5 CONCLUSIONS

Life-cycle reliability of PC girder in a marine environment was estimated considering the spatial distribution of steel weight loss. RSM was included in the proposed life-cycle reliability formulations for improving the computational efficiency. Effect of the difference of modeling the steel corrosion distribution on the life-cycle reliability of PC girder was presented in the case study.

The results indicate that it is important to take into account the spatial variability of steel corrosion distributions.

Optimum Strengthening Strategy for Deteriorating Reinforced Concrete Bridges

H. Baji & C.Q. Li
RMIT University, Melbourne, Australia

ABSTRACT: Corrosion of reinforcing steel in concrete is the one of the most predominant causes of deterioration in reinforced concrete (RC) bridges. This paper presents an optimal strengthening strategy for corrosion-affected RC bridges. By combining concepts of strengthening and maintenance optimization, an innovative strengthening strategy for structures strengthened by different methods such as FRP composites can be developed. Formulation of the proposed strategy is based on cost optimization. In this strategy, the optimum strengthening time and quantity of the strengthening material can be determined. Application of the proposed methodology is presented in a worked example for a corrosion-affected RC bridge girder strengthened with Fibre Reinforced Polymers (FRP) sheets. The paper concludes that the developed strategy can be a useful tool, which can assist asset managers in developing rehabilitation plan for deteriorated RC bridges under their management.
df

1 INTRODUCTION

Most of reinforced concrete (RC) structures are exposed to continuous deterioration from harsh environment such as exposure to chloride ions, carbon dioxide, sulphate dioxide, etc. This deterioration results in reduction of load carrying capacity leading to structures with service life shorter than the anticipated design life. For instance, in Australia, 30,000 bridges are approaching the end of their lifespan (Australian Local Government Association, 2013). Furthermore, these structures might become subjected to increasing demand during their operating lifetime. For instance, the demand for increasingly heavier truckloads is forcing bridge owners to upgrade the existing structures. One apparent solution to deal with deterioration and increasing demand is to replace the infrastructure. However, this is very costly if not impossible. The most viable and practical solution for maintaining safe operation of these structures is to restore and/or increase their capacity using strengthening schemes.

Due to their excellent mechanical and chemical properties, ease and efficiency of application and relatively low cost, strengthening using Fibre Reinforced Polymers (FRP) is emerging as an alternative to the traditional methods and is becoming an increasingly popular strengthening technique among researchers and practitioners worldwide. The effectiveness of FRP confinement in increasing the strength and structural performance is attributed to its ability to avoid or delay undesirable failure, such as, concrete crushing or longitudinal reinforcing bar buckling. FRP strengthening techniques have been used for flexural and shear strengthening of RC beams and slabs (Bonacci and Maalej, 2000, El Maaddawy et al., 2007, Capozucca, 2013, Al-Saidy et al., 2016, Xie and Hu, 2013) and strengthening of RC columns (Bae and Belarbi, 2009, El Maaddawy, 2008, Pantazopoulou et al., 2001, Wei et al., 2009). It has been shown that significant increase in strength and structural performance can be achieved using FRP strengthening.

There has been extensive research on methods of FRP strengthening for RC members. Nonetheless, strategies that determine the optimal required amount of FRP strengthening and more importantly the appropriate time to perform such an action have received less attention. Although various maintenance strategies in which optimum maintenance times are obtained can be found in the current literature (Akgül and Frangopol, 2005, Baji et al., 2017a, Barone et al., 2013, Mori and Ellingwood, 1994, Thoft-Christensen and Sorensen, 1987), in most of these strategies only the time of maintenance actions is optimized. In these studies, it

is assumed that after each maintenance action the structure is reinstated to its original condition without giving any details of how this is achieved. Furthermore, these strategies deal with repair of the structure rather than strengthening (Baji et al., 2017b).

In this paper, an optimal strengthening strategy for corrosion-affected RC bridges is presented. The optimal time for strengthening and amount of strengthening material are the output of the optimisation. Deterioration of strength is modelled as a stochastic process and the probability of structural failure is calculated using the first passage reliability method. In order to illustrate application of the proposed strategy, a numerical example of a corrosion-affected RC bridge girder strengthened with FRP composites is given.

2 METHODOLOGY

2.1 *Formulation of the strengthening strategy*

Due to corrosion, area of reinforcing steel is decreasing leading to strength loss, which in turns increases the probability of structural failure. In order to restore strength of structural RC members to an acceptable level, structural rehabilitation in terms of either repair or strengthening would be necessary. Nonetheless, strengthening of structural members does not stop the deterioration process, and even after repair or strengthening, the structure is still subject to deterioration. Major structural strengthening is generally a once in a lifetime action, which is intended to increase the structural strength so that it can meet the intended design service life. Therefore, service life of structure can be divided into pre and post-strengthening phases. Schematic strength degradation before and after strengthening is shown in Figure 1(a). In this figure, R_0 and R_a are the initial strength and the acceptable residual strength (beyond which structure is deemed to fail), respectively. From structural safety point of view, it is required to keep the probability of structural failure smaller than a predefined acceptable level for the whole service lifetime. The rationale for the proposed strategy is that, whilst keeping the probability of structural failure under control throughout its lifetime, the total expected cost, which is the sum of the expected cost of failure and cost of preventive strengthening action, is minimized. This concept is illustrated in Figures 1(b). p_f and p_a are the probability of failure and the acceptable probability of failure, respectively. As can be seen in Figure 1(b), the optimum repair time, t_p, is found in a way that before and after strengthening using FRP, the probability of failure, p_f, is less than the acceptable probability of failure, p_a. From this strengthening strategy, the optimal strengthening time and quantity of strengthening material can be determined.

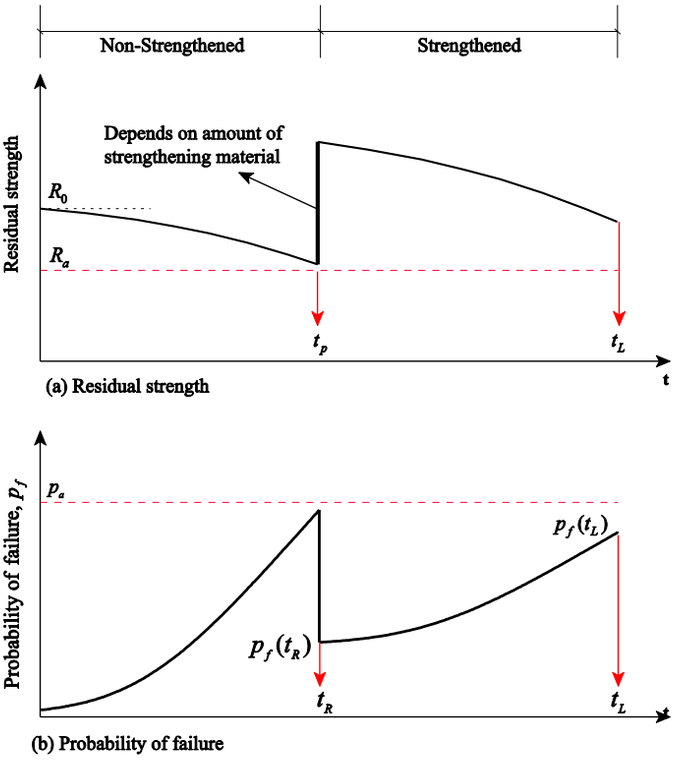

Figure 1. Degradation before and after strengthening

Referring to Figures 1(a and b), the optimum strengthening problem can then be mathematically formulated as follows,

$$\text{Minimize: } E(C_T) = E(C_R) + E(C_F) \quad (1a)$$

$$\text{Subject to: } p_f(t_R) \le p_a \,;\, p_f(t_L) \le p_a \quad (1b)$$

where, E denotes the expected value, t_R = strengthening time, t_L = predefined lifetime of the structure, C_T = total cost of maintenance, C_F = cost of failure and C_R = cost of repair and strengthening actions. Cost of repair includes cost of material required for strengthening, installation and indirect cost due to unavailability of the structure during repair. Cost of failure includes the direct cost of replacement as well as the indirect cost such as traffic delay. By having the unit cost of repair, c_r, and failure c_f, the cost terms in Equation 1a can be calculated as follows,

$$E(C_R) = c_r \quad (2a)$$

$$E(C_F) = c_f \left\{ E\left[N_F(0,t_R)\right] + E\left[N_F(t_R,t_L)\right] \right\} \quad (2b)$$

where $E[N_F]$ = expected number of failures. Using the annual discount rate all the costs are converted to the present cost. According to Equation 2b, the cost of failure is divided into two parts: before and after strengthening. These costs are two competing costs where by delaying the strengthening action time, t_R, the expected cost of

failure before strengthening increases, while the expected cost of failure after strengthening decreases. Combining these competing costs with the cost of strengthening action, results in the total expected cost for which a minimum point exists.

The design variables in the optimization problem defined in Equations 1a and 1b are the strengthening time, i.e., t_R and the amount of strengthening material, which determines the jump in the residual strength after strengthening [see Figure 1(a)]. The amount of strengthening also affects the expected number of failures after strengthening, i.e., $E[N_F(t_R, t_L)]$, in Equation 2b.

2.2 *Evaluation of expected number of failures*

The expected number of failures is a key factor in solving the proposed optimization problem. Assuming the structural system under ultimate strength as a renewable system, the renewal theory approach (Elsayed, 2012) can be used for calculating the expected number of failures. However, in the first passage probability method, the outcrossing rate, i.e., the rate at which the random process outcrosses a critical barrier or level can be used to evaluate the expected number of failures. The outcrossing rate can be interpreted as the expected number of failures per unit time (Ditlevsen and Madsen, 1996, Andrieu-Renaud et al., 2004). Having this rate, the probability of failure can also be calculated. This unique feature in the first passage probability method simplifies the optimization procedure, as by having only the outcrossing rate both the expected number of failures and the probability of failure can be determined.

For problems involving stochastic process of structural response, $S(t)$, the structural reliability depends on the time that is expected to elapse before the first occurrence of $S(t)$ outcrossing a critical level (the threshold) $R(t)$ sometime during a given time interval $[0, t]$. Under the assumption that the outcrossing events are independent, i.e., Poisson assumption, the outcrossing rate can be determined (Melchers, 1999). An analytical solution to Equation (5) has been derived in Firouzi et al. (2016) when $S(t)$ is a Gaussian process and the threshold $R(t)$ is deterministic. This is expressed as follows,

$$\nu_R^+ = \frac{\sigma_{\dot{S}|S}}{\sigma_S}\phi\left(\frac{R-\mu_S}{\sigma_S}\right)\times \left[\phi\left(\frac{R-\mu_{\dot{S}|S}}{\sigma_{\dot{S}|S}}\right)-\frac{\dot{R}-\mu_{\dot{S}|S}}{\sigma_{\dot{S}|S}}\Phi\left(\frac{\dot{R}-\mu_{\dot{S}|S}}{\sigma_{\dot{S}|S}}\right)\right] \quad (3)$$

where ν_R^+ is the outcrossing rate of the response process $S(t)$ relative to the threshold R, $\dot{R}$ is the slope of R with respect to time, $\dot{S}(t)$ is the time derivative process of $S(t)$. $\phi()$ and $\Phi()$ are standard normal density and cumulative distribution functions, respectively. μ and σ denote the mean and standard deviation, and "|" denotes the condition. For a given Gaussian stochastic process with mean function $\mu_S(t)$ and auto-covariance function $C_{SS}(t_i, t_j)$, all variables in Equation 3 can be determined (Papoulis and Pillai, 2002).

For stationary processes with deterministic barrier, the outcrossing event is a homogeneous Poisson process with a constant rate. In non-stationary random processes, on the other hand, the outcrossing event follows the non-homogeneous Poisson process with variable rate. The expected number of failures and the expected cost of failure considering the annual discount rate in the interval [0, t] are calculated by,

$$E\left[N_F(0,t)\right] = \int_0^t \upsilon_R^+(\tau)d\tau \quad (4a)$$

$$E\left[C_F(0,t)\right] = c_f\int_0^t \upsilon_R^+(\tau)\exp(-\gamma\tau)d\tau \quad (4b)$$

where γ = the annual discount rate. Equation 3 can be used for calculating the outcrossing rates.

2.3 *Evaluation of probability of failure*

The limit state can be formulated as follows,

$$G(R,S) = R(t) - S(t) \quad (5)$$

In the first passage probability method, the outcrossing events at which $G(R, S) < 0$ follow the Poisson distribution (homogeneous or non-homogeneous) with mean rate of υ_R^+. In the time-dependent reliability, the interest lies mainly in the time expected to elapse before the first outcrossing. The probability of the first occurrence of such an excursion is the probability of structural failure $p_f(t)$ during that time period. This is known as the "first passage probability" and under the assumption of Poisson processes it can be expressed as follows [e.g., Melchers (1999)],

$$p_f(t) = p_f(0) + \left[1-p_f(0)\right]\left(1-\exp(-\int_0^t \nu_R^+(\tau)d\tau)\right) \quad (6)$$

where $p_f(0)$ is the probability of structural failure at time $t = 0$. Since it is unlikely that the structural response exceeds a critical limit at the beginning of structural service, the probability of structural failure at $t = 0$ is zero, i.e., $p_f(0) = 0$.

3 APPLICATION

3.1 *Case study*

In order to illustrate application of the proposed strengthening strategy, a reinforced concrete bridge

girder is considered. The bridge is subjected to corrosion. In the considered strengthening scheme, an FRP strip is epoxy-bonded to the soffit of a degraded RC girder to enhance its bending capacity. It has been shown that by using this strengthening scheme, the ultimate flexural strength of RC sections can be enhanced by up to 100% of its original strength with considerable improvement in mitigating flexural cracks development (Saadatmanesh and Ehsani, 1990). It is assumed that the performed maintenance action does not affect level of steel corrosion rate, i.e., the rate of deterioration before and after the strengthening action is the same. However, after FRP strengthening, in addition to reduction in the reinforcement area, deterioration of the FRP material also contributes to strength degradation. In order to consider different environmental conditions, which govern amount of damage done to the reinforcement and consequently to the overall strength of RC girder, variety of corrosion rates represented by the corrosion current density ranging from 1.0-4.0 $\mu A/cm^2$ is considered.

For the purpose of illustration, height, h, and width, b, of 1000 mm and 400 mm are assumed for the RC beam girder, respectively. The width of the external FRP sheet attached to the soffit of the girder, b_f, and number of FRP layers are treated as the optimisation variables of strengthening strategy. The thickness of one layer FRP is 1.2 mm. Reinforcing steel bars with a 25 mm diameter with reinforcement percentage of 1% are embedded into RC girders with an average cover thickness of 100 mm, as is shown in Figure 2.

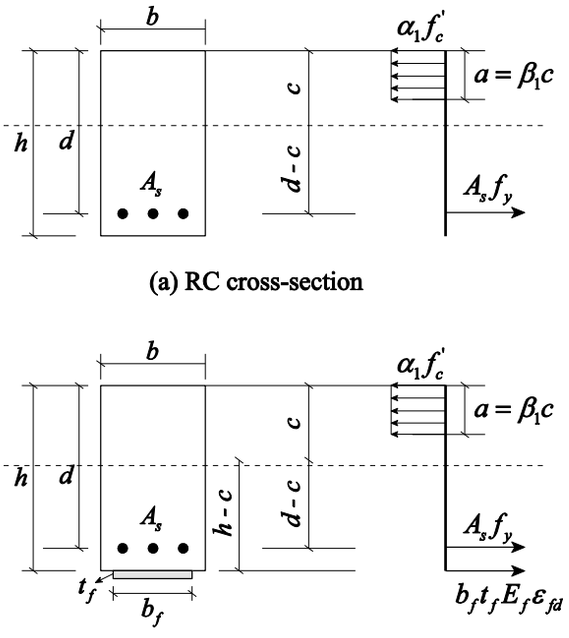

Figure 2. Geometry of RC girder cross-section

Preventive maintenance, which includes repair and strengthening in this study, is a maintenance action that only requires minimal repair as well as strengthening. It is generally known that the total cost associated with failure is greater than that associated with a preventive maintenance, i.e., the cost of maintaining a structural system before its failure is lower than the cost of maintaining it after failure (Elsayed, 2012). The failure and preventive costs of an RC structure include direct costs such as material, labour cost, and some other indirect cost, e.g., traffic delay cost in bridge structures. In this study, a sensitivity analysis by considering a range of c_f/c_r ratio is carried out. The strengthening strategy is designed for a 100 years lifetime. A discount rate, γ, of 2% is used in the optimisation.

The flexural failure of the cross-section is considered as the dominant failure mode. Therefore, the structural strength, R, is the flexural strength. Li (2003) suggested taking the limit of 70% of the original strength, i.e., $R_a = 0.70 \times R_0$ as the acceptable level of residual strength. This value is considered as a deterministic variable in this study. Therefore, the limit state used in the time-dependent reliability analysis can be formulated as follow,

$$G = 0.70R_0 - R(t) \tag{7}$$

where R_0 is the initial strength. With treatment, the residual strength, $R(t)$, is taken as the random process and the $0.70R_0$ is considered as the acceptable resistance. Formulation of the limit state in Equation 7 is similar to that shown in Equation 5. This problem mathematically represents a down crossing problem and its solution is the same as that of outcrossing, when the problem is looked at "upside-down". The acceptable probability of failure, p_a, is taken as 0.01.

3.2 *Strength degradation*

Strength of under-reinforced RC beam sections occurs due to crushing of concrete in the compressive side, i.e., when maximum compressive strain in this zone reaches the ultimate strain capacity of concrete, of the cross-section. At this state, the reinforcement has already yielded. The ultimate flexural strength of the cross-section, used as R in the limit state, can be evaluated as follows,

$$M_{u,RC} = A_s f_y \left(d - \frac{a_{RC}}{2} \right) \tag{8a}$$

$$a_{RC} = \frac{A_s f_y}{\alpha_1 \beta_1 f_c' b} \tag{8b}$$

where α_1 and β_1 = the equivalent rectangular stress block parameters, b = cross-section width, A_s = reinforcement area, f'_c = compressive strength of concrete and f_y = yield strength of reinforcing steel.

On the other hand, failure of an FRP-strengthened RC cross section is most likely to occur either by crushing of the concrete in the compression zone or by debonding of the FRP sheet from the RC girder. There are other possible failure modes such as concrete cover separation and plate end interfacial debonding (Ceci et al., 2012). However, here, it is assumed that the FRP reinforcement is anchored at its ends so that such failures do not occur. Debonding dominates when the strain at the interface of concrete and FRP reaches a limiting value, ε_{fd}, which is generally less than the ultimate strain in an FRP coupon determined from a direct tension test, ε_{fu}. The model chosen for this study is based on a fracture mechanics approach, which is adopted by the ACI 440.2 (2008) guidelines. In this model, the tensile strain at which debonding initiates can be calculated as,

$$\varepsilon_{fd} = 0.41\sqrt{\frac{f_c^{'}}{E_f t_f}} \le 0.90\varepsilon_{fu} \quad (9)$$

where E_f and t_f are the young's modulus and thickness of the FRP sheet and f'_c is the compressive strength of concrete. The ultimate flexural strength of RC cross-section strengthened with FRP sheet with width of b_f and thickness of t_f can be determined as follow,

$$M_{u,FRP} = A_s f_y\left(d - \frac{a_{FRP}}{2}\right) + b_f t_f E_f \varepsilon_{fd}\left(h - \frac{a_{FRP}}{2}\right) \quad (10a)$$

$$a_{FRP} = \frac{A_s f_y + b_f t_f E_f \varepsilon_{fd}}{\alpha_1 \beta_1 f_c^{'} b} \quad (10b)$$

Due to the corrosion process, the rebar area and consequently, the structural strength decrease over time. Because of material degradation, reinforcement area and mechanical properties of the FRP material deteriorate over time. Using material degradation models for physical corrosion and FRP properties available in the literature, the residual cross-sectional strength can be determined by employing standard concrete design codes [e.g., ACI 318 (2014)]. The remaining reinforcement area, A_{net}, can be calculated as follows,

$$A_{net}(t) = \left(1 - \frac{0.0232 i_{corr} t}{d_b}\right)^2 A_s \quad (11)$$

where d_b and A_s are the diameter and cross-sectional area of the original rebar. i_{corr} is the corrosion current density and t is time since corrosion initiation in years. Degradation model for mechanical properties of FRP material is taken from Karbhari and Abanilla (2007) study and can be expressed as follows,

$$\sigma_{fu,net}(t) = \left[1 - 0.0337\ln(365t)\right]\sigma_{fu} \quad (12a)$$

$$E_{f,net}(t) = \left[1 - 0.0042\ln(365t)\right]E_f \quad (12b)$$

where σ_{fu} and E_f are the original ultimate strength and modulus of elasticity of the FRP sheet and $\sigma_{fu,net}$ and $E_{f,net}$ are the remaining ultimate strength and modulus of elasticity.

Table 1 shows the probabilistic models for basic random variables used for finding statistics of the residual strength over time. The probabilistic models for section dimensions are from Nowak & Szerszen (2003) study. The probabilistic model for concrete compressive strength is based on Bartlett and MacGregor (1996) study. For yield strength of reinforcement, the model proposed by Bournoville et al. (2004) is used. For FRP mechanical properties, models from Atadero & Karbhari (2008) are used. In this table, δ shows the model error in evaluating the flexural strength of RC girder. The probabilistic model is taken from Baji et al. (2016) study. It is assumed that the model error for RC and FRP-strengthened cross-section is the same.

Table 1. Probabilistic models of basic variables

Variable	Nominal	Bias*	COV**	Distribution
b mm	400	1.00	0.02	Normal
d mm	900	1.00	0.04	Normal
f'_c MPa	32	1.20	0.18	Lognormal
A_s	$0.01bd$	1.00	0.02	Normal
f_y MPa	518	1.12	0.05	Beta
t_f mm	1.20	1.00	0.05	Lognormal
σ_{fu} MPa	887	1.17	0.15	Weibull
E_f GPa	64.9	1.00	0.20	Lognormal
δ	1.00	1.00	0.12	Lognormal
i_{corr}, $\mu A/cm^2$	1.0-4.0	0.50	0.58	Uniform

* Bias = Mean/Nominal

** COC = Coefficient of Variation

Using the Monte Carlo simulation technique, with 50,000 runs, statistics of the strength process, i.e., mean and standard deviation, are determined.

3.3 *Results*

If the remaining lifetime is longer than the specified service lifetime of the structure, no strengthening is required. Otherwise, strengthening is required. Based on the assumptions made for the considered case study, remaining lifetime of the RC girder considering the ultimate limit state shown in Equation 7 can be predicted.

Figure 3 shows the probability of failure over time considering different corrosion rates. The predicted lifetime is based on the acceptable

probability of 0.01. Considering the specified lifetime of 100 years, for all the assumed corrosion rates except the low corrosion rate (i_{corr} = 1.0 μA/cm^2) the remaining lifetime of the considered RC girder is less than the specified 100-year service life. Therefore, strengthening action within service life of the structure is not required.

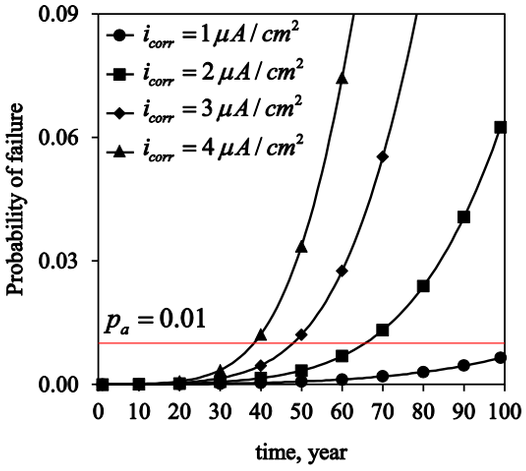

Figure 3. Probability of failure for different corrosion rates

In order to find the solution to the formulated optimized strengthening strategy, a generic computer code was programmed. The Genetic Algorithm method was used to minimize the cost function defined in Equations 1a, b. For the considered case study with i_{corr} = 2 μA/cm^2, c_f/c_r = 100 and γ = 0.02 the result of optimization is shown. Any strengthening action within this feasible time satisfies the two constrains shown in Equation 1b. As Figure 4(a) shows, after around 58 years, residual strength of the considered RC girder decreases to an unaccepted level, i.e., the probability of failure becomes less than the acceptable probability of failure, p_a, [see Fig. 4(b)]. By applying one layer of FRP with 135 mm width, the strength is restored [see Figure 4(a)]. The optimum time corresponds to minimum expected cost during the whole life of structure as is shown in Figure 4(c). Figure 4(b) shows that in the whole service life of the structure, probability of structural failure does not exceed the assumed acceptable level (0.01 in this example).

For higher deterioration rates, i.e., higher corrosion rates, in order to keep the structure in the safe region, more FRP layers are required. To investigate the effect of the corrosion rate represented as the corrosion current density i_{corr} on optimum strengthening time and number of required FRP layers, various values of the corrosion current density ranging from 2.0 to 4.0 μA/cm^2 corresponding to low-to-high corrosion intensities are examined. The result is shown in Figure 5. As is expected, for high corrosion rates, earlier strengthening action with higher number of FRP layers is required. Furthermore, with increasing the corrosion rate, the expected number of failures increases and, as such, the total expected cost goes up. Nonetheless, the optimum cost is in the same range, as for higher corrosion rates more FRP material is used.

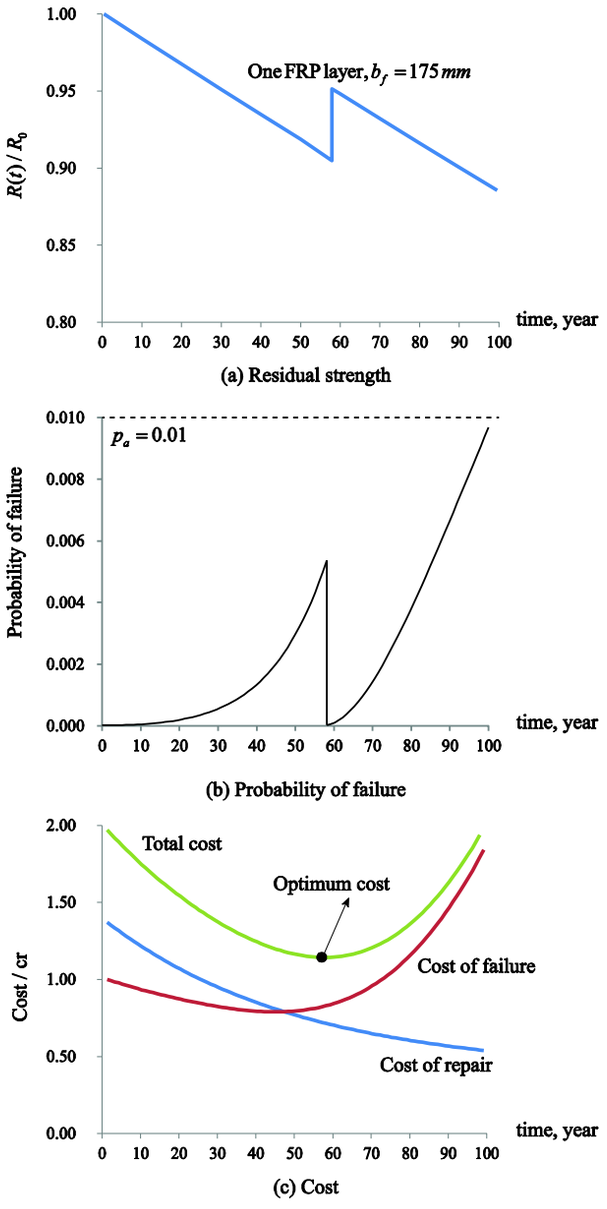

Figure 4. Optimum strengthening strategy for i_{corr} = 2 μA/cm^2

Figure 6 shows the influence of the unit cost of failure c_f on the optimal strengthening time, where the cost of failure ranges from $c_f = 50c_r$ to $200c_r$. In this case, the corrosion current density is 2 μA/cm^2 and the discount rate is assumed 2% in the calculations. It can be seen that the value of the optimal strengthening time decreases when the cost of failure goes up. In the case with a lower cost of failure, the optimal strengthening time can be delayed, and lower total cost is expected. Furthermore, for higher cost of failure more FRP material is required.

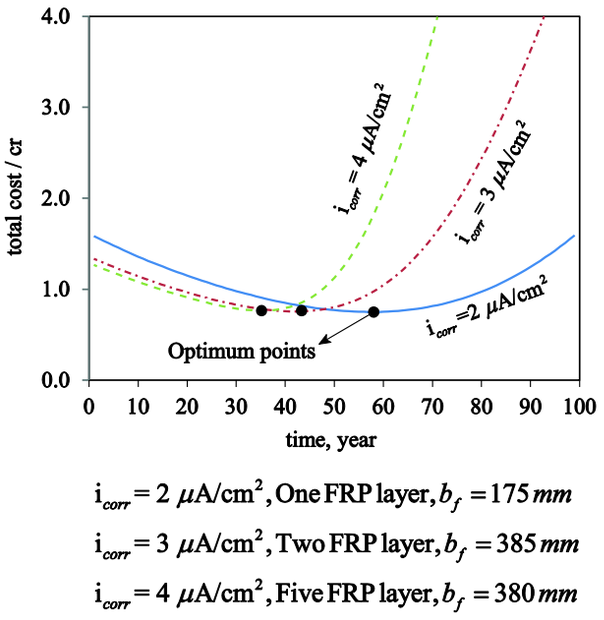

Figure 5. Effect of different corrosion rates

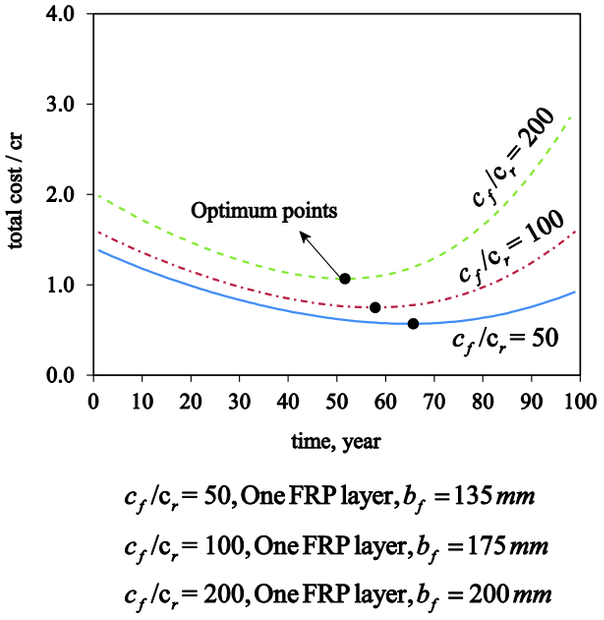

Figure 6. Effect of different costs of failure

In order to make an informative decision on strengthening of an RC structure with FRP composites, wide range of environmental and economic factors need to be considered. Outcome of the strengthening strategy should cover all the possible scenarios. Using results of the strengthening action and based on the available information at any time, decision makers can decide on the right strengthening strategy.

4 CONCLUSION

In this paper, a methodology for optimal strengthening strategy for RC bridges has been proposed. With this strategy, the optimum time for strengthening and required amount of strengthening in terms of number and width of FRP sheets can be optimized based on minimization of total expected cost. The developed strategy incorporates time-dependent reliability analysis in which the structural deterioration is modelled as a stochastic process and the probability of structural failure is calculated with advanced outcrossing method. An example of a corrosion-affected RC bridge girder strengthened with FRP composites is provided to illustrate the application of the developed strategy. It has been found in the paper that the proposed methodology can determine the optimum strengthening time and amount of FRP strengthening, i.e., number and width of required FRP layers efficiently. It has also been found that the deterioration rate represented by the corrosion current density and the cost of failure are the key factors in determining the number of required FRP layers. It can be concluded that the developed strategy can equip structural engineers and asset managers with a useful tool for effective strengthening of deteriorated structures in the management of vast asset of deteriorating bridges.

Strengthening of Reinforced Concrete Bridges by External Prestressing

L. H. B. Pinheiro, L. M. Trautwein & L. C. Almeida
University of Campinas - UNICAMP, FEC - SP, Brazil

ABSTRACT: The lack of maintenance along with the increase of the weight of (Brazilian) road vehicles require the strengthening of bridges in Brazil. Rehabilitation techniques and structural reinforcement can make this strengthening technically and financially viable. However, since there are no specific rules on how to carry out this type of analysis in Brazilian bridges, or procedures for the calculation of specific reinforcements, several methods are not considered while choosing the type of structural reinforcement, and neither the right efforts are taken for a proper assessment. This work studies the flexural reinforcement of structures in reinforced concrete by external prestressing, exposing advantages and disadvantages of its use and the characteristics of this reinforcement method. Finally, a calculation methodology is proposed employing a theoretical example of structural reinforcement of an old Brazilian bridge by external prestressing with the use of lubricated steel wire ropes, reinforced concrete deviators and anchor blocks. In order to base the calculation the rules of the bridge project were used to find the project efforts and the existing steel area. Based on the current standards and the bridge expansion project, new efforts were determined on the main beams. Considering these new efforts and the existing steel area, the necessary prestressing steel area was determined so that along with the existing passive steel rebars the bridge can withstands the new traffic conditions

1 INTRODUCTION

Due to market demands, freight vehicles often carry a very heavy weight, previously considered as rare or impossible for a single truck. The bridges over which these vehicles travel may be exposed to strains higher than those assumed in the original project, calculated in line with the standards of the period when the construction took place.

Old bridges were submitted to different types of forces and exposed to bad weather conditions which along with the lack of maintenance leads to the development of defects, which can corrode the reinforcement, wear out the concrete and cause various anomalies, reducing the strength of the bridge as well as its expected utility.

The greater amount of cars on the highways demand the expansion of the roads and also the bridges that are part of these roads.

The expansion of freight vehicles, the increase in weight of freight vehicles and the reduction of the original strength of the bridges, requires the reinforcement of their structure in order to increase their capacity to resist tensions and to safely support new working conditions.

Out of the various existing techniques of structural reinforcement, the prestressing of the main beams by external cables anchored to them can function as a competitive alternative taking account the implantation of the bridge in traffic, material savings and efficiency in increasing resistance.

2 OBJECTIVES

The objective of this work is to exemplify a methodology for the analysis of the structural reinforcement by external prestressing of a theoretical Brazilian bridge, calculated with old norms and assuming that there will be a need of amplification, besides the adequacy of the resistance for the design loads suggested in the current norms.

3 ADVANTAGES AND DISADVANTAGES

A single external cable system can be used to reinforce multiple stresses simultaneously, such as positive and negative bending moments and shear stresses, due to cable tilt and compression effect. Other advantages can be cited:

- Less amount of concrete used, since it eliminates the need to thicken the entire element;
- Reduction of formwork and shoring;
- Low weight added to existing structure;
- Less frictional prestress losses due to the use of lubricated steel wire ropes;
- Easy determination of the eccentricity between applied forces and the center of gravity, since the fixing of deviator and anchor blocks are at determined heights;
- The main beams can be reinforced with the bridge in traffic;
- It is not necessary to correct deformations before structural reinforcement;
- Possibility of maintenance and exchange of lubricated wire ropes;

• Better distribution of bending moments and shearing forces along the hyperstatic beams (SOUZA & RIPPER 1998);
• Decrease of deformations;
• In a bridge widening, this reinforcement may exempt the need for additional beams;
• Prestressing equipment are lightweight, making it easier to use at heights. (ALMEIDA 2001);

Even with so many advantageous features, some aspects must be observed when considering this type of structural reinforcement. Among them, we can highlight:
• Unconventional equipment and techniques, require specialized labor;
• Requires high corrosion protection especially on anchorages and deviators;
• The reinforcement is externally exposed, allowing impacts or fire action;
• Failure at one point ends up disabling the entire reinforcement cable;
• The difficulty in the execution of reinforced concrete anchor and deviator blocks, as well as drilling the existing beams might make this type of reinforcement unfeasible;
• The weight of the deviator and anchor blocks in concrete should be considered in the structural calculation;
• There may be a relevant second-order effect due to the eccentricity between the structural displacements and the non-adherent prestressing cable;
• The introduction of the prestressing force can be damaging to the low compressive strength concrete, especially at points of stress concentration (deflectors and anchorage);
• We need to calculate the hyperestatic prestressing efforts;

4 MAIN COMPONENTS OF THE SYSTEM

This technique consists of anchoring cables externally to the structure at its ends and then prestressing them, and there may be deviations in its trajectory by deviator blocks. The rectilinear cable with deviations is called polygonal, widely used for external prestressing, where the cables are free from contact with the structure, except for the anchorage and deviator regions, where they introduce forces of opposite direction to the requests, as shown in Figure 1.

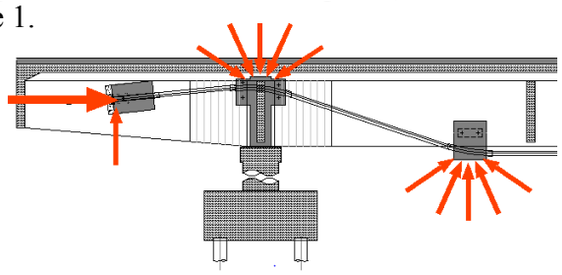

Figure 1. Forces from the external prestressing

Firstly, the elements for anchoring and diverting cables are installed. These anchors and deflectors may be metallic, as in Figure 2 or in reinforced concrete as shown in Figure 3, but cross girders and other elements of the structure can be used for this purpose.

