consist the support vectors. In the case of non-separable data, a soft margin hyperplane is defined to allow errors ξ_i (slack variable) in classification. Hence, the optimization problem is formulated as follows (Ben-Hur et al. 2010):

$$\underset{w,b}{\text{minimize}} \frac{1}{2}\|w\|^2 + c\sum_{i=1}^{n}\xi_i \qquad (2)$$
$$subject \quad to: y_i\left(w^T x_i + b\right) \geq 1-\xi_i, \xi_i \geq 0.$$

where $\xi_i \geq 0$ are slack variables that allow an example to be in the margin ($0 \leq \xi_i \leq 1$, also called a margin error) or to be misclassified ($\xi_i > 1$). Since an example is misclassified if the value of its slack variable is greater than 1, $\sum_i \xi_i$ is a bound on the number of misclassified examples. Our objective of maximizing the margin, i.e., minimizing $\frac{1}{2}\|w\|^2$ will be augmented with a term $C\sum_i \xi_i$ to penalize misclassification and margin errors. The trade-off between maximization of the margin and minimization of error is controlled by cost parameter C (Burges et al. 1998; Drosou et al. 2014). In this way, classification is performed by the optimal hyperplane at a high-dimensional space. As a result, the nonlinear separation is performed in the original input space (see Fig.1-(c)).

In a nonlinear case, a kernel function is introduced to map the low-dimensional input space to the high-dimensional feature space. There are many possible choices of the kernel functions, such as the linear, polynomial, radial basis function (RBF), and sigmoid function. In this study, the RBF kernel (Gaussian kernel) given by the following function was used:

$$f(x) = \sum_{i=1}^{n} \alpha_i \kappa(x, x_i) + b \qquad (3)$$

where $\gamma > 0$ is a parameter that controls the width of Gaussion. When designing an SVM, one must choose a kernel function, set kernel parameters γ, and determine a soft margin constant C (penalty parameter). The Grid algorithm is an alternative to finding the best C and γ when using the RBF kernel function (Ben-Hur et al. 2010).

In this study, we decided to classify the bridge structure members' health into two classes ("Good" and "Poor") and then training the model.

2.2 *The ROC curve*

The ROC curve was introduced by the signal processing community in order to evaluate the capability of a human operator; this was done to distinguish an informative radar signal from noise. The ROC curve has mostly been used in the medical decision-making community to assess the usefulness of diagnostic tests (Rakotomamonjy et al. 2004).

Traditionally, the evaluation of a learned model is done by minimizing the estimation of a generalization error or some other related measures. However, the accuracy (the rate of correct classification) of a classifier is the most frequently used performance measurement (Rakotomamonjy et al. 2004). The ac-curacy can be obtained from the confusion matrix, as shown in Table 1. The accuracy can be considered as follows:

$$Accuracy = \frac{TP+TN}{TP+FP+FN+TN} \qquad (4)$$

where TP (True Positives) is positive records that correctly predicted as positive. FN (False Negatives) is positive records that incorrectly predicted as negative. FP (False Positive) is negative records that in correctly predicted as positive. TN (True Negatives) is negative records that correctly predicted as negative.

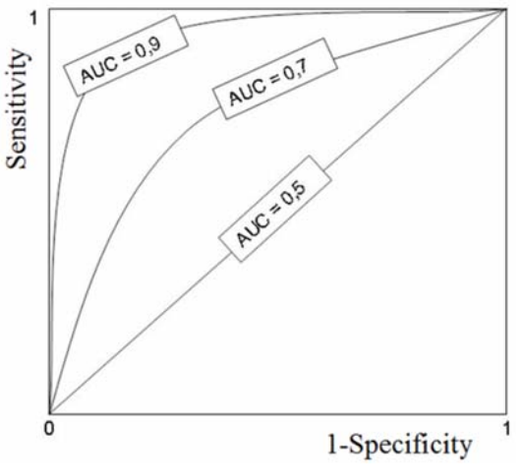

Figure 2. The ROC curve (refer Simundic et al. 2012)

Obtaining the optimal balance classification ability is described effectively in terms of sensitivity (or true positive rate or positive class accuracy) and specificity (or true negative rate or negative class accuracy) as follows:

$$Sensitivity = \frac{TP}{TP+FN} = 1 - Type\ II\ error \qquad (5)$$

$$Specificity = \frac{TN}{TN+FP} = 1 - Type\ I\ error \qquad (6)$$

More precisely, sensitivity measures the proportion of actual positives that are identified correctly. Specificity measures the proportion of actual negatives that are identified correctly.

Table 1. Confusion matrix

		Predicted Class	
		Positives	Negatives
Actual Class	Positives	TP	FN
	Negatives	FP	TN

Table 2. Interpretation of the AUC Curves (refer Simundic et al. 2012)

AUC	Diagnostic Accuracy
0.9-1.0	Excellent
0.8-0.9	Very good
0.7-0.8	Good
0.6-0.7	Sufficient
0.5-0.6	Bad
<0.5	Test not useful

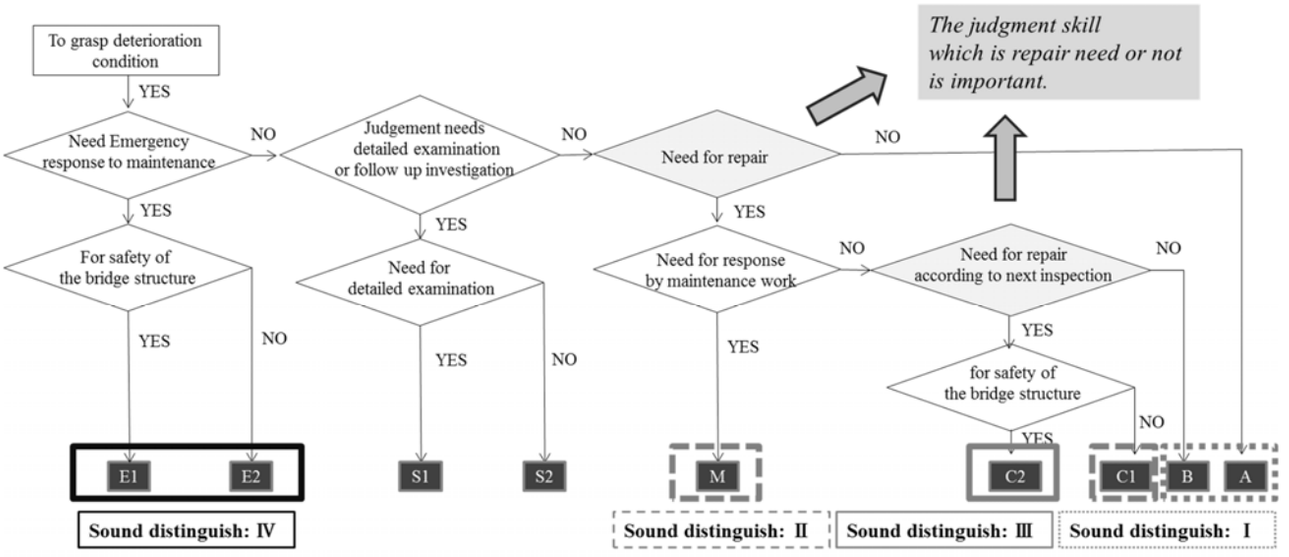

Figure 3. Sound distinguish flow

In addition, the trade-off between sensitivity and specificity can be represented graphically as an ROC curve. It can be understood as a plot of the probability of correctly classifying the positive examples against the rate of incorrectly classifying true negative examples. The ROC curve can be constructed by plotting these pairs of values on the graph with 1-specificity on the x axis and sensitivity on the y axis. In fact, when the data are strongly unbalanced, accuracy may be misleading, since the all-positive or all-negative classifier may achieve a very good classification rate. Situations in which datasets are unbalanced arise frequently in real-world problems; in these cases, model evaluation is done with criteria other than accuracy. Metrics extracted from ROC curves, such as the area under the ROC curve (AUC), can be a good alternative for model evaluation; this is because the ROC curve can determine the difference between errors on positive or negative examples (Rakotomamonjy et al. 2004).

Ana-Maria Simundic's (Simundic et al. 2012) study on diagnostic accuracy shows the shape of an ROC curve, and the AUC helps us estimate how high the discriminative power of a test is. The area under the curve can have any value between 0 and 1, and it is a good indicator of the overall quality of the test. A perfect diagnostic test has an AUC of 1.0, whereas an excellent test has an AUC around 0.9 to 1.0, a very good test has an AUC around 0.8 to 0.9, a good test has an AUC around 0.7 to 0.8, a sufficient test has an AUC around 0.6 to 0.7, a bad test has an AUC around 0.5 to 0.6, and a useless test has an AUC of 0.5 or less than 0.5. Generally, the relation between AUC and diagnostic accuracy (as described in Table 2) and the ROC curve can be plotted like in Fig. 2 (Simundic et al. 2012). In our study, the AUC rating was determined according to Table 2.

3 CASE STUDY ON SMALL AND MEDIUM BRIDGES

3.1 *Visual inspection of bridges*

There are approximately 700,000 road bridges in Japan, and ministerial orders stipulate that close visual inspections of all components should be conducted every five years (Tamakoshi et al. 2015). The Gifu Prefecture tried a unique bridge inspection method by remote viewing with binoculars; they also created a unique bridge inspection manual (Road Maintenance Division of Gifu Prefecture Government 2010) to ensure appropriate inspection accuracy (Hosoe et al. 2006).

According to the Regular Inspection Procedure for Road Bridge (2014), which is regulated by the MLIT, all bridges in Japan with a span longer than 2 meters must be inspected at least once every five years. In response to this, the Gifu Prefecture revised the Revision Bridge Inspection Manual (Ministry of Land, Infrastructure, Transport and Tourism 2014; Road Maintenance Division of Gifu Prefecture Government 2016). To plan the priority maintenance scheme, the bridge's integrity and degree of deterioration are needed in order to make engineering decisions. Maintenance urgency ratings are diagnoses given by experienced engineers in a very subjective manner, recommending necessary actions that should be completed by the next inspection (Masahiro et al. 2013).

For every structural member in each bridge span, the results of a sound diagnosis can be categorized into one of four ranks, which are listed in Table 3. In the new criteria, a bridge's sound diagnosis has four levels, which are Ⅰ, Ⅱ, Ⅲ and Ⅳ, corresponding to the conventional criteria. In the conventional criteria, a bridge's sound diagnosis has five levels, which are

denoted in Arabic numerals as 5, 4, 3, 2, and 1, respectively. The flow of remedial work urgency ratings is shown in Fig. 3. From the flow, bridge need for response by maintenance work and also bridge need for repair according to next inspection shows a bridge inspector's required knowledge and judgement skill, which helps determine whether the bridge's owners need to repair the bridge. It is important to distinguish the soundness rank as being Ⅰ, Ⅱ, or Ⅲ.

In our study, we followed the conventional criteria to classify structure members' degree of health. Table 4 shows the standard for classifying inspected members. Additionally, we focused on the main girder of the single-span steel girder bridge as well as the multi-span continuous steel girder bridges. Table 5 shows the standard deformation type. We only examined steel members (steel girders) in this study.

Table 3. Diagnosis of soundness in Gifu prefecture

New Criteria		Description	Refer Conventional Criteria	
Ⅰa	Good	No obstacle to the function of the structure.	5	Health
Ⅰb			4	Almost health
Ⅱ	Preventive maintenance phase	There is no obstacle to the function of the structure, but it is desirable to take preventive maintenance.	3	Start repair: Deterioration occurs
Ⅲ	Early rehabilitation phase	There is a possibility that the function of the structure may be hindered, so a rehabilitation strategy must be taken.	2	Intermediate repairs required: Large deterioration
Ⅳ	Emergency repair phase	Presence of an obstacle to the function of the structure, or a possibility of occurrence is extremely high. An urgent action must be taken.	1	Possible structure failure: Critical deterioration

Table 4. Standard of classifying inspected members

Damage classification					
superstructure			substructure	bearing	others
Main girder	Cross beam	slab			

Table 5. Standard deformation type

Material type	Deformation type
Steel member	Corrosion, crack, fracture, others
Concrete member	Cracks, cracks on the slab, others
others	Dysfunction of bearing, others

3.2 *Numerical analysis results using the SVM*

In this study, we statistically analysed the two categorized levels of health; the classified levels ("Good" and "Poor") were found on the main girder of steel girder bridges; this was based on actual bridge inspection data from the Gifu Prefecture. In this study, the priorities of the inspection items through the SVM analyses are examined using the bridge structural health assessment by professional inspector. These analyses were obtained through the SVM analysis software Waikato environment for knowledge analysis (WEKA) version 3.9. We conducted this experiment by using the classification solver in a library for support vector machine (LIBSVM) with a grid search optimal parameter. The input data were the degree of deterioration for each span girder's inspection item, and the output data were the main girder's degree of health. As a numerical example, 124 pieces of inspection data of steel bridges in the Gifu Prefecture were used. We represented a "Good" health class with "Y" if the health rating of conventional criteria was equal to or greater than 4. If the health rating was less than 4, it was "Poor". For the inspection data of this study, health integrity was assessed by seven inspectors. The inspection attributes and class label are shown in Table 6. The optimal parameter is shown in Table 7.

Table 6. List of features and class label

Feature	X_1	section location: 1 = edge part, 0 = middle of span, -1 = intermediate support
	X_2	construction year, years
	X_3	painting year, years
	X_4	deformation of main girder (health rating: 1, 2, 3, 4, 5)
	X_5	missing bolt (health rating: 1, 2, 3, 4, 5)
	X_6	abnormality of joint gap (health rating: 1, 2, 3, 4, 5)
	X_7	deterioration of corrosion protection (health rating: 1, 2, 3, 4, 5)
	X_8	corrosion in main girder (health rating: 1, 2, 3, 4, 5)
Label	Y	poor (health rating: 1, 2, 3), good (health rating: 4, 5)

Table 7. Parameter C and γ

Inspector	C	γ
Training data	1000	1.0
Testing data	1000	1.0

In this study, we used feature combinations to indicate some relationships. Because all feature meanings were available, we were able to manually identify some useful pairs of features. We used the training data, which was from an experienced inspector, to test the effectiveness of different feature combinations by predicting the class label of "Y". To estimate a feature's importance, we exploited the performance measurement of AUC, which was conducted for each combined feature.

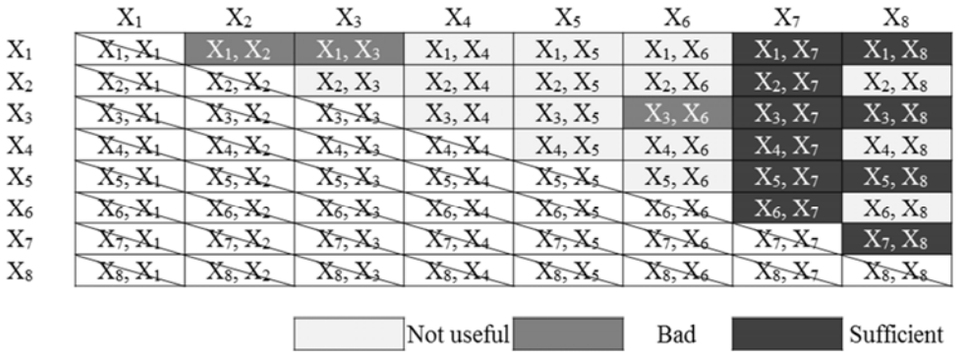

Figure 4. Useful attribute combines

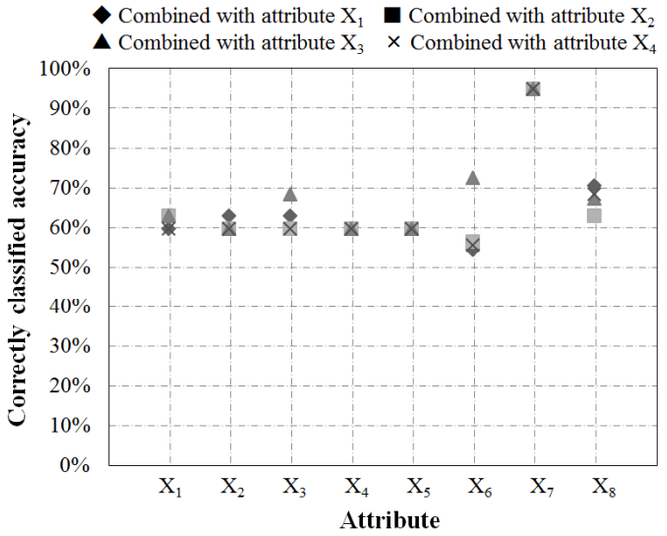

Figure 5.1. Correctly classified accuracy of combined attribute X_1, X_2, X_3, X_4

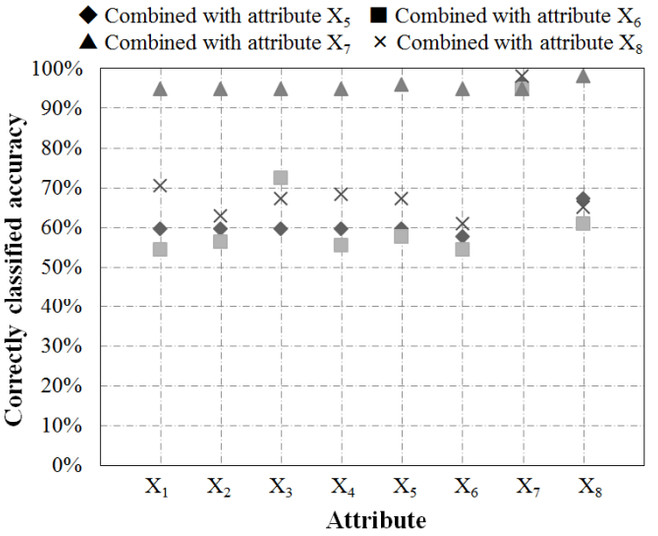

Figure 5.2. Correctly classified accuracy of combined attribute X_5, X_6, X_7, X_8

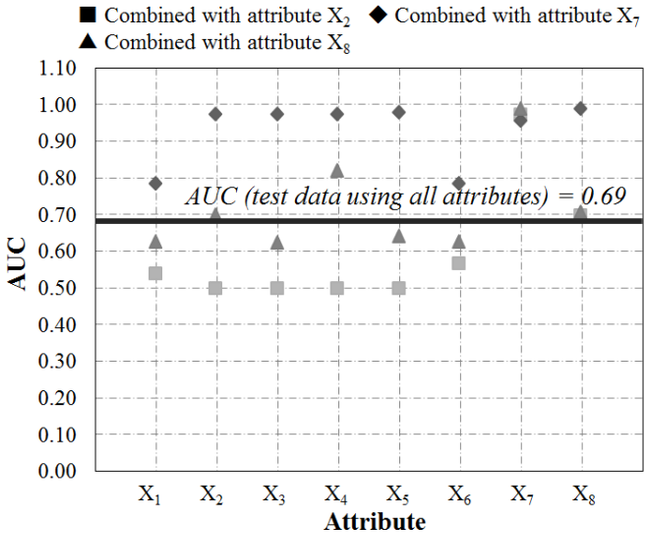

Figure 6.1. AUC of good level (health rating:4,5) which combined with attribute X_2, X_7, X_8

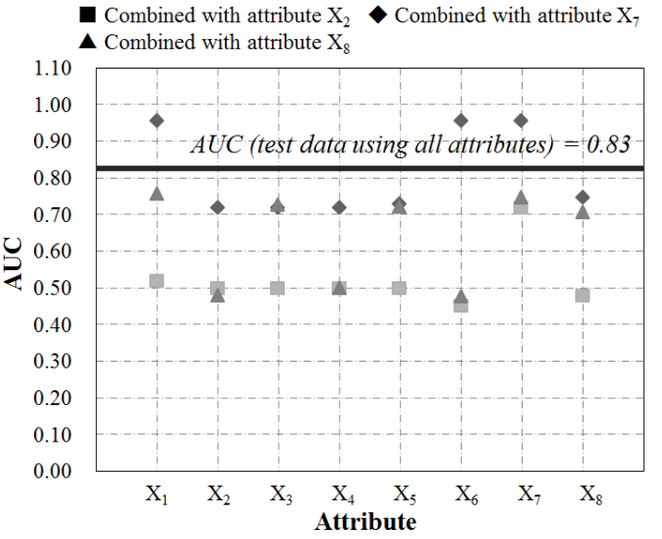

Figure 6.2. AUC of poor level (health rating:1, 2, 3) which combined with attribute X_2, X_7, X_8

In additional, the two-combined feature opportunity set contained eight features, and, in this study, it had 28 settings of two-combined features in order to perform the analyses. The useful feature combinations were tested and shown in Fig. 4. A dark black block denotes a sufficient (useful) feature combination. A black block denotes a bad feature combination. A light black block denotes a feature combination that is not useful. Fig. 5.1 shows the results of correctly classified accuracy when the other attribute combining X_1 (section location), X_2 (construction year), X_3 (painting year), and X_4 (de-formation of main girder). Based on the Fig. 5.1 shown results, it can be seen that X_1, X_2, X_3, and X_4, combining with attribute X_7 (deterioration of corrosion protection)

gives a high accuracy of correct classification. Fig. 5.2 shows that the other attribute combining X_5 (missing bolt), X_6 (abnormality of joint gap), X_7 (deterioration of corrosion protection), and X_8 (corrosion in main girder) resulted in correct classification accuracy. Based on the Fig. 5.2 shown results, it can be seen that X_5, X_6, X_7, and X_8, combining with attribute X_7 (deterioration of corrosion protection) gives high accuracy of correct classification. Based on the above results, attribute X_7 (deterioration of corrosion protection) gives more meaningful to assess the priority of inspection items.

Table 8. The AUC result of good level (health rating:4, 5)

	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8
X_1	0.50	0.54	0.55	0.50	0.31	0.59	0.78	0.63
X_2	0.54	0.50	0.50	0.50	0.50	0.57	0.97	0.70
X_3	0.55	0.50	0.66	0.36	0.35	0.58	0.97	0.62
X_4	0.50	0.50	0.36	0.50	0.50	0.58	0.97	0.82
X_5	0.31	0.50	0.35	0.50	0.50	0.61	0.98	0.64
X_6	0.59	0.57	0.58	0.58	0.61	0.52	0.78	0.63
X_7	0.78	0.97	0.97	0.97	0.98	0.78	0.96	0.99
X_8	0.63	0.70	0.62	0.82	0.64	0.63	0.99	0.71

Table 9. The AUC result of poor level (health rating:1, 2, 3)

	X_1	X_2	X_3	X_4	X_5	X_6	X_7	X_8
X_1	0.50	0.52	0.52	0.50	0.74	0.42	0.96	0.76
X_2	0.52	0.50	0.50	0.50	0.50	0.45	0.72	0.48
X_3	0.52	0.50	0.66	0.72	0.73	0.79	0.72	0.73
X_4	0.50	0.50	0.72	0.50	0.50	0.44	0.72	0.50
X_5	0.74	0.50	0.73	0.50	0.50	0.45	0.73	0.72
X_6	0.42	0.45	0.79	0.44	0.45	0.52	0.96	0.48
X_7	0.96	0.72	0.72	0.72	0.73	0.96	0.96	0.75
X_8	0.76	0.48	0.73	0.50	0.72	0.48	0.75	0.71

Depending on whether the data are unbalanced, correctly classified accuracy may be misleading; this is because the all-good or all-poor classifier may achieve a very good classification rate. We must use the ROC curve (and the AUC) to differentiate between errors on good or poor examples. Fig. 6.1 shows the AUC result of a good level, which has the other attribute combining X_2 (construction year), X_7 (deterioration of corrosion protection), and X_8 (corrosion in main girder). The good level of the AUC result using all attributes is equal to 0.69. In good classification, the combination of X_3X_2, X_4X_2, and X_5X_2 gives, results close to 0.5. Fig. 6.2 shows the AUC result of a poor level, which has the other attribute combining X_2 (construction year), X_7 (deterioration of corrosion protection), and X8 (corrosion in main girder). The poor level of the AUC result using all attributes is equal to 0.83. In poor classification, the combination of X_1X_2, X_3X_2, X_4X_2, X_5X_2, X_6X_2, and X_8X_2, gives results close to 0.5. Base on the Ana-Maria Simundic's (Simundic et al. 2012) study on diagnostic accuracy (see Table 2.), the AUC results around 0.5-0.6 gives a bad test result. So the useful feature combinations were X_1X_7, X_2X_7, X_3X_7, X_4X_7, X_5X_7, X_6X_7, X_1X_8, X_3X_8, X_5X_8, and X_7X_8. The AUC result's details are shown in Tables 8 and 9.

4 DISCUSSION

Feature importance and selection can give an objective utility of features. We need to manually create an objective utility feature of inspection items. Above the SVM numerical results, a useful feature combination denote in Fig. 4. The other attribute combine with attribute X7 (deterioration of corrosion protection) gives important effectiveness assessment of inspection site work for regional government's inspector.

The concept of a proposed diagnostic optimization method for bridge integrity is described in Fig. 7. Regional governments are constantly distressed by the lack of a maintenance budget and maintenance experts. This proposed diagnostic optimization method can assist regional governments in determining bridges' health and integrity, which are generally decided by own experience of each maintenance experts.

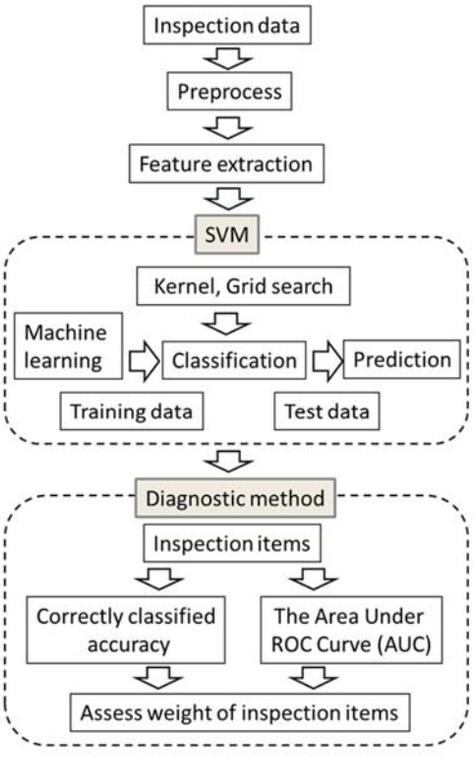

Figure 7. Concept diagram of sound diagnosis

5 CONCLUSION

In this study, we obtained a useful feature combination of inspection items by using a machine learning

algorithm. According to the SVM analysis, the correctly classified accuracy and the AUC can obtain the effectiveness assessment of different feature combinations by using an experienced inspector's training data to predict the class label. Thus, this proposed bridge integrity evaluation method can help and assist regional governments determine bridges' degree of health.

Evaluation of slab lifting strategies for maintenance of middle slabs in double-deck tunnels

S.M. Kim, Y.K. Cho & B.K. Park
Kyung Hee University, Yongin, Korea

ABSTRACT: The major difference between double-deck tunnels and general tunnels is the existence of middle slab in double-deck tunnels. Both sides of the middle slab lie on the brackets along the longitudinal direction and the bearing pads between slab and bracket may need to be replaced for maintenance. In this case, part of the middle slab needs to be lifted for the replacement of the bearing pads. The objective of this study is to evaluate slab lifting strategies of the middle slab in double-deck tunnel when replacement of bearing pads lying between slab and bracket is needed. The middle slabs have been divided into three different sections as normal, expansion joint, and emergency passageway sections. At each section, several different slab lifting methods have been applied and analyzed to investigate the stress distribution in the slab and to evaluate the maximum tensile stresses. The analysis results show that the optimal slab lifting method that reduces the maximum tensile stresses of the slab is different depending on the section type of the middle slab.

1 INSTRUCTION

Double-deck tunnels (Fig. 1) are of interest in many countries recently because of their advantage in economics and construction. Some of them include Fuxing tunnel in China, M30 tunnel in Spain, SMART tunnel in Malaysia, A86 tunnel in France, Istanbul Strait Road tunnel in Turkey (Arlet 2012, Kannapiram 2005, Kim, 2010, Santhiman & Weei 2006). Other countries such as the Netherlands, Russia, USA, Australia, and Korea also have recently opened or planned double-deck tunnels.

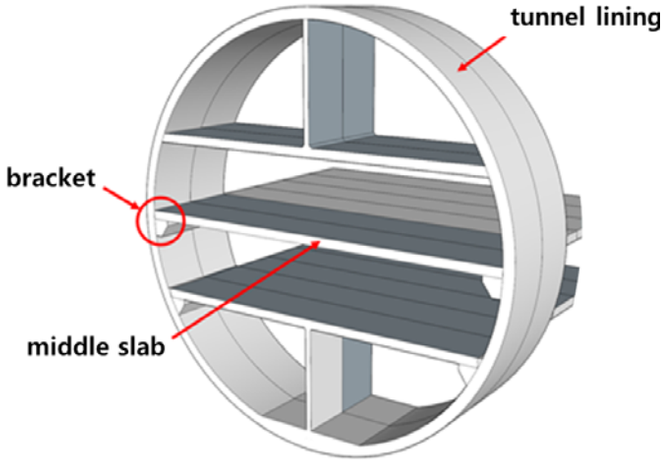

Figure 1. Middle slab in double-deck tunnel

The major characteristic of the double-deck tunnel is the existence of middle slab as shown in Figure 1 (Park et al. 2017). Both sides of the middle slab lie on the brackets along the longitudinal direction and the bearing pads between slab and bracket may need to be replaced for maintenance. In this case, part of the middle slab needs to be lifted for the replacement of the bearing pads.

Several different methods to replace bearing pads can be considered. For bridge slabs, the entire width of the slab can be lifted to replace bearing pads as shown in Figure 2. For beams, each supporting point can be lifted as shown in Figure 3. For some cases as shown in Figure 4, many lifting devices can be used all together.

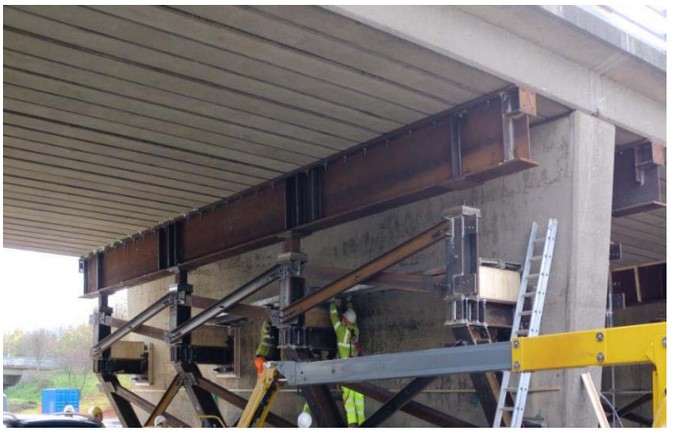

Figure 2. Bridge slab lifting (Freyssinet 2017)

Figure 3. Beam lifting (Constructionspecifier 2017)

Figure 4. Lifting using multiple devices (Heavyliftnews 2017)

The objective of this study is to evaluate slab lifting strategies of the middle slab in double-deck tunnel when maintenance such as replacement of bearing pads lying between slab and bracket is needed. Several different slab lifting methods have been applied and analyzed to investigate the stress distribution in the slab and to evaluate the maximum tensile stresses.

2 ANALYSIS MODEL

The middle slabs have been divided into three different sections as shown in Figures 5-7: normal section, expansion joint section, and emergency passageway section. The finite element models of those middle slab sections have been developed using a finite element analysis program (ABAQUS 2007) and Figure 8 shows a half of the finite element model of the emergency passageway section. The slab thickness is 400 mm and the longitudinal length of the slab considered in this study is 100 m. Both side edges of the slab are simply supported along the longitudinal direction. Only the dead weight of the slab is considered as the applied load since the traffic is not allowed when the slab lifting work is being conducted.

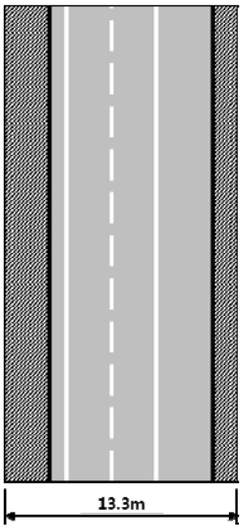

Figure 5. Normal section of middle slab

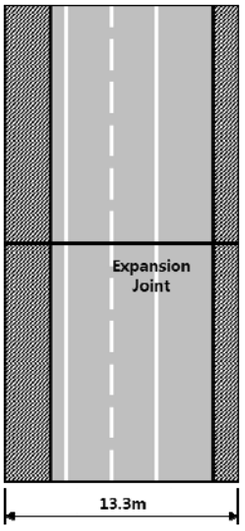

Figure 6. Expansion joint section of middle slab

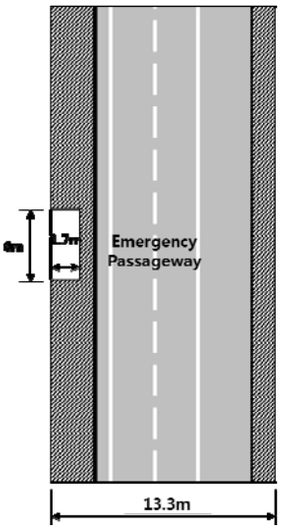

Figure 7. Emergency passageway section of middle slab

The major parameters of the slab lifting methods are basically the number of lifting points and the distances between the lifting points as shown in Figure

9. Lifting at one side and at both sides of the slab are also considered as shown in Figure 10.

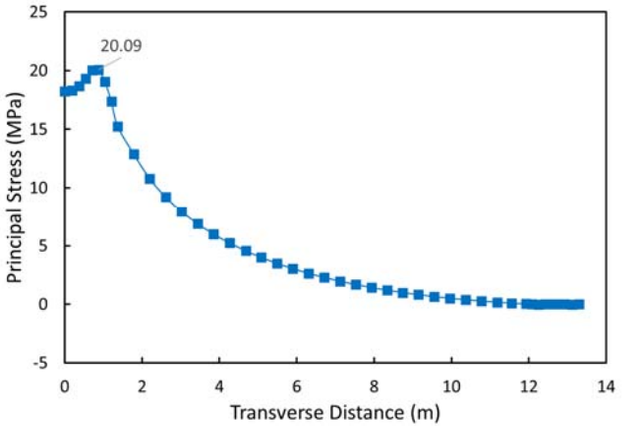
(b) Both-side lift

Figure 10. One- and both-side lifts

3 ANALYSIS RESULTS

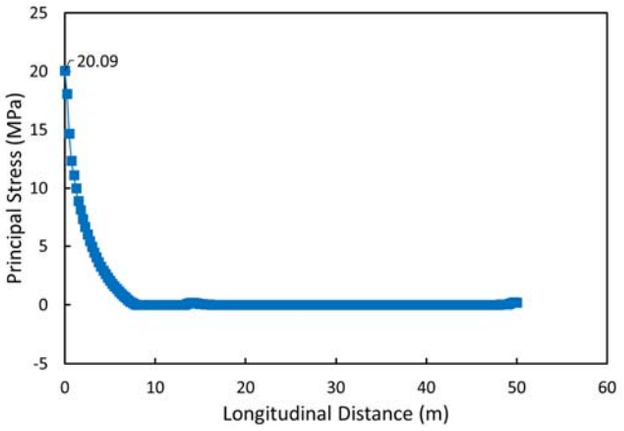
3.1 *Stresses at normal section of middle slab*

In order to find the stresses when the middle slab is lifted at the normal section to replace bearing pads, several lifting methods are considered as listed in Table 1. The numbers of lifting points considered in this study are 1, 2 and 7. A continuously distributed lifting method is also considered using Equation (1) even though this method cannot be applied in practice. The maximum lifting height is 50 mm at the center of the lifting points. The distance between the lifting points for 2-point lifting method is 2 m. The distances to the lifting points from the center for 7-point lifting method are -12, -8, -4, 0, 4, 8, 12 m.



$$D(z) = 0.025 \times \cos\left(\frac{z \times \pi}{25}\right) + 0.025 \quad (1)$$

Table 1. Lifting methods at normal section



Lifting points	One-edge lift	Both-edge lift
1	T-1E-1P	T-2E-1P
2	T-1E-2P	T-2E-2P
7	T-1E-7P	T-2E-7P
Distributed	T-1E-D	T-2E-D

Figure 11 shows the principal stresses along the transverse and longitudinal directions when the mid-

dle slab is lifted at one-side edge using 1-point lifting method. In the transverse direction, the maximum stress occurs at the lifting point and the stress becomes gradually smaller as the transverse distance increases from the lifting point. In the longitudinal direction, the maximum stress occurs at the lifting point and the stress decreases rapidly as the distance from the lifting point increases up to about 7 m and then no stresses are observed after the distance.

(a) Along the transverse direction

(b) Along the longitudinal direction

Figure 11. Principal stresses at normal section of middle slab under T-1E-1P

The analyses have been performed to find the maximum stresses under the lifting methods listed in Table 1 and the results are shown in Figure 12. Generally, as the number of lifting points increases, the maximum stresses become smaller. For the same number of lifting points, the maximum stresses under both-side lifting methods are generally smaller than those under one-side lifting methods. For one-side and both-side lifting methods, the smallest maximum stresses occur when the continuously distributed lifting method is applied. However, that method cannot be applied in practice because the supporting beam to lift the slab cannot be fabricated to exactly match the curvature of the slab. If the curvature of the slab is smaller than that of the supporting beam, just the center of the beam will support the slab and this case will be the same as the 1-point lift. On the other hand, if the slab curvature is larger than that of the supporting beam, the slab is lifted at both ends of the beam. Therefore, the 7-point lifts at both sides of the middle slab will be the most appropriate method to reduce the slab stresses under the slab lift for replacement of bearing pads.

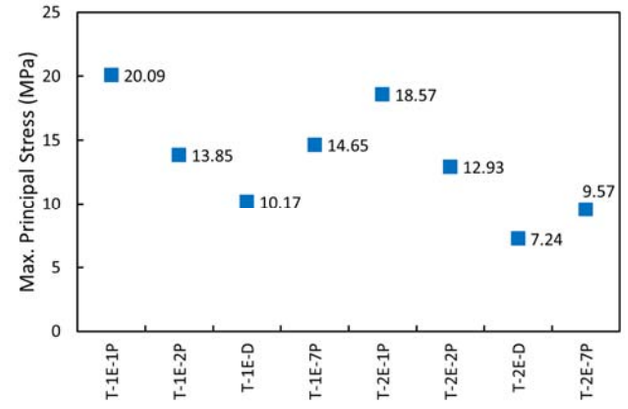


Figure 12. Maximum stresses at normal section of middle slab

3.2 *Stresses at expansion joint section of middle slab*

The stress distribution of the middle slab when the slab is lifted at the expansion joint section is also investigated. The lifting methods considered at the expansion joint section are listed in Table 2. The 1-point lifting method represents the slab lift conducted at the expansion joint. The 2-point lifting method is that the lifting is conducted at 1 m left and 1 m right from the expansion joint, so it is actually 1-point lift at 1 m apart from the expansion joint. The same situation happens on the 7-point lifting method, and just 4 points are lifted from the expansion joint to one direction.

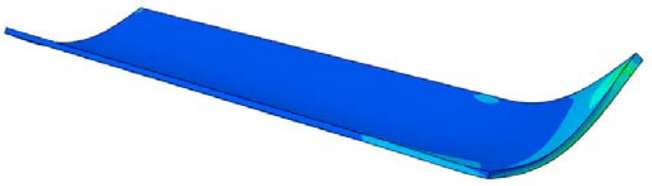

Table 2. Lifting methods at expansion joint section

Lifting points	One-edge lift	Both-edge lift
1	EJ-1E-1P	EJ-2E-1P
2	EJ-1E-2P	EJ-2E-2P
7	EJ-1E-7P	EJ-2E-7P
Distributed	EJ-1E-D	EJ-2E-D

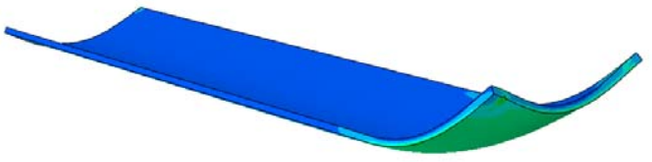

Figure 13 shows the typical deflected shapes and stress distribution when the middle slab is lifted at the expansion joint section under the one-side and both-side lifting methods.

The maximum stresses under different lifting methods listed in Table 2 are obtained and the results are shown in Figure 14. The both-side lifts show smaller stresses compared with the one-side lifts when the number of lifting points is the same. The smallest maximum stress occurs when the mid-

dle slab is lifted at both side and two points, one each from the expansion joint, are lifted. This result is different from the result at the normal section. The smallest maximum stress at the normal section occurs when the continuously distributed lifting method is chosen, as previously examined.

(a) One-side lift

(b) Both-side lift

Figure 13. Deformation and stresses of expansion joint section

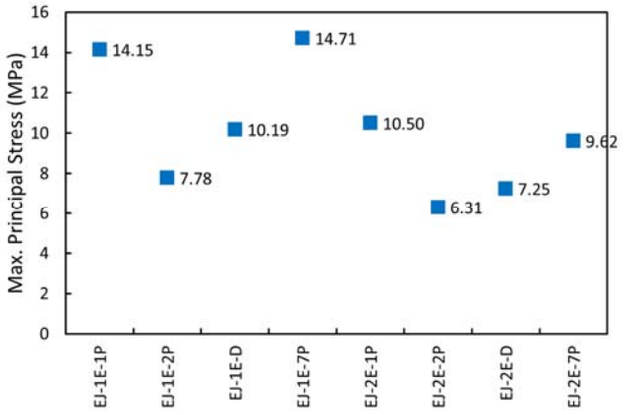

Figure 14. Maximum stresses at expansion joint section of middle slab

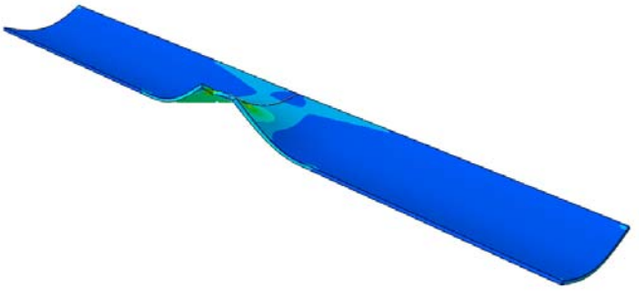
3.3 *Stresses at emergency passageway section of middle slab*



The stresses of the middle slab are also analyzed when the slab lifting is conducted at the emergency passageway section of the middle slab. The primary difference of the emergency passageway section from the normal section is the existence of the empty space at one side of the slab for movement between upper and lower levels. The slab lifting methods considered at the emergency passageway section are listed in Table 3. For the continuously distributed lifting method, Equation (2) is used at the passageway side (stair side) and Equation (1) shown previously is used at the opposite side (non-stair regular side). The distances between lifting points of the 2-point lifting method are 2 m and 8 m for the regular side and the passageway side, respectively. The 7-point lifting method at the regular side is the same as that for the normal section, and the 6-point lifting method is applied at the passageway section. In this case, the distances to the lifting points from the center of the passageway are -12, -8, -4, 4, 8, 12 m.

$$D(z) = 0.025 \times \cos\left(\frac{z \times \pi}{13} - \frac{\pi}{4}\right) + 0.025 \quad (2)$$

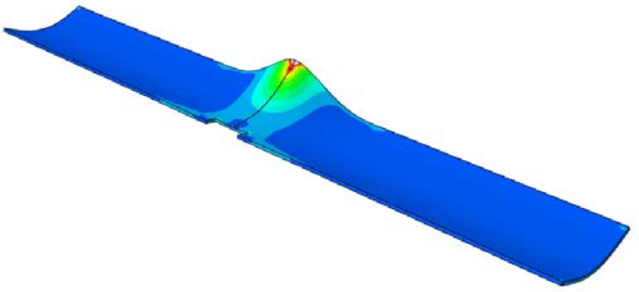


Table 3. Lifting methods at emergency passageway section

Lifting points	One-edge lift (stair side)	One-edge lift (regular side)	Both-edge lift
1	EPS-1E-1P	EPR-1E-1P	-
2	EPS-1E-2P	EPR-1E-2P	-
6 or 7	EPS-1E-6P	EPR-1E-7P	EP-2E-7P
Distributed	EPS-1E-D	EPR-1E-D	EP-2E-D

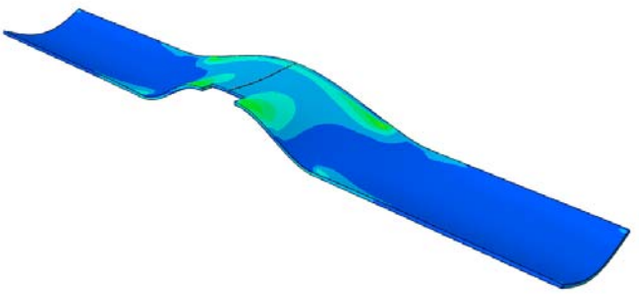

Figure 15 shows the typical deflected shapes and stress distribution of the middle slab when the slab is lifted at the emergency passageway section under the stair-side, regular-side, and both-side lifting methods.

(a) Stair-side lift

(b) Regular-side lift

(c) Both-side lift

Figure 15. Deformation and stresses of emergency passageway section

The maximum stresses of the middle slab when the slab is lifted using the methods listed in Table 3 are analyzed and shown in Figure 16. For one-side lifts, the maximum stresses are smaller when the regular side is lifted compared with the stair side lifting if the number of lifting points is the same, except for the 1-point lifting method. If the continuously distributed lifting methods are applied, the maximum stresses are the smallest. However, as mentioned previously, the continuously distributed lifting method is not practically used. Therefore, if the both sides are lifted at the same time with 7 lifting points at the regular side and 6 lifting points at the stair side, the maximum slab stresses can be reduced.

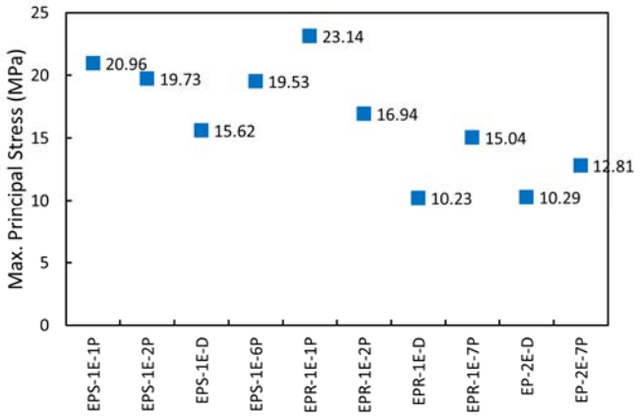

Figure 16. Maximum stresses at emergency passageway section of middle slab

4 SUMMARY AND CONCLUSIONS

This study was performed to evaluate slab lifting strategies of the middle slab in double-deck tunnel when the bearing pads between the slab and bracket are needed to be replaced with new ones. Several different slab lifting methods were examined at different sections of the middle slab to find the minimal stress occurrence during the slab lifting work. The main conclusions from this study are as follows:

- The optimal slab lifting method that reduces the maximum tensile stresses of the slab is different depending on the section type of the middle slab.
- At the normal section of the middle slab, the multiple-point lifting, such as the 7-point lifting, at both sides of the slab is the most appropriate to reduce the maximum tensile stress of the slab.
- At the expansion joint section of the middle slab, the 2-point lifting, one each from the expansion joint, at both sides of the slab is the most acceptable method.
- At the emergency passageway section of the middle slab, the multiple-point lifting at both sides of the slab, such as the 7-point lifting at the regular side and the 6-point lifting at the passageway side, is the most appropriate.
- At any section of the middle slab, the slab lifting at both sides at the same time is recommended since it decreases the maximum tensile stresses of the slab compared with the slab lifting at just one side of the slab.
- If the optimal slab lifting methods are considered depending on the section type of the middle slab, the economical design of the middle slab can be achieved.

ACKNOWLEDGEMENTS

This research was supported by Development of Design and Construction Technology for Double Deck Tunnel in Great Depth Underground Space (14SCIP-B088624-01) from Construction Technology Research Program funded by Ministry of Land, Infrastructure and Transport of Korean government. The authors wish to express their gratitude for the financial support.

ABSTRACT: This paper explores the feasibility of using a composite deck system with Hybrid Fiber Reinforced Lightweight Aggregate Concrete (HFRLAC), shear studs on Orthotropic Steel Deck (OSD) to reconstruct the Zhicheng Yangtze River Combined Highway-Railway Bridge(HRCB)， without disrupting train traffic. The mix of HFRLAC were introduceed. The fatigue test for the scale model of composite deck pavement was carried out under equivalent loading. The Finite Element Analysis(FEA) was conducted based on the simplified deck pavement. The field tests results and service condition have proved the maintenance for the HRCB is effective since 2013.

KEYWORDS: combined highway-railway bridge;maintenance;composite deck system ; HFRLAC; shear studs; FEA; scale model and field test.

1 INTRODUCTION

Many bridges in service appear to have operational problems (Imam & Righiniotis, 2010). A large number of studies that feature reasonable maintenance decisions and choosing the proper maintenance scheme have been carried out (Dan & Biondini, 2014). However, there is only a few researches involving the maintenance for highway-railway combined bridges.

Due to the nature of the structural characteristics of a combined highway-railway bridge, weight reduction are important for the bridge safety.Lightweight aggregate concrete could greatly reduce the dead loading for a bridge, and it will be widely used if the brittleness could be eliminated. Fibers can significantly enhance the lightweight aggregate concrete (Hassanpour, Shafigh & Mahmud, 2012; Victor, 2007).Experimental results showed that even low content fibers could remarkably improve properties such as the splitting tensile strength, flexural strength, and toughness (Balendran, Zhou, Nadeem & Leung, 2002; Shi & Riefler, 2005). Studies found that the addition of hybrid steel fibers and polypropylene fibers,can greatly improve the mechanical properties of lightweight aggregate concrete made with natural pumice (Huo, Shen & Cui, 2007; Düzgün, Gül & Aydin, 2005). Altun & Aktaş (2013) successfully developed a high performance PVA (polyvinyl alcohol) fiber reinforced lightweight concrete (FRLWC) that showed high flexural strength, high flexural ductility, and excellent toughness.

Zhicheng Yangtze River Combined Highway-Railway Bridge (“Zhicheng Bridge”) ,built in 1971 China, is a steel truss continuous girder bridge with total span 1280m(Fig.1-2). The original highway deck pavement of Zhicheng Bridge is made up of 12cm C30 reinforced concrete slab, 4cm concrete layer, and covered with 1.5cm asphalt sand layer (Fig.3). Inspections showed that the original bridge deck pavement was damaged seriously(Fig.4)

This paper foucsed on the maintenance of combined highway-railway bridge using composite deck pavement based on the HFRLAC & shear studs ,where the scheme were verified by finite element analysis, scale model and field test.

2 MAINTENACE SCHEME & FEM

2.1 *Maintenance of Zhicheng Bridge*

For the maintenance of Zhicheng Bridge，a new orthotropic steel deck (Fig.5(a)), with the pavement consisting of HFRLAC, shear studs,mesh reinforcement & a stress absorbing waterproof layer between the HFRLAC layer and the SMA layer. The details of the deck pavement can be seen from Fig.5(b)

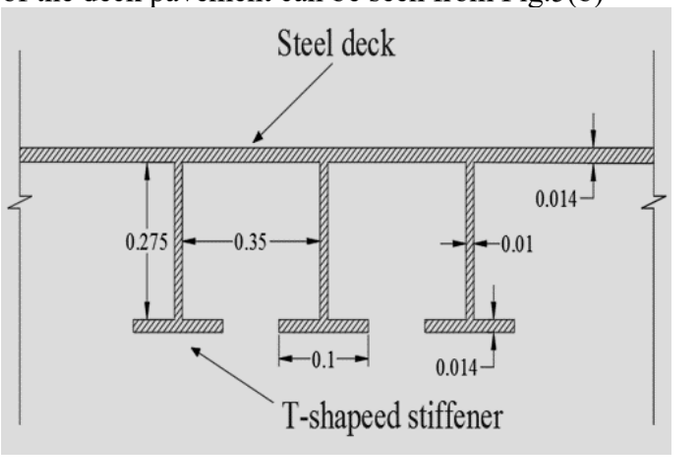

Figure 5(a). The new OSD

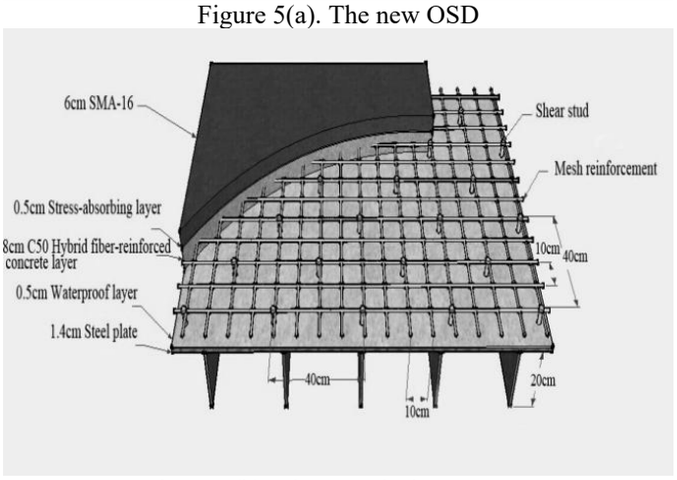

Figure 5(b). The new deck pavement

2.2 *FEM of Zhicheng Bridge*

In this study, a global FEM(Fig.6 & Fig.7) for the Zhicheng Bridge was built. The shear studs & mesh reinforcement has been dealt with equivalently in the HFRLAC. The Shell63 element was used to simulate OSD, HFRLAC and SMA. The truss and triangle brackets were simulated by Beam188 element. The boundary conditions of the model were the same as those of the actual bridge. Table 1 showed the parameters of FEM for the deck pavement.

Table 1. Parameters of the deck pavement

Parameters	Elastic modulus E / Pa	Thickness h / m	Poisson's ratio μ	Density ρ /（$kg \cdot m^{-3}$）	Bending stiffness D/（$kN{\cdot}m^2$）
Orthotropic Steel Deck	2.10E+11	0.014	0.3	7850	3769
HFRLAC	3.50E+10	0.08	0.25	2470	19911
SMA	1.00E+09	0.06	0.25	2400	320

4 SCALE MODEL TEST & CONSTRUCTION

4.1 *Scale model test*

In this experiment, the fatigue performance of n ew pavement structure was determined using an MTS fatigue testing machine at a scale of 1:2 c ompared with the actual deck pavement. The ma ximum load capacity of the test machine is 100 0kN, load measurement accuracy is less than 0.5 %, and the machine has an applied load frequen cy range of 0.01~30Hz. The test procedure can be summaryzed as follows: a stress level of 0.7 and a cyclic stress ratio of 0.1 was selected; t he loading frequency was set at 10Hz and the c yclical load was applied. The test was automatic ally stopped after a cycle count of 2 million wa s reached. The stress level was increased and th e test was repeated. At each stress level, 3 tensi le fatigue specimens were made The test results showed that the fatigue cycles exceed 2 million times, which can meet the requirements of brid ge service

Figure 12 showed the maintenance for the combined highway-railway bridge with HFRLAC and shear studs.And after successful application,the Zhicheng Yangtze River Combined Highway-Railway Bridge has been in service for 5 years.

5 RESULTS AND DISCUSSION

5.1 Strain results

The results of finite element analysis, presented in Figure 13, showed that the maximum longitudinal tensile strain and the maximum transverse tensile strain of the bridge deck pavement under different loads were less than the allowable value of the materials. Figure 14 showed the calculated vertical displacement of deck pavement under different loads. The maximum displacement of the bridge deck pavement under coupled loads of vehicle and train is 5.16 cm, which was almost the same as measured results

From Table 5, the maximum stress values of the bars after maintenance were not only lower than the corresponding values before maintenance, but also less than the allowable stress value. This difference dispalyed that the safety of the bridge was increased after the reconstruction work. According to the calculation results, the strain and displacement of deck pavement and the stress of truss, are all satisfied with the design requirements.

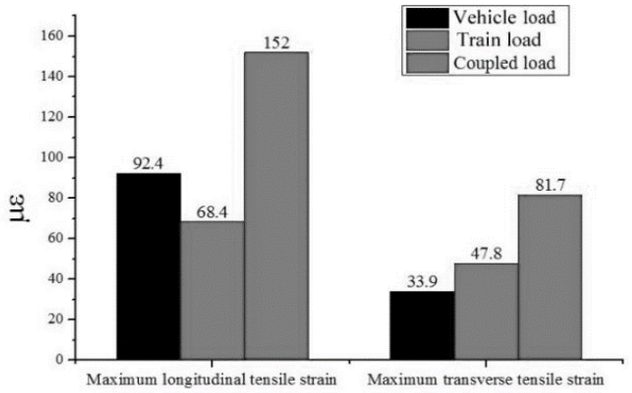

Figure 13. Strain results

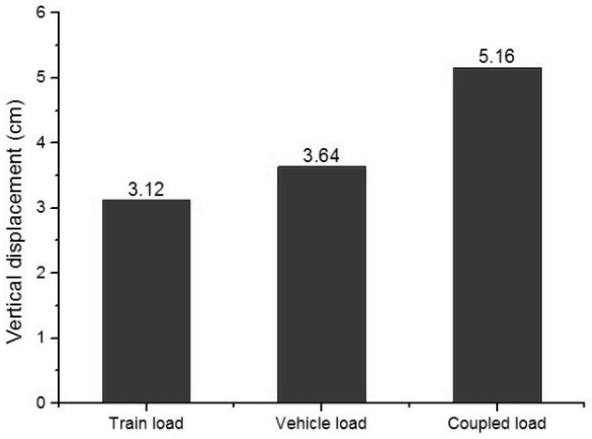

Figure 14. Vertical displacement results

5.2 comparision between New pavement & Original pavement

Figure 15 showed the values of vertical displacement resulting from the coupled train & vehicle loads before and after the maintenance. It was clear that all verdital dispalacement of new pavement scheme was smaller than the original one.So the Zhicheng bridge is benefical from the new deck pavement with more safe allowable.

As shown in Figure 16 ,there were 6 measuing points in Zhicheng bridge for the comparsion of strain.The theoretical strain values were greater than the measured values, which indicateed that the bridge had a great redundancy after the maintenance.

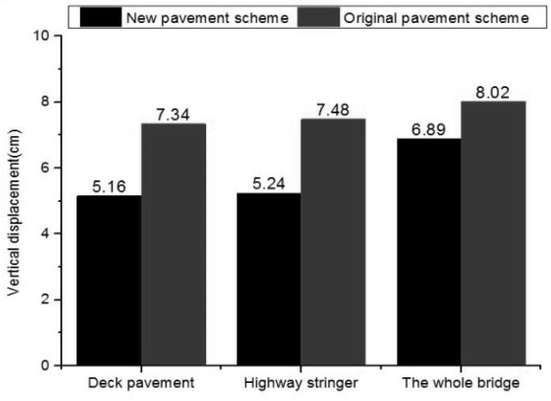

Figure 15. Comparison of Vertical displacement

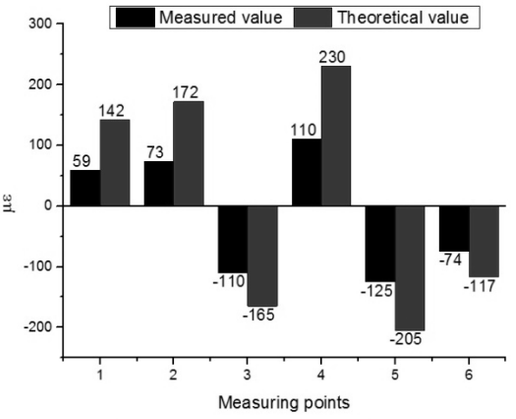

Figure 16. Comparison of strain

6 CONCLUSIONS

The composite deck pavement,based on OSD, HFRLAC and shear studs,could proviod a new idea for combined highway-railway bridge maintenance.

FEM analysis,scale model testing & field test proved the maintenance could meet the design requirements under the coupled loading of vehicles and train.

According to the comparision between New pavement & Original pavement, the composite deck pavement design & construciton could be suitable for combined highway-railway bridge maintenance,espially without disrupting train traffic.

Fuzzy Based Tool to Measure the Resilience of Communities

O. Kammouh, A. Zamani Noori, M. Domaneschi, G.P. Cimellaro
Politecnico di Torino, Italy

ABSTRACT: Last decades have been characterized by an increasing number of disasters all over the world. Therefore, the concept of community resilience has attracted the attention of the scientists who started to explore and assess the ability of communities to recover after undesirable events. In this work, a method for assessing the earthquake community resilience based on the PEOPLES framework is presented. PEOPLES is a framework that defines community resilience using seven dimensions. Each of the dimensions is defined through a set of indicators to describe the different aspects of resilience. The exact evaluation of the indicators is usually not possible due to the lack of deterministic data related to the damaged system after the disaster. The proposed method exploits a knowledge-based fuzzy modelling to allow the quantitative evaluation of the PEOPLES indicators taking into account uncertainties. The output of the implemented fuzzy method is a resilience index.

1 INTRODUCTION

According to "The International Disaster Dataset" (EM-DAT), the number of natural disasters and the corresponding number of people affected, with related economic losses, have shown an upward trend in the last years. This implies that communities are often not sufficiently resilient to natural catastrophes. Consequently, the concept of resilience has been deepened in the engineering field to assess the ability of a community to recover after an undesirable event. Indeed, since the adoption of the Hyogo framework in (Manyena 2006), strategies involved in hazard planning and disaster risk reduction have experienced a paradigm shift from a vulnerability assessment approach to a resilience-based approach (Mayunga 2007).

Since the concept of resilience is applicable in several disciplines, different definitions are available in the literature. Cimellaro et al. (2016) have conducted a comprehensive review on this topic. In their work, the resilience definition provided by Bruneau et al. (2003) emerges: resilience is "the ability of social units to mitigate hazards, contain the effects of disasters when they occur, and carry out recovery activities in ways to minimize social disruption". This definition has been later improved by Cimellaro et al. (2010) who define resilience as: "a function indicating the capability to sustain a level of functionality or performance for a given building, bridge, lifeline network, or community, over a period defined as the control time (T_C) that is usually decided by owners, or society (usually is the life cycle, life span of the system etc.)". Thus, resilience can be defined analytically as the area under the serviceability performance curve $Q(t)$ of a system, normalized accordingly to the considered control time (T_C):

$$R = \int_{t_1}^{t_r} \frac{Q(t)}{T_C}\, dt \tag{1}$$

where R is the resilience index; $Q(t)$ is the system functionality at time t; t_1 is the moment when the disturbance occurs and the system functionality drops from its initial value q_0 to q_1; t_r is the moment when the initial serviceability is completely recovered and equal to q_r; T_C is the control time. Figure 1 shows the performance curve derived using Equation 1. The serviceability $Q(t)$ ranges between 0% and 100% to indicate the complete absence of functionality of the service and its complete effectiveness, respectively.

Here, community resilience is evaluated exploiting a novel method, which benefits from the PEOPLES framework (Renschler et al. 2010, Cimellaro et al. 2016). PEOPLES is a layered framework: each dimension is divided into components, and each component is divided again into a set of indicators. (Kammouh et al. 2017b) conducted a comprehensive review on community resilience indicators that led to identifying 115 of them. They also proposed a method to transform the framework from a qualitative to a quantitative model through the measure-

ment of indicator parameters. However, in specific scenarios, some indicators may be difficult to obtain and quantify, as well as the interdependency among them. In order to track and represent such uncertainties, a method that enhances the one proposed by Kammouh et al. (2017b) is presented herein. The method introduces a fuzzy logic-based modelling of PEOPLES indicators that accounts for the uncertainties involved in the assessment process.

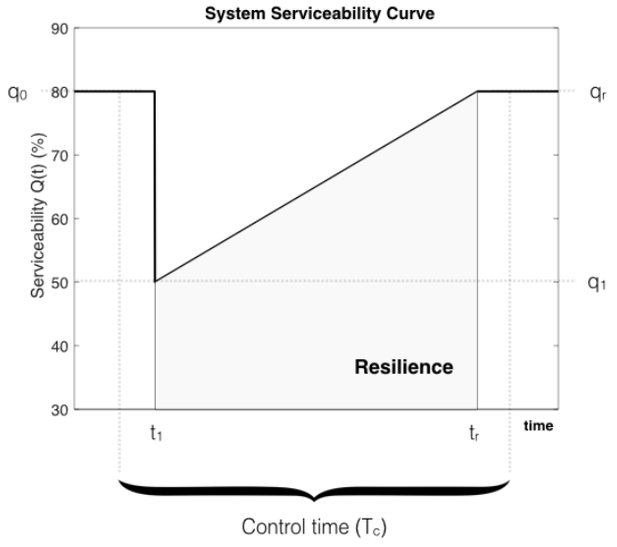

Figure 1. Example of a serviceability function and resilience evaluation.

2 PEOPLES FRAMEWORK

Challenges to make the concept of resilience operational have been addressed by Cimellaro et al. (2016) who defined the so called PEOPLES framework. The framework has been developed at the Multidisciplinary Center of Earthquake Engineering Research (MCEER) and has enhanced the initial research on resilience characteristics. By evaluating the functionality performance of community components (both in time and space), this framework guarantees a qualitative assessment of the community resilience. The acronym "PEOPLES" stands for seven community dimensions:

1 Population and demographics: it includes parameters that describe the social-economic composition of the community. This dimension measures the social vulnerability that could hinder the functionality of the emergency and recovery systems (e.g. population density, age distribution, presence and integration of minorities and socio-economic status.)
2 Environment and ecosystem: it estimates the capability of the environment and of the ecosystem to get back to its pre-hazard conditions. It includes water, air and soil assessments as well as a measure of the biodiversity and the sustainability relations.
3 Organized government services: it covers the services that the government guarantees before and after an extreme event. A great importance is given to the mitigation and recovery processes, which include the preparedness to hazards and all disaster risk reduction measures.
4 Physical infrastructure: it considers the buildings and facilities that are the prevalent interests of civil engineers and traditional resilience analysis. Particularly, two different aspects are analyzed in this dimension: facilities, which includes housing and services which are not crucial for the emergency response, and lifelines, which instead consists of the services that are of vital importance for the management of critical situations.
5 Lifestyle and community competence: This dimension takes into account the capability of a community to face problems by means of political partnerships. This includes both the abilities of a community (i.e. the skills of their components) and its perceptions (i.e. the judgements and feelings that a community has on itself.)
6 Economic development: it describes the economic situation of the community. It can be easily divided in two terms, a static component, which measures the present economic condition, and a dynamic one, which instead takes into account the development and economic growth of the community.
7 Social-cultural capital: This last dimension contains an evaluation of the community's attitude to react to disasters and to return to the pre-event conditions. It includes a lot of subcategories that measure the people's commitment in the community and the social-cultural heritage.

3 FUZZY LOGIC

Zadeh (1965) introduced the concept of fuzzy set and the theory behind it. This theory comes with the absence of any mathematical framework that is able to describe the complexity and vagueness included in processes where human intervention is significant. While in the crisp logic the variables belong only to one class, in the fuzzy logic a variable x can be a member of several classes (fuzzy sets) with different membership grades (μ). Thus, each fuzzy set is characterized by a membership function that associates to any input x a real number (μ) ranging between 0 (x does not belong to the fuzzy set) and 1 (x completely belongs to the fuzzy set) (Zadeh 1965). The strength of inference systems based on fuzzy logic relies on the following two main aspects:

– fuzzy inference systems can handle both descriptive (linguistic) knowledge and numerical data;

– fuzzy inference systems exploit approximate reasoning algorithm to formulate relationships between inputs by which uncertainties can be propagated throughout the whole process (Tesfamariam & Saatcioglu 2008a)

Designing a fuzzy logic-based system follows two fundamental steps: 1) defining the membership functions and the fuzzification process; 2) designing the fuzzy inference system. Fuzzy methods have been widely developed and applied in several fields (Ross 2009). In the context of earthquake engineering, fuzzy methods have been exploited in different applications (e.g. (Tesfamariam & Saatcioglu 2008a, b, Tesfamariam & Saatcioglu 2010, Tesfamariam & Sanchez-Silva 2011, Tesfamariam & Wang 2011)). Fuzzy methods have been widely used also for developing structural control systems (Casciati et al. 2004). A clear procedure for the application of fuzzy logic can be found in (Tesfamariam & Saatcioglu 2008b).

A fuzzy logic system (FLS) can be defined as the nonlinear mapping of an input data set to a scalar output data. A FLS consists of four main parts: fuzzifier, rules, inference engine, and defuzzifier (Figure 2).

The process of fuzzy logic is: a crisp set of input data are gathered and converted to a fuzzy set using fuzzy linguistic variables, fuzzy linguistic terms and membership functions. This step is known as fuzzification. Afterwards, an inference is made based on a set of rules. Lastly, the resulting fuzzy output is mapped to a crisp output using the membership functions, in the defuzzification step.

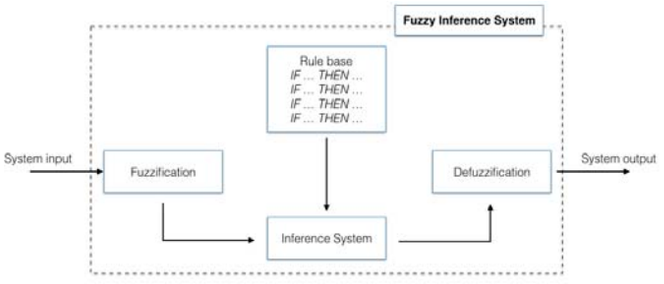

Figure 2. The Fuzzy inference system

3.1 *Fuzzification*

The basic input parameters have a range of values that can be clustered into linguistic quantifiers, for instance, very low (VL), medium low (ML), medium (M), medium high (MH) and very high (VH). The process of assigning linguistic values is a form of data compression and it is called *granulation*. The fuzzification step converts the input values into a homogeneous scale by assigning corresponding membership functions with respect to their specified granularities (Tesfamariam & Saatcioglu 2008b).

Membership functions are used in the fuzzification and defuzzification steps of a FLS, to map the non-fuzzy input values to fuzzy linguistic terms and vice versa. A membership function is used to quantify a linguistic term. Note that, an important characteristic of fuzzy logic is that a numerical value does not have to be fuzzified using only one membership function. In other words, a value can belong to multiple sets at the same time. There are different forms of membership functions such as triangular, trapezoidal, piecewise linear, Gaussian, or singleton. The most common types of membership functions are triangular, trapezoidal, and Gaussian shapes. The type of the membership function can be context dependent and it is generally chosen arbitrarily according to the user experience (Mendel 1995).

3.2 *Fuzzy Rules*

The fuzzy rule base (FRB) is derived from heuristic knowledge of experts or historical data to define the relationships between inputs and outputs. The most common type is the *Mandami* type, which is a simple IF-THEN rule with a condition and a conclusion. For instance, considering two inputs, the i^{th} rule has the following formulation:

$$R: IF\ x_1\ is\ A_1\ AND\ x_2\ is\ A_2\ THEN\ y\ is\ B \quad (2)$$

where x_1 and x_2 are the inputs variable, A_1 and A_2 are input sets, y is the output, B is the output set. The completeness of a fuzzy model is determined by the description of the behaviour for all possible input values and requires a large number of rules. The rule base is the union of all the rules:

$$R = \bigcup_{i=1}^{n} R_i = R_1\ ALSO\ R_2\ ALSO \ldots ALSO\ R_n \quad (3)$$

In some cases it is possible to regulate the degree of influence of each rule on the final output. This can be done by adding weightings based on priority or consistency, in a static or in a dynamic way.

3.3 *Fuzzy Inference System (FIS)*

After evaluating the result of each rule, the results are combined to obtain a final output. This process is called *inference*. Several accumulation methods can be used to combine the results of the individual rules. The maximum algorithm is generally used for accumulation. The evaluations of the fuzzy rules and the combination of the results of the individual rules are performed using fuzzy set operations. The operations on fuzzy sets are different with respect to the operations on non-fuzzy sets.