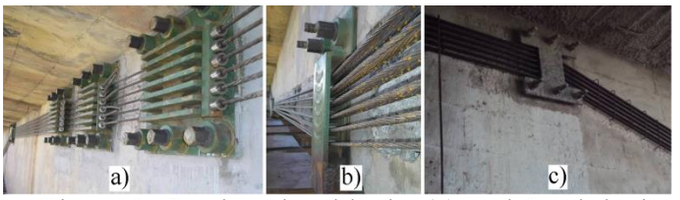

Figure 2. Steel anchor blocks (a) and Steel deviator blocks (b), (c).

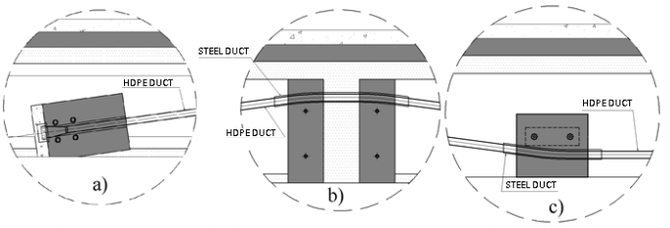

Figure 3. Reinforced concrete anchor blocks (a) and deviator blocks (b), (c).

Non-adherent prestressing cables consist of lubricated wire ropes coated by high-density polyethylene (HDPE). To increase the tensile strength, several of these may be joined within a duct, such as that of Figure 4, which is filled internally with epoxy resin or cement paste.

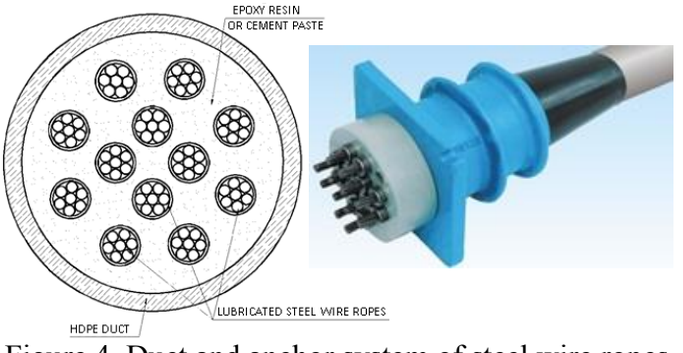

Figure 4. Duct and anchor system of steel wire ropes

This system, which is widely used in reinforcements by external prestressing, has several advantages such as protection against ultraviolet rays due to HDPE, against corrosion due to grease, possibility of replacing, controlling and maintaining internal cables during the life of the bridge.

5 THEORETICAL EXAMPLE

In order to exemplify this technique of flexural reinforcement of main beams, we will analyze a typical situation in which a bridge built in the late 1970s must be expanded, but we do not have its original design. After an inspection of the bridge we obtain the mechanical characteristics of the existing concrete as well as the geometry of the bridge.

Structural analysis is done with this information, based on the norms valid in design period, by calculating the forces for which the bridge was originally projected, then the reinforcement is calculated, ensuring that it withstands the forces of the enlarged bridge, which will be verified by the current norms.

5.1 *Bridge characteristics*

The fictitious bridge analyzed has span of 20 m, and longitudinal beams supported on the mesostructure. It is a typical structural system of this period (DNIT 2004) in two reinforced concrete girders and 5 cross girders.

The total width of the cross section is 10 m, 830 cm of traffic lanes. There is no protection between the lane and the sidewalks, only guardrails protect bridge cross section ends.

This bridge was designed to withstand the 360 kN of a vehicle with load, in line with the old NB-6 1960.

Figures 5 and 6 show the design of the original bridge.

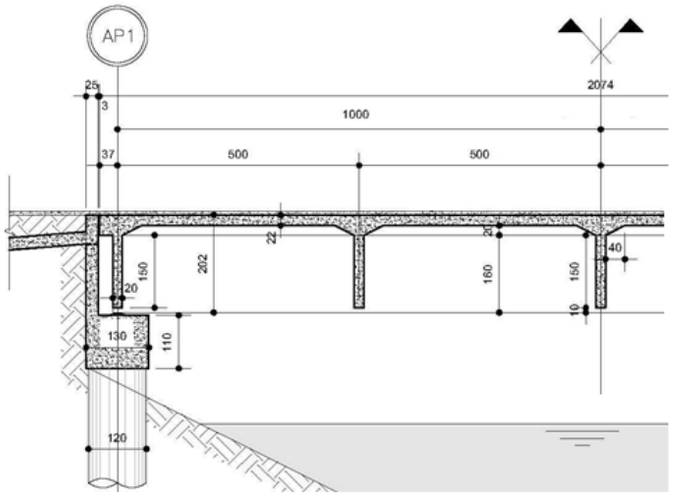

Figure 5. Longitudinal half elevation (dimensions in cm)

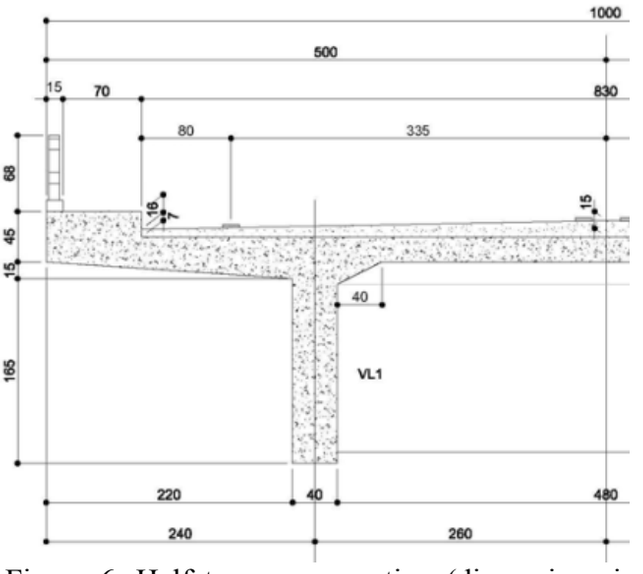

Figure 6. Half transverse section (dimensions in cm)

The enlarged bridge will have the characteristics of Figure 7, with 11,30 m of total width, being 10,50 m of traffic lane and must withstand the 450 kN of vehicle with load (NBR 7188, 2013).

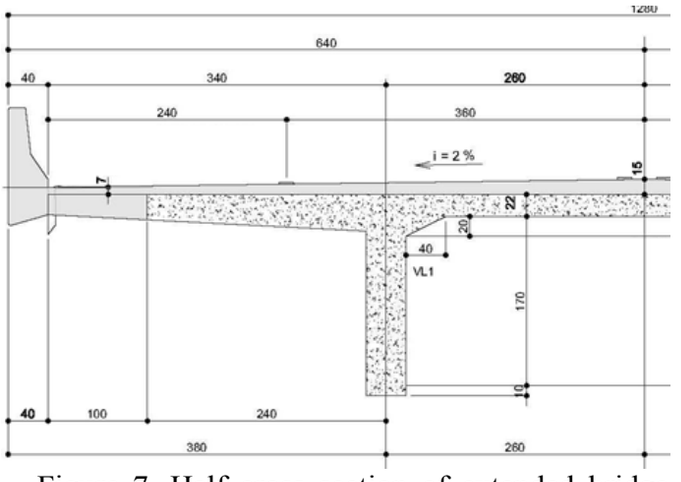

Figure 7. Half cross section of extended bridge (dimensions in cm)

5.2 *Structural analysis of the old bridge*

The original dead loads were determined by the geometry of the elements detailed by the bridge inspection, resulting in the forces of Figure 8

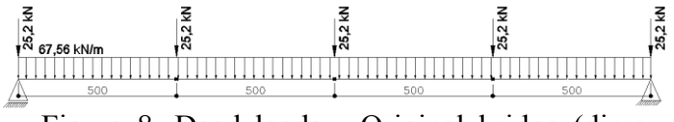

Figure 8. Dead loads - Original bridge (dimensions in cm)

For the vehicular live loads of the project, we used the old standard of bridges and road loads, NB-2 of 1961 and NB-6 of 1960, which considers the standard vehicle of 360 kN weight.

This vehicle and the distributed load is placed on the most unfavorable position for each girder, that results in the static load scheme of Figure 9 for the most requested beam (calculated by influence line on cross section).

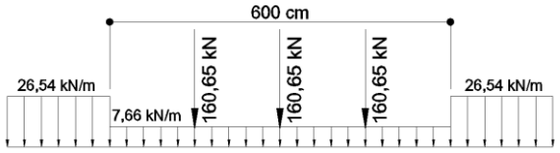

Figure 9. Vehicle live loads - Original bridge.

The previous loads resulted in the following bending moments, shown in Table 1:

Table 1. Project bending moments of the original bridge (M_0, units in kN.m).

Efforts	Partial values (S_k)	Final value (S_d)
M_{0G} (dead load)	3630,0	9262,4
M_{0Q} (vehicle live load)	2986,0	

With the values of Table 1, and characteristics of the existing bridge, according to the Brazilian concrete standard of the design period, NB-1 1978, the existing reinforcement was determined, resulting in 118 cm² AC- 50 steel.

5.3 *Structural analysis of the enlarged bridge*

For the new conditions of the bridge, extended and longer runway length, considerable efforts are expected to increase in the main beams.

Considering the external reinforcement solution with anchor and deviator blocks in reinforced concrete, these elements were arranged according to Figure 10 and their weights considered in the dead loads with the weight of the other elements, according to Figure 11.

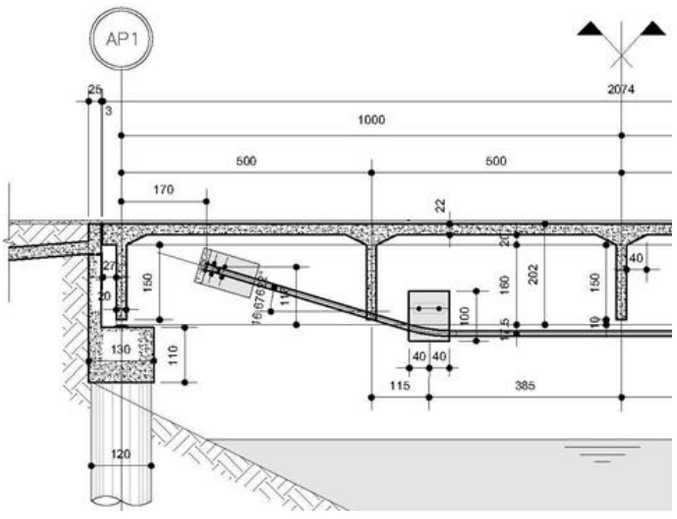

Figure 10. Prestressing system on longitudinal half elevation (dimensions in cm)

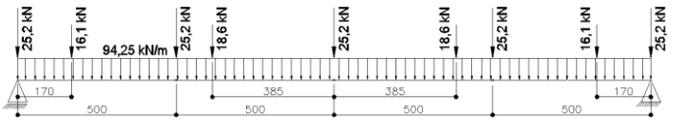

Figure 11. Dead loads - Enlarged bridge (dimensions in cm).

The corresponding Brazilian standard, NBR 7188 of 2013, was used to determine the final vehicle live loads, shown in Figure 12, for each main beam.

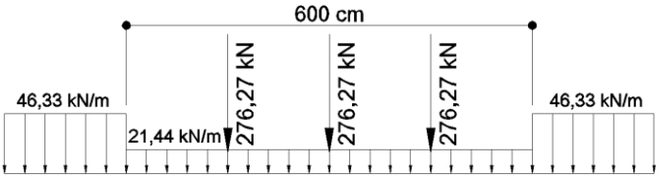

Figure 12. Vehicle live loads - Enlarged bridge.

For the calculation of the efforts, Brazilian multiplier coefficients were used, 1,35 for dead loads and 1,5 for live loads, resulting in the values shown in Table 2.

Table 2. Enlarged bridge bending moments (M_F, units in kN.m).

Efforts	Partial values (S_k)	Final value (S_d)
M_{FG} (dead load)	5106,25	14953,79
M_{FQ} (vehicle live load)	5373,5	

5.4 *Comparison of forces*

Table 3 shows an increase of about 60% of the efforts, an increase that must be resisted by the external prestressing system.

Table 3. Comparison of bending moments (M, units in kN.m).

Forces	S_k	S_d	ΔS_d
M_{0G}	3630,00	9262,40	5691,39 (61,4%)
M_{0Q}	2986,00		
M_{FG}	5106,25	14953,79	
M_{FQ}	5373,50		

5.5 *Reinforcement calculation*

As a result of updating of standards, some parameters taken into account changed, such as the resistant section considered, which was changed in relation to the flanges.

A steel pretension area is adopted to withstand increased stress. This steel is pulled to its limit (determined by the Brazilian standard of reinforced concrete), anchored eccentrically and with inclined geometry, that generates concentrated efforts at the points of deviation and anchorage.

In this case, the prestress steel area was determined to withstand the total value of the bending

moment request. From this total steel area, the existing steel portion was subtracted and this value was adjusted for commercial steel areas, resulting in two cables by girder, with 7 steel wire ropes of 12,7 mm of CP-190 RB steel (steel effective area = 13,82 cm²).

The concentrated forces, conferred by this initially adopted reinforcement, are represented in Figure 12.

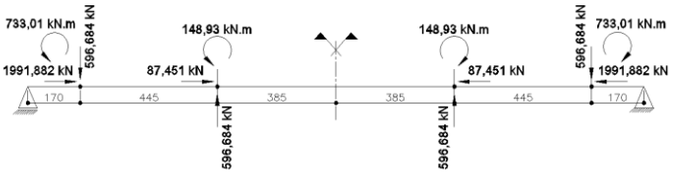

Figure 12. Equivalent loads by external prestressing

The forces explained in the previous figure generate bending moments of opposite direction to the vehicles live and dead loads, according to Figure 13.

Figure 13. Bending moments diagram from external prestressing.

The combination of these forces with those of the dead loads and the vehicle live loads constitute the new requesting effort. This value may be smaller than the initially acting force, because it also contains the inverse force, applied by the reinforcement.

The values of requesting moments are:

$M_{Dead\ loads} = 5106{,}25\ kN.m$;

$M_{Vehicle\ live\ loads} = 5373{,}5\ kN.m$;

$M_{External\ Prestressing} = -3537{,}18\ kN.m$;

Applying the Brazilian standards coefficients to these values, the final actuating bending moment value (M_{df}) is determined, resulting in:

$M_{df} = 11770{,}23\ kN.m$.

For the resistant section considered, with the existing passive steel area and active steel area calculated, the bending moment resistant M_{rd} = 13616 kN.m. This value is greater than the final acting bending moment M_{df}.

Once this condition is confirmed, the armature previously adopted is sufficient to withstand the increase of bending moments, being this armature constituted of two cables by girder, with 7 steel wire ropes of 12,7 mm of CP-190 RB steel.

If M_{rd} were smaller than M_{df}, it would be necessary to consider another larger area of prestressing steel, to recalculate the applied concentrated forces (equivalent loads), to recalculate the forces generated by it, determining the new bending moment, then calculating the resistant bending moment M_{rd} of the section with the new steel area until the condition $M_{rd} > M_{df}$ is satisfied.

6 CONCLUSION

For this theoretical case, the existing bridge with two cables by girder, with 7 steel wire ropes of 12,7 mm of CP-190 RB steel (steel effective area = 13,82 cm²) are sufficient to absorb the 61.4% increase of bending moments.

This reinforcement can be done without interrupting traffic on the bridge, probably with less inconvenience than a conventional situation of reinforcement by enveloping or by adding metal plates.

Inhibiting corrosion of prestressed cables using an ultrasonic impregnation process

X. Hallopeau
Freyssinet International & Cie, Rueil-Malmaison, France

P. M. Dubois & D. Michaux
PMD-ATEAV Systems sprl, Ophain, Belgium

ABSTRACT: The civil engineering process stabilizes in the long term the corrosion of prestressed concrete cables. The process principal idea is to saturate the protective grout of the cables - irrespective of the cables condition - with an inhibiting solution conveyed by a vibrating ultrasonic power pump. The process is slightly intrusive. A map of the injection faults within the existing cement grout can be established. Additional cement grout can be injected where needed. The process was applied to a viaduct for the first time in 1994. The effectiveness of the treatment was assessed in 2012 when the entire viaduct was demolished. The process is regarded as a long-lasting and durable treatment.

1 INTRODUCTION

Often older types of construction were built with bonded prestressed cables. When cables become corroded, the treatment can be challenging in different ways. The cables are embedded within the inner concrete structure of the beam. They are barely accessible. Since they are threaded within a metallic sheath, no electrochemical protective process can be applied. Therefore, the authors imagined how to gain access another way. First an appropriate corrosion inhibitor saturates the existing protective cement grout, then additional cement grout is further injected where injection faults are discovered.
The rehabilitation process of prestressed cables was devised and applied in 1994 as a test case to a span of a five girder of the Lultzhausen viaduct, in the Grand Duchy of Luxembourg, close to the high head dam of Esch-sur-Sûre and crossing the lake of La Haute-Sûre. The bridge was constructed in 1960, each beam was prestressed by 11 cables (each with 12 wires of 7 mm diameter). Exposure to moisture was minimal (precipitation during 120 days) and the number of ice days are around 20 days between 1961 and 1990. The Belgian Scientific Center for Construction Engineering (Belgian Building Research Institute – BBRI) validated the process between 2000 and 2008. Many bridges have been treated since 1994: Rail bridge Duferco 1999 (Belgium), Huccorgne Viaduct 2004 (Belgium), Courrier Viaduct Highway E411 2008 (Belgium), Colmar-Berg Bridge 2008 (Grand Duchy of Luxembourg), Courcelles Viaduct on the Wallonia highway 2011 (Belgium), Bridges 118 and 211 on the Highway A7 close to Lyon 2014-2016 (France). A detailed communication was published in SETRA paper #59 of November 2008. Several communications were presented at the Structural Faults and Repair Congress in Edinburgh in June 2008, at the "Le Pont" Symposium in Toulouse in 2005 and 2008. Some results were also presented on the Huccorgne Viaduct build in 1968, cable type 12 wires of 7 mm diameter, subjected to de-icing salt, and treated in 2004. Some wires treated and non-treated were autopsied in 2014.

2 METHODOLOGY

2.1 *Principle*

The unique idea of the process is to take advantage of the energetic properties of ultrasonic waves in order to impregnate the existing cables and to permeate the surroundings with the inhibiting solution. The effect of ultrasound on the inhibiting solution is to build up a cavitational condition in vapour phase. The energy released by the cavitation effectively clears the pores in the grout at the site of the prestressed cable interface and the inhibiting solution has direct access to the prestressed steel to be protected. The open path is the same path that the corrosive agents (water, oxygen, chlorides) have used over the decades of the lifecycle of the structure. The main difference is that ultrasound makes it possible to cover the paths in a few hours. The cavitational condition in the vapour phase is generated by an al-

ternating ultrasonic power pump. It expands and contracts generating alternating overpressures and underpressures at an ultrasonic frequency of approximately 23000 Hz (Figure 1). Consequently, the impregnation of the cable surroundings by the inhibiting solution occurs under low pressure.

Figure 1. Impregnation of the inhibiting solution using the ultrasonic transducer after boring and installing the injection nozzles.

The selected inhibiting solution is a calcium nitrite solution whose effectiveness - with or without chlorides present - is proven by several studies and practical findings over thirty years, Schiebl et al. 2000. Calcium nitrite transforms permeable ferrous oxide into impermeable ferric oxide which restores the natural passivation coating of the steel embedded in sound concrete, causing no secondary effect to the steel behaviour. The calcium nitrite concentration was defined in excess to chloride content in a ratio of $[Cl^-]/[NO_2^-]$ equal to 0,7, Elsener et al. 2003.

2.2 *Experimental procedure*

The treatment consists of three stages:

- Stage #1: Installing the injectors
- Stage #2: Impregnating the corrosion inhibitor
- Stage #3: Filling the grout faults

During the treatment the progress of the inhibitor from one hole to the next is timed. A mapping of the migration timings is obtained revealing details about the quality of the grout filling or packing. The following mapping (Figure 2) provides the migration time of the inhibitor versus location of injection point with color code, for instance in yellow the migration time between 2 points of injection is around 15 min to 30 min indicating relative bad grout filling quality, and in black superior to 120 min indicating a compact grout.
This mapping quantifies and localises how serious the injection faults are visualized in Figure 3 for a Type 12 cable of 7 mm diameter.

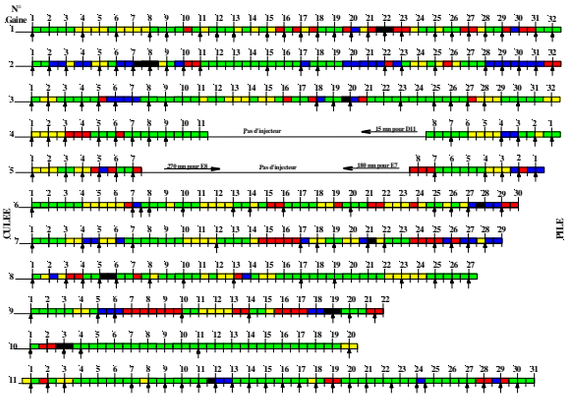

Figure 2. Mapping the migration times of the inhibiting solution. The arrows mark the injection points (11 treated cables in 1 beam).

Figure 3. Illustrates the injection faults (Cable type 12, diameter 7 mm).

After the injection of the inhibiting solution has been completed and based upon the mapping obtained earlier, the nozzles are reused to inject a very fluid Portland cement-based microgrout, In the case of a complete empty gap of long range within the injection site, grout is injected.

2.3 *Re*sults

2.3.1 *Case Lultzhausen viaduct*

The last and rare opportunity to validate the process occurred when the Lultzhausen viaduct was replaced, a decision made because of concerns about the stability of several beams in spans left untreated in 1994. The viaduct deck was demolished and replaced with a new deck in 2012. The span treated in 1994, Figures 4, merited a special soft demolishing procedure as illustrated in Figures 5.
Scaffolding supported the span which was then cut into sections. The cutting of the sections was visually inspected in detail. One section was selected to undergo tests in the lab. The test was completed in 2012. The findings of the analysis are commented on below.
Investigations performed in 1990 revealed that many cracks were present along the prestressed cable pathways with water leaks and lime deposit emanations.
Many cables were poorly or not injected, showing some advanced corroded condition, but still unbroken with no reduction in bearing capacity.

Figure 4. Locating the 1994 treated span of the Lultzhausen viaduct

Figure 5. Saw cutting demolition and test element.

Selection of the preserved beam section for analysis was conducted in order to keep sufficient longitudinal length of the treated prestressed cables as well as transverse prestressed cables left untreated in 1994. The beam of a little more than 30 m in length was sawn in approximately ten sections of more or less 3 m length, all inspected.

A test program on one representative cut, including six treated core samples (Figure 6) and two non-treated core samples, had been entrusted to the Laboratory of Construction Materials of the University of Liège, Belgium 2012. The test program included the following investigations:

- Macroscopic description
- Chloride content per cement weight by potentiometric titration
- SEM observation on polished section
- Semi-quantitative analysis of nitrite content by colorimetric method
- Cement content analysis
- XRD mineralogical identification

Figure 6. Core localization

The visual examination of the sawed cuttings indicates that the microgrout reinjection is in excellent condition (Figure 7). The interface front between the older grout (dark) and the reinjected grout (white) is clearly marked in the last picture.

Figure 7. Visual examination of the cuttings

The retreat of the threads, after the cutting, was almost the same for every cable. This finding confirms the excellent quality of the microgrout reinjection process. It was feared that the action of the nitrites might alter the adherence of the prestressed steel and older/newer grout interface. No such problem occurred and the ULS (Ultimate Limit State) was not modified. Therefore, we can conclude that the waterproof barrier between the prestressed steel and the outside environment was restored along the full cable length and that the input of newer corrosive agents was prevented (water, oxygen, chlorides). The chloride content measurements match to approximately 0.01 % chlorides with respect to the grout mass. Therefore, no significant pollution due to chloride had occurred. Those measurements are coherent with the fact that the work is in a protected area where in principle no salt is spread in winter.
Determining the nitrite content using the colorimetric method with test strips to the treated cables of the longitudinal prestressed and to the untreated cables of the transverse prestressed, shows beyond doubt that the process is effective and long-lasting (Figure 8). The visual examination showed that no further corrosion of the prestressed cables had resumed.
Even though the testing was not quantitative, it can be seen that after approximately 20 years, a significant amount of nitrites are still available in case new aggressive agents appear. The long-lasting effect of the treatment is thus practically unlimited.

2.3.2 *Case Huccorgne viaduct*

Most of the time the corrosion of prestressed cables is initiated by pollution involving chlorides.
In the presence of chlorides, the corrosion velocity and severity level becomes considerably worse even if the pH in the cables environment stays around 11 or 12. In principle a pH of 11 or 12 inhibits corrosion when no chlorides are present. A distinctive characteristic of the nitrites is to enable a corrosion inhibiting effect most notably effective when chlorides are present, provided that the quantity of nitrites is sufficiently available. The application of this process ensures this important point because the process soaks and saturates the environment surrounding the prestressed cables. It should be noted that the use of nitrites in concrete was developed back in the 1970s as inhibiting agents in marine environments.

Figure 8. Treated (left) and untreated (right) prestressed cables

A convincing example to mention is the test application in 2004 to the Huccorgne viaduct on the Wallonia highway in Belgium, applied to particularly damaged prestressed beams. Ten years later, 2014 inspection, the repaired area that may possibly show exemplary evidence of cracks does not present any cracking nor any sign that corrosion had resumed (Figures 9, 10 and 11). A detailed intrusive test assessment on autopsied wires confirms these findings: chemical analysis and SEM observations performed by the Laboratory of Construction Materials of the University of Liège in Belgium showed that the treated wire presented on its surface a thin layer of 20 microns of hydrated calcium aluminosilicate and iron, while the non-treated wire a 150 microns layer of iron oxide Fe_2O_3 and FeO(OH), and ferrous hydroxide $Fe(OH)_2$ demonstrated active corrosion.

Figure 9. Rehabilitation of the Huccorgne viaduct

Figure 10: Cable treated

Figure11: Cable non treated

3 CONCLUSION

The results demonstrate that the effectiveness and long-lasting effect of the process to stabilize the corrosion of the prestressed cables seems to be widely confirmed as a benefit from approximately 20 years experience even if only two treated works have so far been destructively investigated. The other works were inspected annually and no degradation were observed on treated beams. Therefore, we can regard this as a reliable process that takes its place beside other high technology processes like the cathodic protection of reinforced concrete and other electrochemical processes. It is important to note that the process does not require any maintenance phase and that it can be renewed or further completed if needed.

It is important to further highlight how the application process bears little impact to highway traffic since it is usually implemented from the inner side of the bridge structure. The process comes within the scope of durable development since it significantly extends the life of prestressed civil engineering structures endangered by corrosion.

ABSTRACT: Since structural performance of corroded RC members primarily depends on localized corrosion damages on their reinforcements, modelling the spatial steel corrosion is important for the long-term performance assessment of RC structures. To achieve this purpose, there is a need to study the time-variant spatial distribution of steel corrosion. The impressed current technique by means of applying current density has been widely used to investigate the effect of steel corrosion on the structural capacity deterioration. It was reported that current density has great influence on the propagation of average crack width, steel corrosion, and structural behavior of RC members. However, the study of the effect of current density on the spatial variability of corrosion and cracking is scarce. Therefore, the main objective of this paper is to study, using X-ray and digital image processing techniques, the effects of current density on the spatial steel corrosion and corrosion cracking of corroded RC beams.

1 INTRODUCTION

Chloride-induced corrosion is a dominant deteriorating mechanism of RC structures in marine environments. The distribution of corrosion on the steel reinforcements in RC structures due to chloride attack is not uniform; it varies along the length of structures due to several factors such as variability of steel and concrete properties, environmental exposure, and workmanship (Akiyama et al. 2016, Palsson et al. 2002). Since the structural performance of corroded RC members primarily depends on localized reinforcement corrosion, modelling the spatial variability associated with steel corrosion is important for their long-term structural performance assessment.

In order to model the spatial steel corrosion, it is necessary to study how the steel corrosion increases and changes at different corrosion stages (Kashina et al. 2013a,b, Alonso et al. 1998, Vidal et al., Zhang et al. 2014). Such a study requires a continuous monitoring method by a non-destructive method (e.g., Akiyama et al. 2013, Lim et al. 2016, and Lim et al. 2017). In previous studies, without considering the effect of applied current density, Lim et al. (2016, 2017) used X-ray and digital image processing techniques to investigate the effects of water-to-cement ratios and amount of stirrup reinforcement on the spatial variability of steel corrosion and structural performance of accelerated-corrosion RC beams.

However, several studies reported the significant effect of the current density on the corrosion cracks and flexural performance of RC members. El Maaddawy & Soudki (2003) reported that, at the same magnitude of corrosion, the crack width of RC prisms increases significantly with the increase in current densities from 200 to 500 $\mu A/cm^2$. Saifullah and Clark (1994) also found similar results in which crack width increases with the current density (150 to 4000 $\mu A/cm^2$). Mangat & Elgarf (1999) conducting an extensive study on 111 RC beams using different current densities (1000 $\mu A/cm^2$, 2000 $\mu A/cm^2$, 3000 $\mu A/cm^2$ and 4000 $\mu A/cm^2$) found that flexural load-deflection (P-δ) responses of accelerated-corrosion RC beams are more dependent on current density when the steel weight loss increases. They found that at a higher steel weight loss, the flexural load-deflection (P-δ) performance decreased substantially with the increase in the current densities from 1000 to 4000 $\mu A/cm^2$. However, at a lower steel weight loss, the same increase in current densities has marginal effect on the flexural capacity of RC beams. It can be noted that studies on the effects of current densities on the spatial variability of steel corrosion and cracking are scarce.

Therefore, the main objective of this paper is to study, using X-ray and digital image processing techniques, the effects of current density on the spatial variability associated with steel corrosion and corrosion cracking of RC beams.

2 EXPERIMENTAL PROGRAM

The detailed experimental program (e.g., quality of concrete materials and steel reinforcement, RC specimen fabrication, and experimental test) was reported in Lim et al. (2017). The main difference between the experimental program reported in this paper and that of Lim et al. (2017) is that the objective herein is to study the effects of different current densities on the spatial variability associated with steel corrosion of corroded RC beams. Therefore, only a brief review of the experimental program is described herein.

2.1 *Concrete mixing proportion and test specimens*

Two RC beams, I-1 and I-2, with a cross-section of 80 mm × 140 mm were made. Table 1 shows the mixing proportion of concrete of the RC beams, and Figure 1 illustrates the details of RC specimens. The two beams were reinforced with a longitudinal rebar having a diameter of 13 mm (1-DB13) and stirrups with a diameter of 6 mm and space of 100 mm (DB6@100) were provided in the shear spans.

Table 1. Mix proportion of concrete

Notation	Water	Cement	FA*	CA†	AE††
	Kg	Kg	Kg	Kg	ml
I-1 & I-2	181	362	754	961	2715

* Fine aggregate
† Coarse aggregate
†† Air entrained and water reducing agent

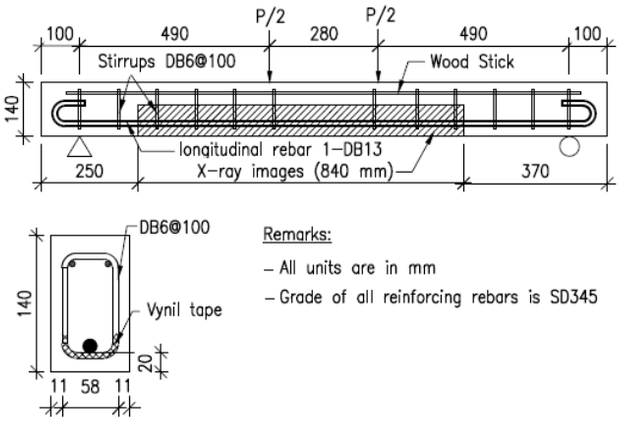

Figure 1. Details of the test specimen.

2.2 *Experimental procedure*

After the curing of the specimens for 28 days, the corrosion of the longitudinal bars was accelerated using the impressed current technique. Figure 2 shows the test setup of the accelerated corrosion test. The RC specimens were partially immersed into the solution containing 3% of NaCl. The steel reinforcement served as an anode, while a copper plate

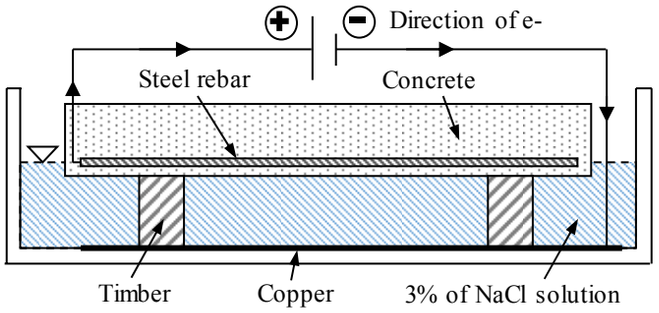

Figure 2. Test setup of the acceleration corrosion test.

served as a cathode. The current densities (I_{cor}) of 100 μA/cm^2 and 500 μA/cm^2 were used for accelerating corrosion of the longitudinal rebars of the beams I-1 and I-2, respectively. During the corrosion process, the corrosion test was halt at three different times so that the spatial variability of steel corrosion and corrosion crack can be assessed at each stage by means of X-ray imaging and digital image processing techniques (see more details in Lim et al. 2017).

At three different stages of corrosion before taking X-ray images, the photographs of corrosion crack that occurred at the bottom of the beam were taken. The locations for taking photographs are the same of the X-ray images (see Figure 1). The surface crack width was measured in 5 mm intervals along the bottom of the beam between the distance of 250 mm to 1090 mm from the left edge of the specimen.

Once before and several times during the corrosion process, X-ray radiography was performed on the undamaged and corroded RC beam to take photograms of the original and corroded rebars inside the concrete beams from 12 different viewing angles (i.e., $\theta_1 = 0°$, $\theta_2 = 30°$, $\theta_3 = 60°$, $\theta_4 = 90°$, $\theta_5 = 120°$, $\theta_6 = 150°$, $\theta_2 = 180°$, $\theta_8 = 210°$, $\theta_9 = 240°$, $\theta_{10} = 270°$, $\theta_{11} = 300°$ and $\theta_{12} = 330°$).

The local steel weight loss per 5 mm, *Rw*, was estimated along the rebar length using digital image processing of X-ray images from eight different viewing angles which can be expressed as:

$$Rw = \frac{1}{k}\sum \frac{W_{\theta_n} - W'_{\theta_n}}{W_{\theta_n}} \times 100 \quad (1)$$

where $W_{\theta n}$ and $W'_{\theta n}$ are the weights of original and corroded rebars at any viewing angle, respectively, the subscript θ_n indicates the viewing angles in which $n = \{1, 2, 4, 6, 7, 8, 10, 12\}$, and k is the number of viewing angles. At the end of the experimental program, the four-point beam bending test was performed as shown in Figure 1. The applied load and mid-span displacement were recorded. The beam was loaded until collapse by the crush of compressed concrete.

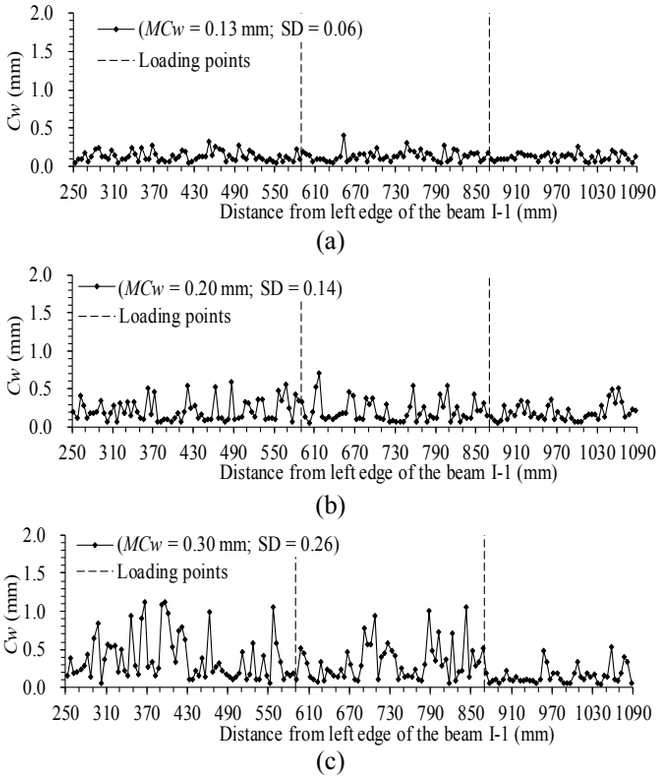

Figure 3 Spatial variability of surface crack width of beam I-1 at different average steel weight loss of (a) *MRw* = 2.13%, (b) *MRw* = 8.03%, (c) *MRw* =12.05%

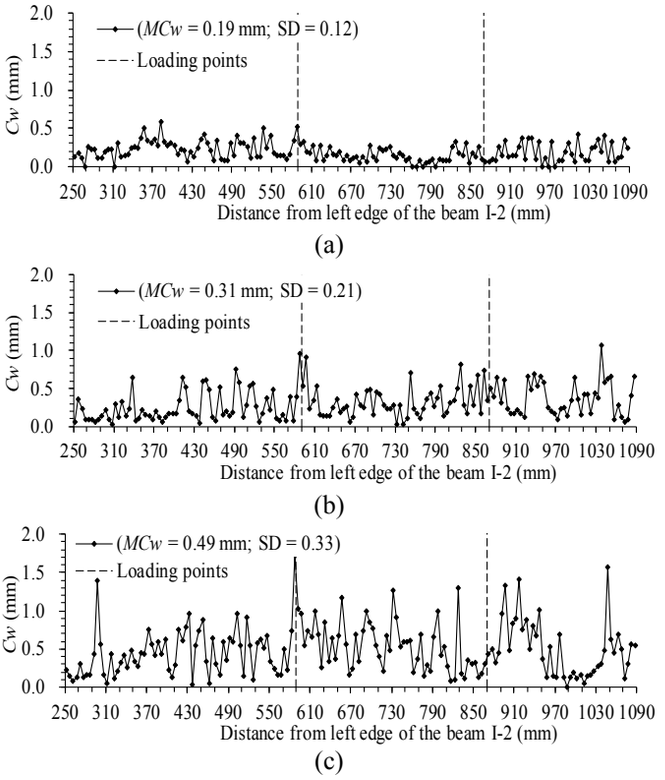

Figure 4 Spatial variability of surface crack width of beam I-2 at different average steel weight loss of (a) *MRw* = 3.05%, (b) *MRw* = 7.02%, (c) *MRw* =12.81%

3 EXPERIMENTAL RESULTS AND DISCUSSION

3.1 *Effect of current density on corrosion crack width*

It was observed in this experimental study that the longitudinal corrosion surface crack only occurs at the bottom of the beams due to the very thin concrete cover. Figures 3 (a), 3 (b), and 3 (c) illustrate the increase in spatial variability of surface crack width *Cw* over the length of beam I-1 at different degrees of corrosion or values of average steel weight loss, *MRw* = 2.13%, 8.03%, and 12.05%, respectively. Figures 4 (a), 4 (b), and 4 (c) show the increase in spatial variability of crack width over the length of beam I-2 at *MRw* = 3.05%, 7.02%, and 12.81%, respectively. For the two beams, it can be seen that the variability of their surface crack width increases with *MRw*. However, with a side-by-side comparison at approximately the same values of *MRw*, the variability of surface crack width of beam I-2, which was corroded using I_{cor} = 500 μA/cm^2, is always bigger than that of beam I-1, which was corroded using I_{cor} = 100 μA/cm^2.