3.4 *Defuzzifcation*

After the inference step, the overall result is a fuzzy value. This result should be defuzzified to obtain a final crisp output. This is the purpose of the defuzzifier component of an FLS. The defuzzification represents the inverse of the fuzzification process. It is performed according to the membership function of the output variable. There are several techniques to perform the defuzzification such as centre of gravity, centre of area, and mean of maximum methods.

4 METHODOLOGY

Recently, (Kammouh et al. 2017b) have developed a novel method to assess the resilience of communities based on the PEOPLES framework. The researchers provided a way to analytically quantify the resilience of communities through the use of indicators. A list of 115 resilience indicators representing the different aspects of a community have been identified. A full list of indicators can be found in (Kammouh et al., unpubl) while a part of the list can be found in (Kammouh et al. 2017b). Each indicator has been defined and computed using a set of parameters: the functionality before the disaster (q_0), the functionality after the disaster (q_1), the functionality after the restoration phase (q_r), and the recovery time (T_r) (see Figure 1). Moreover, a target value (TV) has been identified for each indicator in order to normalize q_0, q_1 and q_r between 0 and 1 to have a computable and comparable dataset. Then, a serviceability function for the whole community is derived from the aggregation of these measurements, where the weighting scheme is defined according to the indicator importance. Finally, the community resilience is computed as the area under the community serviceability curve using Equation (1).

The methodology previously described represents a major break-through in the context of community resilience evaluation. In spite of being very simple, it can be applied to large communities and can serve as a powerful tool in preliminary decision-making processes related to natural catastrophic events. Nevertheless, this method is operable only if indicators can be numerically quantified, which may not be the case in some scenarios.

In this paper, a method that enhances the one proposed by (Kammouh et al. 2017b) is proposed. The method exploits a fuzzy logic-based modelling of PEOPLES indicators in order to deal with uncertainties and missing knowledge. In the following, the fuzzy modelling of PEOPLES indicators and the evaluation of community resilience using information gathered through the fuzzy inference system are discussed. Different approaches are proposed to match different levels of complexity, starting from a two-parameter approach then four-parameter approach and ending with a full translation of the PEOPLES framework. The proposed methodologies are not fully interchangeable and so only one of them should be selected in accordance with the needed details level.

5 TWO-PARAMETER APPROACH

This approach adopts only two of the four serviceability parameters described before, namely serviceability initial drop q^* (previously referred to as q_0) and recovery time T^* (previously referred to as T_0). Fuzzy parameters have been chosen based on the research by (Bruneau et al. 2003) who describes the resilience of a system using the following three indicators: reduced failure probability; reduced consequences from failure; reduced time to recovery. The reduced failure probability has not been taken into account as it is not easily related to the herein adopted mathematical definition of resilience, which considers only the failure consequence q^* and the repair time T^*. Figure 3 presents a hierarchy of the two-parameter approach where both *time* and *initial drop* variables are used as inputs for the fuzzy system. The inputs are combined using a set of rules to obtain the output variable *fuzzy resilience*. The fuzzy output is defuzzified to get a crisp value that serves as a resilience index for the corresponding indicator.

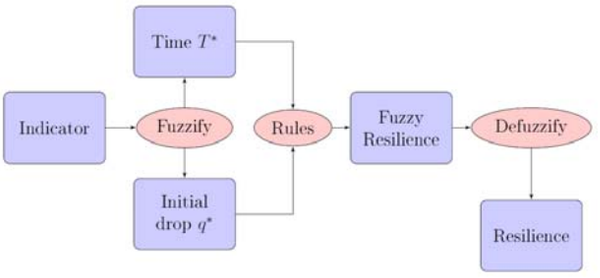

Figure 3. Schematic representation of the two-parameter approach.

5.1 *Evaluating the initial serviceability drop q^*:*

In the authors' opinion, two trapezoidal membership functions can be reasonably adopted in the present case. They are termed as "High" and "Low". The fuzzification used for q* is [High; Low]→[(0, 0, 0.35, 0.65); (0.35, 0.65, 1, 1)]. The membership functions are graphically shown in Figure 4.

5.2 *Evaluating the recovery time T^*:*

When speaking of recovery, the intent is the *full* recovery. Outperforming, or non-complete recovery, as indicated by (Cimellaro et al. 2010), are not generally predictable and therefore they are not included here. For the time variable T^*, three membership functions are suggested by the authors, namely: "short"; "long"; and "very long". The time variable

is normalized based on a 3-year time span, which is normally the time reference for civil applications (i.e., 3 years corresponds to 1 on the horizontal axis). Figure 5 shows the membership functions chosen by the authors. The membership functions are not symmetrical as they have been constructed to the favor of the "Long" and "Very Long" memberships. That is, high range of values of the restoration time T^* variable corresponds to the membership functions "Long" and "Very Long".

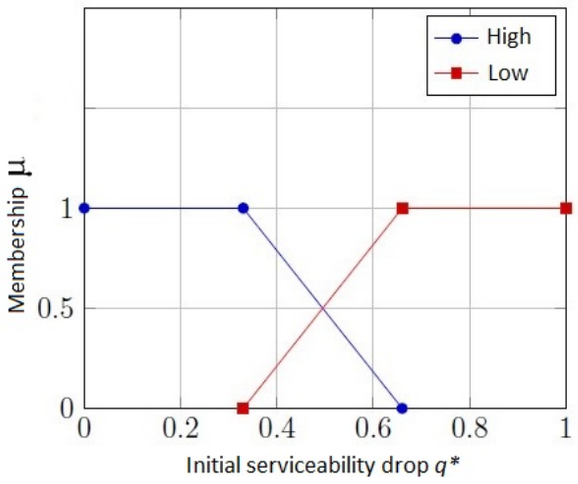

Figure 4. Membership functions for the serviceability variable q^*.

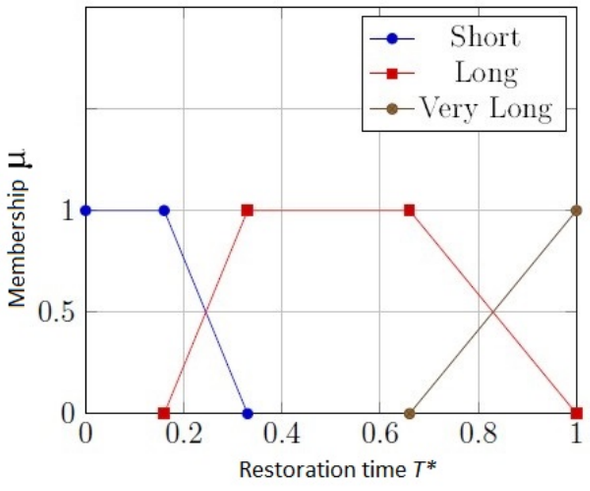

Figure 5. Membership functions for the downtime variable T^*.

The aim is to translate the given input variables (q^* and T^*) into one resilience measure R. This measure is itself fuzzy and so it is defined by a membership function. The chosen membership functions are depicted in Figure 6. Following the fuzzy approach, it is possible to define an output value calculated from the provided inputs on basis of a set of rules. The rules adopted in this study to relate the inputs and the output are shown in Table 1.

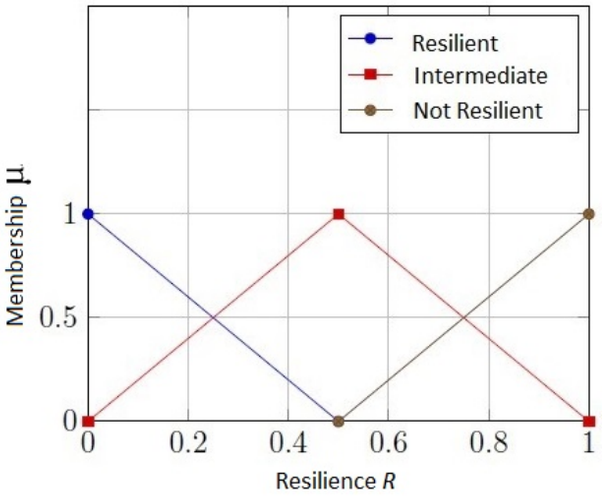

Figure 6. Membership functions for the resilience variable R.

Table 1. Fuzzy rule base for resilience.

T^*	q^*	R
short	high	resilient
Long	high	resilient
Very long	high	intermediate
Short	low	intermediate
long	low	not resilient
Very long	low	not resilient

5.3 *Defuzzification*

The fuzzy output variable is translated (defuzzified) into a numerical value that serves as a measure for resilience. Different methods for defuzzification can be used (Manyena 2006) such as center of gravity, weighted average, mean-max, center of largest area etc. The use of one method rather than another is dependent on the application. Here, the center of gravity method given in Equation 4 is used.

$$CoA = \frac{\int_{x_{min}}^{x_{max}} f(x) \cdot x \, dx}{\int_{x_{min}}^{x_{max}} f(x) \, dx} \quad (4)$$

where $f(x)$ is the function that shapes the output fuzzy set after the aggregation process and x stands for the real values inside the fuzzy set support ([0, 1]).

5.4 *Weighting*

The methodology introduced above applies to each indicator apart. It is often the case to aggregate different indicators into a single measure (i.e. community resilience) through a hierarchical structure. Usually, indicators contribute differently towards resilience and this necessitates weighting them according to their contribution. Different weighting schemes can be applied (Kammouh et al. 2017a, Kammouh et al., in press, Kammouh et al. 2017b). The one used in (Kammouh et al. 2017b) is here

adopted. This can be performed by simply allocating an importance factor (I) ranging between 1 and 3 to each indicator then applying the weighted average rule as follows:

$$R = \frac{\sum_{i=1}^{N} I_i R_i}{\sum_{i=1}^{N} I_i} = \sum_{i=1}^{N} w_i R_i \quad (5)$$

where R is the community resilience measure, R_i is the resilience measure of the i^{th} indicator, I_i is the corresponding importance factor (which can be scaled to preference), and w_i is the weighting factor of the i^{th} indicator. The difference with what was proposed in (Kammouh et al. 2017b) is that in this methodology the serviceability functions are translated into a resilience value before applying the weighting method (Figure 7). This simplifies the fuzzy system as it reduces the number of variables that need to be handled. Another approach that considers the weighting factors within the fuzzy system is introduced later in the paper.

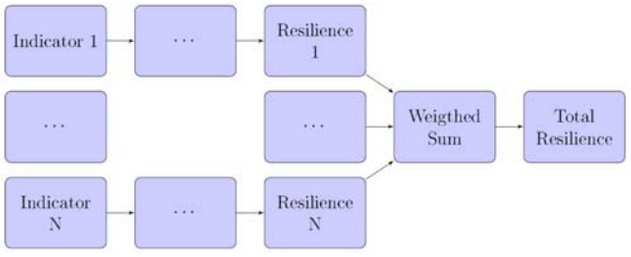

Figure 7. Hierarchical scheme of the fuzzy system with the weighting process.

Practical examples on the application of the fuzzy method to several case studies can be found in (Tesfamariam & Saatcioglu 2008a, b, Tesfamariam & Saatcioglu 2010). The same procedure is applied in this research but with the new variables and membership functions.

6 FOUR-PARAMETER APPROACH

Considering only two parameters to represent a resilience indicator may in some cases be insufficient, thus affecting the mentioned benefits of using the Fuzzy approach. Moreover, this may oversimplify the problem especially when specific information about the structure itself is available and to be added. For this reason, in certain cases it may be beneficial to build up the resilience curve from fuzzy parameters other than the recovery time and the initial drop. In fact, it has been pointed out by Comerio (2006) that further distinction in the repair time is possible. According to his work, the following parameters should be taken into account:

- Construction repair time;
- Mobilization time;
- Economic conditions of the interested region;

The mobilization time in particular, labelled as "irrational" in (Comerio 2006) (e.g. financing, workforce availability, relocation of functions or regulatory changes), is often not properly accounted for and therefore it should be given a special attention when evaluating downtime.

These three indicators may be fuzzyfied with a structure similar to the one adopted for the recovery time T^*. The result is similar to what shown previously with the only difference that new rules and membership functions are to be assigned to the new variables. When resilience measures are calculated, weighting is performed to obtain the system (community) resilience.

7 FULL PEOPLES

Most of the concepts described previously remain valid here. The only difference is that the approach introduced in this section includes the weighting of the variables within the fuzzy system. Normally, choosing adequate weighting factors is subjective and includes uncertainty. Although the inclusion of the weighting factors within the fuzzy system may add additional complexity as more variables are considered, it is certainly beneficial as it solves the uncertainty problem related to the weighting factors. To do that, two alternatives are proposed:

- Include the importance factor in the definition of the rules governing the fuzzy logic. In other words, assign rules such that the output is strongly related to the indicators with highest importance;
- Translate the importance factor into a fuzzy variable itself and include rules for it.

In both cases, rules have to be adapted to account for the importance factors. In the former case, rules are firmly tight to the particular application (i.e. hard to modify and not flexible); the latter case is, in this respect, more flexible but at the cost of additional complexity since additional rules have to be added to include the effect of the importance factor. This approach will be further developed and case studies will be added in future work. Figure 8 shows the logic flow where the weighting process is included as a separate variable in the first step before fuzzification:

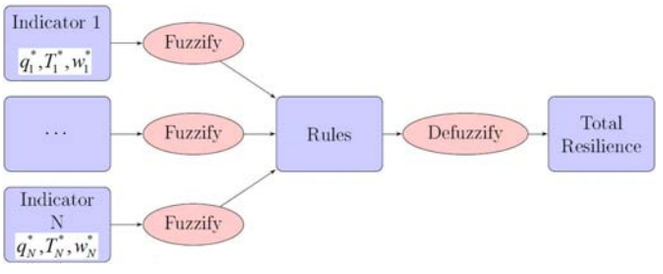

Figure 8. Full PEOPLES approach general hierarchical scheme with the weighting process included in the fuzzy system as a separate variable.

8 CONCLUSION

This paper extends the work previously done on the PEOPLES framework to evaluate the resilience of communities. It takes advantage of the fuzzy theory to account for the uncertainties involved in the evaluation of the PEOPLES' indicators. Different approaches are herein proposed depending on the level of complexity sought and the application type. The former considers only two fuzzy variables and it is intrinsically simple. However, oversimplification can affect the accuracy of the community resilience evaluation. A more comprehensive approach which includes a larger number of parameters with essential benefits in the resilience assessment at the cost of more demanding computational efforts is proposed. Possible developments in the application of weighting factors are also suggested for aggregating different indicators into a single community resilience measure.

ABSTRACT: To improve the resilience of critical infrastructure systems, their intrinsic properties need to be understood and their resilience state needs to be identified. In the literature, several methods to evaluate networks' reliability and resilience can be found. However, the applicability of these methods is usually restricted to small-size networks. In this paper, the transportation network of a large-scale virtual city is considered as a case study. A random removal strategy of the links (roads) is applied to simulate the network's failure. The network reliability is then calculated using the Destruction Spectrum (D-spectrum) method and a Monte Carlo approach has been developed to generate failure permutations that are necessary for the evaluation of the D-spectrum. In addition, the Birnbaum Importance Measure (BIM) has been adopted in this study to determine the importance of the network's components. The methodology adopted in this study can be also extended to all network-based systems. The paper also introduces resilience indicators as a soft tool to predict the performance and the serviceability of the transportation networks.

1 INTRODUCTION

Good physical connectivity in the urban and rural areas is essential for the economic growth of communities. Because of its intensive use of infrastructures, the transport sector is considered an important component of the economy and a common tool used for development. Transport networks need to provide a continuous service for communities, and this necessitates a good understanding of their resilience and reliability states. For instance, understanding how the topology of the network changes under disruptive events can be fundamental in the decision making process. It could also speed up rescue operations and help in evaluating cascading effects on other interdependent networks. This paper explores mostly the reliability of large scale networks. Reliability is a very broad concept and its application is extended to all engineering fields. In general terms, network reliability can be defined as the probability of connecting the nodes of the network (Chang & Li 2014). Other authors consider reliability as the quality of the transportation system in terms of optimal travel time, i.e. the probability that a trip between two nodes takes less than a certain time (Immers et al. 2002). Another widely used concept is the capacity reliability, which is the probability that the network capacity can accommodate a certain traffic volume at a required level of service (Chootinan et al. 2005, Chen et al. 2013, Niu et al., 2017). Reliability has also been studied under specific situations, such as the emergency response, using both ideas of travel time and level of service (Edrissi et al. 2015). Looking at graph theory, Guidotti et al. (2017) have used the connectivity measures as a tool to determine whether a network is reliable or not.

In this work, the reliability of the transportation network of a large scale virtual city is evaluated. The reliability definition adopted in (Gertsbakh & Shpungin 2008, Gertsbakh & Shpungin 2012, Gertsbakh & Shpungin 2016) is considered in this study. According to the researchers, reliability is related to the probability that some nodes, called terminals, remain connected. Thus, the system fails when the terminals are no more connected. The terminal nodes are strategic nodes with pre-defined survival probabilities assigned by the competent authorities. Knowing these probabilities helps greatly in improving the network (Peeta et al. 2010). However, it can be rather difficult to have access to such data. For this reason, a different failure criterion has been chosen in this work. Moreover, another performance parameter, the Birnbaum Importance Measure (BIM), is considered to study the behavior of the analyzed network. This parameter represents the importance of the network's components (Gertsbakh & Shpungin 2012); that is, components with a high BIM index are vulnerable components. The determination of the reliability and BIM indexes is relatively simple for small networks, but when ap-

plied to a large-scale road transportation network, the computational effort becomes a significant aspect to take into account.

The paper also introduces various resilience indicators of transport networks that can serve as a soft tool to predict and assess the resilience and functionality of the transportation system. The indicators are still not exhaustive and they mainly cover the physical aspect of the network only. Further work will be developed to consider organizational and managerial aspects of the network.

The paper is structured as follows: a brief introduction of the performance indexes with their equations is presented in section 2. Section 3 introduces some strategies to overcome the computational issues. A case study is presented in section 4, where the description of the network and the obtained results are provided. Finally, resilience indicators for transport networks are proposed in section 5.

2 NETWORK RELIABILITY AND COMPONENTS' IMPORTANCE

2.1 *Destruction spectrum*

The Destruction spectrum, or simply D-spectrum, is a representation of a network's structure and its failure definition (Gertsbakh & Shpungin 2009). The system in Figure 1 is used to introduce the concept of the D-spectrum. The nodes in the system are assumed reliable while the edges are unreliable; that is, only edges are subject to failure. In this example, the system's failure is defined as the loss in connectivity between the terminal nodes *a* and *c*.

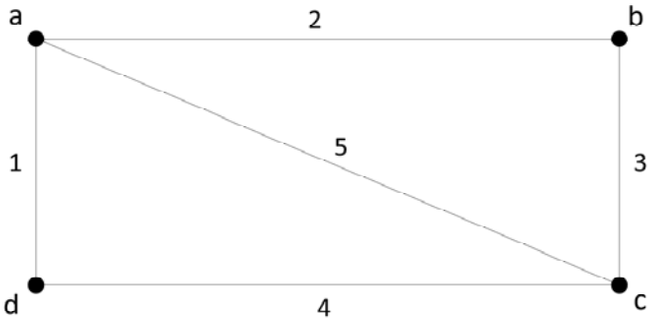

Figure 1. A simple network with two critical nodes.

The system's failure can be reached through different sequences of failing components. For instance, if the edges (1; 2; 5; 3; 4) fail, the two nodes *a* and *c* become disconnected, and thus the system fails. Another permutation leading to the same result can be (3; 5; 4; 1; 2). The failing component at which the system becomes down is called the anchor of the permutation. In the two permutations above, edges 5 and 4 are the anchors respectively. The total number of failure permutations in a system is *k!,* where *k* is the number of unreliable elements. After identifying all failure permutations, the D-spectrum set of the network is computed as follows:

$$D = \left\{ d_1 = \frac{x_1}{k!}, d_2 = \frac{x_2}{k!}, ..., d_k = \frac{x_k}{k!} \right\} \quad (1)$$

where d_i is the i^{th} component of the spectrum, x_i is the total number of permutations whose anchor's order is i, k is the total number of unreliable components. It is obvious from the equation above that the summation of all elements is 1 ($\Sigma_i\, d_i = 1$).

It is worth to note that the failure probability of each edge is not considered in the D-spectrum. One may simply consider a random removal of the edges in the sense that all edges have the same failure probability. Otherwise, a strategic edge removal can be considered but it requires additional analyses. For instance, in transportation networks, the removal of an edge (road) may be linked to the level of damage of the adjacent buildings. This requires fragility analysis to determine the level of damage that each building is subject to.

2.2 *Network reliability*

Generally, a network can be considered reliable when it offers a certain level of service or performance, even during emergency situations. Most of the reliability definitions that can be found in the literature deal with the concept of reliability in probabilistic terms. According to the definition of Gertsbakh & Shpungin (2008), each element of the network (nodes and edges) is given a probability p of being available and a probability $q = 1 - p$ of being unavailable. All these probabilities contribute in the determination of the network's reliability. The formulation used to calculate the reliability index *R(N)* is given in Equation (2). This one is valid when all unreliable components have the same failure probability.

$$R(N) = 1 - \sum_{i=1}^{k} y_i \frac{k!\, q^i\, p^{k-1}}{i!(k-i)!} \quad (2)$$

where y_i is the cumulative D-spectrum, given by the following equation:

$$y_i = \sum_{b=1}^{i} d_b \quad (3)$$

2.3 *Components' importance*

The Birnbaum Importance Measure (BIM) is a parameter that describes the importance of network's components. The vulnerability of the components is what determines their corresponding value of BIM.

This measure can be a tool to identify the critical components of a network in order to strengthen them. The following equation is used to compute the BIM index of a single component *j*:

$$BIM_j = \sum_{i=1}^{k} \frac{k!(z_{i,j} q^{i-1} p^{k-i} - (y_i - z_{i,j}) q^i p^{k-i-1})}{i!(k-i)!} \quad (4)$$

where $z_{i,j} = Z_{i,j} / k!$, in which $Z_{i,j}$ is the number of permutations satisfying two conditions: (a) if the first *i* elements of the network are down, then the network is down; (b) element *j* is among the first *i* elements of the permutation. By doing some manipulation, the expression in Equation (4) can be written in a different form, shown in Equation (5). It is worth to note that both reliability and BIM indexes share a common factor in their equations, and this provides a unique characteristic to compute both indexes in a single operation.

$$BIM_j = \sum_{i=1}^{k} \frac{k! q^i p^{k-1}}{i!(k-i)!} \cdot \left(\frac{z_{i,j}}{q} - \frac{y_i - z_{i,j}}{p} \right) \quad (5)$$

3 METHOD: APPLICATION TO LARGE-SCALE NETWORKS

Theoretical reliability analyses are not always applicable to large problems. For instance, the applications of the above mentioned equations are limited to small networks with defined number of components. This is due to the presence of *factorial* in the denominator of the spectrum set (Eq.(1)). The same problem appears when computing the reliability index *R*, although we know in advance that this is a number between 0 and 1, regardless of the network's size. In this section, we present strategies to apply the D-spectrum to large scale networks and compute the reliability index and BIM-spectra.

3.1 *D-spectrum for large scale networks: a Monte Carlo approach*

We propose the use of a Monte Carlo approach to generate the failure permutations needed to compute the D-spectrum. Hereafter, the algorithm of the Monte Carlo simulation is presented.

Algorithm: Generate permutations and compute the D-spectrum

1) Define a failure criterion for the network (e.g. percentage of failed components, number of disconnected nodes, etc.).
2) Start a permutation counter (n = 1).
3) Choose a component (edge or node) randomly from 1 to k and store it (i.e. the chosen number represents a failed component).
4) Check if the network's failure criterion defined in step 1 is met:
   a. If yes, store the permutation and go to step 5;
   b. If no, choose another number from 1 to k excluding the numbers previously chosen and then go back to step 4.
5) Set n = n + 1 and repeat the steps 3 and 4 for *M* times to generate *M* permutations.
6) Group the permutations according to their anchor's value (i.e. the anchor value coincides with the vector's length of the permutation).
7) Compute the D-spectrum using Equation (1).

In case of targeted removal, the network's components should be linked with given failure probabilities or lifetime distributions. In this case, step 3 is adjusted so that the removal process is not random.

3.2 *Reliability and BIM indexes for large scale networks: incremental computation*

Practically, computing the reliability and BIM indexes is not possible for moderate to large networks. The reason is that both numerator and denominator in the second term of the reliability index (Eq.(2)) and in the first term of the BIM index (Eq.(5)) are too large. However, it is known in advance that the reliability index is a number that ranges between 0 and 1 regardless of the network's size. Symbolic calculation represents an effective tool to solve such kind of numerical problems. Also, a more compact writing of the equation has been used. Defining *M* as shown in Equation (6), it is possible to rewrite the expressions of reliability and BIM indexes (Eqs 7-8).

$$M_i = \frac{k! q^i p^{k-i}}{i!(k-i)!} \quad (6)$$

$$R = 1 - \sum_{i=1}^{k} y_i \cdot M_i \quad (7)$$

$$BIM_j = \sum_{i=1}^{k} M_i \cdot \left(\frac{z_{i,j}}{q} - \frac{y_i - z_{i,j}}{p} \right) \quad (8)$$

4 CASE STUDY: THE TRANSPORTATION NETWORK OF A VIRTUAL CITY

4.1 *Network definition*

The road transportation network of a virtual city has been modeled as an undirected graph (Figure 2). An undirected graph *G = (V, E)* consists of a set of vertices (or nodes), representing the intersections, together with an edge set *E*. The elements belonging to *E* are called edges or links, and represent the roads of the network. In an undirected graph every pair of

nodes is connected, so each path can be passed through in both directions. Actually, a road map would be a directed graph, as the streets have a certain way. However, in emergency conditions, it is likely that respecting the directions becomes a secondary aspect.

Figure 2. The transportation network of the virtual city.

The road transportation system consists of 19,614 edges connecting 15,012 nodes. Mathematically, the network has been described with an adjacency matrix A, which is a square matrix with a side dimension equal to the number of the nodes. The elements inside A can be either 1 or 0. If $a_{i,j} = 1$, it means that there is a connection (road) between node i and node j, while 0 means that the two nodes are not linked. Since the graph is not directed, the resulting adjacency matrix is symmetric. This matrix allows to describe and modify the topology of the network and to automate all the calculations.

4.2 *Network's failure criterion*

The definition of the failure criterion is strictly related to the reliability of the network. Despite its importance, there is not a unique definition for the failure criterion of a network. Gertsbakh & Shpungin (2008) proposed the criterion of terminal connectivity; that is, if critical nodes are disconnected, the network becomes down. This criterion is applicable to small scale networks, but when dealing with large networks a huge computational effort would be needed to identify whether the nodes are connected or not. In this work, a simpler network failure criterion is adopted. The network is considered unavailable when at least 5% of the nodes are isolated (not connected to any edge).

4.3 *Results*

The methodology introduced in section 3 has been applied to the case study. Due to the large size of the analyzed network, the results are not shown using vectors or matrices, but rather using graphs.

First, the above mentioned algorithm has been used to generate the failure permutations of the edges. The number of permutations considered in this case study is 3.5 million. The generated permutations have been subsequently used in the calculation of the D-spectrum. The result of the D-spectrum is shown in Figure 3. It can be clearly seen that there are only few non-zero elements in the distribution, and they are all gathered in a small range. The distribution of the D-spectrum is a perfectly normal distribution confirming that the assumed number of permutations was large enough to represent the problem. The location of the distribution's peak depends greatly on the chosen failure criterion of the network and on the number of components forming the network. More study will be dedicated to know the reason of having a normal distribution and to identify the effect of the failure criterion and number of components on the position of the distribution's peak. Moreover, looking at the definition of the D-spectrum, the sum of all its elements is 1. This is verified in Figure 4, which shows the distribution of the cumulative D-spectrum.

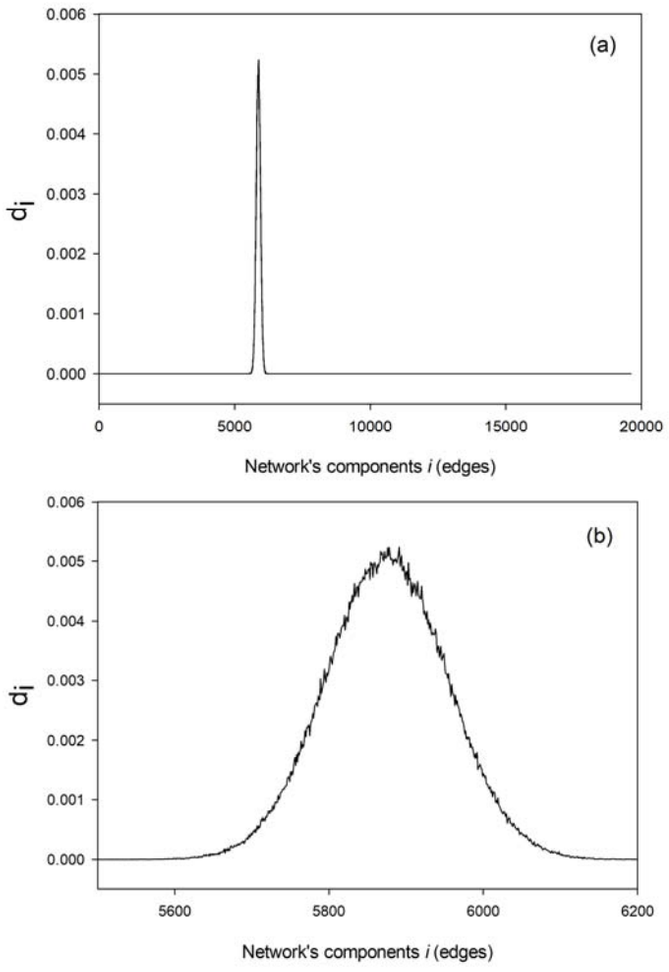

Figure 3. (a) The D-spectrum of all components of the case study network; (b) a zoomed view at the distribution peak.

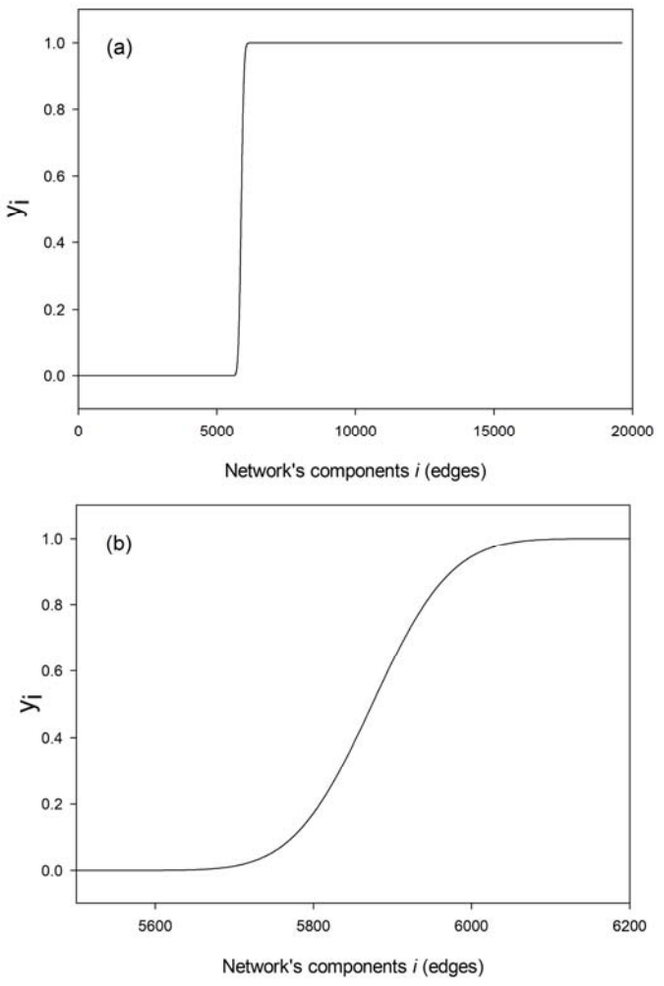

Figure 4. (a) The cumulative D-spectrum of all components of the case study network; (b) a zoomed view at the transitional part.

Following the D-spectrum, the BIM index of the network's components and the network reliability index *R* have been evaluated. The BIM index results of the networks' components have been normalized with respect to the maximum value. Figure 5 shows the BIM results of the first 100 components. The BIM indexes of the other components range between the upper the lower bounds, 1 and 0.98 respectively. This implies that the variance in the results is very small. In fact, the importance index of the edge is ruled by the network configuration and the failure probability of the edge. In our network, we considered an equal failure probability for the edges, which was represented by the random removal process. The small difference in the importance of the edges was only due to the network's configuration.

The reliability of the network was computed using Equation (7). It is worth to mention that the network reliability depends mainly on the following factors: (a) the network size (number of components in the network *k*); (b) the component's failure probability *q*; (c) the network's failure criterion (embedded in the cumulative D-spectrum term *y*); (d) and the network's topography (embedded in the cumula-

tive D-spectrum term *y*). The reliability of the analyzed network was found to be 46%. However, this number considers equal failure probabilities for all network components. This is rarely the case because usually the effect of disruptive events on a network system is not spatially uniform.

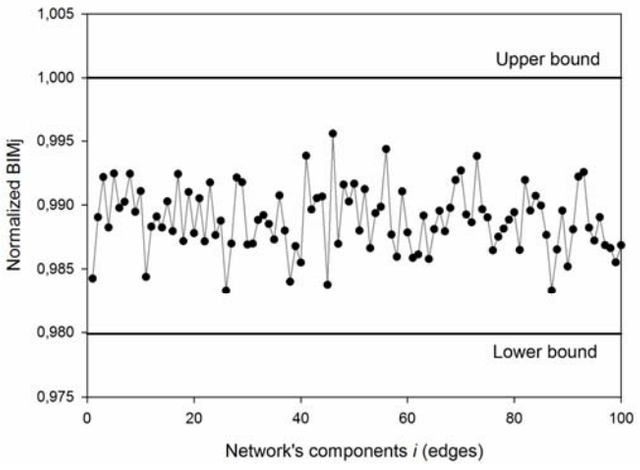

Figure 5. The BIM spectra of the network's components.

5 RESILIENCE INDICATORS FOR TRANSPORTATION NETWORKS

Indicators are quantifiable variables that represent selected characteristics of resilience (Cimellaro et al., 2016; Cutter 2016). Generally, individual indicators can be combined to create a single resilience index (Kammouh et al. 2017b). The index illustrates the multi-dimensional nature of resilience by aggregating multiple indicators, but also condenses its complexity into a single numeric value.

To study the resilience of a critical infrastructure, it is important to tackle the different resilience aspects of the system (Cimellaro et al., 2010, Cimellaro et al., 2015). For example, having a well-planned transportation network can result in a non-resilient system if the organizational and the managerial aspects are not considered. The user-behavior aspect can also contribute in the overall resilience of the analyzed system. While non-physical components are fundamental to study the resilience of transport networks, in this work only the physical aspect in considered.

The functionality of the physical aspect of transportation infrastructure has a great impact on the resilience of entire system. The physical aspect can be divided into two main parts: the inherent physical characteristics of the traffic and the network topography, which is the geometry of the network that defines the location of the links (i.e. roads, subway lines, path, bridges, etc.) and nodes (i.e. intersections, stations, etc.).

The physical characteristics of transportation infrastructure includes factors like resisting strength, pavement condition, road width, number of lanes, lighting system, safety elements, etc. All of these attributes and basic elements control the proper function of transport system, especially when it is under rare events, such as earthquakes, floods, hurricanes, landslides, etc. (which have long-term effect) and frequent events like traffic accidents, road maintenance (which temporarily disable intended function) (Soltani-Sobh et al. 2016).

Generally, an infrastructure with enough redundant capacity can minimize the impact of adverse events and keep the system in a relatively stable state. For example, when a car accident occurs on a road with emergency lanes or with a Variable Message Signs (VMS), travelers can use the extra lane or change to an alternative way that is suggested by the VMS before getting stuck in the traffic. Moreover, the degradation of the road environment influences the driving conditions, which affect the road capacity and result in the failure of the whole system.

In addition to the physical characteristics, the degree of betweenness and connectivity of the network system should be considered to assess the resilience of transportation networks. The concept of *betweenness* quantifies the number of shortest paths that pass through a node (Leu et al. 2010). As shown in Figure 6, node *A* has the highest betweenness among all four nodes. In a previous study, it was proved that a failure of the node with the highest betweenness can cause the maximum damage to the network because it reduces the efficiency and the survivability of the entire system (Zhang et al. 2011). Moreover, Steiglitz et al. (1969) proposed that the residual connections between nodes can increase the performance of the network. In other words, the more number of reliable passageways between an origin and a destination, the more resilient is the transportation system.

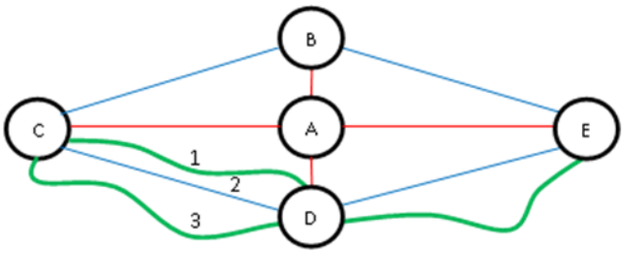

Figure 6. An illustration of the concept of connectivity and betweenness.

This is illustrated in Figure 6, where links 1, 2, 3 represent three alternative paths connecting the two nodes *C* and *D*. So, users would have alternative choices when one of the three routes is closed. This implies that the system has a high redundancy, which is the ability to remain (nearly) unchanged with disturbance.

Table 1 shows an extended list of resilience indicators that describe the physical system of the transportation network. Most of the indicators have been collected from the literature while some of them have been proposed by the authors. The indicators are grouped under different components representing the major aspects of the system. Each of the indicators is accompanied by a *measure* that allows the analytical evaluation of the indicator. Each measure is normalized with respect to a fixed quantity, the target value (*TV*), which is an essential quantity defined by the authority to provide a baseline to measure the corresponding indicator. Moreover, the indicators have been identified by their nature: 'Static indicator (S)' assigned to indicators that are not affected by the perturbation/disaster, and 'Dynamic indicator (D)' assigned to the indicators whose value/serviceability changes after the event.

Indicators must be weighted according to their contribution towards the resilience of the system. Kammouh et al. (2017a) introduced and exemplified three weighting methods for resilience indicators based either on the dependence tree analysis or on the spider plot analysis (Kammouh et al. 2017a, Kammouh et al., in press).

Table 1. Components and indicators of the physical system of transportation networks.

Component/ indicator	**Measure (0≤value≤1)**	**Reference**	**Nature**
1-Links/Connectors			
-Accessibility	Number of links/passageways per destination ÷ TV	(Ip & Wang 2011)	D
-Road density	Number of alternative links between an origin and destination ÷ TV	(Jenelius 2009)	D
-Road width	Average width of road ÷ TV	(Jenelius 2009)	S
-Lanes of road	Number of lanes available ÷ TV	(Litman 2006)	D
-Link (road, track, etc.) condition	% links with full functionality during the event	*	D
2-Vehicles			
-Mode of transport	Number of multi-mode choices per destination ÷ TV	(Ip & Wang 2011)	D
-Service level	Average speed of vehicles in normal condition ÷ TV	*	S
-Characteristics of vehicles	Degree of preference of specific vehicles (regarding performance, comfort level, etc.)÷ TV	*	S
3-Other Facilities/Structures			
-Quality of facilities	1-(% deficiency of facilities in past events ÷ TV)	(Tamvakis & Xenidis 2012)	S
-Critical components	Number of roundabout/emergency lanes ÷ TV	*	S

6 CONCLUDING REMARKS

This paper presents a methodology to evaluate multiple performance indexes for large scale networks. In the literature, several methods to evaluate networks reliability and resilience can be found. The application of such methods to large scale networks is not feasible due to the computational complexity. In this paper, the case of large scale networks is tackled. The case study considered in this work is the transportation network of a virtual city. First, the road map of the city is transformed into an undirected graph, which consists of 15,012 nodes and 19,614 edges. A random removal strategy of the edges is applied as a failure mechanism until the network's failure point is reached. The network reli-

ability is then calculated using the Destruction Spectrum (D-spectrum) method assuming the same failure probability for all edges. A Monte Carlo approach is used to generate failure permutations which are necessary for evaluating the D-spectrum. In addition, the network's edges have been ranked from the most to the least important by applying the Birnbaum Importance Measure (BIM). To overcome the computational obstacles, an algorithm and calculations techniques have been presented and discussed. The results obtained in this study are used to identify the vulnerable components of the network. The vulnerable components are the ones that should be focused on to improve the overall resilience of the infrastructure. The analysis concept adopted in this study is applicable to all network-based infrastructure systems such as water, gas, transportation, etc. Future work is geared towards replicating the analysis methodology to the case of strategic edge removal. The edge removal mechanism will be linked to the buildings' damage assuming a certain destructive event. The paper also proposed a list of resilience indicators for transport networks that describe the physical aspect of the system. Future studies will focus on identifying other indicators related to other aspects of the transportation infrastructure.

ACKNOWLEDGEMENTS

The research leading to these results has received funding from the European Research Council under the Grant Agreement n° ERC_IDEAL RESCUE_637842 of the project IDEAL RESCUE—Integrated Design and Control of Sustainable Communities during Emergencies.

ABSTRACT: Recent natural disasters have raised the question of how communities can recover from extreme events. In the last decade, the research has been focusing on analyzing interdependencies between different networks. This paper deals with the distribution power network, developing a method to estimate a realistic grid of a virtual city called "Ideal City" freely inspired to the city of Turin in Italy. A software called Matpower, developed by the Joint Research Center, has been used for the load flow analysis of the power network. Fragility curves, repair costs and downtime are evaluated using FEMA's database. Finally, a strategy to improve the network resilience is proposed considering the complexity of the environment.

1 I NTRODUCTION

Seismic resilience of urban areas is one of the central topics in the actual scientific fields. Many recent disasters consolidated the idea that much still needs to reduce human and economic losses due to earthquakes.
One of the most affected networks, especially in the first hours after the event, is the electrical distribution network. Indeed, the first news that media report is that a considerable number of people is left without electric supply.
This aspect complicates situations that are already difficult by isolating communications from large parts of the cities, slowing down the rescue and making it harder for people to resume normal lives. It should not be forgotten that the quick restoration of such networks in critical conditions, for example by replacing key elements such as transformers, can have very high costs. Therefore, careful analysis of the electricity grid is mandatory. In this paper the authors present some suggestions for dealing with this kind of problem evaluating the network resilience, possible countermeasures for overcoming issues and improvements.
This paper on electric network is part of a larger study on a virtual city called Ideal City (Zamani Noori et al. 2017) that is developed to be a resilience based designed community. This town is freely inspired to the city of Turin that is a town of about one million inhabitants in North-West Italy.
This study is related on the EPN (Electrical Power Network) but it is focused on the electrical distribution system. The electricity grid starts with generation stations located many kilometers far from urban centers. It continues with the transmission system that usually surrounds the cities and ends with the distribution network directly to the consumers.
The network components in terms of fragility curves are studied. Repair costs and time are also estimated and, finally, the improvement of the network resilience is evaluated.
The power network can be affected not only by earthquakes but also by tornadoes that is the first cause of failure of electricity in USA in terms of MW lost. Indeed, NIST-funded Center for Risk-Based Community Resilience Planning (Unnikrishnan & van de Lindt 2016) explains how the EPN of Centerville, a Virtual Community Testbed of approximately 50.000 people in a Midwestern State, can be studied and losses analysis performed.
This type of approach is not present only in the American or European literature, but it is now a very actual theme in other countries. For example, an interesting work by Arghavani (2017) can be reported. This is a prototype model to analyze the seismic resilience of the transmission grid of the city of Qom, an Iranian center of quite a million citizen. Iran is a high seismic zone and the researchers have built a simplified model of the network implementing also some emergency scenarios. It is a connectivity analysis, i.e. a binary statement 0 or 1, in which some lines fall, and the response of the grid in terms of recovery time is represented by using a gamma cumulative distribution function.
This type of investigation started years ago, from 2004 when Professor Shinozuka (Shinozuka et al. 2004, Shinozuka et al. 2007) studied the resilience

of integrated power and water system of the LADWP (Los Angeles Department of Water and Power). A database related to the effects of several previous events, e.g. the 1994 Northridge earthquake, is used. In this research, the critical points of the distribution network are the transformers and the associated fragility curves. The correct spatial distribution of PGA is modelled within a Monte Carlo approach. The authors computed risk curves of power supply, households without power, economic losses and some system performance criteria.
Finally, it is worth underlining how resilience of distribution network isn't only a university topic. It is also strictly regulated by law. Last year, within the end of March, all Italian DSOs (Distribution System Operators) have been required to deliver a resiliency plan of their networks to national authority for electricity gas and water.

2 METHODOLOGY

2.1 *Model of the network*

The first problem of the present study is the paucity of data. Information about distribution buses of an urban network is very difficult to collect. Sensible data are usually not shared because security standards or economic interest may be compromised. So, the idea is to try to find an electric grid compatible with the map of Ideal City. The approach selected is summarized in Figure 1.

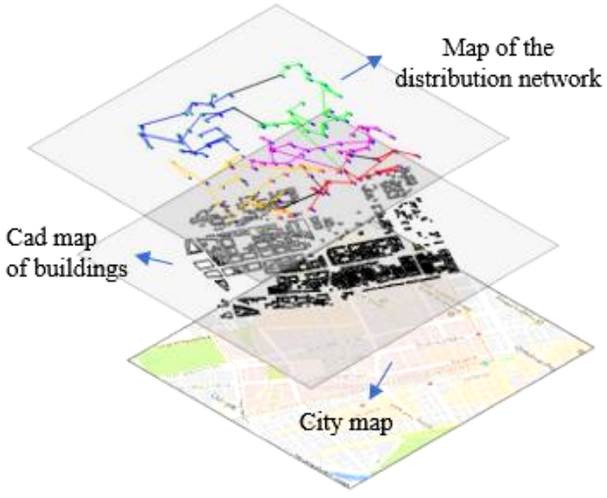

Figure 1. Sketch of the approach

Designing the power supply network for one million people is a critical task. Therefore, a literature review of existing case studies has been performed for selecting a solution that has been adapted to an Ideal City sample.
The European Commission in collaboration with the Distribution System Operators Observatory of JRC (Joint Research Center) released a technical report (Prettico et al. 2016) about representative networks. They have collected data from 79 out of 190 European DSOs that are representative of the 70% of the electricity supplied by all DSOs serving over 100,000 customers. They distribute more than 2,000 TWh of electricity to over 200 million customers per year, covering a total area of more than 3 million square km. This report has been used to build 36 indicators about network structure, network design and distributed generation. From 10 of such indicators, representative distribution networks have been obtained using RNM (Reference Network Model). This is a useful software for large scale distribution planning developed by the Universidad Pontificia Comillas (Domingo et al. 2011).
In the present paper, the "urban" network from JRC database is used for the most densely populated districts and the "semi-urban" ones in the surrounding areas of Ideal City.
The second step consists in making this network independent from the map that JRC has used to realize the model. Information about HV (high voltage), MV (medium voltage) and LV (low voltage) buses with coordinates, branches, electric parameters and protections are provided. In order to apply this realistic network to Ideal City, LV data are relevant only for defining the total amount of consumers, not for their real positions. So, only HV and MV buses are explicitly considered in the model. Finally, the network model is rebuilt writing a new description.
The network has been strictly controlled using Matpower6.0, a package of MATLAB M-files employed for solving power flow problems and developed by PSERC (Power Systems Engineering Research Center) at Cornell University (Zimmerman et al. 2011).
The method for the network performance analysis consists in the computation of the load flow on the entire damaged grid. In this way, a higher precision respect to a simpler and faster connectivity analysis (Arghavani 2017) is provided. Matpower nonlinear analyses are solved through the Newton Raphson (NR) algorithm.
In the AC power flow problem (Zimmerman et al. 2011), the nodal bus injections are defined through those related to loads and generators. The power balance equations are expressed in complex matrix form as

$$g_S\left(V, Sg\right) = S_{bus}\left(V\right) + S_d - C_g S_g = 0 \qquad (1)$$

where $S_{bus}(V)$ is the complex power injections as functions of the complex bus voltages V, S_d are constant power loads, S_g is the generator injections and the C_g is the connection matrix.
This problem can be split into its real P and reactive Q components:

$$g_P\left(\theta, V_m, P_g\right) = P_{bus}\left(\theta, V_m\right) + P_d - C_g P_g = 0 \quad (2)$$

$$g_Q\left(\theta, V_m, Q_g\right) = Q_{bus}\left(\theta, V_m\right) + Q_d - C_g P_g = 0 \quad (3)$$

where θ is the voltage angle and V_m is the voltage magnitude. The power flow problem could be a set of equations in the form

$$g\left(x\right) = 0 \quad (4)$$

and in particular

$$g\left(x\right) = \begin{bmatrix} g_P\left(\theta, V_m, P_g\right) \text{ for PV and PQ buses} \\ g_Q\left(\theta, V_m, Q_g\right) \text{ for PQ buses} \end{bmatrix} \quad (5)$$

where PQ buses are pure load buses and they represent the major part of all of network buses. In these elements P and Q are defined, but θ and V_m must be calculated.
PV buses are connected to the generator and they are a small part of all buses. In these elements P and V_m are defined, but Q and must be calculated (Grainger & Stevenson 1994). Is also important to specify the value of x, as:

$$x = \begin{bmatrix} \theta \text{ for all buses except Reference bus} \\ V_m \text{ for PQ buses} \end{bmatrix} \quad (6)$$

where the Reference bus is the slack bus and it is considered as the number one of the network. In this element, $\theta = 0^o$, V_m is known but P and Q must be computed.
So, a nonlinear system (Dharamjit & Tanti 2012) with n_{pv} + n_{pq} equations and unknowns (n is the number of PV or PQ buses) results. Solving by x, it's possible to determine the generator real power injections at the reference bus and generator power injections.
These solutions are provided using the iterative NR's method. Starting from an initial trial solution, at each iteration, a tolerance must be smaller than a predetermined threshold. So, the passages are these:
It starts with

$$\left[g(x)\right] = \begin{bmatrix} \tilde{} \\ g \end{bmatrix} \quad (7)$$

the solution at first iteration is

$$\left[x\right] = \left[x^{(0)}\right] = \left[x^{(k)}\right] \quad (8)$$

The tolerance is computed as

$$\left[\varepsilon^{(k)}\right] = \begin{bmatrix} \tilde{} \\ g \end{bmatrix} - \left[g\left(\left[x^{(k)}\right]\right)\right] \quad (9)$$

If the tolerance doesn't become smaller than the threshold, the function $[g(x)]$ is represented as a series, involving the Jacobian matrix computed at $[x]=[x^{(k)}]$. They can be written as $[J^{(k)}]$. Finally

$$\left[g\left(\left[x^{(k)}\right]\right)\right] + \left[J^{(k)}\right] \cdot \left[\Delta x^{(k)}\right] = \begin{bmatrix} \tilde{} \\ g \end{bmatrix} \quad (10)$$

and so

$$\left[J^{(k)}\right] \cdot \left[\Delta x^{(k)}\right] = \left[\varepsilon^{(k)}\right] \quad (11)$$