Figure 5 shows the effect of current densities 100 μA/cm^2 and 500 μA/cm^2 on the increase in the average crack width at different values of *MRw* for beams I-1 and I-2, respectively. It can be seen that the corrosion crack width of beam I-2 (I_{cor} = 500 μA/cm^2) increases more quickly than the crack width of I-1 (I_{cor} = 100 μA/cm^2) at approximately the same average of steel weight loss.

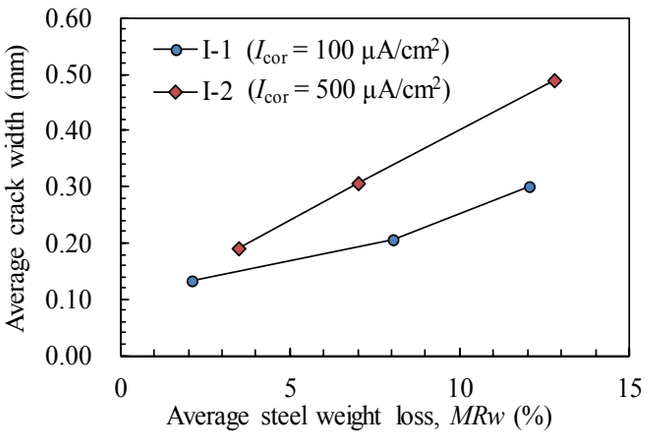

Figure 5 Growth of crack width of beams I-1 and I-2 at different average steel weight loss.

This experimental result indicates that corrosion crack width increases with the current density. Therefore, using the high level of current density to accelerate steel corrosion can lead to a faster expansion of corrosion product, higher internal pressure to the surrounding concrete, and eventually a larger crack width. Mangat and Elgarf (1999) also reported similar results in which the crack width of the corroded RC prisms increased significantly when the impressed current density was increased from 200 μA/cm^2 to 500 μA/cm^2.

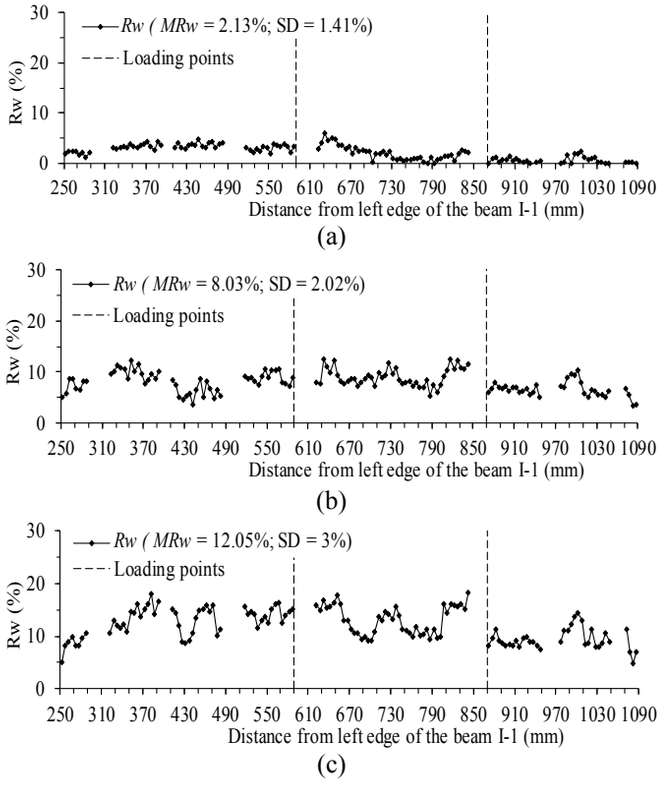

Figure 6 Spatial variability of steel weight loss of beam I-1 at different average steel weight loss of (a) *MRw* = 2.13%, (b) *MRw* = 8.03%, (c) *MRw* =12.05%

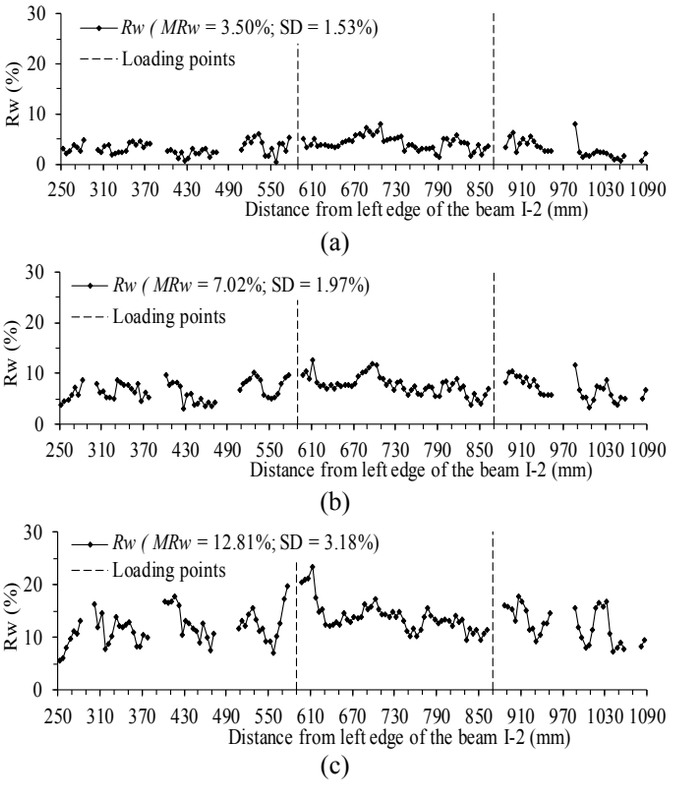

Figure 7 Spatial variability of steel weight loss of beam I-2 at different average steel weight loss of (a) *MRw* = 3.05%, (b) *MRw* = 7.02%, (c) *MRw* =12.81%

3.2 *Effect of current density on the spatial variability associated with steel corrosion*

Figures 6 and 7 depict the spatial variability associated with steel weight loss over the length of beams I-1 and I-2, respectively, at three different degrees of corrosion. Since it is very difficult to obtain exactly the same degree of corrosion, the spatial steel corrosions of the two beams are compared at approximately the same value of average steel weight loss, *MRw*. Generally, it can be seen that the distribution of corrosion is non-uniform over the length of each beam, and the variability in steel corrosion (as indicated by the standard deviation, SD) increases with the corrosion degree (as indicated by *MRw*).

Moreover, it is worth noting that the effect of current density on the spatial steel corrosion seems to be dependent on the degree of corrosion. At a small corrosion degree (*MRw* < 8%), the effect of current density on the spatial variability of steel corrosion is minor since there is no significant difference between the spatial variability of steel corrosion of both beams. However, at larger degree of corrosion of about *MRw* = 12.5%, the effect of large current density becomes more pronounced. In fact, the local maxima of steel weight loss for the beam I-2 at the location of 610 mm reaches approximately 23 % in comparison to the local maxima of steel weight loss of beam I-1 of only about *Rw* = 18%.

This experimental result suggests that as the degree of corrosion become larger, the large current density I_{cor} = 500 μA/cm^2 might induce larger local attack penetration or pitting corrosion than the small current density I_{cor} = 100 μA/cm^2. Therefore, for the experimental study of accelerated-corrosion RC members by means of impressed current technique, one shall limit the maximum current density which might provide corrosion rate similar to that occurring in the field (e.g., Andrade et al. 1989) since using large current density might result in larger pitting corrosion.

3.3 *Effect of current density on the load-deflection response*

The load-deflection curves of the beams I-1 and I-2 are plotted in Figure 8. As expected, the corroded beam I-2 with a large current density of 500 μA/cm^2 has lower flexural performance than the corroded

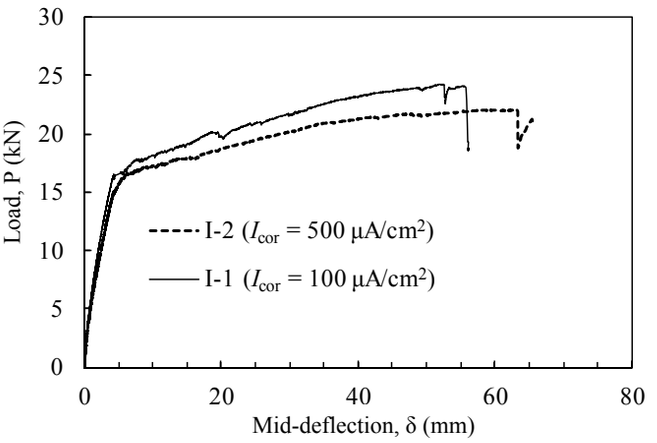

Figure 8 P-δ responses of corroded RC beams I-1 and I-2.

beam I-1 with a small current density of 100 μA/cm^2. The lower performance of the beam I-2 results from the fact that I-2 has larger crack widths and local steel weight loss in the maximum moment region than that of beam I-1 (see Figures 3 (c) and 4 (c), and Figures 6 (c) and 7 (c)).

4 CONCLUSIONS

In this paper, the effects of different current densities (100 μA/cm^2 versus 500 μA/cm^2) on the spatial variability associated with surface crack width and steel corrosion were investigated at different degrees of corrosion or values of average steel weight loss. Moreover, structural performance of RC beams corroded using the current density of 100 μA/cm^2 and 500 μA/cm^2 was investigated and discussed along with their spatial distribution of steel weight loss and corrosion cracking. Based on the experimental results reported, the main findings can be summarized as follows:

1. It was confirmed that the crack width of the accelerated-corrosion RC beams increased significantly with the increase in current density from 100 μA/cm^2 to 500 μA/cm^2. The reason might be attributed to the fact that the large current density induced larger steel corrosion in a shorter time than the small current density. This might lead to a faster expansion of corrosion product, higher internal pressure to the surrounding concrete, and thus a larger crack width.
2. Effects of current density on the spatial variability seems to be dependent on the degree of corrosion. As the degree of corrosion increases, the large current density might induce larger local attack penetration or pitting corrosion than that associated with the small current density.
3. Since the larger current density used increases the surface crack width significantly and can induce larger local pitting corrosion on the steel reinforcement, the use of larger current density results in lower flexural performance.

Seismic failure mode evaluation of bridges with deteriorated isolators

H. Matsuzaki, Y. Kubo, T. Tsumura & S. Unjoh
Tohoku University, Sendai, Japan

ABSTRACT: Isolated bridges are designed so that seismic energy is mainly dissipated at isolators. It is important that seismic safety and reparability of isolated bridges with deteriorated isolators are maintained as well as those with sound isolators. In this study, seismic failure modes of isolated bridges were evaluated considering uncertainties in the material and mechanical properties and aging deterioration of isolators. It was shown that response of isolated bridges is affected by deterioration of the lead core of the isolator and that failure probability of the isolator is mainly controlled by the rupture strain associated with deterioration of the rubber of the isolator.

1 INTRODUCTION

Reinforced concrete bridge columns with isolators subjected to the design ground motion are designed within limited nonlinear response to ensure that seismic energy is mainly dissipated at isolators. From view point of capacity design method, the yield strength of the isolator is set to be lower than that of the reinforced concrete column so that the isolator yields in advance under the design ground motion (Park & Otsuka (1999), Jangid (2007) and Zhang & Huo (2009)). However, lateral force of the isolator can increase due to the post-elastic stiffness under more severe ground motion. This increase in the lateral force of the isolator can result in rupture of the isolator or large nonlinear response displacement of the column. Once isolators are ruptured, several months will be needed to repair permanently, since isolators are designed for each bridge and manufactured after receiving an order. Thus it is necessary to consider strain hardening of the isolator to control seismic response in such a large shear strain range and enhance reparability of isolated bridges after seismic events.

Furthermore, decrease in rupture strain and increase in stiffness of isolators due to aging deterioration has been reported by Hayashi *et al.* (2014) and Shinohara & Hoshikuma (2015). It is important that seismic safety and reparability of isolated bridges with deteriorated isolators are maintained as well as those with sound isolators. Thus dynamic response characteristics of isolated bridges with deteriorated isolators should be investigated. Incremental dynamic analysis proposed by Vamvatsikos & Cornell (2002) is an essential and useful tool to investigate complex nonlinear dynamic response of isolated bridges. It is also noted that required capacity ratios between the isolator and the column to prevent rupture of isolators should be investigated considering effects of aging deterioration on the mechanical properties of isolators.

In this study, performance of isolated bridges will be investigated based on incremental dynamic analysis. Furthermore, effects of deterioration of isolators on the seismic failure modes of isolated bridges will be investigated based on fragility analysis.

2 TARGET BRIDGES AND ANALYTICAL CONDITIONS

2.1 *Target bridges*

Target bridges are reinforced concrete columns with 5 lead rubber bearings (LRB) at the top of a column on the stiff soil. Combinations of 2 types of reinforced concrete columns and 2 types of LRB were considered as shown in Table 1. These isolated bridges were designed based on the design specifications of highway bridges by Japan Road Association (2012) and the manual on bearings for highway bridges by Japan Road Association (2004). Mechanical properties of the isolators and the reinforced concrete columns are shown in Tables 2 and 3, respectively. Mechanical properties in Tables 2 and 3 are calculated using nominal values in the design. Bridges A (C) and B (D) have the same column, but rupture strength of the isolator of Bridge B (D) is higher than that of Bridge A (C).

Table 1. Dimensions of the target bridges

		Bridge A	Bridge B	Bridge C	Bridge D
Superstructure	Mass (ton)	600			
Isolator	Section (mm)	450×450	600×600	480×480	580×580
(LRB)	Total thickness of rubber (mm)	80	140	90	130
	Diameter (mm) and number of lead core	75×4	75×4	75×4	75×4
Column	Section (mm)	2600×2400		3000×2400	
	Height (mm)	10000		14000	
	Mass (ton)	260		352	
	Longitudinal reinforcement ratio (%)	1.41		2.87	
	Volumetric ratio of tie (%)	0.87		1.03	

Table 2. Mechanical properties of the isolators per column

Bridge	Yield strength (MN)	Yield stiffness (MN/m)	Strength at hardening initiation (MN)	Equivalent stiffness (MN/m)
A	0.870	51.4	2.00	14.1
B	0.870	66.0	3.58	13.7
C	0.870	55.8	2.28	14.0
D	0.870	65.2	3.34	13.8

Table 3. Mechanical properties of the reinforced concrete columns

Bridge	Yield strength (MN)	Yield displacement (mm)	Ultimate displacement (mm)

Case	Stiffness ratio	Rupture strain ratio	Shear strength ratio of lead core
0 (Sound)	1.0	1.0	1.0
1	1.2	0.8	1.0
2	1.2	0.8	0.5

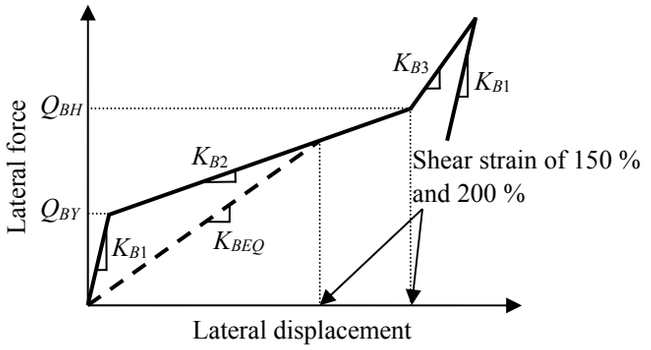

Figure 1. Lateral force-lateral displacement relationship of isolators

It is an advantage of using LRB that property of LRB can be easily controlled by the diameter of lead core and dimensions of rubber, which is associated with capacity ratios R_{QY} by Zhang & Huo (2009) and R_{QU} by Matsuzaki *et al.* (2017), respectively. The values of R_{QY}, R_{QU} and T_{EQ} in Table 4 were calculated using nominal values in the design based on Equations (1)-(3).

$$R_{QY} = Q_{BY} / Q_{CY} \tag{1}$$

$$R_{QU} = Q_{BR} / Q_{CU} \tag{2}$$

$$T_{EQ} = 2\pi \sqrt{(M_U + M_C)(1/K_{BEQ} + 1/K_{CY})} \tag{3}$$

where Q_{BY} is the yield strength of the isolator, Q_{CY} is the yield strength of the column, Q_{BR} is the rupture strength of the isolator and Q_{CU} is the ultimate strength of the column, M_U is the mass of superstructure, M_C is the mass of the column, K_{BEQ} is the equivalent stiffness of the isolator as shown in Figure 1 and K_{CY} is the yield stiffness of the column.

2.2 *Analytical model*

Mechanical properties of deteriorated isolators are modelled with reference to the experimental results of actual isolators reported by Hayashi *et al.* (2014). Three cases were considered as shown in Table 5. In Case 0, the isolator is sound. In Case 1, 20 % increment of stiffness and 20 % reduction of rupture strain associated with deterioration of rubber is assumed, but the lead core is sound. In Case 2, the lead core is also deteriorated in addition to deterioration of rubber in Case 1.

LRB was idealized based on a tri-linear model considering strain hardening of rubber as shown in Figure 1. The ratio of K_{B1} to K_{B2} was set as 6.5:1 based on Japan Road Association (2004) and the ratio of K_{BEQ} to K_{B3} was set as 1:2.59 based on Adachi (2002) in Figure 1. Skeleton and hysteresis of reinforced concrete columns were idealized based on bi-linear model and Takeda degrading stiffness model by Takeda *et al.* (1970), respectively. Thus the ultimate strength was idealized as same as the yield strength of the column. Dynamic response analysis

	Ultimate displacement	Normal	Calculated based on JRA (2012)	1.062	0.181

was conducted by idealizing a reinforced concrete column with isolators as a 2 degree of freedom model. Rayleigh damping was assumed, in which the damping ratios of the column and the isolator were 2 % and 0 %, respectively.

2.3 *Input ground motions*

A total set of 40 lateral components of strong ground motions recorded in Japan were selected as shown in Table 6. Response acceleration spectra S_a calculated using 5 % damping ratio of these original ground motions are shown in Figure 2. Various types of ground motions in terms of response acceleration spectra were included in input ground motions.

2.4 *Uncertain factors and fragility analysis*

Uncertainties in the material and mechanical properties of isolated bridges were included in the analysis. Uncertain factors considered in the analysis are listed in Table 7 with coefficients multiplied by nominal values or calculated values. Statistical values are based on Adachi (2002) and Public Works Research Institute (2013).

Fragility analysis was conducted based on Monte Carlo simulation considering the uncertainties listed in Table 7. Number of trials in Monte Carlo simulation was set as 100,000. In fragility analysis, limit states associated with the lateral displacement of isolators and columns were considered. Threshold values are rupture strain for isolators and ultimate displacement δ_{ls3} for columns based on Japan Road Association (2012). If the response displacement exceeds the ultimate displacement of the column in advance, it is considered that the column is damaged. On the other hand, if response shear strain exceeds the rupture strain of the isolator in advance, it is considered that the isolator is damaged. If the isolator or the column of the bridge is damaged, it is considered that the bridge system is damaged.

Elastic response acceleration at the equivalent natural period S_a (T_{EQ}) was adopted as the intensity measure in the fragility analysis. As input ground motions in the fragility analysis, ground motions adjusted to the required S_a (T_{EQ}) by varying amplitude property was used without varying phase property.

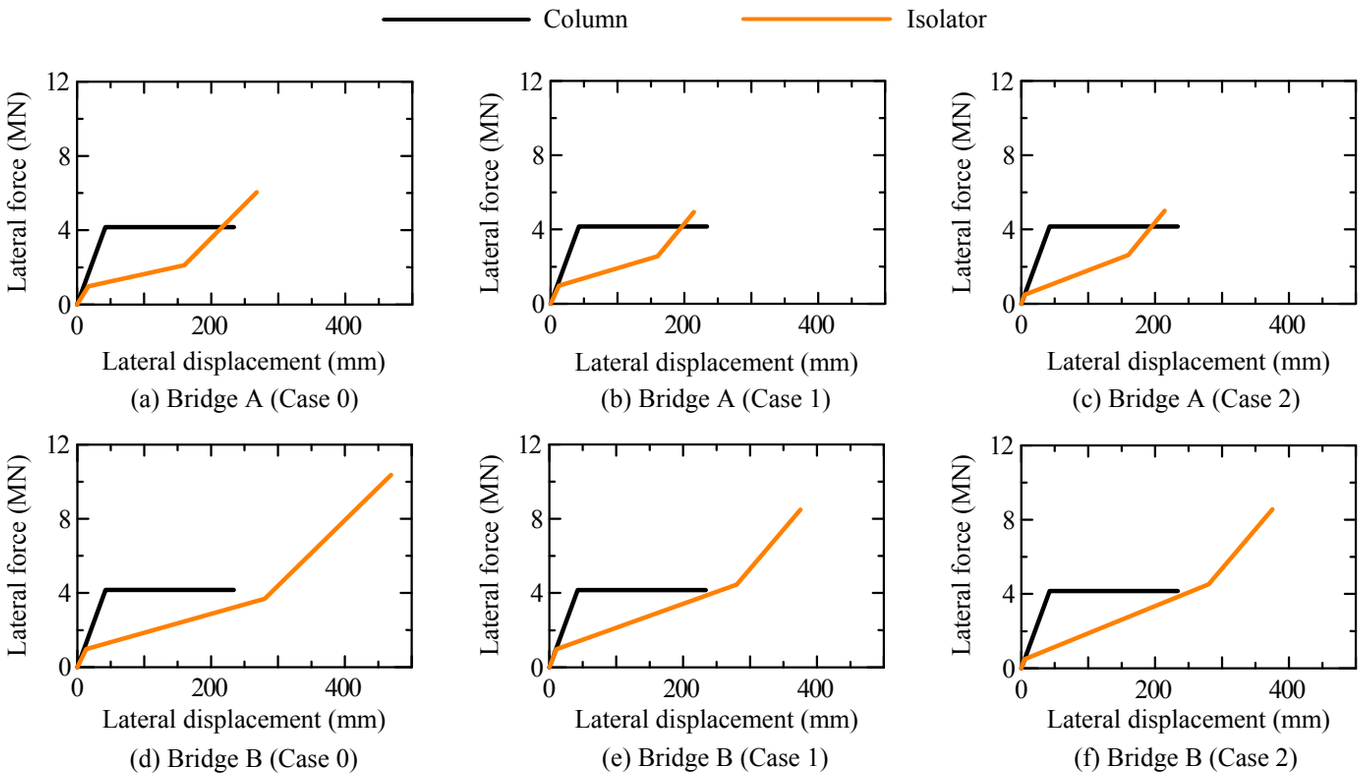

Figure 3. Skeletons of lateral force-lateral displacement relationship of the isolator and the column based on the mean values

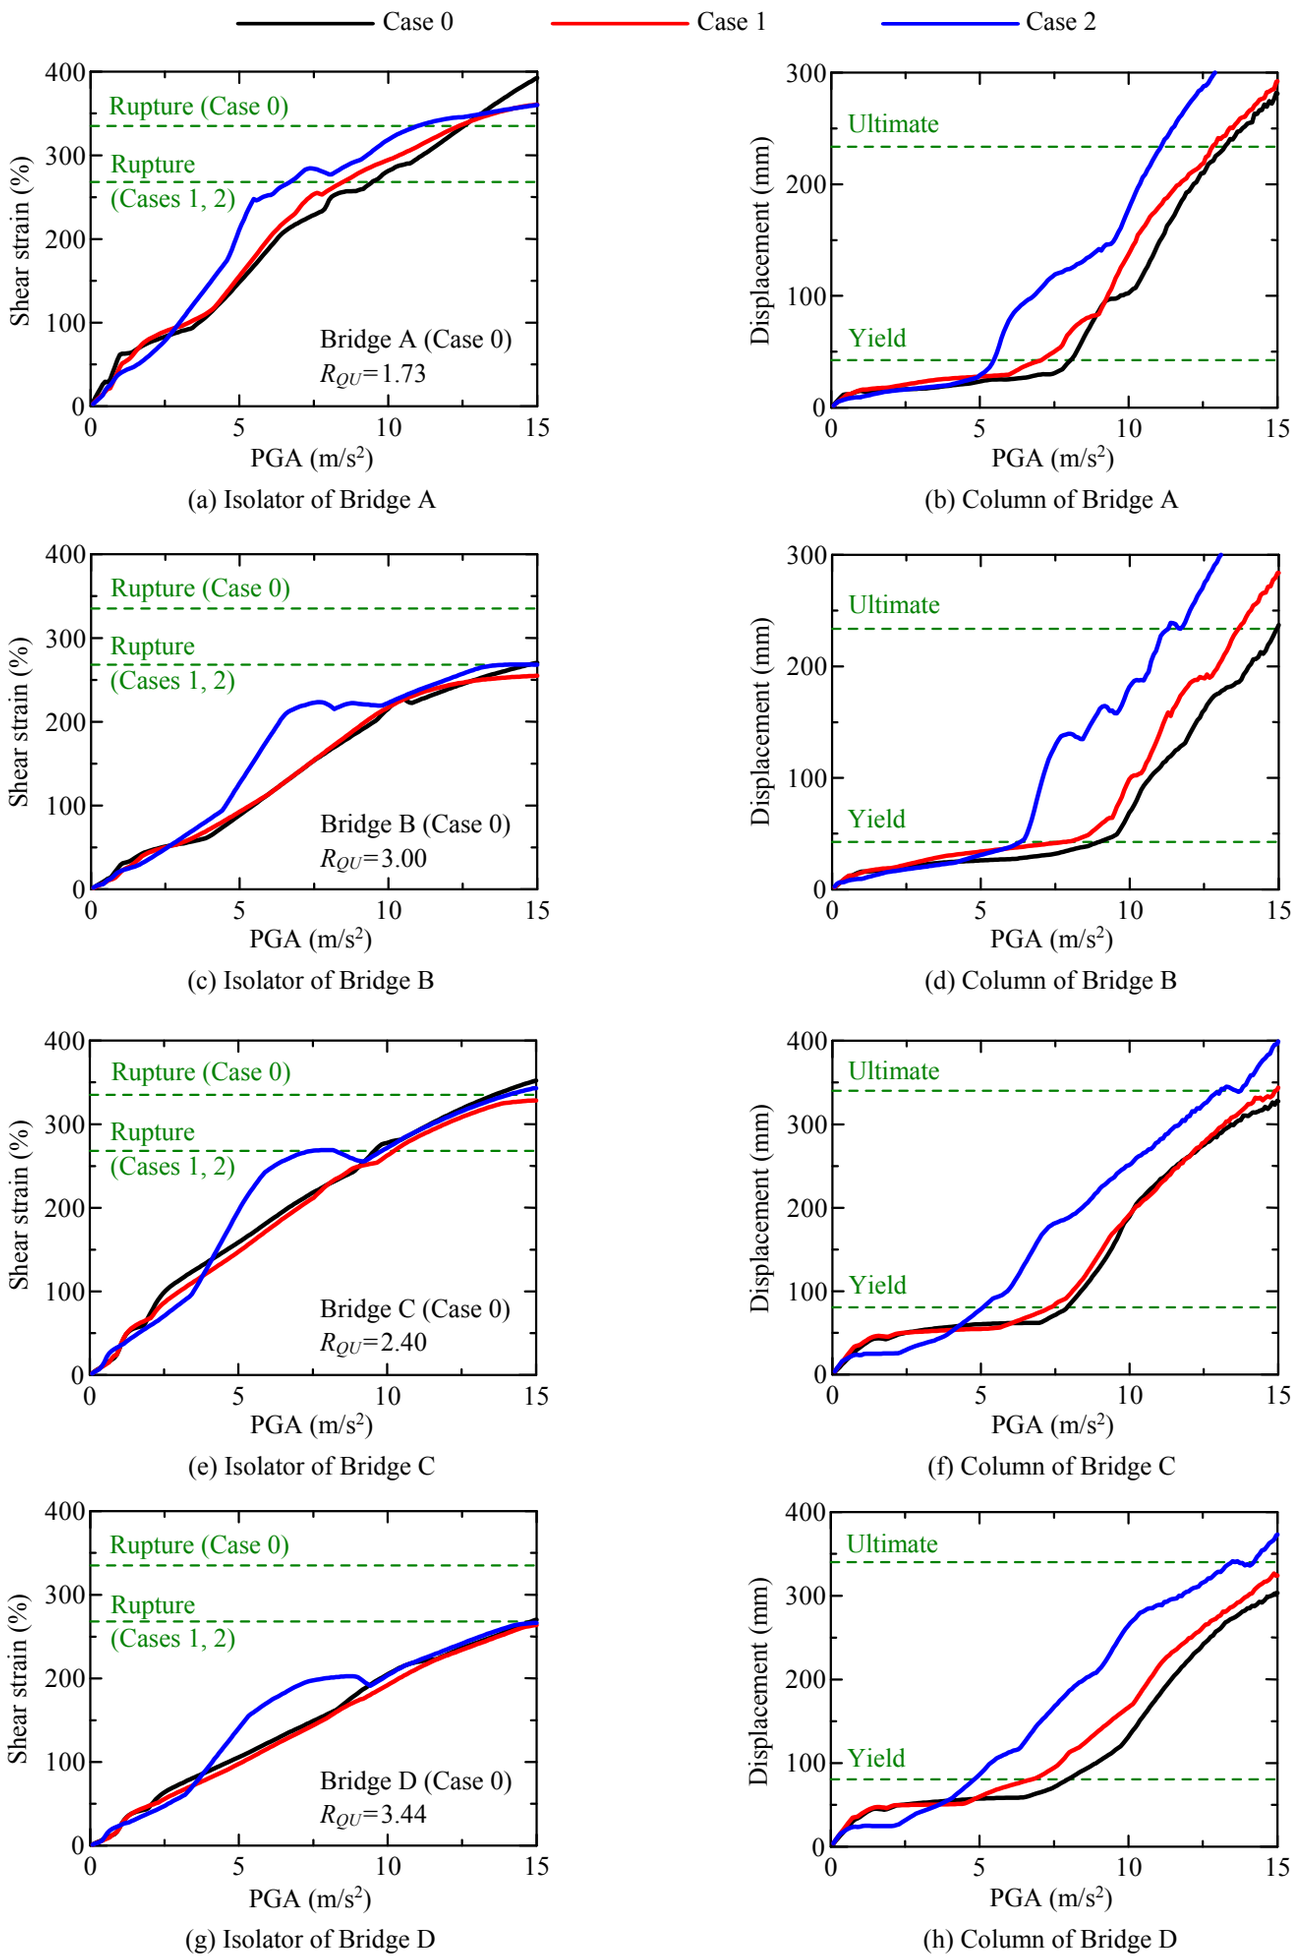
3 FAILURE MODE OF BRIDGES WITH DETERIORATED ISOLATORS

3.1 *Skeletons of force-displacement relationship of the isolators and the columns*

Skeletons of lateral force-lateral displacement relationship of isolators and columns for Bridges A and B calculated based on the mean values listed in Table 7 are shown in Figure 3. Rupture strength of the isolator of Bridge B is much higher than that of Bridge A, and there is an adequate hierarchy between the rupture strength of the isolator and the ultimate strength of the column if the isolator is sound (Case 0) in Bridge B even if effects of the inertia force of the column evaluated by dynamic response analysis is considered.

However, if isolators are deteriorated, there is an insufficient hierarchy between the rupture strength of deteriorated isolators and the ultimate strength of the column, especially in Cases 1 and 2 of Bridge A. It is also noted that the yield strength of the isolator is degraded by deterioration of the lead core in Case 2.

3.2 *Performance of isolated bridges evaluated based on incremental dynamic analysis*



To investigate effects of deterioration of isolators on the seismic performance of isolated bridges, response of the target bridges subjected to NS component of JMA Kobe record during the 1995 Kobe earthquake was evaluated with different intensity by increasing amplitude of the ground motion. Peak ground acceleration of the original NS component of JMA Kobe record is 8.18 m/s^2. Dynamic response analysis was conducted using the mean values listed in Table 7.

Response of the isolators and columns of the target bridges are shown in Figure 4. Response shear strain of the isolator decreases if the capacity ratio R_{QU} increases as shown in Figure 4. This is because lateral force of the isolator is controlled by the lateral force and the inertia force of the column, and the maximum lateral force transferred by the column is the ultimate strength of the column. Thus safety margin for the isolator can be controlled by the capacity ratio R_{QU}.

Figure 4 shows that there is a little difference in the response of isolators between Cases 0 and 1. But it is noted that rupture strain of the isolator in Case 1 is reduced by 20 % compared to that in Case 0. If the lead core of isolators are also deteriorated, response shear strain of the isolator increases due to the reduction of energy absorption at the lead core especially after the column yields. This reduction of energy absorption mainly affects the increase in the response displacement of the columns as shown in Figure 4.

3.3 *Fragility curve*

Fragility curves of the target isolated bridges are shown in Figure 5. Failure members of Bridges A and C, which have low capacity ratio R_{QU}, can be not only the column but also the isolator even if the isolator is sound as shown in Figure 5 (a) and (g).

(a) Isolator of Bridge A

(b) Column of Bridge A

(c) Isolator of Bridge B

(d) Column of Bridge B

(e) Isolator of Bridge C

(f) Column of Bridge C

(g) Isolator of Bridge D

(h) Column of Bridge D

Figure 4. Response of isolators and columns evaluated based on incremental dynamic analysis using the mean values

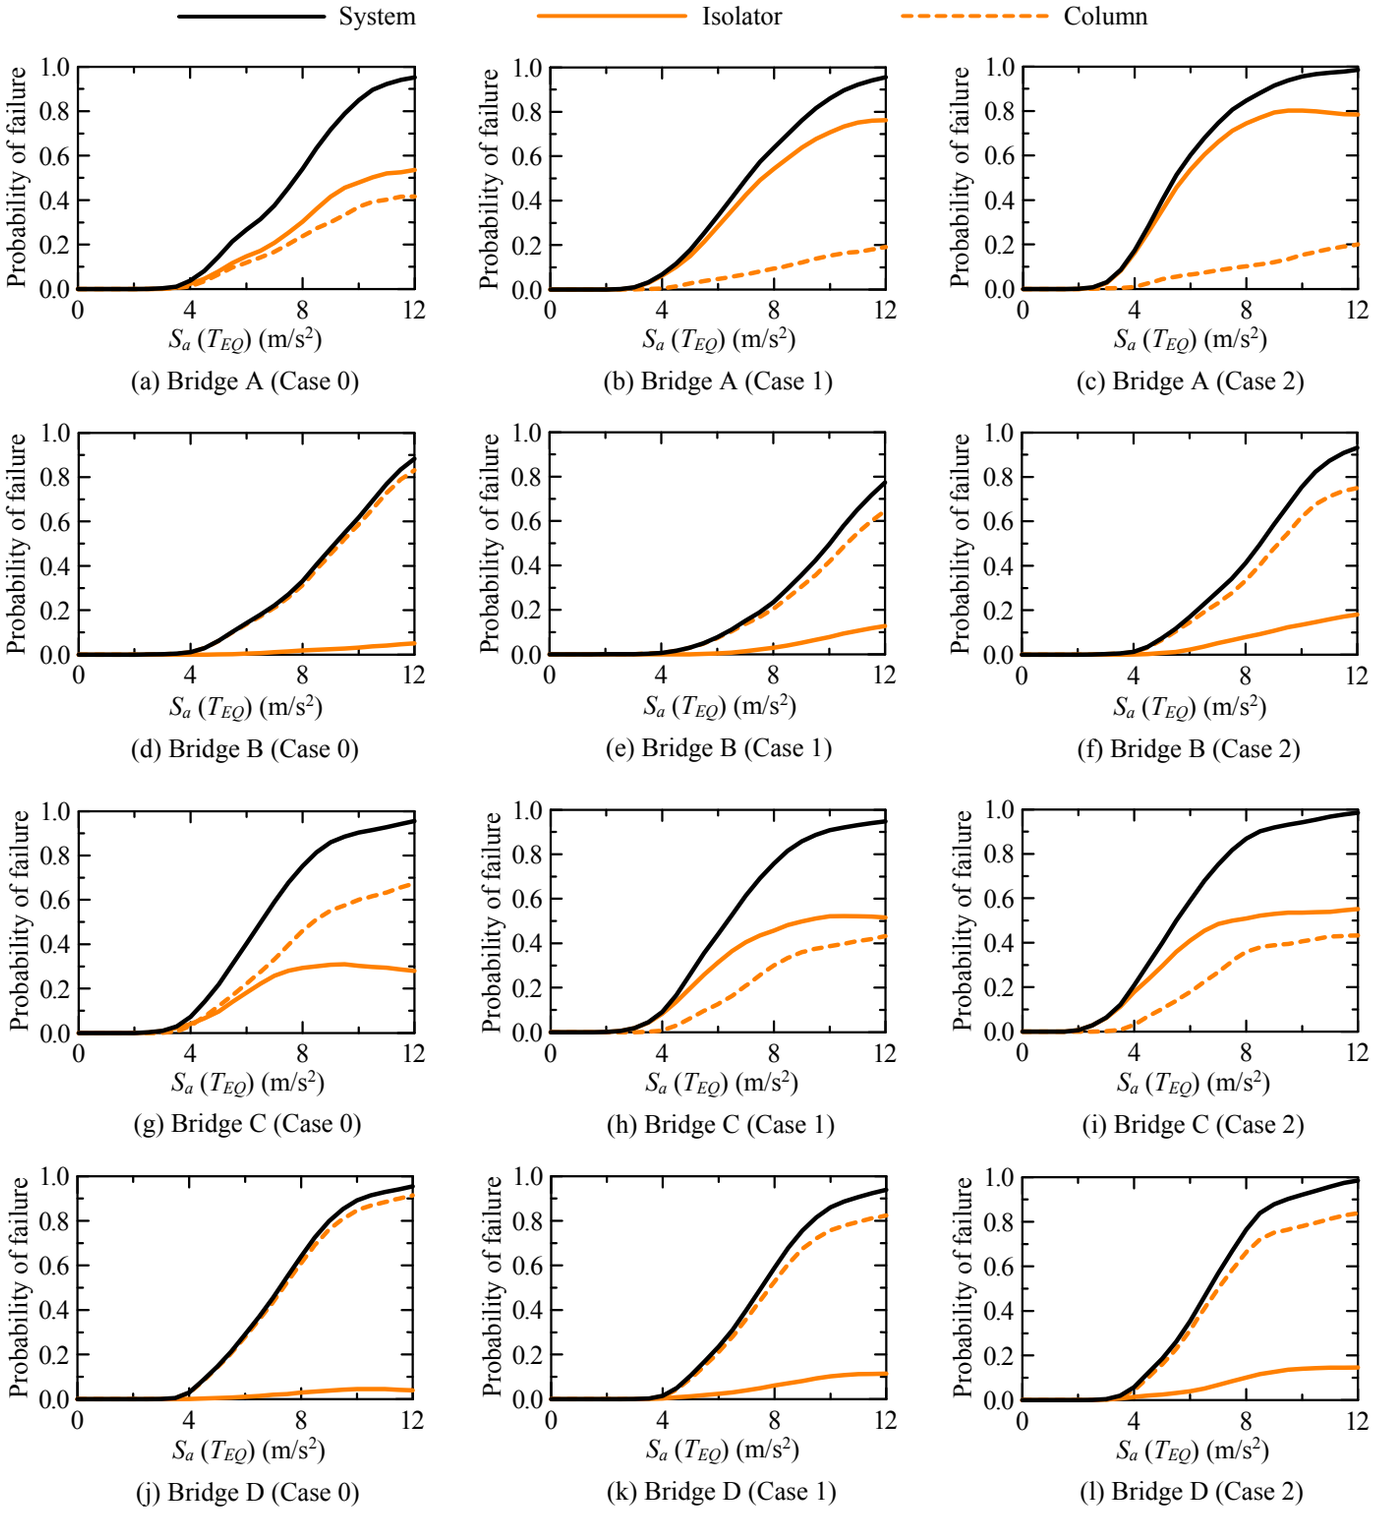


Figure 5. Fragility curves of the target bridges

This is because there is an insufficient margin for the isolator as shown in Figure 4 if capacity ratio R_{QU} is low. On the other hand, rupture of the isolator can be prevented if there is an adequate hierarchy between the rupture strength of the isolator and the ultimate strength of the column by settting an appropriate capacity ratio R_{QU}.

Probability of failure at the isolator in Cases 1 and 2 increases compared to that in Case 0 as shown in Figure 5. It is noted that the difference between fragility curves of Cases 1 and 2 are not significant, even though the lead core is sound in Case 1 and deteriorated in Case 2. This is because failure probability of the isolator is mainly controlled by the rupture strain associated with deterioration of the rubber as shown in Figure 3.

4 CONCLUSIONS

Failure modes of isolated bridges with deteriorated isolators were investigated based on incremental dynamic analysis and fragility analysis based on dynamic response analysis considering uncertainties in

the material and mechanical properties as well as strain hardening of isolators in large shear strain range. The following conclusions were drawn:

1) It is confirmed that safety margin for the isolator increases as the capacity ratio R_{QU} increases by incremental dynamic analysis. This is because the maximum lateral force transferred by the column is the ultimate strength of the column.
2) If the lead core of the isolator is sound, effects of deterioration of rubber on the response of the isolator and the column is not significant. However, response of the isolator and the column is affected by deterioration of the lead core of the isolator. This reduction of energy absorption mainly affects the increase in the response displacement of columns.
3) Failure probability of the isolator is mainly controlled by the rupture strain associated with deterioration of the rubber of the isolator.

ACKNOWLEDGEMENTS

This study was supported by JSPS KAKENHI Grant Number JP26420452. It is appreciated that strong ground motions were provided by K-NET and KiK-net of NIED, JMA, JAEE and NGA database of PEER.

Durability of reinforced concrete bridges in marine environments

R.E. Melchers & I.A. Chaves
The University of Newcastle, Newcastle, Australia

ABSTRACT: Achieving long-term durability for reinforced concrete structures particularly in marine environments remains a matter of much interest. Recent research findings based on observations from actual bridge performance and specially conducted long-term experiments for a wide variety of concretes indicate that chloride concentrations are involved only indirectly in initiating reinforcement corrosion and in serious active corrosion. For high quality concretes loss of concrete alkalinity (i.e. acid neutralizing capacity) as imparted by the cement content rather than direct corrosion attack of the steel reinforcement is the critical aspect. The rate of dissolution of calcium hydroxide, normally very low, is increased by chlorides and by greater internal surface area, such as in poor quality, porous, concretes. Only when the concrete pH drops below sufficiently will large-scale reinforcement corrosion be possible. However, cracking of concrete cover through to the reinforcing bars may cause accelerated localized loss of alkalinity, and thus severe very localized corrosion.

1 INTRODUCTION

Structural engineers rely heavily on prediction - for consequences and for their likelihood of occurrence. This requires good quality models, including for structural deterioration. The models should be robust, valid and defensible for extrapolation. Poor quality models, 'heuristics', 'expert systems', machine learning or similar 'models' not based on solid understanding of the processes involved in deterioration run the risk that predictions based on them will be problematic at best and 'hocus-pocus' at worst.

For reinforced concrete (RC) structures, including bridges, the most common concern is the long-term effect of exposure to marine conditions, principally corrosion of reinforcement caused by seawater (Richardson 2009; Gjorv 2009; Angst et al. 2012). Carbonation and alkali-aggregate reactions are of less concern (Parrott 1987). Often RC structures are given some degree of protection with impressed current systems, or more recently with sacrificial anodes, but these also deteriorate. Usually they require (often expensive) maintenance at least every 10-15 years. Thus, the question must be asked whether these protection or alternative systems are strictly necessary, since there is a considerable history of successful, durable RC structures, exposed, unprotected, to marine environments for long periods of time (e.g. Gjorv 2009; Melchers et al. 2009; Angst et al. 2012; Melchers & Chaves 2017a, 2107b).

A wealth of academic and largely theoretical literature exists about marine corrosion of RC structures but much of this does not appear to relate well to practical experience (Angst et al. 2009; Melchers & Chaves 2017a). Much conventional thinking is founded on the notions of chloride diffusion and the chloride 'threshold', the latter supposedly defining when damaging reinforcement corrosion becomes important (e.g. Richardson 2002; Gjorv 2009). This criterion increasingly has been questioned (e.g. Melchers & Li 2006; Angst et al. 2009) with the result that the current RC corrosion literature now refers to 'chloride-induced' corrosion, indicating that the effect of chlorides is not fully understood.

The next section reviews two bridges exposed to marine environments for which detailed observations were possible. Experiences for many other RC structures also are considered. These experiences are then compared with results and conclusions reported only recently for RC specimens in long-term laboratory exposure conditions.

2 RC BRIDGES IN MARINE EXPOSURES

2.1 *Long-term observation and investigation*

Corrosion of reinforcement in RC structures is a slow process, even in some of the most aggressive exposures. Controlled experimental studies usually are not feasible in conventional university or re-

search laboratory settings. An alternative is to use an 'archaeological' approach, in which existing older structures are examined, with interpretation of the observations based on reconstructions of the likely operational and environmental conditions.

Learning from actual operational experiences with real structures has the draw-backs that (1) usually there are only a few structures available for investigation, (2) they tend to be one-off so that investigation of causative parameters is difficult, and (3) typically they are not well-documented (or the documentation no longer exists or cannot be found). Nevertheless, several investigations along these lines have been described (e.g. Chitty et al. 2005; Melchers et al. 2009; Melchers 2015; Angst et al. 2012). Two Australian examples are given below.

2.2 *Hornibrook Highway Bridge (Brisbane)*

This was a 2.6 km long road bridge completed in 1935 (Melchers et al. 2017). Its RC substructure comprised 292 spans supported on RC headstocks, each supported on 3 precast, driven, RC piles (879 in total). Each pile typically was 380 x 460 mm in cross-section and reinforced with 4 round steel reinforcing bars of 32mm nominal diameter, with 60mm cover. The headstocks were cast-in-situ over the ends of the piles with reinforcement from the piles going into the headstocks. During the 1990s some concrete cracking and spalling of the headstocks was noted and confirmed by detailed surveys in 1998 and 2003. Subsequently its use was limited to pedestrian traffic. The bridge was almost completely demolished in 2011-2. At that time independent observations noted that there was considerable corrosion evident for the headstocks and the RC approach bridges but not for the RC piles. These showed almost no signs of reinforcement corrosion, such as longitudinal cracking, spalling of concrete cover and rust staining. This was the case in the splash zone, in the tidal zone (usually considered the most prone to reinforcement corrosion) and in the immersion zone.

Through good cooperation between the local highway agency, university researchers and, most importantly, the demolition contractor, more detailed investigations were then undertaken, as follows.

During demolition most piles were extracted vertically from the sand foundation material although some had to be cut off. They were then stored in the contractor's demolition yard where many were examined for visible signs of reinforcement corrosion. Randomly selected 2-3 m lengths of piles were transported to the university structural testing laboratory for more detailed examination. These were cored for compression strength testing and cut transversely for examination of the cross-sections. The concrete strength was very high (Table 1), as noted also in the earlier investigations. The concrete pH also was very high, at around pH 12 across more than 95% of the cross-sections. Close inspection showed no significant air-voids around the bars, and this was confirmed by removal of the longitudinal reinforcement from the concrete (Fig. 1). Both are remarkable since at the time of construction concrete compaction most likely was by hand rodding. Also, at the time of construction, adding water to the concrete mix for workability was not prohibited, although the importance of water-cement ratio was recognized. Further, it has been reported that Emmanuel Hornibrook, the bridge designer, was remarkably careful in the design and the construction of the bridge components and, when in doubt, insisted on adding more cement to the concrete (Melchers et al. 2017).

Table 1. Summary of properties of the concretes and corrosion.

Property	Units	
Concrete strength (cores)	MPa	66-76
Concrete cover (typical)	mm	60
Concrete chloride content at bars	kg/m^3	5 - 14
Concrete pH at reinforcing bars		~ 12
Apparent carbonation depth	mm	2-5

Figure 1. Concrete surface adjacent to a reinforcment bar in a randomly selected pile, showing no evidence of air voids or separation between the steel and the concrete.

One of the few locations were some minor reinforcement corrosion was observed on the laboratory-cut cross-sections, the pH local to that corrosion spot was around 7 despite the pH elsewhere on the cross-section being around 12.

Despite the apparently excellent condition of the nearly 900 RC piles overall, one case in particular must be considered. It is the case for which a transverse crack some 60% inward from one face of the pile was discovered (Melchers et al. 2017). When examined, the crack surface was found covered with a layer of watery-looking rust stain. The two reinforcement bars on what would have been the tension side were corroded right through. Each bar showed a conical end some way into the space left by the steel that had corroded away (Fig. 2). Other than very minor rust staining on the outside surface of the pile, there were no signs warning of reinforcement corrosion. Apart from the alarm this case should raise with practitioners, the immediate research question is 'what happened to the corroded steel?" The next question obviously is "why?".

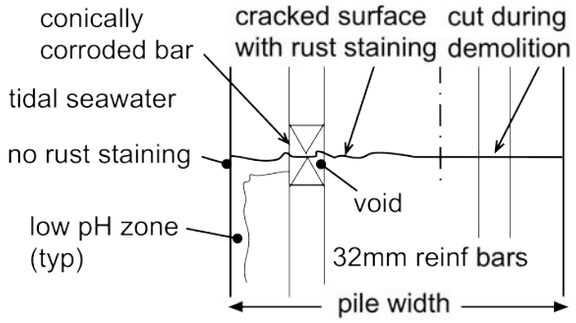

Figure 2. Schematic view of the highly localized reinforcement corrosion found in one of the piles of the Hornibrook bridge. The tidal seawater would remove the highly soluble ferrous chlorides generated by crevice corrosion in the void region.

2.3 *Sorell Causeway Bridge (Tasmania)*

This bridge, constructed in 1957, consisted of 34 simply-supported spans each 13 m long exposed to a marine environment. Each span comprised 14 precast, post-tensioned T beams connected together by transverse post-tensioning (Papé & Melchers 2011). Unlike subsequent post-tensioned bridges, the ducts, made using inflatable tubes, did not contain a steel duct liner. There were two tendons per beam, each consisting of 18 cold-drawn high-tensile wires of 5.1 mm diameter. The remaining space was pressure grouted with mortar. The concrete cover to the tendons in the stem of the T beams was around 25mm. The bridge was demolished in 2002 following observations of visible damage along the line of the profile of the lower tendon. This was the case only for the most exposed T beams.

Three of the beams were transported to the University of Newcastle for load-testing and detailed examination: one considered from visual examination to be the most damaged by tendon corrosion, a slightly damaged beam and a randomly selected, apparently undamaged, beam. The load tests have been described elsewhere, as have results of the detailed examinations (Papè & Melchers 2013). The beam in apparently good condition showed little or no evidence of corrosion of the tendons, such as concrete cracking, spalling or rust stains. For this beam phenolphthalein measurements on the concrete cross-sections showed much of the interior concrete still at pH>12.

The most damaged beam revealed severe corrosion of the prestressing strands, with the pattern of corrosion being worse at one side of the outer layers of strands, with some strands remaining as almost hemispherical in cross-section (Fig. 3). This beam also showed considerable rust staining in the area where most of the corrosion had occurred but only a small amount of deposited rusts, including black and green rusts (Papé & Melchers 2011). It was apparent that most of the metal that had corroded away was not present as corrosion product anywhere within or the outside surfaces of the beam. Some rust was found below the tendon in the region where the concrete T beam stem had split roughly vertically. There was remarkably little rust on the exterior of the T beam stem.

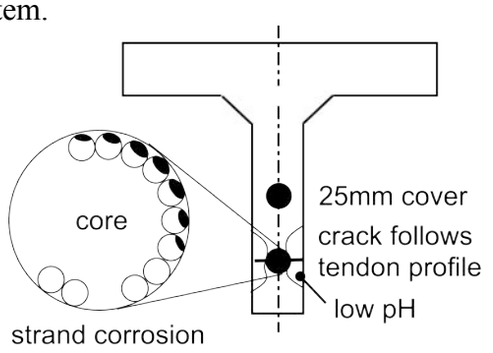

Figure 3. Schematic view of the cross-section of the most damaged T beam, showing corrosion damage of strands forming tendon, low pH regions and location of concrete cracking.

Breaking open the beam showed that much of each tendon duct was filled with grout but also that there were sizeable air-voids that interfaced with the strands of the tendon. Some also appeared to be located at or close to where significant strand corrosion was observed (Fig. 3). At these point the concrete pH was low (around 7-9), but overall the pH of the concrete cross-sections was quite high (>10-12) in most areas. It was postulated (Papé (2008) that the low pH was the result of carbonation. However, whether this is possible, in view of the existence of 25mm of concrete cover and the grout around the tendon, is an interesting question. For good quality concretes carbonation is known to penetrate only a few millimetres into the concrete (Parrott 1987).

2.4 *Other RC structures*

Summaries of experiences with the long-term behaviour of reinforced concrete structures exposed to marine environments or de-icing salts world-wide (Gjorv 2009), including many bridges (Melchers & Li 2009), show many cases with excellent long-term performance, usually associated with structures constructed with ‘good workmanship’ and with high quality, very low permeability concretes. Some of these have been reported in more detail, as summarized by Angst et al. (2012). There also are many cases of poor durability and severe corrosion problems associated with poor quality or undefined concretes. Careful analysis shows that in some cases the effects of other influences have not been properly considered. One example is road bridges without a bitumen wearing or riding course. Detailed rather than cursory observations showed that motor vehicles and lorries often cause physical damage to the concrete cover of the bridge deck and that corrosion damage then followed, rather than the damage being

the direct result of inward diffusion of chlorides from de-icing salts causing corrosion that then cracked the cover (e.g. Lukas 1985; Volkswein & Dorner 1986). Similarly, destruction of the concrete matrix protecting the steel may be caused by volume changes resulting from alkali-aggregate reactions, with corrosion then following (Jensen 1996; Richardson 2002; Gjorv 2009). Structural bending and shear actions also may cause deterioration of the concrete cover and thus long-term corrosion problems, even though cracks in concrete up to about 0.3mm usually are considered acceptable. However, the relevance of this criterion is questionable as it has its origins short duration in laboratory tests (Beeby 1978).

3 FROM FIELD OBSERVATIONS TO THEORY

The conventional model for the commencement and development of reinforcement corrosion as a function of exposure period is attributed to Tuuti (1982) although proposed earlier by Clear (1976) (Fig. 4). It presumes negligible corrosion before the initiation time t_i followed immediately by a high rate of damaging corrosion. A slight modification is allow more time for chloride diffusion after t_i before damaging corrosion starts (Weyers et al. 1997) including allowance for minor cracking of the concrete, such as caused by beam bending, which increases overall permeability (Francois & Arliguie, 1999).

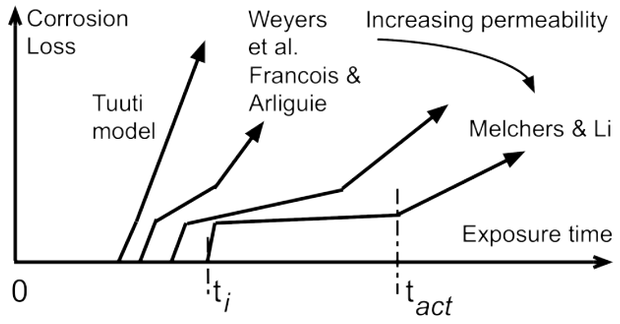

Figure 4. Integrated model for the initiation and development of reinforcement corrosion showing separation between initiation at t_i and start of active corrosion at t_{act}.

A more comprehensive, integrated model is shown in Figure 4. It is based on observations from field studies (Melchers & Li 2006). Unlike the earlier models and proposals, it distinguishes between the quality of the concrete. For dense, impermeable concretes it has serious, active corrosion commencing only at some later time t_{act}. This implies immediately that the mechanisms for the initiation differs from that for active corrosion (Melchers & Li 2006). It also was proposed that active corrosion after t_{act} is the result of loss of concrete alkalinity and in particular the loss of $Ca(OH)_2$ as accelerated by the presence of chlorides. This hypothesis is discussed further below.

The differentiation between t_i and t_{act} was used by Melchers & Li (2009) to review and analyse some 300 individual reinforced concrete structures, using information, of various levels, as reported in the literature and in various reports. This showed that for most structures there were considerable differences between the values of t_i and t_{act} (Fig. 5). Similar results, but with higher values of t_i and t_{act} were obtained for structures with (non-reactive) limestone and dolomite aggregates (Melchers & Li 2009). Independent support for the separation of t_i and t_{act} has been reported for long-term (25 year) laboratory exposures of pre-cracked beams (Yu et al. 2015).

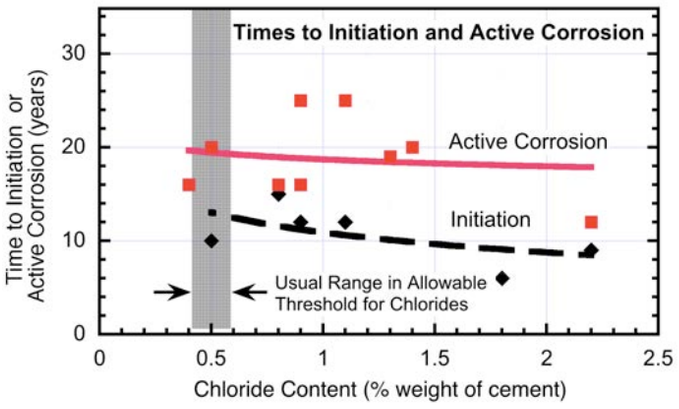

Figure 5. Trends for times to initiation (t_i) or active corrosion (t_{act}) as a function of concentration of chlorides estimated at the reinforcement. The typical range for acceptable chloride concentration threshold is shown.

An interesting feature of Fig. 5 is the relatively low influence of chlorides. This contrasts with many earlier laboratory test results that appear to show that chlorides much increase corrosion losses. However, almost invariably these tests were conducted using a simulated porewater solution under accelerated conditions such as through stirring the solution or using air bubbling. Evidently, these conditions do not properly represent those relevant inside actual concrete structures.

The low sensitivity to chlorides shown in Fig. 5 is unlikely to accidental or fortuitous. Firstly, it was observed also for realistic model reinforced concrete samples exposed for more than 10 years in a high humidity environment (Melchers & Chaves, 2017a). Secondly, it is consistent with corrosion theory and detailed investigations under laboratory conditions for corrosion mechanics, as summarized below.

For corrosion to be possible, it is necessary to satisfy the thermodynamic conditions for the chemical reactions involved. In electrochemistry these are summarized in the Pourbaix diagram (Jones, 1996). It shows that without an applied potential (such as often is applied in electrochemical tests), corrosion of ferrous iron in pure water can occur only for pH <

about 9 (Pourbaix 1970; Jones 1996; Chitty et al. 2005). The addition of chlorides to the solution can initiate pitting corrosion at (much) higher pH values, increasing with the chloride concentration (Pourbaix 1970). These conditions only indicate whether corrosion can occur, not how fast it will progress. The latter is important for infrastructure applications.

In severely corrosion damaged structures very considerable amounts of corrosion product typically are seen, and these are unlikely to be the result only of pitting corrosion. More general, overall corrosion is required. For this to be possible it is necessary for the high alkalinity ('acid-buffering capacity') of the concrete surrounding the steel bars to drop, to a pH of about 9 (Pourbaix 1970; Jones 1996). This also is consistent with field observations (Melchers et al. 2006; 2017). The time taken for the pH to reduce sufficiently will depend on (a) the initial 'alkalinity' (acid-neutralization capacity) of the concrete, (b) the rate of loss of alkalis from the concrete and possibly (c) the rate of 'carbonation'. The first is related to the cement content of the concrete but may be boosted by alkaline materials such as calcium carbonate, while the second and third depend on the rate of diffusion, leaching or dissolution of various species, including chlorides, oxygen, alkalis and, for carbonation, carbon dioxide. These rates depend, in turn, on the permeability of the concrete relative to each species. The alkali of most importance for significant reduction of pH is calcium hydroxide $Ca(OH)_2$ since it tends to maintain a pH of about 12.

The environment for corrosion inside most concretes can be characterized as 'wet and stagnant'. Water is required for corrosion to occur but it must be present at the steel-concrete interface and it must be available. There is evidence from corrosion in soils that moisture may be held in the pore structure and only when the moisture content is sufficiently high (but not too high to exclude oxygen) will corrosion occur (Gupta & Gupta 1979). The stagnant conditions also are important. Classic experiments (Heyn & Bauer 1908) showed that for mild steel immersed in weak stagnant, solutions of about pH=7 corrosion loss was very similar, for variety of dilute solutions of salts, including NaCl. This was explained many years later (Brasher 1967) as the result of stagnant solutions permitting the weak passive film formed on ferrous materials (*cf.* Evans 1960) to remain in place. This is increasingly less likely to occur as the water velocity increases. Carefully controlled laboratory exposure experiments by Mercer & Lumbard (1959) provide direct support - in near-stagnant conditions chlorides had almost no influence on the amount of corrosion. Unfortunately, many laboratory experiments using solutions have been conducted under non-stagnant conditions. Their validity for actual reinforced concrete structures is, therefore, questionable (*cf.* Poursaee & Hansen 2009).

4 TIME TO INITIATION

A long-term experiment, commenced in 2004, throws some light on initiation, as well as active corrosion (Melchers & Chaves 2017a) In the experiment a large number of concrete specimens each 40 x 40 x 160 mm long, with a 6 mm diameter smooth mild steel bar placed centrally in the longitudinal direction and made to a variety of water/cement and aggregate/cement ratios. All were made with the same aggregates. The specimens were cast in steel moulds of high dimensional accuracy and vibrated for an equal amount of time on the laboratory shaking table. They were then continuously exposed to a high humidity (>95% RH) 20˚C laboratory fog-room environment. The specimens were water saturated whenever inspected in the fog room. It is noted that this wet environment ensures carbonation as a cause of any corrosion can be discounted (Parrott 1987).

All except one series (series C) were made using standard commercial (blended) Portland (GP-type) cement, sourced at the same time from one manufacturer. Series C was made with sulphate-resistant cement. Further, except for one test series made with freshwater (series K) all specimens were made with Pacific Ocean seawater. This was done to obviate the time required for chloride ions to diffuse to the steel bar. Since the chloride concentration was high right from the time the specimens were made, initiation of reinforcement corrosion could be expected from first exposure.

One or two specimens from each set of specimens were withdrawn from the fog-room about every 12 months (Melchers & Chaves, 2017b) examined externally, and broken open to reveal the state of the steel bar and of the interior concrete. For the reference set (series B) this showed that after 2-3 years exposure some concrete mixes showed corrosion of the steel bar, but others did not. The latter were the concretes with higher strength, greater density and thus lower permeability. Also, series K showed no corrosion, both in the first few years and for the next 12 years (i.e. to date). Where corrosion was observed (in the B series) it was in the form of pitting or localized corrosion along the lower part of the reinforcing bar, that is, away from the casting direction and closest to the shaking table.

This pattern continued for the following years, with only moderate increases in corrosion observed for the denser concretes and more for the concretes of lower densities and thus greater permeability. After 12 years exposure the concretes with the highest aggregate cement ratios (i.e. lowest overall cement contents), and thus highest permeabilities, showed moderate corrosion all around the reinforcing bars, but still insufficient to cause longitudinal cracking along the bars. This pattern is consistent with Fig. 4.

Examination of the concrete at the concrete-steel interface showed the presence of air-voids, particu-

larly for the less dense concretes, predominantly along the lower part of the bars (i.e. away from the casting direction). Air-voids are known to leave less or none of the alkaline calcium hydroxide layer typically found around reinforcement bars and also have long been considered as involved with the localized or pitting corrosion of reinforcement (Verbeek 1975; Angst, et al. 2017). However a clear link between air-void location and pitting was not established. The present results do show such a connection from sections cut across the specimens (Fig. 6). Also, the higher propensity of air-voids and pitting along the lower parts of the bar is consistent with field experience and attributed to the degree of concrete compaction during construction (e.g. Nawy 2008).

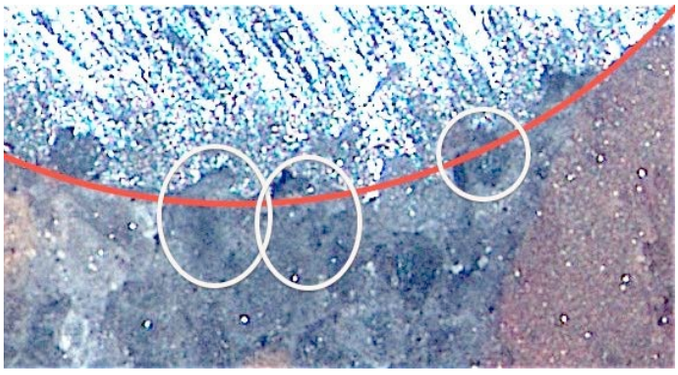

Figure 6. Part cross section of lower part of steel bar showing voids in concrete at interface and localized corrosion.

5 TIME TO ACTIVE CORROSION

The experiments outlined above also have thrown new light on the time to active corrosion, t_{act}. Already after the first few years it was observed that the specimens in series C, made with sulphate-resistant cement, showed a remarkable difference in the colour of the interior concrete. The lighter coloured region was greater for the more permeable concretes and increased with longer exposures. Closer examination of the specimens made with GP cement also showed a (much less obvious) colour difference (Fig. 7).

Analysis of the dark and of the light-coloured concretes revealed interesting differences. In brief, the light coloured concrete appeared permeable, was devoid of $Ca(OH)_2$, showed negligible carbonates and had a pH around 7-8. If it had reached the steel bar, the bar invariably was corroded to some degree. In contrast, the darker concrete was less obviously permeable, showed high concentrations of $Ca(OH)_2$ and high pH (10-12) (Melchers & Chaves, 2016).

The more open structure of the light-coloured concrete indicates loss of material (i.e. calcium hydroxide) and also greater permeability. Taken together, these observations support the proposition (Melchers & Li 2006) that active corrosion for high quality, dense, low permeability concretes is through the loss of calcium hydroxide and that this loss is by leaching from the outside inwards.

Importantly, it is well-known that loss of $Ca(OH)_2$ is governed by its rate of dissolution in water. It is very low for pure water (Sagues et al. 1997; Marinoni et al. 2008) but is accelerated by the presence of NaCl in proportion to its concentration (Johnson & Grove 1931). In this regard, it is noted that the surface area available for the dissolution process is greater for the more permeable concretes, consistent with the experimental observations.

By comparison, the K series made with fresh water showed much less penetration of a light coloured region, and thus a much lower rate of $Ca(OH)_2$ dissolution. For these concretes the pH at 12 years was still high.

Overall, the critical point is that the lighter outer zone of the specimen (Fig. 7) is the result of dissolution and leaching of $Ca(OH)_2$ from the specimen. When this zone eventually reaches the steel bar, the local pH will reduce to below about 9 and allow corrosion to proceed. It is clear from the experimental results that this can occur irrespective of the local concentration of NaCl.

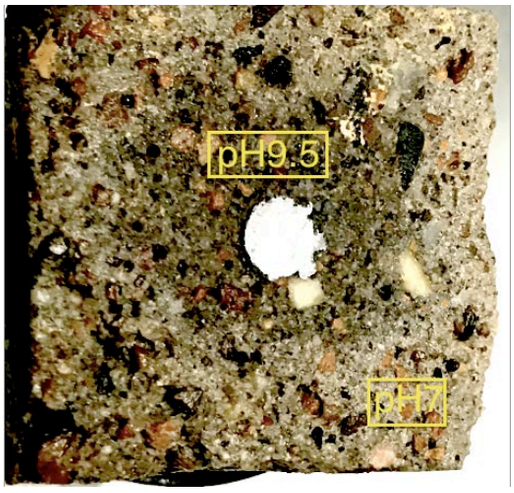

Figure 7. Concrete cross-section of a 12 year old specimen made with GP cement immediately after it was cut open, showing inner darker and outer lighter zones. Indicative spot pH values are shown.

INFLUENCE OF CONCRETE CRACKING

The experiments described above were for uncracked concrete specimens. However, concrete cracking is likely to affect both dissolution and leaching of $Ca(OH)_2$ from the concrete matrix, the latter mainly through reducing the effectiveness of the concrete cover and the alkalinity it holds. This is consistent with experimental results (Francois & Arliguie 1999) although not described in those terms. From short-term experimental results it was concluded that even if cracks penetrated to the rein-

forcement, the severity of any resulting corrosion was directly proportional only to crack width (e.g. Beeby 1978). This was attributed to the alkalinity of the concrete providing 'autogenous healing'. However, large-scale laboratory observations indicate that irrespective of width, transverse cracks penetrating to the reinforcement permit the commencement of corrosion at the crack base (Francois et al. 2012). This is consistent with the notion of loss of alkalinity, facilitated now by the presence of cracks. It is consistent with the severe localized corrosion for the Hornibrook bridge (Fig. 2) and for the Sorell bridge (Fig. 3). In the latter, it also explains the considerable presence of low pH concrete inside the beams, earlier noted as not easily explainable 'carbonation' (Papé 2008) but now explainable in terms of dissolution and leaching of $Ca(OH)_2$ from the concrete matrix. In both these cases, it is likely also that in the longer term corrosion under low oxygen conditions in the crevice corrosion conditions at the concrete-steel interface producing soluble ferrous chlorides also was involved (Wranglen 1974).

6 PRACTICAL IMPLICATIONS

From a practical perspective, the most important parameter to arise from the present work is t_{act}. It describes when serious corrosion can be expected to commence, irrespective of any previous, short-term initiation as indicted by the parameter t_i. In most practical structures, it is the case that once serious corrosion has commenced the lifetime of the structure has been seriously compromised. Certainly simulations can be carried out to ascertain the extra life (to t_L) possible after t_{act} has been reached, but the aim of design or rehabilitation should be to extend the time for t_{act} as long as possible, economically.

The second practical outcome from the present work is the clear indication that cracking, even hairline cracking, of the concrete, particularly transverse cracking through to or close to the reinforcement, such as might result from high bending stresses, can have a very detrimental effect. As noted, the research on which current design Code rules are based used short-term testing and did not allow development of the mechanisms exposed both by the field experience now available and as supported by the present longer-term experimental work and also seen in other recent experimental work (cf. Francois et al. 2012). It follows that design rules for cracking need to be revised, particularly for marine exposure conditions.

The third aspect to arise from the present work is that it reinforces the crucial role of concrete alkalinity. The importance of this has long been recognized as a key factor in maintaining passivity against corrosion of steel reinforcement. The recent experimental results for chloride induced corrosion reinforce this role since alkalinity dissolution is now seen to be critical in the development of conditions that permit commencement of active, serious corrosion of the reinforcement, including in chloride environments. Since high alkalinity conventionally is associated with high cement contents, the immediate inference is that longer durability can be achieved with higher cement content. However, opposing this are the increasing environmental and economic pressures to reduce cement contents in concretes. In this context, other ways of enhancing the alkalinity of concretes are of interest. One possibility is the use a relatively high proportion of low alkalinity aggregates such as limestone and non-reactive dolomites (Melchers & Li 2009). When these were used as aggregates they increased the time t_{act} to active corrosion. This observation is consistent with (anecdotal) experience, for example, in those parts of Europe (Lukas 1985) and in Florida (Lau et al. 2007) where the predominant aggregates are calcareous.

Finally, the overall mechanisms described herein differ from the conventional wisdom in some important ways. They give a role to chlorides that differs significantly from the conventional wisdom, and one that differentiates between initiation of reinforcement corrosion and its eventual serious, active, commencement. Overall, the mechanisms are consistent with fundamentals in corrosion science and, importantly, are consistent with practical experience and observations for high quality reinforced concrete structures. The present results also bring a degree of unity between carbonation-induced and chloride-induced corrosion. In both, it is the loss of protective alkalinity that permits eventual, active corrosion.

7 CONCLUSION

The work reported herein shows that the primary role of chlorides in so-called 'chloride-induced' corrosion of reinforcement lies in accelerating the solubility of the alkaline calcium hydroxide in the concrete matrix, including around the reinforcing bars and thereby eventually allowing depassivation of the steel reinforcement. Evidence was presented also that initiation is largely the result of air-voids at the concrete steel interface and therefore is controlled mainly by concrete mix design and by compaction of the concrete. This relates directly to an important part the usually poorly defined 'good workmanship' required for good concretes.