The NR's method linearizes the nonlinear system and, therefore, the Jacobian matrix is composed by constant values function of the unknown variables.
After the modelling of the network, the load flow is computed through the MATLAB code. If the NR's method converges (Figure 2) and the power restraints are respected, the grid is properly designed.

```
Newton's method power flow converged in 5 iterations.

Converged in 0.78 seconds

2.2 *Resilience Index*

The Italian Regulatory Authority for Electricity Gas and Water suggests to compute the resilience of an electric grid focus on the risk of disabling users in case of hazard or extreme weather conditions (The Italian Regulatory Authority for Electricity Gas and Water, 2017).
This index is called IRI and is calculated as

$$IRI = NUD \cdot PD \quad (12)$$

where NUD is the number of LV users disabled and PD is probability of disservice. This chance is

$$PD = 1 / TR \quad (13)$$

where TR is the return time of the event, calculated in accordance with the European standard CEI EN 50341 (EN 50341-2-13). For a safe calculation we will take 50-years as return time.
An assessment of resilience can be obtained by computing the inverse of the risk index, thus obtaining

$$IRE = TR / NUD \quad (14)$$

where IRE is the resilience index, or calculating the integer over time of the IRI index.
Another resilience rating can be given in term of ENS (Energy Not Supplied) to highlight the power delivered before the event and the time it takes to restore it.

2.3 *Fragility and Restoration*

The first assumption of this study is to concentrate the fragility of the network in medium voltage substations (Figure 3).

Figure 3. Typical indoor MV substation.

To model their fragility researchers have used the HAZUS®-MH MR5 (FEMA 2002) that provides sets of fragility curves for unanchored elements. This means that the components are assumed without any seismic protection and designed with normal requirements. This hypothesis is introduced because the goal is to estimate the worst-case scenario's probability of exceedance.
Medium voltage substations are composed by important equipment as transformers, switches, circuit breakers etc. Furthermore, they are assumed as installed in buildings, so they can be also affected by the structural damages. Table 1 reports the damage conditions.

Table 1. Description of damage states

Damage state	Description
Complete	component OR building 100% damaged
Extensive	component OR building 70% damaged
Moderate	component OR building 40% damaged
Minor	component OR building 5% damaged

Fragility curves of the components implement the PGA (Peak Ground Acceleration in [*g*]) as seismic intensity parameters. They are lognormal function defined through logarithmic mean λ and logarithmic standard deviation ß. Table 2 summarizes the implemented fragility curves parameters. Figure 4 depicts the resulting fragility functions.

Table 2. Fragility parameters for medium voltage substations with unanchored components (Cavalieri et al. 2014).

Damage state	λ	ß
Complete	-0.69	0.4
Extensive	-1.2	0.4
Moderate	-1.61	0.5
Minor	-2.3	0.6

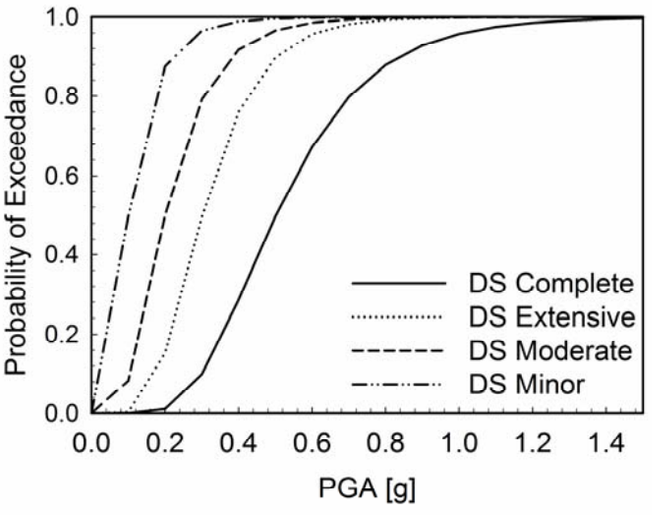

Figure 4. Fragility curves for medium voltage substations with standard components

The simulation considers an increasing set of PGAs and the resulting outcomes of the network are evaluated. In these scenarios, MV substations failed and consumers are without power.
The resilience of the system is evaluated in terms of MW lost due to people without electricity for a certain period, costs and time due to repair activities. About the restoration consequences, authors refer to HAZUS Technical Manual (FEMA 2002). Figure 5 reports the adopted restoration functions.

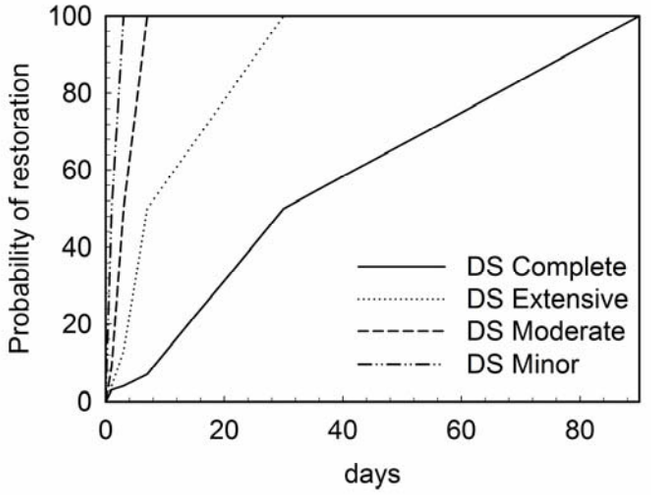

Figure 5. Discretized Restoration Functions for electric substations

In the restoration analyzes the focus is moved on transformers (Figure 6) because they can be considered the most critical substations components.

Figure 6. Typical MV/LV distribution transformer.

In general, (Cataliotti 1983-1999) they are electromagnetic induction static facilities, which modify power values from a primary circuit (receiver) to a secondary one (deliver)

Distribution transformers MV/LV have a three-column core, concentric windings, wire-wired conductors for small sections, flat for the major. They can be classified according to many parameters such as insulating material with which they are protected from high operating temperatures, depending on the service and cooling mode. In this case, however, they have been classified according to the nominal power that can be delivered. There are five classes of transformers (Prettico et al. 2016) as reported in Table 3.

Table 3. Classes of transformers and type of network in which are present

Transformers power (kVA)	Network
100	Semi-urban
250	Semi-urban
400	Semi-urban, Urban
630	Semi-urban, Urban
1000	Semi-urban, Urban

About transformers costs, authors refer to PACT, a FEMA tool to analyze the seismic performance assessment of structural and non-structural components (FEMA P-58-3 2016). Data are given in US dollar (USD) but they have been converted in euros (€) with 1.2 as exchange rate (Figure 7).

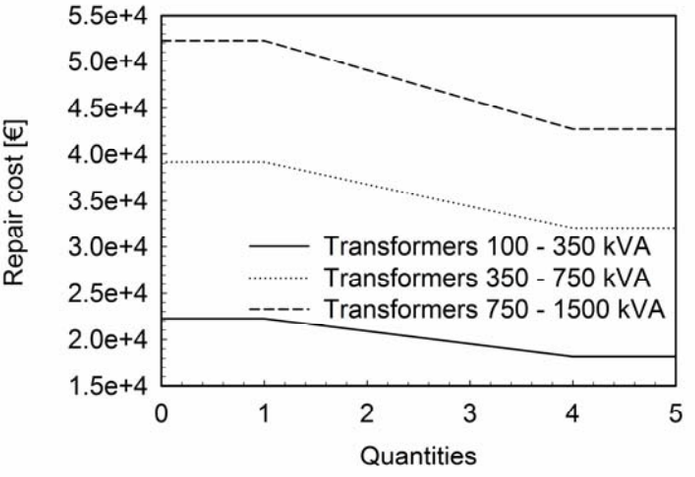

Figure 7. Repair cost of transformers related to their quantities

It is also important to take into account the correlation between the damage state and the transformers serviceability and power availability, as Table 4 summarizes.

Table 4. Relation damage state – power supply

Damage state	Serviceability	Power
Complete	Not repairable	No
Extensive	Operational after repairs	No
Moderate	Operational without repairs	Reduced
Minor	Operational without repairs	Reduced

3 APPLICATION

3.1 *Network description*

The case study employed for the application of the method consists in the Ideal City's district of Crocetta. It is a very central and urbanized area of Turin, full of residential buildings, offices and schools such as the university Politecnico di Torino. The population is about 40,000 people. During the day, such number of population increases.

So, the "urban" network from the JRC database is employed and adapted to the Crocetta's case, being

suitable for about 50,000 users. Figure 8 shows the satellite image of the considered district.

Figure 8. Crocetta's picture from the satellite with its borders highlighted in red

The grid is composed by five feeders, which supply 12735 housing units (supposing a mean of 4 people per unit) and 38 MV consumers. There is only one HV/MV substation from 132 to 20 kV with 80 MVA of rated power and 126 MV/LV substations from 20 to 0.4 kV (Prettico et al. 2016). About the latter 126 MV/LV substations, they are detailed in Table 5.

Table 5. Number of transformers per each class

Rated power (kVA)	Number
1000	34
630	52
400	40

This distribution network is presented in Figure 9, while Figure 10 shows the overlap of the same grid with the district map, as obtained by some simplification from the real map of Turin (Zamani Noori et al. 2017).

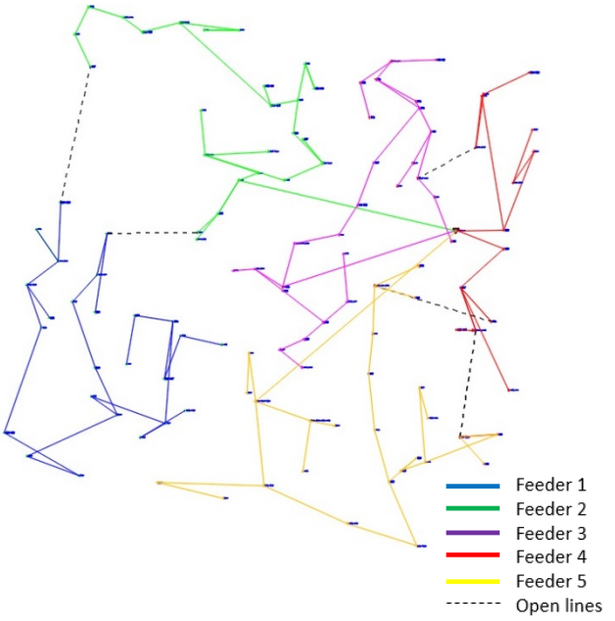

Figure 9. Urban network with MV buses in evidence

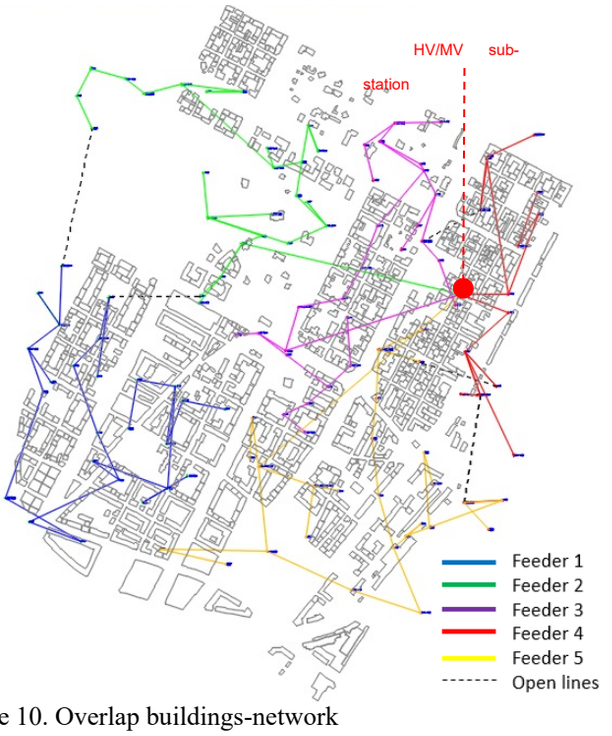

Figure 10. Overlap buildings-network

3.2 *Crocetta fragility and resilience*

In this work, repair costs and down time analysis are evaluated, so it is supposed to refer to a "damage state" situation for the network. In particular, "extensive" damage in Table 4 (with NO power and "Operational after repairs" conditions) for the network is considered. It is assumed that power can be feed only after grid restoration, which consists in components repairing. Indeed, resilience is studied for limited damage conditions, not for complete damage of components and buildings.

Looking at the correspondent fragility curve (Figure 4) it is clear that up to 0.2g the grid does not suffer

any damage. From 0.3g level, substations have the 50% probability of exceedance and with a 0.5g this percentage goes to about 90%.
So, an event with a magnitude between 0.3g-0.5g, can cause the power interruption and the steps until the complete restoration are considered for the present application.
Observing the repair time for MV buses, that is the substation (Figure 5), there is more than 50% chance of having the complete restoration in less than 10 days. In the following, the transformers case is analyzed in detail and the repairs specifications (FEMA P-58-3 2016) are shown is in steps (Table 6).

Table 6. Steps of repairs

After	Transformers repaired
4 days	400 kVA
6 days	400, 630 kVA
7 days	400, 630, 1000 kVA

To give an assessment of resilience we calculate the IRI risk index, if the event occurs at the hypothetic day 2 of a simulation. (Figure 11)

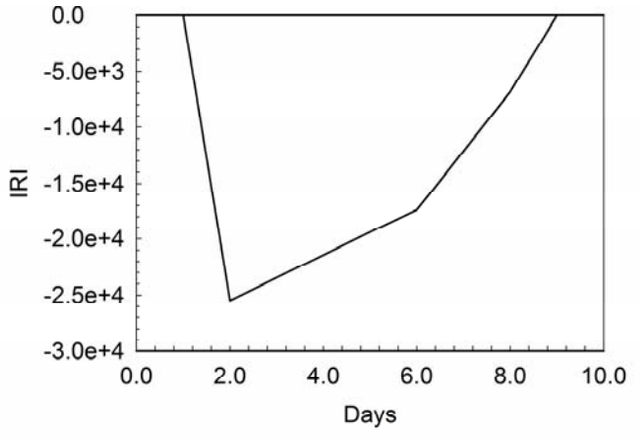

Figure 11. IRI index

A second evaluation can be given in terms of lost energy, the ENS trend is as follows (Figure 12).

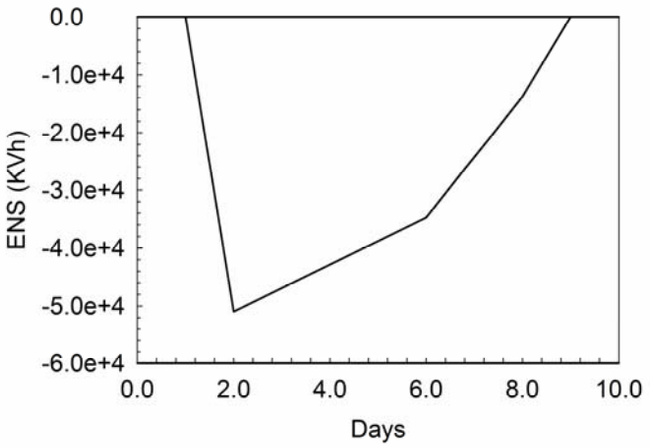

Figure 12. ENS per day

3.3 *Cost analysis and improvements*

As has been shown, a week is necessary for the complete restoration and this implying a huge loss of power. For an assignment of 4 kWh per user, the total amount for a district of the Ideal City, as the Crocetta case, consists in about 0.3 GWh. Considering the typical single-band price of 0.065€/kWh, the economic losses amount over 20,000 €. Accounting the repairs costs, losses further increase.

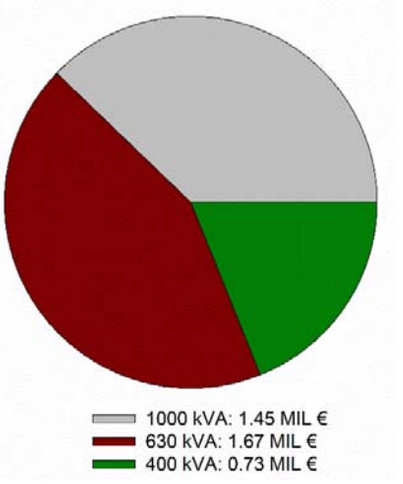

Figure 13. Transformers repair costs repartition

As reported in Figure 13, for the PGA in the range 0.3g-0.5g, the total amount of costs for the transformers consists of 3.85 million euros. Adding the ENS costs with those ones from the restoration of the electrical equipment, 4-5 million euros result.
To improve network resilience, it may be useful to employ substations specifically designed for seismic conditions. Indeed, they are characterized by different fragility curves (Figure 14) with respect to the standard case in Figure 2. Fixing 0.5g PGA, the standard case defines about 90% probability of failure while the seismic case 50%. So, an essential difference can be highlighted.

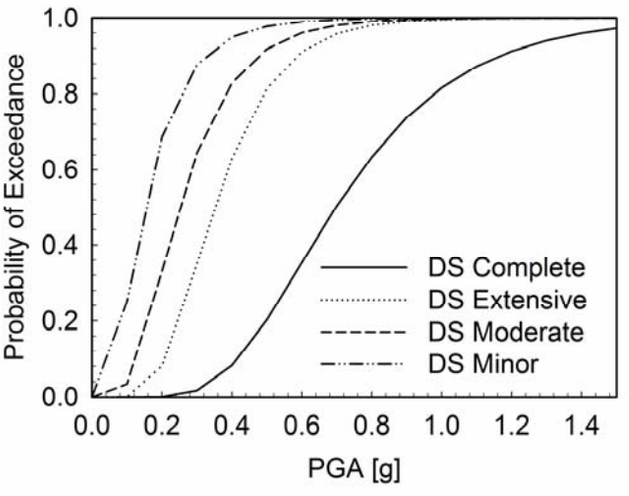

Figure 14. Fragility curves for medium voltage substations with seismic components

Finally, the networks interdependency has to be taken into account following the approach developed by Cimellaro et al. (2016). The fragility of electrical components is connected to failure's probability of buildings system in the district, where substations are installed. Besides, the electric network failure itself induces a series of cascading effects, as summarized in the scheme of Figure 15.
This research team (Cimellaro et al. 2016, Zamani Noori et al. 2017, Cimellaro et al. 2017) is deepening the cascading effects at the urban scale, creating a macroscale model through finite element (FE) analysis of buildings structures, debris and through connectivity matrices of the networks nodes.

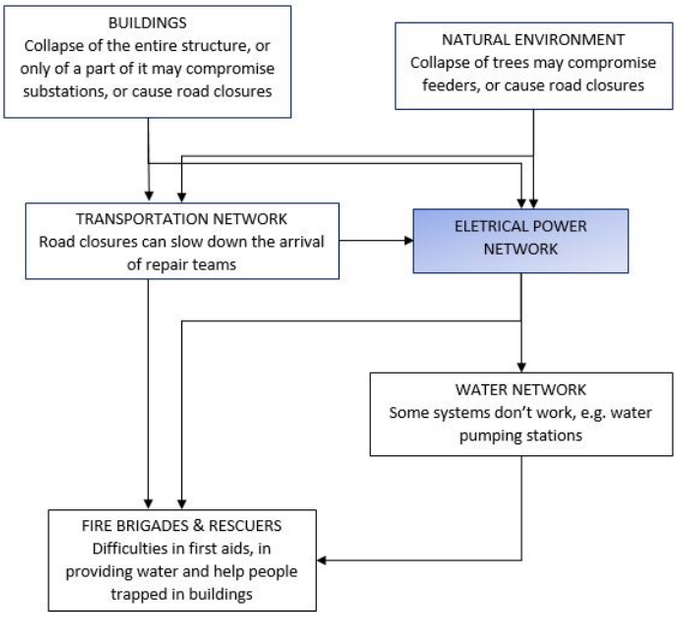

Figure 15. At the top of the figure is shown the indirect fragility of the power grid. At the bottom are presented some cascading effects triggered by blackouts or power reductions.

4 CONCLUSION

This paper is proposing a new methodology to estimate the performance and its inherent resilience of a power distribution network.
The steps are the following: (i) referring to electrical characteristics of urban representative network. (ii) Adapting the data to a specific map focusing on MV buses. (iii) Applying an earthquake hazard with a certain PGA. (iv) Estimating the grid response using fragility curves of MV substations and finally (v) determining the economic losses with repair costs and time curves.
Furthermore, measures for improving resilience are suggested by employing seismic retrofits in substations. The interaction of EPN with other networks is also mentioned and will be studied in further researches in the future.

5 AKNOWLEDGMENT

The research leading to these results has received funding from the European Research Council under the Grant Agreement n°ERC_IDEal reSCUE_637842 of the project IDEAL RESCUE—Integrated DEsign and control of Sustainable CommUnities during Emergencies.

ABSTRACT: A disproportionate collapse can be avoided by improving collapse resistance, reducing the vulnerability of the structure or increasing structural robustness. While vulnerability depends on the individual structural components, robustness depends on the whole structural system. Besides collapse resistance, a disproportionate collapse can also be prevented by reducing the exposure of the structure to external actions. Robustness of buildings and bridges is defined as the insensitivity of a structure to the initial damage. Such characteristic has been recognized as a desirable in structural systems, being able to exclude progressive and disproportionate collapses. The robustness of bridges is investigated in this research work at the numerical level by employing a model of a cable-supported bridge. Several earthquake records are employed for the robustness assessment of the bridge at increasing intensity. The role of the redundancy in the structural scheme of the bridge is then evaluated as the strategic measure for limiting disproportionate collapses and improving robustness. Furthermore, solutions for reducing the time for recovering functionality, after the damage occurrence, are also evaluated and discussed within a resilient community framework. Indeed, this study can provide valuable information that can facilitate decision making, enhance planning for disaster mitigation and recovering of critical infrastructures as the transportation network, reducing social and economic losses.

1 INTRODUCTION

In recent years several studies on progressive collapse have been developed. Much attention was paid for buildings, leaving the bridges' field still uncharted. The failure of one structural element can lead to the failure of further structural elements and thus to the collapse of large structural sections or the entire structure. In many cases, the initial triggering event and the resulting damage are disproportionate (Haberland et al. 2012). According to design codes, reducing the vulnerability of the structure or by increasing its the robustness, the collapse due to local effects can be avoided. For cable-stayed bridges, collapse resistance is primarily achieved by robustness (Haberland et al. 2012). Although such systems possess a high degree of static indeterminacy and internal continuity, their redundancy and robustness deserve careful consideration. The cable failure constitutes a local effect that may take like result a progressive collapse. The loss of cables can lead to overloading and rupture of adjacent cables. The cables are easily accessible and exposed to accidental or malicious action; their cross section is relatively small which makes it difficult to provide with specific local resistance; a cable loss could happen nearly instantaneously producing an impulsive dynamic loading; the system might respond in a non-ductile manner. When a catastrophic event such as an earthquake occurs in a bridge, the distance between the cables plays a fundamental rule in term of robustness. The prevention of disproportionate collapse of cable-stayed bridges is of major concern as such structures are of high economic value and their collapse would be accompanied by a large loss of human life (Wolff & Starossek 2010). The importance of providing system redundancy was also highlighted by the collapse of the Mississippi River Bridge in Minneapolis (Salem & Helmy 2017), Minnesota in 2007, in which the whole bridge, which has been classified as non-redundant by the National Transportation Safety Board (NTSB) (2008), catastrophically collapsed after the failure of a gusset plate connection. This paper examines the response of a current stay-cable bridge for progressive collapse. A model of the bridge through Applied Element Method (AEM) is implemented and validated. A solution in order to avoid the disproportionate collapse and increase robustness and redundancy is analyzed and discussed.

2 CASE STUDY

2.1 *Applied element method*

The proposed study investigates the progressive collapse of a real bridge through the nonlinear dynamic analysis. For this research an Applied Elements Method (AEM) based software is used. The AEM is an innovative modeling method adopting the concept of discrete cracking (Applied Science International 2017). Through two decades of continuous development, AEM was proven to be the method that can track the structural collapse behavior passing through all stages of the application of loads: elastic stage, crack initiation and propagation in tension-weak materials, reinforcement yielding, element separation, element collision (contact), and collision with the ground and with adjacent structures. The possible analysis domain of AEM method in comparison to FEM method is shown in Figure 1. Although the FEM is accurate and reliable for analysis of continuum structures, the onset of element separation is difficult to automate and modeling of debris collision is time consuming.

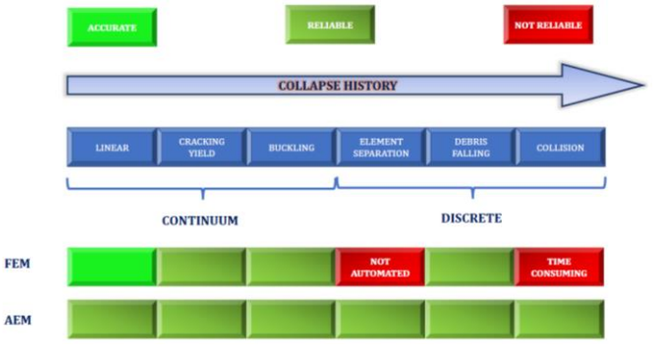

Figure 2. Modeling of structure to AEM.

With AEM, the structure is modeled as an assembly of small elements, which are made by dividing the structure virtually, as shown in Figure 2. The two elements shown in Figure 2 are assumed to be connected by one normal and two shear springs located at contact points, which are distributed around the elements edges. Each group of springs completely represents stresses and deformations of a certain volume as shown in Figure 2.

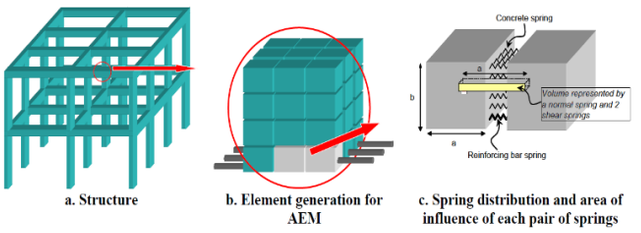

Figure 2. Modeling of structure to AEM.

These springs reflect the different material properties; strain stresses and failure criteria are all calculated and estimated using these springs.

2.2 *AEM for bridge*

Using the AEM method the cables of the bridge can be implement like link members. The link member is a special spring that has the ability to connect two separate solid elements with any angle of inclination as shown in Figure 3. The link member hence carries only axial stresses.

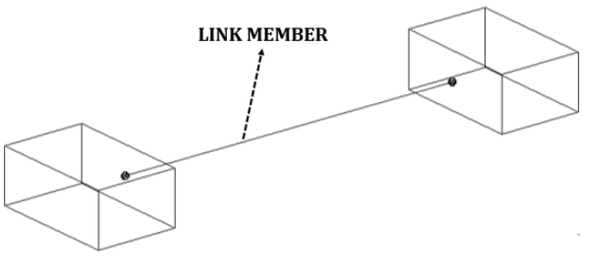

Figure 3. AEM link member.

In order to obtain a real performance of cables, a "tension-only bilinear material" is assigned. As shown in Figure 4, the bilinear material behaves linearly up to the yielding point without any plastic deformations in normal stresses. After yielding point, plastic deformations take place and the stress-strain relation beaves linearly up to failure. After failure, the strength drops to zero but springs remain till they reach separation strain where the elements are separated from each other and springs no longer exist. A stress-softening parameter is used after failure. Tension-only bilinear material is a special case of the bilinear material where the elements can carry only tensile stresses.

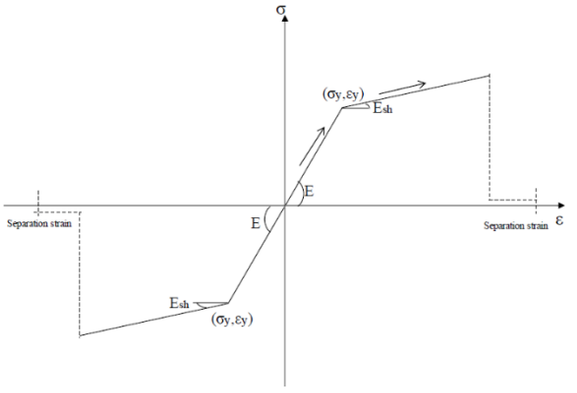

Figure 4. stress-strain of a bilinear material.

The reinforcing steel bars into concrete are modeled by springs that represent the material properties, exact location and dimensions of the bars. The generation of these springs is automatically performed in the software Extreme Loading for Structure (2017).

2.3 *Description of the case study*

The analyzed bridge is described by Li et al. (2014). Yong-he bridge is one of the first cable-stayed bridges constructed in mainland China (Fig.5). It has two main spans of 260 m and two side spans of 25.15 + 99.85 m each. The bridge is 510 m long and 14.5 wide. The towers, connected by two transverse beams, are 60.5 m tall. There is a total of 88 pairs of cables containing steel wires of 5 mm in diameter. Each cable can contain from a minimum of 69 to a maximum of 199 steel wires. To validate the AEM model a comparison with the FEM model, described by Li et al (2014) is performed (Figure 6).

Figure 5. Yong-he Bridge, China

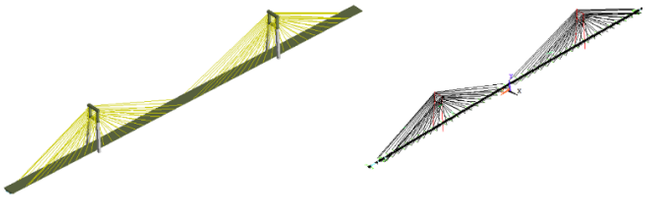

Figure 6. AEM model vs FEM model.

Static and dynamic comparison are made. The shape modes obtained by two models are analyzed. They are computed using the stiffness matrix obtained by the static analysis. The criterion used to verify the correlation between modes is the *modal assurance criterion* (MAC). According to Pastor et al. (2012), the Modal Assurance Criterion is a statistical indicator that is most sensitive to large differences and relatively insensitive to small differences in the mode shapes. The MAC is calculated as the normalized scalar product of the two sets of vectors $\{\phi_A\}$ and $\{\phi_X\}$. The resulting scalars are arranged into the MAC matrix.

$$MAC(r,q) = \frac{|\{\varphi_A\}_r^T\{\varphi_x\}_q|^2}{(\{\varphi_A\}_r^T\{\varphi_A\}_r)(\{\varphi_x\}_q^T\{\varphi_x\}_q)} \quad (1)$$

The MAC takes value between 0 (representing no consistent correspondence) and 1 (representing a consistent correspondence). Values larger than 0.9 indicate consistent correspondence whereas small values indicate poor resemblance of the two shapes. Seven shape modes are taken into account as shown in Table 1.

Table 1. Shape modes. Vertical symmetrical = V.S., vertical asymmetrical =V.A., transverse asymmetrical = T.A.

Mode	Frequency-FEM	Frequency AEM	Shape	ΔFrequency	MAC
	Hz	Hz	-	%	-
1	0.417	0.416	V.S.	0.24%	0.991
2	0.593	0.643	V.A.	-7.78%	0.978
3	0.877	1.012	V.S.	-13.34%	0.945
4	1.044	1.297	V.A.	-19.51%	0.946
5	1.089	1.349	V.S.	-19.27%	0.930
6	1.213	1.515	V.A.	-19.93%	0.889
7	0.311	0.280	T.A.	11.07%	0.928

In Figures 7-13 the mode shapes obtained through FE code and AE code are represented.

3 ROBUSTNESS AND REDUNDANCY

Anitori et al. (2013) have discussed several competing approaches for the deterministic evaluation of structural robustness and redundancy. Robustness is defined as the insensitivity of a structure to an initial damage (Starossek and Haberland 2010). Restelli (2007) evaluates robustness using indicators that are related to the global displacement of a structure composed of parallel members, using

$$\rho = \frac{s_0}{s_d} \qquad (2)$$

where s_0 is the displacement of the undamaged system; and s_d is the displacement of the damaged system. This index decreases from 1 and approaches to 0 as damage spreads within the system. The purpose of this parameter is to evaluate the system susceptibility to degrading damages spreading through the structural elements. A no damaged structure, in elastic field, subject to dynamic action, presents a robustness chart as shown in Figure 15. On the horizontal and vertical axes respectively, the time and the robustness index are reported.

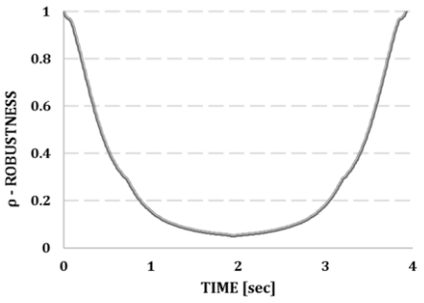

Figure 15: Robustness curve.

Accordingly with Eq. 2, as increasing the displacements decreases the robustness. In addition, as decreasing the dynamic actions, the structure tends to initial configuration and robustness to one. If the structure is damaged the ascending part of robustness curve is reduced or total absent due to the presence plastic deformations. As reported by Ghosn & Moses (1998) and Liu et al. (2000), structural redundancy is defined as the capability of the system to continue to carry load after the failure of one main member. They proposed three different indices. As reported in Figure 16, two indices are related to the overloading of the originally intact bridge configurations of the structure and are defined as the ability of the structural system to resist collapse and/or avoid the loss of structural functionality. The third index is calculated for a damaged configuration of the structure and permits evaluation of the capability of the system to carry some emergency load after the damage of one main member.

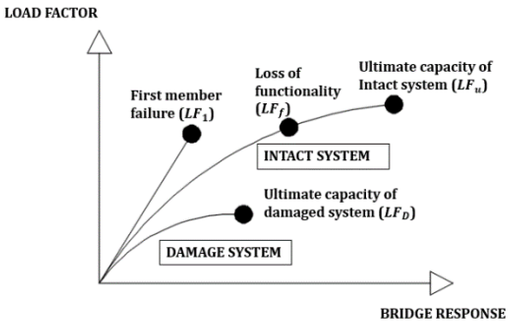

Figure 16: Load measures needed to calculate the redundancy of bridge systems.

These parameters compare the system's capacity to the capacity of the system to resist first member failure, making them applicable for evaluating alternative designs, because current bridge engineering practice is based on member design criteria. These indices are defined in terms of the *system reserve ratios* (Liu et al. 2000) such as R_u, R_f, R_d for the ultimate, functionality and damaged condition limit states, respectively. They are given by following equations:

$$R_u = LF_u/LF_1 \quad (3)$$
$$R_f = LF_f/LF_1 \quad (4)$$
$$R_d = LF_d/LF_1 \quad (5)$$

where LF_1 is the load that causes the failure of the first member; LF_u is the load that causes collapse of the system; LF_f is the load that causes the functionality limit state of the initially intact structure to be exceeded; and LF_d is the load factor that causes the collapse of a damaged structure that has lost one main member. In this paper, an algorithm is implemented to extend this methodology to the case of a time history analysis. Indeed, the methodology presented by Liu et al. (2000) is related to push over analysis, so to the nonlinear static domain. For nonlinear dynamic analyses the load factor cannot be used and a different approach has to be developed.

In the first step of the proposed procedure the accelerogram is converted to positive values only, as shown in Figure 17.

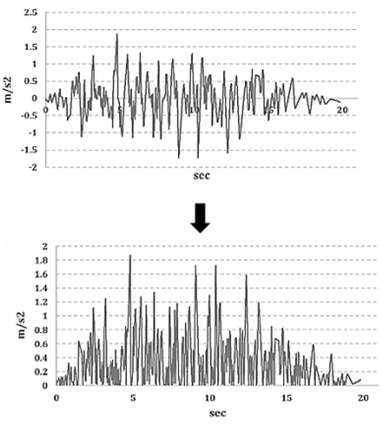

Figure 17. Algorithm – first step.

In the second step, the obtained accelerogram is integrated between 0 and the time corresponding to the failure of the first member (Fig. 18), to compute an equivalent value for LF_1. Integrating between the time corresponding to the failure of the first member and the system collapse time, an equivalent value of LF_d is obtained. In similar way it is possible to calculate also LF_f and LF_u.

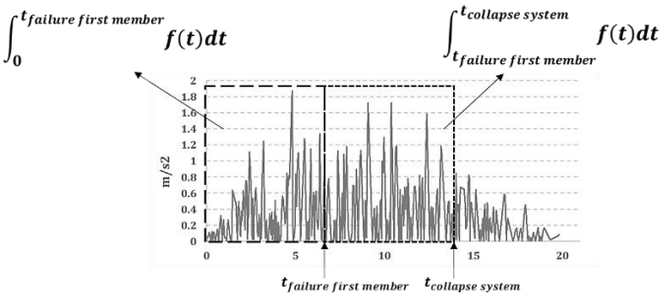

Figure 18. Algorithm – second step.

In other words, to satisfy the target redundancy level, the accelerogram's area that causes the system to collapse or lost functionality must be a percentage higher than the accelerogram's area that causes the first component failure.

4 SEISMIC RESPONSE SIMULATION

4.1 *Seismic simulation of Yong-he Bridge with current cables-configuration*

The loss of a cable is investigated by nonlinear dynamic analyses in the time domain, taking into account large deformations. This direct time integration is used to solve the equation motion. Haifan (1983) analyzed the influence of phase-difference effect on the earthquake response of the Yong-he Bridge. The accelerogram calculated by Haifan (1983) is used for the analyses (Figure 19). It is compatible with design spectrum of China Code.

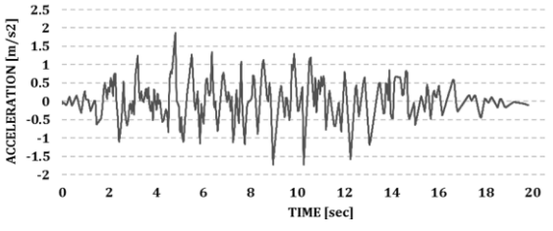

Figure 19. Haifan (1983) accelerogram.

The AEM simulation of the bridge with the dynamic action in Figure 19 results in a disproportionate collapse, as shown in Figure 20.

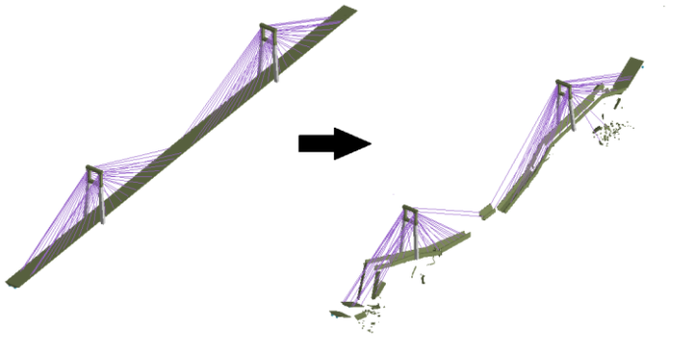

Figure 20. AEM simulation – disproportionate collapse.

In order to identify the source of the collapse, the stresses, in the highlighted cables in Figure 21, are analyzed.

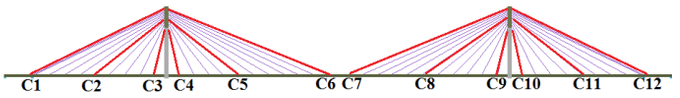

Figure 21. Cables analyzed.

In Table 4 the max values of stresses in the cables are shown.

Table 4. Normal stress cables

Cable	σ_{MAX}	$time(\sigma_{MAX})$
	Kg/cm^2	sec
C1	3648	6.2
C2	3664	11.3
C3	3857	13.1
C4	4166	13
C5	4679	12
C6	4677	6.2
C7	4679	7.5
C8	4676	8
C9	4440	8.8
C10	3629	5.1
C11	3957	16
C12	3646	6

As reported by Li et al., the design stress for the cables is about 4600 Kg/cm^2. From charts, it results that the Cable C6 fails at 6 seconds. Fig.22-23 show the stress in cables C6-C7 obtained by AEM simulation.

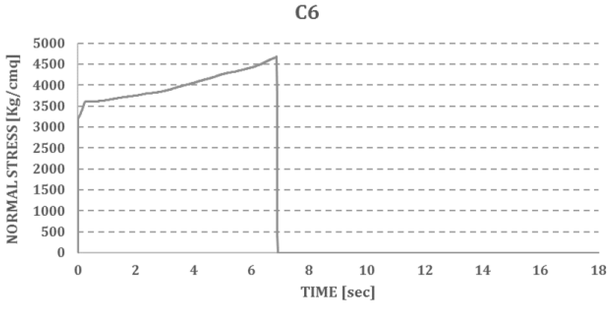

Figure 22. Normal stress cable C6.

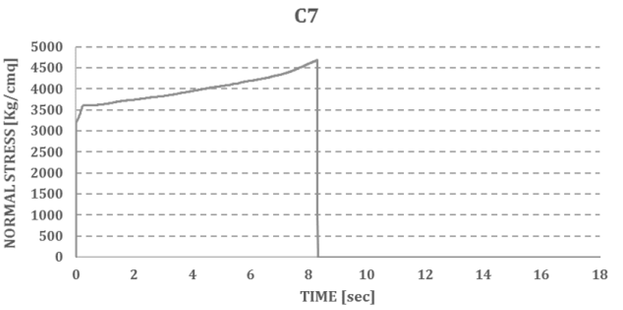

Figure 23. Normal stress cable C7.

The failure of cables C6 and C7 cause the overloading and the consequently ruptures in the adjacent cables. The loss of cables, which leads to a reduction of the capacity of the supporting system, increases the risk of the global failure of the structure. As a result, the bridge collapse due to ground motion cannot be avoided. Some authors indicate that this phenomenon occurs when the distance between the first failure cable and the adjacent cables is about 10 meters (Wolff & Starossek 2010). In Figure 24, the robustness variation with respect to time is reported. After the failure of the cable, the robustness decreases until the collapse of the entire bridge (disproportionate collapse). In Table 5, the redundancy values are shown.

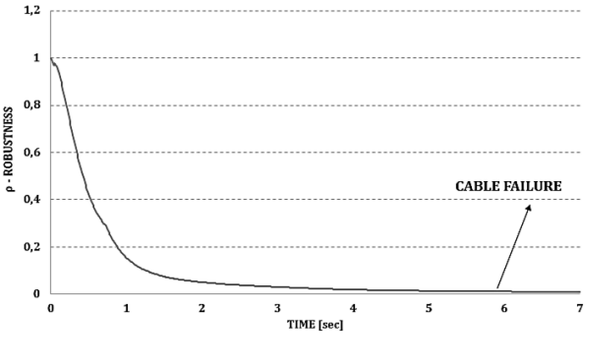

Figure 24. Robustness chart.

Table 5. Redundancy values

Redundancy	
	-
R_u	1.71
R_f	1.09
R_d	1.21

4.2 *Seismic simulation of Yong-he Bridge with new cables-configuration*

A new configuration for the center span stays is proposed to improve the bridge response, as shown in Figure 25. The geometrical distance between the cables is decreased. For cables adjacent to C6 and C7, the distance between the cables is 8 meters while for the cables adjacent to C4 and C9 it is 10 meters. This configuration allows to decrease the stress in cables C6 and C7 that are responsible of the disproportionate collapse (previous section).

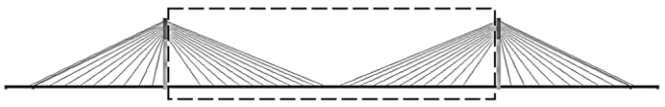

Figure 25. New cables configuration.

As shown in Figure 26, with this new configuration the disproportionate collapse is avoided. The failure of the main girder is due to high tensile stresses in the concrete.

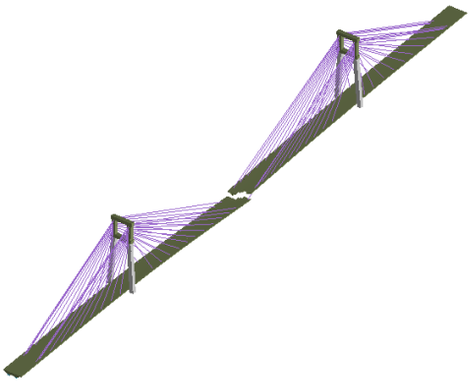

Figure 26. AEM simulation – collapse bridge.

In Figures 27-28 the stresses in cables C6 and C7, the responsible of the disproportionate collapse in the previous bridge configuration, are reported. In the new configuration, stays' failure are not verified.

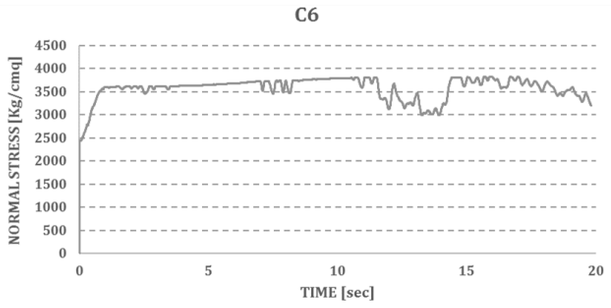

Figure 27. Normal stress cable C6.

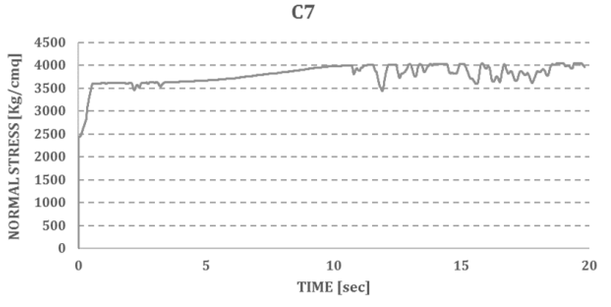

Figure 28. Normal stress cable C7.

The lateral strength of the reinforced concrete deck is abruptly reduced after reaching its ultimate deformation due to the rupture of rebar or the concrete crushing. In Table 6 the max values of the stresses in the cables are shown. They are far to the ultimate limit.

Table 6. Normal stress cables

Cable	σ_{MAX} Kg/cm^2
C1	3803
C2	3784
C3	3715
C4	3742
C5	3788
C6	3815
C7	4041
C8	3700
C9	3731
C10	3748
C11	3726
C12	3709

The deck displacements are extracted and, according to Restelli (2007), the robustness is calculated for each time step as shown in Figure 29. Table 7 reports the redundancy values calculated.

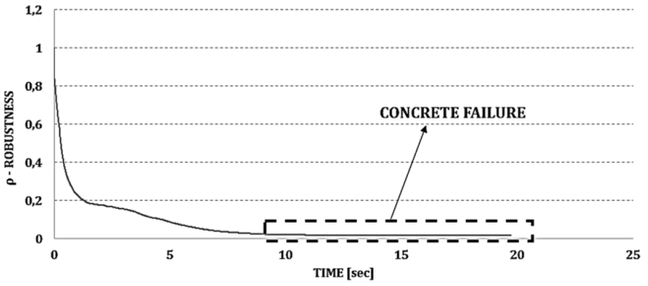

Figure 29. Robustness chart.

Table 7. Redundancy values

Redundancy	-
R_u	4.34
R_f	2.71
R_d	3.37

Comparing the values of Tables 5 and 6, a remarkable improvement in terms of redundancy is highlighted. Table 8 compares the redundancy values in terms of percentage improvements of the new bridge configuration with respect to the original configuration.

Table 8. Redundancy comparison

Redundancy	Δ Redundancy %
R_u	39.4
R_f	40.2
R_d	35.9

Furthermore, in the new configuration, the robustness also results higher than robustness measured in the previous configuration (Figures 24 and 29).

5 CONCLUSIONS

The problem of disproportionate collapse of an existing cable-stayed bridge is investigated through nonlinear dynamic analysis and the Applied Element Method. The analyses show that the bridge cannot sustain the failure of more than two cables without showing a disproportionate collapse. Conversely, it can be avoided through a new cables-configuration. This is closely connected with robustness and redundancy improvements. However, the new configuration results not enough in order to guarantee the functionality of cable-stayed bridge after a strong motion event, because the stresses in the bridge deck compromise the structural stability. Therefore, additional strengthening would be necessary in the main girder for overcoming that issue and avoiding functionality losses. This work can support decision-makers to explore the performance of bridge structures in seismic affected area, to plan strategies and resilience improvements to minimize both losses and recovery time.

ABSTRACT: The efficient movement of goods is crucial to the economic growth of communities. This makes the existence of seaports essential for the marine transportation system. Due to their natural location, ports are continuously threatened by natural hazards such as wind action, which necessitates a continuous monitoring and assessment for their performance. The work presented here aims at assessing the resilience of ports against natural disasters. This is done by identifying the performance and the recovery rate of such infrastructure during the period following the event. The research commenced with gathering information about the port's main components that are influenced by natural hazards. The collected data has been compiled in the form of indicators, which have been filtered and grouped under four dimensions in the proposed "PORT framework". Each of the indicator has been allocated a *measure* to enable its quantitative evaluation. The aggregation of the indicators' values allows identifying the port resilience.

1 INTRODUCTION

Ports are a main component of the physical infrastructure of coastal communities. Despite their importance, they are often overlooked in the disaster resilience engineering. Seaport infrastructure is fundamental for marine transportation at both local and national scales. Normally, ports are significantly exposed to natural and manmade disasters (Kron 2011), which necessitates assessing their resilience and performance in order to set mitigation plans for extreme disruptive events.

Although much effort has already been made to boost research on resilience measurement (Cimellaro et al., 2010), there is still no acceptable method for the evaluation of the resilience of large infrastructure systems like ports, and there are still challenges in developing real evaluation strategies.

Different kind of approaches are presented in the literature to measure the seaport resilience: some consider specific scenarios in their studies to measure the performance of given port components, such as the destruction of quays under a seismic event (Safieezadeh et al.2014), while others focus on identifying port performance indicators (e.g. number of TEU's (Twenty-foot Equivalent Unit), tons of dry and liquid bulk material (Pant et al. 2014), etc.), which are used to build performance evaluation frameworks (Berle et al. 2011, Baker et al 2013, Heinsen et al. 2014, Kurapati et al 2015, Mohd Salleh et al. 2015, Gharehgozli et al 2016, Mcintosh et al. 2017). Both kind of approaches have advantages and disadvantages. The first one considers a thorough investigation of a single problem but it does not capture the complexity of the different scenarios that may affect the activity of the port, like communication or organizational problems, and it often only tackles the resilience of structural elements of the port, like berth or cranes. The second approach, on the other hand, uses several generic indicators to determine the resilience of ports. The indicators are assessed independently at a given time without considering their interdependency. In this type of approaches, no final port resilience measure has been proposed in previous work and so the overall performance of the port has not been identified. Indeed, the existing resilience approaches do not actually measure the resilience but rather the performance of ports because resilience is a dynamic process that needs to be assessed for a given period of time following the perturbation and not only at a given instance of time.

The approach introduced in this paper fulfills the mentioned shortcomings by proposing a framework that covers all the significant aspects of port activities at both structural and organizational levels. The interdependency among the ports' elements is consid-

ered through the use of weighted indicators. The final output of the framework is a dynamic port resilience measure.

2 METODOLOGY

Measuring the seaport resilience under natural hazards such as wind actions is a challenging task. Although the use of indicators is perceived as an important instrument to measure resilience, developing a standardized set of resilience indicators is clearly challenging for such a dynamic, constantly reshaping and context-dependent concept.

Among the various resilience approaches in the field of engineering, the ones proposed by Bruneau et al. (2003) and Cimellaro et al. (2016) are the most suitable for developing a resilience framework for port infrastructure. For the purpose of this study, the resilience definition given by Bruneau (2003) is considered: resilience is "the ability of community units to mitigate hazards, contain the effects of disasters when they occur, and carry out recovery activities in ways to minimize disruption and mitigate the effectors of further events".

Kammouh et al. (2017c) proposed a novel method for evaluating community resilience. The method starts by collecting all community resilience indicators found in the literature and then allocating them into homogeneous components, classified under seven dimensions (Kammouh et al. 2017c, Kammouh et al., unpubl). A measure is assigned to each indicator allowing it to be quantified. The measure is not represented by a scalar value but rather a normalized continuous function that marks the serviceability of the community in time (Figure 1). All measures are weighted according to their contribution in the overall resilience assessment. The methodology takes as inputs the indicators' serviceability before and after a given hazard and turns as an output the serviceability curve of the community as well as a resilience measure. The resilience is then computed as the area under the serviceability function for a defined control time (T_1 -T_f) following the disaster (Figure 1).

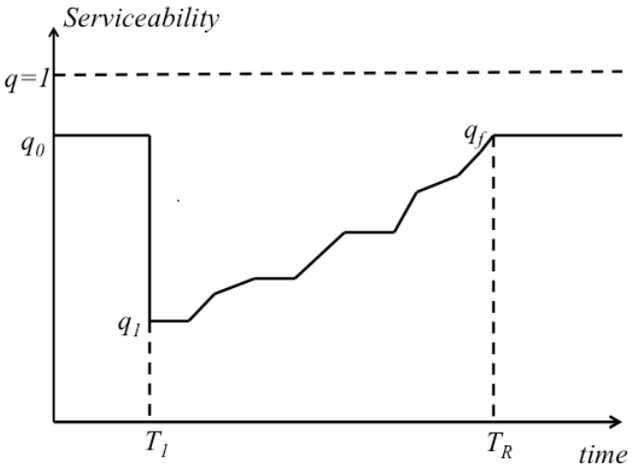

Figure 1. The concept of Serviceability function: q_0 initial serviceability, T_1 disaster event time, q_1 post-disaster serviceability, q_f final serviceability after T_R

The method proposed in this paper is inspired by the work previously done in (Kammouh et al. 2017c) as it uses the same algorithm. However, a new and exhaustive list of indicators that are applicable only for port infrastructures is introduced in this paper.

The identification of a set of port-specific indicators was fundamental for identifying the main ports elements that could be influenced by the natural hazards. This task has been completed through a wide literature research on port indicators and several visits to the VTE (Voltri Terminal Europa), the main container terminal of the Port of Genoa and one of the most important in the Mediterranean area. The collected data have been compiled in the form of *indicators*, which have been filtered and classified under a set of *components*. Finally, the components have been grouped under four *dimensions*: Physical Infrastructure, ICT and Equipment; Organization and Business Management; Resources and Economy Development; and Territory, Environment and Stakeholders, summarized under the acronym "PORT" (Table 1). Each indicator has been assigned a measure to make it quantifiable and then weighted according to its interdependency with the other indicators.

Table 1 Dimensions and components of the PORT framework

Physical Infrastructure, ICT and Equipment	**Resources and Economy Development**
1.1 Quay Cycle	3.1 Financial Flows
1.2 Trucks Cycle	3.2 Financial Services
1.3 Rail Cycle	3.3 Port Business and Costs
1.4 Yard	3.4 Employment Services
1.5 Port Buildings	
1.6 Containers	
1.7 Port Utility Services	
1.8 Technical Services Availability	
Organization and Business Management	**Territory, Environment and Stakeholders**
2.1 Terminal Policy	4.1 External Physical Access
2.2 Internal and External Communication	4.2 Environment Sustainably
2.3 Human Resources	4.3 Reputation
2.4 Resources Planning	
2.5 Risk Assessment and Mitigation	
2.6 Preparedness, Response and Recovery	

Several weighting techniques exist in the literature (Kammouh et al. 2017a, Kammouh et al., 2017b, Kammouh et al. 2017c). At this stage, the weighting

factors are assumed in the range between 1 and 3 on the basis of qualitative judgment. Future work will be addressed to a quantitative definition of such factors Table 1 lists the dimensions and the components of the PORT framework.

3 PORT FRAMEWORK STRUCTURE

Figure 2 shows a simple scheme of the port areas and the principal activities that are adopted in this work as indicators. Three cycles (train, quay and trucks cycles), the yard and the buildings are the main intermodal areas of the Port, where the most important activities are carried out. Containers are moved from the Quay Cycle to the Yard and to the Trucks and Train Cycles in order to be shipped through the external Railway and Roadway System and vice versa.

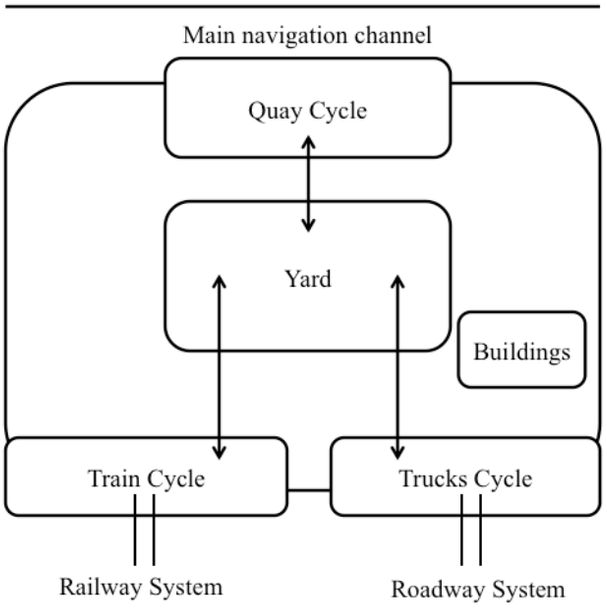

Figure 2. Schematic representation of different port area ort Areas and their interconnections.

A full list of dimensions, components, and indicators can be found in Appendix. In this table, a measure has been assigned to each indicator to allow its quantitative evaluation. The measures have been defined in close collaboration with the port experts to insure that the proposed data actually exists in the port terminals databases.

TV is the "Target Value" of the indicator, usually defined by the terminal experts and safety&security manager. This quantity is used as a baseline to normalize the measures. For instance, if we consider the measure "Quay gantry cranes low profile (indicator 1.1.1 in Appendix), the output of the measure would be *the daily number of TEUs handled by port cranes low profile type*. The output in its current shape can not be combined with other measures until it is normalized. This is done by dividing over the corresponding *TV*. In this case, *TV* represents the *ideal number of TEUs that the crane can handle as expected by port operators*. This operation (normalization) allows comparing and considering different heterogeneous variables related to different port aspects, such as physical infrastructure, port communications and the economic resources

I is the importance factor of each indicator which is determined according to the indicator's contribution in the overall resilience assessment.

Nat describes the nature of the indicator: The indicators can be either Static (*S*) or Dynamic (*D*). Static indicators are the ones that are not affected by the disastrous event and their values do not change after the disaster, while Dynamic indicators are the ones whose values change after the disaster's occurrence.

In the following, each dimension with selected components (in **bold**) and indicators (in *italic*) are described in details.

3.1 *Physical Infrastructure, ICT and Equipment;*

Eight components are considered to describe this dimension: **Quay Cycle**, **Trucks Cycle**, **Train Cycle**, **Yard**, **Port Buildings**, **Containers**, **Port Utility systems** and **Technical Services Availability**. The first four components represent the areas where the most important operations of the port take place. The critical elements needed to run the operations in the mentioned port areas have been investigated. The "crane" has been spotted as the most critical element to run most operations in the different port zones. That is, in case of crane interruption, most port activities break in.

In the **Quay Cycle**, cranes are placed on rails near the dock for loading and unloading goods from the ships. Their configuration is designed to meet specific height limits, especially when the port is close to an airport. Two different crane types are considered: *quay gantry cranes low profile type* and *quay gantry cranes gooseneck type*. These two types of cranes are therefore chosen as indicators for the Quay Cycle component.

Figure 3. VTE's quay gantry cranes - gooseneck type

In the **Trucks Cycle**, which is the area where the containers are loaded and unloaded to and from the *trucks*, there are the *rubber-tired gantries (RTGs*), which are mobile gantry cranes mounted on rubber tired used to stack the containers in the yard

In the **Train Cycle**, cranes are placed near the railroad tracks of the port area. They are defined as *Rail-Mounted Gantries cranes* and they are equipped with tracks in order to move easily along the length of the *freight train*.

In the **Yard**, to facilitate the internal container storage movements, cranes can be mounted both on Rubber or Rail as *Rubber-tired gantries* and *Rail-Mounted Gantries* respectively. For each of these elements, the most representative measure is "the daily number of congested containers". This measure applies to both loaded and unloaded containers. In addition, the two elements: *Prime Mover* and *Reach Strakes* are necessary for the internal movement in the terminal area (i.e., to move the TEUs from one cycle to another or to carry them to the rubber vehicles in the storage yard) and therefore they are chosen as additional indicators.

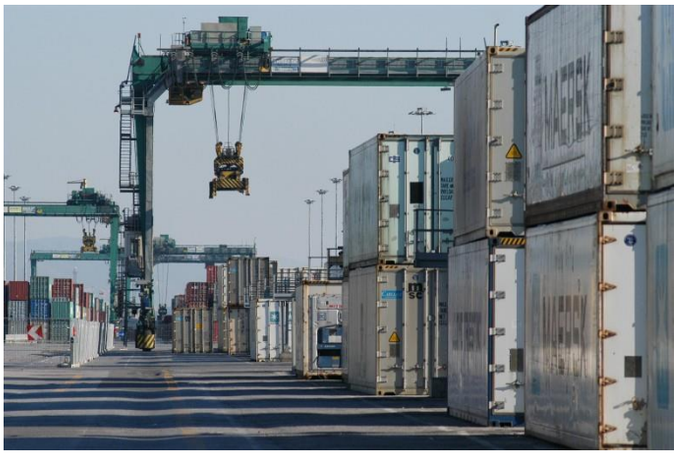

Figure 4. The Yard with the rubber-tired gantries and rail-mounted gantries

Buildings serviceability is determined according to their resistance. An event that significantly reduces the building capacity implies the building's closure or destruction, with consequences on both the human life and the port activity.

The **Containers** are fundamental for organizing the entire port activity. Containers can be stored in temperature controlled environments and they can be either empty or full. *Empty container*, in particular, is chosen as an indicator for the **Containers** component due to their critical role during emergencies, where the goods in the damaged containers are moved to the empty ones. Other indicators for this component can be found in Appendix.

The **Utilities,** such as *gas* and *electricity*, are critical for the operation of the port cranes. *Electricity* is crucial also for the operation of *ICT* equipment (informational and communication technology), which is essential for the internal management of the port handling and storage.

The availability of **Technical Services** facilities represent a main component to run the port activities. If these services are absent or unavailable, the entry of ships into the dock becomes more complex or even impossible. Therefore, **Technical Services** has been chosen as a component for this dimension.

3.2 *Organization and Business Management;*

Port Organization activity components are divided into two main categories: ordinary organization practices and extraordinary organization practices. Ordinary organizational practices are: **terminal policies**, **internal and external communications**, **human resources**, and **resources planning**. Extraordinary organizations are related to **risk assessment and mitigation**, **response preparation and reconstruction**.

Terminal Policy: considers the *Health and Safety Executive* (HSE), which measures the effect of the perturbation on the workers' safety and health. It also considers the serviceability of the *Informational Technology system,* which plays a central role in the port main activities (e.g. the operation of the *cranes)*. For example, a computer system block can lead to the immediate cessation of all port activities as it becomes impossible to know the location, destination, and contents of the containers. It is measured with "the number of *IT* block events that cause the port activities to stop". Another indicator is the *Terminal security,* which depends on the ISPS code (International Ship and Port Facility Security Code). Destructive events cause the terminal security to be weakened as the level of control is reduced.

Internal and external communication plays an important role in the port organization serviceability. One of the most weighted indicators for this component is the *internal terminal communication indicator* (location, destination, and container contents), known as EDI connectivity (Electronic Data Interchange).

The component **Human resources** is divided into four indicators: *operational personnel*, *staff planning operational activities*, *supervisory staff* and *Manning of Dockers*. In the scenario of a destructive event, the *operational personnel* indicator becomes particularly sensitive due to the fluctuation in the amount of work carried out.

Resources Planning: concerns the *Berth Window occupancy delays*, the average permanence of a container within the yard (*Turnaround Time*) and the *berth occupancy rate*.

The second part of the components related to this dimension concern the **assessment and mitigation of risks** and the **preparation and allocation of resources** to mitigate the effects of the disaster event. These components are present in Appendix but are not described in the paper.

3.3 *Resources and Economy Development*

Ports usually require good **Financial Flows** to allow the investments in port activities. For ports, investments are fundamental to ensure their competitiveness and serviceability. Measuring the financial flow is crucial in order to evaluate the serviceability of a port system and its potential to expand and develop. Investments for which a capital is required may be of several types, superstructures such as cranes, maintenance and drainage, and expansion of the storage space. An additional effect of the destructives event on the financial capabilities of a port is the difficulty to access the *Financial Services.*

The **Port business** component is related to those indictors through which the economic outlook of a port is commonly assessed. The most relevant indicator for **port business** is the number of containers (*tonnage*) that is handled annually by the port.

3.4 *Territory, Environment and Stakeholders*

In this last component, the port elements that are located outside the port terminal are considered: the **access routes** to the port terminal, the quality of the environment **(environment sustainability)** and the port's social **reputation**. The first component concerns the serviceability of access roads such as the *highway access infrastructure*, the *incoming rail,* and the *navigation channel* through which ships depart and arrive. The environmental sustainability of the port activity includes the *quality of air*, *water* (can be reduced by ship spills), and *noise pollution,* which can have a strong impact on the surrounding citizenship.

The impact of the port activity on the citizens' lives may seriously affect the *port's social image*. This indictor is of special importance to the port terminal operators as it can lead to the closure of port activities in extreme cases.

4 CONCLUSION

This paper introduces a resilience measurement tool for seaports. The introduced PORT framework consists of a large number of resilience indicators that cover the main aspects of a port activity and management. A wide literature review has been made and several port experts and port authority personnel have been interviewed in order to conclude the presented indicators list.

Future work aims at defining quantitatively the weighting factors and validating the proposed framework by applying it to a real case study, such as the Genoa port. A user-friendly software tool in which the above methodology is implemented will also be introduced.

5 ACKNOWLEDGMENT

The research leading to these results has received funding from the European Research Council under the Grant Agreement n° ERC_IDEAL RESCUE_637842 of the project IDEAL RESCUE—Integrated Design and Control of Sustainable Communities during Emergencies. The research has also been financially supported by "Compagnia di San Paolo" Project "Wind monitoring, simulation and forecasting for the smart management and safety of port, urban and territorial systems" (grant number 2015.0333, ID ROL: 9820),. Authors gratefully acknowledge PSA Voltri-Pra QSE & Risk Management Manager Stefano Mordeglia, who gave valuable information about the critical aspects of seaports..

Seismic damage assessment of a virtual large-scale city model

M. Domaneschi, S. Marasco, G. Scutiero, A. Zamani Noori, O. Kammouh, V. Taurino, G.P. Cimellaro
Department of Structural, Geotechnical & Building Engineering, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129, Turin, ItalyPolitecnico di Torino, Italy.

ABSTRACT: Recent social developments and economic transformation have changed the engineering design approach from building design level towards community design level (city, region, country). The latter approach involves modeling of interconnections between different systems (buildings, transportation, water network, etc.) rather than designing the buildings individually. Thus, new analysis tools are expected to be developed to simulate the complex response of a community subsequently to disasters. The need of such rational tools is the object of this research work. Two different numerical approaches to simulate the response of a large-scale built environment after a seismic scenario are explored by developing multipurpose numerical codes. A district of a virtual city is considered as a case study and the level of damage for built environment is estimated. This work could be the first step for further urban loss analysis, e.g. through agent-based models that could be updated online with the proposed simulation.

1 INTRODUCTION

Disaster events devastate the nature and human beings of a community. When a catastrophic event such as an earthquake occurs in a built environment, the consequential structural damage may cause high losses (casualties, repair costs, and repair time). The main goal of the paper is the seismic damage evaluation on the built environment through dynamic analysis. For seismic damage assessment of an urban area, computer-based simulation has become the most feasible and efficient methodology for scientific research and engineering application (Lu & Guan 2017). Given large-scale and complicated structural system, a computational model with balanced accuracy and efficiency is critical for earthquake disaster simulation. In this study two methodologies, based on the tri-linear and bi-linear backbone curve, are compared to evaluate in detail the seismic performance of the regular buildings.

Many studies claimed that the tri-linear backbone curve model can accurately represent the building's response in terms of inter-story (Vamvatsikos & Cornell 2005, Shi 2014). The first proposed approach is based on a nonlinear multi degrees of freedom system (MDOF) developed by Marasco et al. (2017). Nonlinear MDOF shear models are recognized able to satisfactorily capture the nonlinear properties of multi-story buildings, predict the Engineering Demand Parameters (EDPs), and assess a reasonable level of damage (Lu et al. 2014, Xu et al. 2014). The second methodology, developed by Cimellaro et al. (2017), is based on a simplified approach to obtain an equivalent single degree of freedom system (SDOF) through linear hypothesis.

The proposed methods have the ability to output the displacement contours for different time steps, thus making it possible to generate an animation of the building seismic responses. According to the Hazus (2012), the seismic damage is classified into five levels: slight, moderate, extensive, and complete damages. The same district of a virtual city model, called Ideal City, freely inspired to the city of Turin in Italy, is developed for evaluating the seismic effects at increasing intensities through proposed methodologies. It will be the starting step for further urban loss analyses, e.g. through agent-based models, which will be updated with respect to performance losses.

2 METHODOLOGY

2.1 *High fidelity model (HFM)*

The proposed methodology is discussed by Marasco et al. (2017). In this approach, the inter-story behavior of a regular building is simulated through a tri-linear backbone curve (Figure 1). The three main points of the curve are evaluated using a nonlinear static approach for a MDOF system. To achieve this goal, a MATLAB algorithm has been developed considering

the uncertainties on the geometric and mechanical parameters used in the analyses. Variation of the parameters within an acceptable range is considered through a Monte Carlo Simulation (MCS) obtaining a set of tri-linear backbone curves for each building.

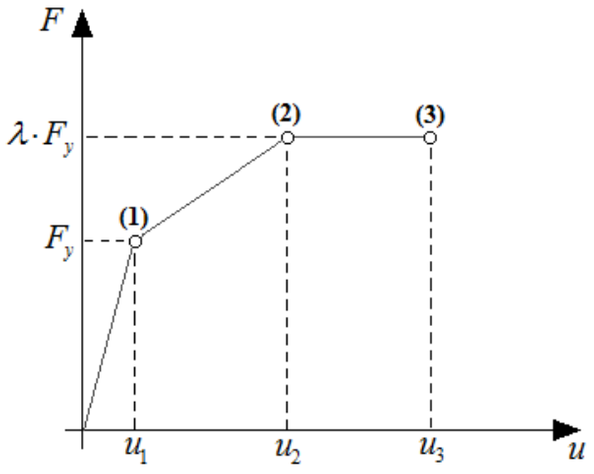

Figure 1. Tri-linear backbone curve.

The ranges of the main building's parameters are selected according to the knowledge level of the building. In addition, the deterioration of the mechanical properties (such as strength and elastic modulus of concrete) is taken into account through the aging equation proposed by Eurocode 2 (EC2 2004) according to the year of construction. Once the Matlab algorithm evaluates the tri-linear backbone curve at each step of MCS, the SAP2000 API is used to apply to all the buildings the data set obtained by the algorithm. This automated procedure is capable of reducing the computational time and analyze the dynamic responses dispersion caused by the data uncertainty. Therefore, the mean response and associated dispersion for each building within the virtual city can be estimated.

This approach is suitable to allow a decision-maker the ability to explore how their community responds to a disruptive event and quantify the mean performance of buildings and their uncertainty in the dynamic response after a hazard. Assimilating the dynamic nonlinear response of a structural system to a unique backbone curve leads to analyze the building as a nonlinear equivalent Single Degree Of Freedom (SDOF) model. The SDOF system simplification allows for a reduction in the computational efforts needed to assess the response of a large number of structures.

Finally, the hysteresis is considered according to the Takeda model (Takeda et al. 1970), as implemented inSAP2000. Figure 2 shows in detail the software data flow used in the simulations.

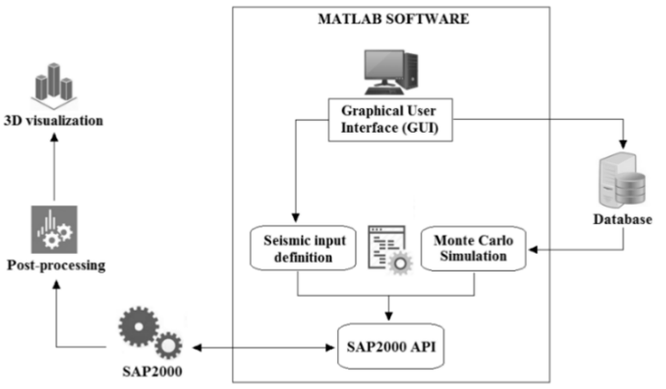

Figure 2. Software data flow.

According to the maximum drift, the structural damage is assessed for each building and the associated level of damage is evaluated (slight, moderate, extensive, complete). A 3D visualization tool is also provided, which shows the dynamic response of the building within the virtual.

2.2 *Simplified approach model (SAM)*

The proposed methodology is presented in Cimellaro et al. (2017). The building behavior is reproduced through a single degree of freedom (SDOF) model within a multipurpose FE software (Figure 3). A SOLID185 Element (eight nodes) represents the structure in ANSYS. It is fixed to the ground and has the same section of the real building's footprint. The mass is concentrated on the top of the building's model.

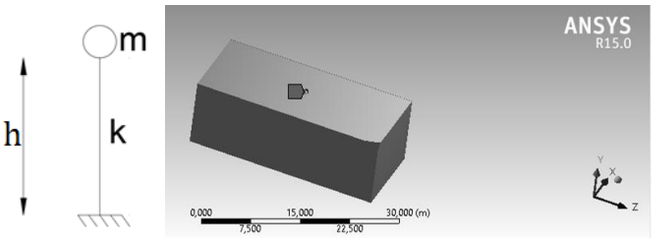

Figure 3. SDOF model and 3D visualization.

A self-weight for floor of 11 KN/m^2 is adopted accordingly with a widely accepted range of 10-12 KN/m^2. The period of structure (T) and equivalent SDOF stiffness of the building (k) are calculated by following:

$$T = CH^{3/4} \tag{1}$$

$$K = \left(\frac{2\pi}{T}\right)^2 m_{tot} \tag{2}$$

$$K = \frac{GA_s + 3EI}{H + H^3} \rightarrow E \tag{3}$$

where C is computed by Eurocode 8 (1998), H is the building's height in meter, m_{tot} is the mass in Kg, T is the period of the first vibration mode in seconds,

K is the stiffness of building, G is the shear modulus, and E is the elasticity modulus. The total mass is given by:

$$m^* = \sum m_i . \varphi_i \quad (4)$$

where m_i is the mass for floor and it can be assumed equal to 11 KN/m^2 and φ_i is the eigenvector of the building at floor i. Importing a 3D-GIS file into the FE code, the geometrical model of the regular buildings in a single step can be defined. Figure 4 exemplifies the general procedure for performing the solid FE mesh of the ideal city.

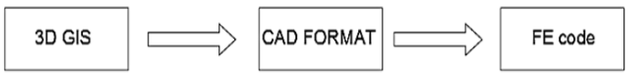

Figure 4. Method to import the geometrical model in a FE software.

The discretization of all buildings through this approach results very useful for both the polygonal visualization of the virtual city and, at the same time, for limiting the computational costs (low number of degrees of freedom). The seismic damage is classified as slight, moderate, extensive/complete. To assess the seismic damages of buildings through a linear approach, the force-based damage criterion in Xiong et al. (2016) is exclusively adopted. Thus, the bi-linear backbone curve consists in two key points (Figure 5).

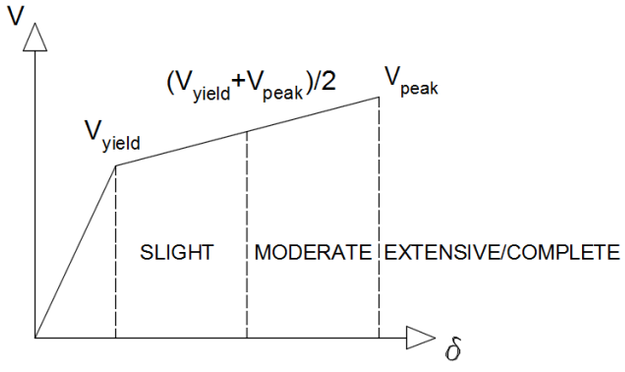

Figure 5. Bi-linear backbone curve.

The first one corresponds to yielding that is the turning point between the linear and the nonlinear behavior. According to Xiong et al. (2016), it is calculated such as:

$$V_{yield} = \Omega_1 V_{design} \quad (5)$$

where Ω_1 is the yield overstrength ratio of RC frames. As reported by HAZUS, a value of Ω_1 equal to 1,1 is adopted. The second point is the peak one corresponding to the peak strength.

$$V_{peak} = \Omega_2 V_{design} \quad (6)$$

To determine Ω_2, the statistical analysis is performed by Xiong et al. (2016) on RC frames designed following the Chinese seismic design code. For base shear forces that exceed the V_{peak} in Figure 5, the resulting damage is assumed in the range extensive/complete. Because, through a linear analysis, the displacement associated to highly nonlinear structural response can not be reasonably evaluated. The resultant base shear strength is calculated for each building and compared with the limit values in Figure 5.

3 DISTRICT SEISMIC RESPONSE SIMULATION

3.1 *Case study description*

A medium-size district of a virtual city model, called Ideal City, freely inspired to the city of Turin in Italy, has been considered to firstly assess the overall procedure and the structural behavior during an earthquake. The district is situated in Turin and contains nine regular buildings (Figure 6 and Table 1). Structures with "L" shape in reality are parts of buildings with a rectangular shape divided by a seismic joint.

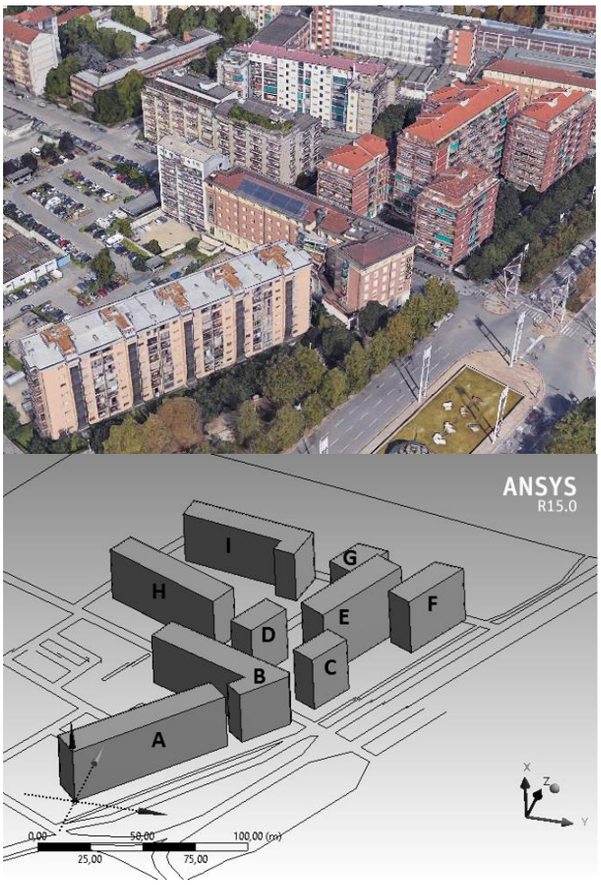

Figure 6. Case study buildings.

SIMQKE_GR software is used for generating the seismic acceleration input (Figure 7) as function of the geographical coordinates of the city, the soil type, the topography of the area, the total duration of the ground motion. The seismic input is applied to the virtual city at increasing intensities as shown in Table 2.

Table 1. Geometric building parameters.

Building	Height	Area
	m	m^2
A	28.9	1258

5	0.28
6	0.38
7	0.46

3.2 *Damage assessment by HFM*

Figure 8 shows the HFM results for different input motions corresponding to each building. On the horizontal and vertical axes respectively, the number of input motion and the maximum displacements on the top of the building values for the seven input motions are reported. The damage levels of the buildings for the different input motions are reported (S: slight, M: moderate, E: extensive, C: complete) in Table 3.

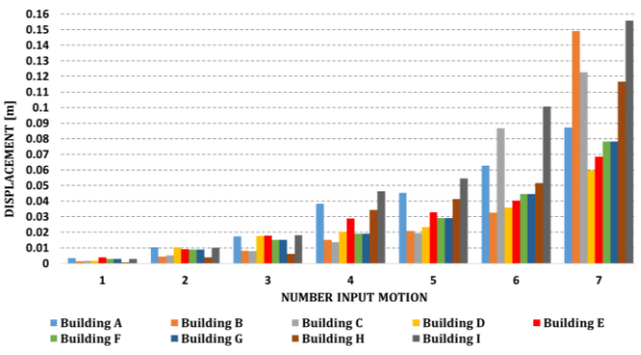

Figure 8. Maximum displacements evaluated by HFM.

Table 3. Damage state through HFM: S=slight, M=moderate, E=extensive, C=complete.

Building	Input motion number						
	1	2	3	4	5	6	7
A	<S	<S	<S	<S	<S	S-M	M-E
B	<S	<S	<S	<S	<S	S-M	M-E
C	<S	<S	<S	<S	<S	M-E	M-E

F	<S	<S	<S	S-M	S-M	S-M	M-E
G	<S	<S	<S	<S	S-M	M-E	M-E
H	<S	<S	<S	S-M	M-E	M-E	E-C
I	<S	<S	<S	S-M	S-M	M-E	M-E

3.3 *Damage assessment by SAM*

The results obtained by SAM for different input motions for each building are reported in Figure 9 in terms of maximum displacements. Obviously, being computed through linear analyses, they are halved with respect to those of HFM in Figure 8. Again, on the vertical axis, the maximum displacements on the top of each building are reported, while on the horizontal axis the number of input motion.
Table 4 reports the damage level for different input motions corresponding to each building of the district. Figure 10 illustrates an example of building visualization provided by SAM.

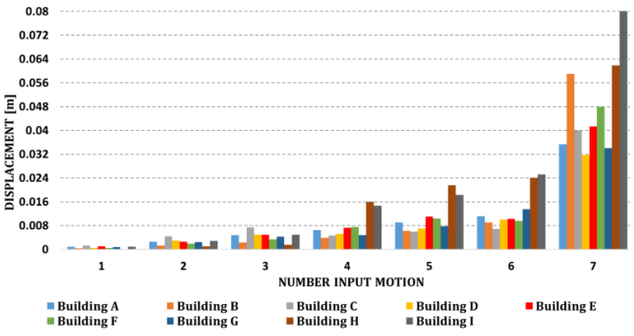

Figure 9. Maximum displacements evaluated by SAM.

Table 4. Damage state through SAM: S=slight, M=moderate, E=extensive, C=complete.

Building	Input motion number						
	1	2	3	4	5	6	7
A	<S	<S	<S	<S	<S	S	S-M
B	<S	<S	<S	<S	<S	S	M

I	<S	<S	<S	S	S	M	M

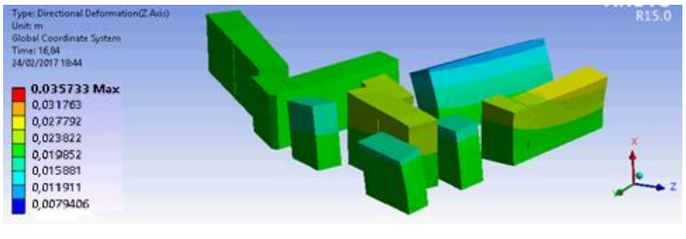

Figure 10. Example of visualization provided with SAM.

3.4 *Comparison between methodologies*

From the comparison between the outcomes of the two methodologies, similar responses can be found at the lowest input levels that are mainly characterized by linear behavior. For higher input motions, the linear response method by Cimellaro et al. (2017) obviously underestimates the displacements as shown in Figure 11 to Figure 19. Dynamic equilibrium equations are solved using direct integration method.

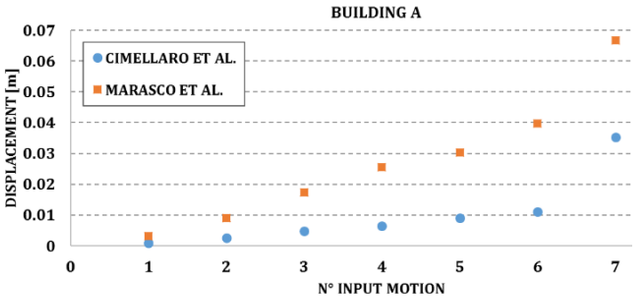

Figure 11. Comparison between two methods (Building A).

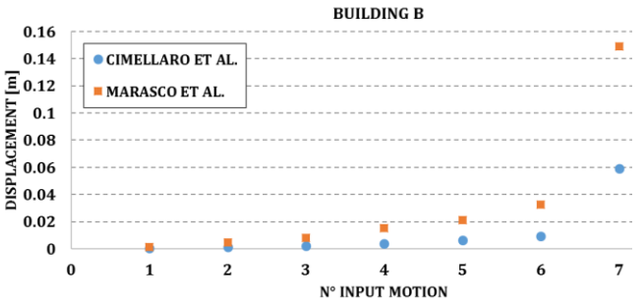

Figure 12. Comparison between two methods (Building B).

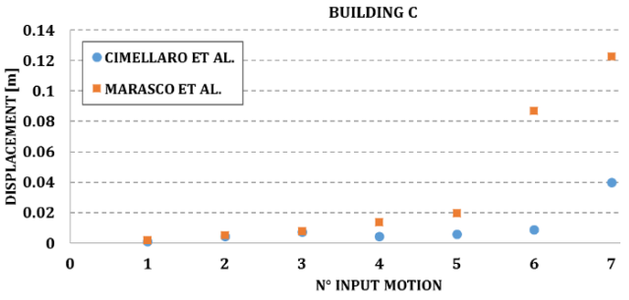

Figure 13. Comparison between two methods (Building C).

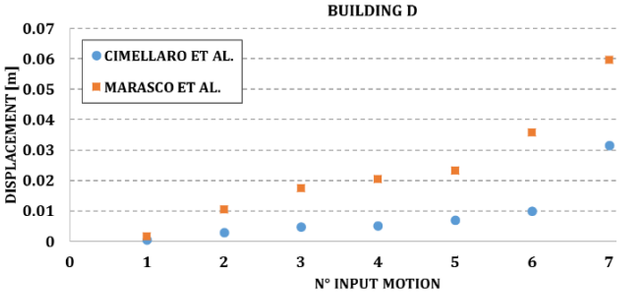

Figure 14. Comparison between two methods (Building D).

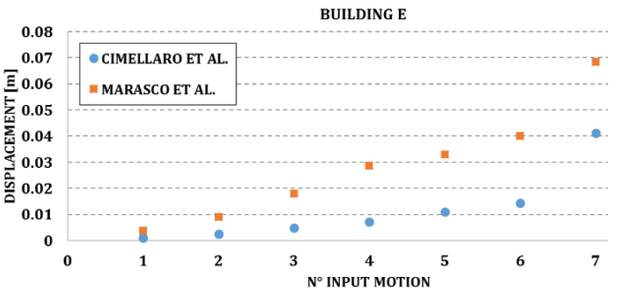

Figure 15. Comparison between two methods (Building E).

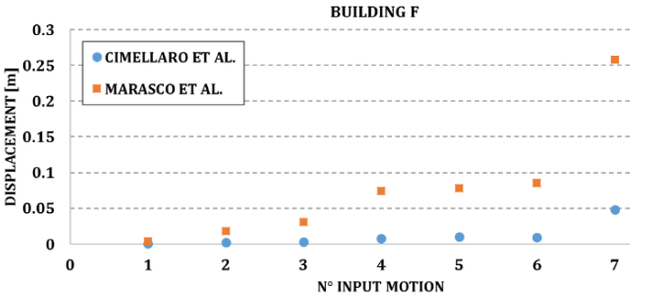

Figure 16. Comparison between two methods (Building F).

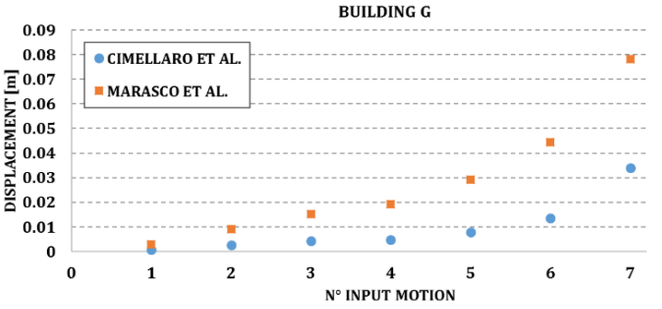

Figure 17. Comparison between two methods (Building G).

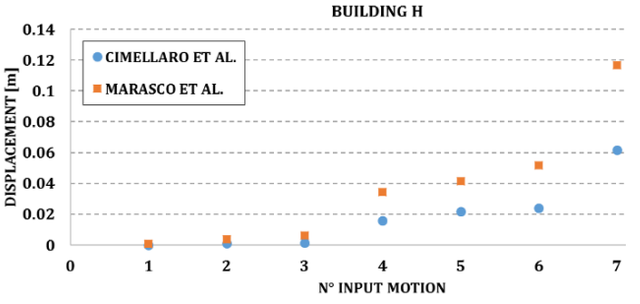

Figure 18. Comparison between two methods (Building H).

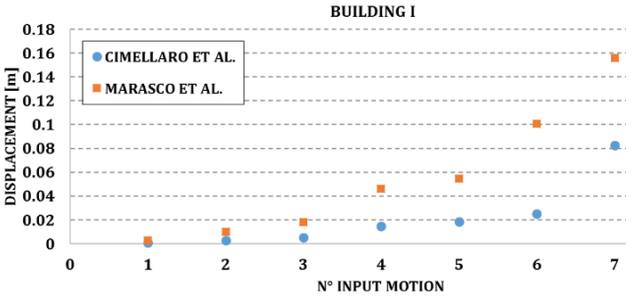

Figure 19. Comparison between two methods (Building I).

The natual vibrating periods of the equivalent SDOF models of both the methodologies are shown in Table 5. The SAM periods are lower than those obtained by HFM method, consistently with the adopted different methodologies. Indeed, in HFM the parameters of the equivalent SDOF are computed through 3D nonlinear dynamic analysis of the buildings.

HFM estimates the base shear (F_{yield}) and top displacement (u_{yield}) values corresponding to the formation of the first plastic hinge. Thus, the secant stiffness of the equivalent SDOF is given by:

$$K = \frac{F_{yield}}{u_{yield}} \tag{7}$$

Differently, SAM evaluates the equivalent SDOF stiffness (k) according to Eurocode 8 (see Equation 1 and Equation 2).

Table 5. Period equivalent SDOF

Building	T-High fidelity model	T-Simplified approach
	Sec	Sec
A	0.86	0.68
B	0.77	0.57
C	0.80	0.68
D	0.81	0.66
E	0.87	0.76
F	0.83	0.60
G	0.90	0.64
H	0.84	0.62
I	0.74	0.66

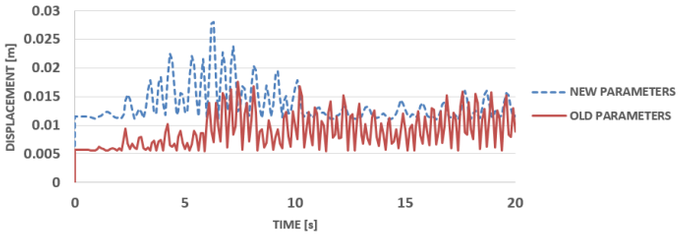

Figure 20. Displacements Building H – SAM

In order to deepen the comparison between the two methodologies, the building H is implemented in the linear SAM approach using the mechanical parameters computed by HFM. Figure 20 depicts the new displacements compared with those previous obtained through SAM employing input motion 4. The maximum displacement computed with new parameters, tends to solution computed with HFM.

Increasing the intensity of the input motion in HFM, the buildings' displacements belong to the nonlinear domain. As shown by previous results on damage state in HFM (Table 3), for PGA greater than 0.1g, buildings F, H, and I highlight elastic-plastic response and slight-to-moderate damage levels. Consistently, SAM also highlight modifications in the damage level with respect to lower input intensity levels but limited to slight damages.

Figure 21 depicts the linear and nonlinear response characteristics of SAM and HFM respectively. Accordingly to the linear approach, the displacements increase proportionally to the magnitude of seismic actions. Keeping constant a generic force (F) in plastic field, the displacement (u_2) of a nonlinear model is larger than the displacement (u_1) of a linear model.

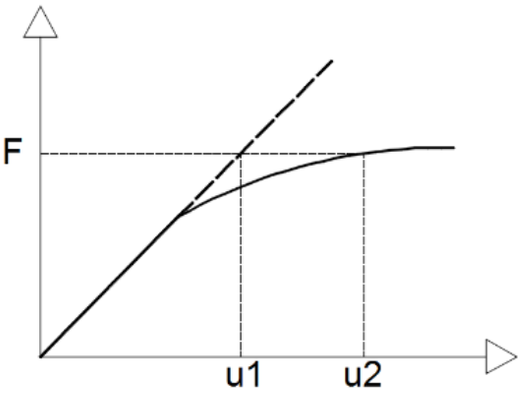

Figure 21. Linear model vs. nonlinear model

A further comparison is done in order to clarify the deviation between the two methodologies during the input motion 7. Table 6 summarizes the drift ratios obtained where HFM highlights larger responses consistently with the adopted nonlinear approach.

Table 6. Drift ratios for input motion n°7.

Building	HFM	SAM
	-	-
A	0.54	0.12
B	0.55	0.22
C	0.54	0.14
D	0.40	0.10
E	0.19	0.11
F	0.70	0.18
G	0.43	0.12
H	0.53	0.21
I	0.56	0.28

The study by Xiong et al. (2016) has been originally developed for predicting damage conditions through nonlinear time-history analysis. This hypothesis justifies the limited damaged levels in Table 4 with respect to Table 3.

Furthermore, the damage assessment method in SAM adopts a force criterion only. This assumption is reasonable at the earlier stage of seismic damage, when the stiffness of the structure is high and a small variation in deformation will lead to a significant change in the internal forces. For structural conditions beyond the peak shear force V_{peak} , the damage is assumed in the range "extensive/complete".

A further development of the present study will be focused on the modification of the trilinear curve by Xiong et al. (2016), for adapting the original methodology to the adoption of linear structural analyses.

The HFM method evaluates each building individually through nonlinear analysis. Tri-linear backbone

curves are accordingly defined. Despite the different approaches to simulate the buildings response, both methods evaluate compatible levels of damages for the considered case study.

4 CONCLUSION

Two different approaches to implement dynamic time history analyses for damage assessment in a built environment of a virtual city are proposed. The simplified linear approach model (SAM) reduces the computational time but underestimates the damage states with respect to the high-fidelity model (HFM). This last is based on a nonlinear approach with higher computational costs with respect to SAM.
Both the methodologies are reasonable simplified approaches in order to calculate the damage state in built environment as long as the buildings are perfectly regulars. Therefore, they can give a significant contribution to disaster resilience analysis and prevention in urban areas through numerical implementation in the virtual city models. Furthermore, they are capable to significantly reduce the computational time in large dimension models reducing the total number of degrees of freedom.
The proposed methodologies can support decision-makers to explore how their communities respond to a disaster event, quantify the performance of buildings, and to plan the better resilience-building strategies to minimize losses and the recovery time.

5 ACKNOWLEDGEMENTS

The research leading to these results has received funding from the European Research Council under the Grant Agreement n° ERC_IDEAL RESCUE_637842 of the project IDEAL RESCUE-Integrated Design and Control of Sustainable Communities during Emergencies.

Seismic retrofit of truss bridge for highway and railway

T. Hanai, T. Tamura & Y. Hirayama
Honshu-Shikoku Bridge Expressway Co. Ltd. (HSBE), Japan

ABSTRACT: For the steel truss portion of the Hitsuishijima viaduct, seismic performance evaluation was conducted and it was found that some members were damaged. Although the replacement of all the road deck bearings by isolation bearings was initially planned, scaffolding installation over the rail lines was limited within only three hours at midnight and heavy protection was required. In order to minimize work over the rail lines, isolation of truss girder was studied, which is unprecedented method for the highway-railway combined bridges in Japan. For the truss girder isolation, i) structural feasibility, ii) constraining effect of long rail, and iii) the running safety of the train were studied. By this method, the retrofit became minimal and economical.

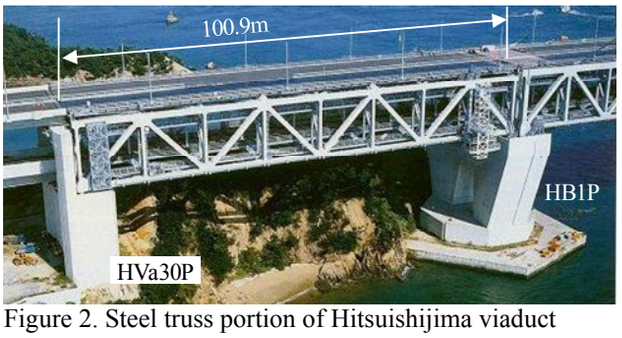
1 INTRODUCTION

The Seto-Ohashi Bridges are highway-railway combined bridges and consists of three suspension bridges, two cable-stayed bridges, and truss bridges and viaducts. The construction of the Bridges started in 1978, and the Bridges were opened to traffic in 1988 as a first direct link between Honshu and Shikoku Island among three routes of Honshu-Shikoku Bridges. The Bridges were designed by original seismic design code. In the original seismic design code, although a plate boundary earthquake with magnitude of 8 was considered, an inland near field earthquake was not considered. And there is concern that large-scale earthquakes which are larger than that of the original design, would occur in the near future. Therefore seismic retrofit of the Seto-Ohashi Bridges started in 2013 and will be completed by 2020. As a seismic retrofit measure of the steel truss portion of the Hitsuishijima viaduct (hereinafter referred to as "truss bridge"), isolation of truss girder, which is unprecedented method for the highway-railway combined bridges in Japan, was selected. In this paper, selection process of the truss girder isolation and technical consideration to realize the method are explained.

2 EVALUATION OF TRUSS BRIDGE

The truss bridge is adjacent to the prestressed concrete viaduct portion and consecutive cable-stayed bridges, Hitsuishijima Bridge and Iwakurojima Bridge, in the north and south respectively (Figure 1). The truss bridge has simply supported truss girder with span length of 100m (Figure 2).

Figure 1. Hitsuishijima Island



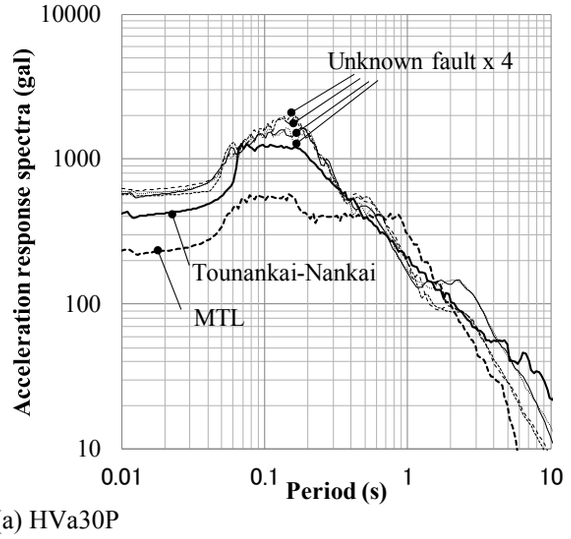


Figure 2. Steel truss portion of Hitsuishijima viaduct

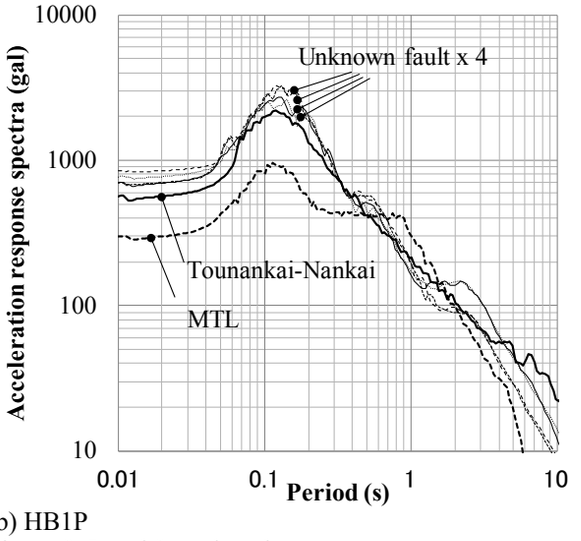
Seismic performance evaluation of the truss bridge was conducted based on the Specification for Highway Bridges (JRA 2012) that is a Japanese standard for highway bridge design.



Seismic ground motions of the large-scale earthquakes (Level 2 earthquake) used for the seismic evaluation and seismic retrofit design are shown in Figure 3. They are the ground motions at the base of

the pier foundations calculated from the rock outcropping motions on the bedrock whose S-wave velocity is about 1500m/s by the one-dimensional wave propagation method. Two types of scenario earthquakes were considered. One is the Tounankai-Nankai Earthquake which is plate boundary earthquake with a magnitude of 8.6, the other is an earthquake with a magnitude of 7.5 coming from the Median Tectonic Line (hereinafter referred to as MTL) which is an inland active fault and is located about 35km from the bridge. A fault model for the Tounankai-Nankai Earthquak is shown in Figure 4. In addition to the two types of scenario earthquakes, four types of seismic ground motions generated by unknown fault earthquakes with a magnitude of 6.8 occurring just beneath the site were considered. This means the consideration for the possibility that an unknown inland active fault might exist near the site. All the seismic ground motions were estimated by a hybrid method (Green's function method + 3D finite difference method or discrete wave number method).

Analytical model used for the evaluation and retrofit design is shown in Figure 5. For the truss members and piers, nonlinear fiber elements are used. The road decks, road deck bearings, rail girders, and rail girder bearings are modeled with linear element. In the analysis, geometric nonlinearity is also considered.

(b) HB1P

Figure 3. Level 2 earthquake

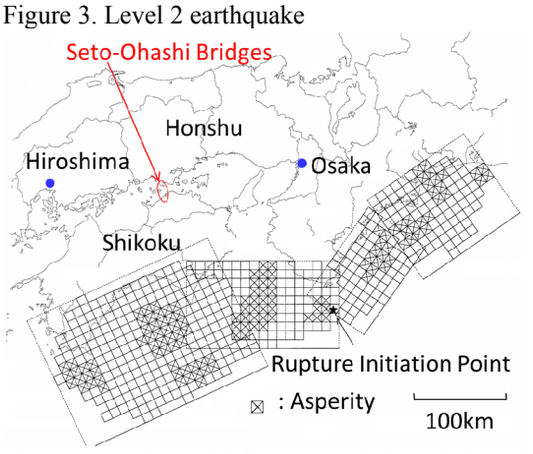

Figure 4. Fault Model for Tounankai-Nankai Earthquake

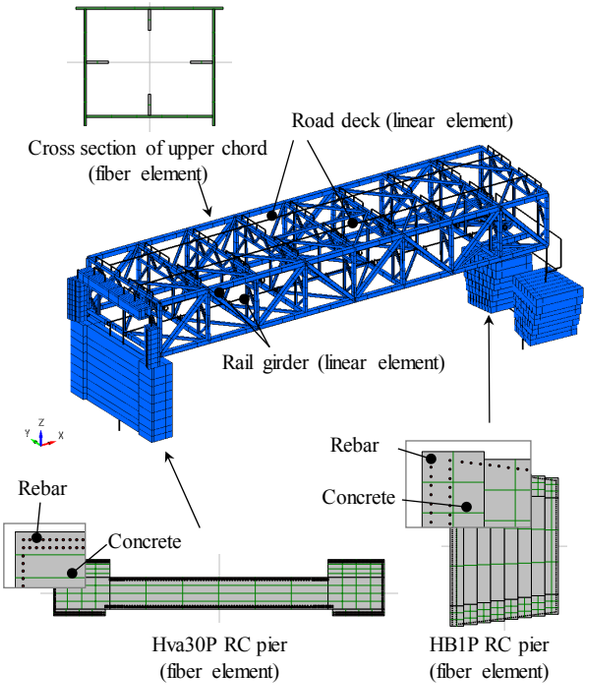

Figure 5. Analytical model

Evaluation result of the truss bridge is shown in Figure 6 and Table 1. It was found that the damages occur in the truss member near the supports and road girder bearings. Horizontal members above rail lines in the floor truss are also damaged. Because these members are immediately above the railway lines

and support overhead lines (Figure 7), maintenance work is conducted exclusively by the railway operator and workable time is limited within a few hours at midnight. Since the retrofit of these members is virtually impossible in reality, alternative schemes are studied.

Evaluation: response / allowable value

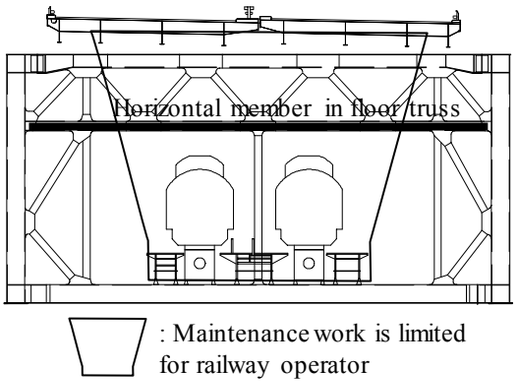

Figure 7. Damaged horizontal member

3 ALTERNATIVES OF SEISMIC RETROFIT

To avoid the retrofit of the horizontal members above the rail lines, alternative schemes were studied.

3.1 *Distribution of horizontal force in road deck supports*

By the replacement of road deck bearings by rubber bearings, inertial force of the road deck will be distributed. Result is shown in Figure 8. Although the number of damaged members is reduced, damage of the truss girder bearings remain. Without reinforce method of truss girder bearings, this scheme is not feasible.

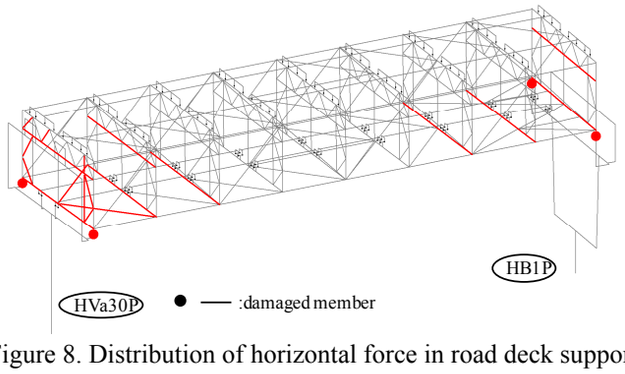

Figure 8. Distribution of horizontal force in road deck supports

3.2 *Road deck isolation*

By the replacement of road deck bearings by isolation bearings, inertial force transmitted from road decks to truss girder will be reduced and damages in the truss members will be reduced. However, all the truss members will not be saved by the road deck isolation only. Additional reinforcement of the truss members is required (Figure 9).

The replacement of the road deck bearings requires installation of scaffoldings and protections. Since these works are conducted above the railway lines, there are many restrictions during the retrofitting work.

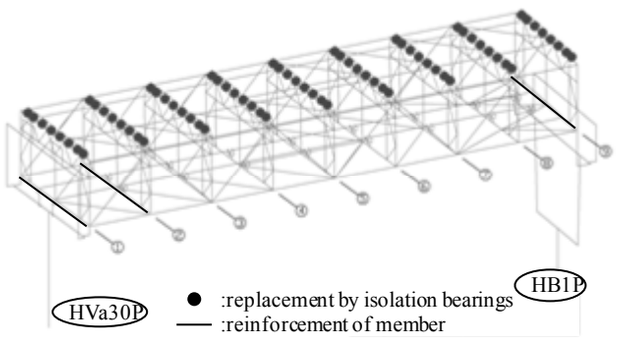

Figure 9. Retrofit by road deck isolation

3.3 *Truss girder isolation*

In this scheme, original hinged supports (Figure 10) for truss girder will be replaced by the rubber isolation bearings (Figure 11). The isolation bearings absorb seismic force and the inertial force acting on road deck and truss girder will be reduced to protect truss members from damage. Since this scheme reduce the work above the railway lines, it will reduce the retrofit cost compared with the road deck isolation scheme. However, since the scheme is unprecedented for highway-railway combined bridges in Japan, it requires technical consideration.

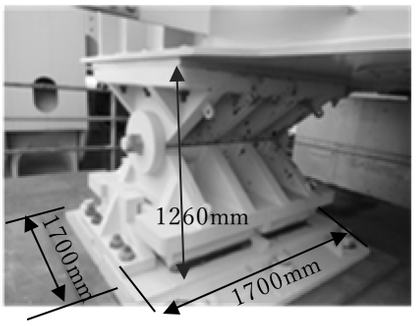

Figure 10. Original hinged support for truss girder

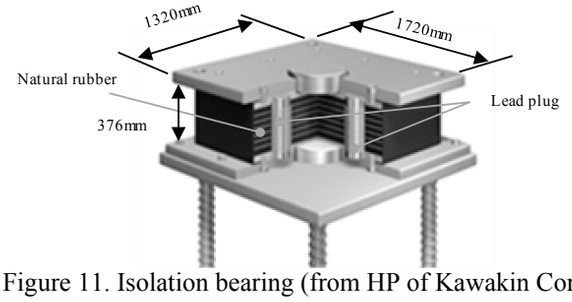

Figure 11. Isolation bearing (from HP of Kawakin CoreTech)

4 STUDIES FOR TRUSS GIRDER ISOLATION

In order to realize truss girder isolation, several issues were studied.

4.1 *Structural feasibilities*

Since the bridge is supported by two bearings at each end, reaction force becomes large and the required area for the rubber bearings becomes large. By assessing the current live load and dead load, it is confirmed that the required area for the rubber bearing is under the manufacturer's limit.

If the uplift force occurs during earthquake, function of isolation bearing cannot be taken into account (JRA 2012). By the calculation during earthquake, it is confirmed that the uplift will not occur and the bearing can be designed.

Because of the large area of rubber bearing, size of the upper shoe becomes larger than the current one. To accommodate this problem, steel saddle can be used to transmit reaction force (Figure 12).

For the replacement of the bearings, the truss girder is jacked up. It is confirmed that the jack up is possible with the reinforcement of truss members near jack points.

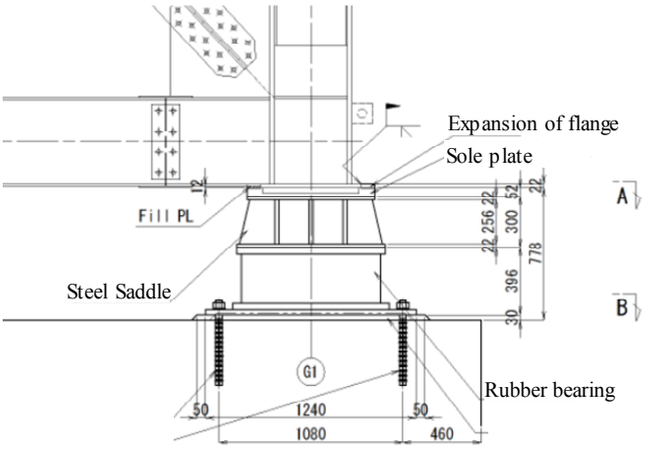

Figure 12. Rubber bearing with steel saddle

4.2 *Constraining effect of long rail*

Since the rail line is continuous to the adjacent concrete viaduct, longitudinal constraining effect of the long rail in the truss girder isolation is concerned. To clarify this effect, analysis using simple model was conducted (Ikeda et al. 2014). Analytical model is shown in Figure 13. Constrain between rail and structure is modeled by the nonlinear hysteresis model proposed in Ikeda 2014. Adjacent concrete viaduct has total length of 1,165m and 29 spans (4+4+3+8+10). It has very complicated structures such as two-level rigid frame and the soil conditions varies for each section. Therefore, instead of using full bridge model, the simplified model was used. The adjacent concrete viaduct was modeled as one-degree-of-freedom system with spring and mass. Total mass of the viaduct was used for the 1DOF mass. Spring constant was calculated by the target natural periods of 0.5s, 0.65s, and 0.8s. Target natural periods are selected referring natural periods of the viaduct.

Natural periods of the bridge are shown in Figure 14. By the constraining effect of long rail, natural period decreases by 13%. However, variation of the natural period of adjacent viaduct does not affect much.

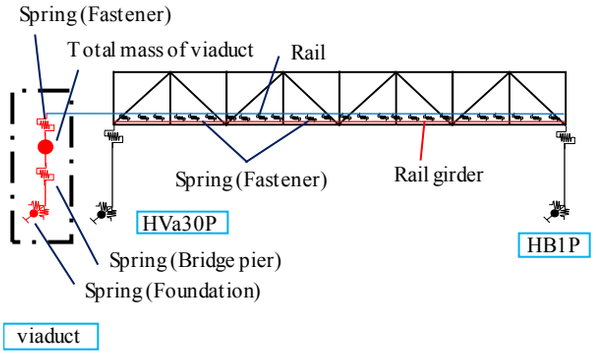

Figure 13. Analytical model

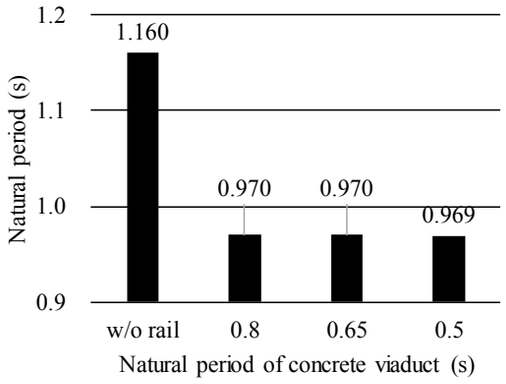

Figure 14. Natural period of the bridge

Response in the truss member is shown in Figure 15. The value in the figure is response divided by the allowable value. The response increases as natural period of concrete viaduct decreases. Even in the worst case, response is under the allowable value.

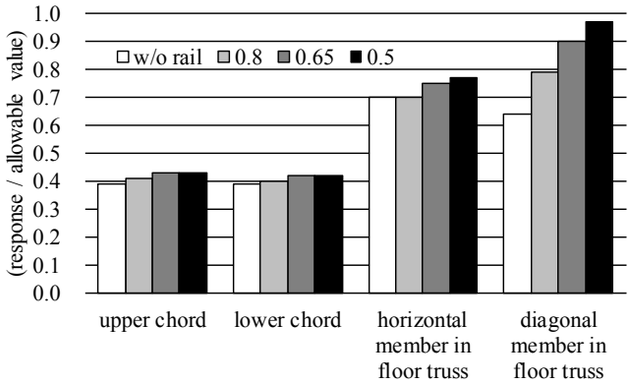

Figure 15. Response of the truss members

The number of damaged road deck bearings is shown in Figure 16. By the constraining effect of long rail, longitudinally-fixed road deck bearings at above Hva30P are damaged. With the increase of the natural period of the concrete viaduct, the number of damaged bearings decreases.

By the parametric study, it was found that damage becomes large when the natural period of adjacent concrete viaduct decreases. The natural period of the concrete viaduct ranges from 0.3 to 0.95. However, since the closest portion of the viaduct has the natural period of 0.75s, 0.65s is used for the seismic retrofit design.

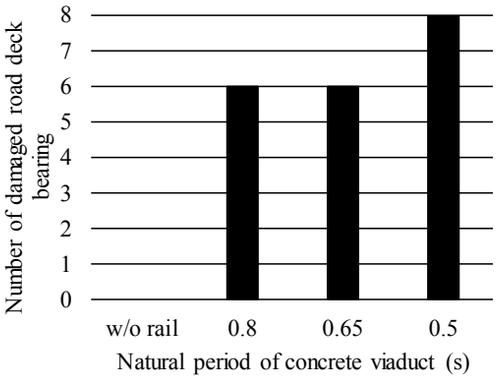

Figure 16. Number of damaged road deck bearings

4.3 *Running safety of train*

4.3.1 *Running safety of train during earthquake*

Running safety of the trains during the earthquake with high probability of occurrence for the bridge service life (Level 1 earthquake) shall be examined for the structure after the truss girder isolation according to the RTRI 2012. Using the analytical model, acceleration of each support point of rail girders were calculated with Level 1 earthquake. Acceleration data is then integrated to obtain displacement and vertical angle change at each support point. The result is shown in Figure 17. By the truss girder isolation, vertical angle change increases from about 1/1000 to 2/1000. However, the values are far below the critical value of 6/1000.

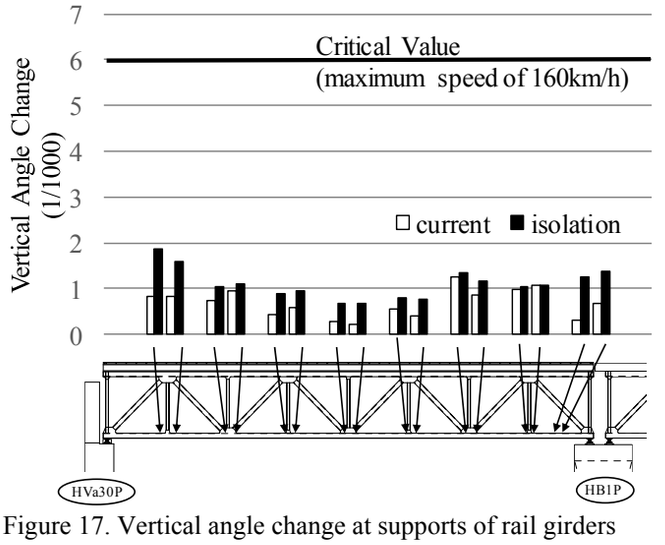

Figure 17. Vertical angle change at supports of rail girders

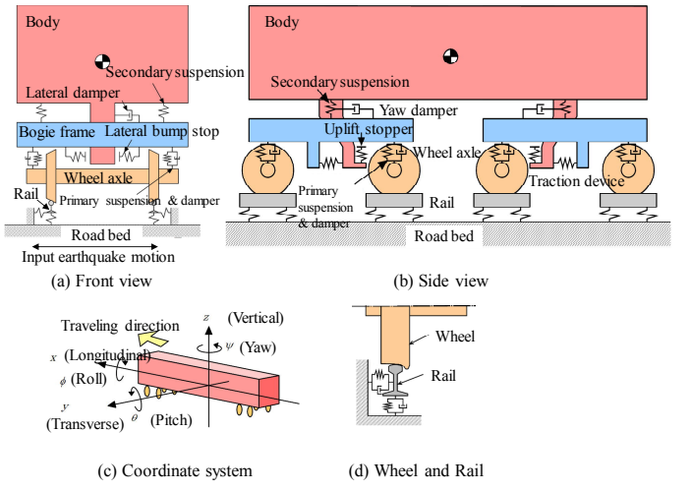
With Vehicle Dynamics Simulator (Miyamoto et al. 1998), behavior of train car under Level 1 earthquake was analyzed. The Simulator can input longitudinal, transverse, and vertical vibration and simulate jumping of the train car and large roll motion. Since it is confirmed that the results of single car model and formation model are similar, single car model was used. The model is shown in Figure 18.



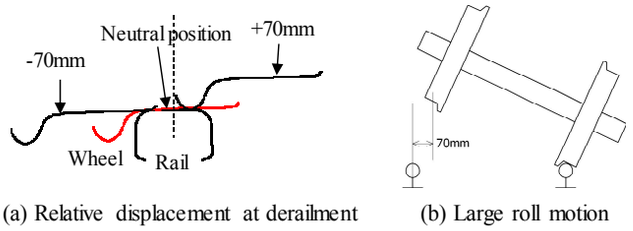


Figure 18. Simulation model

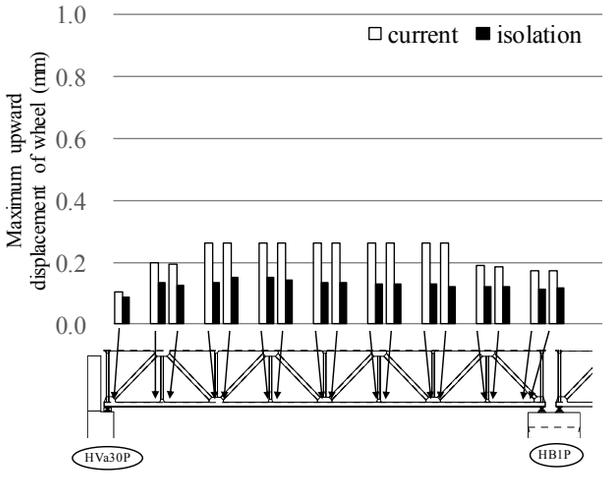
Derailment was judged by the relative displacement between wheel and rail. When this displacement reaches ±70mm, it is judged to be derailed (Figure 19).



(a) Relative displacement at derailment (b) Large roll motion

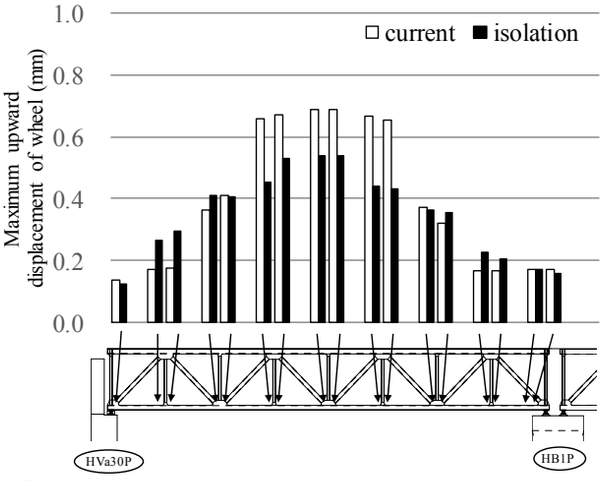


Figure 19. Criteria of derailment

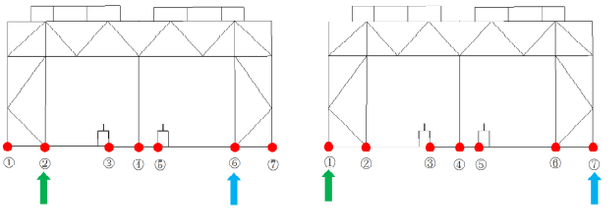
In the analysis Japanese bullet train (Shinkansen) and local train operating on Seto-Ohashi Briges were examined. For the local train, mass of passengers were also taken into account. Input seismic motion is the one calculated for the previous analysis for vertical angle change.

Results are shown in Figure 20. For all the cases, maximum upward displacements are less than 1mm, far below the critical value of 70mm. All the movements were caused by transverse movement of the wheel and the wheels were not detached from rail (Figure 18 (a)). For bullet train, displacement becomes small by the truss girder isolation. For local train, effect of the isolation varies.

(a) Bullet train (Shinkansen)



(b) Local train

Figure 20. Maximum upward displacement of wheel

4.3.2 *Running safety during bearing replacement*

During the replacement of bearings, the vertical displacement of the rail must be smaller than the value specified by the railway operator. In order to examine this, forced upward displacement is applied at jack point until the reaction force of the replaced bearing becomes zero and calculate the vertical displacement of the rail. Jack points for each end are shown in Figure 21. Calculated vertical displacement of rail is shown in Table 2. It was found that the vertical displacement of the rail is well under the specified displacement limit.

Specified limit	16	16	38	38

5 SEISMIC RETROFIT

From the above mentioned study, “truss girder isolation + reinforcement of road deck bearings” are selected as the seismic retrofit scheme for the steel truss portion of the Hitsuishi viaduct (Figure 22). The outline of the retrofit is as follows.

– For the isolation of the truss girder, current four hinged bearings for the truss girder are replaced

with isolation bearings (spring confined lead rubber bearings).
- For the replacement of the truss girder bearings, portions of floor truss and lower chord are reinforced for jack up.
- Eight road deck bearings above HVa30P are reinforced.
- For the settlement prevention devices (concrete blocks), vertical members in floor truss are reinforced in HB1P. For HVa30P, since the location of settlement prevention devices coincide with jack point, additional reinforcement is not required.

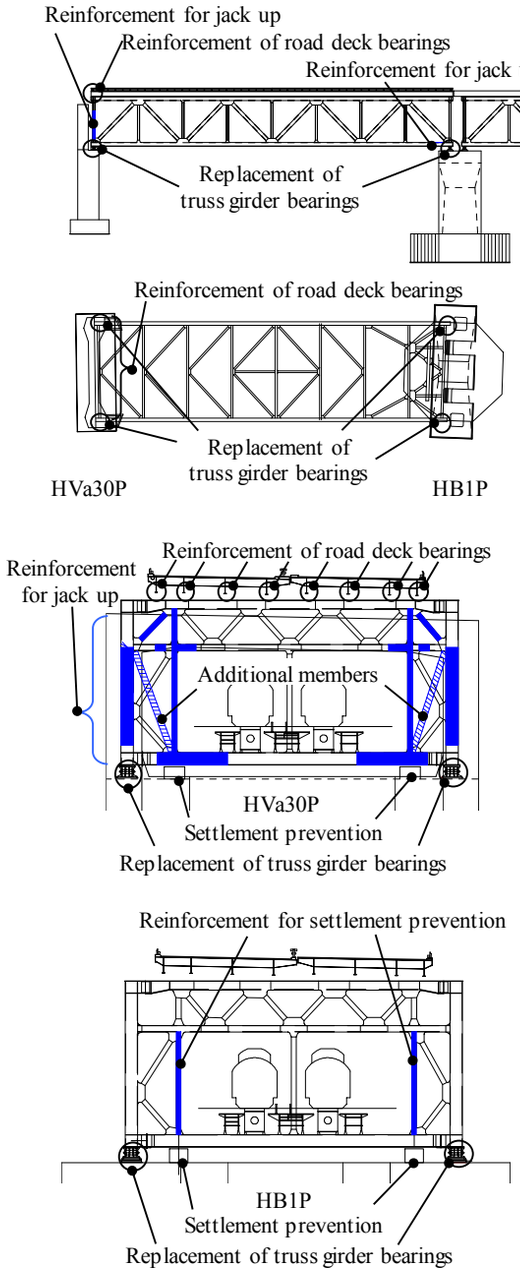

Figure 22. Seismic retrofit

6 CONCLUSION

As the seismic retrofit of truss bridge for highway and railway, truss girder isolation, which is unprecedented method for highway-railway combined bridges in Japan, was studied. For the retrofit design, constraining effect of long rail was taken into account. And it was confirmed that the running safety of train is secured after the truss girder isolation. Seismic retrofit work began in 2017 and will complete in 2018.

ABSTRACT: In this paper, the case of the transportation of an extremely heavy equipment of the combined heat & power generator is presented with the application of the live load factor for the assessment of the bridge for the special permit vehicle. The live load model (KL510) of the domestic highway bridge design code is used as the nominal live load and the statistical characteristics of the load model are reviewed for the application of the evaluation for the special permit vehicle. An example of the special permit for the modular transporter vehicle which carries an extremely heavy equipment for a power plant facility is presented. After the precision safety diagnosis with load test and the numerical analysis using a commercial finite element program, most of the bridges are short of the capacity and needed additional strengthening. After the completion of the transportation, a manual for permit process of the extra-heavy vehicle operation was written.

1 INTRUDUCTION

As the national economy develops, the industries are expanding and the technical capacities for transportation are increased. The demand for transporting larger or heavier cargo is continuously emerging. Also, the transportation of importing cargo which is not under the domestic weight or size regulation is inquired. These transporting vehicles might operate beyond the level of the ordinary traffic situation for which the safety level of the road facilities are designed and maintained. This is a very important issue in securing public safety for the road facilities and traffic.

The limitation criterion on vehicle operation is essential for the safety of the road structure, traffic, and environment. It is necessary for the road in conducting the inherent functions such as smooth transportation of logistics as a core network of a nation. Accordingly, most countries are establishing and operating limitation criterion on the size and weight of the vehicles considering each country's situation.

Generally, the limitation criterion on the weight of the vehicle driving on the road is divided into the axial weight limitation criterion and the gross weight limitation criterion. In this context, the limitation criterion of the axial weight is aimed at securing the safety of the road pavement, and the limitation criterion of the gross weight is based on the engineering theory and policy judgment for the purpose of securing the safety of the road structure, especially the bridge structure.

The size and weight of the vehicle that runs on the road in accordance with the Road Law in Korea are specified as limited to 2.5m in width, 4.0m (or 4.2m) in height, 16.7m in length, 10ton in axle weight and 40ton in gross weight. The purpose of restricting the operation of the over-sized or over-weighted vehicle is to preserve the road structure and to prevent the danger caused by the operation of this vehicle on the road.

According to the National Energy Basic Plan, the construction of the energy development complex is continuously increasing. In this paper, the case of the transportation of the combined heat & power generator is presented. The application for the permit to transporting the generator and the major equipment for a combined heat and power plant was requested in 2016 in Wonju Regional Construction and Management Administration. As the total weight of the equipment is about 1,200 tons, the application was rejected at the beginning and the alternative transportation via water channel had been recommended.

After considering the difficulties in other means of transportation and the public contribution of the power plant, the regional administration conditionally accepted the transportation. The applicant is required to verify that the safety of the road facilities and traffic is secured. In order to secure the safety of the road structures due to the over-weighted vehicle passage, the checking items for securing the structural safety of the bridges and the buried structures were examined by conducting the precision safety diagnosis before and after passing the structures. If necessary, the appropriate strengthening of the structure is designed and conducted.

After a complicated work between the administration, applicant and engineers, the transportation is completed (MLTM 2017a). The regional administration examined the existing regulations of the process for permit vehicle and wrote a manual for improving the efficient management of either restriction or permission of vehicle operation based on the experience of the transportation of the generator (MLTM 2017). The contents are summarized in this paper.

2 SAFETY ASSESSMENT FOR PERMIT VEHICLE

2.1 *Safety in design live load*

The Korean highway bridge design code (KHBDC) adopts the limit state design method and the live load model was determined based on the statistical and probabilistic study on t he domestic measured data. The safety margin in the design of the bridge is mainly achieved from the conservative selection of the live load and the load and resistance factors applied in the design combination.

The live load model of KHBDC is KL-510 and is composed of a standard truck model with four axles multiplied by 0.75 and a uniformly distributed load as shown in Figure 1. The weight and distance of axes were determined after a series of statistical study on the measured domestic truck data. (KIBSE 2015) The equivalent truck traffic to KL-510 is presented in Paik & Jeong (2017) and briefly summarized.

A reliable data measured from WIM system for highway vehicles in Korea was obtained. The statistical analysis method was applied to the data to estimate the weight for a 100-year design life of bridges. The moments obtained by applying the estimated weight are compared with KL-510.

The weight and type of vehicle model that yields the same load effect as KL-510 were obtained. The vehicle type which governs the load effect on bridges are the cargo truck with five axles. Depending on the span length, the single truck and the serial trucks govern the load effect. Figure 2 shows the consistency of the load effect by the statistically estimated trucks compared to the KL-510. Figure 3 shows the weight of the single truck which governs the moment for 15 meter span. Similarly, Figure 5 shows the weights of the two trucks in series for 30 meter span.

It is assumed that the distance between two back-to-back trucks is 5m with no impact and the distance between three back-to-back trucks is 15m each and the impact is 10%.

In order to consider the multi-lane loading condition, the statistically estimated load effect by the parallel two trucks is compared to that of KL-510. The two lane moment effect is shown in Figure 5. It shows that the KL-510 is very consistent with the statistically estimated truck load effect

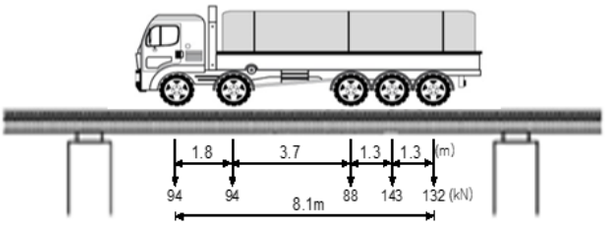

Figure 3 Estimated weight of a single truck on 15m bridge

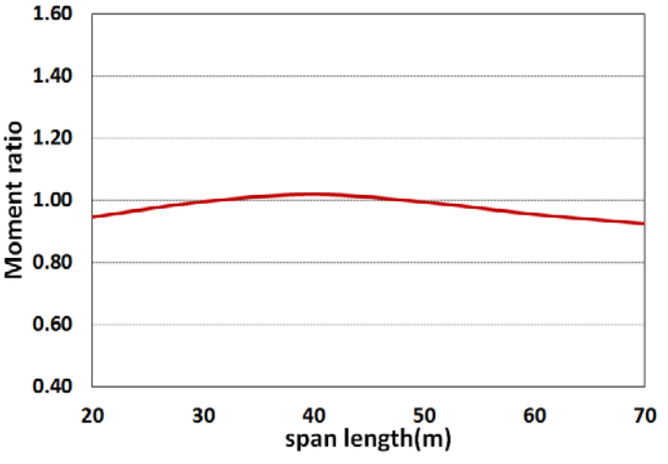

Figure 4 Moment ratio by estimated two serial trucks on two lane loading to KL-510

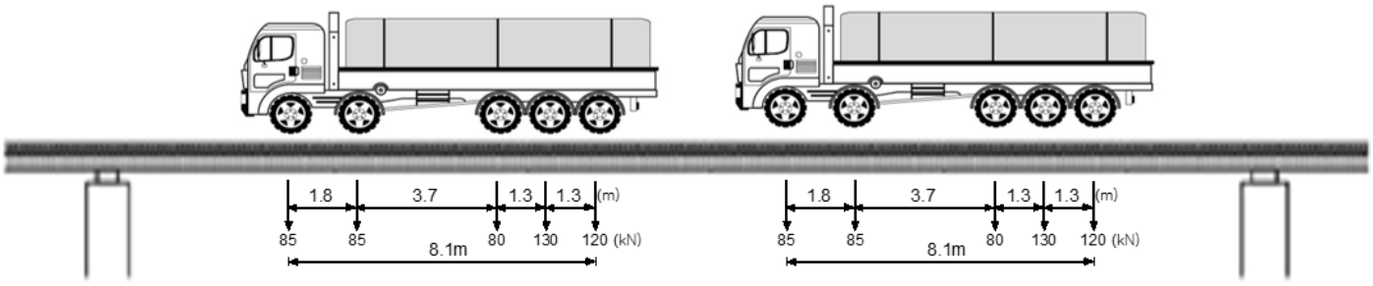

Figure 5 Estimated weight of two serial trucks on 30m bridge

2.2 *Live load factor for special permit vehicle*

The target reliability index for an existing bridge is usually lower than the target reliability index for a new bridge. This is because the uncertainty concerning the load and the bridge are reduced. Also, it is reflected that the cost required to increase the safety rate of the existing bridge is remarkably higher than that of the new bridge.

The design life of KHBDC is 100 years, and the target reliability index is 3.7. The design satisfies the target reliability by applying a live load factor of 1.80. On the other hand, the live load factor for a permit vehicle is 1.40. The Manual for Bridge Evaluation (AASHTO 2011) proposes a live load factor of 1.15 for the special permit with escorted crossing. As the weight of each axle of the permit vehicle transporting the generator was weighed on site, the uncertainty of the load from the vehicle was greatly reduced. For the safety check for the bridges on the route, the live load of 1.30 was applied.

3 EVALUATION OF BRIDGES FOR TRANSPORTATION OF GENERATOR

Precision safety diagnosis was carried out for all the bridges and buried structures on the route. The evaluation process followed the guidelines for the safety inspection and precision safety diagnosis (KISC 2008).

The precision safety diagnosis procedure is as follows. The possible route for transportation and the dimension and specification of the vehicle were collected and analyzed. The road surface inspection and the condition evaluation of the facilities on the route were carried out. The load test by testing trucks was carried out for the structures.

After the evaluation, it was decided that 13 bridges were strengthened by installing the temporary supports and 6 were bypassed among 20 bridges on the transporting route.

Structural behaviors were tested and measured by applying testing truck loads to the actual bridges and the results were compared with that of the structural analysis. Based on the safety assessment, the temporary supports were installed on the bottom of the bridge.

An example of the evaluation process is as follows. The example bridge located on the transportation route is a reinforced concrete slab bridge as shown in Figure 6. It is a 2-span continuous bridge and the total length is 20 m and the width is 19.5 m.

The total length of the vehicle was 38.6m and the width was 5m as shown in Figure 7. The vehicle regulation for protecting the safety of the road facility and traffic is 16.7m in length and 2.5m in width. In addition the height of the transporting trailer was 6.1m which is much higher than the height limitation of 4.0m for protecting the cross-road structures including overpass.

The weight of the transporting modular trailer was double checked by measuring all the axles by the portable weight meters at the site. The total weight of the vehicle specified on the application for permit was 469 tons and the measured value was 491 tons which was 4.6% higher than the application and was accepted. The total weight of the trailer was extremely larger than 40tons limitation for a single vehicle. As there were 12 tires in one row in the direction of the width of the trailer and the width and length of the trailer was much larger than the ordinary single vehicle, the weight density applied by the trailer to the bridge structure might be somewhat relieved but was still much too large.

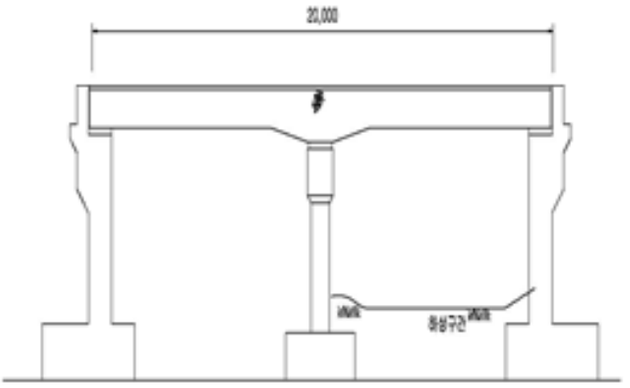

Figure 6 Longitudinal section of the example slab bridge

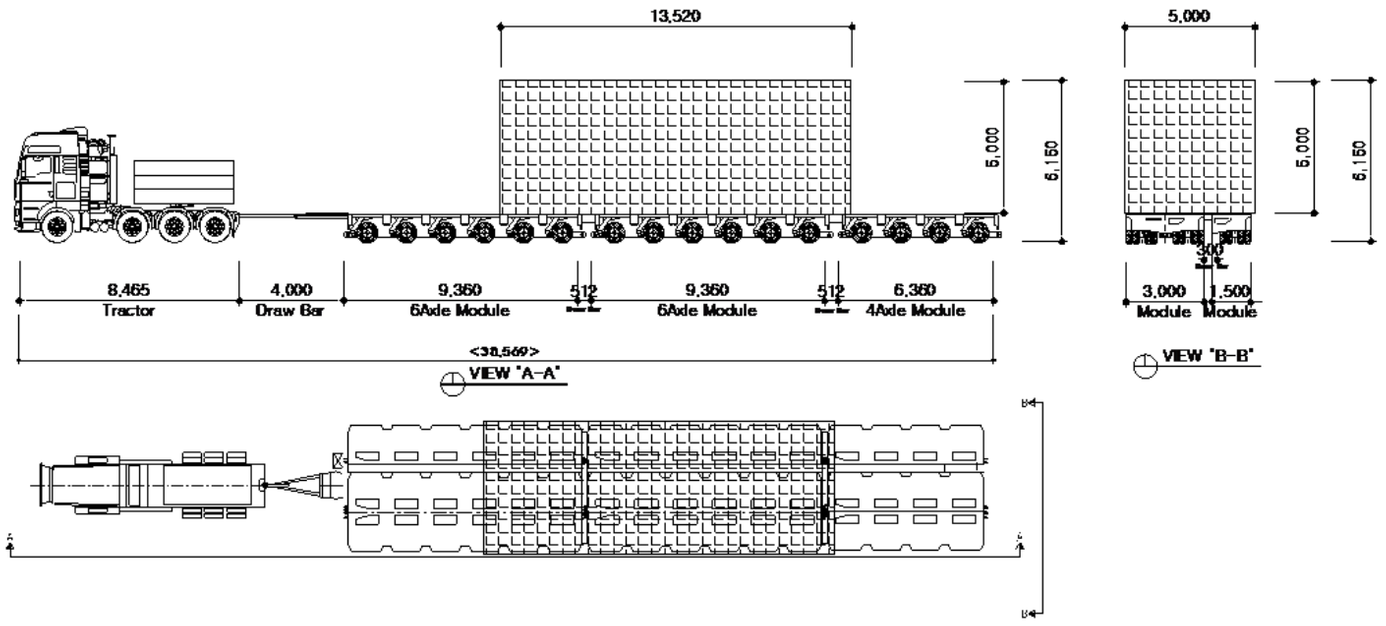

Figure 7 Dimension of the modular trailer transporting the generator

The numerical analysis was performed by using a commercial finite element program Midas Civil 2016. The bending moment diagram of the slab due to the modular trailer is shown in Figure 8. It was evaluated that the factored member force generated by the heavy load on the upper slab was larger than the design strength of the section. For this example bridge, the shear force near inner support much exceeded and the negative moment was below the capacity of the slab. Therefore, it was judged that the strengthening of the slab through the lower support was required when the heavy vehicle passes through.

The temporary support was designed and installed under the slab with the foundation of the support treated as shown in Figure 9.

Figure 10 shows the predicted displacement from the result of the numerical analysis for the supported slab bridge. After installing the support the shear force on the slab decreased and the resulted within the capacity of the bridge. The negative moment also decreased and fell within the capacity of the section.

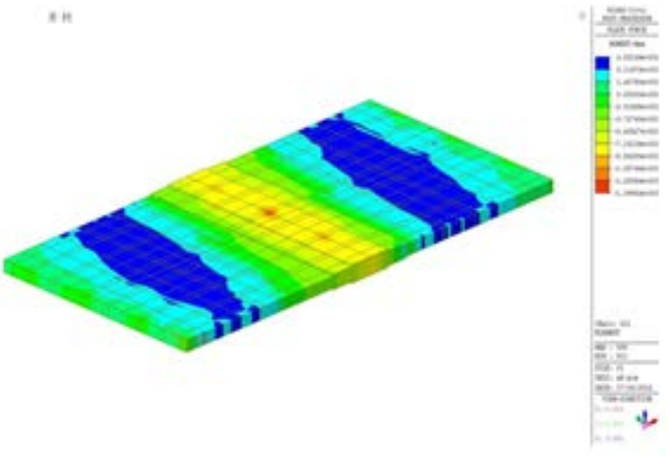

Figure 8 Bending moment diagram of slab bridge subject to modular trailer

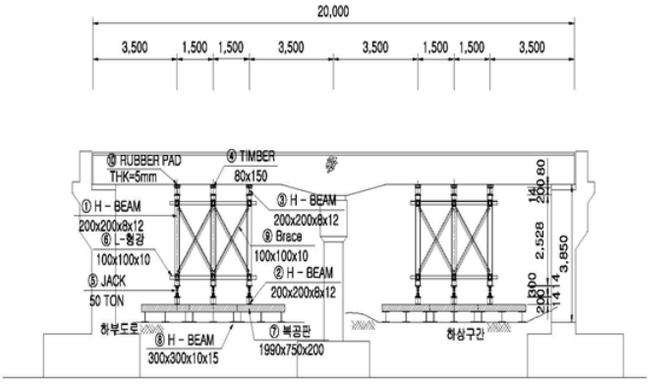

Figure 9 Longitudinal Section of the supported slab bridge

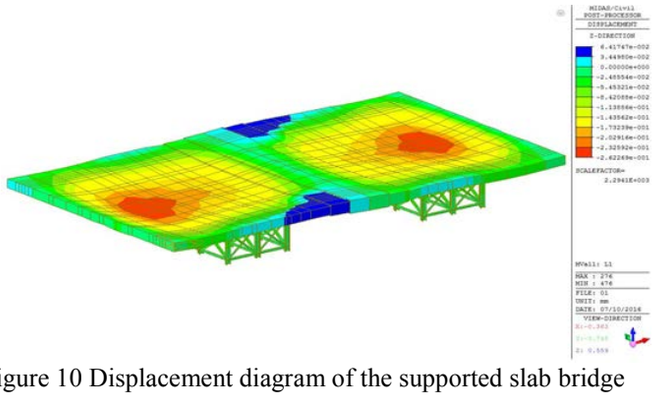

Figure 10 Displacement diagram of the supported slab bridge subject to modular trailer

4 TRANSPORTATION OF GENERATOR

The actual transportation was finally permitted after all the relevant regional authorities over the route to operate the vehicle were agreed. The agreement came after the preliminary measures for the operation of the permissible vehicle such as the measures for securing the road facilities and traffic safety, organizing the emergency action plan and insurance etc. were all met.

The specially permitted vehicle operated in the state where the person in charge of the relevant authority and the safety manager are present at the operation site. The applicant should operate an emergency service organization that could act as a control tower at the permitted vehicle operation site and report the operation result of the permitted vehicle to the road management office.

After completion of the transportation of the combined heat & power generator, the safety inspection and the pavement status survey was conducted within one month. The current status of the road facilities were compared with those before transportation and the maintenance and reinforcement should have been carried out in case of damage.

Bridges, culverts, etc., were subjected to safety diagnosis by specialty companies. No additional damages were observed except in some repaired sections. The inspection showed there were no serious defects that could impair the safety of the facilities

In order to secure traffic safety during the permit vehicle operation and to prevent and respond quickly to possible accidents, a number of supporting vehicles such as guide vehicles, spare cars, working vehicles, and ambulance are arranged in front of and behind the permit vehicle as shown in Figure 12.

5 CONCLUSION AND MANUAL OF PERMIT PROCESS FOR HEAVY TRANSPORTATION

After the consultation and review period for about 4 months (March to June) and the preparation process for about 4 months (July to November) afterwards, about 200km of transportation was completed.

In relation to the special permit for the operation of a super large and heavy vehicle, the present law stipulates the entity of the permission, object of the permission, authority for issuing the permission condition, and kind of document required for permission application and approval condition through Road Law. However, there is a limit to the operation of a special permit system for operating very large and heavy vehicles only by the current applicable regulations. In particular, the problems due to lack of procedural and method specificity for securing the safety of both of the road structure and traffic act as a big obstacle in the operation of the system.

In order to improve these problems, several things were proposed. First, the applicant should implement and establish various reviews and plans necessary for the operation of the permit vehicle before applying for the special permit. Second, the Road management office conducts document screening and permission reviewing. Third, only after passing the relevant review, the field demonstration and proactive measures should be conducted. Fourth, under the control of the control tower, the vehicle shall be operated according to the authorized vehicle operation plan. Fifth, after completion of vehicle operation post-measures should be carried out.

The followings are the procedures and methods that were established to the special permits for the operation of extra-large and heavy-weight vehicles considering road structure and traffic safety.

Evaluation of adhered sea-salt particle amount to bridge, anti-adhesion countermeasures

A. Toktorbai uulu & H. Katsuchi, H. Yamada
Department of Civil Engineering,
Yokohama National University, Yokohama, Japan

ABSTRACT: Bridges located near coastal areas are easy to get decreased their service life by corrosion attack. Airborne sea-salt particles adhered to bridge surfaces are the most influential and they are the reason for a significant section deterioration of bridge members. This paper investigates the amount of adhered sea salt particles at various parts of bridge girder surfaces. As a methodology, a wind-tunnel test was conducted. Bridge model was tested at the two kinds of wind velocity: 5.4m/s & 3.5m/s. Phenol particles were ejected as a role of sea-salt particles. Clearance effect was also tested at three different heights. Results showed the differences of adhered particle amounts at different part of girder surfaces. Finally, four possible methods are proposed to decrease the amount of adhered particles inside the bridge girders.

1 INTRODUCTION

Nowadays, the importance of bridge maintenance has been increasing. The reason is that the age of infrastructures, especially bridges, is getting old in the developed countries as well as in Japan. The bridges located near coastal areas are easy to get decreased their service life by corrosion attack. The governing factors of corrosion are temperature, humidity and various dusts on the surfaces. Among them, the adhered sea-salt particles are the most influential and they are the reason for a significant section deterioration of bridge members. Hence, for the efficient maintenance program, it is necessary to evaluate the behavior of the airborne sea salt particles at different part of a bridge deck.

It was reported that the site painting criteria or applicable criteria for weathering steel: the weathering steel is safe from corrosion and does not need painting if the amount of the adhered sea-salt particles to the bridge surface is less than 0.05mg/dm²/day (mdd) (Ohya 2009).

Because of the negative effect of the airborne sea salt particles for the steel bridges, on-site measurements of the amount of airborne sea salt particles have been carried out. There are two main methods that are extensively used in order to measure the amount of airborne sea salt particles in Japan. One is so-called "Doken tank" method (Public Works Research Institute method), the other one is the dry gauze method. The "Doken tank" method uses the special sampler tank to collect the airborne sea salt particles. The dry gauze method grabs particles with its dry gauze-patch which is exposed near bridge surfaces. However, from only the results, it is difficult to evaluate how much airborne sea salt particles can be adhered to the surfaces of a bridge when equipment is fixed in one position. Therefore, various methods have been developed to predict the detailed behaviors of airborne sea-salt particles by other researchers. For example, Obata et al. (2008) proposed a numerical framework to predict the adhesion behavior of sea-salt particles on a bridge surface. Moreover, they made an in situ observation in order to estimate the concentration and amount of airborne sea-salt particles. Iwasaki et al. (2007) proposed an observation method to estimate the level of partial corrosion of a bridge exposed to airborne sea-salts. Besides, they conducted a numerical simulation to compare the simulation data with their observation data. Hasebe et al. (2015) developed an experimental method to estimate the amount of the adhesion to the surface of a bridge model by ejecting a mist included salt particles.

Our work was to evaluate the adhesion behavior of sea-salt particles at the bridge girder and investigate the amount of adhered airborne sea-salt particles at different part of bridge girder surfaces by wind-tunnel which has unique test facilities. Additionally, CFD analysis was carried out for further understanding the wind-tunnel experiment results. Finally, four kinds of countermeasures were proposed to decrease the amount of the sea-salt particle's adhesion at the inside of bridge girders.

2 WIND-TUNNEL EXPERIMENT

2.1 *Experimental settings and conditions*

An open wind-tunnel with unique test facilities of Yokohama National University (YNU) was used for the measurement of the airborne sea-salt particles' behaviors. Figure 1 shows the general view and the inside of working section of the wind-tunnel in YNU. The size of the working section is 1.3m wide and 1.3m high. Figure 2 illustrates the experiment setting. In the wind-tunnel test, phenol particles were ejected from the ejection nozzle to the model bridge side as a role of sea-salt particles since their properties are close to the real sea-salt particles. As a target bridge, a highway four I-shaped steel girder bridge was chosen and its model was made up at the scale of 1/60. The model bridge was tested at two kinds of wind velocity: 5.4m/s and 3.5m/s which are the annual wind speed of Naha city (Okinawa prefecture) and Yokohama city, respectively. The reason of choosing Okinawa is that many bridges are suffering from corrosion in Okinawa due to the sea-salt particles because they are located close to ocean. Wind-tunnel experiment settings, conditions and other parameters are shown in table 1. Phenol particles were ejected for 2 minutes and 5 times at the same conditions. Before starting the test, the adhesive tapes with the size of 1cm² was attached to the parts of model bridge girder surfaces in both sides at the parts of top flange, web top, web center, web bottom and both surfaces of bottom flange to capture the particles colliding with girder surfaces. Figure 3 illustrates the positions of the attached tapes at the each part of girder surfaces.

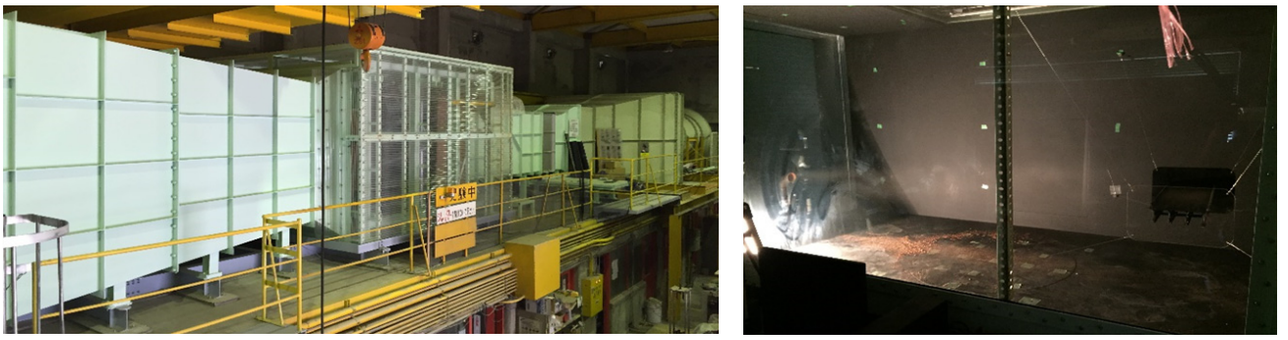

Figure 1: General view of YNU wind-tunnel (left) and its working section (right)

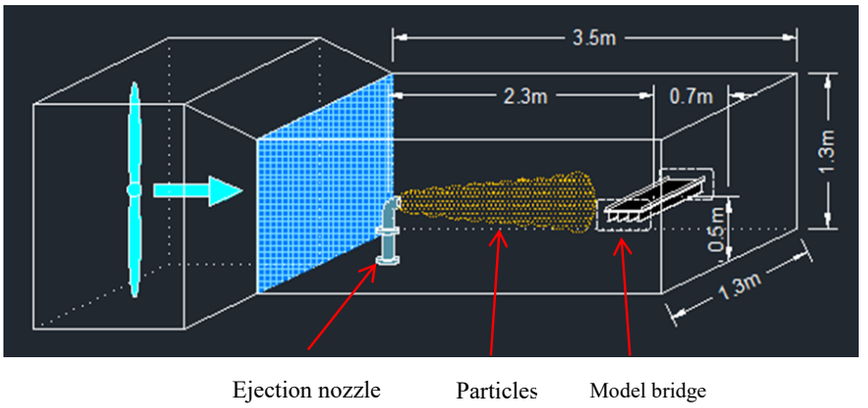

Figure 2: Experiment settings

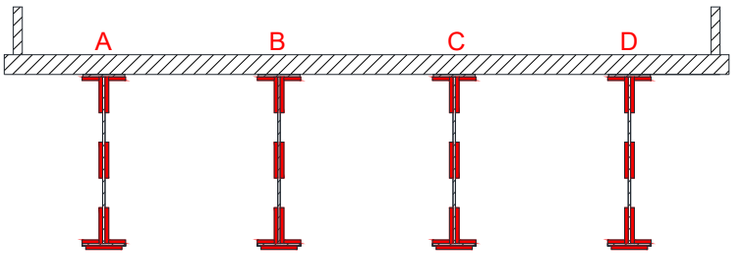

Figure 3: Positions of attached adhesive tapes on girder surfaces.

Table 1: Wind-Tunnel experiment settings and conditions

Settings	size and conditions
Working section	1.3m x 1.3m
Model scale	1/60
Blockage ratio	5%
Ejected particle	Phenol particles
Wind velocity	5.4m/s and 3.5m/s
Temperature	17ºC

2.2 *Reference test*

In order to check the uniformity of the particle flow ejecting from the nozzle, a reference model was tested before starting a test for the bridge model. The reference model which has a same height with the model bridge girder was fixed at the same height with the ejection nozzle. Adhesive tapes were attached to upside, middle and down side of the reference model surface. The model was tested at 5.4m/s three times (3 cases) repeatedly at the same ejection time that mentioned before. Figure 4 shows the adhered particles to the upside, middle and down side. The results showed that the differences in the amount of adhered particles are not significant. It indicates that the incoming particles are uniform (figure 5). Table 2 shows the average value of three cases and the ratio of amounts of adhered particles between them. Converted values into mdd were shown as well. The middle part has 4% more adhered particles and 12% more particles obtained from the down side. Obviously, particles mostly adhered to down parts because of the gravity force and wind load when the positions of the nozzle and model were located at the same level.

Middle	70	1.04	11.4
Downside	75	1.12	12.2

2.3 *Model bridge test*

After making sure that the income flow is uniform, the model bridge was fixed at the same position where the reference model was fixed. First, it was tested at the wind velocity 5.4m/s for the particle ejection time mentioned before. After finishing the experiment the amount of adhered particles was calculated from the each tape. Repeatedly, this experimental procedure was conducted 5 times at the same conditions. Thereafter, the average value of the amount of adhered particles of five cases was taken to get more accurate results. These sequences of experiments were applied for the wind velocity 3.5m/s as well. Figure 6 illustrates the amounts of the adhered particle distributions of the both wind velocities.

From the results it is shown that, at the wind velocity 5.4m/s has a slightly higher amount of adhered particles comparing with the wind velocity 3.5m/s. Front surfaces of both cases have an extremely large amount of adhered particles. It is because of the direct collision. However most of them may be washed down by the rain. It is important to estimate the amount of adhered particles inside bridge girders where no exposure to the rain. As for the inside, particles mostly adhered to the rear standing girders; those are the surfaces between “C” and “D”. This can be assumed that, for the stream separated from the leading edge it is hard to roll in between the anterior standing girders: “A” and “B”. On the other hand, it is easier to roll in between the rear standing girders.

2.4 *With clearance effect*

Some bridges and overpasses located in the urban area or over the small rivers may have a low clearance (distance between the down surface of a bridge or overpass till the water or earth surface). Bridges with this kind of a low clearance might have significant adhered airborne sea-salt particles due to the earth effect. This time, the model bridge with three kinds of clearance heights: 3m, 6m and 9m was tested in the wind-tunnel. An artificial floor was installed as a role of “earth” and the distance between the artificial floor surface and the lower part of the model bridge was regulated at each case of test according to the heights of clearances. The experimental conditions are same with the previous test. The clearance effect was tested only at the wind velocity 5.4m/s. Figure 7 illustrates the adhered particle distribution of three clearance heights.

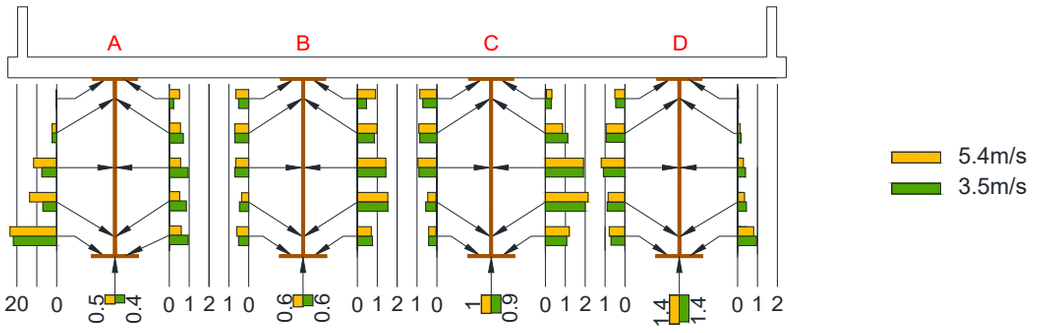

Figure 6: Adhered participle distributions (unit: mdd)

The results indicate that, the biggest amount of adhered particles was calculated from the case of the highest clearance (9m). It can be assumed that, the more space under the bridge, the bigger amount of the airborne sea-salt particles may attach to the bridge girder surfaces (range is up to 9m). However, as for the bottom flange surfaces, the biggest number of the adhered particles can be seen on the second girder "B", and the lowest is on the forth girder "D" (excluding first girder "A") in case of the lowest clearances (3m). As the clearance height is going to increase, the amount is changing to opposite. Specifically, in case of 6m clearance, the amounts of adhered particles are almost equal at the each bottom flange surfaces excluding first girder "A". In case of 9m clearance, the biggest amount is obtained from the last girder "D". This phenomenon can be explained as when the clearance is low, the separated stream from the leading edge is accelerated as it passes a narrow space under the bridge. Accordingly, the accelerated particle stream instantly (depending on wind speed) goes up and attaches to the closest object (girder "B"). When it has a higher clearance, the separated stream passes wider space under the bridge and mostly reattach to the ending part of bridge deck ("D"). Hence, the amounts of adhered particles at these bottom flange surfaces vary highly due to the different clearance heights.

Results of clearance effect (clearance 3m) were compared with the real observation data. Iwasaki and Nagai observed the amount of the adhered particles to the web surfaces of the bridge near the Niigata city with the clearance height of 2m (Figure 8). Since, our particle ejection time and density differed from the observation, we will compare only the distribution tendencies of adhered particles to the web surfaces. Thus, the observation data has the biggest amounts of adhered particles at the web-center. In our experiment, we obtained the biggest amounts of adhered particles from the web-center as well (figure 9).

3 NUMERICAL SIMU-LATIONS

3.1 *CFD analysis settings and conditions*

For further understanding the results of the wind-tunnel experiments, CFD (Computational Fluid Dynamics) analyses were performed. The visualization of the flow around the bridge girders was illustrated by CFD, which is difficult to obtain from the experimental work. Numerical analyses were performed using the CFD software program STAR-CCM+ that is able to simulate micro particles and their adhesion to solid surfaces. Figure 10 shows the domain size and notations of analyses which followed the recommendations of Sohankar (1998). According to his recommendations, the distance between inlet and model is 15D (D is a height of model) and the distance between the model until outlet is 25D. The height of domain region is 25D. Top wall was set as slip boundary. Bottom wall was set as slip boundary as well, but in case of "Clearance effect check", it was changed into non-slip boundary. Inflow stream is set uniform along the inlet boundary and the outlet boundary is set as where a pressure gradient is equal to zero along any stream lines. All the bridge surfaces are modelled as non-slip boundaries. The geometric dimensions of the model bridge were chosen to be same with the bridge model of wind-tunnel experiment. As for the meshing domain, the tetrahedral mesher was selected. The mesh size around the CAD model is much finer, 0.25cm. Fine mesh is important around the model for the more accurate visualization of flow. Then mesh size is going to be bigger (1cm and 5cm) as going far from the model area as shown in the figure 11. Non-steady state air flow analysis of 20 seconds was carried out for every simulation. After initial 7 seconds, 100 units of particles per one parcel representing the sea-salt particles are injected uniformly from the inlet every 1 second. It should be noted that the concentration of airborne particles is inversely proportional to wind speed under this particle injection condition. The other conditions of analysis are given in Table 3. The size 10μm of particle is determined according to the sea-salt particle originated from the ocean. The density was set 2.2 x 10^3 kg/m³. Wind velocities: 5.4m/s and 3.5m/s and the temperature applied to analyses are same with wind tunnel experiment settings. Relative humidity was set 0% since it has a negligible effect.

3.1.1 *Simulation results*

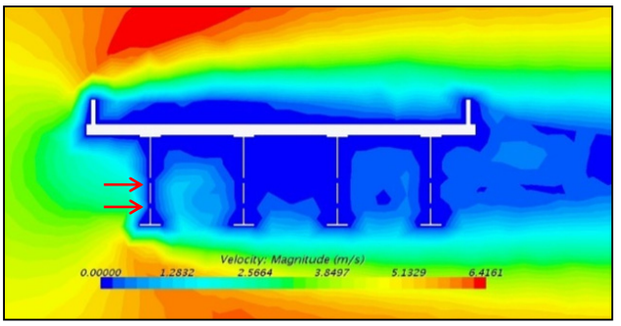

Figure12 illustrates the air velocity magnitude distributions of the two kinds of wind velocities: 5.4m/s and 3.5m/s around the bridge deck. The red areas on the top and bottom indicate the highest flow velocities, the green areas on the front and after red areas represent intermediate velocities and the blue color arrows around the bridge deck and inside of bridge deck indicate the lowest velocity magnitude distributions. In figure 13, the red points illustrate the image of adhered airborne sea-salt particles to the bridge surfaces. A comparison of the results showed no noticeable differences of the adhered particles distributions between the CFD analysis and experimental work.

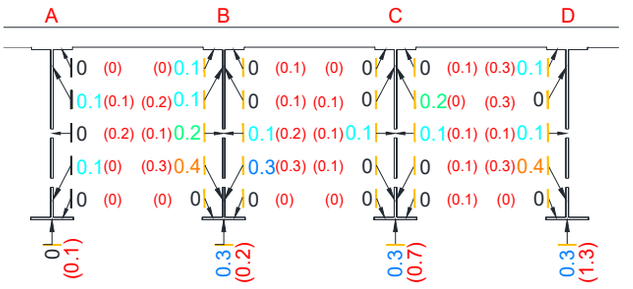
3.2 *Countermeasures*



Four possible methods in order to decrease the amount of adhered airborne sea-salt particles inside the bridge girders were investigated by the CFD methodology as shown in figures 14-17. The pictures on left side of each figure illustrate the derived results for the air velocity magnitude distribution. The flow direction of airborne sea-salt particles affected depending on these air velocity magnitudes. For instance, particles mostly attached where the higher air velocity magnitude shown around the model bridge. The pictures on right side show the results of the quantitative amounts of adhered particles of each method. The red colour numbers are present the amount of adhered particles in case of normal bridge without countermeasures. They were written in order to compare with the amounts of the countermeasures those were written in other colour numbers. Specifics of each countermeasure and their results are explained below.

3.2.1 *First method: Hole in girder*

Occasionally, a hole is open on the girders of bridges in order to pass through a water pipe, gas pipe or cables. Obviously, they consider the strength and safety of bridge girders. Following this, we tried to make holes with a diameter of 10cm at the centre and lower part of webs of bridge model section. It is expected that some incoming particles may pass together with an air flow through these holes of webs and the amount of adhered particles to the girder surfaces will be reduced. As shown in figure 14, the amount of adhered particles reduced inside the girders but not significantly.

Figure 16: Third method: Adding members at bottom flanges with an angle of 35º

Air velocity magnitude distribution

Quantitative amount of adhered particles

Figure 17: Fourth method: Adding members at bottom side between the girders

3.2.2 *Second method: Adding members at inflow and outflow sides*

With a 50cm length a member (stainless steel, aluminium or other metals that do not rust) can be added horizontally to the bottom flanges at inflow side and outflow side symmetrically. The purpose is to separate the incoming flow largely and create difficulty for this to roll inside the girders. Figure 15 shows the image of added member with the results of simulation. As shown in the results, the number of adhered particles significantly decreased but inflow side of last girder has still a slightly adhered particles.

3.2.3 *Third method: Adding members at bottom flanges with an angle of 35°*