Damage accumulation in aging highway bridges considering multiple earthquake events

B. Panchireddi, U. Yadav & J. Ghosh
Indian Institute of Technology Bombay, Mumbai, India

ABSTRACT: Aging highway bridges exposed to harsh environmental conditions and located in active seismic regions may reveal a cumulative increase in earthquake-induced damage along their service lives when compared to pristine structures. While environmental degradation mechanisms are typically continuous throughout the lifetime, earthquake shocks are intermittent that depend on the seismicity of the region. Among different aging mechanisms commonly observed in bridges, this study focuses on corrosion deterioration of critical bridge components such as bridge piers. A framework is proposed that simultaneously considers multiple earthquake occurrences and corrosion deterioration of bridge components in determining the damage accumulation. Along with the statistical uncertainty associated with corrosion deterioration and occasional main-shock occurrence, uncertainties stemming from material properties is also considered in this study. For a representative case-study bridge in California, an appreciable increase is observed in the cumulative damage index while considering the effects of corrosion deterioration as compared to pristine bridge structures.

1 INTRODUCTION

The health and prosperity of transportation infrastructure is critical for the growth of the nation. Highway bridges, which are the critical components of the transportation infrastructure are facing substantial structural problems. For example in United States, more than one in nine bridges are labeled as structurally deficient or functionally obsolete and moreover many bridges among them are at the end of their service life period (FHWA 2016). In India, investigations by Wakchaure & Jha (2011) revealed that total road network includes 70,934 km of National Highways. It is found that in about 14,500 bridges on the National Highways, 1713 bridges are in distressed condition that may require repair or rehabilitation and 2018 bridges to be old and weak that may require reconstruction.

Highway bridges are subjected to a multitude of stressors along their service life when exposed to the outside environment. Among such stressors, corrosion deterioration emerges as a primary mechanism that affects the performance of highway bridges (Vu & Stewart 2000). Bridges as well as any other structures in nature, deteriorate over time. Corrosion is a continuous process that deteriorates the bridge throughout its service life and is random in nature, often marked by significant level of uncertainty (Enright & Frangopol 1998, DuraCrete 2000, Choe et al. 2008). In recent times efforts have been made to include the corrosion in the performance prediction, design, construction and maintenance of the reinforced concrete (RC) structures.

Across the globe, many highway bridges are located in seismically active regions and are likely to experience continued exposure to earthquakes in the form of main shocks and aftershocks throughout their service life. Repeated earthquake loads lead to the damage accumulation in the bridge which may eventually cause a structural collapse if the threshold limiting capacity is exceeded. The prediction of the remaining life period of the partially deteriorated bridges is necessary for the optimum management of the bridge. The inherent weakening of the bridge structure after the first earthquake may finally lead to collapse of the structure for relatively lesser intensity subsequent earthquakes. Repeated seismic loads on the RC structures weakens the structures elements which may increase the cost of retrofitting and repair of the structure. The annual direct costs of repair of these bridges are estimated to be in billions. Hence the prediction of level of damage in an RC structure due to earthquake loads is utmost necessary. The critical step here is to choose an indicator which actually represents the cumulative damage of bridges under repeated seismic shocks. This study adopts Park and Ang damage index as it has consistency and good correlation with experimental test

data for buildings and bridges (Chai et al. 1994, Williams & Sexsmith 1997).

Even though the determination of damage accumulation after multiple earthquakes for RC structures is critical, very few studies have been reported in the literature. Lee et al. (2009) evaluated the effect of repeated earthquakes on RC bridge piers considering one real and one artificial earthquake loads. Investigations by Wen & Kang (2001a, b), Ghosh & Padgett (2010) and Sanchez-Silva et al. (2011) while calculating the seismic life-cycle analysis of pristine or deteriorating bridges assume that the bridges are completely repaired to pristine level before the occurrence of next earthquake. Kumar & Gardoni (2012) emphasized the importance of considering the occurrence of more than one damaging earthquake during the in seismic design. Abdelnaby & Elnashai (2014) reports that the structures subjected to series of seismic loads may occur as a result of significant reduction in the stiffness and strength properties of structural components. Nazari et al. (2015) and Zhai et al. (2014) focused on the quantification of the amount of damage accumulation in buildings. Ghosh et al. (2015) have investigated on the damage accumulation in bridges that are subjected to multiple earthquakes. However, the deterioration mechanism due to corrosion in conjunction with multiple earthquake occurrences is not considered in most of the above studies. The present study mainly focuses on the damage accumulation in bridges subjected to multiple main-shocks considering the effect of uniform corrosion deterioration in California region where the environmental condition is mostly marine.

The next section of the paper discusses the process of corrosion deterioration in RC structures and its ill-effects on bridge components.

2 CONTINUOUS DEGRADATION OF BRIDGE COMPONENTS DUE TO CORROSION

Corrosion is a natural process that may cause weakening of the structural components and lead to reduction in the load carrying capacity or even failure of the critical components of the structure (Kayser & Nowak 1987). In RC structures, corrosion process consists of two phases:- the corrosion initiation phase and the corrosion propagation phase (Liu & Weyers 1998).

2.1 *Corrosion initiation phase*

Chloride penetration in concrete causes the corrosion in RC structures as the protecting passivating layer around the steel is dissolved by the chloride ions. Corrosion initiates when the chloride concentration exceeds a critical threshold value around the steel reinforcement. For marine environmental conditions under chloride induced corrosion, this study adopts the initiation time (T_i) from DuraCrete (2000).

2.2 *Corrosion propagation phase*

In reinforced concrete structures, after the end of corrosion initiation phase, the propagation phase begins. Corrosion rate is an important parameter in determining the extent of deterioration (loss in reinforcing area, cover and core concrete strength etc.) and the resulting damage from corrosion. This study adopts the parametric equation for corrosion rate proposed by DuraCrete (2000) as a function of relative humidity, temperature and chloride content that clearly are the parameters influence by corrosion. More details can be found in DuraCrete (2000).

2.3 *Effects of corrosion on material properties*

The corrosion process not only reduces the area of reinforcing steel bars but may also lead to the loss of ductility of material that could possibly cause the brittle failure in concrete members (Coronelli & Gambarova 2004, Stewart 2009). Almusallam (2001) stated that even for a limited mass loss of steel (about 13%) makes its behavior more brittle. The formation of oxidized products due to corrosion leads the propagation of longitudinal cracks and spalling of the concrete cover. In addition to area loss of steel, other secondary effects considered in this paper are presented below.

2.3.1 *Effects of corrosion on concrete*

To estimate the residual capacity of the bridge that is affected by corrosion, the reduction in the properties of cover concrete strength has to be taken into account. This study adopts the reduced cover concrete strength due to micro-cracking from rust formation as proposed by Coronelli & Gambarova (2004) and Molina et al. (1993).

2.3.2 *Effects of corrosion on reinforcing steel*

Experiments conducted by Du et al. (2005) reveals that the residual strength of reinforcing steel depends on the residual area of the steel. It is obvious that the residual area of steel depends on the rate of corrosion. The residual strength of steel is given by

$$f(t) = \left(1.0 - 0.005\, Q_{corr}(t)\right) f_0 \tag{1}$$

where, f and f_0 are the yield or ultimate strengths of corroded and non-corroded reinforcing bars respectively, Q_{corr} is the amount of corrosion of reinforcement (%) which depends on the residual area of reinforcement and is given by

$$Q_{corr}(t) = \frac{A_{s0} - A_s(t)}{A_{s0}} \times 100 \tag{2}$$

where, $A_s(t)$ is the average cross-sectional area of the corroded reinforcement and A_{s0} is the initial cross-sectional area of non-corroded reinforcement.

The next section of the paper explains the determination of damage accumulation index in bridges subjected to multiple earthquakes with and without considering corrosion deterioration.

3 INTERMITTENT DAMAGE DUE TO EARTHQUAKES AND DAMAGE ACCUMULATION FRAMEWORK

Bridges located in moderate to high seismic zones are more likely to experience multiple earthquakes in the form of multiple main-shock events or mainshock-aftershock sequences. This study limits only to multiple mainshock events during the service life period of the bridge. The framework for prediction of damage index in the bridge due to multiple main-shocks for both pristine and corroded bridge conditions is detailed below.

3.1 *Predictive damage accumulation indices*

The Park & Ang (1985) damage index considers both the limit states such as: a) ductility or monotonic structural deformation, and b) dissipated hysteric energy. This index estimates the level of damage in reinforced concrete elements and structures that are subjected to cyclic loading as:

$$D = \frac{\mu_m}{\mu_u} + \beta \frac{E_h}{M_y \theta_y \mu_u} \tag{3}$$

where, D is the Park and Ang damage index, μ_m is the maximum ductility caused by the earthquake, μ_u is the ultimate ductility capacity under monotonic loading, E_h is the total dissipated hysteretic energy, M_y is the yield moment capacity, θ_y is the yield rotation angle, and β is a dimensionless constant usually assumed to be 0.05 for RC structures. The engineering demand parameters (*EDP*s) μ_m and E_h are directly correlated with the intensity of ground motion and the properties of the structure. For instance, Cornell et al. (2002) highlighted that the *EDP*s can be related to the intensity of ground motions using the equation given by

$$EDP = a(IM)^b \tag{4}$$

where, a and b are regression coefficients and IM is the peak intensity of seismic shocks. To represent linear regression model, the Equation 4 can be transformed into linear equation as

$$\ln(EDP) = \ln(a) + b\ln(IM) \tag{5}$$

For single shock events, the damage index D is expected to be linearly varying with IM as shown in the equation

$$\ln(D_1) = \alpha_1 + \beta_1 \ln(IM_1) \tag{6}$$

where, D_1 is the damage index after the first earthquake excitation, α_1 and β_1 are the regression coefficients and IM_1 is the ground motion intensity of the first earthquake shock.

However, when the corrosion deterioration is considered, the damage index after first shock depends on both the intensity of the earthquake, as well as the time along service life of degrading bridge structure when this first shock occurs. So, for the same single shock events, the damage accumulation index for corrosion case (say D_{1C}) is expected to be a linearly varying with IM and the time to first shock (t_1).

$$\ln(D_{1C}) = \alpha_{1C} + \beta_{1C} \ln(IM_1) + \gamma_{1C}\, t_1 \tag{7}$$

where, D_{1C} is the damage index after the first earthquake excitation considering corrosion, α_{1C}, β_{1C} and γ_{1C} are the regression coefficients, IM_1 is the ground motion intensity of the first earthquake shock and t_1 is the time to first shock.

Unlike single shock events, the damage index evaluation due to multiple earthquake shocks also depends on previous damage and hence the history of previous earthquake shocks. The total energy dissipated (E_h) due to multiple earthquakes will be cumulative (Equation 8) while the maximum ductility (μ_m) may have achieved during the most immediate seismic pulse or during any of the previous seismic pulses depending on the intensity of earthquake shocks (Equation 9).

$$E_h = E_{h1} + E_{h2} \tag{8}$$

The maximum curvature ductility is given by

$$\mu_m = \max(\mu_{m1}, \mu_{m2}) \tag{9}$$

where, E_{h1} and E_{h2} are the dissipated hysteretic energy after the first and second earthquake respectively, μ_{m1} and μ_{m2} are the corresponding maximum curvature ductilities due to first and second earthquakes.

The damage index in the structure increases with every shock as represented by the following equation

$$D_n > D_{n-1} > D_{n-2} > .... > D_2 > D_1 \tag{10}$$

where, D_n is the damage index of the structure after it has been exposed to n shocks. Consequently, the damage index after n earthquake shocks can be described as a multilinear regression model and is given as following (Ghosh et al. 2015).

$$\ln(D_n) = \alpha_n + \beta_n \ln(IM_n) + \gamma_n \ln(D_{n-1}) ... \\ ... + \delta_n \ln(IM_n)\ln(D_{n-1}) \tag{11}$$

where, D_n is the damage index after the n^{th} earthquake shock with ground motion intensity of IM_n. $D_{n\text{-}1}$ is the damage index after n-1 earthquake

shocks. The parameters α_n, β_n, γ_n and δ_n are the regression coefficients.

Consideration of corrosion deterioration in bridges located in seismic regions is expected to further contribute to damage accumulation. In other words, the damage accumulation in the corroding structure subjected to n earthquake shocks is likely to be greater than that of the damage accumulation for the same structure subjected n shocks in pristine condition (Equation 12).

$$D_{nC} > D_n \tag{12}$$

The index (D_{nC}) representing damage index of the corroded structure after it has been exposed to n shocks, can be expressed as the following equation

$$\ln(D_{nC}) = f\left[IM_n, D_{(n-1)C}, t\right] \tag{13}$$

where, $D_{(n\text{-}1)C}$ is the damage index after n-1 earthquake shocks considering corrosion deterioration and t is the time to n^{th} seismic shock. While some of the proposed functional forms for damage index calculation in corroding structures may be speculative, the adequacy of the models will be demonstrated later in the case-study example.

3.2 *Damage index exceedance probabilities: Lifetime main shock hazard*

As indicated earlier, the damage accumulation index is now a multi-dimensional parameter and can be expressed as a regression equation. The probability of exceeding different levels of damage given the structure is subjected to certain number of earthquakes is calculated. This probability expressed as $P[D>d \mid n\ shocks]$, can be evaluated using Monte Carlo trials. Based on the earthquake occurrence probabilities, first a large number of earthquake intensities are generated. The probability of exceeding a certain level of damage index is then computed using Equation 14.

$$P\left[D>d \mid n\,shocks\right] = \frac{1}{N_{MC}} \sum_i I\left[D_{ni} > d\right] \tag{14}$$

where N_{MC} is the total number of Monte Carlo simulations, D_{ni} is the accumulated damage index after n shocks for the i^{th} Monte Carlo simulation and I[.] is the indicator function which equals to 1 when I[.] is true and 0 if I[.] is false. The damage accumulation framework for deteriorating bridges and pristine bridge structures is demonstrated in the next section using a case-study example.

4 CASE STUDY

Given the potential of frequent earthquake events, this study demonstrates the proposed damage accumulation framework for a case-study bridge located in California. While several researchers have investigated the potential vulnerability of highway bridges (as-built or aging) in California (Mackie & Stojadinović 2001, Zhang & Huo 2009, Alipour et al. 2010), literature on damage accumulation due to repeated earthquake events and aging is negligible.

4.1 *Representative case-study bridge: Bridge attributes and numerical modelling*

Ramanathan (2012) has conducted extensive review of the different bridge types in California region and revealed that the highest percentage of overall bridge inventory are the multi-span continuous box-girder bridges. The current study considers a typical 2-span box-girder bridge with 3 cells. The layout of the adopted box-girder bridge is illustrated in the Figure 1. In this study single square column bents are adopted instead of rectangular columns without altering the typical crosssectional area for simplicity.

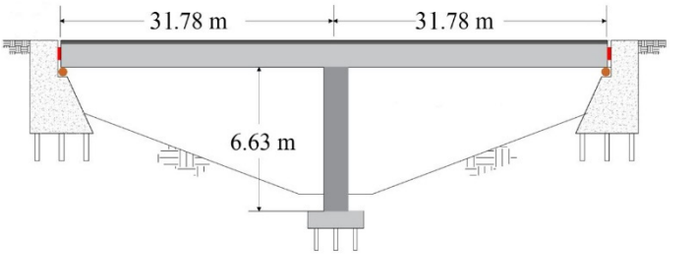

Figure 1. Layout of adopted two-span box-girder bridge

This study adopts the basic material properties such as concrete compressive strength (f_{ck}), yield strength of steel (f_y), bridge properties such as column height (H), span length (L) based on the extensive review of bridges conducted by Mangalathu et al. (2016) using in-house database obtained from Caltrans. The weight of the super structure is calculated to be 5200 kN for the case-study bridge. Since the present study limits to the modeling of the bridge column, the super-structure mass including the self-weight of the column is assumed to be represented as a lumped mass on the column. The column consists of 1.29 m × 1.29 m section and longitudinal steel reinforcement ratio of 2.25% of the cross-sectional area. The bridge column is modeled in OpenSees (Mazzoni et al. 2009) as a beam-column element using nonlinear *RCSection2d*. The concrete is modeled using *Concrete04* material and steel is modeled using *Hysteretic* material which is capable of considering the strength degradation during repeated load cycles. *RCSection2d* command allows area updating that is necessary to determine damage accumulation of aging highway bridges. However, material property updates are newly introduced in this paper as will be elaborated in the later section.

The probability distribution of parameters involved in determining the corrosion initiation time is adopted from Choe et al. (2008) and DuraCrete (2000). The average corrosion initiation time considering a cover depth of 38.1 mm (Choe et al. 2008)

for the case-study bridge is observed to be 10 years. Figure 2 and Figure 3 shows the variation of cover concrete strength and reinforcement area of steel with service life period along with the uncertainty band (mean ± standard deviation) that indicates the variability around the mean value.

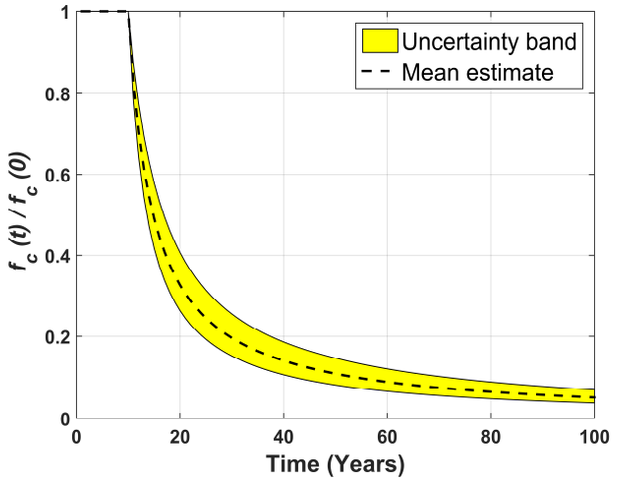

Figure 2. Variation of cover concrete strength with time

Figure 2 indicates that the cover concrete strength of the bridge column greatly affected by corrosion deterioration. There is a substantial concrete strength loss of about 90% in the exposure period of 100 years. Figure 3 reveals that the reinforcing area of steel reduces to about 75% of its original value after the exposure period of 100 years.

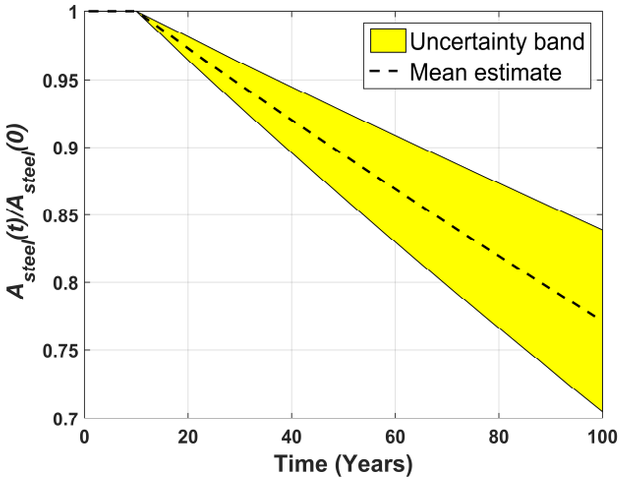

Figure 3. Variation of reinforcing area of steel with time

4.2 *Effect of corrosion deterioration on flexural capacity of case-study bridge column*

To determine the effect of corrosion deterioration on the flexural capacity of the bridge column, pushover analysis is performed on the pristine column and deteriorating column under uniform corrosion at 25, 50, 75 and 100 years of service life of the bridge. The moment and curvature values obtained through the analysis are recorded for all the cases.

Figure 4 shows the idealized moment-curvature plots along with the yield and ultimate points. It can be seen that the corrosion deterioration leads to the reduction in the yield moments which increases the curvature ductility of the structure. The Park and Ang damage index thereby increases indicating the impact of corrosion on flexural capacity of column. Compared to pristine bridge column, the yield moment of the steel has been reduced by 6.8%, 12.25%, 15.4% and 24.28% for the cases of uniform corrosion deterioration for 25, 50, 75 and 100 years respectively. From Figure 4 it can also be observed that the ultimate curvatures and ultimate moments being reduced with the exposure time period which clearly indicates that the corrosion deterioration effects the flexural capacity of bridge column.

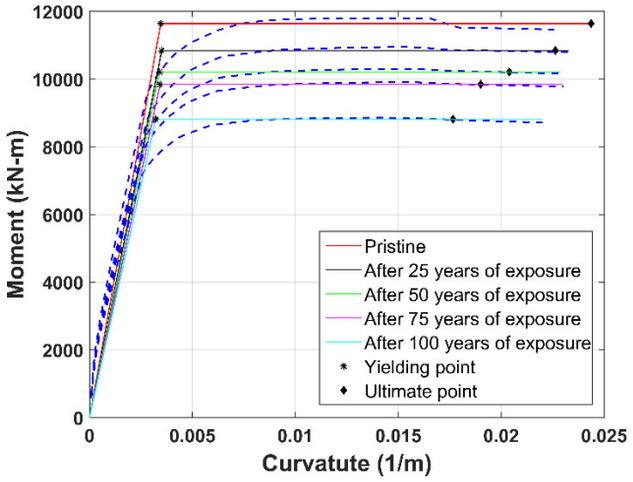

Figure 4. Pushover curves for the case-study bridge column in pristine condition and corrosion deterioration condition after 25, 50, 75 and 100 years of service life.

4.3 *Damage index measurements for single and multiple earthquakes*

The damage index measurement for the non-linear time history analysis of the bridge structures subjected to earthquake loads requires the estimation of maximum curvature ductility caused by the earthquake, the ultimate ductility capacity obtained from the pushover analysis and the dissipated hysteretic energy as explained earlier (Equation 3). Earthquake pulses from a suite of 100 ground motions develop by Gupta & Krawinkler (2000) and Krawinkler et al. (2003) for the California region are adopted for the present study. The peak ground accelerations (PGAs) of these ground motions range from 0.03-1.3 g and the duration varying from 28.7- 99.96 sec.

4.3.1 *Single earthquake scenario*

To quantify the damage index, the bridge column is subjected to single earthquake shock selected randomly from 100 available ground motions. The analysis was carried out for both the pristine and corroded bridge column conditions. Figure 5 pre-

sents the linear regression fit of the damage index with intensity of the single earthquake ground motion for a pristine bridge condition. The fitted linear regression equation is obtained as following

$$\ln\left(D_1\right) = 0.14 + 1.72\ln\left(PGA_1\right) \quad (15)$$

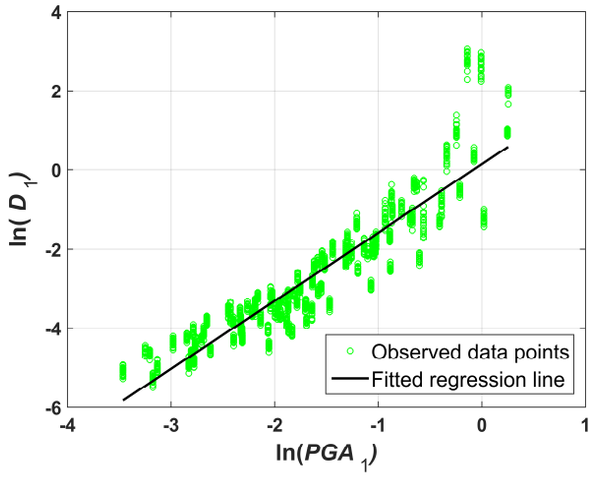

Figure 5. Linear regression model for predicting the damage index following a single shock occurrence for a pristine bridge

A good value of the coefficient of determination (R^2) of 0.84 and a relatively low estimate root mean squared error (*RMSE*) of 0.44 indicates that the model regression fit is adequate.

When the corrosion deterioration is considered, the damage index after the first shock (D_{1C}) depends also on time to first shock (t_1). Since the time when the earthquake occurs during the service life of the bridge is uncertain, a uniform distribution is assumed. Figure 6 shows the multi-linear variation of damage index for a corroded bridge subjected to a single shock. It can be clearly seen that for larger intensity earthquakes, the damage index at end of service time is very critical.

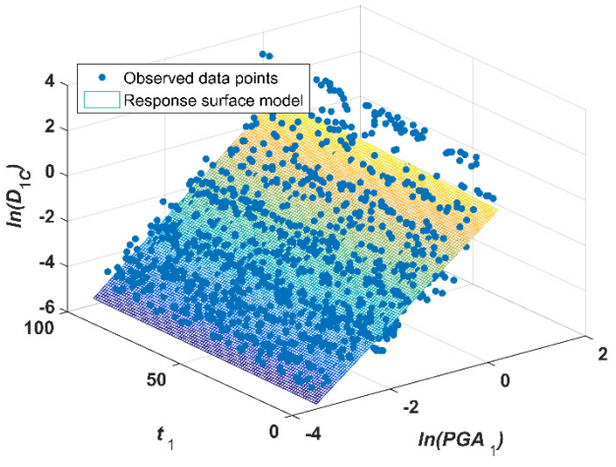

Figure 6. Multilinear regression model for predicting the damage index of a corroded bridge section subjected to single earthquake shock

The multilinear regression equation for D_{1C} in terms of PGA_1 and t_1 is given by

$$\ln\left(D_{1C}\right) = 0.18 + 1.76\ln\left(PGA_1\right) + 0.003t_1 \quad (16)$$

The regression equation has a coefficient of de termination (R^2) of 0.81 and a relatively low root mean squared error (*RMSE*) of 0.55 indicating the regression fit to be adequate.

4.3.2 *Multiple earthquake scenario*

Damage accumulation in bridges due to multiple shocks depends on the accumulation of damage in bridges due to previous earthquakes and the impact of ongoing corrosion deterioration. This study limits the number of earthquake shocks to two for damage accumulation comparison in pristine and deteriorating bridge structures. It should be noted that when the corrosion deterioration is considered, the material properties need to be updated before analyzing the response of the bridge subjected to second and subsequent earthquake shocks. Hence, the bridge column that is modeled using OpenSees should now be capable of updating the material properties of steel and concrete, area of steel and other parameters that are affected by corrosion while still maintaining the damaged or deformed structure shape after the previous earthquake. However, while the *RCSection2d* command is capable of updating the area of the steel whenever necessary, other parameters such as concrete and steel material properties that are likely to change due to corrosion deterioration also requires updating. Consequently, new material definitions for concrete and steel are added to the source code which have the same baseline properties as that of *Concret04* and *Hysteretic* material, but with additional capability of updating the parameters whenever necessary. This procedure is briefly explained in the following section.

4.3.2.1 *Modification of OpenSees source code*

Each material defined in OpenSees has a C++ code file (with a ".cpp" extension) and an associated header file (with ".h" extension). Similar in lines to the already existing *Concrete04* and *HystereticMaterial* files, this study added two new material files. These new materials were named *ConcreteUpdate* and *HystereticUpdate* and have no functional difference when compared with their non-updatable precursors. After reviewing the source files of already existing materials with updatable parameters it can be observed that the updation of parameters is possible only if the material class contains certain virtual functions of the class MovableObject defined in MovableObject.h. Additionally, every updatable parameter is identified by its parameterID. Consequently, three functions namely setParameter, updateParameter, activateParameter were identified and added to the new material classes in the header files and their definitions were stated externally in the .cpp files of the new materials. These functions were identified as critical components to implement

the parametric updating of the material properties. In order to create the user input for a material in OpenSees an OPS function is declared in the model builder files: TCLModelBuilderUniaxialMaterialCommand.cpp. The header file <OPS_Globals.h> and the input function definition is now added in the new material files respectively and all the parameters are initialized in the constructor. For a successful compilation of the source code with new materials, it is also necessary to modify the software development files namely material.vcxproj and material.vcxproj.filters. With all the above mentioned changes, this new source code of OpenSees was compiled successfully leading to a new OpenSees executable. This step ensures that in addition to the area of steel for a corroding and already damaged bridge, the material characteristics of steel and concrete can also be simultaneously updated. The dynamic analysis of the bridge subjected to the second earthquake followed by the first earthquake is conducted using the new updated OpenSees executable

4.3.2.2 *Damage index determination*

The multilinear regression equation for damage index calculation when the corrosion deterioration is not considered is as follows

$$\ln\left(D_2\right) = 0.07 + 0.14\ln\left(PGA_2\right) + 0.07\ln\left(D_1\right)\ldots \\ \ldots - 0.34\ln\left(PGA_2\right).\ln\left(D_1\right) \tag{17}$$

When the corrosion deterioration is considered the damage index after the second earthquake (D_{2C}) is not only a function of PGA_2 and D_{1C} but also the function of time to second shock (t_2). The multilinear regression equation is found to be

$$\ln\left(D_{2C}\right) = 0.36 + 0.27\ln\left(PGA_2\right) + 0.002t_2\ldots \\ \ldots + 0.11\ln\left(D_{1C}\right) - 0.32\ln\left(PGA_2\right).\ln\left(D_{1C}\right) \tag{18}$$

The above equations are fitted to have a minimum value of the coefficient of determination (R^2) of 0.80 and a relatively low estimate root mean squared error (*RMSE*) of 0.5 indicating that the model regression fits are satisfactory.

4.3.3 *Damage index exceedance probabilities for both corrosion and non-corrosion cases*

Figure 7 depicts the probability of exceedance of different levels of damage index as the column is subjected to two main shocks for both corrosion and non-corrosion cases using Equation 14. The figure reveals that the probability of structural damage increases with number of shocks. Additionally, irrespective of the number of shocks, the probability of failure is higher for the corrosion case as compared to that of a pristine structure. For instance, say at a damage index value of 0.5, the percentage difference between the damage exceedance probabilities for corrosion and non-corrosion cases are found to be 19% for the single shock scenario and 36% for the two-shock scenario. These results clearly indicate the necessity of considering aging mechanisms within a probabilistic framework while estimating the seismic performance of highway bridge structures.

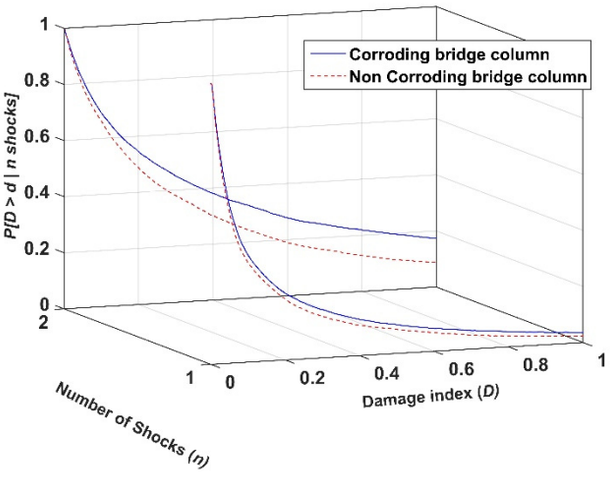

Figure 7. Probability of exceedance of different levels of damage index subjected to different number of earthquake shocks ($P[D > d \mid n\,shocks]$).

5 CONCLUSIONS AND FUTURE WORK

Bridges, which have a unique role in the transportation network and are more susceptible to corrosion deterioration due to which these bridges are turning to be structurally deficient and their number is increasing greatly. Also, bridges located in high seismic regions may experience continued exposure to earthquakes. Low intensity earthquakes may not directly collapse the structure but impart damage accumulation in it. The quantification of this damage considering the continuous effect of corrosion deterioration should be performed in order to assess the condition of the bridge. A damage accumulation framework for single and multiple earthquake scenarios for both pristine and corroded bridge condition is detailed in this study. The OpenSees source code for the concrete and steel materials are rewritten in such a way that they are capable of updating the parameters whenever necessary as the damage accumulation in the bridges for multiple earthquake events needs the material properties to be updated. An appreciable impact of corrosion deterioration on the damage accumulation index is observed through this study for the single earthquake events. For instance, say at a damage index value of 0.5, the percentage difference between the damage exceedance probabilities for corrosion and non-corrosion cases are found to be 19% for the single shock scenario and 36% for the two-shock scenario. A structure expected to be in moderate damage state that can be repaired to reuse may actually be in severe damage

condition that requires reconstruction when the effect of corrosion deterioration is considered.

The present study worked on damage accumulation in bridges considering multiple main-shocks events only. The effect of mainshock-aftershock sequences on the performance of corroded bridge structure could be a studied later. Seismic damage accumulation in highway bridges considering improved corrosion degradation models could be a future scope for study.

Optimum lifetime inspection and maintenance planning for bridges considering utility

ABSTRACT: Highway bridges are constantly subjected to deterioration mechanisms that contribute to an overall decrease in structural resistance and increase in loads over their life-cycle. In order to ensure that the performance of bridges is maintained throughout their lifetime, cost efficient bridge intervention planning must be considered. An optimization procedure for life-cycle inspection and maintenance planning of highway bridges is proposed herein. The proposed approach considers three objectives: the minimization of life-cycle costs, the maximization of sustainability, and the minimization of the expected damage detection delay, all in a probabilistic, life-cycle context. Utility functions are used in order to consistently quantify and compare the three aforementioned objectives. Overall, the proposed approach can be used to establish optimum lifetime inspection and maintenance plans for highway bridges considering life-cycle costs, sustainability, and expected damage detection delay.

1 INTRODUCTION

The performance of deteriorating highway bridges can be quantified at the cross-section, component, or overall structural (system) level. Typically, performance assessment activities associated with the components rely on visual inspections results. Visual inspection results are usually employed to establish a condition rating index to measure the bridge's remaining load-carrying capacity. The conditions of bridges in the United States are rated using two different methods based on visual inspection (i.e., National Bridge Inventory (NBI) condition rating system and Pontis). Generally, bridge management systems characterize the performance of structural elements by discrete condition states which incorporate predefined degrees of damage (Hawk & Small 1998; Thompson *et al.* 1998). Based on the identified condition states, maintenance interventions may be prioritized among all inspected structural components.

As a result, it is advantageous to study the effect of inspections on the maintenance activities of a bridge. In order to ensure that the performance of deteriorating highway bridges is maintained throughout their lifetime, cost efficient bridge intervention planning must be considered. An optimization procedure for life-cycle inspection and maintenance planning of highway bridges is proposed herein. The proposed approach considers three objectives: the minimization of life-cycle costs, the maximization of sustainability, and the minimization of the expected damage detection delay, all in a probabilistic, life-cycle context. Utility functions are used in order to consistently quantify and compare the three objectives. The outputs of the proposed optimization procedure are optimal lifetime inspection and maintenance plans for a bridge (e.g., when to inspect and repair the bridge). Ultimately, this decision support tool can be employed to ensure that decision makers implement cost optimized decisions regarding inspection and maintenance associated with highway bridges.

2 SUSTAINABILITY ASSESSMENT

Within the context of life-cycle and structural engineering, two definitions of sustainability are typically considered when establishing sustainability metrics. The first representation of sustainability defines it as: "meeting the needs of the present without comprising the ability of future generations to meet their own needs" (Adams 2006). The second definition of sustainability is sometimes referred to as the "triple bottom line" because it emphasizes that economic, environmental, and social objectives must be simultaneously satisfied within a sustainable design or plan (Elkington 2004). Considering these definitions, it is important to measure the performance of highway bridges whose functionality is vital for economic and social purposes. Generally, sustainability should be quantified in terms of economic, social,

and environmental metrics, as indicated in Figure 1. In this section, the procedure for determining the sustainability associated with a particular lifetime maintenance plan using utility theory and the widely accepted definitions of sustainability is outlined.

The inclusions of societal and environmental impacts along with economic consequences effectively encompass the concept of sustainability within a robust risk analysis framework. Combining the economic, societal, and environmental, risk metrics allows decision makers to make informed decisions regarding the lifetime intervention planning by providing them with a complete picture of system performance (Sabatino *et al.* 2015, 2016). Generally, a structure is more sustainable if its life-cycle cost is relatively low. On the other hand, a structure is more sustainable if the energy, carbon dioxide emissions, and user delays arising from its maintenance are low. For highway bridges under repair, in general, the social metrics may include downtime and fatalities.

Utility theory is used herein in order to depict the relative desirability of lifetime intervention strategies (e.g., lifetime inspection and maintenance plans) to the decision maker. In general, utility is defined as a measure of value to the decision maker; utility theory provides a framework that can measure, combine, and consistently compare these relative values (Ang and Tang 1984, Sabatino *et al.* 2015, 2016). Multi-attribute utility theory can then be used to transfer the utility of each attribute involved in the performance assessment (e.g., economic, social, and environmental risks) into one utility value that effectively combines the effects of all risks investigated as shown in Figure 2. This flowchart shows the computation procedure for calculating a sustainability metric that is expressed as a multi-attribute utility value. In this procedure, u_i and k_i represent the utility function and associated weighting factor corresponding to the ith risk attribute.