Members with an angle of 35 degree are added to the bottom flanges at inflow side and outflow side of every girder to suppress the flow of particles coming to the inside of girders. Figure 16 shows the results of the air velocity magnitude distribution and the adhered particles inside the girders. The Figure indicates a good result but not better than the second method.

3.2.4 *Fourth method: Adding members at bottom side between the girders*

Added members in front side and rare side are same with the second method but additional members with a length of around 1 meter added between the girders as shown in figure 17. The purpose is to decrease the scope of particles entering to inside girders. Closing all gaps completely would be the best choice, but the bridge owner needs to maintain inside the girders. Hence, a space that human or equipment can enter inside is necessary. The result shows not a big change comparing with the second method.

Among the four cases of countermeasures, the second method showed the best result. Simply by adding members at inflow and outflow sides symmetrically, it was able to decrease the biggest amount of adhered particles inside the bridge girders.

4 CONCLUSIONS

The study has investigated the adhesive behaviours of the sea-salt particles to the girders of four I-shaped steel girder bridge. Based on experimental and numerical analyses, the following conclusions can be highlighted:

- Both the experimental test and the numerical simulations showed that the higher the wind speed is the bigger number of the adhered particles to the bridge surfaces is obtained.
- Amount of adhered particles with the clearance effect had a good agreement with the observation data. The amounts on the down flanges are highly variable depending on the clearance height.
- The visualization of the airflow and the distribution of sea-salt particles to bridge surfaces were derived by CFD.
- A comparison of the results showed no noticeable differences of the adhered particle distributions between the CFD analysis and experimental work.
- Methods of countermeasures confirmed that by adding members to a bridge, it is possible to decrease the amount of adhered particles to the girder surfaces. Among them, the second method showed the best result.

Influence of collision on structural performance of steel girder

E. Yamaguchi, Y. Tanaka & H. Tsuji
Kyushu Institute of Technology, Kitakyushu, Japan

ABSTRACT: An overpass is occasionally damaged by a truck running underneath. Typical collision damage in a steel girder bridge includes the deformation of a main girder, the buckling of a transverse stiffener and the removal of a transverse stiffener from the web. The influence of the damage on the safety of the bridge needs be judged. Yet it is not always an easy task, since the load-carrying capacity of a girder damaged by collision has not been studied much. The first author has been involved in the evaluation of a highway steel girder bridge damaged by collision. Based on the data obtained from that bridge, the load-carrying capacity of the deformed girder is studied numerically in the present study. To be specific, the deformation of the main girder due to collision is reproduced by the finite element analysis and the deformed steel girder is loaded to evaluate the load-carrying capacity. The result indicates that as far as the damage is confined to the deformation of the girder, the collision does not threaten the safety of the bridge even when the deformation is quite large.

1 INTRODUCTION

Occasionally a truck running on a highway collides with a bridge across the highway. It is required to evaluate the influence of the accident on the bridge to ensure the safety of traffic on it. However, study on such influence appears very limited. As a result, the bridge tends to be attended overly.

In Japan, the construction of railways preceded that of highways. Therefore, the clearances under quite a few railway bridges do not satisfy the current requirement, which leads to more collisions of trucks with railway bridges. Some technical reports on collision damage in railway bridges are available in the literature (Nieda & Suzuki 2000, Suginoue et al. 2006, Nakayama et al. 2008 among others). Most of those technical papers describe only damages and the first-aid measures employed without touching on the safety issues such as the influence on the stiffness and the load-carrying capacity. The investigation by Nakayama et al. (2008) is one of a very few studies on the influence of collision damage on the load-carrying capacity of the damaged main girder.

Nakayama et al. (2008) first studied the characteristics of collision damage in the steel railway bridge. They stated that out of 14 damaged bridges, eight bridges were subjected to severe damage such as the deformation of track, the fall from the bearing and crack in the main girder, which have resulted in the immediate closure of those railway bridges. The remaining six girders underwent only the deformation of the main girders. The major deformations of those six girders were found to be classified into three groups: local upward deformation of the lower flange, horizontal deformation of the lower flange and the combination of the two. Focusing on the damages of the first two groups, Nakayama et al. (2008) have investigated the load-carrying capacity of the deformed girder experimentally and numerically. To that end, they prepared three girder specimens. The span of each girder was 5360 mm long and the difference between the three girder specimens lies in the initial deformation: one had no deformation, another girder had a locally upward displacement of the lower flange up to 78 mm and the lower flange of the other girder was displaced horizontally up to 27 mm. These initial deformations were decided referring to the maximum values they observed in the actual railway bridges damaged by the collision. Their research results have revealed that the damages they considered have insignificant influence on the load-carrying capacity. They have observed the tendency that the collision increased the capacity. They stated that a possible reason for this phenomenon was the strain-hardening due to the deformation caused by the collision.

The first author has been involved in the safety evaluation of a highway steel bridge damaged by collision. The damage of the main girder was severer than the one investigated by Nakayama et al. (2008). Yet no cracks in the web plate and no significant damage around the bearings were found. The main

Figure 1. Damaged bridge.

Figure 2. View from underneath.

concern was therefore the load-carrying capacity of the damaged girder. The present paper deals with this issue.

2 OVERVIEW OF BRIDGE

The highway bridge to be studied is a single-span steel girder bridge across an expressway and was damaged by collision (Fig. 1). The bridge is 29.8 m long and the span is 29.0 m long. The superstructure consists of two main girders and orthotropic deck. The main girder has transverse stiffeners while the orthotropic deck has longitudinal stiffeners and cross girders. Lateral struts are also installed to support two pipes. The view of the bridge from underneath is given in Figure 2.

3 DAMAGE

Only one of the main girders was found damaged. This is because the expressway below the damaged part of the bridge is uphill. The lower flange and the web were displaced outward, as is shown schematically in Figure 3. The cross girders set in the upper

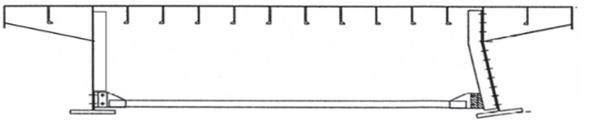

Figure 3. Deformation due to collision.

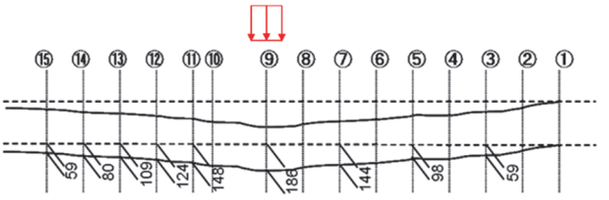

Figure 4. Horizontal displacement of lower flange.

part of the web restricted the web deformation only to the lower part. The residual horizontal displacements of the lower flange due to the collision were measured, the results of which are presented in Figure 4.

29 transverse stiffeners are welded to each web in addition to those at the bearings. The cross section having the transverse stiffener is given the number; the section closest to the abutment A2 is Section 1 and the section closest to the abutment A1 is Section 29. The circled numbers in Figure 4 correspond to those section numbers.

Figure 4 indicates that the largest horizontal displacement was caused around Section 9, which is 8.8 m away from the A2 bearing. A truck must have collided with around Section 9. The displacement at Section 9 is 186 mm, which is 1/156 of the span length. Note that the residual displacement of the girder studied by Nakayama et al. (2008) is 1/199 of the span length and that the Japanese design specifications (Japan 2012) requires the initial deflection to be less than 1/1000 of the member length.

The deformation of the main-girder web and the lower flange are not the only damage. In addition to them, some transvers stiffeners were bent and/or buckled; some welded connections between the transvers stiffeners and the web were fractured, separating the transvers stiffeners from the web; and some bolted connections between the transvers stiffeners and the lateral struts were broken, separating the lateral struts from the transverse stiffeners.

4 COLLISON LOAD

It was observed that the lateral strut at Section 11 was separated from the transverse stiffener and that it was held between the two main girders. Since the residual horizontal displacement at Section 11 is 148 mm, the phenomenon can be created if and only if the maximum horizontal displacement of the lower flange at Section 11 due to the collision had been equal to or

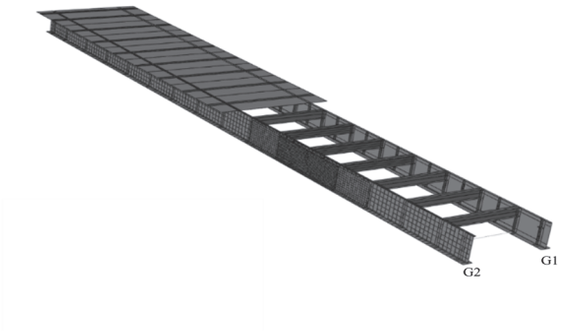

Figure 5. Finite element mesh.

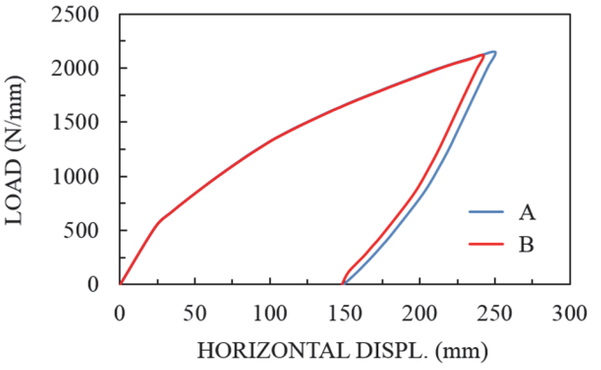

Figure 6. Horizontal load- lower-flange displacement curve at Section 11.

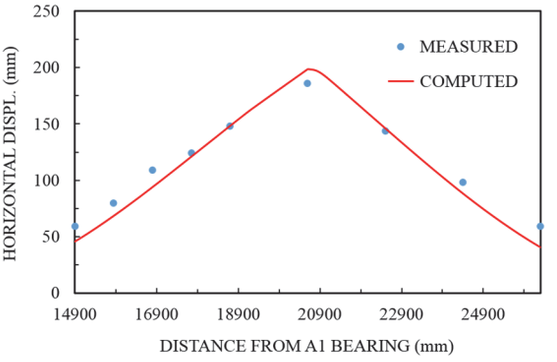

Figure 7. Horizontal displacement of lower flange.

greater than 148 mm while the residual displacement would have been smaller than 148 mm if not for the lateral strut at Section 11.

Herein the static load that can cause the above situation is estimated by the finite element analysis that takes into account the material and geometrical nonlinearities. This load has the effect virtually equivalent to the collision and so it is called the collision load in this study. For this analysis, ABAQUS (Dassault 2008) is used. Shell elements are employed for all the members except for the lateral struts that are modelled by beam elements. Since major deformation of the web is in the lower part and the primary role of the orthotropic deck is to provide the main girders and the cross girders with the clamped edge, the deck is modelled as a very stiff plate for the sake of simplicity. The finite element mesh is shown in Figure 5.

Steel used for the bridge is SM490Y specified in Japan Industrial Standard. Young's modulus E is 205 GPa and Poisson's ratio 0.3. Yield stress is 365 N/mm^2 for the plate thickness t less than 16 mm and 355 N/mm^2 for 16 mm $\leq$ t < 40 mm. Beyond the yield stress, the uniaxial material stiffness is assumed to be E/100. The elastic-plastic behavior of von Mises type with the kinematic hardening rule is assumed.

As noted earlier, the largest horizontal displacement was found around Section 9 (Fig. 4). The coating on the bottom surface of the lower flange was scratched out near Section 9. It is then legitimate to conclude that the collision had happened in this portion.

In the present study, based on the observation of the scratch on the coating of the lower flange, the collision load is assumed to be the uniformly distributed load over 400-mm range, as the red arrows in Figure 4 indicate. With this load, various analyses are conducted and it is found that once the load is increased up to 2145 N/mm, the total removal of the load leaves the displacement of 148 mm. The load-displacement curve A in Figure 6 represents this mechanical behavior. The curve A also shows that the displacement is 148 mm at 1650 N/mm. Therefore, the collision load must be between 1650 N/mm and 2145 N/mm for the lateral strut at Section 11 to be sandwiched between the main girders.

The lateral strut at Section 11 was found bent by 8 mm. The finite element analysis of this member under axial load is conducted using shell elements and the axial load that causes the 8-mm deflection turns out to be 45 kN.

The bridge is then analyzed again together with the point load of 45 kN, the reaction from the lateral strut, at the lower flange of Section 11. It is found that the collision load of 2120 N/mm leaves the horizontal displacement of 148 mm with the presence of the point load: the load-displacement curve B in Figure 6 is the result with the point load of 45 kN at the lower flange of Section 11. The computed residual horizontal displacement of the lower flange is plotted together with the measured displacement in Figure 7. Fairly good agreement is observed, confirming the validity of the present analysis.

5 INFLUENCE OF COLLISION DAMAGE

5.1 *Load-carrying*

To evaluate the influence of the damage caused by the collision, the load-carrying capacity of the damaged girder by itself is computed by the nonlinear finite element analysis. The girder to be analyzed here is taken out of the bridge deformed by the collision

Figure 8. Loading condition.

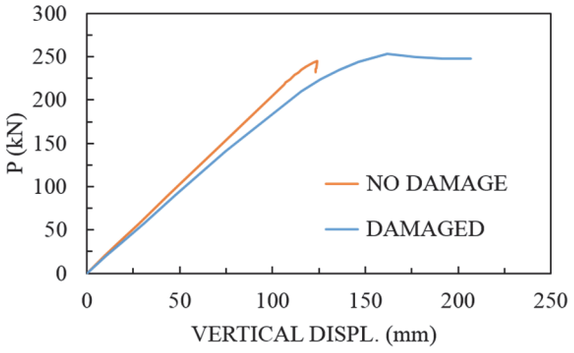

Figure 9. Load P – vertical displacement relationships at Point C (influence of damage).

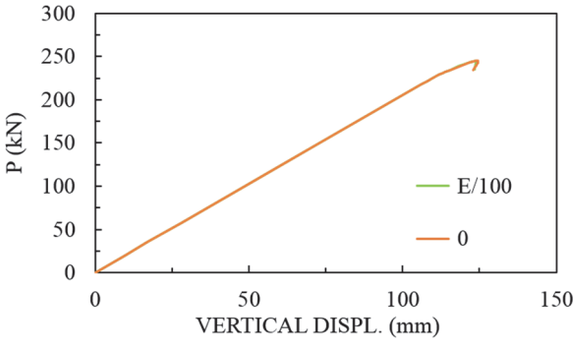
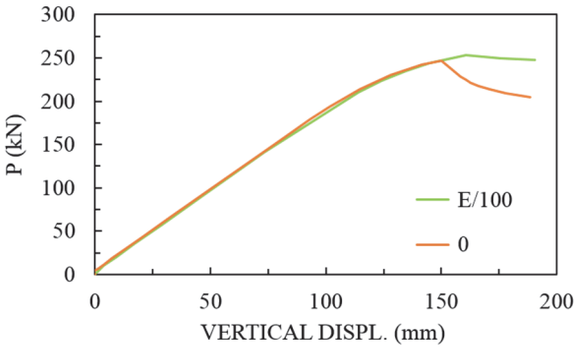
load in the previous section.



The girder is simply supported. The out-of-plane displacement, the rotation around the vertical axis and the rotation around the girder axis (torsion) are constrained along the top of the girder. As shown in Figure 8, two point-loads are applied at the top ends of Sections 8 and 10, as the severest damage is around Section 9. Point C is located at the bottom of the web at the center between Sections 8 and 10. To quantify the influence of the damage, the original (intact) girder is also analyzed.

The numerical results in terms of the load P and the vertical displacement at Point C are presented in Figure 9. The figure shows that while the stiffness is reduced by 8%, the 3% increase in the maximum load, from 243.0 kN to 253.0 kN, is observed. The intact girder exhibits little nonlinear behavior, but the damaged girder undergoes nonlinear response rather extensively.



Nakayama et al. (2008) conducted the similar study and observed the same phenomenon of the increase in the load-carrying capacity due to the collision damage. Their study is based on the girder which has the largest horizontal displacement of 1/200 of the span length. This magnitude is just about the maximum they observed in their investigation of the damaged railway bridges. Note that the damage in the present study is 1.4 times larger than theirs.

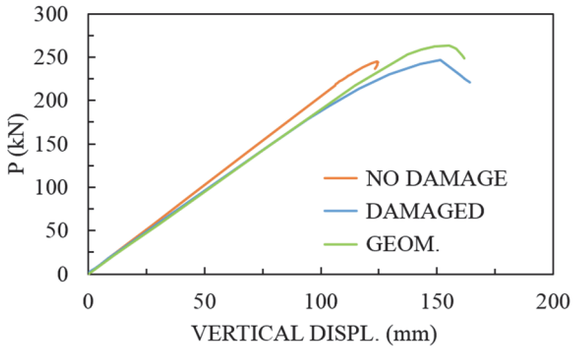
5.2 *Effect of strain-hardening*

Nakayama et al. (2008) have suggested that the increase in the load-carrying capacity is caused by the strain-hardening associated with the plastic deformation due to collision. To study the effect of strain-hardening, the numerical analysis is conducted,

(a) Intact girder

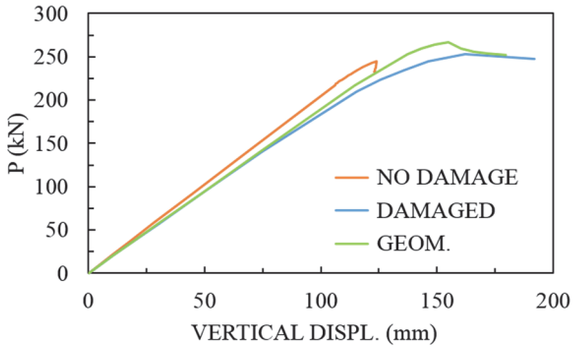
(b) Damaged girder

Figure 10. Load P – vertical displacement relationships at Point C (influence of plastic modulus).



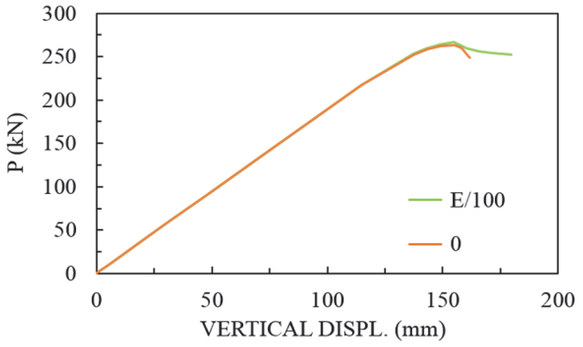
assuming zero second slope in the uniaxial material behavior in addition to E/100.

The numerical results in Figure 10 show that the load-carrying capacity of the intact girder is 245.0 kN for 0 and E/100 while those of the damaged girders are 246.7 and 253.0 for 0 and E/100, respectively. The load-carrying capacity becomes larger with the increase of the plastic modulus. But the load-carrying capacity has increased from 245.0 kN to 246.7 kN even when no strain-hardening is assumed. This result indicates that the phenomenon of the increase in the load-carrying capacity due to the collision damage cannot be explained well from the viewpoint of the strain-hardening.



5.3 *Effect of configuration change*

The difference between the intact girder and the damaged girder lie in the residual stress and the geometrical configuration. To see the influence of the configuration change solely, the residual stress is eliminated from the damaged girder and then analyzed. The results are shown in Figure 11 as GEOM together with the others.



Regardless of the magnitude of the second slope, the initial stiffness is the same as that of the respective girder analyzed in the previous section, the one with both the residual stress and the configuration change (DAMAGED). The change in the configuration is

(a) Zero second slope

(b) Second slope of E/100

(c) Influence of plastic modulus (GEOM.)

Figure 11. Load P – vertical displacement relationships at Point C (influence of configuration change).

therefore the main cause for the reduction in the stiffness. Even in the case of the zero second slope, the load-carrying capacity increases from 245.0 kN to 262.9 kN. Hence, it can be stated that the configuration change must be responsible for the increase in the load-carrying capacity.

The residual stress influences the plastification quite much. With the presence of the residual stress, plastic deformation starts in smaller load while without the residual stress, the maximum load is reached with little plastic deformation, resulting in the small influence of the second slope on the load-carrying capacity (Fig. 11(c)).

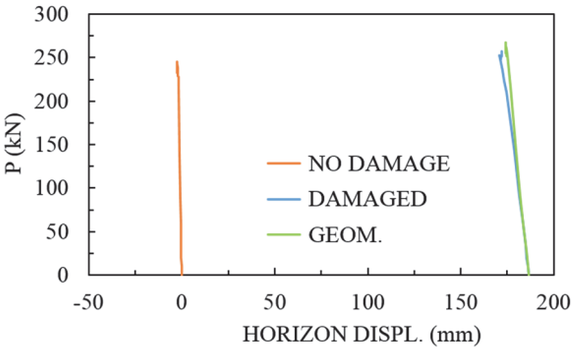


Figure 12. Load P – horizontal displacement relationships at Point C (E/100).

5.4 *Mechanical Behavior*

Figure 12 shows the relationship between the load P and the horizontal displacement at Point C. Except the intact girder, the horizontal displacement is not zero even before the loading, i.e. at P = 0, which represents the collision damage. With the point-loads increasing, those horizontal displacements tend to decrease: the deformed girders are returning to the original positions. The phenomenon is caused by the tensile stress acting in the bottom flange. The mechanical behavior of the deformed girder is thus quite different from that of the intact girder.

6 CONCLUDING REMARKS

The influence of the deformation of the steel bridge girder due to collision was studied. Through the nonlinear finite element analysis, the collision load was identified first, which gave the residual horizontal displacement of the lower flange comparable to that of the actual bridge. The influence of the damage due to the collision was then investigated. While the initial stiffness was found reduced by 8%, the bending strength becomes 3% larger. The subsequent analyses showed that the phenomenon was attributable to the configuration change that led to a quite different mechanical behavior from that of the original girder.

From the results thus obtained, it may be concluded that the deformation of the girder doesn't necessarily threaten the safety of the bridge. It needs be noted, however, that there is a chance that the damage other than deformation, if found, may lead to a completely different conclusion.

Institute of Construction and Environmental Engineering, Seoul National University, Seoul, South Korea

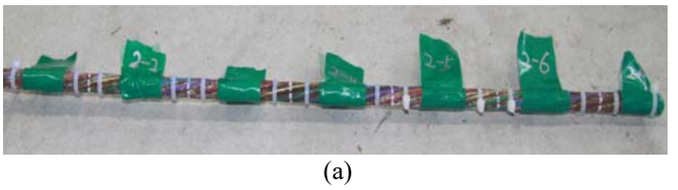
ABSTRACT: In bridges which had a tendon-like structural member, the corrosion is a main cause of deterioration of the structural resistance. For assessing the effect of corrosion in tendon, the transition of corroded section should be identified. For this purpose, strand samples were collected from prestressed concrete bridge site which had suffered the corrosion caused by chloride contamination. By utilizing camera and macro lens, corroded wire sections are scanned as pictures. Based on these pictures, the geometric properties of corroded wire sections such as pit angle and pit depth are analyzed. The corrosion of wire spreads rapidly with tangential direction at the early stage of corrosion. As the corrosion grows, the main direction of corrosion is changed to radial direction. Furthermore, the uncertainties of pit angle and maximum pit depth decrease as the corrosion of wire progresses. This research can help the modeling the corrosion in corroded wire under chloride contamination.

1 INTRODUCTION

In bridges which had a tendon-like structural member, the corrosion is a main cause of deteriorating the structural resistance. For assessing the effect of corrosion in tendon, the transition of corrosion in corroded section should be identified. Val and Melchers (1997) and Hartt and Lee (2016) assumed the shape of corrosion without verifying actual deformation of corroded section for assessing the effect of corrosion.

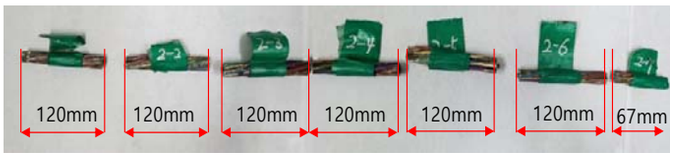
For identifying the shape of corrosion, 3D scanning technique was utilized in Kashani et al. (2013). However, this method is hard to apply in 7-wire strand because there is inner space in strand to which the sight of 3D scanner cannot reach. Therefore, this paper adopts taking a close-up pictures of corroded wire sections. From these pictures, the geometric properties of the corroded wire and the corrosion characteristics of the corroded tendon are analyzed.

2 DATA OF CORRODED WIRE SECTIONS



2.1 *Strand samples*

Strand samples were collected from prestressed concrete bridge site. The tendons of this bridge site has suffered chloride contamination with grout void occurred from bleeding of grout. Strand samples were selected whether there is a visible corrosion. Strand samples were cut into about 1m length for conducting fatigue test (Park et al., 2017). Corroded wire sections were investigated after this fatigue test.



For acquiring more wire section samples, strand samples were sliced into several number of pieces. The number of pieces is determined with considering the geometric form of strand and wire as shown in Figure 1. The twisted angle α around which outer wires wind center wire is about 82.5°. The radius of outer wire and center wire, r_o and r_c, are 2.5mm and 2.6mm, respectively. The length for putting outer wire in place is 243mm ($=2\pi r_h \tan\alpha$). With considering this length, strand samples were divided into 8 pieces which have about 120mm length. Figure 2 indicates the strand sample before and after cutting.

Figure 1. Geometric form of strand and its cross-section

(a)

(b)

Figure 2. Strand sample (a) before cutting, (b) after cutting

2.2 *Close-up photos*

Before extracting the information of corroded wire sections, one more preprocess for converting corroded wire sections to information of corroded surface is needed. Gonzalez et al. (1995) used a scale for measuring weight loss and a micrometer for measuring pit depth. Kashani et al. (2013) used a 3D scanning optical measurement technique and developed 3D solid models of corroded bars. The method used by Gonzalez et al. (1995) is good for pulling out the information related with average weight loss within samples, but hard to discover individual characteristics of corrosion surface. The method employed by Kashani et al. (2013) is effective in catching detail characteristics of corrosion surface. However, this method is difficult to apply in 7-wire strands because there is unobservable space where sight of 3D scanner cannot reach in 7-wire strands. Therefore, the method with utilizing camera and macro lens is selected. This method can check distinct corrosion boundary of corroded wire sections.

The configuration for taking close-up photos is represented in Figure 3. Camera with macro lens can classify the precise corrosion boundary as shown in Figure 4.

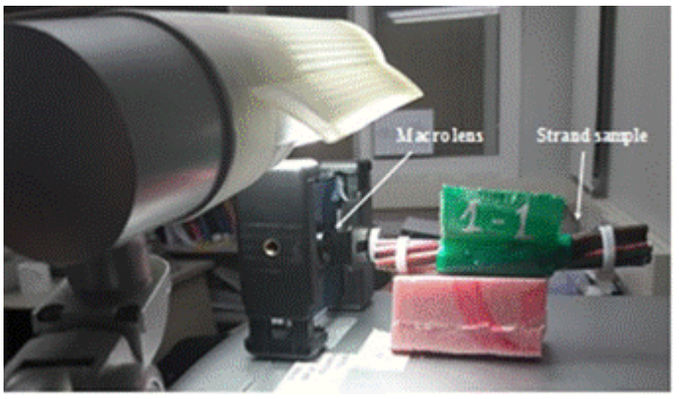


Figure 3. Configuration of taking close-up photos

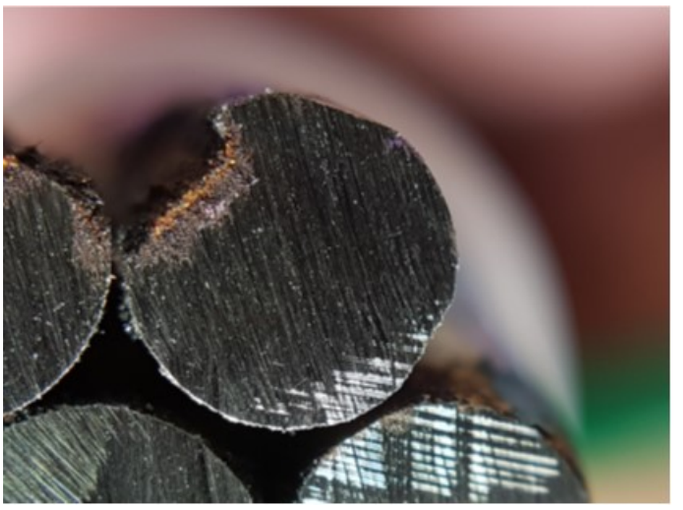

Figure 4. Example of close-up photo

2.3 *Geometric properties of corroded wire sections*

The shape of corroded boundary was identified from close-up photo of corroded wire sections. Two geometric properties as shown in Figure 5, pit angle θ and pit depth d, were extracted from close-up photos. Pit angle θ represents a tangential length of corrosion surface. Pit depth d is defined as a radial distance between outline of wire and corroded surface. In here, the maximum value among pit depth, $d_{\max}$, derived as Eq. (1) is mainly used in the analysis.

$$d_{\max} = \max\left(d_1, d_2, ..., d_n\right) \tag{1}$$

where $d_1, d_2, ..., d_n$ are pit depths obtained in same wire section.

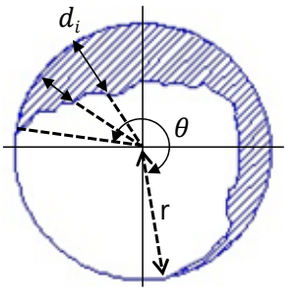

Figure 5. Geometric properties of corroded wire section

3 RESULTS AND DISCUSSIONS

3.1 *Pit angle and maximum pit depth of corroded wire sections*

The pit angle θ and pit depth $d_{\max}$ for each corroded wire sections were extracted from close-up photos. Corrosion was founded by total 90 wires. The results are represent in terms of average and coefficient of variation (COV) of pit angle and maximum pit depth in Figure 6 and 7, respectively. As can be seen in Figure 6, pit angle grows rapidly compared with maximum pit depth in the early phase of corrosion. On the contrary, maximum pit depth becomes deeper in the late phase of corrosion. This means that the direction of corrosion progress toward tangential direction at the early of corrosion stage. As the corrosion grows, the main direction of corrosion is changed to radial direction. Figure 7 describes that the variation of pit angle and maximum pit depth among wires decreases as the section loss increases.

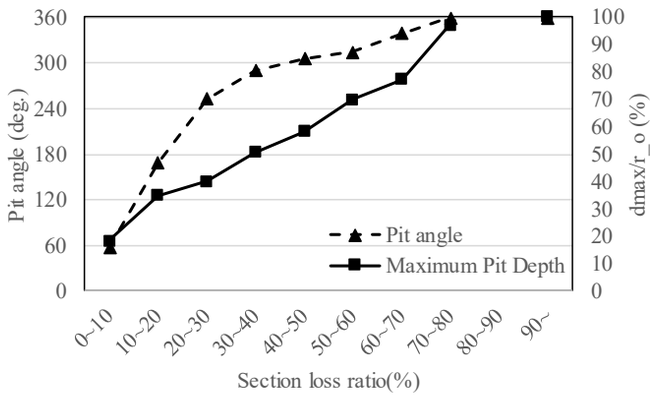

Figure 6. Average of Pit angle and pit depth versus section loss ratio

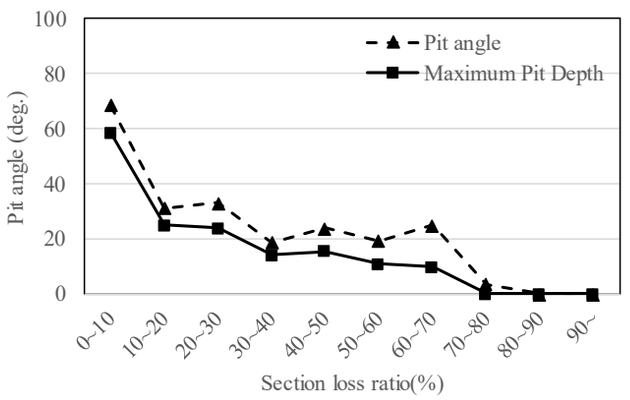

Figure 7. COV of Pit angle and pit depth versus section loss ratio

3.2 *Dispersion rate of corrosion in strand*

The corrosion characteristics of strand is analyzed with 47 corroded samples in the unit of strand. For this purpose, the section loss ratio which equals to section loss over cross-section of wire are calculated against the number of corroded outer wires and as shown in Figure 8. It can be shown that the section loss ratio increase as the number of corroded outer wires increase.

When only one outer wire is corroded among 6 outer wire, whole corrosion in strand is occurred in one wire. So its dispersion rate is 100%. If there are two corroded outer wire with same sectional loss, both wire has 50% of dispersion rate. Figure 9 represents a dispersion rate of corrosion in strand samples. It can be said that corrosion of strand is dispersed as the number of corroded outer wires increase

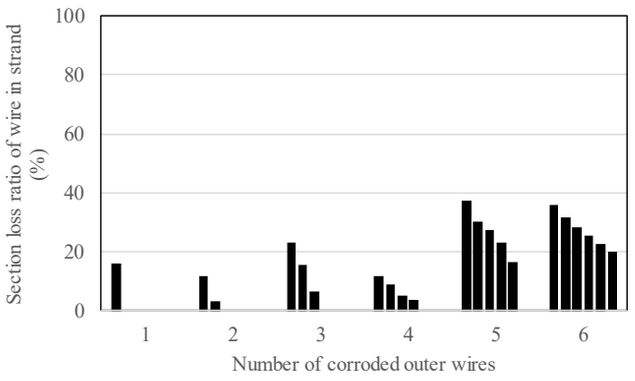

Figure 8. Section loss ratio versus the number of corroded outer wires

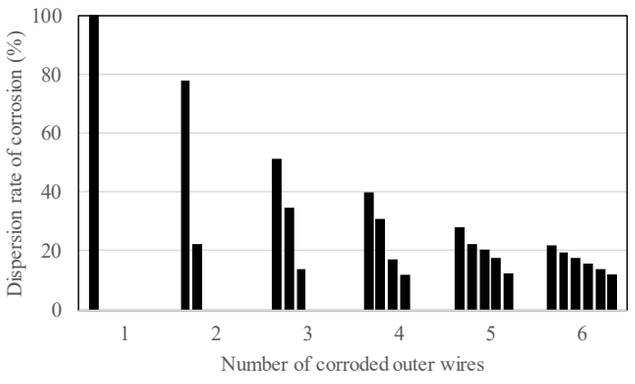

Figure 9. Dispersion ratio versus the number of corroded outer wires

4 CONCLUSIONS

Strand samples were collected from prestressed concrete bridge site which has suffered corrosion cause by chloride contamination. By utilizing camera and macro lens, corroded wire sections are scanned as pictures. Based on these pictures, the geometric properties of corroded wire sections such as pit angle and pit depth and the corrosion characteristics in strands are analyzed. The corrosion of wire spreads rapidly with tangential direction at the early stage of corrosion. As the corrosion grows, the main direction of corrosion is changed to radial direction. Furthermore, the uncertainties of pit angle and maximum pit depth decrease as the corrosion of wire progresses. In terms of corrosion of strand, the number of corroded outer wires shows an increasing tendency as corrosion grows. Also, it can be said that corrosion of strand is dispersed as the number of corroded outer wires increase.

This research can help the corrosion modeling of the corroded wire under chloride contamination.

GA-based Model Updating for Existing Bridges

J.C. Kim
Byucksan Engineering, Seoul, Korea

J. Yoon & S. Shin
INHA University, Incheon, Korea

ABSTRACT: In this research, a model updating technique based on GA(genetic algorithm) is developed and applied to an existing PS concrete girder bridge. Usually, numerical model updating requires long hours of optimization process and has troubles in accessing to a reliable target solution. To reduce the computational time and improve the accessibility, we developed a program whose whole process runs only in *Matlab* environment. The parameters used in the proposed model updating process include the design range of the crossover probability, mutation probability, and the step parameter adjusting the amount of increment of the parameter. It was confirmed that the model updating performance is improved when the gene arrangement of the chromosome is closely related to the property of an actual bridge and the static and dynamic characteristics are well applied to the fitness function. The importance of selecting parameter values was determined by complex model formation and the design range of reasonable parameters of the current model.

1 INTRODUCTION

According to the 2017 survey of Korean MLIT (Ministry of Land, Infrastructure, and Transport), about 10% of existing bridges in Korea are over 30 years old but the statistics will jump to more than 30% after 10 years from now on. Therefore, a reasonable and reliable way of evaluating existing bridges is critical to the safety and maintenance of existing bridges in Korea.

In evaluating a bridge, some formalized processes are already known to us; including investigation, NDT, loading tests, and evaluation of load rating, etc. In evaluating the load-carrying capacity of a bridge, an analytical model for the bridge should be determined. The methods of such model updating for bridge structures can be classified as direct methods and iterative methods. The direct methods include methods based on NN(neural network) and GA(genetic algorithm). Because direct methods simply minimize numerical errors in the system matrix so that it is difficult to have any physical meaning in the finally obtained model for a structure (Baruch and Itzhac 1978). In iterative methods, sensitivity matrix is usually utilized to search for optimal stiffness and mass properties. This approach is effective in improving the structural characteristics but it is difficult to apply for a complex structure because every parameter should be updated based on the sensitivity matrix (Mottershead and Friswell 1993). To overcome such problems in both methods, a model updating scheme was developed by combining a GA and commercial software for structural analysis (Kim 2016). However, one handicap of this approach is still the computation time required in running the repetitive process between independent GA program and a commercial software.

In this paper, a similar computational process is proposed between a GA program and structural analysis program but runs all in *Matlab* environments. The developed program has been examined through an application to a PS concrete girder bridge and the results are summarized.

2 APPLICATION OF GENETIC ALGORITHM

2.1 *Operation process*

The process of GA is illustrated in the left column of Figure 1; starting from the generation of initial population to elite strategy and termination criteria.

In creating initial population, the research created evenly distributed random numbers and utilized uniform pseudo-random sampling method to determine individual population (Ripley 1981, Maaranen *et al*. 2007).

The fitness function $f(x)$ is defined by the combination of an objective function $J(x)$ and a penalty function $p(x)$.

$$\textit{Minimize} \quad f(x) = \max \frac{1}{J(x) + p(x)} \tag{1}$$

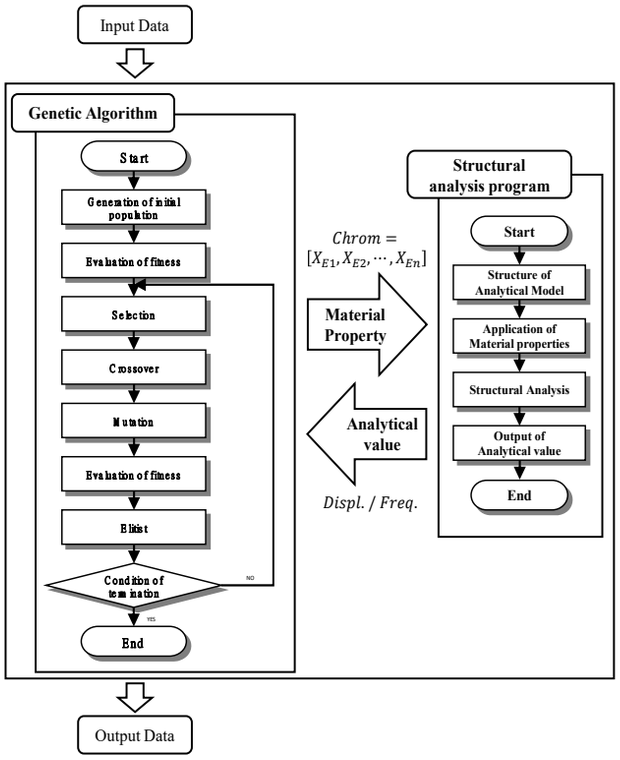

Figure 1. Process of GA-based analytical model updating.

For the penalty function, a variable penalty method of Eq.(2) by Cho(1999) was applied by indicating the increase of penalty factor as the number of population increases.

$$p(x) = (r \cdot k)^2 \sum_{i=1}^{m} g_i^2(x), \quad (k = 1, \ldots, n) \tag{2}$$

where r = penalty factor, k = number of population, n = total number of population, m = number of constraints, $g_i(x)$ = violation of constraints which equals to 0 when it satisfies the penalty function.

To select population, the gradient-like reproduction scheme by Jin and Joo(2000) was applied. For the cross-over, the homo-sexuality scheme by Yang and Kim(1995) was applied. For the mutation, a modified uniform or dynamic mutation scheme by Eq.(3) was applied.

$$X_i = \begin{cases} a_i + (UB - a_i) \cdot \lambda \cdot step_k & (\tau = 0) \\ a_i - (a_i - LB) \cdot \lambda \cdot step_k & (\tau = 1) \end{cases} \tag{3}$$

where UB = upper bound, LB = lower bound of design value X_i, λ = random number between 0 and 1, a_i = the i-th design variable among the mutation values, and $step_k$ = input variable defined by Eq.(4) between 0 and 1.

$$step_k = \left\{(step)^{1/n}\right\}^{k-1}, \quad (k = 1, \ldots, n) \tag{4}$$

When the fitness of the current generation is lower, a simple elite strategy is applied by changing the best fit in the current generation and the best fit in the previous generations (De Jong 1975).

Table 1. GA parameters suggested in the previous researches.

Parameters	Chung (2007)	Lee* (2000)	Grefenstette (1986)	Schaffer (1989)	De Jong (1975)
Population	30~200	-	30~100	20~30	50~100
Crossover Probability	.6~.95	.4~.8	.45~.95	.75~.95	.6~.95
Mutation Probability	.005~.01	.002~.05	.01	.005~.01	.001~.01

* When the mutation probability is 0.05, the design point tends to flow to the next optimal solution.

Table 2. Range of design parameters (Kim 2016)

Parameters	Population Size	Crossover Probability	Mutation Probability	Step
Design Range	30	0.1~0.9	0.01, 0.05 0.1	1, 0.1 0.01, 0.001

2.2 *Design parameters*

Because there is no clear theory about the effect of parameter values on the performance of genetic algorithms, the crossover, mutation, and the parameters at each step were determined through trial and error and summarized in Table 2 based on the previous researches shown in Table 1.

2.3 *Process of GA-based model updating*

GA-based model updating program is divided by two parts; one of GA part and the other of structural analysis as shown in Figure 1. Both parts of programs are developed in *Matlab* environments in this research. A lot of feedbacks are iterated with different initial populations. Because a stand-alone internal structural analysis program instead of using a commercial software was utilized, a lot of communication time in connecting GA program and analysis program could be saved.

Input data include information on initial parameters, fitness function, and initial analytical model for a bridge. Output prints the improved gene sequence of material characteristics.

3 APPLICATION TO A PSC GIRDER BRIDGE

3.1 *Overview of the PSC girder bridge*

A PS concrete girder bridge of a simple span as shown in Figure 2 was selected for tests. The length of the simple span part of the bridge is 30 m and the width of the section is 12.6 m. The bridge locates in an express highway in Korea. The total length of the bridge including the test span is 273 m of seven spans.

Detail dimensions of the span and sections are in Figure 3. In addition, the locations of LVDTs and accelerometers for the tests are also given.

3.2 *Loading test*

Static and dynamic loading tests were carried out with measuring sensors of Figure 3. For static loading tests, eleven different load cases were considered. The loading cases are illustrated in Figure 4. Static deflections were measured at each girder in the mid-span and natural frequencies were identified

from the measured accelerations as summarized in Table 3 and Table 4.

Dynamic loading tests were carried out with different truck speeds of 10~100 km/hr. The natural frequencies in Table 4 were averaged from the identified modal data of different speeds.

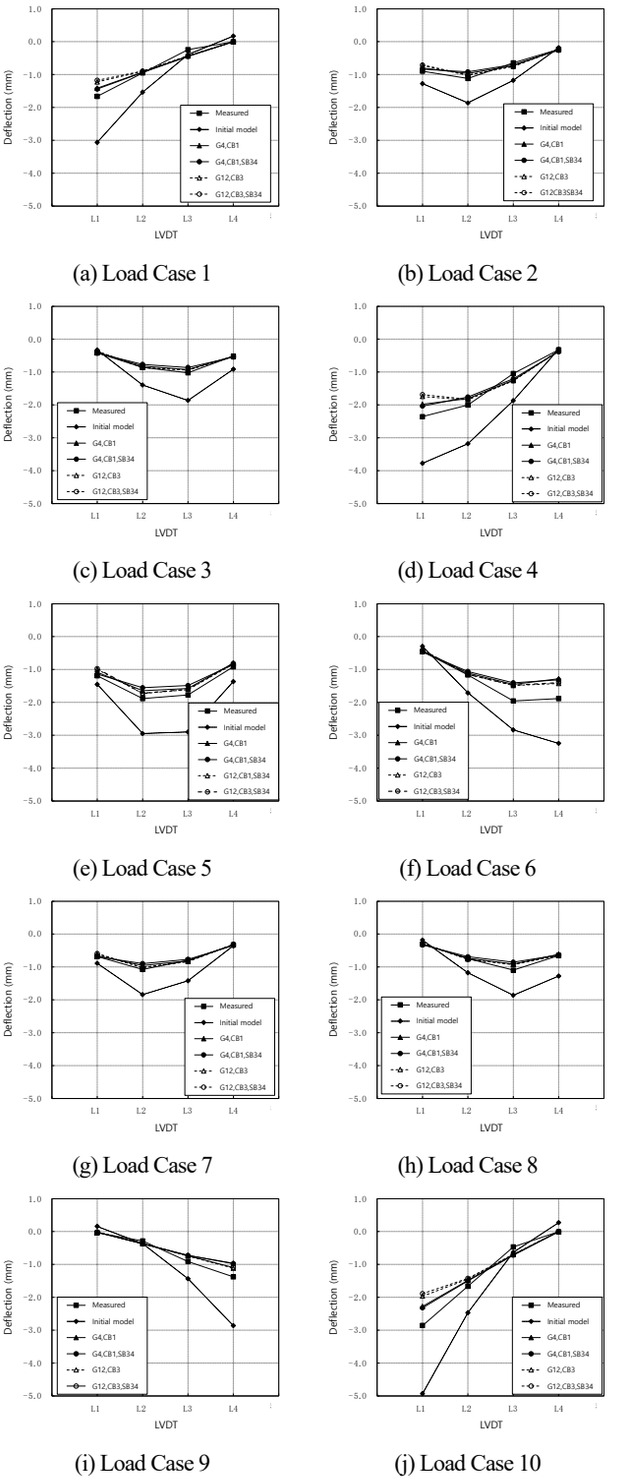
3.3 *Analytical model for the PSC girder bridge*



A simple grid model using 3-D frame elements as shown in Figure 5 was utilized to represent the bridge. The deck system and the prestressing tendons were not separately considered in the model. Rather its stiffness was included in the girder elements. The number of nodes are 44 and 40 composite elements and 9 crossbeams were modeled. The supports were replaced by spring elements as additional parameters.

Two fitness functions were applied for the model by only using measured static displacements (case 1) and by using both measured static displacements and the identified first natural frequency (case 2).

$$f(x_i) = a_i f_1(x_i) + b_i f_2(x_i) = a_i \sum_{k=1}^{n_i} \left(\sum_{l=1}^{m_i} \left(\frac{\delta_{k,l}^{\text{int}} - \delta_{k,l}^{anl}}{\delta_{k,l}^{\text{int}}} \right)^2 \right) + b_i \left| \frac{f_r^{\text{int}} - f_r^{anl}}{f_r^{\text{int}}} \right| \quad (5)$$

With constraints of

$$g_k(x_i) = a_i f_{1,k}(x_i) - 0.1 \le 0 \qquad g(x_i) = b_i f_2(x_i) - 0.1 \le 0 \quad (6)$$

Figure 6 shows that static deflections at 4 girders are getting closer to the measured deflections as model is updated by the proposed algorithm.

The errors between the measured and estimated static deflections at each load case are summarized in Table 5 and Table 6 with 4 different models. Applied models are (1) model 1 with parameters of 4 girders and 1 crossbeams, (2) model 2 with parameters of model 1 plus 10 support springs, (3) model 3 with parameters of 12 composite sections plus 3 crossbeams, and (4) model 4 with parameters of model 3 plus 34 spring elements. At each model applied, the maximum deflection error is less than 10%, which satisfies the KCI guideline (2010). From Table 5 and Table 6, it can be observed that deflection errors by case 2 using both static deflection and natural frequency are smaller than those by case 1.

3.4 *Selection of optimal parameters*

The parameters considered in the study include crossover probability, mutation probability, and step parameters. By comparing the fitness function according to different design values, the performance of the genetic algorithm was compared.

As the crossover probability increases, more crossover is taking place and thus searching capability improves. Table 7 summarizes the calculated minimum objective function depending on the design rage of the crossover probability. Table shows the best performance when the probability is 0.5, 0.6, and 0.9.

As the mutation probability increases, the probability of converging to the global optimal solution is increased by generating various genes. However, it should be noted that the result will be equal to that of random search, if it is too big. Table 8 shows that the minimum objective function could be obtained when mutation probability is 0.05.

Step is a parameter that controls the magnitude of crossover and mutation increments. When it is equal to 1.0, the increment is uniform. When it is less than 1.0, the increment decreases so that the local search capability can be improved. Table 9 shows that the

performance is the best when the step is equal to 1.0 with a long array. When the array becomes shorter with less than 1.0, the performance improves better with step of 0.001.

4 CONCLUSIONS

A modified GA program for updating analytical models is proposed and applied to a simply span PS concrete girder bridge. To improve an analytical model, measured static deflections and the first natural frequency were used in defining the fitness function in the study. In addition, the performance of the algorithm was evaluated with different range of design parameters of crossover probability, mutation probability, and the step size.

In the study, a grid model using 3-D frame elements for the PS concrete girder bridge was improved by using four gene arrays. In updating analytical model for the actual bridge, the error rate of the fitness function was small in the case of the models 3 and 4 rather than the other two models. It is concluded that even if the computation time may be longer, the results will be improved with gene arrays close to the actual situation.

Two different fitness functions were tested in the study: one only with static deflections and the other with static deflections and natural frequencies. In overall, the case of using both measured data of static deflections and modal frequencies provides a little smaller error in the determined deflections. However, the error gap is negligibly small.

Use of spring elements at the supports could improve the estimation error with smaller error in deflection estimation in most of the test cases. But in some load cases, errors were rather larger than those without considering the spring elements at the supports. However, in general, it can be concluded that the error behavior can be improved by using an analytical model that can consider the boundary condition effects.

D.M. Frangopol
Department of Civil and Environmental Engineering, ATLSS Center, Lehigh University, Bethlehem, PA, USA

ABSTRACT: A survey on life-cycle performance of civil structure and infrastructure systems has been conducted among researchers and experts from universities, industries, engineering firms and agencies active in the field of life-cycle civil engineering. The survey was aimed at gathering information about successful practices and explore avenues to overcome obstacles to filling the gap between theory and practice. The results of the survey were reported in the January 2018 issue of the ASCE Journal of Structural Engineering. In this paper, the survey database is further processed considering only the group of respondents working in the bridge engineering sector to investigate the role of life-cycle performance indicators in design, assessment and maintenance of deteriorating bridges. The main results are presented and discussed with emphasis on the need to incorporate life-cycle concepts, criteria and methods in bridge structural design codes, standards and guidelines.

1 INTRODUCTION

The economic growth and sustainable development of countries require to preserve and possibly improve the safety, serviceability, reliability, redundancy, robustness and resilience of critical structures and infrastructure facilities under uncertainty. Considering the high impact of aging and deterioration processes and their interaction with other multiple natural and man-made hazards, structural engineering is undergoing a profound change towards a life-cycle oriented design philosophy. This is particularly important for bridges and infrastructure systems, as pointed out by rating systems such as the Report Card for America's Infrastructure issued by the American Society of Civil Engineers (ASCE 2017): "The U.S. has 614,387 bridges, almost four in 10 of which are 50 years or older. 56,007 – 9.1% – of the nation's bridges were structurally deficient in 2016, and on average there were 188 million trips across a structurally deficient bridge each day. While the number of bridges that are in such poor condition as to be considered structurally deficient is decreasing, the average age of America's bridges keeps going up and many of the nation's bridges are approaching the end of their design life. The most recent estimate puts the nation's backlog of bridge rehabilitation needs at $123 billion."

Guiding policies and support decision-making processes are hence necessary for reliable design of durable bridges and rational planning of maintenance, repair, or replacement of existing bridges. Relevant advances have been accomplished in the fields of modeling, analysis, design, maintenance and management of deteriorating bridges and infrastructure systems (Frangopol 2011, Biondini & Frangopol 2016a). These advances are based on a rational approach to life-cycle design of structures and infrastructures. However, further efforts are necessary to filling the gap between theory and practice and foster the incorporation of life-cycle concepts in structural design codes, standards and specifications.

In fact, the codified procedures for bridge design generally refer to the structural performance in terms of structural safety and reliability. However, when aging and deterioration are considered, the evaluation of the system performance should account for additional performance indicators aimed to provide a comprehensive description of the life-cycle structural resources (Barone & Frangopol 2014, Biondini 2009, Biondini et al. 2008, 2014, 2015, Biondini & Frangopol 2014, 2016a, 2017, Frangopol & Saydam 2014, Frangopol & Soliman 2016, Frangopol et al. 2017, Ghosn et al. 2010, 2016a, 2016b, Okasha & Frangopol 2010, Saydam & Frangopol 2011, Zhu & Frangopol 2012, among others).

In addition, the progressive and/or sudden deterioration of structural performance develops under significant uncertainties related to material and geometrical properties, damage mechanisms, mechanical and environmental stressors, inspection and monitoring outcomes, maintenance and repair interventions, life-cycle cost models and decision making processes. A probabilistic approach for a proper modeling

of these uncertainties and of their propagation over time is therefore essential to quantify the life-cycle structural performance, safety, reliability and risk of bridges and infrastructures (Frangopol 2011).

To this purpose, research and applications are promoted within the Structural Engineering Institute (SEI) of ASCE by the Technical Council (TC) on Life-Cycle Performance, Safety, Reliability and Risk of Structural Systems (Frangopol & Ellingwood 2010). The archival work product of the SEI/ ASCE TC for the first five years of existence is presented in a recent collection of papers representing the consensus as to the current state of the art in life-cycle performance assessment and risk-informed decision making in structural engineering (Biondini & Frangopol 2016a, Ghosn et al. 2016a, 2016b, Lounis & McAllister 2016, Sánchez-Silva et al. 2016). Recent activities of SEI/ASCE TC included a special project approved by the SEI Technical Activities Division Executive Committee for the development of a state of the art report outlining the current status and research needs in the fields of life-cycle of civil structure and infrastructure systems (Biondini & Frangopol 2016b). The tasks of the special project included a survey to investigate the level of development and implementation of criteria, methods and tools in this field. The main results of the survey were presented in Biondini & Frangopol (2018). In this paper, the survey database is further processed considering only the group of respondents active in the bridge engineering sector and the results are presented and discussed with emphasis on the role of the life-cycle bridge performance indicators and the need for their incorporation in design codes and implementation in design practice.

2 SURVEY

The survey was disseminated to about 400 individuals, including members of the SEI/ASCE Technical Council, members of the International Association for Life-Cycle Civil Engineering (IALCCE), and other selected experts from universities, industries, engineering firms and agencies active in the field of life-cycle civil engineering. The survey included about 50 questions. The objective was to obtain information about the development and the implementation of criteria, methods and tools for life-cycle design and assessment of civil structure and infrastructure systems and to gather information about successful practices, and explore avenues to overcome real and perceived obstacles to filling the gap between theory and practice. The percentage of respondents was about 20%. In particular, 68 of the respondents (85%) are working in the bridge engineering sector. In the following, a brief summary of the main findings based on the survey data associated only with this group of respondents is presented.

3 PERFORMANCE INDICATORS

Aging and deterioration are complex phenomena that mainly include corrosion, fatigue, aging, chloride penetration and carbonation processes, and other causes of environmental damage such as alkali-silica reaction, erosion, sulfate attack and frost attack, among others. The evaluation of the aging and deterioration effects on bridges and related structural facilities should account for multiple deterministic and probabilistic time-variant performance indicators aimed at providing a comprehensive description of the life-cycle structural resources and detect the possible occurrence of critical failures.

In addition to the classical concepts of structural safety, serviceability and reliability, there are other important time-variant structural performance indicators that can be effectively related to the possible occurrence of local and global failures, including structural redundancy and failure times, structural robustness, and system resilience (Biondini 2012, 2009, Biondini et al. 2014, 2015, Biondini & Frangopol 2008, 2014, 2016a, 2017, Bocchini et al. 2015, Decò et al. 2013, Dong & Frangopol 2015, 2016, Ghosn et al. 2016a, 2016b, among others).

Structural redundancy denotes the ability of the system to redistribute among its members the loading which can no longer be sustained by damaged members after the occurrence of a local failure. The load redistribution capacity is a desirable structural feature to ensure suitable system performance under accidental actions and extreme events, but the concept can be extended over time to account for the time-evolution of the redistribution mechanisms due to deterioration processes. However, structural redundancy refers to a prescribed point in time and does not provide a measure of the failure rate, which depends on the damage scenario and damage propagation mechanism. Failure times should be computed to this purpose and the time interval between subsequent failures, such as the first local failure and structural collapse, could represent an effective indicator of the damage tolerance of the system and its ability to be repaired after local failures.

The terms redundancy and robustness are often used as synonymous, but they refer to different system performance. Structural robustness is the ability of the system to suffer an amount of damage not disproportionate with respect to the causes of the damage itself. According to this definition, a measure of robustness should arise by comparing the system performance in the original state, in which the structure is fully intact, and in a perturbed state, in which a prescribed damage scenario is applied. Robustness is generally evaluated with respect to damage suddenly provoked by accidental actions and abnormal loads. However, depending on the damage propagation mechanism, aging and progressive deterioration may also involve disproportionate effects.

Finally, resilience can be related to the capability of structures, infrastructures, and communities, to withstand the effects of extreme events and recover efficiently the original performance and functionality. Resilience is often investigated with reference to damage and disruption caused by seismic events. In this context, a life-cycle approach is necessary because aging and structural deterioration can modify the seismic performance and functionality and, consequently, make the system resilience depending on the time of occurrence of the seismic event.

4 IMPLEMENTATION

The brief overview on structural performance indicators emphasizes the importance of considering a suitable set of indicators for a comprehensive evaluation of the life-cycle bridge performance. The survey results listed in Table 1 show that this is clearly perceived by bridge engineers. In fact, life-cycle performance indicators provide the essential metrics to support and properly instruct the decision making process underlying actions regularly applied in practice for bridge management by organizations such as agencies and authorities. This includes effective inspection procedures, evaluation and rating systems, maintenance and repair plans, as indicated by the survey results listed in Table 2.

Table 1. Time-variant system performance indicators to be considered for life-cycle analysis of bridges.

Indicators	Responses	Percentage
Safety	59	86.8%
Serviceability	52	76.5%
Reliability	51	75.0%
Redundancy	27	39.7%
Robustness	29	42.6%
Resilience	44	64.7%
Sustainability	36	52.9%
Other	5	7.4%

Table 2. Activities applied with regular frequency in organizations such as agencies and authorities.

Indicators	Responses	Percentage
Inspection	39	57.4%
Evaluation/Rating	39	57.4%
Maintenance/Repair	28	41.2%
Other	7	10.3%

Life-cycle analysis of bridges is developed in practice considering different structural performance indicators and by using different tools, models, and/or resources. The survey results listed in Table 3 indicates that the use of probabilistic methods in bridge engineering is predominant due to the need of handling uncertainties.

Table 3. Tools and resources for life-cycle analysis of bridges.

Indicators	Responses	Percentage
Probabilistic methods	39	57.4%
Engineering judgement	32	47.1%
Guidelines provided by codes	31	45.6%
Guidelines provided by owners	18	26.5%
Guidelines outlined by companies or agencies abroad	14	20.6%
Other	9	13.2%

However, there is also a tendency to mitigate the lack of knowledge on the uncertainty involved in the problem by using engineering judgement and relying on design codes and, when available, guidelines provided by owners or outlined by companies or agencies abroad. In fact, in most cases (74%) official guidelines to regulate the implementation of life-cycle criteria and methods are not available to practitioners. Moreover, Table 4 shows that advances in the standardization of the life-cycle design procedures for bridges should be complemented with an increasing awareness of the society, political system, industries, and owners.

Table 4. Factors to be improved for promoting life-cycle analysis of bridges in design practice.

Indicators	Responses	Percentage
Design codes and standards	51	75.0%
Design guidelines	44	64.7%
Owners awareness	34	50.0%
Social and political awareness	31	45.6%
Industry awareness	18	26.5%
Other	1	1.5%

Future directions to accomplish these goals in bridge engineering are the selection of the pertinent codes/standards/specifications/guidelines such as ASCE/SEI 7-16 (2017), AASHTO (2010), and EUROCODES (2002), that could serve, if appropriate provisions will be implemented, as a vehicle to consider life-cycle concepts in design practice.

5 CONCLUSIONS

The results of the survey indicate a significant gap between research advances and applicative implementation of life-cycle performance indicators in the design, assessment, and maintenance of bridges under uncertainty. The availability of bridge design codes, standards and specifications incorporating life-cycle concepts and addressing life-cycle methods and procedures is extremely important and represents an important target to be accomplished for the successful implementation in practice of a modern and rational life-cycle oriented probability-based approach to bridge engineering.

ACKNOWLEDGEMENTS

The support from the SEI Technical Activities Division Executive Committee is gratefully acknowledged, with special thanks to Robert Nickerson, SEI Board of Governors and SEI TAD Executive Committee Contact of the Technical Council. Special thanks are due to Andrea Titi of Politecnico di Milano for the dedicated work and contributions to the development of the survey. The information available from previous surveys conducted by ASCE are also gratefully acknowledged, particularly the ASCE survey on Utilization of Life-Cycle Cost Analysis and Performance Based Design, organized by Dan M. Frangopol, Mohamed Soliman and Samantha Sabatino, Lehigh University, and the SEI/ASCE TC TG2 TG3 survey on Implementation of Risk-Based Methods for the Design of Structure and Infrastructure Systems, organized by Michel Ghosn, City College of New York, Ming Liu, U.S. Department of the Navy, and Bruce R. Ellingwood, Colorado State University.

Seismic resilience of road bridges: lessons learned from the 14 November 2016 Kaikōura Earthquake

A.I. Sarkis & A. Palermo
University of Canterbury, Christchurch, New Zealand
O. Kammouh & G.P. Cimellaro
Politecnico di Torino, Turin, Italy

ABSTRACT: The 14th of November 2016 Kaikōura Earthquake sequence has highly affected the transport infrastructure in New Zealand. From the perspective of life-safety, the overall bridge performance was satisfactory; however, based on the observed undesirable sub-system performance of the damaged bridges, further investigation into possible improvements of the current design philosophy was warranted.
This paper describes the structural performance of the most severely damaged bridges during the Kaikōura Earthquake. The study is based on observations made during site inspections, on subsequent computational analyses performed and on a functionality database collected during the period following the event. The paper also introduces resilience indicators as a tool to predict the lifecycle performance and functionality of bridges. Finally, conclusions on the resilience and functionality of the bridges in the aftermath of the earthquake are raised, highlighting the main performance issues and suggesting strategies and technologies to enhance their seismic resilience during future events.

1 INTRODUCTION

The Kaikōura earthquake, with a moment of magnitude equivalent to M_w=7.8, occurred two minutes after midnight on the 14th of November 2016 (NZST). The epicenter was about 60km south-west of the town of Kaikōura, New Zealand (NZ), while the hypocenter was at a depth of approximately 15km. The event was a summation of multiple fault ruptures over a large spatial domain, and its complexity has resulted in the reassessment of many assumptions about earthquake processes.

The transportation network of the entire northeast portion of the South Island was badly affected. In this area, there are over 268 State Highway (SH) bridge structures, most of which are made of reinforced concrete, and 636 local road bridge structures (Palermo et al., 2017).

The performance of bridges during major earthquakes is of interest for reviewing the assumptions that are made during the seismic design or assessing the structure and its approaches. Therefore, the overall aim of this paper is to present general observations for the performance and resilience shown by the most severely damaged road bridges in the Kaikōura Earthquake, and to open the discussion on how to improve seismic resilience of road bridges during future events.

The four bridges covered by the present paper are located within 5km radius of one another and within 11km of the township of Waiau, which is the closest town to the earthquake epicenter. Except for the Wandle River Bridge, which is on a shallow soil site, the bridges are situated on sites underlain with deep layers of dense gravels and sand, and it is likely that they were subjected to similar intensity of ground shaking (Wood & McHaffie, 2017). Table 1 shows the main general information of the four bridges analyzed, together with a map of their location in Figure 1/

Table 1. Bridges assessed in the present report

Bridge Name	Year of design	Length	Number of spans	High-way	Distance of epicenter
		m			km
Lottery River	1984	123	6	Inland Route	11
Lower Mason River	1984	164	8	Inland Route	7
Mason River	1979	197	12	River Road	5
Wandle River	1987	51	3	Inland Route	13

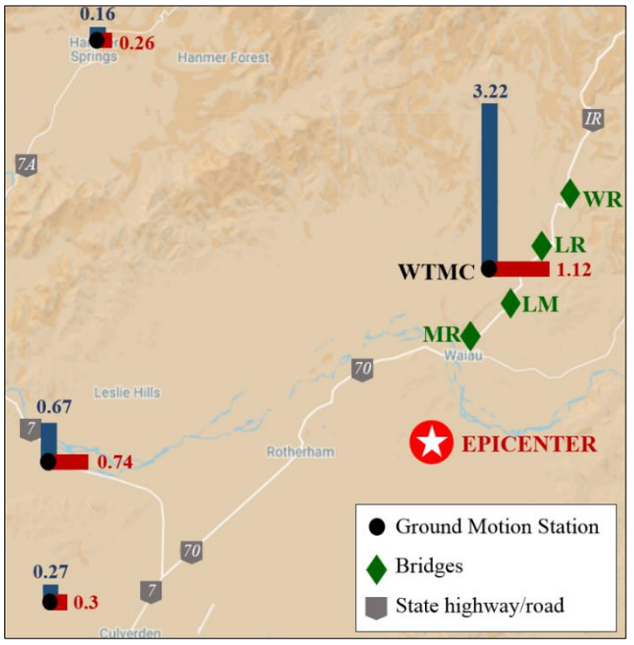

Figure 1. Map of bridges analyzed in the Hurunui District with the maximum measured PGA

2 EARTHQUAKE GROUND MOTIONS

During the Kaikōura earthquake, there was a large spatial variation in the shaking intensity, even within the moderate distances within the same district. When judging the level of damage to bridges, on top of the earthquake intensity, the variation in the design philosophy and the seismic detailing need to be taken into account as they can dictate either desirable or undesirable performance.