The first step in the sustainability assessment is to evaluate the performance of a bridge considering the

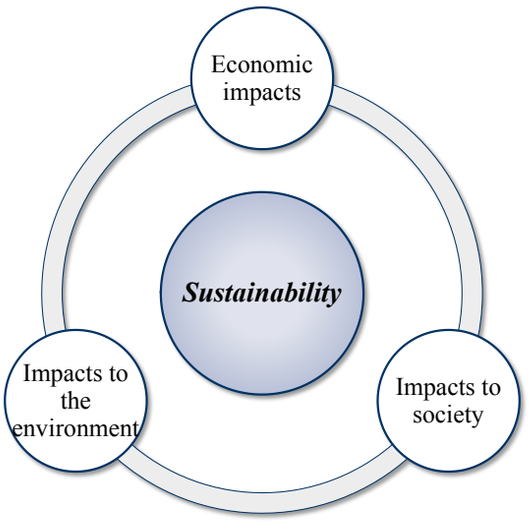

Figure 1. The three metrics of sustainability

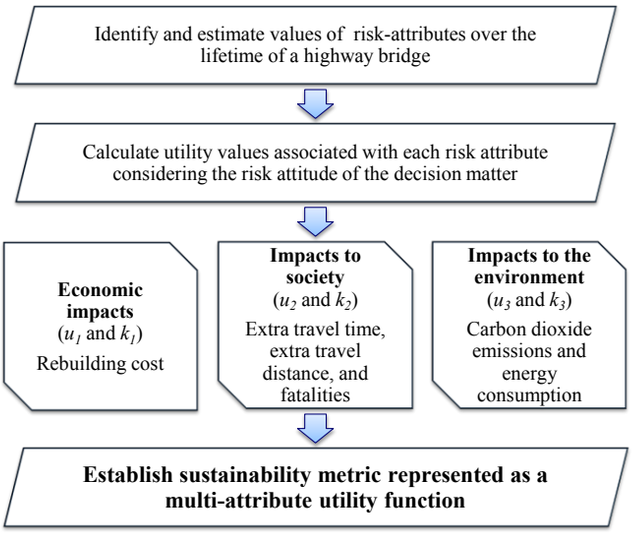

Figure 2. Procedure for calculating the multi-attribute utility value representative of sustainability

associated hazards. An increase in live loads and the effect of chloride contamination are the hazards considered herein for bridge superstructures. For the proposed decision support tool, the probability of system failure is considered as input information. The next step includes the risk assessment process. The risk attributes investigated herein include the rebuilding and repair costs, extra travel time and distance that drivers endure, fatalities that may occur, energy consumption, and carbon dioxide emissions.

After estimating the lifetime risks associated economic, environmental, and societal consequences of failure, the decision maker can assign utility values to the investigated attributes (e.g. risk attributes) associated with each alternative considering his/her risk attitude. Utility theory is applied in order to normalize each attribute value corresponding to solution alternatives (i.e., lifetime intervention plans) to a number between 0 and 1; this ensures that all attributes are directly comparable to each other. The formulation of the utility function corresponding to each attribute depends on the knowledge, preferential characteristics, and risk attitude of the decision maker. For the risk attributes analyzed, each of the corresponding utility functions may be formulated as monotonically decreasing functions. Considering an exponential formulation, the utility associated with a single attribute (e.g., economic, social, and environmental risks) can be expressed as (Ang and Tang 1984, Sabatino *et al.* 2015, 2016):

$$u_x = \frac{1}{1-\exp(-\gamma)}\left[1-\exp\left(-\gamma\frac{x_{\max}-x}{x_{\max}-x_{\min}}\right)\right] \quad (1)$$

where x is the mean of the attribute under investigation, x_{max} and x_{min} denote the maximum and minimum value of the attribute, respectively, and γ is the risk attitude of the decision maker. Note that $\gamma > 0$ indicates risk-aversion and $\gamma < 0$ denotes risk-acceptance.

A multi-attribute utility function that effectively represents all aspects of sustainability can then be obtained by combining the utility functions associated with each risk attribute. The multi-attribute utility function representative of sustainability of a highway bridge is (Sabatino *et al*. 2015)

$$u_s = k_1 u_1 + k_2 u_2 + k_3 u_3 \quad (2)$$

where k_1, k_2, and k_3 are the weighting factors corresponding to each sustainability metric, economic, social, and environmental attributes, respectively and u_1, u_2, and u_3 are the utility functions for the economic, social, and environmental attributes, respectively.

3 EXPECTED DAMAGE DETECTION DELAY ASSOCIATED WITH INSPECTION

Damage detection using particular inspection methods and the analysis and interpretation of inspection data are associated with significant uncertainties, including the randomness of damage occurrence and the imperfection of an inspection method. Because there are two events corresponding to an inspection results of "no damage" (i.e., no damage occurrence or damage occurs but is not detected), it is imperative to include the probability of detecting damage and the inspection quality within this probabilistic lifetime intervention planning framework (Mori & Ellingwood, 1994, Frangopol & Estes 1997, Enright & Frangopol 1999, Estes & Frangopol 2001, Onoufriou & Frangopol 2002). This section describes the procedure for calculating the expected damage detection delay associated with an inspection schedule. The procedure for calculating the expected damage detection delay associated with an inspection schedule is outlined in Figure 3.

The ability to detect damage depends upon the quality of inspection technique being employed, severity of damage, and number and timing of inspections. Considering the severity of the damage, the quality of inspection method can be quantified with a detectability function $P_{ins}(\delta)$. The detectability function represents the probability that a particular damage intensity, characterized by δ, is detected at time t (Frangopol *et al.* 1997).

$$P_{ins}(\delta) = \Phi\left(\frac{\delta - \delta_{0.5}}{\sigma_\delta}\right) \quad (3)$$

where $\Phi(\cdot)$ = standard normal cumulative distribution function, $\delta_{0.5}$ = damage intensity at which the inspection method has a 50% probability of detection, and σ_δ = standard deviation of the damage intensity $\delta_{0.5}$

Damage detection delay is defined as the duration between the point in time when a structure has been damaged and the instance in time when the damage is identified by inspection (Kim & Frangopol 2011,

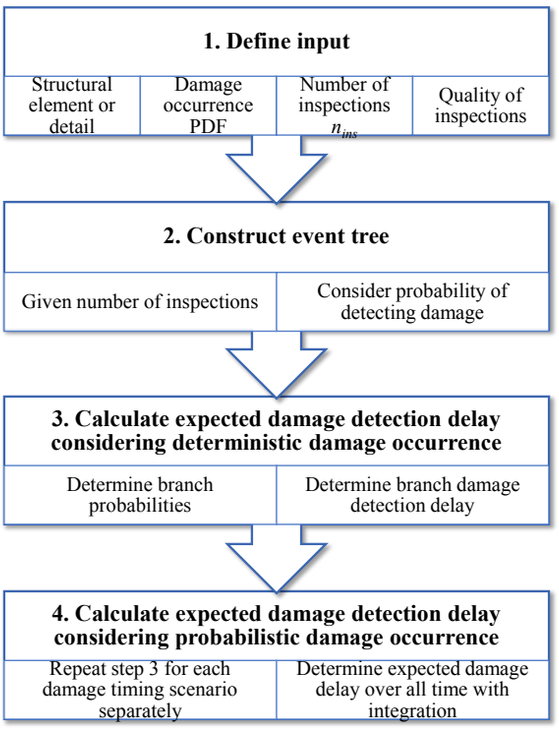

Figure 3. Procedure for calculating the expected damage delay associated with an inspection schedule

Kim *et al.* 2013, Sabatino & Frangopol 2017). The detection delay is calculated as

$$t_D = t_{ins} - t_d \quad (4)$$

where t_d = actual time that damage occurs and t_{ins} = time of inspection. Equation 4 assumes that the inspection method employed is perfect; however, inspections are imperfect and uncertainties in the detection of damage are present. In order to account for the probability of damage detection, an event tree model can be established considering b_n = 4 inspections, as shown in Figure 4. This event tree encompasses all the possible events associated with detection and no detection at every inspection. Using the event tree model in Figure 4 and the branch probabilities and associated damage detection delays listed in Table 1, the expected damage detection delay can be expressed as (Kim & Frangopol 2011):

$$E[t_D] = \sum_{i=1}^{b_n} \left(P_{b,i} \cdot t_{D,i}\right) \quad (5)$$

Where b is the number branches considered in the event tree, $P_{b,i}$ is the probability occurrence of branch i, and $t_{D,i}$ is the damage detection delay associated with branch i.

The damage detection delay is also affected by the uncertainty of damage occurrence and propagation, in addition to the uncertainty associated with the inspection method. If four inspections are used, damage occurrence between each inspection must be considered. For instance, damage can occur before the first inspection (case 1), between the first and second inspection (case 2), between the second and

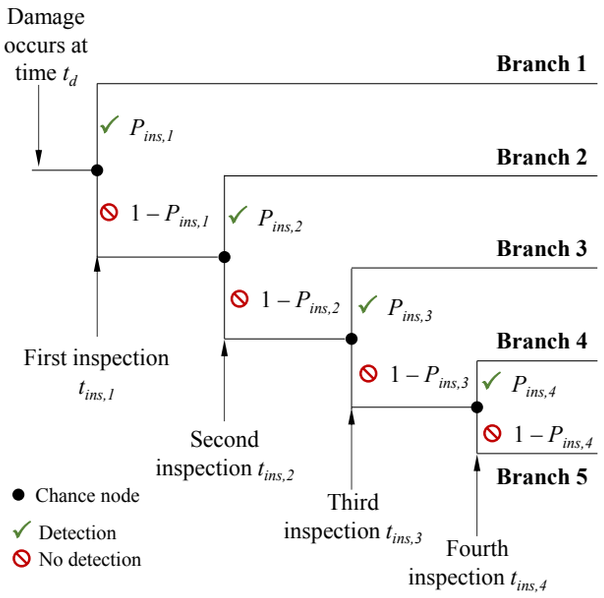

Figure 4. Decision tree for damage detection delay considering one element with four inspections

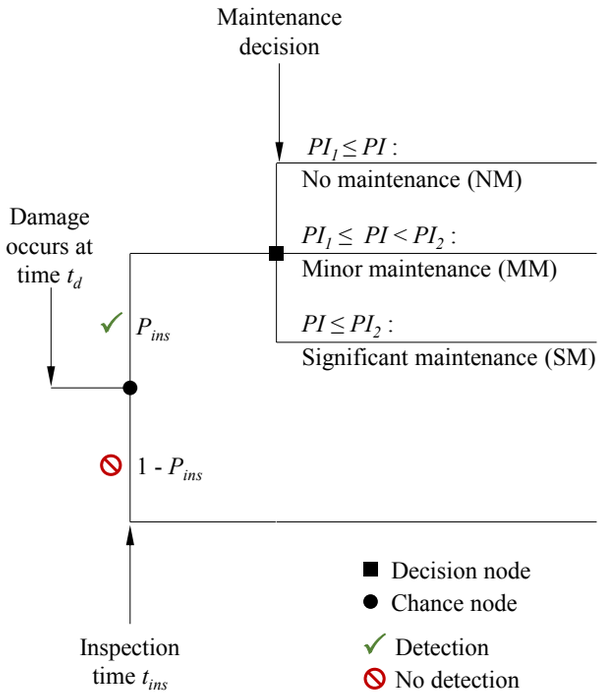

Figure 5. Decision tree for one inspection and maintenance of a structural element

third inspection (case 3), or between the third and fourth inspection (case 4). Considering these four cases when damage may occur and given the damage occurrence probability density function $f(t)$, the expected damage detection delay is (Kim & Frangopol 2011)

$$E[t_D] = \sum_{i=1}^{b_n} \left(\int_{t_{ins,\,i-1}}^{t_{ins,1}} \left(E[t_D]_{case,i} \cdot f(t) \right) dt \right) \quad (6)$$

Where $E[t_D]_{case,i}$ is the expected damage detection delay, when the damage occurs between the $(i-1)$th inspection and the ith inspection.

The interaction between inspection and maintenance plans are depicted in Figure 5. For each inspection detecting damage, a check is performed using a performance indicator PI and two prescribed threshold levels of this performance indicator, PI_1 and PI_2. If damage is detected and $PI \geq PI_1$, then no maintenance should be performed. However, if $PI_1 \leq PI < PI_2$ or $PI \leq PI_2$, then minor maintenance (e.g., preventative maintenance) or major maintenance (e.g., essential maintenance) should be implemented, respectively.

Once the expected damage detection is calculated for a particular lifetime inspection plan, then it may be converted to a utility value using Equation 1. This utility value u_d incorporates the risk-attitude of the decision maker to depict the relative value or attractiveness of using such an inspection plan.

Table 1. Event tree branch probability of occurrence and damage detection delay

Branch	Branch probability	Damage detection delay
1	$P_{ins,1}$	$t_{ins,1} - t_d$
2	$P_{ins,2}\ (1 - P_{ins,1})$	$t_{ins,2} - t_d$
3	$P_{ins,3}\ (1 - P_{ins,1})\ (1 - P_{ins,2})$	$t_{ins,3} - t_d$
4	$P_{ins,4}\ (1 - P_{ins,1})\ (1 - P_{ins,2})\ (1 - P_{ins,3})$	$t_{ins,4} - t_d$
5	$P_{ins,5}\ (1 - P_{ins,1})\ (1 - P_{ins,2})\ (1 - P_{ins,3})\ (1 - P_{ins,4})$	--

4 LIFE-CYCLE COST

One of the most critical metrics in the evaluation of bridge performance is life-cycle cost. The optimal allocation of resources can be achieved by minimizing the total cost while ensuring structural performance is always at a desired level. In the proposed decision support tool for bridge decision makers, the expected life-cycle cost considering lifetime interventions associated with a bridge structure can be expressed as

$$C_I = C_{ins} + C_{maint} \quad (7)$$

where C_{ins} is the expected cost of inspections and C_{maint} is the expected maintenance cost. Once the life-cycle cost of an intervention plan (e.g., inspections and maintenance actions) is calculated, the corresponding cost utility u_c may be determined considering Equation 1 and a maximum budget.

5 OPTIMAL LIFETIME INSPECTION AND MAINTENANCE PLANS FOR HIGHWAY BRIDGES

The lifetime intervention optimization formulation herein requires the computation of life-cycle performance indicators, specifically sustainability, ex-

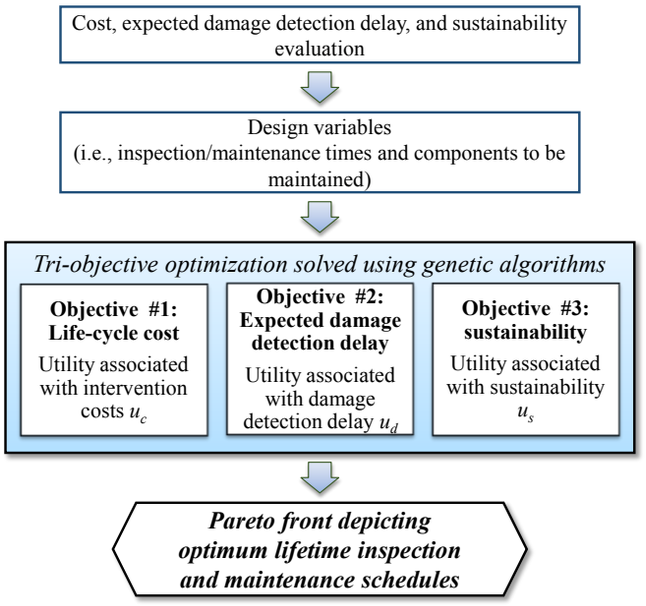

Figure 6. Flowchart describing the tri-objective optimization procedure

pected damage detection delay, and life-cycle cost. Given a maximum budget, a decision maker's risk attitude, and the number of inspections performed throughout the life-cycle, a decision maker could use the output of the proposed optimization procedure to ensure that the optimal intervention planning in terms of cost and performance is being implemented. A flowchart describing the methodology developed for this particular optimization problem is shown in Figure 6. The three objectives employed in this optimization are simultaneously maximized to achieve optimal intervention schedules.

The tri-optimization problem described herein can be solved using Genetic Algorithms with an adequate number of generations. The final result is a 3D Pareto front, depicting the simultaneous balance between utility associated with life cycle cost u_c, expected damage detection delay u_d, and sustainability u_s. Embedded within this Pareto front are lifetime intervention plans detailing when to perform inspections and maintenance throughout the life-cycle of a highway bridge. Bridge decision makers can use the three-dimensional Pareto front to make decisions based upon their budget or desired performance (e.g., sustainability or expected damage detection delay).

6 CONCLUSIONS

The proposed decision support tool allows for informed choices to be made regarding bridge inspection and maintenance interventions. Utilizing the established methodology, optimal lifetime inspection and maintenance plans are determined for highway bridges. All three objectives employed in the adopted optimization procedure are expressed in terms of utility, measured on a consistent scale from 0 to 1. Sustainability is calculated considering the risks associated with the economy, the environment, and society. Additionally, expected damage detection delay is determined considering the uncertainties that lie in inspection quality and damage detection. The total life-cycle cost is calculated as the cost of inspection and maintenance throughout the lifetime of a bridge. Overall, this decision support tool can be used to ensure that financial resources are being efficiently allocated to inspection and maintenance operations throughout the lifetime of highway bridges.

ABSTRACT: Modeling the expansion and damage generated by alkali-silica reaction (ASR) in reinforced concrete structures is quite complex, yet necessary to obtain accurate predictions of the structural responses of distressed concrete members. Several ASR models have been developed over the past decades to predict expansion and damage at the material (microscopic) or the structural (macroscopic) scales. However, those models tend to either neglect or overemphasize the critical physicochemical parameters of the reaction, which limits their applicability. Therefore, a new simple yet reliable finite element approach is proposed in order to fill this gap. It accounts for the most important parameters affecting ASR through an engineering approach, without the need for non-technical guesses or to "fit" model parameters. The proposed model is validated through the computational simulation of reinforced concrete specimens cast and monitored in the laboratory. An application example of a real ASR-affected bridge is also provided.

1 INTRODUCTION

Alkali aggregate reaction (AAR) is a concrete distress mechanism that results from a chemical reaction between the alkalis from the concrete pore solution and some mineral reactive phases from the aggregates used to make concrete. AAR is normally divided into two different mechanisms, so-called alkali-silica reaction (ASR) and alkali-carbonate reaction (ACR), ASR being by far the most commonly found around the world according to Fournier & Bérubé (2000).

The authors state that to develop ASR, three components are considered necessary1) aggregate containing reactive mineral phases, 2) high moisture content (normally assumed ≥ 85%) and 3) high alkali content. As by Saouma et al. (2015), the ASR mechanism is considered to be fairly well understood (at least in its major steps) and, its development can be described overall in four major stages. The first stage is defined as 'nucleation', where the reaction products start forming and filling surrounding aggregates, matrix voids and flaws. It is followed by a second step ('development') where significant expansion occurs with minor crack formation. Then, a third stage ('acceleration') takes place with the presence of important crack formation. Finally, the fourth and last stage is defined as 'deterioration' (which could also be called the deceleration phase), during which severe damage is found as well as a levelling off trend of ASR expansion, which might likely be caused by leaching (often found in laboratory testing) or by theoretical completion of the reactive mineral within the aggregates.

It is clear that ASR is a complex and non-linear mechanism, both physically and chemically, and even more so in the case of reinforced concrete structures where the influence of anisotropic confinement and stress states must be considered. Therefore, to accurately predict the structural implications of the reaction on concrete structures, an ASR expansion and damage model must be able to properly simulate both aspects.

2 ASR COMPUTATIONAL MODELS

Esposito (2016) classifies the existing ASR models in 4 different categories:

1- Models based on ion diffusion/reaction products, which describe the chemistry involved in great detail (micro-models). They take into consideration the dissolution and diffusion of alkali and silica ions as well as water availability. Examples of micro-models include those by Poyet et al. (2007) and Multon et al. (2009).
2- Models based on gel production, which describe the deterioration process at the aggregate level (micro-meso-models). They generally express the reaction kinetics as a function of the change in mass or volume of the gel and associate these variations to imposed strains or

pressure. Examples of micro-meso-models include those developed by Ulm et al. (2002), Grimal et al. (2008a, b) and Pignatelli et al. (2013).

3- Models based on internal pressure, which are capable of characterizing damage within the different constituents of the concrete (coarse aggregate, fine aggregate, cement paste, interfacial transition zone, etc.) by analyzing a representative elementary volume (meso-models). Examples of meso-models include those by Wu et al. (2014) and Esposito (2016).
4- Models based on concrete expansion, in which the effects and structural implications of the ASR expansion are modeled by imposing an expansive time-dependent strain to the concrete elements (macro-models). The strain is either based on phenomenological laws or on reaction kinetics laws of thermodynamics. Examples of macro-models include those developed by Charlwood (1994), Ulm et al. (2000) and Saouma & Perotti (2006).

Even though important progress has been accomplished in the field recently, most existing approaches either neglect or overemphasize the critical physico-chemical parameters of the reaction. This leads the models to become either incapable of assessing the distress mechanism properly, or too complex, requiring heavy computer programing/processing and, more importantly, the need to "fit" some of the variables with literature data or non-technical guesses. This fact, unfortunately, tends to make these models less useful and attractive in practice.

This work aims to develop a new simple yet reliable engineering-based finite element approach to assess damage in reinforced concrete structures affected by ASR. The macro-model (based on concrete expansion) intends to be a middle ground between the existing overcomplicated and oversimplified approaches. It is capable of technically accounting for the most important parameters influencing the chemical and physical aspects of the reaction, thus removing the need to "fit" certain (sometimes unmeasurable) parameters. Moreover, the model uses the widely used FE software Abaqus/CAE v.6.14 – Simulia (2014), making it easily accessible for the engineering community.

3 RESEARCH SIGNIFICANCE

Currently, according to Sanchez (2014) and Sanchez et al. (2015), some of the biggest challenges in civil engineering are:

1- How to detect the damage degree of an ASR-affected structure/structural member (i.e., diagnosis);
2- To understand the structural implication of the damage;
3- To establish an accurate correlation between ASR development, the losses in mechanical properties and durability of the affected material;
4- To assess the influence of confinement from internal reinforcement, boundary conditions and loading;
5- To understand the reaction`s potential to produce further damage (i.e., prognosis).

Such information is essential in selecting efficient remedial/rehabilitation strategies for existing structures in the field. This project aims to develop a practical and accurate FE model capable of predicting ASR future expansion and damage behaviour (prognosis) and structural implications in affected infrastructure.

4 IMPLEMENTATION

4.1 *Reinforced Concrete*

Abaqus offers several material models to represent non-linearity and damage in concrete. Three of the most well-known are smeared cracking, brittle damage and concrete damaged plasticity (CDP). Based on the mathematical implementation and customization options, it was determined that CDP was the model that better fit the needs of the current work.

CDP is based on the principle that the damage in quasi-brittle materials (i.e., concrete) can be defined by evaluating the dissipated fracture energy required to generate micro-cracks, as by Chaudhari & Chakrabarti (2012). According to Wahalathantri et al. (2011) and Bompa & Onet (2010), based on the CDP`s mathematical implementation and on the Drucker-Prager hyperbolic function, the material model is capable of representing the elastic and inelastic hydrostatic pressure-dependent behaviour of concrete under compression and tension. The main failure mechanisms are assumed to be either concrete crushing or tensile cracking. An idealized triaxial representation of a concrete failure surface, like the one used in the material model, is presented in Figure 1.

Lastly, the model is capable of qualitatively estimating the cracking intensity and orientation by evaluating the plastic strain. If an element or region passes the elastic limit, it starts developing plastic strain locally until global equilibrium is reached. As the load increases the plastic zone also increases, therefore simulating damage accumulation.

Reinforcement is usually modeled as either shared nodes, smeared reinforcement or through the use of constraints. For this work, the shared nodes approach was selected as the best option due to its simplicity and wide applicability.

The CDP material model was previously validated by modeling six beams tested by Vecchio and Shim (2004). On average, the proposed FE model overesti-

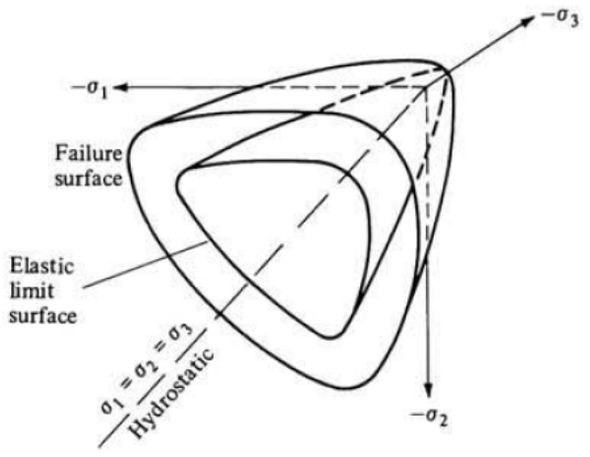

Figure 1. Schematic failure surface in three-dimensional stress space. Source: Chen (2007).

mated the ultimate load by 4% and underestimated the ultimate deflection at midspan by 11%, therefore proving its capability of accurately modeling undamaged reinforced concrete.

4.2 *ASR*

In order to assess the chemical aspects of the reaction, which can be understood as the reaction kinetics and expansion prediction over time, a physico-chemical analytical model was adopted. This model was previously developed at the Concrete Research Group (CRG) at the University of Ottawa and is able to describe the free evolution of the reaction over time based on Larive's equation, as by Larive (1997) and seven of the most important parameters of the reaction. Hence, the equation was found to be capable of describing the free expansion of the reaction over its lifespan only based on simple (and measurable) parameters as by Sanchez et al. (2016a).

Larive's equation (Equation 1) is a time dependent exponential function that represents the reaction phases previously described only three coefficients: τ_c characteristic time, τ_l latency time and ε^{∞} expansion at infinity, as illustrated in Figure 2.

$$\varepsilon(t) = \frac{1-e^{-\frac{t}{\tau_c}}}{1+e^{-\frac{(t-\tau_l)}{\tau_c}}} \times \varepsilon^{\infty} \qquad (1)$$

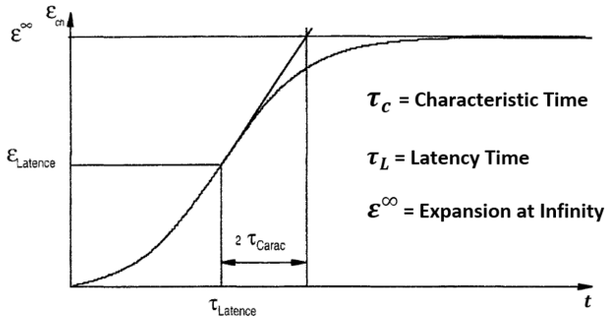

Figure 2. Larive's Equation. Source: Adapted from Larive (1997)

The seven parameters considered by the analytical equation are the type of reaction (ACR or ASR), aggregate type (coarse, fine or coarse and fine), aggregate reactivity (from negligible to very high damage degree based on Sanchez et al. 2016b), temperature, moisture (relative humidity), alkali content in the mix and exposure conditions. Moreover, the model is capable of assessing the variation of some parameters such as temperature and moisture content over time. This allows the development of expansion curves that simulate the real climatic conditions of the structure under evaluation.

Another consequence of ASR expansion that has to be accounted for is the mechanical properties deterioration, according to Sanchez et al. (2017). The ASR-affected mechanical properties that are considered are the compressive strength, the tensile strength and the modulus of elasticity, which are reduced over time as a function of the expansion level. This reduction is a direct consequence of the physical degradation (cracking) of the aggregate particles and cement paste. The model provides the reduction percentage of each parameter for each aggregate type at different expansion values and the parameters are assumed to vary linearly between the data points.

Therefore, the chemistry involved is computationally implemented in the model by imposing an equivalent ASR strain based on the free ASR expansion model. The curve obtained from this analytical approach can be understood as the input (reference) expansion curve for the model because it represents the free (i.e., unrestrained and unconfined) expansion over time expected to be observed.

The physical aspects of the reaction were assessed by taking into consideration the triaxial stress-state dependency of the expansion. Gautam et al. (2017) proposed a non-linear mathematical approach that states that the expansion due to ASR is reduced in the compressed direction and redistributed to the less stressed/unstressed directions. The expansion can be reduced to 34% or increased up to 232% of the reference expansion, depending on the stress state of the analyzed direction as well as the other two directions. It is important to note that the effect of tensile stresses on the reaction is not considered, therefore any regions that are not being compressed automatically have the expansion equal to the reference.

In order to implement the relationship developed by Gautam et al. (2017), an Abaqus user subroutine (USDFLD) was developed. As the reaction progresses, it is possible to state that the effect of confinement (due to the reinforcement, for example) and localized structural damage will influence the structure's stress state and, consequently, the local development of the reaction in terms of expansion and damage. Therefore, to take this into consideration, the subroutine was developed so that at every time increment, it updates the values of the expansion along

each principal direction in each finite element as a function of the current stress state.

In order to properly simulate the confinement effect as the expansion progresses, the steel reinforcing bars were modeled as beam elements instead of truss elements. The former tends to generate higher and more realistic confinement values because it presents both axial and transverse stiffness, while the latter presents only axial stiffness.

5 VALIDATION

Sanchez et al. (2016a) performed a push-off test to analyze the effect of ASR damage on the shear capacity reinforced concrete members. They designed, fabricated and tested S-shaped push-off specimens with different reinforcement ratios, damage degree levels and confinement configurations. The expansion of the unloaded specimens parallel to the main stirrups with 0.12% ± 0.01% final expansion was measured over time and was used as validation for the proposed ASR expansion FE model. The specimen taken as the reference was not reinforced. Figure 3 shows the specimen that was analyzed, which has two 400R steel 10M stirrups (total of 400 mm^2) crossing the shear plane and a reinforcement ratio (ρ) of 0.76%. All specimens were 650 mm high, 450 mm wide and 200 mm thick. The reactive aggregate used was the highly reactive New Mexico gravel combined with the non-reactive Laval sand. The concrete was 35 MPa, it had 4.63% of alkalis, and the specimens were stored at 38° C at 100% relative humidity. Lastly, leaching was noticed during the experiment, which likely led to a reduction of the final expansion expected for the specimen.

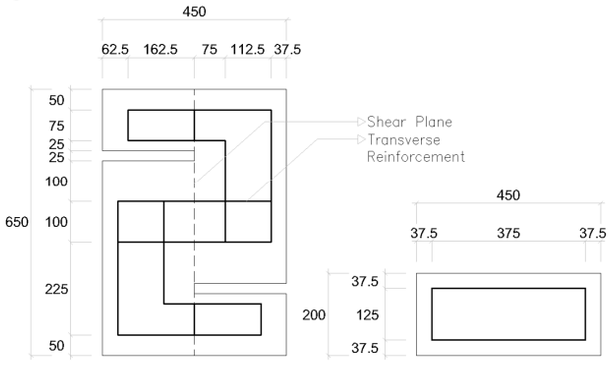

Figure 3. Push-off specimen design (dimensions in mm). Source: Adapted from Sanchez et al. (2016a).

A total of three analyses were performed in order to investigate the importance of accounting for the anisotropy of the reaction and the deterioration of the mechanical properties. The first analysis applied the anisotropic stress-state relationship and reduced the mechanical properties over time, therefore it is referred to as "anisotropic with damage" and it is the model`s standard. The second analysis is referred to as "anisotropic without damage" and it assumes that the reaction is anisotropic but ignores the deterioration of mechanical properties due to ASR development. The third analysis assumes that the reaction is isotropic and maintains the initial mechanical properties throughout the analysis, therefore titled "isotropic without damage".

According to Sanchez et al. (2017), the reduction in the modulus of elasticity was 5% at 0.05% expansion and 27.3% at 0.12% expansion for concrete mixtures cast with this aggregate. The tensile strength was reduced by 31.8% at 0.05% expansion and by 45.8% at 0.12% expansion. The compressive strength was slightly increased by 4.4% at 0.05% expansion and then reduced by 11.7% at 0.12% expansion. It is worth noting that the increase happened because the gain of compressive strength over time was larger than the reduction due to the deterioration of the material at 0.05% expansion. Otherwise, at 0.12% expansion the deterioration mechanisms already govern the overall behaviour, thus leading to a reduction of the compressive strength.

The expansion vs time curves reported by Sanchez et al. (2016a) and determined through the FE model for the specimens with no stirrups (0S) and 2 stirrups (2S) are plotted in Figures 4-5. Note that since the stress field of the no stirrups (0S) case is totally undisturbed, the FE results are exactly equal to the input free expansion curve obtained using the analytical model described in Section 4.2.

It is important to note that the expansion curve based on the analytical ASR model corresponding to the same mix, aggregate and conditions described by Sanchez et al. (2016a) provides a final expansion of 0.20%, which is much higher than the 0.125% measured in the test after 9 months. This is likely attributable to alkalis being lost in the early stages of the reaction (leaching), which is not accounted for in the expansion equation. Therefore, the strategy adopted was to reduce the alkali content available in the mix using one of the model`s coefficients to indirectly account for this phenomenon. It was determined that the best fit was for a reduction of 9.3% in the alkali content (from the original 4.63% to 4.20%).

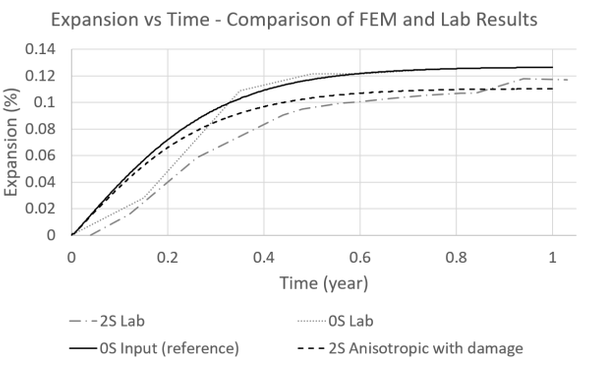

Figure 4. Expansion vs time curve – lab results and FEM results.

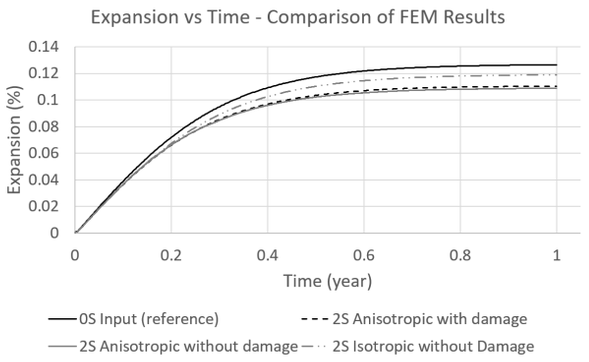

Figure 5. Expansion vs time curve – comparison of FEM results.

Both the values measured in the test and calculated through the FE model were extracted from the same location, approximately 2.5 cm below the main stirrups. This means that the curves represent the behaviour of the specimens' core and not the concrete cover.

The damage extent (plastic strain) is presented in Figure 6. The dark zones are assumed to be undamaged (uncracked) and the colored zones go from little damage extent (dark blue) to large damage extent (light blue).

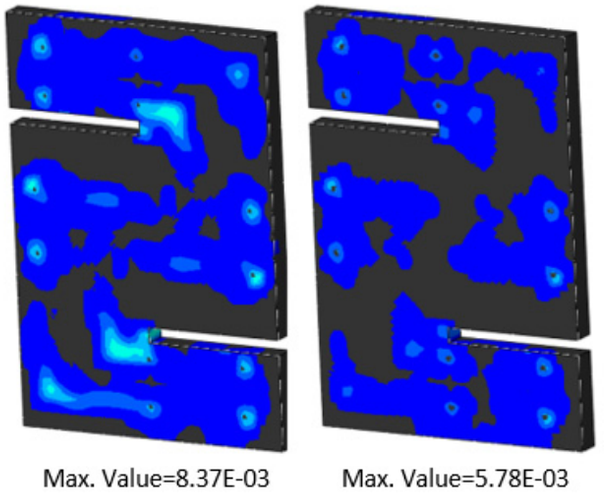

Figure 6. Push-off specimen's core (anisotropic with damage case on the left and anisotropic without damage on the right) – qualitative crack size and distribution (plastic strain)

Figures 7-8 display the stresses along the X direction for the 2S anisotropic with damage and 2S isotropic without damage cases, respectively. The grey zones are zones where tensile stresses govern. All other colored regions are governed by compressive stresses.

Lastly, the parameter entitled "field variable" along the X direction is presented in Figure 9. This parameter represents the reduction or increase of the expansion compared to the reference (free expansion input curve). If the value is equal to 1.0, the expansion is equal to the reference. However, if the parameter is

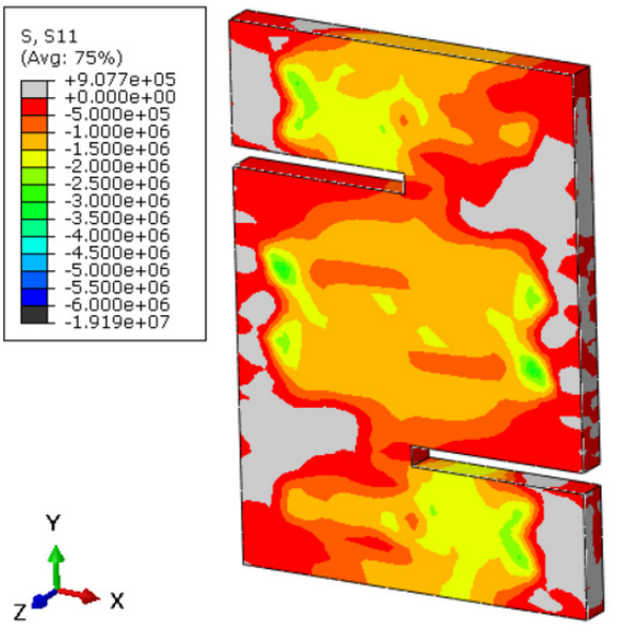

Figure 7. Push-off specimen's core (anisotropic with damage case) - stress field in the X direction.