Figure 2 shows the geometric mean (of the two horizontal components) of the 5% damped elastic horizontal pseudo-spectral accelerations measured in Te Mara Farm Waiau station (WTMC), located close to Waiau (see Figure 1). Overlaid are the NZ elastic design spectra used during three design eras. The present day elastic design spectra was taken from NZS1170.5:2004, it was obtained for a Bridge Manual Importance Level 2 (1/1000-year annual probability of exceedance, ULS) structure, soil class C, and having a Hazard factor Z = 0.45, with no near fault effects. The two oldest design spectra, based on working stress design, were taken from Kaiser et al. (2017), and modified for compatibility with limit state design by Palermo et al (2017).

The bridges studied were designed in the period ranging from 1980 to 1987, hence, using the design spectra from the 1965-1987 era. The corresponding design spectra was greatly exceeded, as it can be seen in Figure 2. Most bridges had elastic periods of vibration within the range of 0.2 s to 1.0s, which is the period of vibration where the ground shaking at WTMC exceeded even the modern design spectra (Figure 2). The bridges had a transverse period of vibration in the range of 0.2s to 0.6s and the pseudo-spectral acceleration experienced by these bridges greatly exceeded 1.5g.

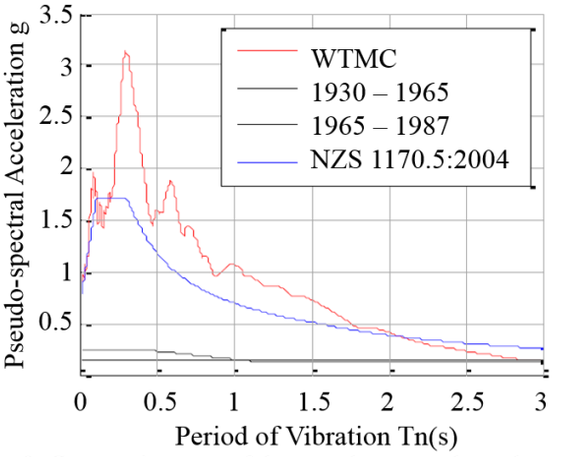

Figure 2. Geometric mean of the pseudo-spectral acceleration measured at WTMC strong motion station (Palermo et al., 2017)

3 STRUCTURAL PERFORMANCE AND DAMAGE

3.1 *Structural configuration of the bridges*

The Lottery River, Lower Mason River, Mason River, and Wandle River bridges (Figure 3) are structurally similar to one another. They are all multi-span precast concrete bridges supported on single column piers with hammer head pier caps. Further structural details are summarized in Table 2.

Table 2. Main structural details and main damage summary for the four bridges under study (Wood & McHaffie, 2017)

Bridge Name	Superstructure	Pier type	Pier founda-tion	Main damage
Lottery River	Continuous RC deck, joint at middle pier, twin 20m prestressed I beams	Single column	Single cylinder	Severe hinging in columns & buckling of column rebar
Lower Mason River	Continuous RC deck, joint at middle pier, twin 20m prestressed I beams	Single column	Single cylinder	Severe hinging in columns & fracture/buckling of column rebar
Mason River	Five 16m pretensioned double core deck units	Single column	Steel H pile group	Hinging in columns, superstructure joint damage
Wandle River	Five 16m pretensioned double core deck units	Single column	Single cylinder	Severe hinging in columns - Bridge demolished

In the way they resist lateral loading, the Lottery River (Figure 3a) and Lower Mason (Figure 3b) bridges are identical. The transverse interaction has been isolated by the omission of transverse shear keys at the central pier (Palermo et al., 2017). In addition, they use a rudimentary form of seismic isolation under transverse loading such that they can displace

an appreciable amount on the supporting elastomeric bearings before contacting the shear keys. As a result, the bridges make use of the low lateral stiffness of the bearings to elongate the period of the structure.

Figure 3. Bridges under study: (a) Lottery River Bridge; (b) Lower Mason River Bridge; (c) Mason River Bridge; (d) Wandle River Bridge (Palermo et al., 2017).

The longitudinal interaction between each half of the bridge has been isolated by a movement joint with knock off detail. The deck beams are tied together longitudinally except over the central pier. The beams rest on wide seats, thus, all piers resist longitudinal lateral loading, except the central pier, which is effectively much more flexible. Until the beams contact the shear keys, the overall transverse response can be thought of as rigid body translation of each half of the superstructure.

Similarly, the Mason River Bridge (Figure 3c) is split in two with a central movement joint. There are transverse shear keys at the abutments and internal longitudinal shear keys and linkage bars over all of the piers except the central pier. At the central pier, provision is made for longitudinal movement with loose linkage bars but steel plate lateral support stubs cast into the piers restrain the transverse movement. Therefore, the overall transverse response can be thought of as the deck having a curved displaced shape where the largest transverse displacement occurs at the central pier (Palermo et al., 2017).

The Wandle River Bridge (Figure 3d) is curved in plan and has a slope in the longitudinal direction. Linkages, shear keys and elastomeric bearings restrain the transverse and longitudinal movement over the piers, but only linkage bars resist both the transverse and longitudinal movement at the abutments. Longitudinal movement towards the backfill at the abutments is resisted by the abutment back-wall which is cast against the beams.

3.2 *Bridge performance and observed damage*

At the Lower Mason Bridge, all piers, except for the central, formed fully developed plastic hinges (PH) at the base. As mentioned, the central pier is located below a movement joint in the deck and has shear keys restraining the superstructure. Extensive cover spalling and a significant number of buckled and fractured longitudinal bars were seen. Pier damage at the Lottery River Bridge was similar but without an evidence of bar fracture. Figure 4 illustrates the damage patterns found on the column rebar of both bridges.

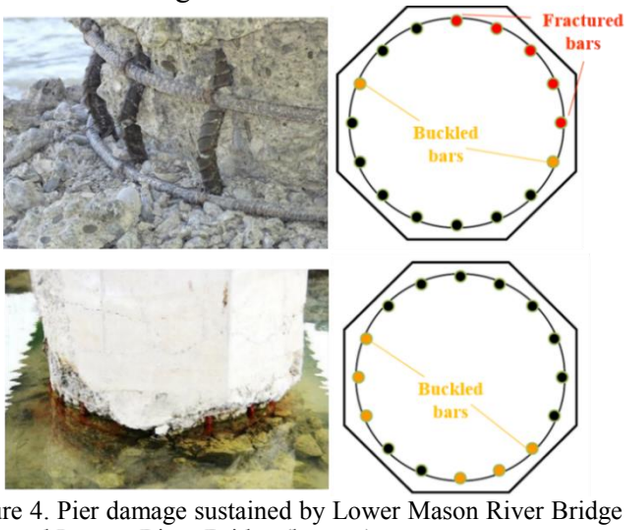

Figure 4. Pier damage sustained by Lower Mason River Bridge (top) and Lottery River Bridge (bottom).

Together with the PH zones, observed damage common to both bridges, Lower Mason and Lottery, included: damage to the knock-off block at the central

pier movement joint, failure of the abutment knock-off blocks; residual displacement of most of the elastomeric bearing pads at the piers and abutments; and residual displacements at the central pier and abutment movement joints. Damage to the abutments is illustrated in Figure 5.

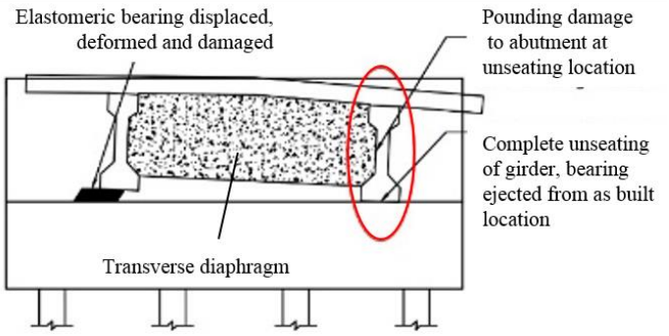

Figure 5. Abutment damage schematics for the Lower Mason River Bridge (modified from: Palermo et al, 2017)

Similar damage observations were made for the Mason River Bridge, where the deck joints had opened or closed, and pier PH with bar buckling and concrete spalling were observed with increasing degree of damage towards the central pier. The pier damage pattern was interesting at this bridge as concrete spalling and rebar exposure occurred mainly at the face of the piers facing south, and tended to be more in the longitudinal loading direction.

The damage observed to the Wandle River Bridge was extensive, and included: separation between the hollow core deck units at the south end of the bridge; translation of deck units in the downstream direction; hinging and rotating of piers towards the upstream side (up to 7° rotation); opening of the deck joints at the abutments, along with significant approach damage (Figure 6).

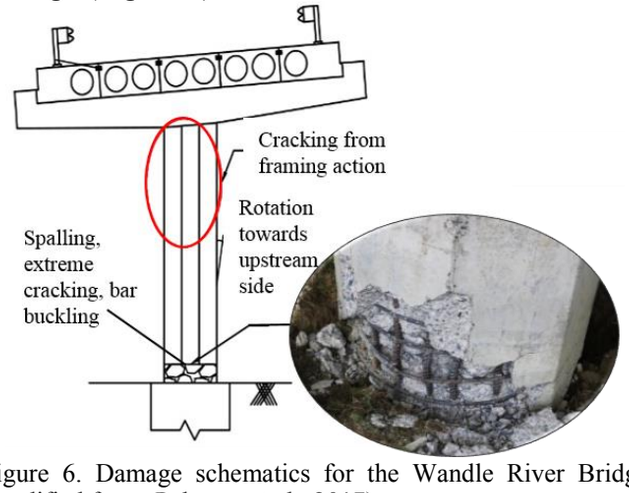

Figure 6. Damage schematics for the Wandle River Bridge (modified from: Palermo et al., 2017)

The displacement capacities for the bridges were estimated by Wood & McHaffie (2017) using a tributary mass type Displacement Based Design (DBD) analysis of a single pier, at the Damage Control Limit State (DCLS). They are compared in Table 3 with the displacement demand for transverse direction loading estimated from spectra computed from the WMTC records.

Table 3. Displacement capacity and WMTC demand

Bridge Name	DCLS Capacity	Demand from WMTC Records	Ratio Capacity/ Demand	Secant Period at WMTC Demand
	mm	mm		s
Lottery River	130	300	0.43	2.1
Lower Mason River	160	290	0.55	2.2
Mason River	180	130	1.38	1.1
Wandle River	180	350	0.51	1.8

Based on the assumption that the WMTC records are a reasonable representation of the bridge site ground motions, the displacement demands on the bridges were considerably greater than the DCLS capacity displacements, explaining the severe damage observed in the PH zones.

It can be concluded that the piers performed well, as they developed PH at the pier bases and went through the expected failure mechanism. However, significant instability was visible in the Wandle Bridge, where most likely all orthogonal motions were interacting with the bridge structure, causing large displacements and separation gaps between some of the deck beam units.

4 RECOVERY PROCESS

After the earthquake, the priority was to restore access to Kaikōura Township and surroundings, which were cut off by earthquake damage, and establish a safe and reliable alternative route. To achieve this, the Inland Route, via Waiau, was identified as the best option since the main route, through SH1, was completely blocked due to landslides.

It took 38 days after the earthquake to reopen the Inland Route. This was mainly due to earthquake induced damage on the road such as significant rock fall and slips that needed to be cleared, in addition to the associated construction activity which also contributed to the hazard. The bridges were able to be reopened, to some level of service, within a few days. However, it took up to three months to complete their repairs. It is important to highlight that repairs to the bridges so far are considered temporary in some extent and permanent restoration of the bridges is to be planned

In general terms, the bridge structures withstood the earthquake sequence well, demonstrating considerably robustness. However, many bridge approaches were damaged due to settlement and horizontal movement, thereby making some bridges

impassable. Approach reconstruction through the placement of fill and resealing quickly made the majority of these road bridges usable again.

Figure 7 illustrates the recovery rate of the Inland Route and the bridges under study during the first one hundred days following the earthquake using the maximum speed allowance as a functionality indicator for normal, Class 1, vehicles. The earthquake occurred at 12:02 am on the 14th of November, causing the Inland Route to be immediately closed by the Civil Defense Emergency Management. The route remained closed until it was given access for the NZ Defense Force convoys to get through with emergency supplies to Kaikōura, on November 25th, 12 days after the earthquake (point A in Figure 7).

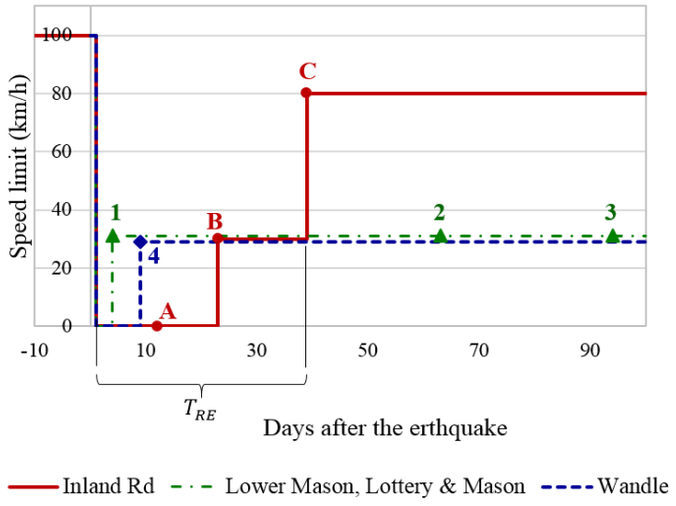

Figure 7. Functionality based on the maximum speed limit for the Inland Route and the four bridges under study.

The route remained fragile and hazardous, closed to the general public until the 6th of December, day 23 after the earthquake (point B in Figure 7), when controlled emergency and resident access was allowed with a speed limitation of 30km/h, 70% less than the pre-earthquake speed limit of 100km/h. Works undertaken during these days to make the severely damaged road safe enough included clearing the road of more than fifty slips, stabilizing slopes, and assessing the damage to the bridges.

It was only until the 21st (point C in Figure 7) of December when the public were granted unrestricted access to the Inland Road, bringing the first unrestricted road connection back to Kaikōura, for a total recovery time T_{RE} of 38 days after the earthquake.

The Lower Mason River Bridge was opened to traffic on November 17th, day 4 after the earthquake, (point 1 on the graph) with a speed restriction of 30km/h and a sign "one heavy vehicle at a time". Overweight vehicles were to use the adjacent ford that was installed on the day after the earthquake. Prior to opening the bridge, the following works had been completed: detailed inspection of the bridge, removal and appropriate filling of the knock off device at the central expansion joint, and approach repairs and re-levelling. To reinstate the original seismic capacity, a pile jacketing was issued for all pier columns, which was finished around mid-January (point 2 in Figure 7). After the pile jacketing was completed, the one-heavy-vehicle-at-a-time restriction was removed but the 30km/h restriction remained due to the uneven road surface.

The recovery process for the Lottery Bridge was very similar to the Lower Mason, since they share similar structure type and damage. Pier columns were unable to be inspected on the first days after the earthquake due to the bed and water level, yet, damage was anticipated to be less than at Lower Mason due to the shorter bridge columns. Excavation of pier piles occurred on November 25th confirming that damage was of a lesser extent, and pier jacketing was issued and completed around mid-February (point 3 in Figure 7).

Likewise, the Mason River Bridge shared the same timeline, however no security works have been carried out on this bridge as the earthquake damage was considered not to affect the serviceability of the structure. Investigation is currently underway to expose bridge piers and replace buckled bars.

For the Wandle River Bridge, decision was made on November 15th to install a Bailey bridge upstream with a 33m span. Installation was completed by November 21st and opened to traffic on the 22nd, nine days after the earthquake (point 4 in Figure 7). The Bailey bridge was able to be erected so quickly, within eight days, because New Zealand Transport Agency (NZTA) maintains an emergency stock of Bailey bridges with a contractor also in place to respond in the event of emergencies. The Bailey bridge provided largely unrestricted access across the Wandle River, however, a 30km/h speed restriction was installed due to the alignment and to provide impact protection to the bridge. The Wandle Bridge was demolished in May 2017 and a new bridge design is programmed with a low priority for 2018.

Permanent recovery works on the bridges have been given a low priority. The initial response works intended to restore an acceptable level of service for the Inland Route that would enable access into and out of Kaikōura following the November earthquake. Once this was achieved, the priority of works was switched to recovering SH1. There is also reluctance to undertake further significant work on the Inland Route, as this route acts as a bypass to SH1 to access Kaikōura from the south.

It is important to note that while the route may have been at open, pre-earthquake speed limits of 100km/h, heavy vehicles would still have to comply with lower speed requirements. Additionally, all bridges are single lane, therefore, it is unlikely that even normal vehicles were travelling across the bridges at maximum speed.

5 HOW TO PREDICT STRUCTURAL RESILIENCE?

The NZ South Island transportation network had a resilient response, as it counted with alternative routes connecting locations, allowing to restore access to isolated communities within a relatively reasonable time. On the other hand, access to Kaikōura was closed during the first 23 days for the general public, what makes us wonder, resilience for whom?

Furthermore, in terms of bridge performance, the bridge structures withstood the earthquake sequence well. Bridges demonstrated considerably robustness and hence resilience as, even if damaged, they allowed the transit of vehicles and therefore to reinstate functionality in the route. But, as they are still awaiting for permanent repairs to be undertaken, what is the current damage resistance capacity or probability of failure? Can we expect them to show resilience for future events? What leads us to the question, how can we assess and predict structural resilience?

5.1 *Resilience assessment*

In studies dealing with seismic hazard, resilience can be considered as a performance indicator that quantifies the residual functionality along with the effort in responding to the seismic event (Deco et al, 2013). In this conceptual approach, performance can range between 0 and 100%. In case of an earthquake, usually serviceability of a structure drops to a lower level, being 0% a complete loss of service, followed by a recovery process after the disaster, and then finishes when there is a restoration of the serviceability to its "normal" performance level. This characterization of system performance leads to a broader conceptualization of resilience, where a resilient structure can be understood as one with the ability to present reduced chances of failure, reduced consequences from failures and reduced recovery time (Bruneau et al, 2003).

Within the *Technical Guidance for Engineering Assessments* (2017) in NZ, structural resilience is defined as the ability of the structure to continue to perform in earthquake shaking beyond an Ultimate Limit State (ULS) shaking demand level. Therefore, the bigger the space between the point of onset of nonlinear behavior and the point of brittle behavior of the structure, which would lead to collapse, the more resilient is a structure. Structural resilience can be thought as an inherent characteristic of structures designed to the new codes or even older well designed structures, as their performance will follow the desirable hierarchy of element failures, which was the case of the bridges under study. There can be the case where a structural system has a low resilience and is susceptible to sudden reduction in their performance and functionality as the earthquake shaking increases beyond a particular value.

Measuring resilience has been an exploding field of inquiry in the past decade. Disaster resilience assessment approaches fall into three primary categories: indicators, scorecards, and tools (Cutter, 2015). In the following section the assessment of resilience through the use of indicators will be further discussed.

5.2 *Resilience indicators for road bridges*

Indicators are quantifiable variables that represent selected characteristics of resilience (Cutter, 2015). Generally, individual indicators can be combined to create a resilience index (Kammouh et al. 2017b). The index illustrates multi-dimensional nature of resilience by aggregating multiple indicators, but also condenses its complexity into a single numeric value.

Recent bridge design codes consider performance uncertainty by including specific factors in the computation of structural resistance and load. However, this does not comply the uncertainties in loading and deterioration processes which make the prediction of lifecycle performance of bridges so complex. Prediction of time-dependent bridge performance under uncertainty may require the use of several indicators, thus, it is important to select adequate indicators to evaluate and predict the structural performance and functionality of bridges.

Significant research has been done on quantifying structural performance with deterministic and probabilistic indicators (Frangopol & Saydam, 2014). For example, system reliability measures, such as the probability of failure or the reliability index, are adequate for quantifying the safety of a structure with respect to ultimate limit states, but the system redundancy index is required to evaluate the availability of warning before a system's failure (Frangopol & Saydam, 2014). Additionally, performance indicators related to damage tolerance of structures, such as vulnerability and robustness are essential to consider for bridges under deterioration together with the indicators related to system safety.

Subsequently, it is required to consider multiple indicators when evaluating the seismic resilience of a bridge. Indicators must be weighted according to their contribution towards the resilience of the system, so that resilience is quantified as a normalized value of the area inside the enclosed shape made by linking the adjacent indicators weights or scores. Kammouh et al. (2017a) introduced and exemplified three weighting methods for resilience indicators based either on the dependence tree analysis or on the spider plot analysis (Kammouh et al. 2017a, Kammouh et al., in press).

Table 4 shows some examples of resilience indicators for bridges. They have been divided into two categories, 'soft' and 'hard' indicators, according to the difficulty involved in their measurement. Soft

indicators, in general, can be determined qualitatively through surveys, data compilation or specific sample procedures, whereas hard indicators would require a higher effort, whichever computational, numerical or probabilistic. They can be calculated using mathematical formulas and/or matrices in order to approximate and understand the characteristic of the system under study.

Table 4. Examples of 'soft' and 'hard' type of resilience indicators for bridges

Soft Indicators	Hard Indicators
Speed Limit	Safety factor
Travel time	Reliability index
Physical access	Probability of failure
Weight allowance	Redundancy index
Operative utility systems	Vulnerability
Condition Ratings	Robustness

Indicators can be measured at a member or a component level, an overall structure or a system level, and a group of structures or a network level. For example, when evaluating stability problems, the performance is normally quantified at a member level, and normally, this is enough to ensure an adequate level of safety. However, when evaluating resilience, a member level approach might not provide the necessary information about the overall performance of the bridge or the bridge network.

6 LESSONS LEARNED

Since all bridges were subjected to similar ground motions, it is informative to compare the damage to them and the design features that influenced their structural performance and resilience. The following sections summarize the main issues raised and lessons learned from study of these bridges.

6.1 *Bridge intervention and route recovery*

An acceptable level of service was able to be restored within a short period of time. This can be attributed to a combination of a number of factors:

- Both NZTA and the Hurunui District Council, entities in charge of the bridges, had a Bridge Consultant (Opus International Consultants) in place to respond in the event of an emergency.
- The Bridge Consultant was familiar with the affected bridge stock and had information readily available through an established and maintained Bridge Information System.
- Network contractors (Downer and Sicon) were in place to respond in the event of an emergency.
- Emergency procedures in place to coordinate a response, inspections and works.
- Emergency bridge stock and contractor in place to erect Wandle Bailey Bridge.
- Clients, Consultant and Contractors experienced from Canterbury Earthquake Sequence on 2010-2011.
- Very knowledgeable client able to make informed decisions.

6.2 *Bridge response and behavior*

In modern design, there is a tendency to design more efficient structures, with longer spans and reduced foundations with a reliance on acceptable damage and dissipation through the use of PH. While this was largely observed on the bridges on the Inland Route, a few things that eventuated were undesirable such as the buckling and the fracture of the reinforcement and the large residual deformations for Wandle Bridge.

In this event, older bridges that had not been designed to modern standards performed better than expected. The likely reason for this is that these structures were designed with a greater level of redundancy, thanks to their shorter spans, more piers and more piles for the foundations.

For the Inland Route around the Waiau area, the earthquake demands from the Kaikōura Earthquake were severe, in excess of a 1000 year return period. As such, it is considered a significant earthquake with a low probability of occurring in the bridges' typical design life. On more critical routes, such as SH1, the design philosophy tends to shift towards designing to meet higher importance levels. For bridges on critical routes, the design would typically be for a return period of 2500 years at the DCLS and a return period in the order of 10 000 years at the Collapse Limit State.

6.3 *Reparability and influence of the structural form*

The structural scheme can play a part in the repair strategy, costs and hence resilience. In the case of monolithic bridges, repair of PH should be considered at the design stage. On the Lottery and Lower Mason bridges, the 1.5m diameter cylinder foundations located directly beneath the 1.0m diameter columns of the piers simplified the repair (Figure 8a). New reinforcement could be doweled into the existing pile and the pier re-cast, restoring the moment capacity of the column (Figure 8b). In contrast, for the Mason Bridge, repair is more difficult due to the shape and size of the pier cap (Figure 8c), as the geometry will make it very difficult to dowel in additional bars in and re-cast concrete. The result will be a significant repair cost and potential downtime for the structure.

Designing and detailing monolithic connections taking into account the repair strategy for different design level events would optimize the recovery after an earthquake event. Furthermore, if the bridges were designed for damage avoidance, incorporating energy dissipation and reparability, performance and recovery of the bridges could be improved. Hence, full restoration on the functionality of the route could be accomplished immediately after the earthquake.

Figure 8. Plastic hinge repair: (a) PH in Lower Mason Bridge; (b) repair of PH by epoxy grout bars; (c) geometry at Mason River Bridge PH zones.

7 CONCLUSIONS

Resilience indicators for bridges are important tools for predicting and evaluating the structural performance and functionality of bridges given a seismic event. They can help to characterize the basic elements of the structure under analysis and thus help to raise the awareness on the benefits of mitigation technologies and strategies, and making the business case for understanding the investments and results of enhancing resilience at different scales. This paper provides a general conceptualization of resilience indicators as a starting point for future research to be undertaken on the prediction of structural performance and resilience of bridges.

A brief overview of the structural performance and resilience shown by the most severely damaged bridges during the Kaikōura Earthquake has been given. At the time of initial inspection, the bridges were rapidly assessed and were generally only open to emergency traffic. Since then, temporary repair works allowed public access through these routes; however, long term repair or replacement strategies are still being considered by the managing authorities. From the perspective of life safety we can consider the overall performance as satisfactory.

The bridges, even if damaged, behaved as expected from design and allowed to reinstate transit of vehicles and restore the functionality in the route. This made possible to restore access to isolated communities within a relatively reasonable time of 23 days, thanks to the availability of an alternative route which has worked as a bypass. However, was this a satisfactory performance in a seismically active developed country or do we need to improve our current design philosophy so that we can warrant enhanced resilience during future events?

Renewal-theory-based Life-cycle Risk Assessment of Bridge Deck Unseating under Hurricanes

David Y. Yang & Dan M. Frangopol
Department of Civil and Environmental Engineering, ATLSS Engineering Research Center, Lehigh University, 117 ATLSS Drive, Bethlehem, PA 18015-4729, USA

ABSTRACT: Hurricanes pose a major threat to coastal bridges. For bridge superstructures, hurricane-induced surge and wave loads can lead to bridge deck unseating, which has been identified as the most common failure mode for coastal bridges under hurricanes. This paper proposes a novel method for life-cycle risk assessment of coastal bridges under this hazard. The proposed method considers both capacity deterioration of unseating-resistant systems (e.g. connection dowels) and the reoccurrence of hurricanes in the service life of bridges. Renewal theory is leveraged to consider repairs after deck unseating failure. A prestressed concrete box-girder span is used to illustrate the proposed method. Based on the assessment, it is found that non-deteriorating unseating-resistant systems can significantly reduce the life-cycle risk of bridge unseating.

1 INTRODUCTION

Coastal bridges are vulnerable to hurricanes and hurricane-induced floods. Recent hurricane events (e.g. hurricanes Harvey and Irma in 2017) revealed that the failure of bridges under these events hinders prompt hazard response and post-hazard recovery, posing devastating losses and long-lasting consequences to the afflicted communities. For bridge superstructures, hurricane-induced surge and wave loads can lead to bridge deck unseating. Based on a recent review on causes and mechanisms of bridge failure, deck unseating under hurricanes and hurricane-induced floods is one of the most common causes of bridge failure during the period 1989 to 2000 in the United States (Deng et al. 2016).

Apart from hurricane hazards, coastal bridges are also located in a very corrosive environment that can lead to severe deterioration of bridge performance. According to the latest report card by American Society of Civil Engineers (ASCE 2017), 9.1% of the nation's bridges are structurally deficient. Many of these bridges are situated along the coastline. Therefore, the deterioration of bridge capacity against deck unseating should be considered in the risk assessment process.

Due to the high consequences of bridge failure under hurricanes, extensive studies have been dedicated to this topic, including modeling of hurricane-induced loads on bridges, bridge response under these loads, likelihood of deck unseating, and risk assessment and mitigation (e.g. Ataei & Padgett 2013a; Mondoro et al. 2016). However, most of the existing studies deal mainly with the likelihood and risk of deck unseating under one possible hurricane event and its surge and wave loads. The analyses usually end with the fragility curves/surfaces of bridges under hurricanes. Structural deterioration and reoccurrence of hurricane events in the bridge's service life have not been properly considered. Recently, Mondoro et al. (2016) conducted a life-cycle risk analysis that considered structural deterioration and modeled hurricane occurrence as a binomial process. However, this study did not account for the repairs of bridge deck after unseating failure. In addition, the deterioration of unseating-resistant systems themselves was not considered.

In this paper, a novel method for life-cycle risk assessment of bridge deck unseating is proposed based on renewal theory. The reoccurrence of hurricanes is modeled as a Poisson process. To include post-hazard repairs into the life-cycle analysis, the proposed method uses renewal-reward processes to model the occurrence of unseating failures and the associated repairs. Pitting corrosion in dowel bars (i.e. a typical unseating-resistant system in concrete bridges) is also taken into account. A prestressed concrete box-girder span is used to illustrate the application of the proposed method. It is acknowledged that various corrosion-resistant materials (e.g. stainless steel and fiber reinforced polymer) have been applied in aggressive environments to enhance the long-term performance of bridges (Soliman & Frangopol 2015; Yang & Teng 2018). Therefore, the cost-effectiveness of using these new materials in unseating-resistant systems is also investigated based on the proposed method.

2 HURRICANE-INDUCED LOADS ON BRIDGE SUPERSTRUCTURE

2.1 *Hazard analysis*

Hurricane hazards can be quantified by the associated wind speeds. In probabilistic analysis and risk assessment of hurricanes, the wind speed can be considered in two approaches. The first approach is based on the statistics of maximum annual gust wind speed. The characteristics of hurricanes are then considered by modifying the obtained statistical model (Peterka & Shahid 1998). The end-product of this approach is a probability distribution of annual wind speed that can be used in fragility and risk analyses (Stewart 2003; Li and Ellingwood 2006; Mondoro et al. 2016; Dong and Frangopol 2017). The second approach is to directly analyze the records of tropical cyclones including hurricanes and hurricane-akin phenomena such as tropical storms and tropical depressions for a specific region. The results of this analysis are the site-specific return period and the statistical distribution of wind speed associated with a tropical cyclone event (Li et al. 2016).

In this paper, the second approach is used in the proposed method. Compared to the first approach, it is believed that the statistics of the wind speed in the second approach should better match the applicable scope of the model of hurricane-induced loads presented in the following subsection. It should also be noted that, in order to obtain a full range of wind speeds, the second approach uses data from all tropical cyclones, including less critical events to deck unseating such as tropical storms and tropical depressions. Therefore, the proposed method uses probabilistic transformation to obtain the wind distribution in a more relevant event and its associated return period. Specifically, if a minimal wind speed v_{min} is specified, the conditional probability distribution density function (PDF) of wind speed can be expressed as

$$f'_V(v) = \frac{f_V(v)}{1 - F_V(v_{min})} \quad \text{for } v \geq v_{min} \tag{1}$$

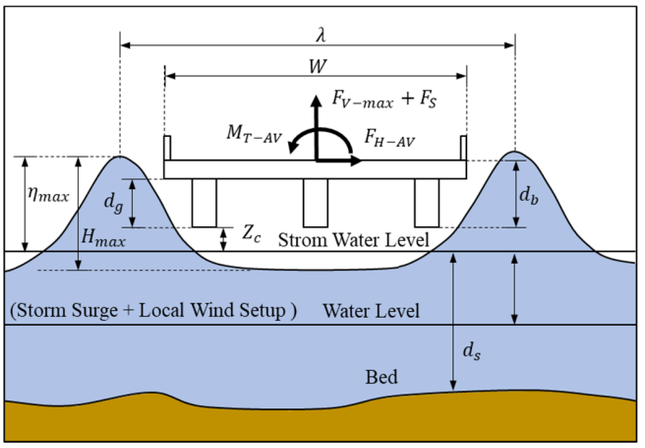
where $f'_V(\cdot)$ is the conditional PDF of wind speed; $f_V(\cdot)$ is the original PDF of the wind speed obtained using the second approach; $F_V(\cdot)$ is the original cumulative distribution function (CDF) of the wind speed. The return period of the wind speed following the PDF in Equation 1 can be then calculated by the following equation:

$$T_{hurr} = \frac{T_{cycl}}{1 - F_V(v_{min})} \tag{2}$$

where T_{cycl} is the return period of tropical cyclones; T_{hurr} is the return period of hurricanes with a minimal wind speed v_{min}. For instance, the wind speed distribution and the return period of a hurricane in category 3 and above can be obtained using Equations 1 and 2, respectively, with $v_{min} = 50$ m/s.

Conversely, if the return period of a hurricane is specified, the associated minimal wind speed can be determined by the following equation:

$$v_{min} = F_V^{-1}\left(1 - \frac{T_{cycl}}{T_{hurr}}\right) \tag{3}$$



where $F_V^{-1}(\cdot)$ is the inverse function of $F_V(\cdot)$. The wind distribution can then be obtained using Equation 1.

2.2 *Hurricane-induced surge and wave loads*

Hurricanes, along with their associated heavy precipitation, can induce high waves and surge storms that pose threats to bridge superstructures. Hurricane-induced surge and wave loads can be attributed to various factors including buoyancy, drag and inertia forces, forces associated with added mass, and vertical slamming forces, among others. Quantification of these loads on bridges requires considerable numerical modeling, systematic experiments and on-site observations. Various studies have been conducted based on the hindsight of disastrous hurricanes, hydrodynamic experiments, and numerical simulations using computational fluid dynamics (e.g. Douglass et al. 2006; Chen et al. 2009; Jin & Meng 2011; Ataei & Padgett 2015; Do et al. 2016). Results from serveral of these studies have been instilled in the first design guidelines for coastal bridges vulnerable to hurricane-induced storms, released by the American Association of State Highway and Transportation Officials (AASHTO 2008). In this paper, the model in AASHTO (2008) are used to consider the hurricane-induced surge and wave loads on bridge superstructures.

Based on AASHTO (2008), bridge superstructures under hurricane-induced surge and waves are subjected to a horizontal force representing drag and inertia forces, a vertical force representing uplifting and wave slamming, and a moment due to uneven distributed forces under the bridge deck. These loads are shown schematically in Figure 1. For bridge deck unseating, the most critical force contributing to the failure is the maximum total vertical force, i.e. the summation of the maximum uplifting force F_{V-MAX} and the vertical wave slamming force F_S (Ataei & Padgett 2013b). AASHTO (2008) provided detailed computation procedures that start with the prediction of significant wave height and wave period and end with the calculation of F_{V-MAX} and F_S. Due to space limitation, specific equations are not presented herein. Nevertheless, related parameters are summarized, as shown in Figure 1. It should be noted that the obtained vertical load involves many uncertainties. Probabilistic analyses including both aleatory and epistemic uncertainties can be found in Ataei & Padgett

(2013b) and Mondoro et al. (2016). Their studies are followed herein to consider these uncertainties given the occurrence of a hurricane.

η_{max}	=	wave crest height above storm water level
H_{max}	=	maximum wave height
λ	=	wave length
d_s	=	storm water depth at the bridge
d_b	=	girder height + deck thickness
d_g	=	girder height
Z_c	=	positive or negative distance from storm water level to the bottom of the girder
W	=	deck width

Figure 1. Hurricane-induced loads and their controlling parameters [adapted from AASHTO (2008)]

3 MODELING OF TIME-DEPENDENT CAPACITY

3.1 *Unseating-resistant systems*

The resistance to the aforementioned hurricane-induced loads decides the capacity of the bridge superstructure against unseating failure. The vertical resistance of a superstructure includes its self-weight and the resistance provided by unseating-resistant systems such as dowels, shear keys, and tie-downs, among others. Retrofitting measures, e.g. drilling holes in bridge deck, can also be used to reduce the demand side of the unseating risk. A brief description of these systems can be found in Mondoro et al. (2016). In this paper, the analysis is focused primarily on the vertical resistance provided by the dowels connecting the bridge superstructure and the abutment. A typical dowel setup in a concrete bridge is shown in Figure 2.

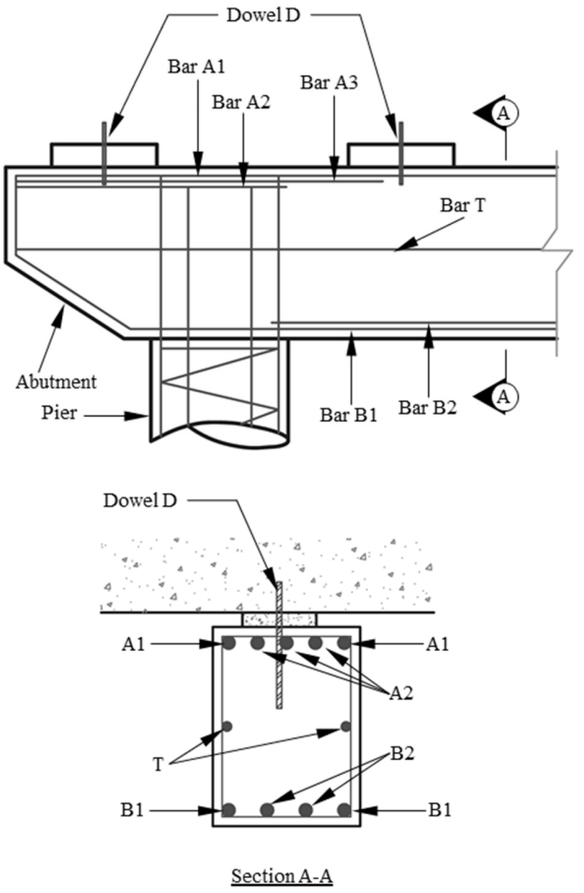


Figure 2. Typical dowel anchorage [adapted from Ataei & Padgett (2013b)]

The capacity of the dowel anchorage can be determined based on the design specification of American Concrete Institute(ACI 2014). It is assumed herein that the embedment length of the dowel is greater than the required development length. Therefore, the pullout strength is controlled by the yield strength of the dowel bar and can be calculated using the following equation (ACI 2014):

$$F_D = n_D \cdot A_{se} f_y \tag{4}$$

where F_D is the total pullout strength provided by all dowels; n_D is the number of dowels; A_{se} is the area of one dowel bar; f_y is the yield strength of the dowel bar. Therefore, the total capacity against unseating failure, including self-weight and dowel resistance, can be expressed as

$$F_c = F_{sw} + F_D \tag{5}$$

in which

$$F_{sw} = \left(d_d W + A_g n_g\right)\gamma_c \cdot L_s \tag{6}$$

where F_c is the capacity; F_{sw} is the self-weight; d_d is the deck thickness; A_g is the area of one girder; n_g is the number of girders; γ_c is the unit weight of reinforced concrete; L_s is the span length.

3.2 *Deterioration due to corrosion*

As mentioned previously, coastal bridges are located in a highly corrosive environment due to airborne chloride and seawater splashes. Chloride-induced corrosion is detrimental at cracks and interfaces where chloride ions and other reactants can easily reach the surface of steel bars. It can be seen from Equation 4 that the corrosion can lead to the reduction of bar areas and consequently the decrease of pullout strength.

Corrosion of steel bars can occur in two forms: uniform corrosion and pitting corrosion (Val & Melchers 1997). For coastal bridges above seawater, pitting corrosion is of more relevance. In order to consider the capacity deterioration due to corrosion, the remaining area of a corroded bar is estimated by the following equation (Val & Melchers 1997):

$$A_r = \begin{cases} A_{se} - A_1 - A_2 & \text{if } p(t_{corr}) \le \dfrac{D_0}{\sqrt{2}} \\ A_1 - A_2 & \text{if } \dfrac{D_0}{\sqrt{2}} < p(t_{corr}) \le D_0 \\ 0 & \text{if } p(t) > D_0 \end{cases} \tag{7}$$

in which

$$p(t_{corr}) = 0.0116 \cdot t_{corr} \cdot i_{corr} \cdot R_{pit} \tag{8}$$

$$A_1 = \frac{1}{2}\left[\theta_1 \left(\frac{D_0}{2}\right)^2 - a\left|\frac{D_0}{2} - \frac{p(t_{corr})^2}{D_0}\right|\right] \tag{9}$$

$$A_2 = \frac{1}{2}\left[\theta_2 p(t_{corr})^2 - a\frac{p(t_{corr})^2}{D_0}\right] \tag{10}$$

and

$$a = 2p(t_{corr})\sqrt{1 - \left[\frac{p(t_{corr})^2}{D_0}\right]} \tag{11}$$

$$\theta_1 = 2\arcsin\left(\frac{2a}{D_0}\right) \tag{12}$$

$$\theta_2 = 2\arcsin\left[\frac{a}{p(t_{corr})}\right] \tag{13}$$

where A_r is the remaining area; D_0 is the diameter of the uncorroded bar; t_{corr} is the time after corrosion initiation in years; $p(t_{corr})$ is the pitting depth in t_{corr}; i_{corr} is the corrosion current density in μA/cm^2; R_{pit} is the pitting factor (Val & Melchers 1997; Stewart & Al-Harthy 2008). It is assumed herein that the corrosion initiates instantly due to the existence of concrete-to-concrete interface (see Figure 2). Therefore, the time of corrosion t_{corr} is equal to the exposure time. The reduction of yield strength due to corrosion is also considered using the following equation (Du et al. 2005):

$$f_y(t) = \left[1 - \frac{0.5(A_{se} - A_r)}{A_{se}}\right] \cdot f_{y0} \tag{14}$$

where $f_y(t)$ is the yield strength at time t; f_{y0} is the yield strength of the uncorroded bar.

By considering the cross-section and yield strength reduction due to corrosion, time-dependent capacity against unseating failure can be determined using Equations 4 and 5, in which the resistance provided the dowels is time-dependent. Similar to the hurricane-induced loads, uncertainties are considered for the modeling of capacity.

Recently, corrosion-resistant materials such as stainless steel and fiber reinforced polymer have been applied in aggressive environments to reduce or even eliminate the adverse effects of corrosion. Although the use of these materials usually indicates a higher initial cost, it has been shown that the life-cycle cost, considering maintenance, is lower than the structures with conventional steel (Soliman & Frangopol 2015; Yang & Teng 2018). In this study, the application of these materials in risk mitigation is investigated. For brevity, it is directly assumed that the cross-sectional area of the dowel and its yield strength does not change with time.

4 LIFE-CYCLE RISK OF REPAIRABLE SYSTEMS

Life-cycle risk is defined herein as the expected consequences of bridge deck unseating during the bridge's service life. As can be realized from the previous sections, the life-cycle risk of deck unseating should account for the reoccurrence of hurricanes and the deterioration of unseating-resistant systems when applicable. Conventionally, life-cycle risk of structures under hazards is usually determined based on the annual risk, as represented by the following equation (Decò & Frangopol 2011):

$$\bar{R}_{f,0}(t_L) = \sum_{i=1}^{t_L} C_{f,i} P[F|H_i] P[H_i] \tag{15}$$

where $\bar{R}_{f,0}$ is the life-cycle risk; t_L is an integer representing the service life of the bridge; $C_{f,i}$ is the monetary consequences in year i; $P[F|H_i]$ is the probability of failure given a hazard occurs in year i; $P[H_i]$ is the probability of hazard occurrence in year i. This formulation implies that the hazard occurrence follows a binomial process with discrete time interval of one year. Another important implication of Equation 15 is that the structure is abandoned after the failure. Therefore, Equation 15 calculates the expected consequences up to the first failure within the time horizon t_L.

For deck unseating, such an implication is invalid because after deck unseating, a new superstructure is most likely to be reinstated. In reliability engineering, such a system is referred to as a repairable system. For a deteriorating but repairable system, its life-cycle risk cannot be determined using Equation 15 as $P[F|H_i]$ is, in this case, related to the failure history of the system. However, if it is assumed that the repair action restores the capacity to its original level, the life-cycle risk can be obtained based on renewal theory, with which the occurrence of unseating failure and its associated repair action is modeled as a renewal-reward process. One realization of this process is shown schematically in Figure 3.

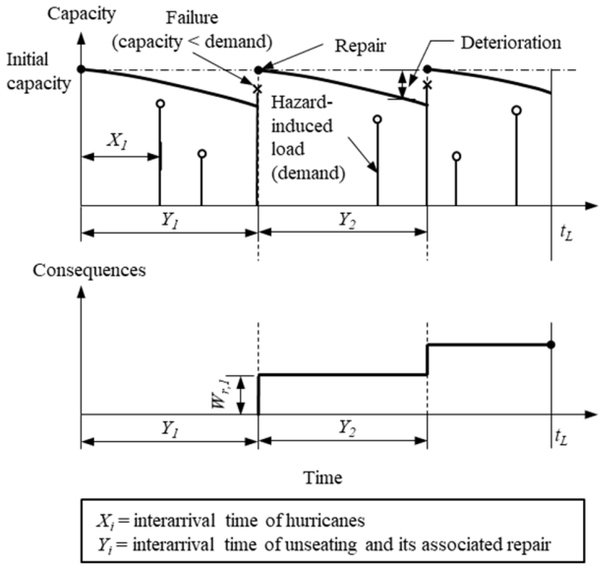

Figure 3. Life-cycle performance of repairable systems under hazards

Based on renewal theory, the expected life-cycle consequences (i.e. risk) of a deteriorating but repairable system can be expressed as (Yang & Frangopol 2017)

$$r_f(t_L) = E\left[\sum_{i=1}^{N_r(t_L)} W_r \cdot e^{-\alpha T_{r,i}}\right] = \int_0^{t_L} w_r \cdot e^{-\alpha\tau} dU(\tau) \tag{16}$$

where $r_f(t_L)$ is the life-cycle risk; $E[\cdot]$ is the expectation operator; $N_r(t_L)$ is the number of unseating failures (and the associated repairs); W_r is the monetary consequences (cost) due to the unseating failure and repair; α is the discount rate of money; $T_{r,i}$ is the time of occurrence of the ith unseating failure; w_r is the mean value of W_r; $U(\cdot)$ is the renewal function of the renewal process of unseating occurrence. The renewal function describes the expected number of event occurrence and can be expressed as

$$U(t) = E[N_r(t)] = \sum_{m=1}^{\infty} \Psi^{(m)}(t) \tag{17}$$

where $\Psi(t)$ is the time-dependent failure probability up to time t; $\Psi^{(m)}(\cdot)$ is the m-fold convolution of $\Psi(\cdot)$. In this paper, the following two-degree polynomial function is used to represent the capacity deterioration:

$$C(t) = k - bt - at^2 \tag{18}$$

where $C(t)$ is the time-dependent capacity; k is the initial capacity; a and b are parameters of the deterioration function. It also hypothesized that the magnitude of demand associated with each hurricane event follows exponential distribution with rate parameter μ. Based on these assumptions, the value of $\Psi(t)$ can be determined using the following closed-form expression:

$$\Psi(t) = 1 - \exp[-\lambda \cdot \varphi(t) \cdot \exp(-\mu k)] \tag{19}$$

in which

$$\varphi(t) = -\left.\frac{\sqrt{\pi} e^{-\frac{\mu b^2}{4a}} \operatorname{erf}\left(-\sqrt{-\mu a} \cdot x + \frac{\mu b}{2\sqrt{-\mu a}}\right)}{2\sqrt{-\mu a}}\right|_{x=0}^{x=t} \tag{20}$$

where λ is the occurrence rate of hurricanes; $\operatorname{erf}(\cdot)$ is the error function. If the system does not deteriorate (e.g. due to the use of corrosion-resistant dowels), $\Psi(t)$ can be expressed as

$$\Psi(t) = 1 - \exp[-\lambda t \cdot \exp(-\mu k)] \tag{21}$$

As mentioned previously, the capacity is a random variable due to the various uncertainties involved. Therefore, the life-cycle risk considering the capacity uncertainties can be expressed as

$$\bar{R}_f(t_L) = \int_0^{\infty} r_f(t_L|k) \cdot f_K(k) dk \tag{22}$$

where $\bar{R}_f(t_L)$ is the expected life-cycle risk considering all uncertainties; $r_f(t_L|k)$ the expected life-cycle risk given the initial capacity k, which can be determined using Equations 16-21; $f_K(\cdot)$ is the PDF of initial capacity. In general, sampling method is needed for the evaluation of Equation 22.

It should be noted that the assumptions mentioned above should be verified for a specific application. In more general cases, closed-form expressions similar to Equations 19-21 are no longer guaranteed to exist. Efficient sampling methods such as that in Yang et al. (2017) may become the only feasible option to evaluate the time-dependent failure probability $\Psi(t)$ and the integral in Equation 22.

5 ILLUSTRATIVE EXAMPLE

The proposed method is illustrated using a 15.2 m simply supported span from a prestressed concrete box-girder bridge located in a coastal region. The water depth below the bridge is 3 m. The span is subjected to hurricanes with the fetch length equal to 50 km. For hurricane events, their return period and the distribution of wind speed are obtained from Li et al. (2016). Specifically, the wind speed follows Weibull distribution with shape and scale parameters equal to 2.06 m/s and 35.9 m/s, respectively. The return period associated with this wind speed is 4.08 years. For reasons mentioned previously, the tropical cyclone statistics are converted to hurricanes with a return period equal to 20 years. The hurricane-induced loads are determined based on the AASHTO design specifications. The variables used in the analysis are summarized in Table 1 (Ataei & Padgett 2013b). The time horizon of interest is 100 years.

Table 1: Variables for capacity and demand modeling

(a) Deterministic variables

Variable	Value	Variable	Value
W	10.9 m	d_a	0.38 m
d_d	0.12 m	D_0	32 mm
n_a	2	n_D	4
A_a	0.58 m^2	i_{corr}	2 μA/cm^2

Note: W = span width; d_d = deck thickness; n_g = number of girders; A_g = cross-sectional area of one girder; d_g = height of one girder; D_0 = diameter of dowels; n_D = number of dowels; i_{corr} = corrosion current density.

(b) Parameter of random variables

Variable	Mean	COV	Distribution
f_{y0}	413 MPa	0.08	Lognormal
f_c	25 MPa	0.15	Normal
R_{pit}	7.17	0.19	Gumbel

Note: f_{y0} = initial yield strength; f_c = concrete strength; R_{pit} = pitting factor.

Based on the hurricane statistics, the demand upon each hurricane occurrence is modeled using Monte Carlo simulation. Figure 4 shows the histogram of the simulation results. It can be seen that the demand follows exponential distribution approximately. The mean value and median value of the load are 588.53 kN and 407.94 kN, respectively.

By virtue of the capacity and deterioration models, the time-dependent capacity against unseating failure is modeled using Monte Carlo simulation. The evolution of the capacity is presented in Figure 5. Equation 18 is used to fit the deterioration of mean capacity. The obtained values for a and b are 0.06178 and 1.473, respectively.

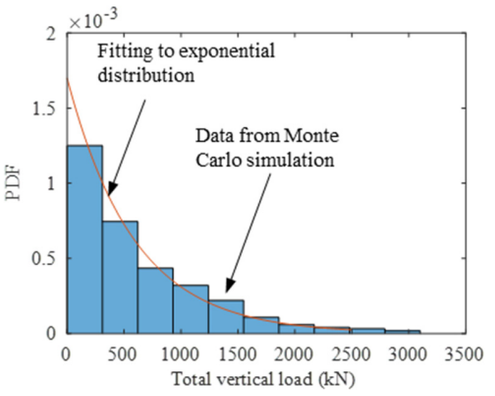

Figure 4. Probabilistic analysis of hurricane-induced loads

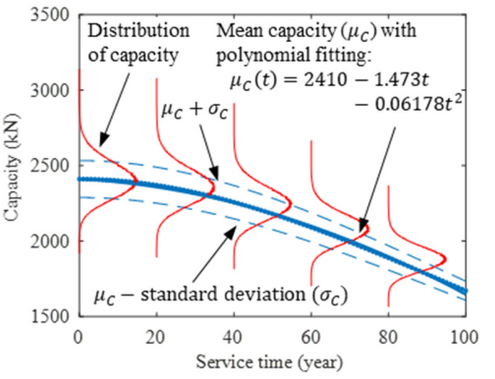

Figure 5. Probabilistic analysis of capacity deterioration

The samples of the initial capacity generated herein can be further used to carry out the integration in Equation 22. The convergence of this integration is shown in Figure 6, in which both deteriorating and non-deteriorating dowels are considered based on Equations 19 and 21, respectively. The discount rate of money is assumed to be 0, indicating that the nominal interest rate is the same as the expected inflation rate (Mondoro et al. 2016). In the analysis, the expected cost associated with unseating failure is assumed to be 100 monetary units, i.e. $w_r = 100$. It can also be regarded as a percentage value to the real monetary cost. The obtained risks for deteriorating and non-deteriorating systems are 16.05 and 8.57 monetary units, respectively. Since no discount rate is considered, the obtained results indicate that the expected numbers of unseating failures in 100 years are 0.161 and 0.086 for deteriorating and non-deteriorating dowels, respectively.

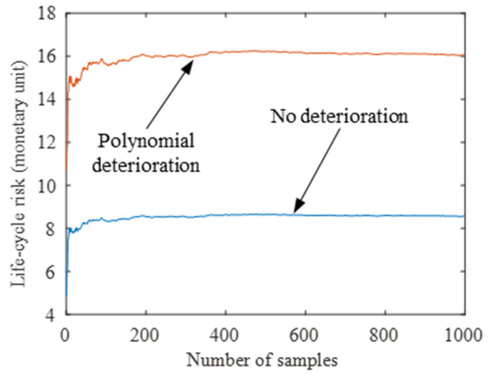

Figure 6. Monte Carlo simulation of unseating risk

In order to quantify the economic benefit of dowels in risk mitigation, the life-cycle risk of the same span without any dowels is also analyzed. In this case, the capacity side of the problem includes only the self-weight, and no deterioration is applicable. The obtained life-cycle risk is 111.35 monetary units, indicating that, on average, the number of unseating failures in 100 years is around 1.11 if no dowels are provided. Therefore, both deteriorating and non-deteriorating unseating-resistant systems can considerably mitigate the life-cycle risk of deck unseating under hurricanes. The economic benefits of both systems can be quantified by subtracting the risks with dowels from that without dowels. In particular, the benefits of deteriorating and non-deteriorating systems are 95.3 and 102.78 monetary units, respectively. If the failure cost is perceived as percentage value (100%), non-deteriorating systems can further reduce 7.48% of the failure cost compared to deteriorating systems. As the cost of deck unseating failure is usually considerably higher than the cost of dowels, the higher initial cost of non-deteriorating dowels can be well justified.

6 CONCLUSIONS

In this paper, a new method is proposed for life-cycle risk assessment of bridge deck unseating under hurricanes. The uncertainties from both demand and capacity sides are taken into account. The proposed method considers both hurricane reoccurrence as a stochastic process and capacity deterioration due to pitting corrosion. Life-cycle risk is formulated for (non)deteriorating but repairable systems based on renewal theory. A number of conclusions are drawn:

1. Unseating-resistant systems are important for risk mitigation of coastal bridges under hurricanes. The benefit of such systems can well outweigh the associated cost.
2. For unseating-resistant systems, capacity deterioration should be considered in the risk assessment. The use of non-deteriorating systems shows better cost-effectiveness in risk mitigation despite the higher initial cost.
3. Occurrence of unseating failures and the associated consequences can be modeled as a renewal-reward process. As a result, life-cycle risk of repairable systems can be assessed using renewal theory. In the most general sense, sampling-based methods are needed for risk assessment.
4. Future work based on the proposed method should consider climate change effects. This can be achieved by hazard analysis pivoting on general climate models and by extending the current risk formulation to nonstationary processes.

Life-cycle seismic resilience of aging bridges and road networks considering bridge capacity correlation

L. Capacci & F. Biondini
Department of Civil and Environmental Engineering, Politecnico di Milano, Milan, Italy

ABSTRACT: The definition of proper design, maintenance, and management policies for aging structural facilities is a strategic priority for communities exposed to multiple natural hazards. In this paper, the probabilistic life-cycle seismic resilience of aging bridges and road networks is investigated by means of a congestion-based performance measure. The level of structural deterioration and seismic damage associated with different limit states is related to traffic restrictions that are progressively removed depending on the recovery times of each bridge in the network. This approach is applied to reinforced concrete (RC) bridges exposed to chloride-induced corrosion and different earthquake scenarios in terms of magnitude and epicenter location. Simple road networks with series and parallel bridge configurations are investigated considering different levels of bridge seismic capacity correlation. The results show the effectiveness of the proposed framework in quantifying the detrimental combined effects of bridge structural deterioration and seismic damage and the influence of bridge seismic capacities correlation on the life-cycle resilience of road networks with different connectivity patterns.

1 INTRODUCTION

During the last decades, the consequences of natural catastrophes showed how communities are largely affected by disruption and downtime of critical infrastructures induced by mechanical damage and loss of functionality of key structural facilities. The impact of distressing events on infrastructure systems has recently intensified along with the increase in complexity and interdependency of lifelines in modern communities (Faturechi & Miller-Hooks 2014).

Structures and infrastructure systems are called to guarantee adequate life-cycle performance under the interdependent harmful effects of sudden extreme events, such as earthquakes, and continuous deterioration processes (Biondini & Frangopol 2016). In order to improve the capability of infrastructure systems to cope with multiple interacting hazards, resilience has recently gained a prominent importance in design and assessment of aging structural facilities, as well as in the definition of risk mitigation programs. Indeed, the concept of resilience relies on the need to quantify the effectiveness of proactive interventions and emergency response in promptly and efficiently restoring the integrity and operability of damaged facilities to recover the pre-event system functionality (Bruneau *et al.* 2003, McDaniels *et al.* 2008, Bocchini *et al.* 2012, Ouyang *et al.* 2015, Ayyub 2015).

In this context, the assessment of the operability of bridge networks under emergency activities is a fundamental task to ensure optimal life-cycle management of road transportation systems (Zhou *et al.* 2010, Chang *et al.* 2012, Decò *et al.* 2013, Ertuğay *et al.* 2016, Capacci *et al.* 2016). Along with the network topology (Bocchini & Frangopol 2012) and hazard scenario (Baker & Jayaram 2008), the functionality and resilience of road networks depend on the correlation between the time-variant performance of the exposed structures. Furthermore, the correlation between bridge failures can be addressed based on their surveyed conditions, network topology, and functional road classes (Rokneddin *et al.* 2013).

In this paper, the probabilistic life-cycle seismic resilience of aging bridges and road networks is investigated by means of a congestion-based performance measure. The correlated seismic capacities of spatially distributed reinforced concrete (RC) bridges exposed to chloride-induced corrosion are assessed to define the time-variant damage probability under different earthquake scenarios. The post-event seismic damage and its progressive restoration due to recovery actions are related to vehicle transit limitations

and traffic analyses are carried out to assess the functionality of the road network from the event occurrence up to the complete recovery. A probabilistic measure of multi-hazard life-cycle seismic resilience is hence proposed to assess the impact at the network scale of structural aging, earthquake scenario, and bridge seismic capacity correlation. In particular, simple road networks with series and parallel bridge configurations are investigated to show the effectiveness of the proposed framework in quantifying the detrimental effects of both structural deterioration and seismic damage and the influence of correlation between bridge seismic capacities on the life-cycle resilience of transportation infrastructure systems.

2 SEISMIC ASSESSMENT OF RC BRIDGES

2.1 *Time-variant effects of corrosion*

The main effect of corrosion in RC structures is the reduction of the cross-section of reinforcing steel bars (Bertolini *et al.* 2004). The steel mass loss is quantified by a time-variant damage index $\delta_s = \delta_s(t) \in [0;1]$. Corrosion may also affect the ductility of steel bars. This effect is related to the steel mass loss by means of a reduction of the steel ultimate strain capacity $\varepsilon_{su}=\varepsilon_{su}(\delta_s)$, as shown in (Biondini & Vergani 2015). It is worth noting that the formation of oxidation products may lead to propagation of longitudinal splitting cracks and concrete cover spalling (Biondini & Vergani 2015, Biondini & Frangopol 2016). However, deterioration of concrete induced by corrosion is not considered as a critical issue for the applications presented in this paper. Corrosion initiation is associated with a critical threshold of chloride concentration C_{cr} and corrosion rate is related to the concentration $C=C(t)$ by means of a damage rate coefficient q_s. Fick's laws of diffusion are used to describe the chloride ingress process and the diffusion equations are solved numerically by means of cellular automata. Further information about diffusion simulation and damage modelling can be found in Biondini *et al.* (2004) and Biondini & Vergani (2015).