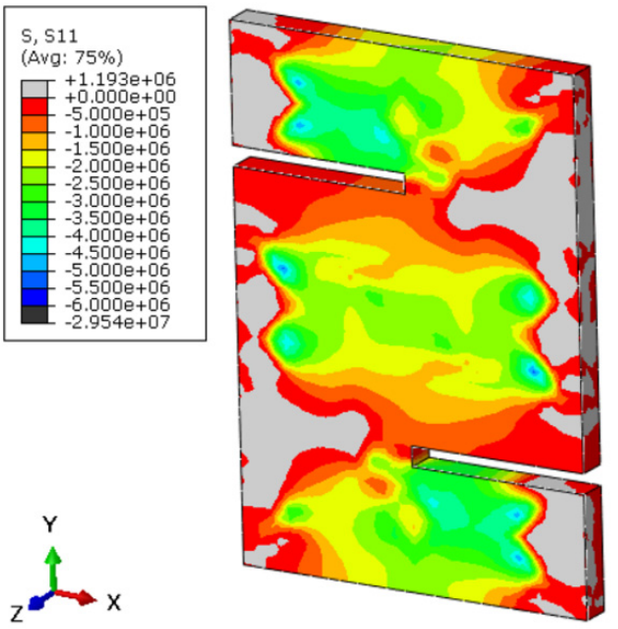

Figure 8. Push-off specimen's core (isotropic without damage case) - stress field in the X direction.

greater or smaller than 1.0, that value represents the percentage of the reference expansion that is being applied to the specific element. For example, if the region has a value of 0.6 it means that an expansion equal to 60% of the reference expansion will be applied there.

6 DISCUSSION OF RESULTS

From Figure 4, it is clear that the model for the no-stirrups case (0S input reference curve) represents the

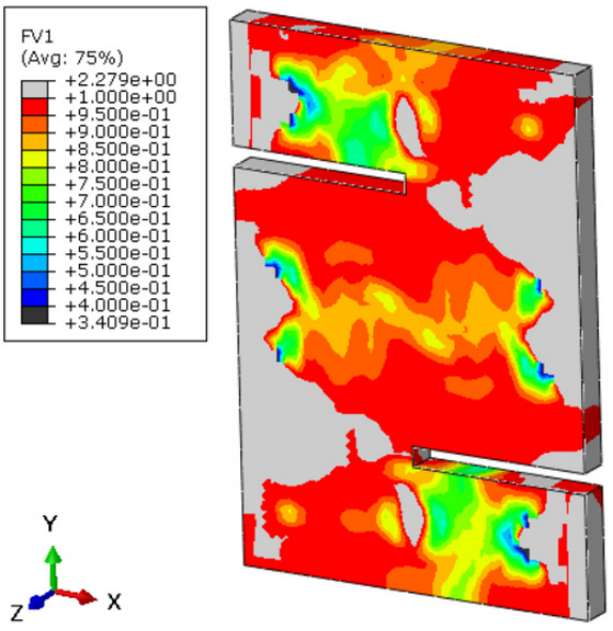

Figure 9. Push-off specimen's core (anisotropic with damage case) –field variable in the horizontal direction.

measured values well, except for the initial stages of expansion (between 0 and 0.30 years). This is very likely due to the fact that the analytical free expansion model does not take leaching into consideration.

As previously mentioned, the strategy adopted to indirectly take the effect of leaching into consideration was to reduce the coefficient that describes the alkali content available in the mix. However, having less alkalis available in the mix and losing alkalis over time (leaching) are two different phenomena chemically and physically speaking, which probably led to the observed inconsistency in the beginning of the reaction. This indicates that leaching has an effect not only on the final expansion (like the alkali content in the mix) but also on the reaction kinetics as it seems to increase the reaction's latency time (i.e., it seems to decrease the expansion in the early stages). Therefore, the analytical free expansion model could be improved to account for this phenomenon.

Likewise, the same initial behaviour for the 2-stirrups case is expected, wherein the calculated expansion is higher than the one measured in the tests, as shown in Figure 4. As predicted by Gautam et al. (2017) and verified by Sanchez et al (2016a), the expansion was reduced due to the reinforcement confinement effect in the concrete core, leading to a lower expansion vs time curve. The results illustrated in Figure 4 validate both the stress-strain relationship programmed through the user subroutine and the capability of the reinforced concrete model to simulate reinforcement confinement.

As shown in Figure 5, it is possible to state that reducing the mechanical properties (2S anisotropic with damage case) does not have a significant impact on the expansion of the specimen over time. The only difference observed in the curves was that the expansion keeps increasing very slowly when damage is considered, due to the widening of cracks as the values of the mechanical properties are reduced as a function of the expansion. On the other hand, when there is no damage and only the original mechanical properties are assumed, the expansion tends to reach a plateau without increasing further.

Even so, there are two significant consequences of reducing the mechanical properties in the model. As Figure 6 illustrates, the cracks are considerably larger (lighter blue areas) and the undamaged zone (dark region) is considerably smaller when the mechanical properties are reduced. Also, this reduction would impact the structural response of the specimen if loads were applied to the structure, likely leading to larger deformations. The only reason why this was not observed in the specimens is because the case analyzed was unloaded, which is not the case for most real structures in service.

Figures 7-8 clearly show that assuming isotropic expansion does not yield results as accurate as the anisotropic stress state-dependent relationship proposed by Gautam et al. (2017). Not only is the expansion over time further from the recorded lab data but also the isotropic case stresses are unrealistically high when compared to the anisotropic case. When isotropic expansion is assumed, the expansion keeps increasing regardless of the confinement, which leads to incoherent larger compressive stresses in the concrete and tensile stresses in the reinforcement. Thus, it is possible to state that the approach widely used in the past of simply imposing an equivalent isotropic expansive strain to the entire structure would not be capable of accurately simulating the structural implications of the reaction.

Lastly, it is important to emphasize that the largest reduction in expansion observed in Figure 9 happened where the compressive stresses are the largest, as predicted by Gautam et al. (2017). These regions basically include the regions where the reinforcement was passing through along the Z direction (small blue-green zones) and region between stirrups (central orange-yellow region).

7 APPLICATION EXAMPLE – ROBERT-BOURASSA/CHAREST OVERPASS

According to Sanchez et al., (2016b), the Robert-Bourassa/Charest (RBC) overpass was a highway bridge structure in Quebec, Canada, consisting of a deck supported by Y-shaped piers (Figure 10). It was built in 1966 using an alkali-silica reactive limestone aggregate, which led to the development of ASR over time. Especially over the last 3 decades, many signs of distress such as reinforcement corrosion and map cracking were spotted on the structure. Further analyses indicated that the map cracking was caused by

ASR and freeze-thawing cycles, which also aggravated the effect of corrosion. The extent of damage led to its demolition in 2010-2011; however, detailed evaluations (i.e., visual inspection, mechanical, microscopic and residual expansion assessment, displacement measurements, etc.) were performed and recorded before that took place.

Figure 10. RBC overpass (QC, Canada). Source: Sanchez et al. (2016b).

As an example of the applicability of the proposed model, it was implemented to analyze the pier of the RBC overpass. The plastic strain (cracking intensity) and the maximum absolute stresses (positive or negative) are presented in Figures 11-12, respectively.

Figure 11. RBC overpass pier – Cracking pattern comparison – RBC pier on the left and FE model on the right. Source: Sanchez et al. (2016b).

It is easy to see the resemblance of the cracking pattern between the FE model and the RBC pier in Figure 11. The largest crack is clearly at the bottom following the longitudinal reinforcement. However, damage on the laterals of the inferior region are noticeable, as well as where the arms connect and at the connection with the pier. Lastly, the cracks along the arms were not captured in the FE model, which implies that the model still needs adjustments to fully capture the behaviour of the concrete member.

Figure 12 shows that most of the pier is under compression, as expected. However, it is clear that the left

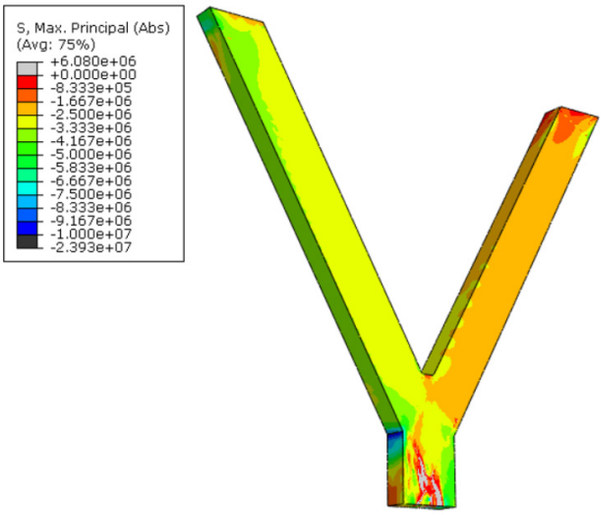

Figure 12. RBC overpass pier – Maximum absolute stresses in the concrete.

arm is under a greater compressive stress as a consequence of the dead load of the longer span. The only region under tension is at the bottom where large cracks are forming, according to Figure 11.

8 LIMITATIONS AND FUTURE RESARCH

Even though the presented results are very promising, there are still a number of aspects that must be further accounted for and evaluated to fully describe ASR-distress behaviour of real structures in the field. Some of the most important phenomena that should be accounted for to a certain degree in the reinforced concrete model are creep, shrinkage, concrete confinement effect and concrete/reinforcement bond, as well as freeze and thaw cycles, leaching and porosity in the ASR model. Moreover, aspects such as the effect of loading on the mechanical properties loss and on boundary conditions still have to be analyzed in greater depth.

Future work for the authors will be to further improve the FE analysis by comparing the results of the RBC overpass to measurements obtained from the technical inspections, and extending the analysis to predict structural response. Since the behaviour over time is being correctly modeled, the methodology can be applied to assess at what point in time the structure would reach a critical stage requiring rehabilitation or to be removed from service.

9 CONCLUSIONS

Based on the analysis and results presented, several conclusions can be made:

1- The CDP model in Abaqus was capable of accurately simulating the behaviour of ASR-affected reinforced concrete structures.

2- The analytical free expansion model predicted the ASR reaction well, except for the overestimation at the beginning, very likely because it does not account for leaching.
3- The anisotropic stress-strain relationship proposed by Gautam et al. (2017) yielded better results than the isotropic case.
4- The effect of reinforcement confinement on ASR expansion was observed and it described the experimental results well.
5- Accounting for degradation of mechanical properties did not noticeably affect the expansion over time for the unloaded specimens considered in this study, but it led to wider cracks and an overall larger damaged zone.
6- The proposed FE model was validated using experimental push-off test specimens tested by Sanchez et al. (2016a) and proved to be capable of accurately simulating ASR. Therefore, it can be used to evaluate real ASR-affected structures like the RBC overpass.

Techniques to Rehabilitate Bridge Columns Affected by Alkali-Silica Reaction (ASR)

L.F.M. Sanchez
Assistant professor, University of Ottawa
M. Noël
Assistant professor, University of Ottawa
V.A.A. Santos
Postdoctoral-fellow, University of Ottawa

Robert-Bourassa/Charest (RBC) overpass was a highway bridge structure (Quebec, Canada) that was built using an alkali-silica reactive limestone aggregate. Over nearly 5 decades, many signs of distress developed on the various structural members of the structure mainly due to alkali-silica reaction (ASR), freeze-thaw (FT) cycles, as well as steel corrosion. One of the major concerns regarding RBC structural long-term performance was related to the distress degree of the Y-shaped columns and thus a number of rehabilitation techniques including surface treatments (rigid coatings, silane/siloxane based products) and structural confinement (GFRP wrapping systems) were adopted to suppress further ASR-induced expansion and damage. In 2010/2011, prior to its demolition, several cores were extracted from the different members of RBC, which enabled the microscopic and mechanical characterization of damage from the various treated columns. This paper presents a comparison of the efficiency among the different rehabilitation techniques used to mitigate ASR in RBC columns. Results show that different damage degrees are found according to the group of columns; greater SDI and PDI and lower modulus of elasticity values were obtained from the North-West specimens, followed by the South-West/East cores. Microscopic analyses showed evidence of ASR and freeze and thaw mechanisms and marginal to moderate expansion & damage levels were obtained from the distinct columns assessed.

1 INTRODUCTION

1.1 *Alkali-silica reaction (ASR)*

Alkali-silica reaction (ASR), one of the most harmful distress mechanisms affecting concrete structures worldwide, is a chemical reaction between "unstable" silica mineral forms within the aggregates and the alkali hydroxides (Na, K – OH) dissolved in the concrete pore solution. ASR generates a secondary product, the so-called alkali-silica gel, that upon moisture uptake induces expansive pressures within the reacting aggregate material(s) and the adjacent cement paste, thus causing microcracking, reduction of material's properties (mechanical/durability) and, in some cases, functionality in the affected structure (Fournier & Bérubé, 2000).

Currently, one of the most significant challenges in dealing with aging damaged infrastructure is to establish the correlation between the distress "signatures" caused by a given damage mechanism (e.g., ASR), and the reductions in mechanical properties, physical integrity, durability and performance of the affected material, as well as their structural implications (Sanchez et al. 2015a). In this context, studies dealing with a multi-level evaluation proposed by Sanchez et al. (2017), suggest that both the *Stiffness Damage Test (SDT)* and the *Damage Rating Index (DRI)* (respectively mechanical and microscopic procedures) are able to provide a diagnostic evaluation of the "*actual damage degree*" of concrete affected by ASR. Although very promising, this multi-level approach was initially developed using laboratory (i.e., well controlled) samples and has barely been used for the condition assessment of aging infrastructure. Therefore, there was a need to further verify the efficiency and reliability of this approach for the evaluation of real damaged concrete structures.

1.2 *Robert-Bourassa/Charest Bridge*

The Robert-Bourassa/Charest (RBC) overpass was a highway bridge structure (Quebec, Canada) that was built in 1966 using an alkali-silica reactive limestone aggregate. The bridge was made of a deck resting on reinforced concrete Y-shaped columns, themselves supported by massive concrete foundations (Figure 1). No specific information is available on the concrete mix designs; however, technical reports indicate that the 28-day concrete design strengths were 24 MPa for the foundation blocks and 28 MPa for the columns and decks (ICAAR Visit Report, 2000).

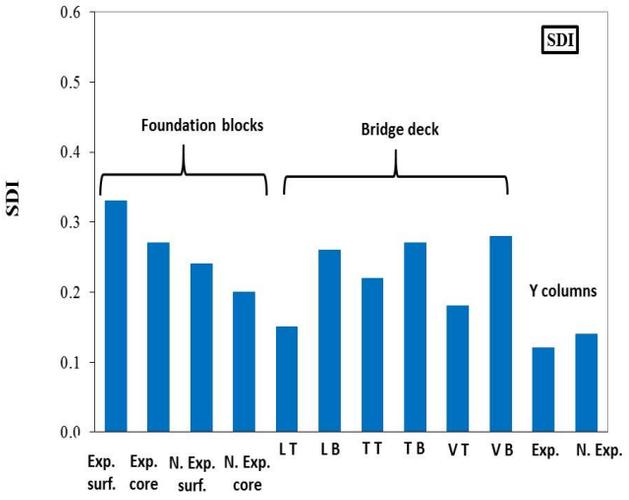
Over the last three decades, many signs of distress developed on the various elements of the structure. This included extensive steel corrosion and concrete delamination/spalling at the level of the deck; map cracking, scaling, disaggregation and pop-outs affecting the massive concrete foundations due to ASR and freeze-thaw (FT) cycles; and concrete spalling and steel corrosion on the columns and foundations exposed to salt-water spray from traffic on the Robert-Bourassa highway (Bérubé et al. 2005).

One of the central concerns regarding RBC structural long-term performance was related to the distress degree of the Y-shaped columns, and thus a

number of rehabilitation techniques including surface treatments (rigid coatings, silane/siloxane based products) and structural confinement (GFRP wrapping systems) were adopted to suppress further ASR-induced expansion and damage. In 2010/2011, RCB was demolished, yet prior to its demolition, several cores were extracted from its structural members (bridge deck, columns and foundation blocks), which enabled the use of the multi-level assessment proposed by Sanchez et al. (2017) for the overall condition assessment of the bridge.

Figure 1. Robert-Bourassa/Charest overpass after nearly 50 years in service (Sanchez et al. 2016).

1.3 *Preliminary condition assessment results*



Sanchez et al. (2014, 2015a, 2015b, 2017) developed a multi-level approach for evaluating ASR-affected concrete. After analyzing a wide range of concrete strengths (25, 35 and 45 MPa) and more than ten different aggregate types, a chart of damage values was developed (Table 1). It is worth noting that this chart was created using laboratory samples under free-expansion conditions whereas expansion in real structures is constrained by reinforcement and boundary conditions, as well as triaxial stress states. Nevertheless, this chart might be used as "benchmark" and considered as the "worst scenario" for ASR-affected concrete.

Table 1. ASR damage multi-level assessment (Sanchez et al 2016)

ASR damage degree (%)	Reference expansion level (%)	Multi-level assessment	
		SDI	DRI
Negligible	0.00 – 0.03	0.06 – 0.16	100 - 155
Marginal	0.04 ± 0.01	0.11 – 0.25	210 - 400
Moderate	0.11 ± 0.01	0.15 – 0.31	330 - 500
High	0.20 ± 0.01	0.19 – 0.32	500 - 765
Very High	0.30 ± 0.01	0.22 – 0.36	600 – 925

Sanchez et al. (2016) applied the multi-level approach developed in the laboratory to assess different RBC members such as the bridge deck (BD), untreated columns (C) and foundation blocks (FB). Figures 2 and 3 demonstrate respectively the mechanical (i.e.) SDT and microscopic (i.e., DRI) results obtained while the condition assessment.

A) SDI: different reinforced concrete members

B) PDI: different reinforced concrete members

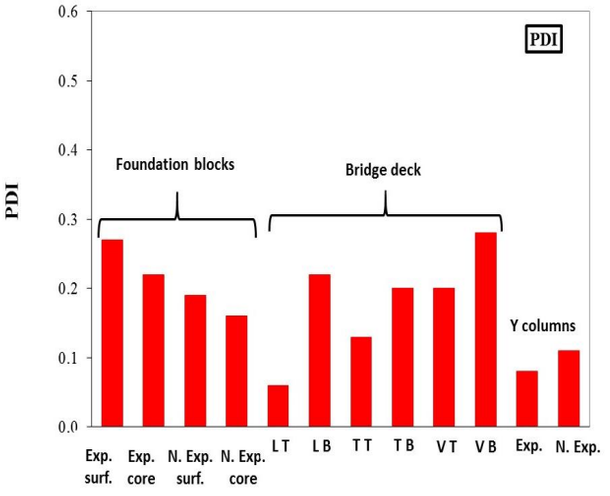


Figure 2. SDI and PDI for members of the RBC bridge (Sanchez et al. 2016).

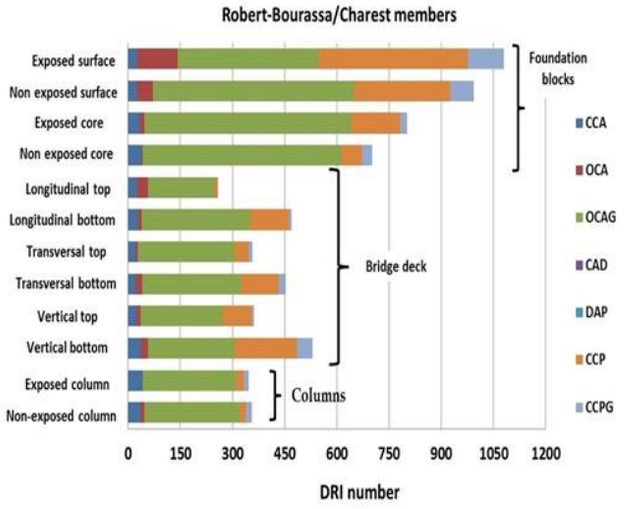
Considering the mechanical and microscopic results, and comparing those with the benchmark provided in Table 1, it can be observed that the actual damage degree of the FB, BD and C could be classified as very high, high, and moderate, respectively, with "free expansion" values around 0.30%, 0.20% and 0.12%. These values suggested that the unconstrained concrete expansion in some members had actually surpassed the yielding threshold of the steel reinforcement (0.20%). Otherwise, no appraisal was performed on the columns previously treated with the different rehabilitation techniques illustrated in

1.2 and thus no assessment of their performance in stop/mitigating ASR-further expansion and damage was performed.



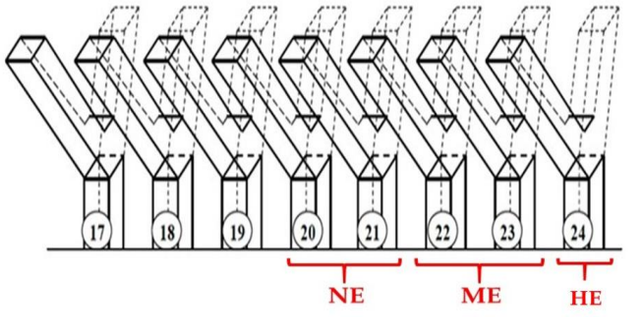


Figure 3. DRI numbers for members of the RBC bridge (Sanchez et al 2016).

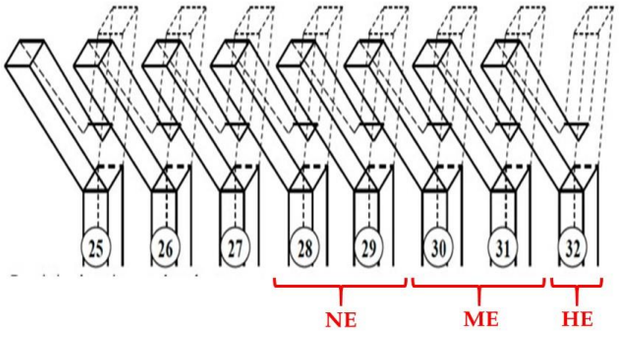

2 SCOPE OF THE WORK

This paper presents the test results of the condition assessment of cores extracted from 10 Y-shaped treated (T) & untreated (UN), highly exposed (HE), moderately exposed (ME) and non-exposed (NE) to the environment columns of RBC according to Figure 4 and Table 2. The objective of this work is to assess the influence of the exposure class and the different ASR mitigation actions used in the different RBC columns to control ASR further expansion and damage.

A) North-West group of columns

B) South-West group of columns

C) South-East group of columns

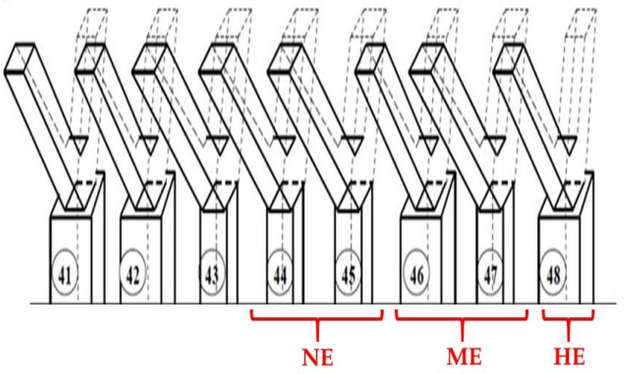

Figure 4. Identification of RBC treated columns: a) North-West group; b) South-West group and; c) South-East group.

Table 2. Number of cores extracted from the different RBC treated columns with their respective treatment techniques.

Colum number	Exposure class	Treatment	Test Samples		
			SDT	DRI	fc
17	HE	UN	3	2	3
22	ME	T; Waterproof sealant + Cementitious coating	3	2	3
23	ME	T; Waterproof sealant + Silane/siloxane sealants	3	2	3
24	HE	T; GFRP sheet	3	2	3
25	HE	T; Waterproof sealant	3	2	2
28	NE	T; Waterproof sealant	3	2	-
29	NE	T; Epoxy sealant	3	2	-
30	ME	T; Waterproof sealant + copolymer modified coating	2	2	-
32	HE	UN	3	2	2
42	NE	UN	2	2	2

3 MATERIALS AND METHODS

3.1 *Column's treatments and visual inspection*

In 2000, RBC columns were treated using different techniques to try to mitigate further expansion and damage caused by ASR and freeze and thaw coupling. A number of techniques were selected and applied on exposed and non-exposed members and bi-annual visual inspections were performed in the coming years. The description of the different products selected for use can be found hereafter.

- Waterproof polymer-modified sealant (WPMS): is a hand spray applied material to stop water leakage and/or moisture uptake into the structural member;
- Cementitious coating: is a protective coating applied to concrete members to prevent moisture uptake and improve the member's aesthetics;
- Silane/siloxane sealants: is a water repellent material which does not provide the member with a bar-

rier effect. Normally used to decrease the moisture uptake from the environment.
- GFRP sheet: high-performance carbon sheets are often used to reinforce distressed concrete structural members, prevent water leakage and also avoid moisture uptake;
- Epoxy coating: is a protective polymeric coating applied to concrete members to prevent moisture uptake;
- Copolymer modified coating: is a high-build copolymer modified coating formulated for use on concrete to avoid water leakage and moisture uptake.

The bi-annual visual inspections performed on the distinct RCB columns after the application of the above systems were not that conclusive. Over the years. Therefore, questions arose on their efficiency to mitigate ASR/freeze and thaw further induced expansion and damage. Moreover, the "initial" damage value of the different columns was never obtained prior to the application of the rehabilitation products, and thus visual comparison was found to be inaccurate. Otherwise, with RCB demolishment in 2010/2010, various cores were extracted from the different columns, which enabled the use of the multi-level assessment proposed by Sanchez et al. (2017) and thus the evaluation of the damage degrees attained in each of the different columns. A detailed visual inspection was also performed on all columns prior to the cores extraction.

3.2 *Laboratory test methods*

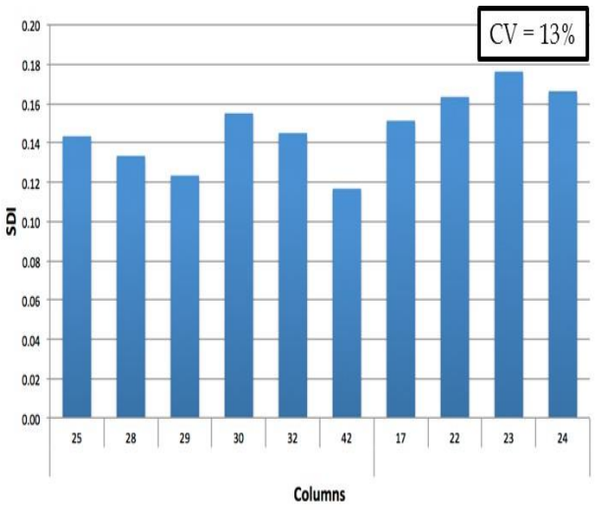
3.2.1 *Stiffness Damage Test (SDT)*

The Stiffness Damage Test (SDT) is used to quantify the damage degree of concrete affected by AAR (Sanchez et al. 2014, 2015a, 2015b). The method is based on cyclic loading (using 40% of the compressive strength of sound concrete with the same characteristics as the tested material. In this work, it was assumed 40% of the compressive strength of the least damaged column, i.e., column 32) of concrete samples (cylinders or cores). The full procedure is described in Sanchez et al. (2014, 2015a, 2015b) and the same parameters were adopted in this study. Using a controlled loading rate of 0.10 MPa/s, five cycles of loading/unloading were applied on each set of samples presented in Table 2. Each set comprised of three concrete cores extracted from the same column and with the same characteristics (i.e., environmental conditions and depth from surface).

3.2.2 *Damage Rating Index (DRI)*

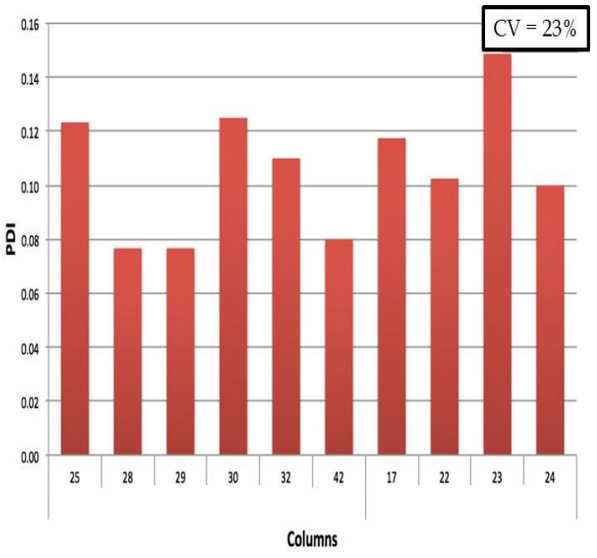
The DRI is used to quantify the degree of damage in concrete affected by AAR through a semi-quantitative petrographic analysis (Grattan-Bellew & Mitchell, 2002; Powers & Shrimer, 2007). A microscopic analysis is performed with the use of a stereomicroscope (15-16x magnification) where damage features generally associated with ASR are counted within a 1 cm^2 area drawn on the surface of a polished concrete section. The number of counts corresponding to each type of petrographic feature is then multiplied by weighting factors to balance their relative importance in terms of the material's overall distress. Ideally, a surface of at least 200 cm^2 should be used, yet for comparative purposes, the final DRI value is normalized to a 100 cm^2 area (Grattan-Bellew & Mitchell, 2002). The procedure is fully described in Villeneuve & Fournier (2012) and the same parameters were used in this study. The analyses were performed on two companion samples of the cores tested using the SDT according to Table 2.

3.2.3 *Compressive strength*



Although it has been shown that the compressive strength is less influenced by AAR and/or freeze and thaw when compared to other parameters such as tensile strength and modulus of elasticity (Sanchez et al. 2017), it was decided to carry out compressive strength tests on cores extracted from all the columns with two objectives: a) first, to determine the ultimate compressive capacity of the least damaged column so that 40% of that values might be used for stiffness damage testing and; b) to evaluate the structural implications (if any) of ASR and freeze and thaw damage over time of columns treated with different rehabilitation techniques.

4 RESULTS



4.1 *Stiffness Damage Test (SDT)*

Figure 5 presents the results of three SDT output parameters as described by Sanchez (2014) and Sanchez at al. (2015c): A) the *Stiffness Damage Index (SDI)*, a measure of the dissipated energy caused by the closure of cracks under compression loading, B) the *Plastic Deformation Index (PDI)*, which quantifies the slipping across surfaces as the internal cracks close under compression loading and, C) the *Modulus of Elasticity (E)*, that corresponds to the average values obtained from the 2nd and 3rd cycles of stiffness damage testing.

A) SDI: for the different RBC columns

B) PDI: for the different RBC columns

B) Modulus of elasticity: for the different RBC columns

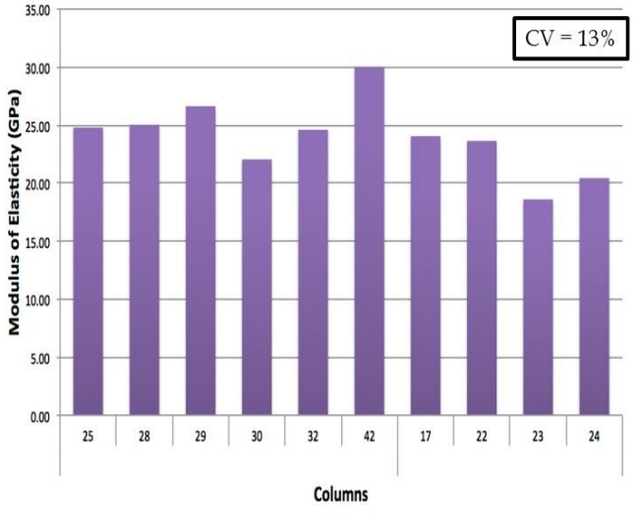


Figure 5. SDT obtained for the different columns of RBC: A) SDI and B) PDI and, C) Modulus of elasticity.

As seen in Figure 5, higher SDI and PDI values were obtained from the North-West specimens, followed by the South-West and South-East cores. Moreover, the untreated (UN) and highly exposed (HE) columns (i.e. 17, 32 and 42) did not necessarily present higher damage degree as it would be expected since one of the conditions for ASR development is the presence of high relative humidity (or moisture). The SDI values obtained from the above columns were 0.15, 0.14 and 0.12 while the PDI results were 0.12, 0.11 and 0.08 respectively.

The columns 22, 23 and 24 presented the highest SDI and PDI values amongst all members: 0.16, 0.18 and 0.17 and 0.10, 0.15 and 0.10, respectively. Those elements were treated and classified ME/HE as per Table 1. Columns 25 and 30 also presented relatively high values of SDI and PDI (0.14, 0.15 and 0.12 and 0.13 respectively). Those are treated and HE and ME columns. Finally, the members 28 and 29 showed the lowest SDI and PDI results, (with the exception of the SDI value of columns 42), being 0.13, 0.12 and 0.07 for both respectively. The latter are treated and non-exposed members.

Overall, the damage degree found in all the columns was considered marginal as per Table 1. Furthermore, the values obtained on the different UN or T columns were lower than the damage results found on the FB and BD cores.

The modulus of elasticity values obtained showed agreement with the SDI and PDI values; i.e. the higher SDI and PDI, the lower the modulus of elasticity. E results ranged from 30 GPa (i.e. column 42- non treated and HE and down to 17 GPa (column 23- treated and ME). Through a structural engineering perspective, some of the results obtained can be considered fairly low compared to the firstly adopted while the design of the bridge.

4.2 *Damage Rating Index (DRI)*

Figure 6 presents the semi-quantitative microscopic responses (i.e. DRI numbers) of all the columns samples. C and S represent core and surface of the columns cage, respectively. It is worth noting that the columns cover was disregarded in the analysis and surface here means nearby the transverse stirrups whereas core means exactly the center of the columns. All of the samples presented closed cracks within the aggregate particles (CCA), which as per Sanchez 2015b might be attributed to other phenomena than ASR (i.e. aggregate production- crushing, sieving and also weathering). However, open cracks with and without gel within the aggregate particles (OCA and OCAG, respectively) are indeed ASR damage features. Likewise, cracks in the cement paste with and without gel (CCP and CCPG) are also caused by ASR and are often found in latter and higher stages of the chemical reaction as per Sanchez et al 2015b.

As seen in Figure 6, most of DRI numbers are in the range between 200 and 400. According to Table

1, that represents a marginal damage degree, which is in agreement with the SDT results.

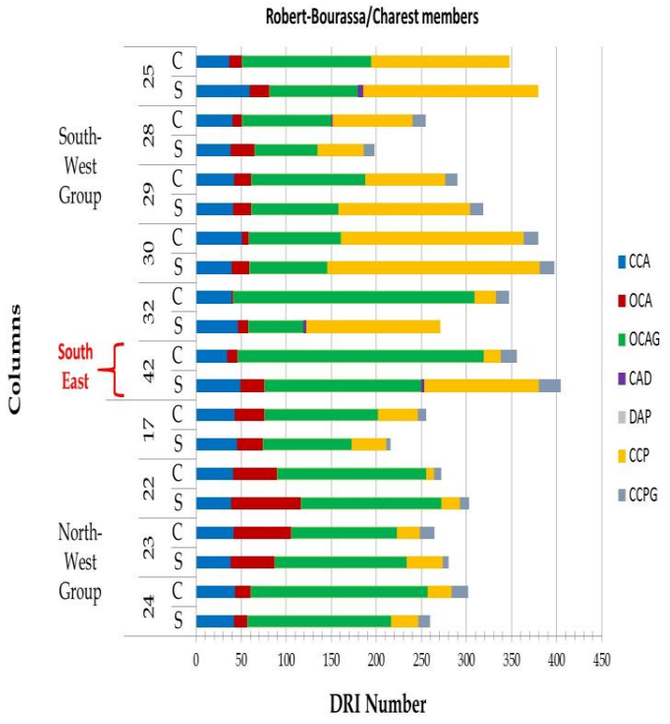

Figure 6. DRI numbers for RBC columns.

The DRI number from cores extracted from the North-West group ranged from 200 to 300. Very few differences were visualized from one core to another and from surface vs core specimens. The results obtained from the South-West/East columns were on average slightly higher. They ranged from 200 to 400. Highly and moderately exposed cores (column 25 and 30) normally presented more damage than NE columns (i.e. 28 and 29). Moreover, important amount of cracks in the cement paste were found when compared with the North-West group which shows that ASR development, although microscopic, was more pronounced on this group of columns. No significantly difference was found from specimens cored from the surface vs core of the columns.

Overall, the damage degree found in all the columns was considered marginal as per Table 1. Furthermore, the values obtained on the different UN or T columns were lower than the damage results found on the FB and BD cores.

4.3 *Compressive strength*

Figure 8 presents the compressive strength results of cores from the distinct columns. The results varied between 32 MPa (columns 23) and 42 MPa (column 32). Most of the samples still presented compressive strength greater than 35 MPa, although technical reports indicate that the 28-day concrete design adopted for the columns was strengths 28 MPa (ICAAR Visit Report, 2000). Therefore, even though microscopic and SDT analysis showed the presence of marginal to moderate ASR, the current damage features seem to still not influence the compressive strength of the affected materials, as state previously by a number of authors (Sanchez et al. 2017, Nixon, & Bollinghaus, 1985, Pleau et al., 1989)

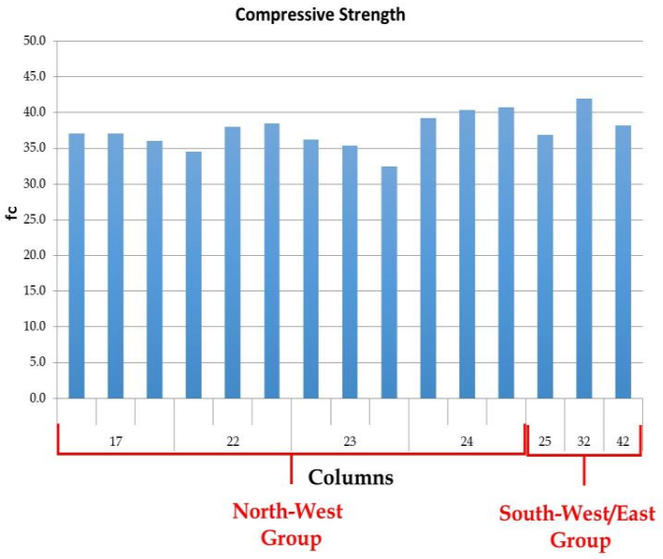

Figure 7. Compressive strength results for RBC columns.