2.2 *Bridge limit states and seismic fragilities*

The life-cycle seismic capacity of RC bridges is investigated under uncertainty by means of time-variant fragilities $P^E_{s,b}=P^E_{s,b}(t_b)$, which provide the probability of exceedance of a limit state s_b given the occurrence of a seismic event of intensity i_b at time t_0, where $t_b=t_0-t_{c,b}$ is the bridge age and $t_{c,b}$ is the bridge construction time (Capacci *et al.* 2018b). The peak ground acceleration is assumed as seismic intensity measure. The bridge seismic capacity is evaluated based on incremental dynamic analysis (Vamvatsikos & Cornell 2002). The damage measure is associated with the maximum drift $\theta_{\max,b}$, defined as the maximum ratio of the bridge pier top displacement to the pier height. The attainment of the damage states s_b is associated with the following time-variant drift thresholds $\theta_{s,b}$ (Capacci 2015):

- Slight Damage (SD, s_b=1): $\theta_{1,b}=\theta_{y,b}$;
- Moderate Damage (MD, s_b=2): $\theta_{2,b}=\theta_{y,b}+0.3\theta_{p,b}$;
- Extensive Damage (ED, s_b=3): $\theta_{3,b}=\theta_{y,b}+0.6\theta_{p,b}$;

with $\theta_{p,b}=\theta_{u,b}-\theta_{y,b}$, and where $\theta_{y,b}$ and $\theta_{u,b}$ are the mean values of the drift at first yielding and ultimate bending curvatures, respectively, at the base of the bridge piers. The time-variant drift thresholds $\theta_{y,b}$ and $\theta_{u,b}$ are computed by means of non-linear static (push-over) analysis. In addition, the bridge is assumed to suffer No Damage (ND, s_b=0) if $\theta_{\max,b}<\theta_{1,b}$, and to reach the limit state of Structural Collapse (SC, s_b=4) when the dynamic equilibrium under ground motion is no longer fulfilled.

The probabilistic analysis is performed by Monte Carlo simulation and the results of the incremental dynamic analyses are processed by assuming lognormal distribution of the fragility functions:

$$P^E_{s,b} = P(s_b \mid i_b, t_b) = \Phi\left(\frac{\ln i_b - \lambda_{s,b}(t_b)}{\zeta_{s,b}(t_b)}\right) \quad (1)$$

where Φ is the cumulative distribution of a normal variate, and $\lambda_{s,b}$ and $\zeta_{s,b}$ are the mean and standard deviation, respectively, of the natural logarithm of the seismic capacity associated with damage state s_b.

2.3 *Seismic hazard and network damage*

The seismic demand is evaluated based on the ground motion prediction equation proposed in Bindi *et al.* (2011). The seismic intensity i_b at the site $\mathbf{x}_b$ of the b-th bridge in the network is related to the earthquake scenario in terms of magnitude M and focal distance between bridge site $\mathbf{x}_b$ and epicenter location $\mathbf{x}_e$ (Biondini *et al.* 2017, 2018a).

The combination of bridge initial damage levels in a given network is defined by means of an integer index s based on the ordered selection without repetitions of the damage states s_b of each bridge:

$$s = 1 + \sum_{b=1}^{N_b} \left(N_{s,b}\right)^{N_b-b} \cdot s_b \quad (2)$$

where N_b is the total number of bridges and $N_{s,b}$ is the number of possible damage states of the b-th bridge.

Along with the seismic scenario, defined in terms of magnitude M and epicenter location $\mathbf{x}_e$, the time-variant probability of occurrence of the s-th damage combination depends on both location $\mathbf{x}_b$ and age t_b of each bridge, as well as on the correlation between the seismic capacity of each pair of bridges. The conditional probability of occurrence of the s-th damage combination can hence be expressed as follows:

$$P_s = P(s \mid M, \mathbf{x}_e, \mathbf{x}_b, t_b, \boldsymbol{\rho}) \quad (3)$$

where $\boldsymbol{\rho}$ is a correlation matrix that collects the linear correlation coefficients of each pair of bridge seismic capacities.

3 RESILIENCE OF ROAD NETWORKS

3.1 *Traffic flow and travel time*

The performance of road networks can be assessed based on the traffic flow response, given the Origin-Destination traffic demand and the network topology. The travel time c_{ij} of the road arc *i-j* can be expressed as a function of the related vehicle flow per unit of time f_{ij}. The flow depends on the arc practicability in terms of practical capacity $f^{cr}_{ij}=n_L(v_{cr}/d_{\min})$ and travel time at free flow $c^0_{ij}=L_{ij}/v_{\lim}$, where: L_{ij}=arc length; n_L=number of open lanes; $d_{\min}$=minimum allowed distance between vehicles associated with the arc road class; v_{cr}=critical speed; v_{lim}=speed limit (either maximum $v_{\max}$ or minimum $v_{\min}$). More detailed information on the traffic model and the relationship between travel time and traffic flow can be found in Capacci (2015).

3.2 *Type of users and traffic limitations*

The traffic capacity of a road arc may be impaired by traffic restrictions applied to regulate the transit on damaged bridges (Mackie & Stojadinović 2006). Three different types of traffic users and related traffic flows are considered: light vehicles, f_l; heavy vehicles, f_h; emergency vehicles, f_e. Traffic limitations on the *b*-th bridge are identified by a decision variable d_b based on the following $N_{d,b}=5$ traffic restrictions (Biondini *et al.* 2015):

- No Restrictions ($d_b=0$): the traffic on the bridge is regular and the speed limit v_{lim} corresponds to the maximum allowed speed *0*;
- Weight Restriction ($d_b=1$): heavy vehicles are forbidden, i.e. $f_h=0$, and the speed limit is reduced to $v_{\min}$.
- One Lane Open Only ($d_b=2$): light and emergency vehicles can transit on only one lane, i.e. $n_L=1$;
- Emergency Access Only ($d_b=3$): the transit of emergency vehicles only is allowed, i.e. $f_l=0$;
- Closure ($d_b=4$): no vehicles can transit over the bridge, i.e. $f_e=0$ or $n_L=0$.

The decision variables $d_b=k$ with $k>1$ are inclusive of the traffic restrictions associated with $d_b<k$. The network restriction combination is defined by means of an integer index *d* in terms of the decision variable d_b, consistently with the criterion proposed for the network damage combinations:

$$d = 1 + \sum_{b=1}^{N_b} \left(N_{d,b}\right)^{N_b - b} \cdot d_b \tag{4}$$

3.3 *Traffic analysis and network functionality*

The vehicle flow f_{ij} of any road arc *i-j* can be identified based on the user-equilibrium condition enforced by the Wardrop's gravitational model (Wardrop 1952), which consists in the minimization of the total travel time *TTT* of all the users of the road network. More details concerning with the traffic analysis, the solution of the related optimization problem and the definition of total travel time $TTT_d=TTT(d)$ under traffic restriction combinations can be found in Bocchini & Frangopol (2011) and Biondini *et al.* (2015).

The functionality level $Q_d=Q(d)\in[0;1]$ of the road network associated with the combination *d* of traffic restrictions is defined as follows (Capacci 2015):

$$Q(d) = \frac{TTT_u}{TTT_d} \tag{5}$$

where $TTT_u=TTT(d=1)$ is the total travel time in unrestricted conditions, i.e. no traffic regulations are applied to any bridge. It is worth noting that the condition of unrestricted transit with $TTT_d=TTT_u$ and $Q=1$ is fulfilled both before the seismic event occurrence and after full recovery of all the bridges.

3.4 *Bridge recovery process*

In the aftermath of a seismic event, each bridge in the network may suffer an initial loss of seismic capacity, leading the road managers to enforce a serviceability limitation. In particular, the traffic restriction $d_b=k$ is applied to the *b*-th bridge if the earthquake induces the damage state $s_b=k$ (Capacci *et al.* 2016)

The idle time $\Delta t_{i,b}$ represents the interval between the occurrence time t_0 and the repair initiation for the *b*-th bridge. In the following, the idle time is neglected and the repair actions of each bridge in the network are assumed to start at time t_0.

The bridge recovery process develops over a series of time steps depending on the initial damage and the specific recovery strategy. The partial recovery times $t_{p,b}$ are related to time instants in which the attainment of intermediate seismic capacity thresholds allows the enforcement of less severe traffic limitations up to the complete reopening of the bridge to all users. In particular, $p=1,\ldots,N_{j,b}$, where $N_{j,b}$ is the total number of jumps in the network recovery process. The final recovery time $t_{r,b}$ is associated with the completion of the repair actions. During the recovery process, each initial traffic limitation $d_b=k$ with $k>0$ is partially released leading to a sequence of progressively less severe restrictions $d_b=h$ with $h<k$. The full serviceability of the bridge, i.e. $d_b=0$, is reached at time $t_{r,b}$.

3.5 *Network recovery process*

At the network level, the repair activities carried out on each bridge lead to define a constant stepwise model for the progressive restoration of the functionality (Padgett & DesRoches 2007). In this way, the road network functionality is described by a discrete set of values associated with the network restrictions *d*, from the initial damage to the fully restored state. The recovery function of network functionality over a time interval $\Delta t_h=(t_h-t_0)$, where t_h is a given horizon time, is hence defined in stepwise form as follows:

$$Q(t) = Q_j, \quad t_j \le t < t_{j+1} \ \forall j \in [0; N_j] \tag{6}$$

where t_j=t_h for j=N_j+1 and N_j=$\sum_b N_{j,b}$ is the total number of jumps in the network recovery process.

A seismic event striking the road network at time t_0 would cause a sudden drop of functionality from the pre-event level to Q_0=Q(d=s) under the traffic restrictions imposed by the initial damage combination s of the bridges. Therefore, post-event restoration activities lead to progressive functionality jumps from Q_{j-1} to Q_j at time t_j with j=1,…,N_j.

3.6 *Resilience levels and resilience measure*

The resilience level R_s associated with the network damage combination s is defined as the average integral of the network functionality over the recovery time interval Δt_h. Considering the stepwise form of the network recovery function, the resilience integral can be reduced to the following sum:

$$R_s = \frac{1}{\Delta t_h} \sum_{j=1}^{N_j} Q_j \Delta t_j \tag{7}$$

where Δt_j= t_j–t_{j-1} is the j-th recovery time step.

The resilience measure R of the road network is inspired by the concept of expected utility (Ang & Tang 1984) and obtained by weighing the resilience levels R_s of the N_s network damage combinations with the corresponding damage probabilities:

$$R = \sum_{s=1}^{N_s} P_s \cdot R_s \tag{8}$$

4 APPLICATION

4.1 *RC box girder bridge*

The four-span continuous RC bridge shown in Figure 1 is considered (Mander *et al.* 2007). The total length of the bridge is 200 m, with spans of 50 m, as shown in Figure 1a. The height of the piers is 14 m. Figure 1b shows the box girder cross-section of the deck. The piers have circular cross-section and are reinforced with 36 steel bars with 30mm-diameter, as shown in Figure 1c. Concrete and steel nominal strengths are f_c=40MPa and f_{sy}=450MPa, respectively.

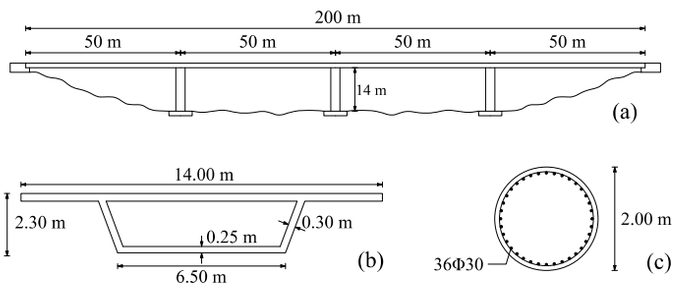

Figure 1. RC box girder bridge: (a) longitudinal profile; (b) deck cross-section; (c) pier cross-section with reinforcement layout.

The bridge piers are exposed to a chloride diffusive attack on the external surface, with nominal chloride concentration C_0=3% [wt.%/c]. A nominal diffusivity coefficient D=15.8×10^{-12} m^2/sec is assumed for concrete. The corrosion damage propagation is evaluated by assuming a nominal damage rate coefficient q_s=(0.02 year^{-1})/C_0, with corrosion initiation related to the attainment of a nominal critical threshold of concentration C_{cr}=0.6wt.%/c.

4.2 *Bridge seismic fragilities under corrosion*

Concrete strength f_c, steel strength f_{sy}, viscous damping ξ, diffusivity D, steel damage rate q_s, surface chloride concentration C_0 and critical chloride concentration C_{cr} are assumed as uncorrelated random variables with prescribed density distributions. The life-cycle fragility analysis is carried out by Monte Carlo simulation based on Latin Hypercube Sampling. The nonlinear time-history dynamic analyses are performed in each realization for a set of 10 artificial earthquakes generated to comply with the elastic response spectrum given by Eurocode 8 for soil type B (CEN-EN 1998). Further details on both the probabilistic modeling and simulation process can be found elsewhere (Capacci 2015, Capacci *et al.* 2016).

Figure 2 shows the time-variant drift thresholds based on the mean values of the drift limits $\theta_{y,b}$ and $\theta_{u,b}$ at first yielding and ultimate, respectively. It is noted that corrosion damage significantly reduces over time the pier displacement ductility. Figure 3 shows the lognormal best fitting of the corresponding time-variant fragility curves over a 100-year lifetime with steps of 10 years. The bridge seismic capacity against the occurrence of first yielding is slightly affected by corrosion. However, the effects of structural deterioration lead to a substantial decrease of bridge seismic capacity for any damage state s_b>1.

4.3 *Road networks and resilience levels*

The road networks shown in Figures 4a and 5a with bridges in series (S) and parallel (P), respectively, are considered. The networks include one Origin and one Destination, two identical bridges B_1 and B_2 built at time $t_{c,b}$=0 at a relative distance of 10km, and a secondary road to detour the traffic flow.

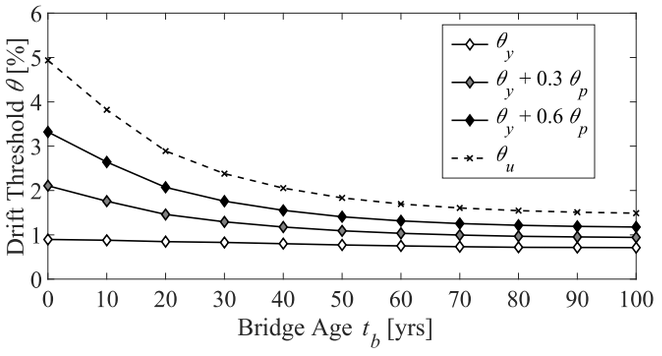

Figure 2. Drift ratios associated with different thresholds.

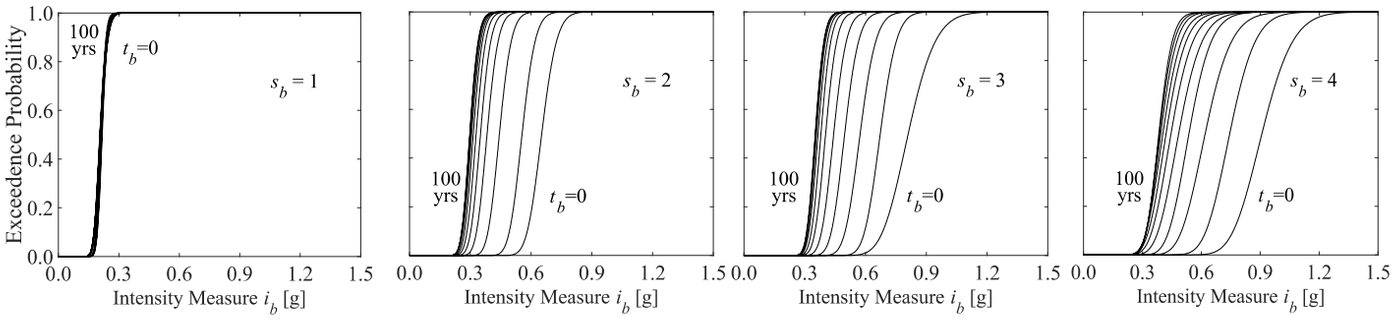

Figure 3. Time-variant seismic fragility curves for a seismic event occurring at bridge age from t_b=0 to 100 years with time steps of 10 years: (a) Slight Damage, (b) Moderate Damage, (c) Extensive Damage, and (d) Structural Collapse.

Given a Cartesian coordinate system $\mathbf{x}=(x,y)$ with origin $\mathbf{x}_c=(0,0)$ in the bridge network centroid and x-axis aligned with the O-D nodes, the coordinates of the bridges are (km): $\mathbf{x}_{b=1}=(-5,0)$ and $\mathbf{x}_{b=2}=(5,0)$ for system S; $\mathbf{x}_{b=1}=(0,-5)$ and $\mathbf{x}_{b=2}=(0,5)$ for system P. Table 1 summarizes the main traffic parameters, with v_{cr}=65 km/h and $d_{\min}$=30 m/cars. The two networks have similar total travel times. Traffic restrictions are applied to the bridges according to the initial damage state and post-event recovery enforcing stepwise increments in the network functionality. Partial and final recovery times are listed in Table 2.

The bar charts shown in Figure 4b and 5b provide the resilience levels for the network damage combinations. The functionality of network S is affected by any damage scenario in which at least one bridge suffers significant damage (Figure 5a), since redundancy is given by the detour only. Conversely, the functionality of network P is significantly reduced only if both bridges are extensively damaged (Figure 5b).

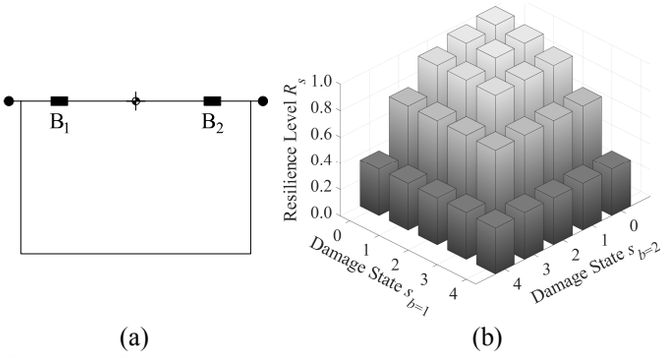

Figure 4. Road network S: (a) connectivity layout with two bridges in series, and (b) bar chart of the resilience levels.

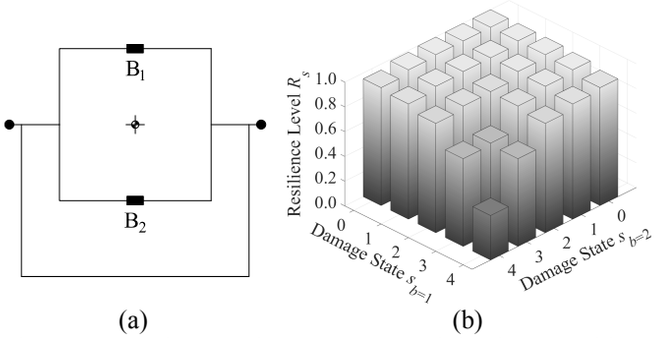

Figure 5. Road network P: (a) connectivity layout with two bridges in parallel, and (b) bar chart of the resilience levels.

Table 1. Traffic parameters of networks S and P.

	Highway in S	Highways in P	Side Road
L [km]	15	18	60
n_L	3	3	2
$v_{\max}$ [km/h]	130	130	90
$v_{\min}$ [km/h]	70	70	50

Table 2. Bridge recovery times for each damage state.

	$t_{p=1,b}$ [days]	$t_{p=2,b}$ [days]	$t_{p=3,b}$ [days]	$t_{r,b}$ [days]
s_b=1	-	-	-	30
s_b=2	39	-	-	90
s_b=3	82	103	-	180
s_b=4	165	218	262	360

4.4 *Seismic resilience of the road networks*

The seismic resilience of the two road networks S and P is evaluated considering different levels of bridge seismic capacity correlation. Consistently with the procedure for the fragility analysis, the network damage probabilities P_s are retrieved by Monte Carlo simulation based on Latin Hypercube Sampling for a sample of 5000 realizations of correlated bridge seismic capacities. Figures 6 and 7 show the 3-D surfaces and the related 2-D contour maps of the resilience $R=R(\mathbf{x}_e)$ of the networks S (Figure 6) and P (Figure 7), for a seismic event with magnitude M=6.75 occurring at time t_0=40 years based on a square grid of epicenters with grid size of 0.2 km. Three levels of linear correlation ρ are considered for the bridge seismic capacities: (a) $\rho = 0$, (b) $\rho = 0.5$, and (c) $\rho = 1$.

The most critical earthquake scenarios for the network S are associated with epicenter locations close to one of the bridges, for all levels of correlation, because of the limited system redundancy. However, the impact of the lack of redundancy is partially mitigated by the bridge capacity correlation when the epicenter is close to the network centroid. In fact, in this case the likelihood of having at least one bridge severely damaged increases as correlation decreases.

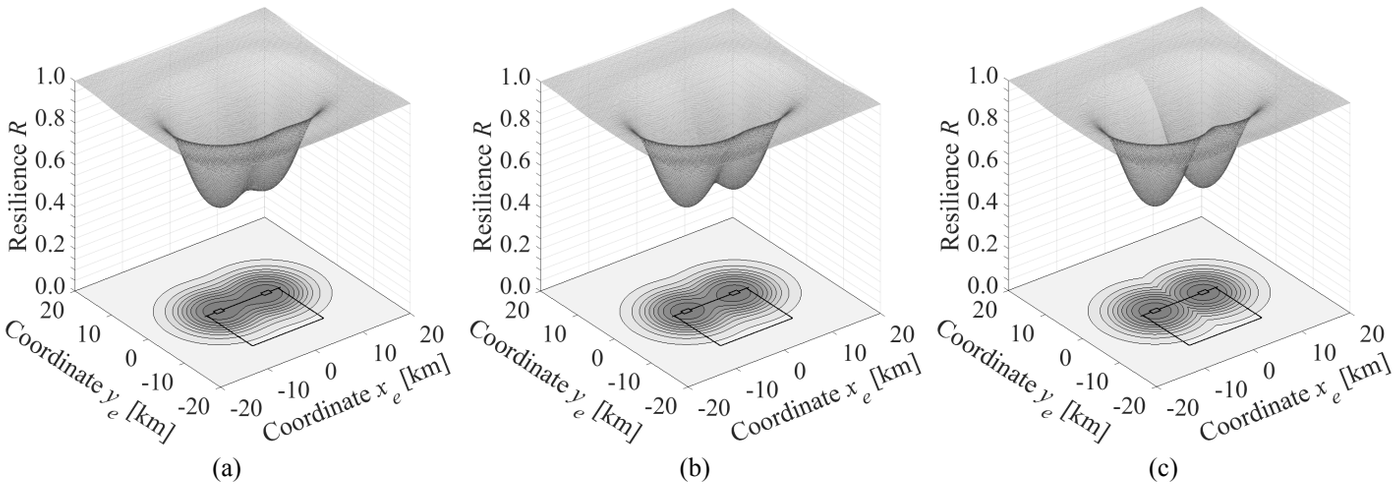

Figure 6. Road network S. Resilience R versus the epicenter location $\mathbf{x}_e=(x_e,y_e)$ of a seismic event occurring at time t_0 = 40 years with earthquake magnitude M=6.75 for different levels of bridge seismic capacity correlation: (a) ρ=0, (b) ρ=0.5, and (c) ρ=1.

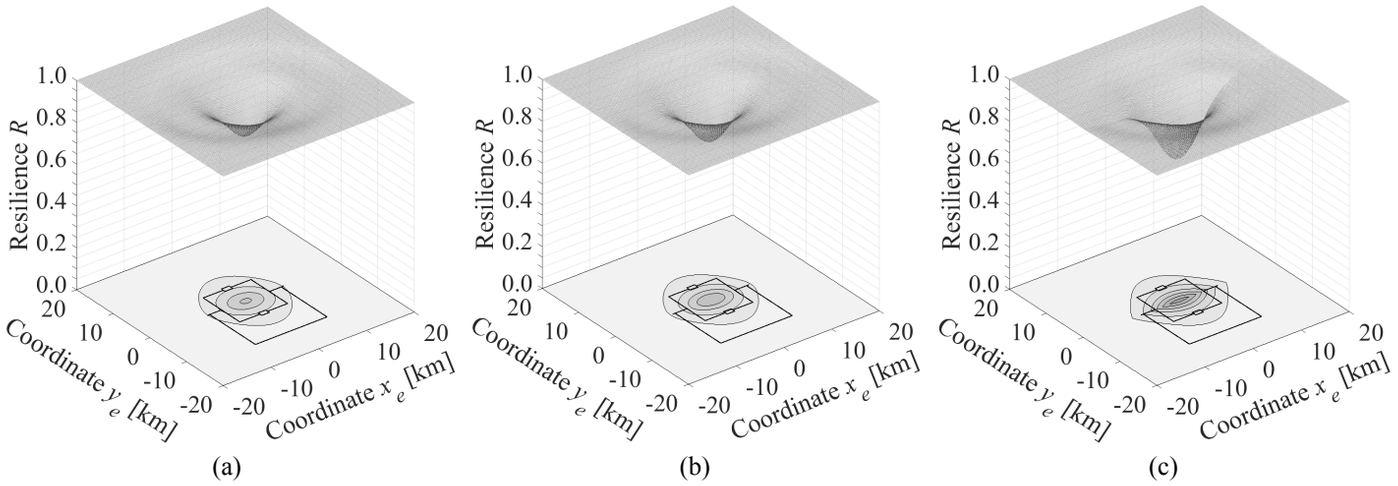

Figure 7. Road network P. Resilience R versus the epicenter location $\mathbf{x}_e=(x_e,y_e)$ of a seismic event occurring at time t_0 = 40 years with earthquake magnitude M=6.75 for different levels of bridge seismic capacity correlation: (a) ρ=0, (b) ρ=0.5, and (c) ρ=1.

Conversely, the most critical earthquake scenarios for the network P are associated with epicenter locations close to the network centroid. This tendency is exacerbated by the correlation of bridge seismic capacities, since for these scenarios the likelihood of having both bridges severely damaged increases with the correlation level.

The influence of the earthquake epicenter location and bridge seismic capacity correlation can be appreciated also from the diagrams illustrated in Figures 8 and 9, which show the seismic resilience R versus the epicenter distance $d_e=\|\mathbf{x}_e-\mathbf{x}_c\|$ from the network centroid along the direction at angle $\alpha_e=\arcsin[(y_e-y_c)/d_e]$ with the x-axis. The resilience curves are shown for $\alpha_e=0$ and $\pi/2$, occurrence times t_0=20, 40 and 60 years, and earthquake magnitudes M=6.25, 6.50 and 6.75. With respect to the contour maps shown in Figures 6 and 7, the diagrams in Figures 8 and 9 show that the role of correlation may be emphasized over time due to structural deterioration and for increasing seismic magnitude. However, the effect of correlation may be substantially reduced under the combined effects of severe corrosion and seismic damage.

In order to show the role of correlation of the bridge seismic capacities over the life-cycle, the following time-variant resilience sensitivity index is defined for the investigated S and P road networks:

$$\Delta r_\rho(M,\mathbf{x}_e,t_0)=\frac{R_\rho-R_{\rho=0}}{R_{\rho=0}} \tag{9}$$

where R_ρ is the network seismic resilience associated with a linear correlation coefficient ρ. Figure 10 shows the resilience sensitivity index Δr_ρ for ρ=1, i.e. $\Delta r_{\rho=1}$, versus the occurrence time t_0 for epicenter location in the network centroid, i.e. $\mathbf{x}_e=\mathbf{x}_c$, and different magnitudes M=6.25, 6.50 and 6.75. These results confirm the opposite trends obtained for the series system S, with $\Delta r_{\rho=1}>0$, and the parallel system P, with $\Delta r_{\rho=1}<0$. Moreover, in both cases the correlation effects tend to increase at the beginning of the service life, after about 10 years, when corrosion damage propagates. However, this tendency is reversed over time under severe deterioration for increasing seismic hazard since both bridges are likely to suffer extensive seismic damage regardless of the level of correlation of their seismic capacities.

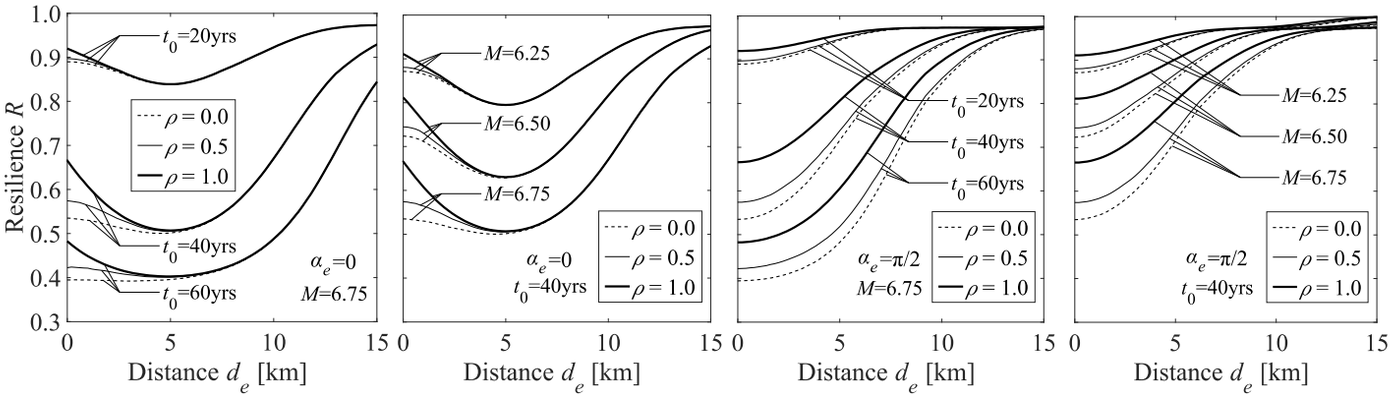

Figure 8. Road network S. Resilience R versus epicenter distance d_e from the network centroid for different angles α_e=0 and π/2, earthquake magnitudes M=6.25, 6.50 and 6.75, and occurrence times t_0=20, 40 and 60 years.

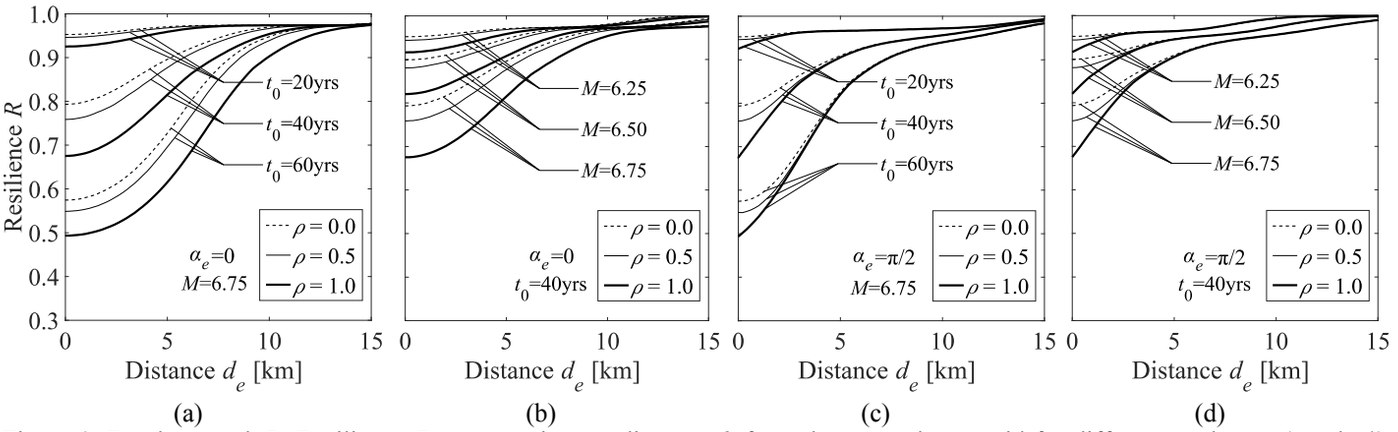

Figure 9. Road network P. Resilience R versus epicenter distance d_e from the network centroid for different angles α_e=0 and π/2, earthquake magnitudes M=6.25, 6.50 and 6.75, and occurrence times t_0=20, 40 and 60 years.

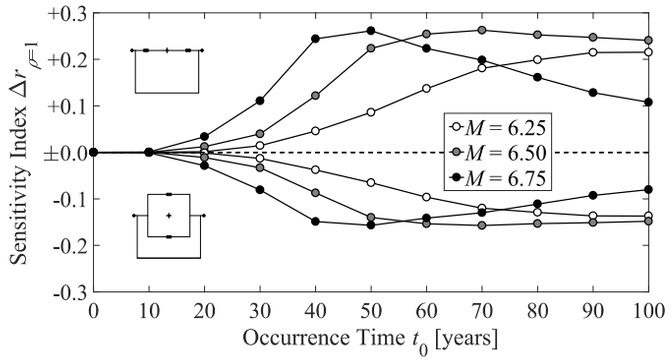

Figure 10. Resilience sensitivity index Δr_ρ for ρ=1 versus the occurrence time t_0 with epicenter location in the network centroid, i.e. $\mathbf{x}_e$=$\mathbf{x}_c$, and different magnitudes M=6.25, 6.50, 6.75.

5 CONCLUSIONS

A multi-hazard probabilistic framework for life-cycle resilience assessment of road transportation networks with spatially distributed RC bridges exposed to chloride-induced corrosion and different earthquake scenarios has been presented. Simple road networks with series and parallel bridge configurations have been investigated to quantify the detrimental effects of both structural deterioration and seismic damage, as well as the influence of bridge seismic capacity correlation, on the life-cycle seismic resilience of transportation infrastructure systems.

It has been shown that for series bridge networks, which rely on detour routes to ensure a certain degree of redundancy, the most critical earthquake scenarios are associated with epicenters close to the bridges. The impact of the lack of redundancy can be partially mitigated by correlation between bridge seismic capacities when the epicenter is relatively far from the bridges. In fact, in this case the likelihood of having at least one bridge severely damaged tends to increase as correlation decreases. Conversely, for parallel bridge networks the most critical earthquake scenarios are associated with epicenters close to the network centroid. This is emphasized by bridge capacity correlation, since in these scenarios the likelihood of having the correlated bridges severely damaged increases with the correlation level. Moreover, for the investigated series and parallel networks the correlation effects tend to increase under moderate levels of structural deterioration. However, over time the combined effects of severe corrosion and seismic damage may significantly reduce such effects. This highlights the importance of a multi-hazard life-cycle-oriented probabilistic approach to seismic resilience assessment of bridges and road infrastructure networks.

Time-Dependent Probability of Exceeding Restoration Levels in Resilience Analysis

F. Nocera & P. Gardoni
University of Illinois at Urbana-Champaign, Urbana, IL, USA
G.P. Cimellaro
Politecnico di Torino, Turin, Italy

ABSTRACT: Resilience typically refers to the ability of a system to adapt to changing conditions, withstand and rapidly recover from disruptions due to extreme/rare events. This paper proposes a methodology to predict the recovery process of a selected system given past recovery data and estimate the probability of exceeding a target value of functionality at any time. A Bayesian inference is used to update the model parameters as new data become available while the recovery process is in progress. The methodology is general and can be applied to continuous recovery processes such as those of economic or natural systems, as well as to discrete recovery process such as those of engineering systems. As an illustration, the proposed methodology is implemented considering a bridge restoration following seismic damage.

Keywords: Decision Support, Metrics, Recovery, Reliability analysis, Resilience.

1 INTRODUCTION

Civil infrastructure enable the movement of goods, services, and resources to communities (Corotis 2009; Ellingwood et al. 2016; Gardoni et al. 2016). Civil infrastructure are vulnerable to natural and anthropogenic hazards. Past disasters have showed their vulnerability and emphasized the relevance of risk mitigation and management (Murphy and Gardoni 2006; Gardoni and LaFave 2016; Gardoni et al. 2016). Natural hazards (such as floods, earthquakes, and hurricanes), and anthropogenic hazards (such as accidents and terrorist attacks) may cause damage to civil infrastructure, leading to loss or reduction in functionality of the infrastructure.

The concept of resilience has gained relevance in the recent past as a desirable feature for communities (Bruneau et al. 2003; McAllister 2013; Caverzan and Solomos 2014; Ellingwood et al. 2016; Guidotti et al. 2016, 2017; Sharma et al. 2017). In the last fifteen years, researchers have connoted the resilience using several definitions and proposing several approaches to measure resilience in different areas (e.g., engineering, and social science). Resilience, in general, has been defined as the ability of systems to recover after disturbances (e.g., Bruneau et al. 2003; Cimellaro et al. 2010a; Bocchini et al. 2012). The recovery process can be described using *recovery curves*, which play a key role in terms of defining the resilience of a system. The recovery curve captures the changes in the performance of a disturbed system over time, and describes how the system recovers toward a desired system state. Neglecting the occurrence of hazards while the recovery is in progress, the recovery curve is, in general, a non-decreasing function. Different studies have attempted to define recovery curves for different engineering systems subject to hazards (e.g., Cimellaro et al. 2010b; Decò et al. 2013; Titi et al. 2015; Bonstrom and Corotis 2016). The recovery curves are defined based on qualitative descriptors such as the preparedness of communities, which can impact the recovery process. However, the recovery curves are not modeled explicitly as functions of influencing variables that shape the recovery process (e.g., available resources). Furthermore, the recovery curves do not account for the underlying uncertainties and, as a result, it is not possible to estimate the probability of reaching or exceeding a target percentile of interest of the ultimate desired state (i.e., target value of functionality.) Finally, it is not clear how additional information that might become

available while the recovery is in process (such as current progress of the work or increased resource availability) may modify the recovery models and affect/reduce the uncertainty involved (Sharma et al. 2017). Sharma et al. (2017) addressed partially these limitations, proposing a mathematical formulation to model the recovery curves based on the work plan of activities involved in the recovery process. As a result, while the work on individual activities may proceed continuously over time, the changes in the system state occur at discrete points in time when a set of activities is completed. As further discussed in Section 2, Sharma et al. (2017) also introduced a set of metrics, analogous to the moments of a random variable, to quantify the resilience of a system.

This paper proposes a methodology to predict the recovery process of a selected system given past recovery data, and estimate the probability of reaching or exceeding a target value of functionality at any time. The proposed methodology is general and can be applied to different domains, e.g. economical, natural, and engineering systems. Specifically, in the engineering domain, the proposed methodology can be used i) in a reliability-based design to make design decisions and ii) in identifying recovery strategies both with the objective of achieving a target value of functionality within a desired time with a specified level of probability for a given hazard.

In the proposed methodology, we first obtain estimates of the resilience metrics defined according to Sharma et al. (2017) using recovery data for different systems. The uncertainties in the estimates are captured by the joint probability density function (PDF) of the resilience metrics. Parametrized recovery curves are then introduced to model the time-varying recovery process and the joint PDF of the model parameters in the recovery curves is obtained as a function of the joint PDF of the resilience metrics. Then, the joint PDF of the model parameters are used to define the variability in the possibly recovery curves, which is used to evaluate the probability of reaching or exceeding a desired target value of functionality by performing a reliability analysis (Ditlevsen and Madsen 1996; Gardoni 2017). Furthermore, we propose to include the Bayesian inference to update the model parameters, combining prior information with the objective information from the new data as they become available during the recovery process. As an illustration of the proposed methodology, we consider a bridge restoration following seismic damage.

Following this introduction, Section 2 reviews mathematical formulations for resilience analysis. Section 3 shows the proposed methodology. Section 4 includes the numerical example to illustrate the proposed methodology. Finally, Section 5 concludes the article.

2 REVIEW OF MATHEMATICAL FORMULATION FOR RESILIENCE ANALYSIS

Mitigation planning and the allocation of resources in pre- and post-disruption scenarios mostly depend on the resilience analysis of engineering systems (Gardoni et al. 2016). In resilience analysis, the performance of a system (e.g., the system functionality), typically indicated as $Q(t)$, is a time-dependent function that defines the system state (Cimellaro et al. 2010a; Bocchini et al. 2012; Bonstrom and Corotis 2016; Sharma et al. 2017). The functionality of a system may experience an instantaneous drop due to an external shock, such as a natural or anthropogenic hazard (Kumar and Gardoni 2014; Kumar et al. 2015; Jia and Gardoni 2017a,b). After the occurrence of the hazard, recovery activities retrieve the system functionality to a desired level, which may be below, same or better than the pre-disruption value (Ayyub 2014, 2015).

Recovery curves capture the changes in the system functionality and define how the system recover to achieve the desired level of functionality at the end of the recovery process. To quantify the resilience, number of researchers (e.g., Bruneau and Reinhorn 2007; Cimellaro et al. 2010b; Bonstrom and Corotis 2016) have defined a measure as a function of the integral over time of the recovery curves. The first attempts to measure the resilience showed the relevance of quantifying resilience in an objective way. These contributions provided partial information on the resilience of a system (Sharma et al. 2017). For instance, Bruneau et al. (2003) introduced the resilience index R, computed as the area of the region bounded by the recovery curve. Chang and Shinozuka (2004) proposed to quantify resilience as the conditional probability of meeting a desired level of performance, in terms of residual functionality and time to recover, given a seismic event. However, as Sharma et al. (2017) noted, such metrics provide only an incomplete description of resilience, showing that these metrics might provide the same value of resilience in the case of different recovery processes. In response to this limitation, Sharma et al. (2017) introduced a set of partial descriptors of the recovery curve as new resilience metrics in analogy with the partial descriptors commonly accepted in probability and statistics (e.g., mean and standard deviation of a random variable). These resilience metrics have two important features: i) the partial descriptors are simple with clear interpretations, and ii) any subset of partial descriptors can be expanded systematically to include higher order descriptions to eventually fully characterize the resilience of a system. Sharma et al. (2017) called $Q(t)$ the cumulative resilience function (CRF). In the case the CRF is a continuous and differentiable function of the time, we can define the

resilience density function (RDF) q as its time derivative. Instead, in the case the CRF is not continuous and differentiable, we can define a resilience mass function (RMF) to describe changes in the recovery as a step-wise function. Based on these definitions, they introduced the center of resilience ρ and the resilience bandwidth, χ as two fundamental partial descriptors. In most cases, ρ and χ are sufficient to characterize a recovery curve, as well as the mean and the standard deviation are able to fully describe a probability density function. Sharma et al. (2017) also introduced higher order of partial descriptors, such as the skewness of the recovery ψ that measures the symmetry of the recovery process around the center of resilience ρ. The analogy between the resilience metrics and the moments in statistics is consistent with the analogy between the CRF, RDF, RMF and the cumulative distribution function (CDF), the probability density function (PDF) and the probability mass function (PMF) of a random variable.

3 PROPOSED METHODOLOGY

This section describes the proposed methodology to predict a probable recovery curve and to estimate the probability of reaching or exceeding a target value of functionality at any time.

In general, the work progress for civil structures and infrastructure is described through a continuous function over time (Klinger and Susong 2006; Gardoni et al. 2007); conversely, the state of a system experiences a change after the completion of a set of activities (Sharma et al. 2017). Therefore, the functionality of a system can be described as a step-wise function with jumps at the completion of each set of activities (Sharma et al. 2017). This behavior is typical for civil structures and infrastructure, or more generally, engineering systems, whereas the recovery curve of natural systems (e.g., recovery and resilience of tropical forests (Cole et al. 2014; van Leeuwen 2008)) might be a continuous function. The proposed methodology is general and can be applied to both processes described by step-wise and continuous recovery curves. The methodology has the following four steps:

Step 1: Obtaining the joint PDF of the resilience metrics. The first step consists in collecting historical recovery data and obtaining estimates for the resilience metrics reviewed in Section 2. Then, we can construct the joint PDF of the resilience metrics with prescribed marginals and covariances (Liu and Der Kiureghian, 1986).

Step 2: Obtaining the joint PDF of the parameters of the recovery curve. The second step calls for introducing parametrized recovery curves to model the time-varying recovery process. We consider a parametrized CRF to describe the recovery process over time of a general performance measure in the following form:

$$Q(\boldsymbol{\Theta},\tau) = Q(\boldsymbol{\theta},\tau) + \sigma\varepsilon \tag{1}$$

where $\boldsymbol{\Theta} = (\boldsymbol{\theta},\sigma)$ is a set of unknown model parameters that needs to be estimated; $\boldsymbol{\theta} = (\theta_1,\ldots, \theta_n)$; and $\sigma\varepsilon$ is an additive model error term of Q (additivity assumption), in which σ is the standard deviation of the model error, assumed not to depend on τ (homoskedasticity assumption), and ε is a standard normal random variable (normality assumption). The homoskedacity and the normality assumptions can be satisfied using an appropriate variance stabilizing transformation from the parametrized family of transformations introduced by Box and Cox (1964). Mathematically, we can write the n^{th} resilience metric, $\rho^{(n)}$, as follows:

$$\rho^{(n)} := \frac{\int_0^{T_R} \tau^n q(\tau)\, d\tau}{\int_0^{T_R} q(\tau)\, d\tau} \tag{2}$$

where T_R is the recovery time, that is the time needed to achieved the desired level of functionality; and $q(\tau)$ is the instantaneous rate of recovery progress (i.e., the resilience density function (RDF).

We can then use compute the joint PDF of the model parameters $\boldsymbol{\Theta}$ based on the joint PDF of the resilience metrics (Hogg et al. 2012). Let the set (ρ, χ,..., $\rho^{(n)}$) follow a joint PDF $f_{\boldsymbol{P}}$ (ρ, χ,..., $\rho^{(n)}$) on a support set C. Based on the definition of the resilience metrics, the resilience metrics are a function of $\boldsymbol{\theta} = (\theta_1,\ldots, \theta_n)$, in the support set D, such that $\rho = k_1(\theta_1,\ldots, \theta_n)$, $\chi = k_2(\theta_1,\ldots, \theta_n)$, up to $\rho^{(n)} = k_n(\theta_1,\ldots, \theta_n)$. We evaluate the Jacobian given by

$$\mathrm{J} = \begin{bmatrix} \frac{\partial\rho}{\partial\theta_1} & \frac{\partial\rho}{\partial\theta_2} & \cdots & \frac{\partial\rho}{\partial\theta_n} \\ \frac{\partial\chi}{\partial\theta_1} & \frac{\partial\chi}{\partial\theta_2} & \cdots & \frac{\partial\chi}{\partial\theta_n} \\ \vdots & \vdots & \ddots & \vdots \\ \frac{\partial\rho^{(n)}}{\partial\theta_1} & \frac{\partial\rho^{(n)}}{\partial\theta_2} & \cdots & \frac{\partial\rho^{(n)}}{\partial\theta_n} \end{bmatrix} \tag{3}$$

and its determinant $|\boldsymbol{J}|$, and then write the joint PDF of $\boldsymbol{\theta}$ as

$$f_{\boldsymbol{\theta}}(\theta_1,\ldots,\theta_n) = \begin{cases} f_{\boldsymbol{\theta}}[k_1(\theta_1,\ldots,\theta_n),\ldots, \\ k_n(\theta_1,\ldots,\theta_n)]\,|J| & (\theta_1,\ldots,\theta_n)\in D \\ 0 & \text{elsewhere} \end{cases} \tag{4}$$

We can now derive the expected recovery curve accounting for the relevant uncertainties based on the distribution of the parameters in Eq. (1).

Step 3: Estimating the probability of reaching or exceeding a target percentile of interest of the ultimate desired state. Once we obtained $Q(\boldsymbol{\Theta},\tau)$, we can estimate the probability of reaching or exceeding a target value of functionality at any time using the conventional rules of the reliability analysis (Ditlevsen and Madsen 1996; Gardoni 2017). We define the limit-state function $g(\boldsymbol{\Theta},\tau)$ as follows:

$$g(\boldsymbol{\Theta},\tau) = Q(\boldsymbol{\Theta},\tau) - Q_T \tag{5}$$

where Q_T is the target percentile of interest of the ultimate desired state, Q_∞. We introduce the time-dependent function $H(\tau)$ that expresses the probability that of reaching or exceeding a target value of functionality at any time as

$$H(\tau) = 1 - \mathbb{P}\left[g(\boldsymbol{\Theta},\tau) \le 0 \middle| \tau \right] \tag{6}$$

Figure 1 shows the conceptual representation of the function $H(\tau)$ over time.

We also propose to use the results from the first order reliability analysis to estimate confidence bounds on the estimate in Eq. (6). Following Gardoni et al. (2002), the variance of the reliability index $\beta(\boldsymbol{\Theta},\tau)$ can be written as

$$\sigma_\beta^2(\tau) \approx \nabla_{\boldsymbol{\Theta}} \beta(\tau) \boldsymbol{\Sigma}_{\boldsymbol{\Theta}\boldsymbol{\Theta}} \nabla_{\boldsymbol{\Theta}} \beta(\tau)^T \tag{7}$$

where $\nabla_{\boldsymbol{\Theta}}\beta(\tau)$ is the gradient of $\beta(\boldsymbol{\Theta},\tau)$ computed at the mean value, and $\boldsymbol{\Sigma}_{\boldsymbol{\Theta}\boldsymbol{\Theta}}$ is the posterior covariance matrix. Therefore, we obtain the one standard deviation bounds, representing approximately 15% and 85% probability levels as

$$\left\{ \Phi\left[-\tilde{\beta}(\tau) - \sigma_\beta(\tau) \right], \Phi\left[-\tilde{\beta}(\tau) + \sigma_\beta(\tau) \right] \right\} \tag{8}$$

where $\tilde{\beta}(\tau)$ is the mean of the reliability index.

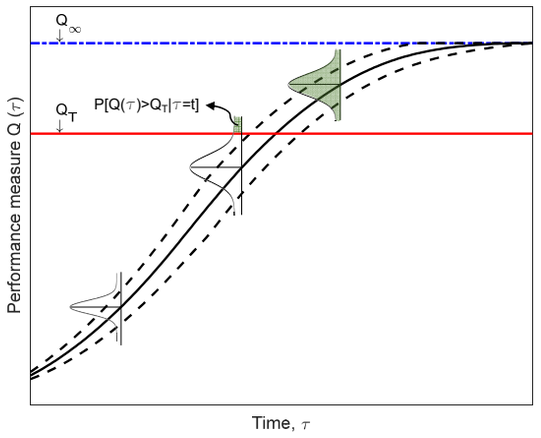

Figure 1. Conceptual representation of probability of reaching or exceeding a target value of functionality at any time

Step 4: Updating the model parameters as new data become available. The fourth step includes the Bayesian inference to update the model parameters, combining prior information with the information from the new data as they might become available during the recovery process. The Bayesian inference allows adjusting the previous prediction based on the observed data in terms of the actual recovery process (Gardoni et al. 2007).

Based on the availability of new data while the recovery process advances, we propose to update the state of knowledge of the parameters $\boldsymbol{\Theta}$ (Gardoni et al. 2002; Gardoni et al. 2007) as described in Step 4 of the proposed methodology. Mathematically, we can write the posterior distribution $f'(\boldsymbol{\Theta})$ as (Box and Tiao, 1992)

$$f'(\boldsymbol{\Theta} \mid \mathbf{Q}) = \kappa L(\boldsymbol{\Theta} \mid \mathbf{Q}) f(\boldsymbol{\Theta}) \tag{9}$$

where κ is a normalizing factor; $L(\boldsymbol{\Theta}|\mathbf{Q})$ is the likelihood function that contains the objective information on $\boldsymbol{\Theta}$; and $f(\boldsymbol{\Theta})$ is the prior distribution, reflecting the state of knowledge about $\boldsymbol{\Theta}$ prior to obtaining the observations $\mathbf{Q} = (Q_1,\ldots,Q_m)$, considering the time at which they are measured.

Furthermore, (9) can be used every time additional information is available to update the model. Therefore, if n independent set of observations are available, we can write as follows:

$$f(\boldsymbol{\Theta} \mid \mathbf{Q}_1,\ldots,\mathbf{Q}_k) \propto L(\boldsymbol{\Theta} \mid \mathbf{Q}_k) f(\boldsymbol{\Theta} \mid \mathbf{Q}_1,\ldots,\mathbf{Q}_{k-1}) \quad k = 2,\ldots,n \tag{10}$$

The prior distribution incorporates the status of knowledge based on previous experiences or engineering judgments. We propose to adopt the joint PDF computed in Eq. (4) as the prior distribution of $\boldsymbol{\theta} = (\theta_1,\ldots,\theta_n)$. Generally, considering the set of parameters $\boldsymbol{\Theta} = (\boldsymbol{\theta},\sigma)$, $\boldsymbol{\theta}$ and σ are assumed independent.

The likelihood function allows transferring the observed information into the model. The benefits of using this approach is in the possibility of including lower, upper and equality data (Gardoni et al. 2002, 2007). A lower bound datum is defined as an observed lower bound Q_t at time τ; an upper bound datum is defined as an observed upper bound Q_t at time τ; an equality datum is defined as the recorded state during the recovery process at time τ. Thus, based on the normality assumption, we write the likelihood function as (Gardoni et al. 2002)

$$\begin{aligned} \mathrm{L}(\boldsymbol{\theta},\sigma) \propto & \prod_{\substack{\text{equality} \\ \text{data}}} \left\{ \frac{1}{\sigma} \varphi\left[\frac{Q_t - Q(\boldsymbol{\theta},\tau)}{\sigma} \right] \right\} \\ & \times \prod_{\substack{\text{lower bound} \\ \text{data}}} \left\{ \Phi\left[-\frac{Q_t - Q(\boldsymbol{\theta},\tau)}{\sigma} \right] \right\} \\ & \times \prod_{\substack{\text{upper bound} \\ \text{data}}} \left\{ \Phi\left[\frac{Q_t - Q(\boldsymbol{\theta},\tau)}{\sigma} \right] \right\} \end{aligned} \tag{11}$$

where $\varphi(\cdot)$ is the standard normal PDF, $\Phi(\cdot)$ is the standard normal CDF, and Q_t is the recorded datum.

The main benefits of the proposed methodology are that the predictive Q is simply defined as a function of resilience metrics, and the prediction can take

advantage of collected data both before and during the recovery process.

4 EXAMPLE

This section illustrates the proposed methodology considering the recovery process of a typical RC bridge subject to a seismic excitation.

4.1 Example: Discrete Recovery Curve for a Single Column Single Bent Bridge

As previously discussed, the functionality of engineering structures can be described as a step-wise function with jumps occurring when a set of activities associated with a change in functionality is completed. In this section, we illustrate the proposed methodology using a typical reinforce concrete (RC) bridge damage by a seismic excitation. Figure 2 shows the configuration of the considered bridge (single column, single bent).

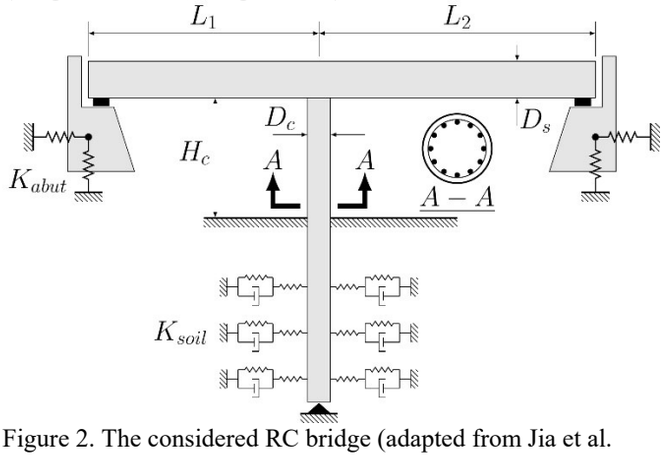

Figure 2. The considered RC bridge (adapted from Jia et al. 2017)

As for the first step of the proposed methodology, we obtain the estimates of the first two resilience metrics, ρ and χ, and their marginal distributions. Based on the observed data, we assume that ρ and χ follow a lognormal distribution, whose parameters are listed in Table 1.

Table 1. Distribution parameters of the resilience metrics

Resilience metric	λ	ξ
ρ	–0.94	0.22
χ	1.14	0.20

Then, we construct the joint PDF of the resilience metrics with the prescribed marginal distributions and covariances. Figure 3 shows the pair (ρ, χ) and their correlation. Most of the data follow in the zoomed range and the correlation coefficient is estimated as illustrated in Fig. 3.

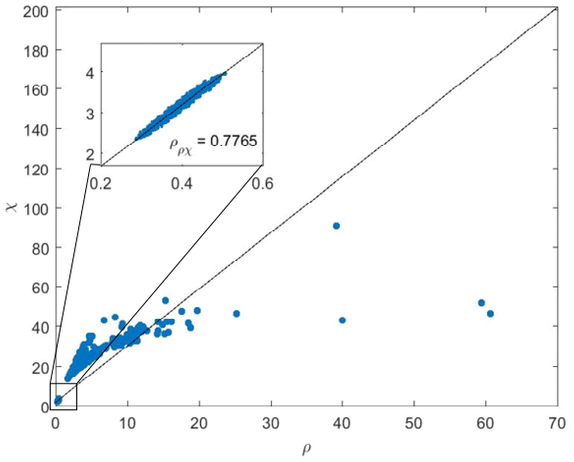

Figure 3. Correlation between the adopted resilience metrics

Then, we introduce a parametrized recovery curve to describe the changes in a selected performance indicator over time. The performance indicator considered in this example is the instantaneous reliability index β. We assume there is only one recovery step that restores the reliability of the bridge, as described in Sharma et al. (2017). Consequently, the mathematical model can be expressed in the form:

$$Q(\boldsymbol{\Theta},\tau)=\begin{cases}\theta_0 & \tau<\theta_1\\ Q_\infty & \tau\geq\theta_1\end{cases} \tag{12}$$

where θ_0 is the residual reliability index after the occurrence of the hazard and before the completion of the recovery, and θ_1 is the time at which the reliability index reaches the ultimate desired state Q_∞. Based on the definition of the resilience metrics, the variables θ_0 and θ_1 can be written as a function of the resilience metrics. Specifically, Figure 4 shows the RMF of the adopted parametrized recovery curve.

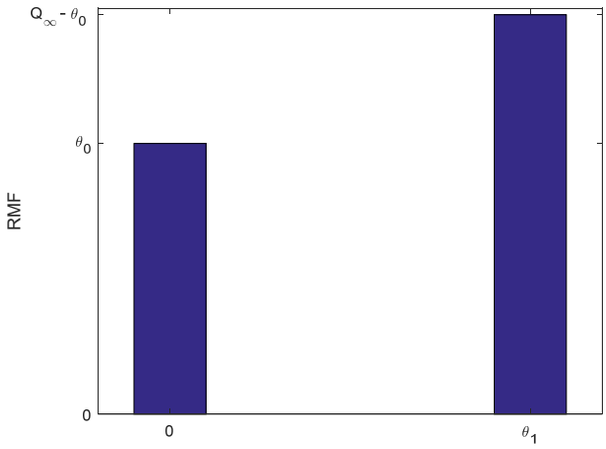

Figure 4. RMF of the adopted parametrized recovery curve

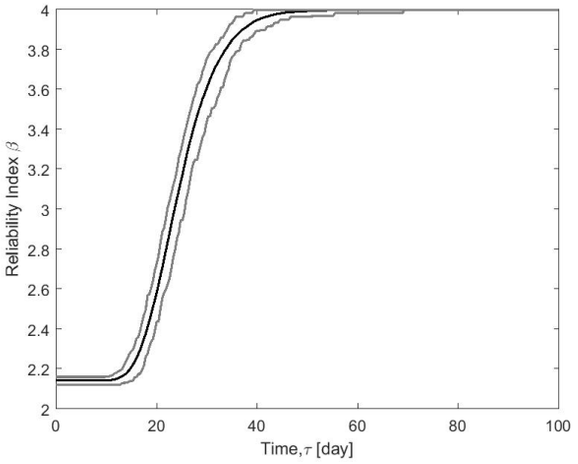

Figure 5. Mean value and corresponding 95% confidence band of the recovery curve

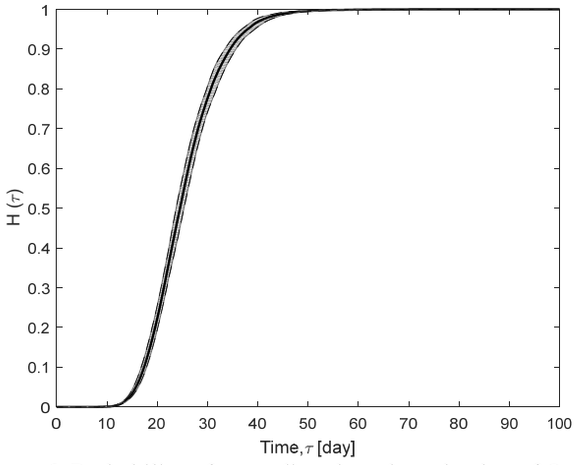

Figure 6. Probability of exceeding the selected value of Q_T = 3.5

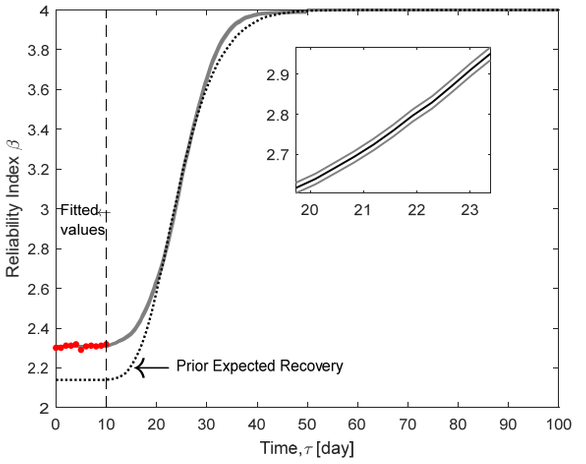

Figure 7. Mean value and corresponding 95% confidence band of the recovery curve after updating the model parameters

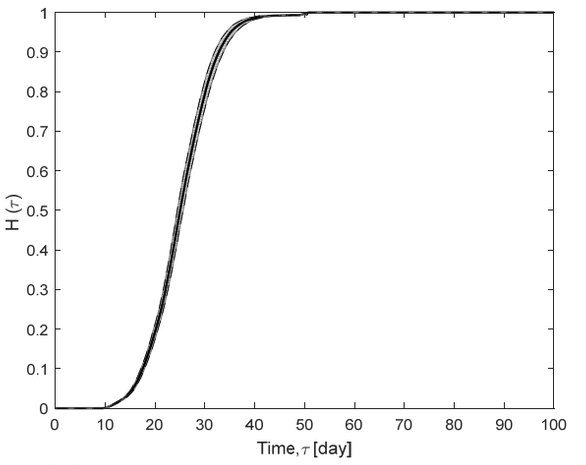

Figure 8. Probability of exceeding the selected value of Q_T = 3.5 after updating the model parameters

Following the proposed methodology, we obtain the joint PDF of the parameters of the recovery curve and the corresponding expected recovery process in terms of the instantaneous reliability index β. Consequently, we estimate the probability of reaching or exceeding a target value of functionality at any time, setting for example $Q_T = 3.5$.

Figure 5 shows the expected changes of the instantaneous reliability over time. Figure 6 shows the probability of exceeding the selected value of Q_T. The figure also presents the confidence band due to the statistical uncertainty in $\boldsymbol{\Theta}$.

To illustrate Step 4 of the propose methodology, we assume that after the occurrence of the hazards, we collect data on the state of damage for the first ten days and we update the model parameters. As a result, we obtain the new expected recovery process and the corresponding probability of reaching or exceeding the same value of the target functionality at any time, as shown in Figure 7 and 8.

5 CONCLUSIONS

This paper proposed a probabilistic methodology to predict a probable recovery curve of a system after the occurrence of a hazard and to estimate the probability of reaching or exceeding target percentile of interest of the ultimate desired state. The methodology consists of four steps.

Based on historical data, first we estimate resilience metrics associated to typical recoveries. Then, parameterized recovery curves are introduced and the joint probability density function (PDF) of the model parameters is obtained using general rules of probability theory as a function of the distribution of the resilience metrics. Then, a reliability analysis is used to estimate the probability of reaching or exceeding a target percentile of interest of the ultimate desired state. The proposed methodology also incorporated a Bayesian updating procedure to update the estimates as new data might become available. The paper showed the proposed methodology by model-

ing the recovery of a typical reinforced concrete (RC) bridge.

Computational Investigation on the Piers of a U-Slab Bridge under Raising Flood Intensity

M. Nasim & S. Setunge & H. Mohseni & SW. Zhou
RMIT University, Melbourne, Australia

ABSTRACT:
The resistance to flood and debris loading is a critical parameter affecting the design of bridges under flood loading. For instance, bridges partially or completely immersed into water in extreme flood will result in very notable hydrodynamic loads on decks and piers. Based on previous studies on the nature of the pressure resulted from the water flow on the structure, we herein investigate the performance of pier under raising intensity of flood using finite element analysis. In addition, we evaluate the effect of bed fixity and the different damage levels of the pier. Furthermore, the probability of the damage in various levels of flood loading is also summarized and analyzed, which will be helpful for enhancing the resilience of the road infrastructures.

1 INTRODUCTION

1.1 *Background*

Flooding caused around $50 billion damages in the U.S. in the 1990s according to the National Weather Service (NWS) estimation (NWS-HIC 2001). Although flood damage fluctuates considerably from year to year, estimates reveal that the trend is still increasing over the past century (Pielke Jr and Downton, 2000).

There are far higher structural and environmental uncertainties, which must be considered when assessing existing bridges. Most concrete structural failures occur during the construction phase or due to massive ecological calamities (Khan, 2014). Based on the Melbourne Water (2005) reports, most costly natural disasters in Australia from 1967 to 1999 are riverine flooding (average $314 million annually) and severe storms ($284.2 million) (Melbourne and Water, 2005). Over the last 30 years, numerous bridges were damaged by flooding. The Schoharie Creek Bridge (Storey et al., 2003) in New York destroyed in 1987. The Hatchie Bridge (Cao et al., 2009) in Tennessee destroyed in April 1989, and the Hintze Ribeiro Bridge (Sousa J.J. and Bastos L., 2013) in Portugal damaged in 2001. The damages to these bridges are entirely or partially attributed to the losses to piers. A vast number of bridges are built across rivers, and usually, the water flow forces on the structure are calculated by the approaches mentioned in the design standards. The acceptable structural design and damage assessment related to the well understanding of each element of the bridge behaviour and the damage mechanisms of each part.

Floods can cause bridges to collapse in a few different ways. Severe floods, such as rapid onset and flash flooding, can cause rivers and creeks to overflow, picking up debris such as trees, cars and parts of houses in the process. When the river passes under a bridge, the high water level smashes the debris into the bridge. The shear impact of the debris can cause immediate bridge failure, or the weight of the debris piled up combined with the immense force of the fast-flowing water pushing on it can cause the bridge to fail more gradually.

Figure1. Bridge collapse cause by Cumbria floods (BBC2009)

Inverted U-slab bridges are one of the most vulnerable and old concrete bridge structures in Australia, specifically in Victoria, based on the Vic-Roads reports (Vicroads, 2014). The piers are slender and fragile to the effect of scour and flood pressure notably when the debris outstandingly increases the pressure on the thin elements of the bridge. Hughes et al. (2007), Investigated the soil subgrade modulus effect on a pile bent's pushover buckling capacity on scoured bridges, under axial loads and a small amount of lateral load has insignificant force except when the soil module is very low (Hughes et al., 2007). Fiang et al. (2015) analysed the impact of extreme scour on the buckling stability of bridge piles in soft layered clay. Schambeau et al. (2014) expanded a screening tool to evaluate the buckling failure of the bridge timber pile bent in extreme scour. Lin et al. (2012) employed the integrated

analysis method to assess the lateral response and the buckling capacity of a bridge pile group to assess the susceptibility of bridges to scour, before, during, or after a scour event (Lin et al., 2012). The significance of stability analysis in the maintenance of the existing bridges has to do with scouring which may cause catastrophic bridge failures (Jackson et al., 1991). The nonlinear stability of the pile group foundation under the scour phenomena are studied, and the soil properties and the soil-structure interaction of the pile are taken into account (Zhao Zhong, 1999) and found that the soil properties have a significant influence on the buckling behaviour of the piles.

Figure 2. Kiewa Valley Highway Bridge, Broken Pier and Debris, December 2010 (Vicroads, 2014)

1.2 *Structural stability*

In civil engineering area, stability means the power of the structure to withstand for an identified time all the loads and forces that may be brought to bear on it. Generally, structures may lose their stability in two ways: buckling and flutter, depending on the system and its environment, as far as static methods are concerned. Buckling of structures is a phenomenon in which an existing state of equilibrium or type of behaviour of the structure subjected to apply compressive loading may suddenly change into a new equilibrium state or a new type of reaction. Stability equations for discrete models may be constructed using various devices. For FEM models only energy methods are practical. All techniques eventually lead to matrix stability equations that take the form of an algebraic Eigenproblem. Reaching a critical point may lead to immediate destruction (collapse) of the structure. Excessive lateral drifts cause visual or functional sagging, failure or cracking on the structure

The plastic limit state of a structure of the perfectly-plastic material, “pl”, is the state in which for the first time in the loading history the displacements, u_i, can increase under constant external forces, if geometrical changes are disregarded. Stability can also be defined regarding the total potential energy Π of the structure. Recall that the sum of the strain energy, U, stored in the deformed elastic body and the loss of the potential of the generalized external forces, If the total potential energy increases during a virtual displacement, then the equilibrium configuration is defined to be stable. If the sum of strain energy decreases or remains unchanged, the configuration is unstable (Yoo and Lee, 2011).

1.3 *Pushover Analysis*

Structural behaviour can be monitored with the nonlinear static analysis in which the load is applied incrementally to the structure. Nonlinear static methods of analysis (pushover) establish the capacity curve of a structure. In pushover analysis procedures, the behaviour of the structure is character bed by a capacity curve. In general, when nonlinear response develops in the pushover analysis, the displacements of the element will increase disproportionately with increasing load (Hernandez-Montes et al., 2004). ABAQUS offers a general framework for material failure modelling that allows the combination of multiple failure mechanisms acting simultaneously on the same material. Material failure refers to the complete loss of load-carrying capacity that, results from progressive degradation of the material stiffness. The stiffness degradation process is modelled using damage mechanics (Systèmes, 2013).

2 VERIFYING MODEL OF THE CONCRETE BEAM USING CONCRETE DAMAGE PLASTICITY (CDP)

2.1 *Concrete and steel reinforcement*

A damaged stage is the stage where plans are made to detect a problem in the structure so that it could be taken care of before the occurrence of a fault (Worden and Dulieu-Barton, 2004). The compressive model used in this study translates the stress-strain behaviour of concrete is the concrete damaged plasticity (CDP) model (Carreira and Chu, 1985). However, in this study, tensile concrete modelling was the focus, so a suitable compressive model was chosen, which depended on the modulus of elasticity and the compressive strength of concrete. The concrete damaged plasticity (CDP) model is capable of carrying out the static and dynamic analysis of RC members with bars embedded. The model includes isotropic material, which accounts for tensile cracking and the compressive crushing modes. The model is also capable of stiffness degradation with the irreversible damage that occurs during the fracture process (Rodríguez Soler et al., 2013). For the CDP model, the default values of the

dilation angle, eccentricity, fb0/fc0, K and viscosity parameter were used as 35, 0.1, 1.16, 0.667 and 0.01, respectively. These parameters were also used with some variations in other models (López-Almansa et al., 2014, Kmiecik and Kamiński, 2011). Two types of steel reinforcement were used. Plain bars with 6 mm diameter were used for the top reinforcement and transverse reinforcement while 10 mm bars were used as the primary tension reinforcement. The properties of the steel reinforcement are from (Hanif et al., 2016)

2.2 *Finite element simulation*

A model of a simply supported reinforced concrete beam with multiple cracks is developed to examine its use for damage detection and structural health monitoring using commercial software ABAQUS 6.14. The model illustrates some nonlinearity in the static response of damaged beam. The force-displacement relationship in the model has been compared with the experimental model studying on the crack model for damage detection in reinforced concrete structure (Hamad et al., 2011). The model's nonlinear behaviour shows a very close trend to the experimental model's behaviour under static loading. Figure 3 shows how the analysis trend is close to the experimental response.

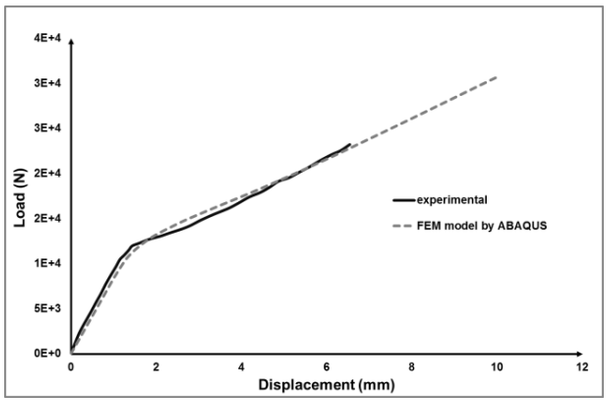

Figure 3: static load-displacement curve for mid-span cracked region

The cracking pattern was compared with the analytically developed flexural model, which is capable of detecting damage through non-linearity in Figure 4 and Figure 5. The reason for crack investigating crack propagation was to validate the capability of the present study for mixed-mode crack formation. The significant cracks seemed to be significantly vertical to match the cracking pattern predicted by similar research.

From the results 11.5 KN forces is the crack appearance phase in the beam, and from the next pushover analysis result, which can be seen in Figure 4, the approximate maximum load that the beam can take is 45 KN. It is comparable with the maximum pressure capacity overtaken by Hanif (Hanif et al., 2016).

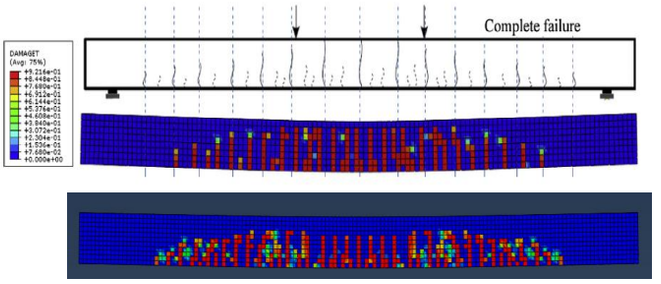

Figure 4: comparison of simulated cracking pattern (below) with Hamad et al., (Hanif et al., 2016, Hamad et al., 2011)(above) and Hanif et a.,l (Hanif et al., 2016) (middle)

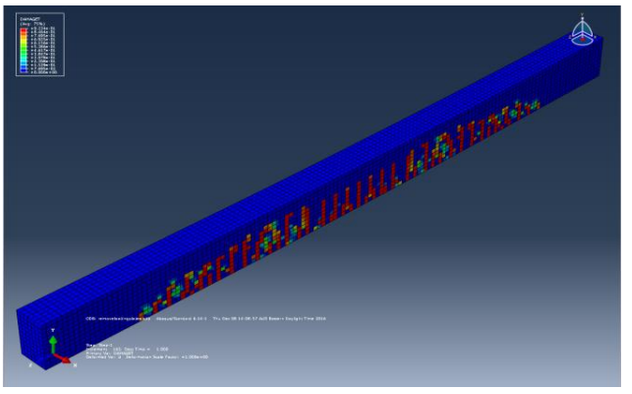

Figure 5: 3-D simulated cracking pattern for 4-point load from ABAQUS

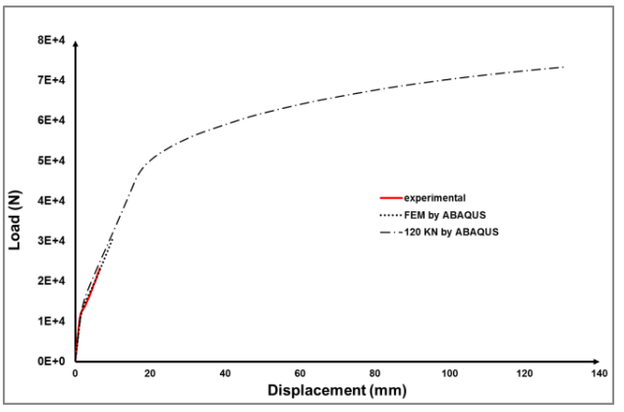

Figure 6: static load-displacement curve for mid-span (envelope curve)

3 SIMULATION AND METHODOLOGY

3.1 *FE simulation and nonlinear analysis*

The verified model in the previous phase is similar to the bridge pier, so the model is decided to be used to recognise the model's behaviour under flood loading as a uniform pressure on its face.

There are two models which the first model is fix in the foundation and is pin for the second model, and

both can rotate from the top. And actually, the piers connection to the superstructure is a simple connection (Vicroads, 2014). The concrete and steel properties are described in table 1 and 2.

Table 1: Mechanical properties of steel reinforcement

Bar type	Diameter (mm)	f_y (MPa)	E_s (MPa)	ε_s	ν	ρ kg/m^3
Plain bars	6	393.600	208,000	0.25	0.3	7850
Main bars	10	540.800	199,200	0.32	0.3	7850

Table 2: Mechanical properties of concrete

Density Tonne/mm^3	f_{cu} MPa	f_{ct} MPa	E_c MPa	ν –
2.4E−9	36.5	3.65	26957.85	0.15

The concrete properties and all damage plasticity models have assumed as well as Hanif et al. (2014). Commercial software ABAQUS 6.14 was used for the analysis. The selected pier is shown in Figure 6. The static push-over analysis is performed with the incremental static load as a percentage of damage. The approximate maximum pressure that the beam can take is 45 KN. The total load was incrementally applied in increments of approximately 10–15% of the maximum load and was specified as the percentage of damage.

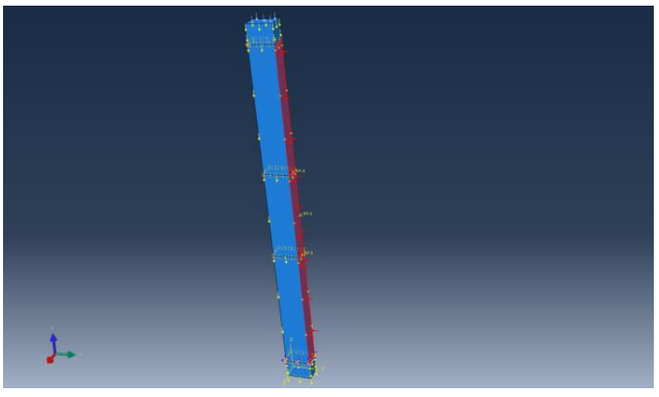

Figure 7: Piers simulation using ABAQUS and the water flow pressure applied on the front face

Based on the previous study on the pressure behaviour of the water flow around a rectangular pier as a case study (Nasim M. et al., 2015), the water flow pattern as a uniform is reasonable for different water flow velocities. Based on this survey the pressure distribution assumed as a uniform pattern along the pier model. The pressure is considered 1 (MPa), in which the force is applied to the model from 0 to 1 incrementally. The piers weight is taking into consideration in the analysis as well as the piers axial load capacity which is calculated based on the axial load capacity of the beam-column theories. Mesh sensitivity analysis has been done to verify the model in the previous phase of verification.

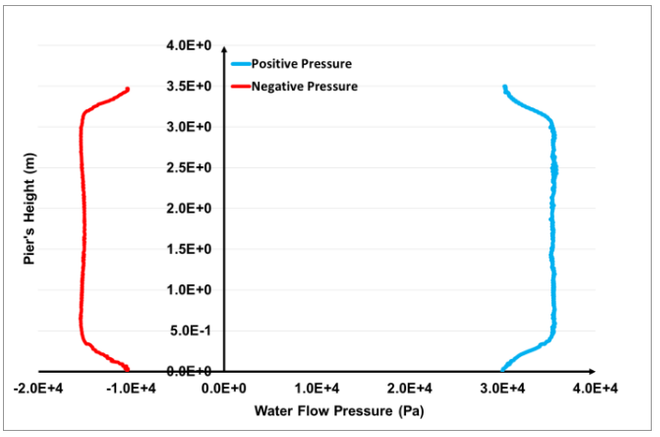

Figure 8: water flow pressure pattern along the pier's height when the water flow velocity is 6.5 m/s.

The boundary condition is a pin at the top of the pier as the pier and superstructure connection is a simple connection and the bed fixity is assumed as a fix when the bed fixity is hard enough and is considered as a pined model to show the very loose soil condition. 3 degrees of freedom are used for the simply supported end. In the analysis, deformation can be represented by three independent displacements (DOF).

3.2 *Methodology*

The beam behaviour under 4 point loads can describe the different damage phases, for example, the first changes in the load-displacement curve are the crack initiation phase in which the system stiffness is decreasing.

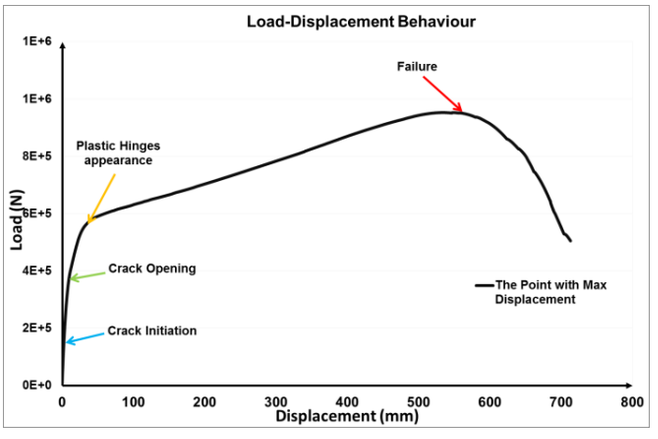

Figure 7: static load-displacement curve for mid-span Maximum load undertaken (envelope curve)

The model's pushover analysis under four-point loads, more than its capacity can give us an idea of the structure's damage levels. Figure 7 is the load-displacement of the mid-span of the beam, and it shows how it is behaving under 4 pints load. Form this curve the four different levels of damage to the

structure is definable. The first level of damage which is crack initiation phase is when the structure's stiffness, which is the curve's slope, is degrading due to increasing the load. The first bifurcation on the envelope curve is the critical load of the structure. The second degradation of the curve slope occurred after second bifurcation point, is when the cracks are starting to be opened and nonlinearity if the concrete is appearing the third phase of damage is when the reinforcement is beginning to yield, and then the nonlinearity of the structure is recognisable. From this level of damage the plastic hinges can appear, and due to that, the structures' stiffness is dramatically decreasing. When plastic hinges appear it does not mean the overall instability of the Structure, while it can tolerate more lateral load, but it shows that the structure is not stiff enough to withstand for the lateral loads and by exceeding the load large displacements can occur. Although plastic hinges appearance is very critical in the structural design and is a fundamental level of damage for all structure still it gives some ideas of replacing the element, on the other hand by increasing the load the element is supposed to be failed when the very bid displacements happen. The structural failure or instability of the structure is happening when the load-displacement curve reaches the ultimate load capacity in which after that point the structural stiffness is the Eigenvalue of the stiffness matrix is zero and then it gets negative. This level of damage is called the instability phase in which the structure has no more capacity to tolerate excess loading.

In this research, a pier has been nonlinearly analysed in two ultimate bed fixity to consider how the bed fixity can affect the structural stability under flood loading. Apart from these two types of the modelling the axial load of the pier, resulted from the superstructure's weight and the other loads, are assumed to be compared in both models. The nonlinear analysis considering all nonlinearity of the geometry and material conducted on the models, and the results compared.

4 NONLINEAR ANALYSIS AND DISCUSSION

4.1 *Stability analysis*

In work described here, a finite element approach has been employed to obtain the regions of damages and instability. Nonlinear analysis can represent the model's different stage of damage while in the linear path you can deliver just a Euler buckling load in which it can be much far from the real damage states (Yoo and Lee, 2011).

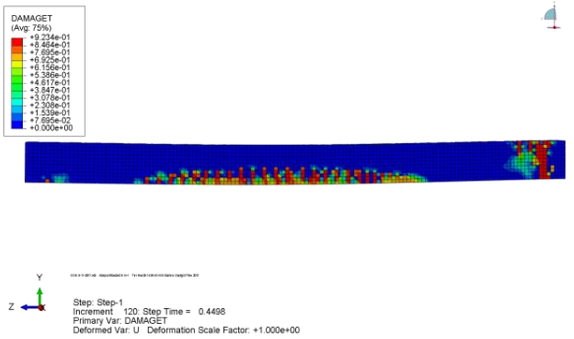

Figure 9: damage state of the fix-pin ended model when it is in 45% of loading

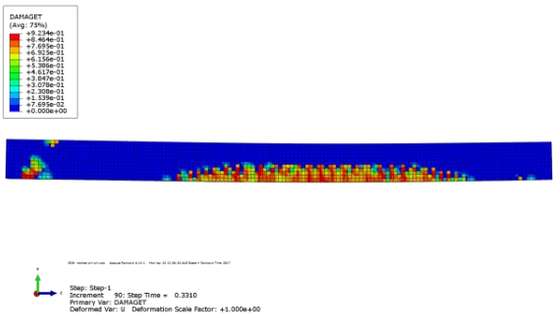

Figure 10: damage state of the pin-pin ended model when it is in 33% of loading

Figure 9 and 10 illustrate the cracks propagation along the pier during flood increasing pressure. Figure 9 is the pier with very hard bed layer of soil in which it can be assumed as a fixed bed, while figure 10 represents a very loose soil. The 2 model analysed under flood loading, pier's weight and the allowable axial load for the element, considering the P-Δ effect (Baji et al., 2012). The axial load helps the buckling happening earlier, and the ultimate load capacity of the structure will be decreased. The two models analysed for the same water pressure loading with the 0.01 initial increments. The crack pattern of both figures 9 and 10m shows that the crack pattern doesn't have specific different unless in the stiffed soil model the bed area is at the risk of damage. It considered that the loss is starting from support area of the fixed support and then the mid-height starts to be damaged the same as the very loose soil condition. The comparison between both models' initial behaviour with the load-deflection response, illustrated in figure 11. As it can be seen the initial stiffness of the models is slightly different in which in the linear zone before any damage happening the in the stiffed soil the elastic stiffness of the structure is 21% more than the loose soil.

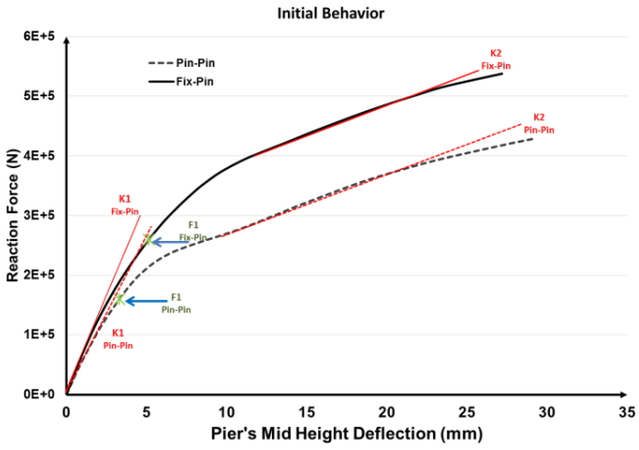

Figure 11: Load-Deflection initial behavior of the structures (envelope curve)

In the first phase of the structural behaviour, there is an elastic behaviour in which the slopes of the curves represent the elastic stiffness of the structures. This stage is called crack initiation phase. As it can be seen in the fix-pin model, this parameter, K_1, is about 6.7E+4 while it is about 5.27E+4 for the pin-pin model. The initial stiffness K_1 of the models are slightly different in which in the linear zone before any damage happening, in the stiffed soil the elastic stiffness of the structure is 21.4% more than the loose soil. The structural response is changing from elastic to elastic-plastic phase reaching to the F_1, at the first bifurcation pion. Crack in the pin-pin model is starting to appear when the horizontal reaction forces in the element reach to 260 KN, F_1, while in the fix-pin model the crack initiation force is about 160 KN, F_1, which is 38.5% less than the F_1 in the rigid soil.

By increasing the water flow pressure on the structure, incrementally, the structural behaviour enters to the second phase of crack propagation and rising. This step starts with a very significant reduction in the structural stiffness. The second bifurcation point loads the second critical load of the structure. For example, the second stiffness, K_2, of the fix-pin model is about 58% of initial stiffness K_1 while it is reduced about 82% in the pin-pin model. In this phase, it can be seen that there is a much-closed stiffness for both models, just 7.8% of the difference. This reduction is happening due to the presence of reinforcements. This phase shows that after crack initiation the behaviours are much closed to each other. In this phase, 85% of the fix-pin and 82.3% pin-pin model's stiffness are dropping which is a considerable decrease in the stiffness. It shows that how cracks can affect the rigidity and applicability of a structure.

Reaching F_2 in both models is the point that the structural behaviour is about to behave plastically. In other words, the structural response is about to be a ductile and very slight increase in water flow pressure can lead a very significant deformation of the damaged area. This means that in the model some plastic hinges have appeared which can reduce the stiffness of the structure dramatically. From the curve above, F_2, loads of plastic hinges occurrence are 556 KN for the stiffed soil condition and about 474 KN for the soft soil condition. These loads are representing 17.2% difference in both model, and it shows that the capacity of the soft soil is still lower than the stiffed soil. In this phase, 92.2% of the fix-pin and 93% pin-pin model's stiffness are dropping which is a very significant reduction. Although the stiffness's of 2 models have 19.6% difference, it seems they are parallel, and it means that in this stage of loading the structure's behaviour is close to each other. This scenario of the damage is ending buy getting the ultimate load of 951 KN and 837 KN for end fixed and end pined model alternatively. After getting ultimate loads, the negative stiffness means that the structure has no more capability of load increasing, so the structure is getting unstable in this case.

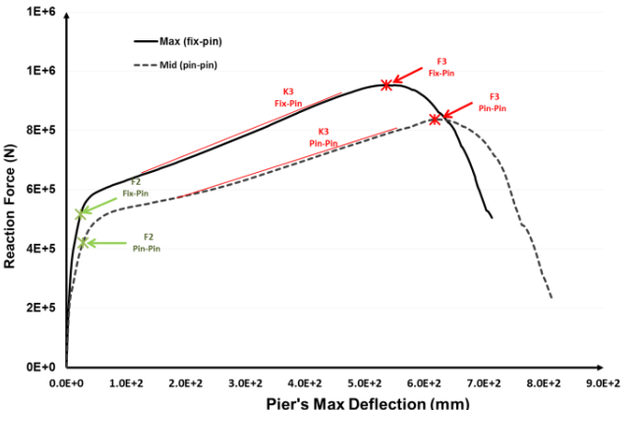

Figure 12: Load-Deflection behavior of the structures (envelope curve)

Table 3 provided all data regarding the structural behaviour during water flow increases.

Table 3: Structural Load-Deflection Parameters

	K1	F1 (N)	K2	F2 (N)	K3	F3 (N)	%(K1-K2)/K1	%(K2-K3)/K2
PIN-FIX	6.70E+04	2.60E+05	10106	5.56E+05	808.4	951910	8.49E+01	92.00079161
PIN-PIN	52686	1.60E+05	9315.5	474362	649.32	836825	82.31883233	93.02968171
2 Models Difference	2.14E+01	3.85E+01	7.82208589	1.72E+01	19.6784	12.089903	-	-

In table 4 the water flow velocity related to these critical values of the forces and pressures has been calculated based on the equation proposed by AS5100 (Standards Australia, 2017).

Table 4: Critical Water Flow Pressures and Velocities

	F1 (N)	P1(Mpa)	V1 (mm/s)	F2 (N)	P2(Mpa)	V2(mm/s)	F3(N)	P3(Mpa)	V3(mm/s)
PIN-FIX	2.60E+05	7.41E-01	3.1	5.56E+05	1.58E+00	4.54	951910	2.71199	5.9
PIN-PIN	1.60E+05	4.56E-01	2.4	474362	1.35E+00	4.18	836825	2.38412	5.5

The structure chosen in this research is slender, and that's why the very low pressure of water flow due to low velocity can cause damage.

From above description, it is concluded that the methodology can provide the deformation related to the different damage scenarios for different kinds of bed fixity. For example, just 3.1 (mm) deformation of the element can cause cracks on the structure in soft soil model, and in the stiff soil foundation, it starts when it gets to 2.8 (mm) which is pretty close to the soft soil model. Cracks will be opened, and plastic hinges are appearing when the deformation is getting to 22 (mm) in fix-pin model and 32 (mm). After plastic hinges, appearance, the model behaves very ductility, and they are failing when the fix-pin model is 53(cm), and the failure value for the soft soil model is 61 (cm). These values and all values described above can give us an idea to calculate damage mechanisms in different water flow velocities.

4.2 *Damage probability*

The probability of the damage in structure cab is described with damage parameter defined by ABAQUS for reinforced concrete. The parameter determined by the ratio of the module of elasticity in each step to the initial module of elasticity (Systèmes, 2013). Figure 13 describes damage parameter for specific critical elements in both soft and stiff soil model. As it can be seen, the pin-pin model is vulnerable in comparison with the fix-pin model for both models the damage is zero when loading is starting, but its value is dramatically increased in the soft soil model as it gets maximum value from 4% of total load to 13% of the whole load. While in the fix-pin model damage in the element starts when it got 9% of total load and increased to a maximum value of the loss when 40% of the total load is applied to the structure. From this outputs, it is considering how the bed fixity can affect the damage behaviour of the elements. In the soft soil, the crack grows dramatically while its growth in the fixed model is little slower.

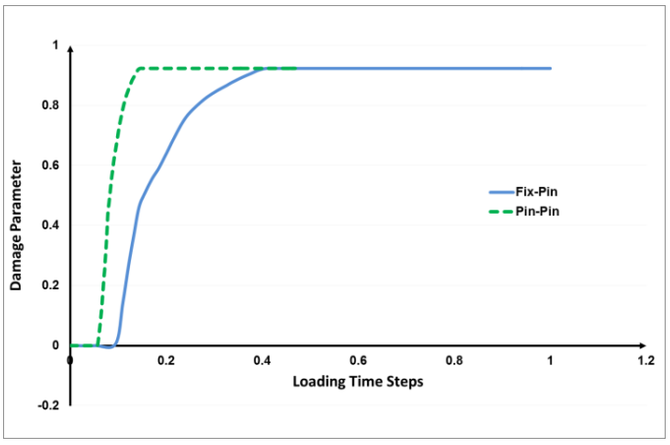

Figure 13: Critical element's damage behavior in both models

Damage parameter is a parameter to understand how the damage can grow in an element but is not able to consider the different damage levels or considering whole structures, so for the future; it is recommended to study more on the damage indices to find the probability of the structures.

5 CONCLUSIONS

The resistance to flood and debris loading is a critical parameter affecting the design of bridges under flood loading. Based on the previous study on the nature of the pressure resulting from the water flow on the structure, various finite element simulation and pushover analysis have been conducted to generalise how the pier would behave under flood intensity raising. The model is verified by an experimental study on the model from literature, and this structure is identified to be examined with the finite element method to figure out the water flow effect on the structural behaviour. Followed by, the effect of bed fixity is discussed in this paper, and the different damage levels of the pier are defined and evaluated in each model. The probability of the damage in various levels of flood loading is studied and based on the research in this area following outcomes are considerable.

- Based on the behaviour of the structure and the reduction on the structural stiffness the different levels of damage can be defined from crack initiation to crack opening and plastic hinges appearance and finally the total failure of the structure.

- Soft soil model has lower critical loadings in different levels of damage while the correspondent load has more significant values of deformation in soft soil model.

- Stiffness reduction is more in the fix-pin model rather than pin-pin model in the first damage occurrence. The decrease in structural stiffness is getting more, in the pin-pin model in the second stiffness reduction.

- Damage behaviour of the structure shows that failure happens after a very significant ductility manner of the concrete element. The real damage can be considered when the model starts its plastic deformation.

The methodology the outcomes can be useful to decide vulnerability assessment of a real structure and enhancing the resilience of bridges during flood disaster.

The dream of building bridges over the Tagus River mouth in Lisbon

P.J.S. Cruz
Lab2PT, School of Architecture, University of Minho, Guimarães, Portugal

ABSTRACT: The Tagus is the longest river in the Iberian Peninsula (in the southwest corner of Europe, comprising most of the Portuguese and Spanish territories) and it forms a wide estuary at its mouth near Lisbon. The need for a permanent bridge between Lisbon and the south bank of the river had long been felt and several solutions have been proposed since the 19th century. However, the construction of the first bridge crossing the river in that area only occurred in the second half of the 20th century. This work represents an opportunity to pay a tribute to the engineers involved in the design and construction of those bridges and to give a valuable insight into construction and technology history.

1 INTRODUCTION

Théophile Seyrig (1843-1923) was an associate of Gustave Eiffel in the firm *Eiffel et Ce.*, from 1869 to 1881. In that period he designed the daring arch of Maria Pia Bridge crossing the River Douro in Porto, built between 1876 and 1877 (Fig. 1). At that time it was the greatest span in the world (160 m). The iron arch was built without falsework, using only suspended cables. It was also one of the first times, if not the first, that calculation on the wind effect was accurately made using a hitherto unused method (Cruz & Cordeiro, 2001).

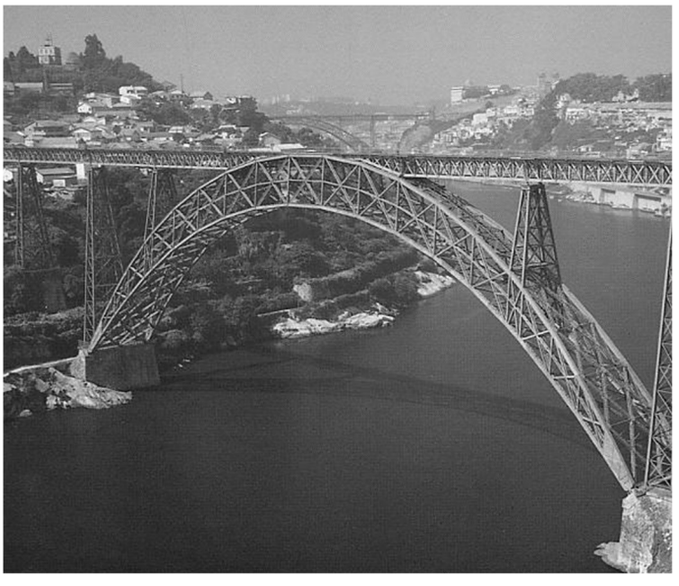

Figure 1. Maria Pia Bridge in Porto.

It was with this bridge that Gustave Eiffel and his company advanced considerably towards international recognition. It also provided them with the necessary experience and accuracy to produce a similar project seven years later - the famous Garabit Viaduct over the Truyère in the Massif Central, near Saint-Flour, in France. It had a 165 m span (five more metres than Maria Pia Bridge). Gustave Eiffel adapted most of the plans of the Portuguese bridge to the French one (Marrey, 1982).

Théophile Seyrig submitted a proposal for the Luiz I Bridge, over the River Douro in Porto, comprised by two metal decks supported by a large iron arch and by five pillars (Fig. 2).

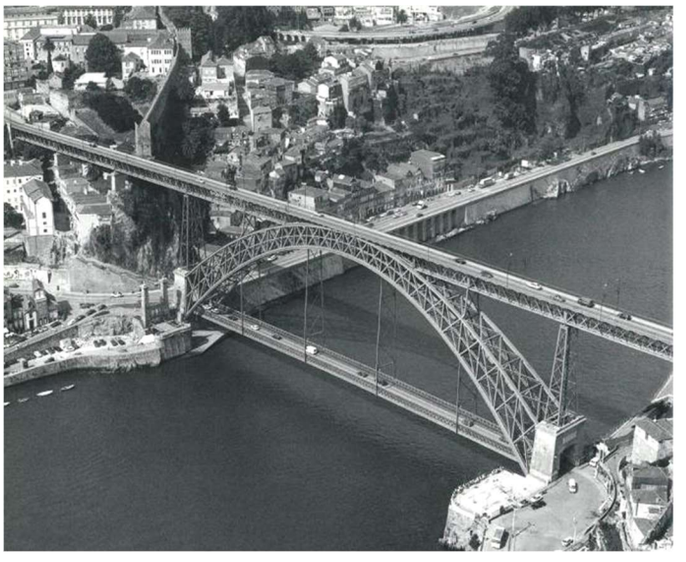

Figure 2. Luiz I Bridge in Porto.

The arch is composed by two divergent parabolic curves, with a chord of 172 m and a rise of about 44.6 m (Cruz, 2016). This bridge still holds the record for the world's largest iron arch. The construction company was a Brussels-based firm called *Société Anonyme de Construction et des Ateliers de Willebroeck*. In December 1881 the official inauguration of the work took place, and on October 1886 the upper deck was opened.

The Tagus River rises in the Sierra de Albarracín of eastern Spain, passes close to Madrid and forms part of the border with Portugal before flowing into the Atlantic Ocean in Lisbon (Fig. 3).

Figure 3. Map of Portugal identifying the Tagus and Douro rivers and the cities of Lisbon and Porto.

In the last two decades of the 19th Century several solutions were proposed to build a bridge between Lisbon and the south bank, being the most relevant the one presented in 1889 by Edmond Bartissol (1841-1916) and Théophile Seyrig. It was a multi-span metal railway solution, with a total length of 2310 m, which at that time would become the longest bridge in Europe (Fig. 4).

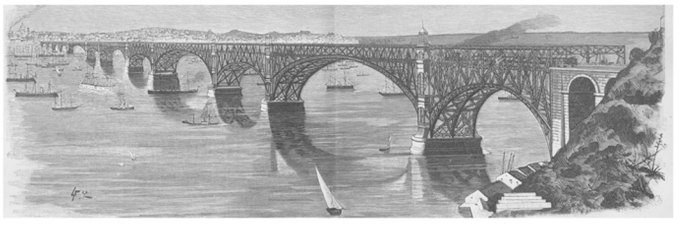

Figure 4. Solution proposed by Bartissol and Seyrig.

The bridge would leave the Rocha Conde de Óbidos towards the castle of Almada, giving way to the railway line that will leave the Rossio station to connect with that of Barreiro, in a 15.5 kilometers route (Fig. 5).

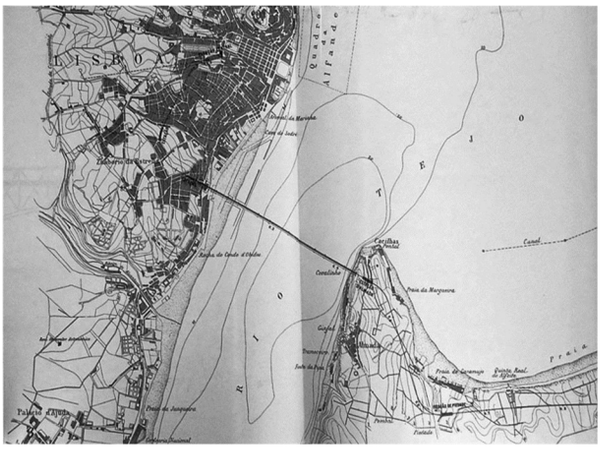

Figure 5. Location of the bridge proposed by Bartissol and Seyrig.

Although Bartissol's enjoyed a strong reputation in public works this project was not approved. Bartissol was responsible for the organization of the railway in Galicia (north-west region of Spain) between 1871 and 1875. In 1875 he moved to Portugal as a representative of *Financière de Paris*. He then undertook major projects, namely those to build the Beira Alta railway line, which crossed Portugal from east to west, as well as many other constructions including bridges and tunnels using innovative techniques for that time. The long-awaited bridge would only come fifty years after Edmond Bartissol's death.

Figure 6. First phase of the 25 de Abril Bridge view.

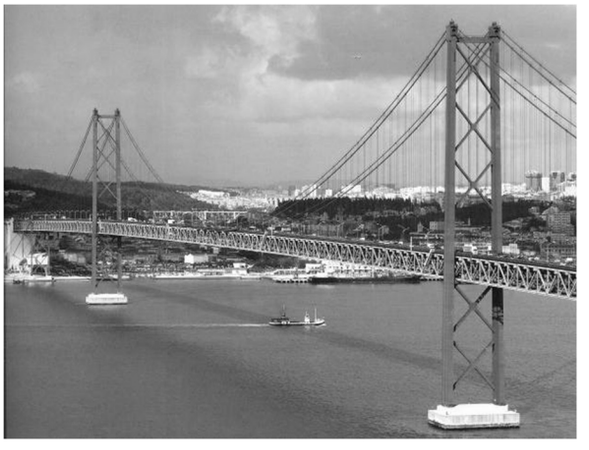

Figure 7. Second phase of the 25 de Abril Bridge view.

The construction of a long steel suspension bridge started in November 1962. The planned implementation period was fifty-one months, ending in February 1967. However, it was possible to shorten this period by six months, opening the bridge to traffic in August 1966. The central span of the suspended bridge was 1012.88 m length.

The project foresaw that, in the first phase, the bridge was exclusively for roadway traffic (Fig. 6) and that later, in a second phase, the installation of the railway could occur.

It was necessary to wait three decades so that in 1996 the works of widening the roadway platform and the inclusion of the railway line could begin. In November 1998 the roadway platform with six car lanes would open to traffic. In July 1999 the exploration of the railway line began (Fig. 7).

2 THE 19TH CENTURY PROJECTS

The aspiration to connect the two banks of the River Tagus began in the second half of the nineteenth century, with a design proposed in 1876 by the Portuguese engineer Miguel Pais, which provided a link between the Grilo area in Lisbon and Montijo in the south bank. The project consisted in a double deck for road and rail traffic with 74 central spans which were 60 m long and the two end spans which were 48 m long. Since then several projects have dreamed a bridge to connect Lisbon with the south bank of the Tagus River (Fig. 8).

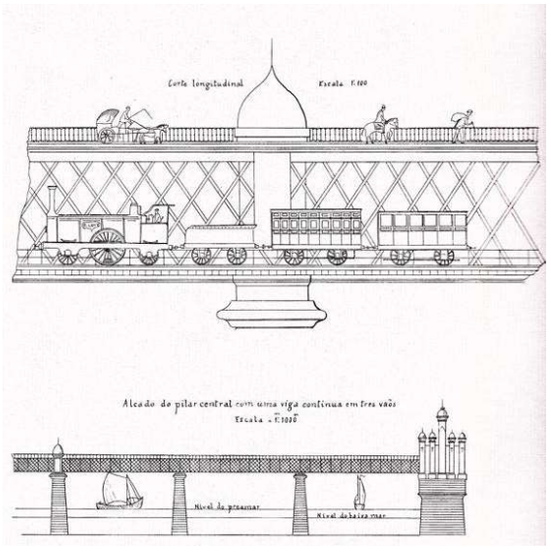

Figure 8. Solution proposed by Eng. Miguel Pais, 1876.

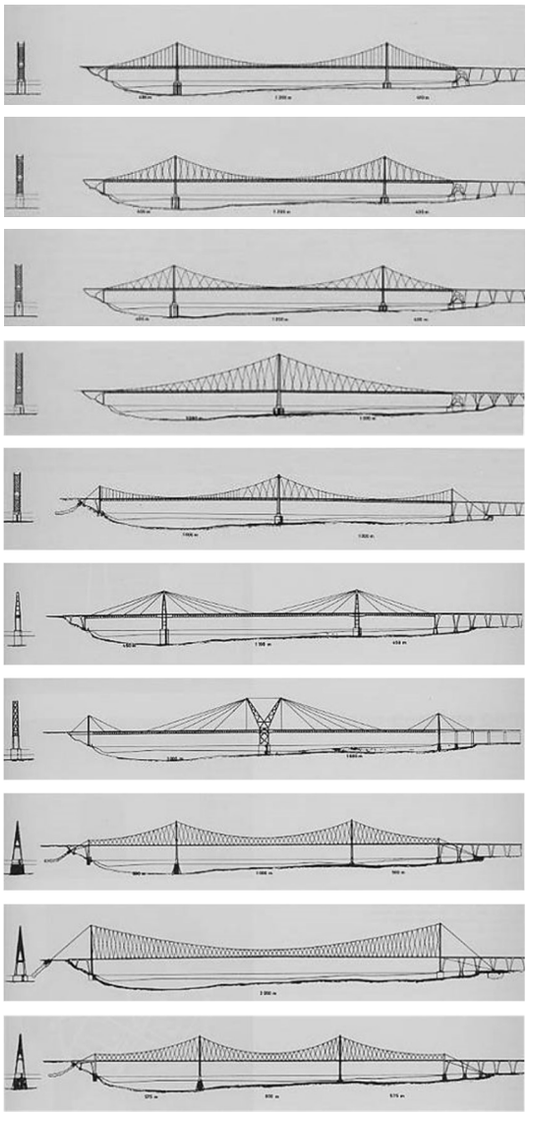
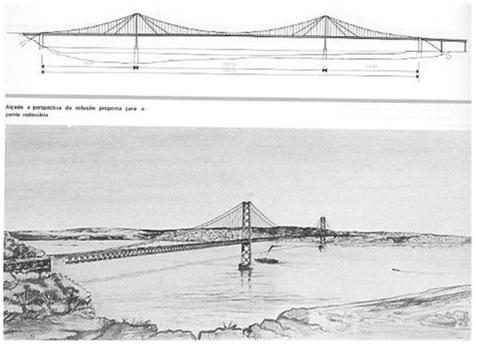
Other projects were proposed by:
- The American Lye, 1888;
- Bartissol and Seyrig, 1889 (Fig. 4);
- André de Proença Vieira, 1890;
- Maschinenbau-Actien-Gesellschaft, a company from Nuremberg, 1890 (Fig 9).

Figure 9. Location of the bridge in the Tagus estuary.

3 THE 20TH CENTURY BRIDGES

3.1 *25 de Abril Bridge*





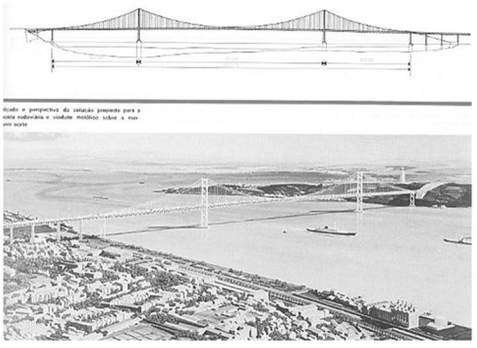


Figure 10. Theoretical reference solutions for the design of the bridge structure (GPT, 1966).

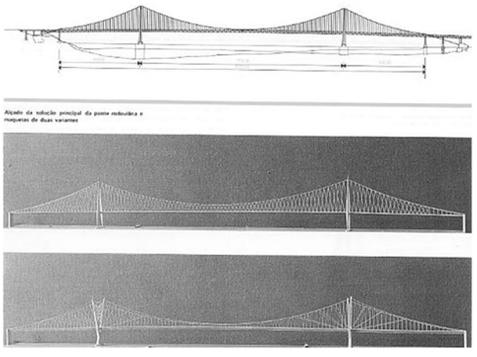
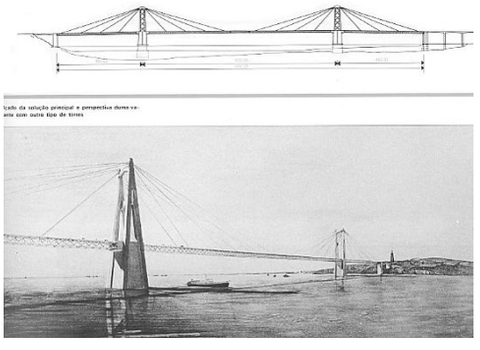
In the 1950's there was a strong demographic and industrial growth in the District of Lisbon, which led to considering the possibilities of using the Tagus southern bank lands. Thus in June 1953 a national commission was set up to work out roadway and railway links between Lisbon and the southern bank.



At the initiative of the Office of the Bridge over the Tagus, between 1959 and 1960, a group of national technicians prepared a study and presented a set of ten theoretical solutions for the structure of the bridge (Fig. 10).



d) Proposal 4 - Professor Kurt Klöppel.

c) Proposal 3 - Steinman, Boynton, Gronquist & London Comp.

b) Proposal 2 - Professor Chadenson.

a) Proposal 1 - Professor Albert Caquot.

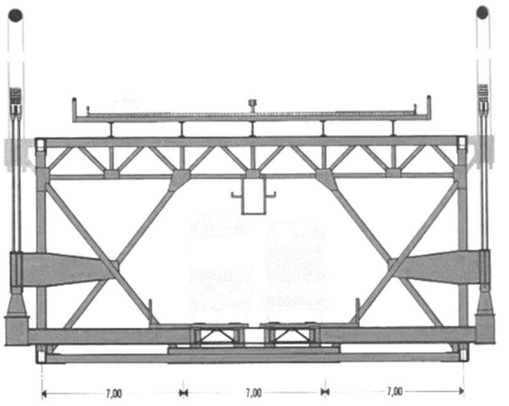


Figure 11. Bridge over the Tagus River in Lisbon, proposals submitted to the competition (GPT, 1966).

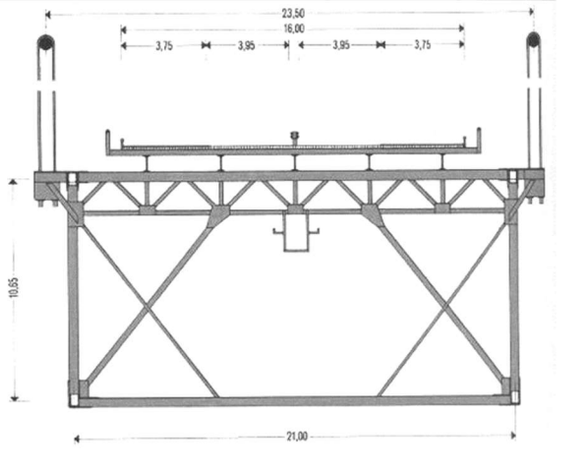
Four proposals were presented to the international public tender (Fig. 11).



Proposal 1 had the lowest costs for the road crossing, whereas proposal 3 was the only one which had a quotation to consider for the mixed roadway and railway bridge and an offer for the external financing covering the entire cost of the work.

In May 1960 the Portuguese Government decided that the work was provisionally adjudicated to competitor number 3 and in February 1961 signed the contract for the execution of the work.

A definitive project was presented in November 1961. It was approved in May 1962 by the Public Works Council and finally adjudicated. The United States Steel International (New York) Inc. based in New York was the prime contractor that associated a significant number of other companies. Thus Steinman, Boynton, Gronquist & London, Consulting Engineers designed the bridge. The Tudor Engineering Company designed the foundations and was responsible for the seismic studies. The American Bridge Division of U.S. Steel Corporation built the steel towers and all the superstructure of the suspension bridge.

b) Phase 2.

a) Phase 1.

Figure 12. Cross section of the stiffness beam (GPT, 1966).

As mentioned before, the project foresaw two phases. In the first one the bridge would be exclusively for roadway traffic and would consist of towers

and anchors, suspension cables and hangers that would support the rigidity beam (Fig. 12a). In a second stage the installation of the railway would be achieved by adding a supplementary structure consisting of two secondary continuous cables, several inclined cables and a beam settled inside the rigidity beam. The shape and location of these reinforcing elements would allow their future installation without interfering with the traffic in the roadway platform tanker (Fig. 12b) (GPT, 1966).

The central span of the suspended bridge was 1012.88 m, the lateral spans were 483.42 m and each margin span was about 100 m. The towers were 190.47 m high (Fig. 13).

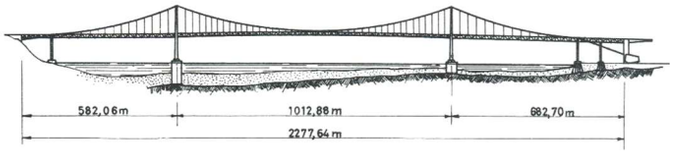


Figure 13. Bridge elevation (GPT, 1966).

The construction began in November 1962. The execution period was estimated to be 51 months, ending in February 1967. However, it was possible to shorten this period by six months and open the bridge to traffic in August 1966, under the name of Salazar Bridge. In 1974 the name would change to 25th of April Bridge.

The upper platform, running 70 m above water, started carrying 4 car lanes, two in each direction, with a dividing guardrail. In July 1990, this guardrail was removed giving way to a fifth reversible lane. In November 1998, the platform was extended to the present six lanes. The first railway crossing would take place in June 1999.

Contrary to what was envisaged by Professor Albert Caquot for the second phase, instead of adding inclined cables to the suspension system, the installation of only two secondary cables was preferred (Fig. 7).

For the installation of the railway deck in the north access viaduct (*Viaduto de Alcântara*) the designer, Professor António Reis, from GRID, opted for a composite solution of steel I beams connected with diaphragms and assembled by incremental launching from both ends (Fig. 14).

The metallic structure was fabricated in the south bank and transported to the site in segments consisting of "half" sections, 16 m and 20 m long (Fig. 15). These segments were connected transversely by welding the diaphragms in situ, after which the horizontal bracings were installed at the level of the lowest flange. The deck was incrementally launched from the north in a length of 452.6 m (Reis, 1997). The cross-section of the superstructure consisted of two I-beams, with a 4500 mm space between webs of. The webs had a constant thickness of 25 mm and the flanges varied between 40 mm in the spans up to 120 mm in the sections over the supports. The width of the flanges varied between 800 mm and 1300 mm. The diaphragms were 6.4 m apart and 20 mm thick with two flanges of 600×30 mm.

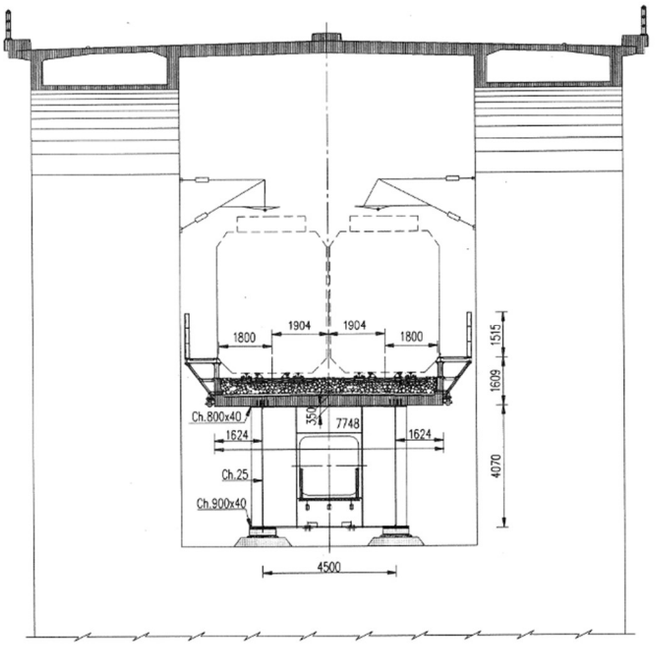

Figure 14. Railway deck in the north access viaduct (Reis, 1997).

Figure 15. North access viaduct - segments consisting of a half section.

The concrete slab was 0.35 m thick and connected to the steel beams by 22 mm diameter studs. Longitudinally the structure works had a beam with two continuous segments of 392.3 m and 526.6 m, separated by an expansion joint (Reis, 1997).

3.2 *Vasco da Gama Bridge*

To avoid that the main traffic between the northern and southern regions had to cross Lisbon and to reduce the traffic in the 25 de Abril Bridge, in April 1994, Lusoponte consortium has been selected to build the Vasco da Gama Bridge. It integrated the fol-

lowing companies: Kvaerner Construction International Limited; Campenon Bernard SGE; Bento Pedroso Construções, S.A.; Somague – Sociedade de Construções, S.A.; Sociedade de Construções H. Hagen, S.A.; Teixeira Duarte – Engenharia e Construções, S.A.; EDIFER – Construções Pires Coelho e Fernandes, S.A.).

The design contract was awarded to a consortium comprising the companies Kvaerner Technology, Europe Etudes Gecti (EEG), *Consultores para Obras, Barragens e Planeamento* S. A. (COBA) and *Projectos de Pontes e Estruturas Especiais* (PROPONTE).

Figure 16. Vasco da Gama Bridge (http://memoria-expo98.com/en/vasco-da-gama-bridge/).

The project was verified by Tejo Ponte Control, a consortium of *A2P Consult - Estudos e Projectos*, Hyder Consulting, *Provia Consultores de Engenharia* and Tudor Engineering.

The Vasco da Gama Bridge is the longest bridge in Europe, with a total length of 12.4 km, including 0.8 km for the main bridge and 11.6 km in viaducts and carries six road lanes (Fig. 16). The curved layout of the bridge enhanced the possible paths of large vessels.

The bridge has a life expectancy of 120 years, having been designed to withstand wind speeds of 250 km/h and to hold up to an earthquake 4.5 times stronger than the historical 1755 Lisbon earthquake (which had an estimated magnitude of 8.5-9.0 on the moment magnitude scale).

The cable-stayed bridge has a central span of 420.2 m and side spans of 204.6 m. The height of the central pylons is 150 m and the deck gives a clearance of 47 m above water level on the navigation channel called North Channel. The deck is a steel-concrete composite structure consisting of a 0.25 m thick prestressed reinforced concrete slab laying on steel transverse beams, spaced at 4.42 m intervals, and two main side solid concrete girds where 2×24 pairs of stays are linked to the pylons.

The H-shaped north and south pylons stand on foundations designed to withstand impact from a 30,000 tonne ship travelling at the cruise speed of 12 nuts. The deepest foundation piles, up to 2.2 m in diameter, were driven down to 95 m under mean sea level.

The construction began in February 1995 and it was opened to traffic in March 1998, two months before the opening of Expo 98, the World's Fair that celebrated the 500th anniversary of the discovery of the sea route from Europe to India by Vasco da Gama.

4 THE THIRD TAGUS CROSSING

4.1 *Introduction*

A decade after the opening of the Vasco da Gama Bridge Portugal strongly committed itself to the construction of three mega projects: a high-speed rail network (Fig. 17), a Third Tagus Crossing and a new airport in the metropolitan area of Lisbon.

The new bridge would accommodate four railway lines, two for the high-speed railway line Lisbon-Madrid, two for Iberian gauge conventional railway lines, and six roadway lanes, three in each direction.

Figure 17. High-speed rail network (www.expresso.pt).

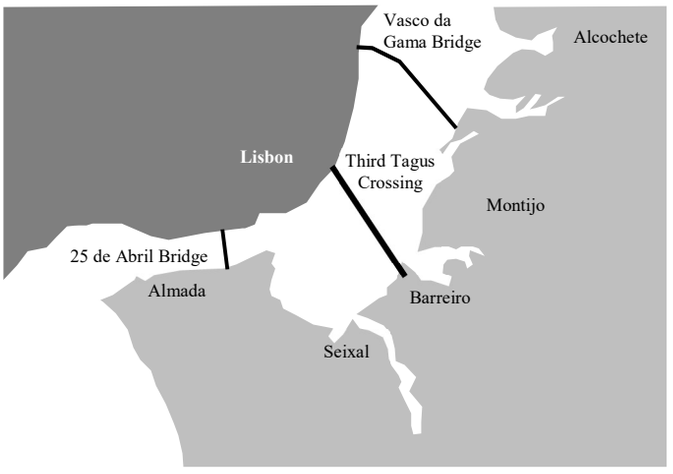

Figure 18. Location of Third Tagus Crossing.

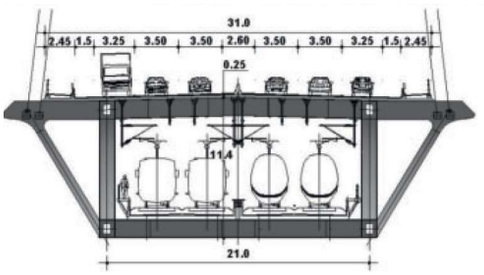

After many studies and discussions about the location of these new infrastructures, in 2008 was selected the Chelas-Barreiro corridor (Fig. 18).

4.2 *Reference design*

Under the initiative of the RAVE - *Rede Ferroviária de Alta Velocidade, S.A.* (High Speed Railway Network), in 2009 a reference design of the new bridge developed by Grid (coordination and structures), Consulgeo (geotechnical studies) and Fialho Rodrigues (geology) was presented. The adopted solution was a cable-stayed structure which had a composite double deck with a total length of 3.7 km, a main span of 600 m and a 200-metre high pylon (Fig. 19).

4.3 *The international public tender*

The international public tender for the construction and concession of the high-speed rail infrastructure in the section between Poceirão and Lisbon, which included the construction of the Third Tagus Crossing between Chelas and Barreiro, was launched in March 2009.

b) Cross section.

a) Elevation.

Figure 19. Preview of the Third Tagus River Crossing Bridge, in Lisbon (GRID, 2009 & Reis, 2008).

With a length of 34 km, the Lisbon-Poceirão section was prepared for mixed traffic (passengers and goods) and had a maximum speed of 200 km/h on the third Tagus crossing and in the Barreiro tunnel and 350 km/h on the rest of the line.

In January 2010, RAVE announced that the two consortia had moved to the negotiation stage of the international public tender:

- *Tave Tejo* consortium, which included the Spanish *FCC - Fomento de Construcciones y Contratas* (26%), the Portuguese *Ramalho Rosa-Cobetar* (1%) and *Conduril* (9%), the Italian *Impregilo* (25%) and *Cimolai* (4%), as well as the holding company *EHST - European High Speed Trains* (35%). The design companies were Adão da Fonseca Engenheiros Consultores, Ideam & Fhecor;
- *Altavia* consortium, which included the Portuguese *Mota-Engil* (17.38%), *Somague* (14.64%), *Teixeira Duarte* (14.64%), *MSF* (10.98%), *Opway* (10.98%), *Esconcesions* (5%), *BPI* (6%), *BES* (1%), banco *Invest (*0.75%) and *Alves Ribeiro - Consultoria de Gestão* (2.25%) and the French *Vinci* (16.38%). The design companies were Arcadis, LCW, A2P, PCA and Betar together with Lavigne & Cheron Architects.

The Altavia solution consisted of a cable-stayed bridge near the Lisbon bank, two bowstrings over the two navigation channels and trusses in the remaining crossing, with a total length of 8 km and a main span of 540 m.

A third proposal, by Elos Consortium, did not reach the negotiation stage. The consortium included the Portuguese Soares da Costa, Brisa, Lena Bento Pedroso, Edifer, Zagope, BCP and Caixa Geral de Depósitos, the Spanish Iridium - Concesiones de Infraestructuras, of the ACS group, and the North American company Babcock & Brown Limited.

According to the preliminary report of the selection board, the price difference of the two tenders, initially 300 million euros, increased to 509 million euros due to adjustments made by the evaluation committee, related with the net adjusted value, which included "construction, maintenance and financial costs". The proposal of the *Tave Tejo* consortium increased from 1870 million euros to 1964 million euros while the proposal of the *Altavia* consortium increased from 2166 million euros to 2473 million euros.

The consortium *Altavia* contested the preliminary evaluation report stating that the proposal by the *Tave Tejo* group did not meet all the specifications requirements - construction of the high-speed line, the third crossing of the Tagus and the north and south accesses of the new bridge.

Figure 20. Tave Tejo solution.

In May 2010, the Government decided to cancel the tender due to the global financial and economic crisis.

The *Tave Tejo* solution is a double steel truss cable stayed bridge with an overall length of 8184 m (Fig. 20). It consists of an 1140-metre long main bridge, two access viaducts of 540 and 950 m and 47 intermediate spans with a total length of 5554 m. The cable-stayed bridge pylons height is 198 m. The width of the road deck is 28.37 m and of the railway deck is 19.00 m.

b) The superstructure of the remaining crossing.

b) Bow-strings over the two navigation channels.

a) Cable-stayed bridge near the Lisbon bank.

Figure 21. Altavia solution.

The *Altavia* solution consists of a cable-stayed bridge near the Lisbon bank, two bowstrings over the two navigation channels and trusses in the remaining crossing, with a total length of 8 km and a main span of 540 m (Fig. 21).

For the railroad crossing a cable-stayed bridge was proposed near the Lisbon bank, two bowstrings over the two navigation channels and trusses in the remaining crossing. The pylons are 190 m high and the foundations are 70 m deep by piles with a diameter of 2.5 m.

5 CONCLUSIONS

It is worth recognizing the outstanding contribution of landmark bridges to the valorisation and development of the territories in which they are implemented.

This work describes the dream of building bridges over the wide estuary of the Tagus River mouth in Lisbon since the 19th Century.

The great diversity of the audacious technical solutions proposed undoubtedly deserves a worldwide diffusion and recognition.

Articulated and continuous cantilever bridges after a century of experience

P.G. Malerba
Dept. of Civil and Environmental Engineering, Politecnico di Milano, Milano, Italy

ABSTRACT: Cantilever bridges made of steel, reinforced and prestressed concrete, with their diverse arrangements, have given a fundamental contribution to the development of bridge construction. Many of these bridges, built more than a century ago, are still in service. Such an extended period of use allows us to ascertain their performances over time and also to highlight their most common draw-backs. With the hindsight of a century and a half of accrued experience, this paper will present an overview of how these bridges are performing today under the wear of time and increasingly heavy traffic intensities.

1 HISTORICAL AND TECHNICAL BACKGROUND

1.1 *State-of-the-art engineering in the XVIII century*

The material characteristics, the building technologies and the theoretical know-how of the past centuries were quite different from those we have today.

About the materials, the industrial process to produce cast iron was perfected at the end of the eighteenth century, while steels with modern characteristics were patented in the middle of 1800. In the second half of the nineteenth century new technologies were proposed: it is this period that Coignet, Monier, and others performed the first experiments on reinforced concrete. E. Freyssinet patented the prestressed concrete technology in 1928. Between 1933 and 1936, Abeles made the first experiments on partially pre-stressed beams and decks.

About the theoretical knowledge, mechanical sciences and theory of structures made a fundamental breakthrough in the nineteenth century. In particular, in the middle of 1800 many studies were devoted to truss structures. Starting from the experiences of trussed wooden bridges and roofs, practitioners and scholars foresaw the possibility of new developments thanks to the exploitation of the superior characteristics of new materials. Remarkable was the contribution of Squire Whipple, who presented one of the first thorough analysis of the behavior of trussed beams (bowstring truss) and proposed to use cast iron for compressed members and wrought iron for tensioned ones. These studies resulted in the construction of longer bridges, many of which served railways lines and allowed to overpass remarkable spans, supporting high traffic loads.

1.2 *The origin of continuous articulated bridges (Gerber type Bridges)*

In a few years, these experiences led to the introduction of new, ingenious arrangements, that brought about what we can collectively describe as articulated or cantilever bridges.

In its first configuration, a cantilever bridge is a continuous bridge having hinges in specific sections, typically at points of contraflexion.

G. H. Gerber designed the innovative Haßfurt Brücke, completed in 1866 and considered the first modern cantilever bridge. This bridge is made of a girder over three spans (29.90 + 37.90 + 29.90 = 77.70 m), having two hinged joints in the central span, which is thus supported by the two lateral cantilevering beams.

The first cantilever bridge in the USA, the "Kentucky River Bridge", designed by G.F. Bouscaren and C. S. Smith (Wilcox 1898), was completed in 1877. It is a three-span bridge ($3 \times 114.27 = 91.4 + 160.0 + 91.4 = 342.8$ m), with two hinges located in the side spans, at a 22.9 m distance from the piers axes.

The "Niagara Cantilever Bridge" was designed by C. C. Schneider and completed in December 1883. Once again, the bridge consists of three spans: two side spans of 114.3 m each and a 36.6 m central span. The two hinges are located in the central span.

These early examples came to characterize specific subtypes of articulated bridges: bridges with hinges located in the side spans are called Kentucky

type bridge, while Niagara type bridges are those having hinges in the central span.

The most notable cantilever bridge of the nineteenth century is the Firth of Forth Bridge, whose construction began in 1881 and was completed in 1890. The bridge was designed by Sir J. Fowler and Sir B. Baker and has a total length of 2,467 km. It consists of two main spans, each 520 m long, having a width of 37 m at the piers and 9.8 m at center; the towers are 110 m tall.

Since then, the cantilever scheme became one of the most common solutions for long-span bridges subjected to heavy loads.

The reasons for the success of the cantilever bridges are many: first, they are or can be easily reduced to statically determined structures. Even if theories and methods to deal with statically indeterminate structures were available at the end of the nineteenth century, dealing with statically determined structures was advantageous in that allowed to obtain reliable and straightforward analytical results and to simplify the search for the maxima and minima of the internal forces. The fact that foundations settlements did not influence the structure behavior was another significant advantage, so were the possibility of arranging specialized equipment for intermediate construction stages, no need of falseworks that would obstruct rivers or canals during construction, and shorter construction times.

1.3 *The introduction of pressed R.C. cantilever bridges*

The first Gerber type bridges were built as steel trusses. The advent of reinforced concrete saw the construction of many R.C. Gerber bridges, but only on very short spans. Only the diffusion of the prestressing technology, after 1950, made it possible to lengthen the spans of the girders, and concrete structures became competitive.

It is worth noting that, notwithstanding the change in construction material and technologies, one hundred years of experience steered designers once again towards Gerber type/cantilever structures. This was not only due to the advantages recalled previously, which still stood, but also to the initial difficulties in obtaining a reliable analysis of the effects of time-dependent behaviors. As a consequence, this scheme was still widely used until the last decades of the twentieth century.

The balanced cantilever erection technique became the most diffused construction method and new girder arrangements, such as the one having a single hinge in the central sections, were introduced.

As known, and excluding particular cases, present standards suggest the use of fully continuous girders over articulated structures.

Other attempts to obtain continuous jointless girders, but maintaining a simple static scheme, are the so-called tie-deck girders, composed of several simply-supported spans, connected through short continuity slabs.

2 THE EVOLUTION OF CANTILEVER BRIDGES

We maintain a distinction between steel and concrete cantilever bridges.

2.1 *Trussed cantilever steel girders*

As already recalled, between the end of 1800 and the beginning of 1900, medium-long girder bridges for both railway and road networks were designed as steel trusses. Relatively simple and statically determined schemes, the so-called “Gerber type” girders, were obtained through the introduction of hinges in suitable points along the spans. Apart from the panel geometry of the truss, the element which differentiates these bridges was the arrangement of the articulations at the internal supports, carrying the suspended ends of a span. The set of bearing supports at one end must remain fixed, allowing rotation only, while the supports at the other end must permit translational longitudinal movement as well as rotation of the ends of the superstructure. Therefore, the supports typically comprise of a fixed hinge bearing support and a roller, or of a rocker-roller or pendulum type expansion bearing.

Figure 1 shows the layout of a bridge rebuilt in 1953. It is a trussed bridge with a double deck, the upper one serving a railway and the lower one a road. The bridge has a west span of 44.00 m, a central span of 56.00 m and an east span of 45.00 m. The mechanisms supporting the central span are located at a distance of 11.20 m at either side of the two central piers and are composed by a couple of pin supports on the west side (Fig. 2) and by a couple of pendula (rockers) on the east side (Fig. 3). Figure 4 shows the roller support at a pier.

In many cases, the pendulum is an oscillating strut, whose length is equal to the depth of the girder, with one end connected to the upper stringer of the supported span and the other to the lower stringer of the cantilever. Figure 5 shows the oscillating pin and hanger assembly, working like a pendulum, between the upper and lower chords belonging to a bridge opened in 1908 and identically rebuilt after the Second World War in 1947. The bridge is 1097 m long. Its central part, 607 m long, is made of Gerber trusses, spanning 75.25 m and supported by masonry piers. The expansion supports lie at a distance of 15.14 m from the nearest pier.

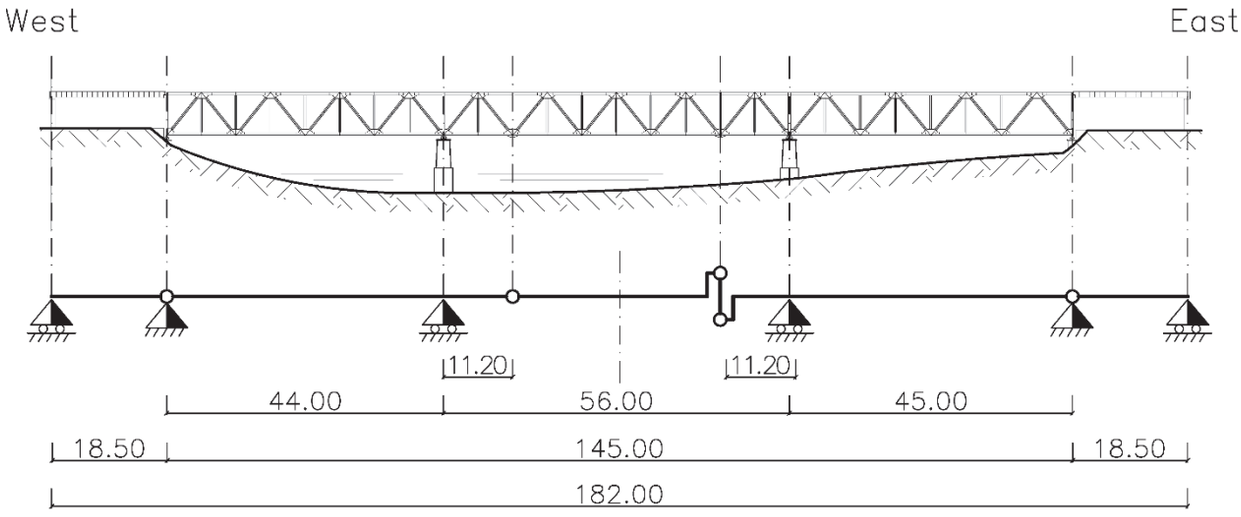

Figure 1. Layout of a truss bridge having the upper deck serving a railway and the lower one a road (rebuilt in 1953).

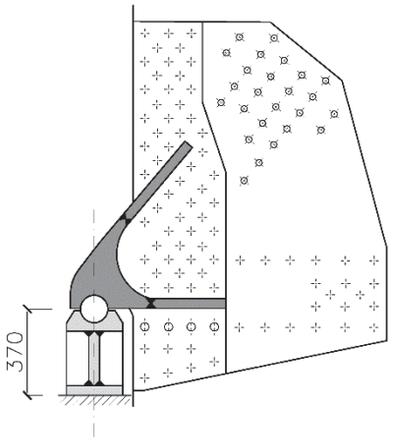

Figure 2. Scheme of the pin support on the west side of the bridge shown in Figure 1.

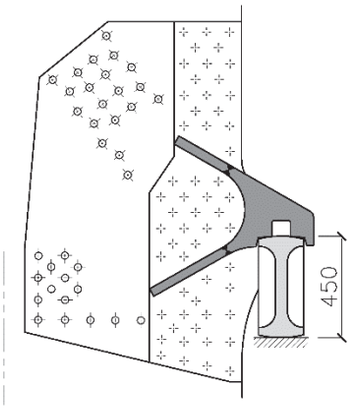

Figure 3. Scheme of the pendulum (rocker) on the east side of the bridge shown in Figure 1.

Figure 4. The roller bearing in correspondence of a pier of the bridge shown in Figure 1.

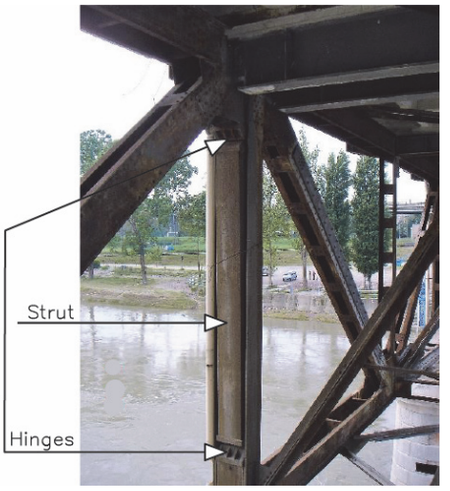

Figure 5. Pin and hanger assembly working as a pendulum between the upper and lower chords in a bridge rebuilt in 1947.

2.2 *Reinforced and prestressed cantilever concrete girders*

From the beginning of the XX century, with the improvement of the reinforced concrete technology, several multi-spans R.C. cantilever bridges were constructed. The length of both cantilevers and suspended spans were limited and, in any case, shorter than those of trussed steel bridges. Their use in railways was uncommon.

The spread of the prestressing technology allowed a remarkable increase in spans that could now exceed 100 m. The three main schemes for reinforced and prestressed cantilever concrete girders are briefly recalled in the following (Mathivat 1983).

2.2.1 *Articulated systems with suspended spans*
In this scheme, the central span is sustained by the two cantilevers projecting from the piers. Basic arrangements are shown in Figure 6 and correspond to those already defined as Niagara (Fig. 6a) or Kentucky (Fig. 6b) type bridges. In European countries, the mechanisms used at the joints for materializing the articulation are called "Gerber hinges". One end of the suspended span is simply supported, while the other end lies on sliding supports, which allow the horizontal displacements due to length changes in the beams caused by time-dependent and temperature effects. Both supports permit rotations. The main advantages of this configuration are a clear and straightforward static scheme (since they are statically determined structures) and the avoidance of spurious effect due to settlements of the foundations.

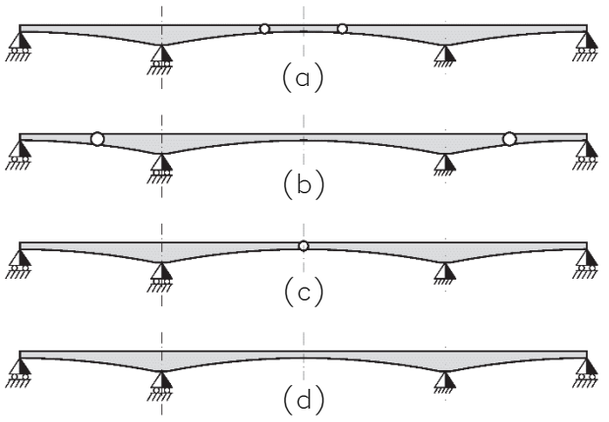

Figure 6. Cantilever bridges basic arrangements: (a) Niagara type; (b) Kentucky type; (c) hinged cantilever; (d) cantilever made continuous.

2.2.2 *Partially articulated systems with hinged cantilevers*
In this arrangement, after the erection phase, the ends of the cantilevers are connected by a key central hinge (Fig. 6c). The bending moment at midspan is zero. The central hinge transmits shearing forces, allows relative rotation between the two ends of the cantilevers and, through a suitable design, allows a free expansion of the girder. The design develops from a simple initial model because the structure is statically determined under the combined effects of self-weight and prestressing. Once the central hinge has been incorporated, the structure becomes statically indeterminate with respect to additional loads due to finishing works and traffic loads. In the final configuration, the statically indeterminate forces for each span are the vertical shear forces exchanged at the central hinge.

2.2.3 *Cantilever systems made continuous*
After the erection phase, the two adjacent cantilevers are connected, rendering them fully collaborating and the girder continuous (Fig. 6d). This type of bridges may be cast on scaffoldings and then prestressed, or build through the so-called balanced cantilever method. In such second case, the adjacent cantilevers are connected by concreting the central segment and then prestressing the girder with cables running along its whole length. Among the three schemes (articulated, partially articulated, continuous) the continuous one is at present the best solution. In fact, many cantilever bridges built according to the other two schemes have over time been modified and rendered continuous.

2.3 *Different joint types for reinforced and prestressed concrete girders*
In these structures, the joints must transmit high-intensity forces from the cantilever to the suspended structure, while also allow suitable relative movements between the coupled structures. These forces are localized over small areas, resulting in highly concentrated stresses. For iron and steel bridges, it was natural to resorts to devices like those used for heavy mechanical machinery. Bearing and expansion supports, rollers, rockers, and sliders are mechanical devices, involving special manufacturing techniques (Fig. 7). The main body of the supports are cast and then worked with a milling cutter, lathe, and borer machines and, in the end, the working surfaces are hardened with chemical and thermal treatments.

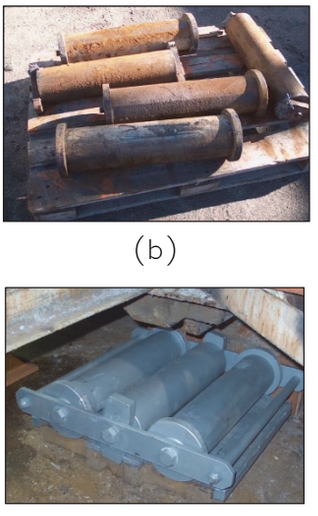

Figure 7. (a) Schemes of bearing and expansion supports used in iron/steel bridges; (b) roller bearings of a railway steel truss after 75 years of service; (c) the new rollers ready to substitute the old ones.

For concrete bridges the situation was different. For short spans, lead pads and elastomeric bearings were initially used. For longer cantilever girders there were attempts to design hinges and rockers with blocks of high strength concrete and special reinforcement arrangements, but in the end, the most

common solution exploited joint connections like those of steel bridges. Nowadays pot bearings, made of an elastomeric disc confined between a steel pot and a circular piston, with or without upper sliding guides, are used.

In truth, for R.C. and P.C. cantilever bridges with articulations, the main problem is the force transmission from the bearing or connecting devices to the body of the structure. The most frequent solution uses joints made of a couple of opposite corbels, like those shown in Figures 8 and 10.

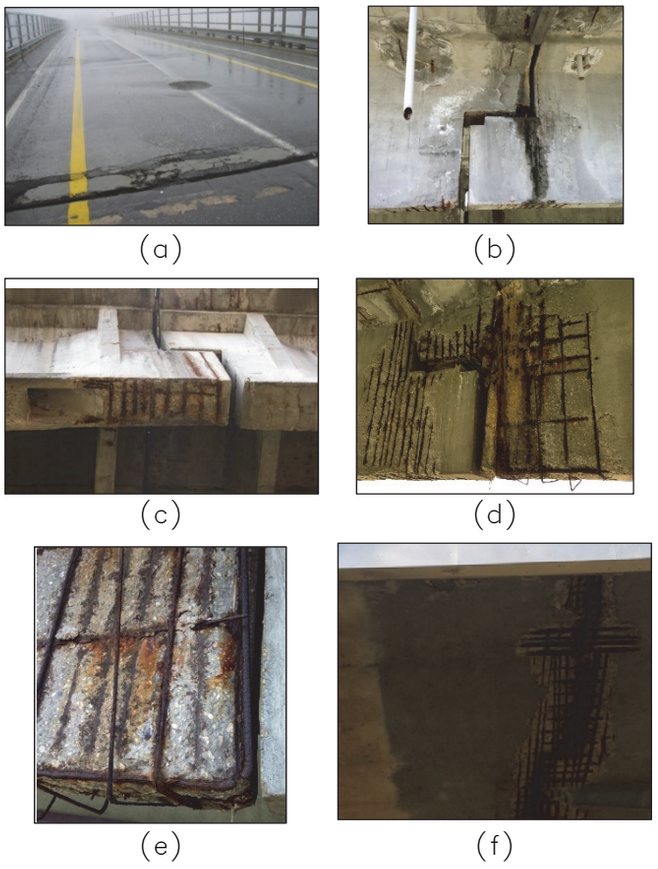

Figure 8. Articulated joints in R.C. Bridges: (a) malfunctioning joints lead to platform cracking; (b-f) the cumulative effects of malfunctionings in the joints and drainage systems cause water leakages that foster reinforcement corrosion.

For girders with hinged cantilevers, the key connections are usually made of massive steel blocks, whose sliding interfaces must be carefully milled and refined. Moreover, the two elements of the key must be assembled with small tolerances, to avoid gaps between the contact surfaces (Fig. 9).

3 IN-SERVICE BEHAVIOUR AND MOST COMMON TYPE OF DAMAGES

3.1 *Common damages*

Cantilever structures have proved to be fundamental in increasing span lengths and introducing new construction techniques. Many of these bridges, now more than one century old, are still in service.

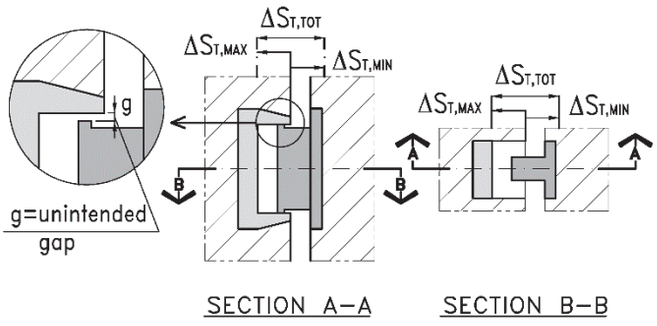

Figure 9. Example of a key central hinge in a R.C. bridge. The occurrence of an unintended gap makes the dowel action discontinuous and causes severe dynamic and hammering effects.

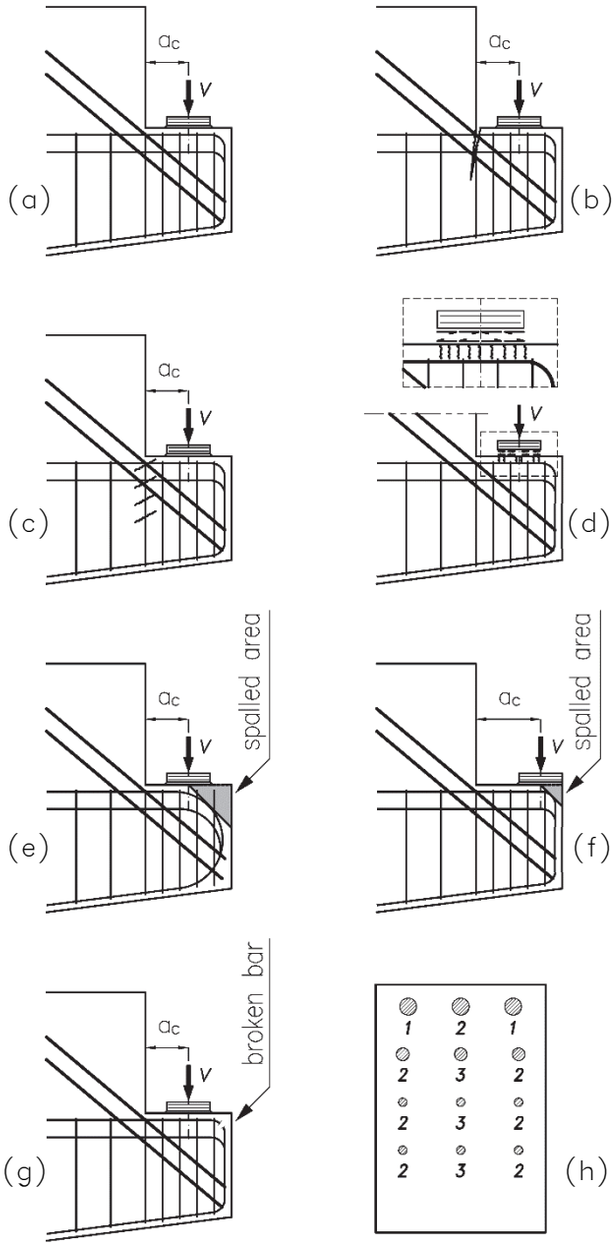

Figure 10. Recurring problems in R.C. Gerber corbels: (a) layout of the typical R.C. corbel; (b) flexural crack; (c) shear cracks; (d) cracking below the bearing pad; (e) incorrect reinforcement layout; (f) incorrect positioning of the bearing pad; (g) breakage at the bend of an exposed corroded bar; (h) sequence of activation of corrosion in rebars (1, 2, 3): the bars closest to the lateral surfaces are the most vulnerable, while internal bars provide an important reserve of strength.

This extended period of use allows us to ascertain their performances over time and to highlight, also, their most significant drawbacks. Such a posteriori evaluation is not intended as a critic of a praiseworthy past, but rather as an opportunity for examining their most common weaknesses, so as to conceive and design practical solutions to extend their service life.

In medium-long span bridges built over the last 150 years, the most common damages are those typical of old structures. They are mainly due to aging and lack of maintenance and can be summarized as surface wearing, with onset and diffusion of steel corrosion and, for R.C. bridges, cracks formation.

3.2 *Typical damages in cantilever girders*

Paying specific attention to cantilever girders, we can today affirm that some design criteria that appeared reasonable in the past, have resulted in dangerous preconditioning in later stages of the structure's life.

Many typical malfunctions have been triggered by: (a) initial choice of static scheme; (b) joints design; (c) an insufficient analysis of time-dependent effects (shortening, excessive deflections); (d) incorrect use of prestressing in governing the static and deformed configuration of the structure.

3.3 *Joints and their static and functional effects*

Joints articulations need to work as hinges. For the same geometry and loading conditions, articulated girders are statically/kinematically equivalent to continuous ones, if the articulations are placed at sections with zero bending moment in the corresponding continuous scheme. These hinges allow relative rotations between the two ends of the cantilevers and permit free longitudinal expansions of the girder. For a given loading condition (e.g. self-weight and permanent loads), the optimal hinge position can be easily determined.

It must be pointed out that small changes in hinge location and/or in loading distribution induce minor changes in the displacement as well as in the corresponding internal forces distributions, but relevant changes in the local relative rotations between the edges of a joint.

In girders with a key central hinge, in case the two edges of the joint end up being separated by an unintentional gap (identified with *g* in Fig. 9), the dowel action becomes discontinuous, causing severe dynamic and hammering effects.

Hence, from the functional point of view, the presence of internal hinges and joints causes slope discontinuities in the road profile and, under permanent loads, such kinks are progressively increased by time-dependent effects (Figs 11a, b).

Local discontinuities foster dynamic effects, reduce ride comfort (Fig. 8a) and cause severe damages to both bearing devices and their interfaces with the main structure. Moreover, the increase in the dynamic effects on the cantilever beams induces fatigue stresses in the upper rebars and tendons for negative moments.

In the end, repeated relative rotations between the joint edges damage the drainage and sealing systems, causing water to leak on underlying surfaces and corrosion of the nearby reinforcement (Figs 8b-f).

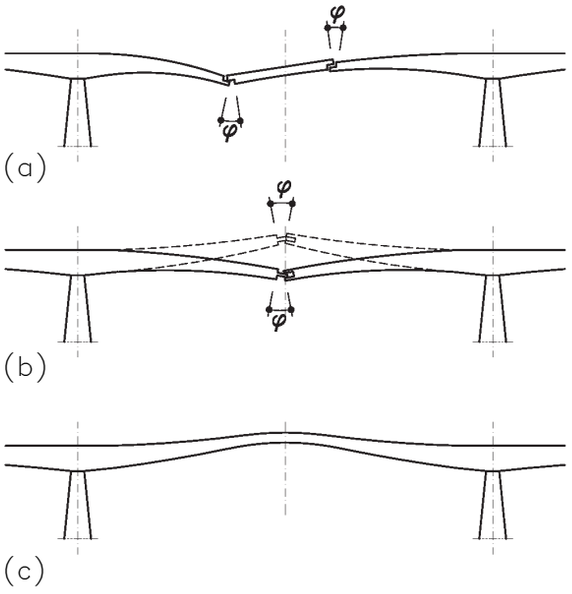

Figure 11. Time-dependent effects magnify irregularities: (a) abnormal slope in the central span (redrawn from Mathivat); (b) significant relative rotation (kink) at the central hinge (redrawn from Mathivat); (c) loss of planarity in a continuous girder.

3.4 *A focus on Gerber corbels*

Leakage of salted water from the platform causes the damaging effects shown in Figure 8, i.e spalling of concrete cover, corrosion of the bars, breakage at the bends of smaller bars like external stirrups. Other damaged states are shown in Figure 10 and consist of flexural or shear type cracks (Figs 10b, c); surface cracking immediately below and nearby the bearing pad (Fig. 10d); spalling of the corner due to an incorrect reinforcement shaping (larger bars involve larger radius of bend, Fig. 10e); spalling of corner due to incorrect bearing pad positioning (too close to the edge, Fig. 10f); breakage at the bend of exposed corroded bars (Fig. 10g). With reference to a hypothetical corbel section, Figure 10h shows the sequence of activation (1, 2, 3) of the corrosion effects The bars closest to the lateral surfaces are more vulnerable to corrosion than the interior bars, that, if present, remain an important reserve of strength.

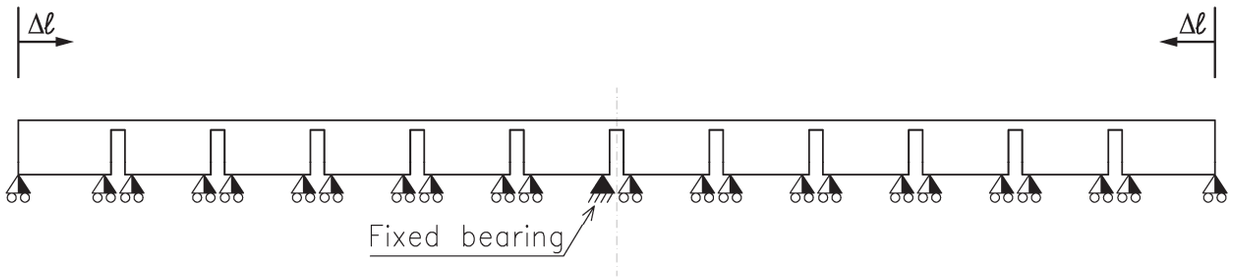

Fig. 12. Scheme representing a so-called "tied-deck girder" or "kinematic chain girder".

Gerber joints or corbel failures were at the basis of many ruinous bridge collapses. In steel bridges, corrosion states reduce the area and the stiffness of the pendulum struts, and lead to states of local instability, with consequences on the whole structure.

In R.C. bridges, the worsening of the damage states previously described may lead to the breakage of the corbel, causing the loss of its supporting action.

Small corbels are more vulnerable. The strut and tie models assumed for their design are reliable if the bottle-shaped struts volume is sufficiently larger than the material sizes of the aggregates, bars, and their bend radius. Moreover, corbels of limited dimensions make it difficult to accurately arrange the bars, resulting in structural details with congested reinforcement.

3.5 *Quasi-continuous bridges (tie-deck girders)*

A so-called "tied-deck girder" or "kinematic chain girder" is a viaduct composed of a train of simply-supported decks, longitudinally connected through short and flexible continuity slabs (Fig. 12). By avoiding joint devices between the spans, such scheme makes the carriageway continuous.

Dealing with long-span bridges, the time-dependent effects (shortening) and temperature excursions, cause longitudinal displacements which increase from the fixed point towards the free ends. In the design phase, it must be verified that, for the worst expected shortening over time, the upper plate of the bearing device will still be insisting on the lower one with a wide-enough contact area.

Experience showed that this might not be sufficient. In multi-span tied-deck-slab bridges, the shortening effects may cause significant changes in the local diffusion mechanisms in the contact zones of the bearing supports. These zones belong to the ends of the beams, where the prestressing action diffuses and stabilizes over a length nearly equal to the depth of the beam itself. In a proper design arrangement, the diffusion the stresses from the bearing supports superimposes the diffusion zone of prestressing, creating a biaxial compression zone. When the relative displacement of the sliding plates of the bearing device is such that the stress field due to the support reactions rest outside that of the biaxially compressed area, a wedge collapse may occur (Fig. 13). This local failure of a zone interested by very intense forces may create further and severe consequences and even lead to the collapse (Malerba 2016).

3.6 *Continuous prestressed bridges. Excessive deflections*

In the beginning, the design of these bridges was mainly focused on the erection stage, checking the stress distributions for the different configuration assumed during the erection and computing the corresponding deflections. As known, the deck is progressively uprising, until, in the final stages, the weight of the last segments and their higher lever arms lower the girder and it reaches the final (straight) trim, expected for the closure.