5 DISCUSSION

5.1 *Thorough evaluation of RBC treated columns*

In Figures 5, 6 and 7, a number mechanical and microscopic parameters were evaluated with respect to the comprehensive damage definition proposed by Sanchez et al., 2017 as presented hereafter: a) mechanical properties loss, b) stiffness reduction and c) physical integrity loss. The results showed that the overall damaged found in the various treated and untreated columns of the North-West and South-West/East can be considered marginal as per Table 1. This was confirmed through the analysis of the DRI number and especially the DRI bar chart (Figure 7) where the low amount of cracks in the cement paste (i.e. orange bar) for the North-West columns indicates an initial ASR state while the higher amount of cement paste cracks in the South-West/East columns group might highlight a more advanced distress degree. However, analyzing thoroughly the South-West/East bar charts, it is clear that although the cement paste cracks are more pronounced on average, the cracks in the aggregate particles are less evident, which likely indicates the presence of other mechanisms than ASR leading or at least contributing to the deterioration process such as freezing and thawing.

Another interesting aspect regarding the overall damage of RBC columns is that very few difference was verified amongst the columns in terms of damage. It was anticipated at the beginning that more exposed columns (HE and ME) might present greater damage degree, which did not actually occurred.

This could be at least partially explained due to the compressive stresses found in the field which could have mitigated partially ASR development and thus decreasing the data scattering from the different columns. Likewise, it was not evident to differentiate the efficiency of the distinct treatments used in the columns since the results obtained were quite close to each other. The compressive stress state cited above could be an explanation and moreover the marginal damage degree of the elements does not contribute for the further understanding on the efficiency of the products.

Finally, through an engineering perspective, the compressive strength values obtained from the columns indicate that the elements present compressive values greater than expected which confirms the capacity of the bright to withstand the design loads. However, lower values of modulus of elasticity might indicate a potential issue with respect to the serviceability (i.e. deformation) of the structure. Visual inspections previously performed had clearly indicated the presence of important deflections of the bridge which now can be at least partially explained by the low modulus of elasticity found in some members.

5.2 *Assessment of the expansion attained to date due to ASR*

As previously mentioned, Sanchez et al. (2014, 217) developed a multi-level approach for evaluating ASR-affected concrete using laboratory samples under free-expansion conditions. Otherwise, it is clear that in concrete structures in the field, confinement effects caused by reinforcement, load configurations and boundary conditions will change the responses and deterioration process of the affected material. Anyway, the multi-level approach previously proposed might be used as "reference values" and considered as the "worst case scenario" of ASR-affected concrete. Furthermore, the beauty of using the multi-level approach is that it correlates with ASR expansion attained to date, and thus provides engineers in charge of affected structures with an idea about the current state of the chemical reaction and its potential for further development, which are essential information while the selection of rehabilitation techniques for damaged structures/structural components. Figure 9 presents the expansion values obtained from distinct columns.

The results show that the expansions attained by the different columns evaluated ranged from 0.05% to 0.11%, indicating a marginal to moderate damage degree on average. North-West columns group presented higher expansion levels than South-West/East group. No clear indication on the efficiency of the treatment could be obtained through this study (very likely due to the low damage states of the columns and the fact that the "0" values of damage – prior to the columns treatment - are not known), although for the majority of the columns, a more exposed condition generated a higher expansion level (e.g. columns 22, 23 and 24 when compared to 28 and 29). Moreover, comparing these results with the ones previously obtained from the FB and BD, it is clear that ASR-induced expansion and damage presented much lower values which indicates a much more sound state.

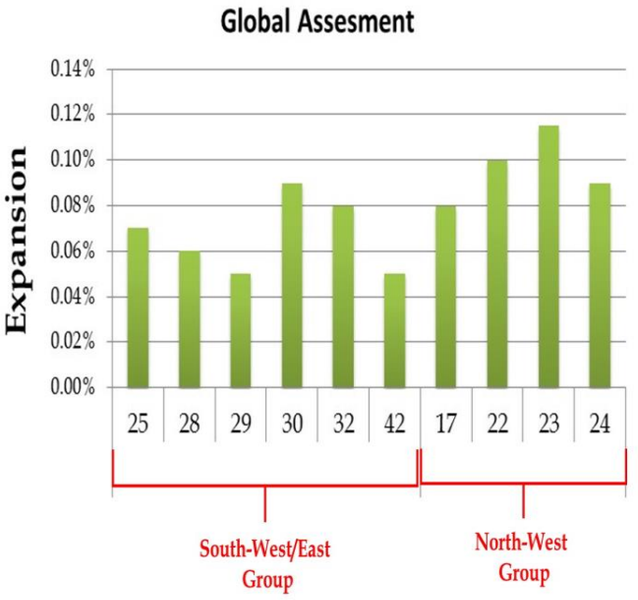

Figure 9. Potential expansion attained for the different RBC columns.

6 CONCLUSION

After performing an important experimental campaign, through the use of the multi-level assessment protocol proposed by Sanchez (2014), on cores extracted from distinct columns of a 50-year old bridge structure affected by ASR, one may conclude that:

- Different damage degrees are found according to the group of columns, greater SDI and PDI values were obtained from the North-West specimens, followed by the South-West/East cores;
- It was anticipated that columns untreated and exposed would present much greater damage compared to non-exposed and treated elements. However, the results did not clearly and significantly vary according to the exposure condition and treatment type of the column, although on average and for the majority of the columns, a more exposed condition generated a higher expansion and damage level.
- The damage degree obtained for the distinct columns was considered to be marginal to moderate as per Sanchez et al (2016, 2017, Table 1). This could likely explain why the different types of treatment could not be compared to each other with respect to their efficiency; i.e.

- The microscopic analysis performed through the DRI showed evidences that some of the columns might have suffered from other deterioration processes than ASR, especially freezing and thawing. According to the DRI charts, Sought-West columns group were likely more distressed due to freezing and thawing whereas North-West columns presented greater ASR distress features.
- The multi-level approach seems to work quite well since the vast majority of results obtained through the mechanical and microscopic tools were similar and complementary;
- Although the damage chart proposed by Sanchez (2014) was developed through the use of laboratory samples under free-expansion, it provides a link between the damage indices and the expansion potential of the affected material, which relates to the management and structural implications of ASR-affected aging infrastructure. In this work, the expansion levels obtained from the different columns ranged from 0.05% to 0.11%, which indicates the initial stages of ASR classified according to Table 1 as marginal to moderate levels.

ABSTRACT: In recent years, breaks of Prestressed Concrete (PC) tendon have been reported. For the maintenance and management of PC structures, it is important to grasp the characteristics of PC structures that have tendon breaks. In this study, with the pre-tensioned PC beam specimens, analytical and experimental approaches are taken. The experimental results show that stress distribution locally changes near the breaking point, whereas the influence on the global behavior is small, when tendons break. If the tendon break occurs in the region where bending stresses are large, crack initiation is induced with reduction of the bending stiffness. Elastic waves resulting from the tendon break tend to propagate throughout the beam and can be captured by monitoring micro vibration of the beam surface. A natural frequency slightly decreased as the number of tendon break increased. In contrast, a damping ratio tends to increase with increasing the number of tendon break.

1 INTRODUCTION

The number of bridge construction has significantly increased in Japan since the late 1960s~1970s. Over decades, structural deterioration has progressed in these bridges. Among several damage cases in aging bridge structures, break of tendons in prestressed concrete (PC) beam is one of the serious damage cases that directly relates the loss of load carrying capacity. Actually, collapsing cases of a PC bridge due to the break of PC tendons have been reported. In order to secure the safety of PC structures, it is important to grasp the behavior of PC beams when PC tendons broken and also to accumulate the data that lead to develop a judgement method for the tendon break.

The objectives of this study are to reveal influence of tendon breaks on stress distribution and bending stiffness, and also to find a method to capture elastic waves generated by the tendon break. Moreover, natural vibration measurement is also performed to understand the change of natural frequency and structural damping. With the pre-tensioned PC beam specimens, FEM analysis is firstly performed to obtain the load-displacement relationship with a parameter of effective prestress level; then, bending experiments are done to evaluate the structural behavior with and without tendon breaks.

2 PRE-EXPERIMENT

2.1 *Finite Element Analysis (FEA)*

In order to grasp bending behavior and the crack initiation load, non-linear static Finite Element Analysis (FEA) is performed by ABAQUS/standard. Figure 1 illustrates the FEM model. The analytical model is created based on the rectangular section. 8-node cubic elements (C3D8) are employed to represent the concrete part, and 4-node 2D rebar elements are used to represent the PC tendon. The mesh size is 10 mm in the whole of the model. Initial stresses are given to the rebar elements to introduce stressing forces into the PC tendon. For the boundary condition, simply-supported condition is modeled. The distance between supports is set to 1900 mm. The loading is given by distributed loads in 200 mm range at the span center.

2.1.1 *Material property of PC tendon*

Table 1 shows the material property of PC tendon. The elastic modulus is 200,000 MPa, the Poisson's ratio is 0.3, and the density is 7850 kg/m^3. As shown in Figure 2, the elasto-plastic constitutive law is set with a yield stress of 1705 MPa, the tensile strength of 1927 MPa and the maximum strain of 0.11 based on JIS. The definition is a bilinear isotropic hardening rule, and the slope of which after the tensile strength is constant.

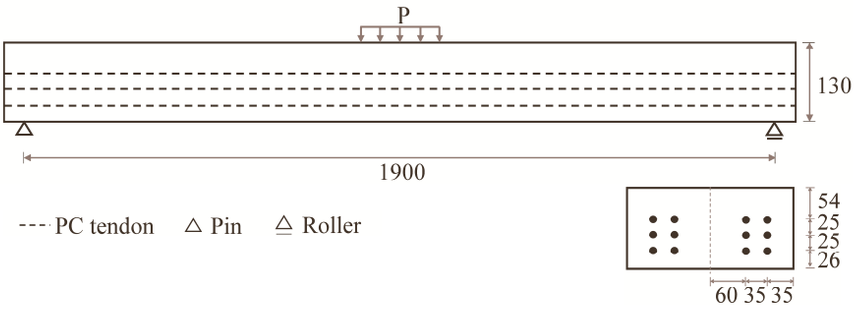

Figure 1. FEM model

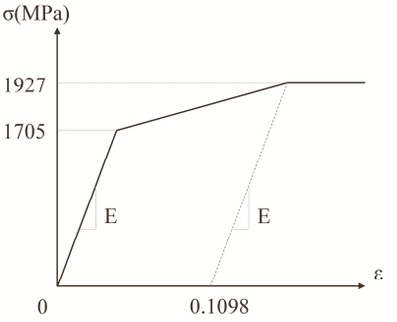

Figure 2. Constitutive law of PC tendon

Table1. Material property of PC sleeper

Name	Physical properties		Unit
Concrete	Elastic modulus	43000	MPa
	Poisson's ratio	0.2	
	Density	2500	kg/m^3
PC tendon	Elastic modulus	200000	MPa
	Poisson's ratio	0.3

	Strength at 0.2% permanent elongation	1705	MPa
	Tensile strength	1927	MPa
	Maximum elongation	0.11	

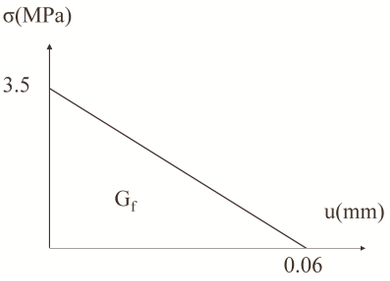

Figure 3. Stress after cracking

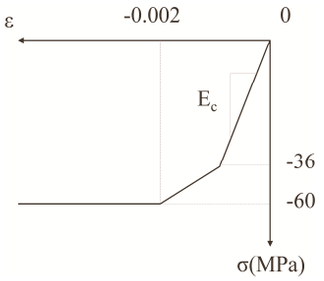

Figure 4. Stress-strain curve

2.1.2 *Material property of concrete*

Table 1 shows the material property of the concrete. The elastic modulus is 43,000 MPa, the Poisson's ratio is 0.2, and the density is 2500 kg/m^3. In regard to the elasto-plastic constitutive law of concrete, Concrete Damaged Plasticity Model is applied. The dilation angle is used 30 degrees. The yield surface applied in this study is the modified yield function developed by Lee and Fenves.

Figure 3 shows the energy curve on stress-deformation relations in the tensile condition after cracking in concrete. The tensile strength is determined f_{tk} = 3.53 N/mm^2 from the calculation Equation 1 by Japan Society of Civil Engineers (JSCE).

$$f_{tk} = 0.23 f_{ck}^{2/3} \quad (1)$$

where f_{ck} = compressive strength.

In order to avoid the problem of localization dependent on element size, the stress after cracking is defined by breaking energy. The value of breaking energy is G_f, which is determined G_f = 100 N/m from the calculation Equation 2 by JSCE.

$$G_f = 10\,(d_{max})^{1/3} \cdot f_{ck}^{1/3} \quad (2)$$

where d_{max} = maximum size of aggregate.

Figure 4 shows the stress-strain curve of concrete in the compressive condition. The compressive strength is 60 N/mm^2, and the ratio of the biaxial compressive strength to the uniaxial compressive strength is 1.16. The strain at compressive strength is 0.002 in accordance with the JSCE. In consideration of convergence of analysis, the stress-strain slope over the compressive strength is set to be zero so that the stress becomes constant in this region. Furthermore, the viscoelastic attenuation by Duvaut-Lions is given to the model.

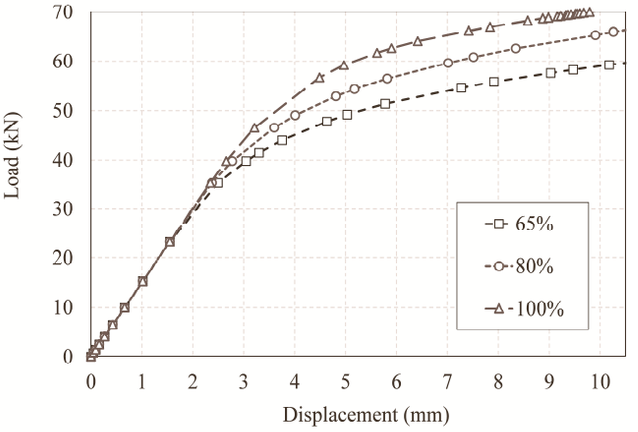

Figure 5. Analysis result

2.1.3 *Analysis procedure*

The analysis processes based on the load control method. The analysis step is divided into two steps. In the first step, introduction of prestress and loading of dead load are carried out, and in the second step, the distributed load is applied to upper surface of the center of the model. Parameters in analysis are introduction values of prestress level to take tendon's relaxation into account. Introduced prestress to the PC tendon are three levels of 100%, 80% and 65% of the initial prestress force.

2.1.4 *Analysis results*

Figure 5 shows the P-δ curve obtained from analysis. The displacement in the graph means the deflection of the lower surface of the beam at the span center. The displacement in Figure 5 indicates the P-δ data in the second step of the analysis. The displacements after the first step were 1.04 mm at prestress 100%, 0.82 mm at 80% and 0.64 mm at 65%, respectively.

No difference in the initial stiffness in each prestress level is seen until the loading load reaches 30 kN. A change of slope appears at 37 kN for prestress 65%, 44 kN for 80% and 50 kN for 100%, respectively. This study defines those load values as the crack initiation load. As the prestress value increases, the crack initiation load shows to go up. From this analysis results, the crack initiation load for the experiment is assumed as approximately 37 kN considering the prestress level was the minimum. The 90% of 37 kN, which is 34.2 kN, is used as the elastic limit that is the maximum load at which cracking does not occur.

2.2 *PC sleeper breaking test*

The experiment is conducted using three specimens which are two tendon break specimens and one healthy specimen. As a PC beam, PC sleepers used in railway are used. Considering the arrangement of PC tendons of the PC sleeper, the specimens are to be upside down. As a loading method, as shown in Figure 6, three points bending is applied (Fig. 6). A PC tendon is artificially cut at three sections of A-A', B-B', and C-C' with a disc grinder. The displacement and strain are measured in each section (Fig. 6). In addition, elastic waves are recorded at two points where are the span center and the span quarter.

2.2.1 *Test specimen*

Figure 6 shows dimensions of the specimen. Longitudinal length is 2000 mm and the cross section is 130 mm × 270 mm at the center. A stranded wire that consists of three wires with the diameter of 2.9 mm each is placed in the concrete as a PC tendon, which has initial tension of 31.8 kN. There are four tendons in a row, in total 3 rows and 12 tendons are in a specimen. For the purpose of cutting a tendon, targeted tendons in tendon break specimens are exposed by chipping the concrete at A-A', B-B' and C-C' sections.

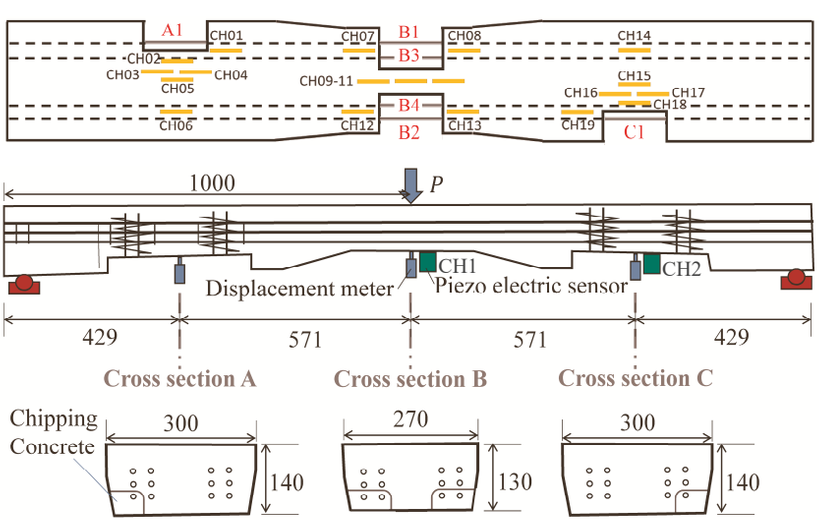

Figure 6. PC sleeper overview and measuring positions

2.2.2 *Measurement method*

19 strain gauges and 3 displacement meters are instrumented in each specimen. In addition, 2 piezo electric sensors are installed for those 2 tendon break specimens. Installed positions are shown in Figure 6. The strain gauge is attached to the lower surface of the concrete of the specimen. Attachment positions of 2 piezo electric sensors are near cross section B-B' and C-C'. The displacement and strain are measured in the vertical and longitudinal direction, respectively.

2.2.3 *Loading procedure*

Figure 7, 8 show the loading procedure. The load is increased to 34.2 kN; that is the elastic limit, determined by the FEM analysis, and then is decreased to 0 kN in each time. Upon loading, dead load ratios $k_1 = 0.5$ and $k_2 = 0.75$ are set as a ratio of the total load to assume a short span bridge and a long span bridge respectively.

In the healthy specimen, beam responses for bending without tendon break are grasped. As shown in Figure 7, loading and unloading are repeatedly given in the order of dead load assumed a short span bridge, dead load assumed a long span bridge, elastic limit load (34.2 kN), and 1.3 times the elastic limit load. Subsequently, the load is increased to the ultimate load.

The other 2 specimens are used to break the tendons and to evaluate the beam behavior to compare with the healthy one. As shown in Figure 8, the tendon is cut when the load is P_1 ($k_1 \times P_2$ or $k_2 \times P_2$) or P_2 (34.2 kN). Before and after cutting the tendon, one cycle of loading and unloading is carried out to grasp the influence of one tendon break on the beam behavior. The exposed PC tendon is artificially cut with a disc grinder in the order of A1, C1, B1, B3, and B2 under loaded condition. B4 tendon is cut by increase of load without the cut work of a disc grinder.

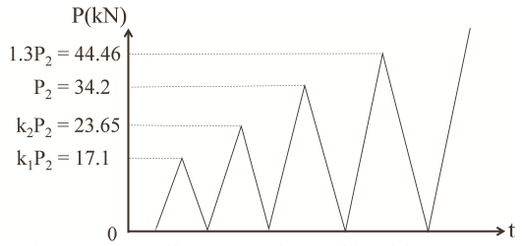

Figure 7. Loading procedure of healthy one

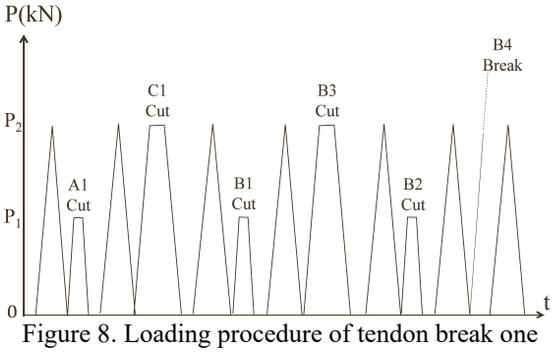

Figure 8. Loading procedure of tendon break one

3 FINDINGS OBTAINED FROM PRE-EXPERIMENT

(1) The validity of the analysis method
Prediction of crack initiation load and prior confirmation of beam behavior are carried out by FEA with a model based on the test specimen. The validity of this analysis method was confirmed because the experimental results were in good agreement with this analysis results of 80% prestress responses (Fig. 10). The assumed elastic limit 34.2 kN was somehow conservative.

(2) Effects of tendon breaks on bending behavior
Stress distribution locally changes near the breaking point, whereas the influence on the global behavior is small, when a tendon break (Fig. 11). If the tendon break occurs in the region where bending stresses are large, crack initiation is induced with reduction of the bending stiffness (Fig. 12).

(3) Possibility of capturing elastic wave for detection monitoring of PC beam break
Elastic waves resulting from the tendon break tend to propagate throughout the beam and can be captured by monitoring micro vibration of the beam surface. In addition, its wave velocity is approximately 3600 m/s (Fig. 13). This suggests that longitudinal waves are predominant in elastic waves due to the tendon break.

4 PC GIRDER RESPONSES DUE TO TENDON BREAK

4.1 *Finite Element Analysis (FEA)*

Before an experiment is carried out, a crack initiation load is analyzed using the FEM model validated in the pre-experiment. Table 2 shows the material property of the concrete and the PC tendon. Figure 14-16 show constitutive laws. Details of the analysis model are shown in Figure 17. The parameter of prestress levels consists of 100%, 80% and 60%. Figure 18 shows the analysis result. The result indicates that the crack initiation load is assumed to be 60 kN. Based on the conservative consideration, the maximum load in the elastic state determined as 54 kN which is 10% less than 60 kN.

Table2. Material property of PC girder

Name	Physical properties		Unit
Concrete	Elastic modulus	33200	MPa
	Poisson's ratio	0.2	
	Density	2370	kg/m^3
PC tendon	Elastic modulus	200000	MPa
	Poisson's ratio	0.3	
	Density	7850	kg/m^3
	Strength at 0.2% permanent elongation	1458	MPa
	Tensile strength	1715	MPa
	Maximum elongation	0.127

Loading method	Bending load

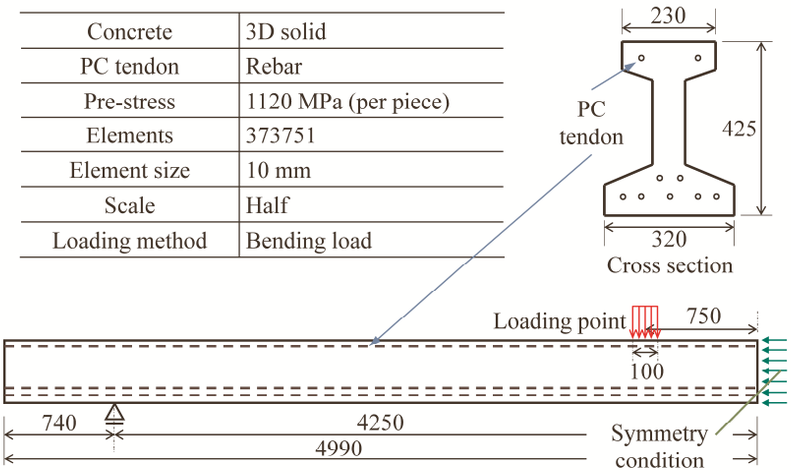

Figure 17. Overview of FEM model based on specimen

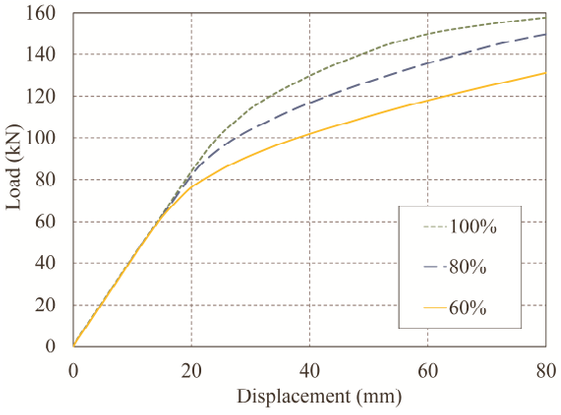

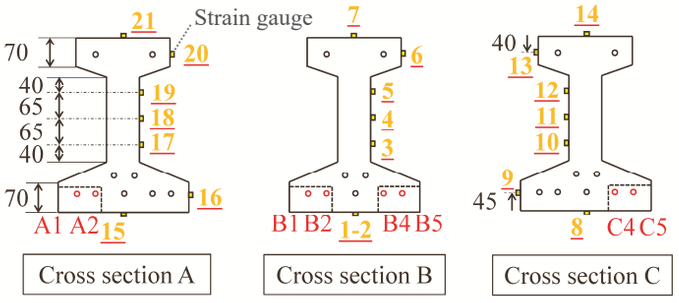

Figure 18. Analysis result

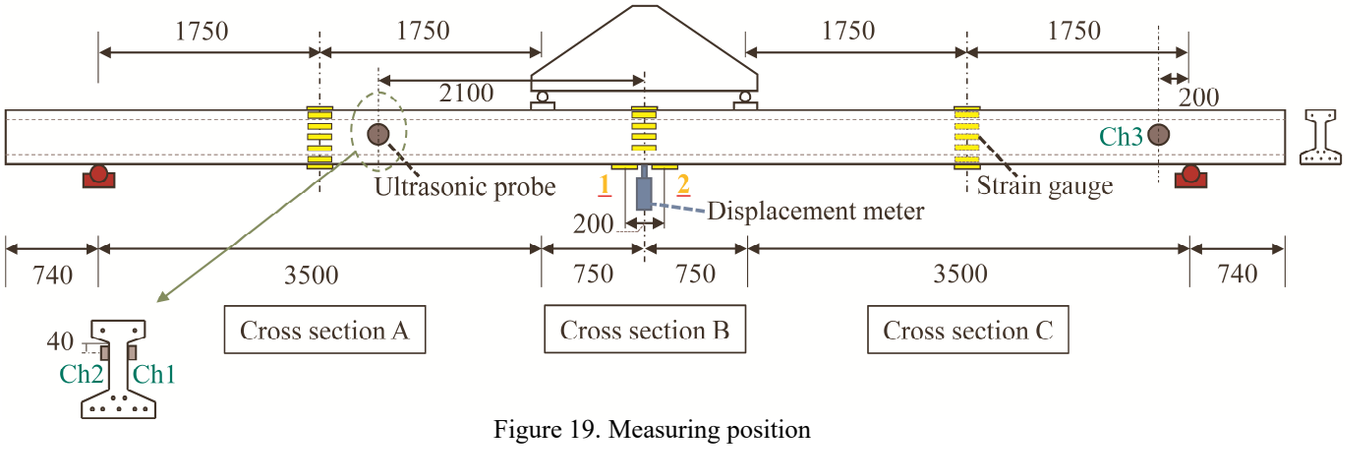

Figure 19. Measuring position

4.2 *Experimental overview*

Loading is given with four-point bending. Three cross sections A-A', B-B', and C-C' are allocated to the specimen as tendon break locations. In those sections, a part of the PC tendons is exposed in advance by chipping concrete. In each experimental phase, a PC tendon is artificially cut with a grinder to simulate actual break cases except the final phase. Regarding measurement, displacement, strain and elastic waves are measured at the position as shown in Figure 19. In addition, natural vibration measurement is performed every time when the PC tendon is cut.

4.2.1 *Test specimen*

Figure 20 shows the overview of the specimen used in the experiment. The body is pretension prestressed girder, the length of which is 9980 mm. The PC tendon is the PC steel stranded wire of 10.8 mm diameter. In total, 9 tendons are placed in the girder. 1128 MPa stress is given to each tendon. The girder specimen was used for more than 30 years in an actual bridge.

4.2.2 *Measurement method*

The apparatus of data acquisition is almost same as the case of pre-experiment; that is, displacement meters, strain gauges, ultrasonic probes as a piezoelectric sensor. Figure 19 shows the installation positions of those. The ultrasonic probe is a 50 kHz wideband vertical probe manufactured by JAPAN PROBE CO., LTD. The probes capture the elastic waves and the waves are logged as voltage. The data sampling rate for the strain and elastic wave data are 500 Hz and 2 kHz, respectively.

Type	Pre-tensioning
PC tendon	9 PC steel strands
Total length	9980 mm
Span length	8500 mm
Cross section	Refer to the figure

Actual appearance

Figure 20. Test specimen overview

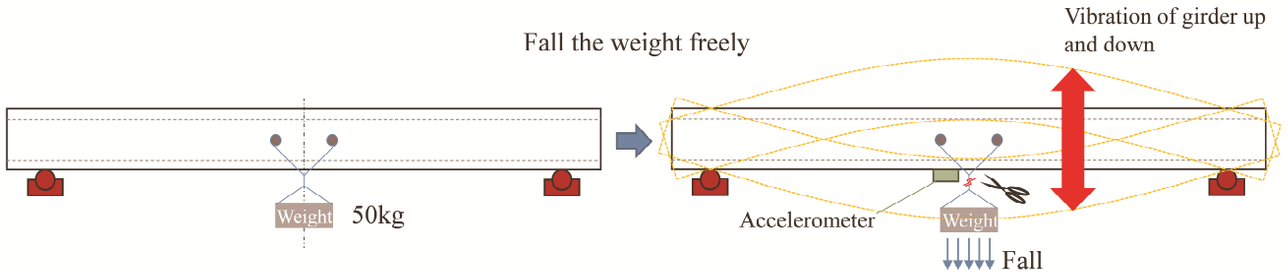

Figure 21. Natural vibration measurement method

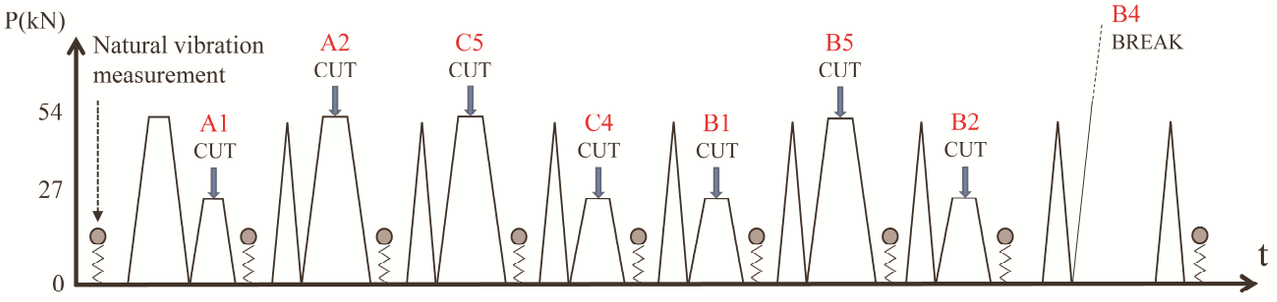

Figure 22. Loading procedure

4.2.3 *Natural vibration measurement*

In natural vibration measurement, free vibration is generated by releasing a 50 kgf-weight suspended from the specimen, and a damping vibration is recorded using an accelerometer installed on the lower surface of the specimen (Fig. 21). In this experiment, this is implemented every time when PC tendon is cut.

4.2.4 *Loading procedure*

Figure 22 shows the loading procedure. The experimental flow is similar to the pre-experiment. In the loading test, the dead load ratio to total load is set to 50% which is 27 kN.

As shown in Figure 22, the exposed PC tendon is artificially cut under loaded condition in the order of A1, A2, C5, C4, B1, B5, and B2. Finally, by increasing the load, PC tendon B4 is broken.

5 EXPERIMENTAL RESULTS

5.1 *P-δ curve*

Figure 23 shows the P-δ curve when PC tendon was cut. When the PC tendon was cut in cross sections A-A' and C-C', the P-δ curve plots no significant change compared with one of B-B'. In contrast, displacement significantly increases after the PC tendon breaks at B-B' where the level of bending moment is large. The influence of PC tendon break on the beam depends on the location. Tendon break may induce concrete breaking cracks if the break location has high stresses. Consequently, the bending rigidity and structural integrity would be reduced.

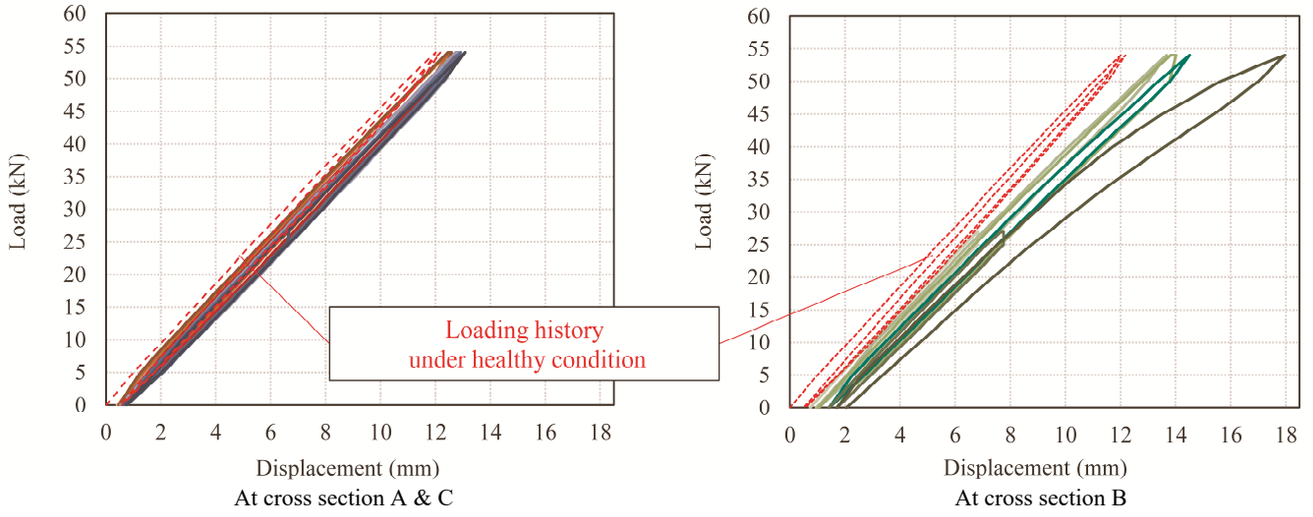

Figure 23. P-δ curve when PC tendon broke at each cross section

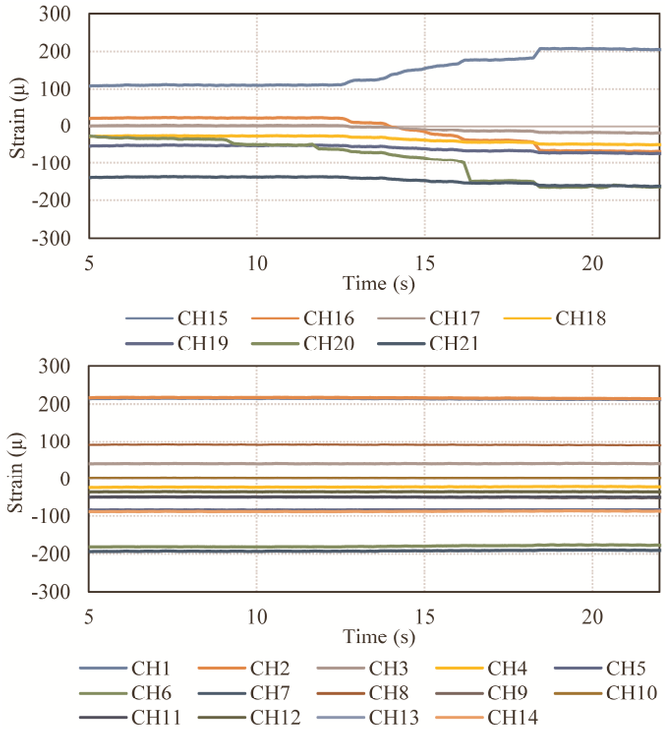

Figure 24. Strain at the time of break in section A

5.2 *Strain responses*

Figure 24 shows strain responses when the PC tendon was cut or had a break. Strain in section A-A' only change in the case that the PC tendon of cross section A-A' breaks. Strain at B-B' and C-C' is not influenced by the tendon cut at section A-A' at that time. Similar phenomenon occurs at section A-A' and B-B' when tendons are cut at section C-C'. Strain responses at the beam surface are not influenced by the tendon cut if the cut location is further than 570 mm. These experimental results also show that stress distribution locally changes in the cross section near the breaking point. The difference in behavior between Figure 11 and Figure 24 depends on the installation position of gauges. These responses mean that bending stress increased after the tendon break. Note that Figure 11 showed the response of lower surface of the specimen. CH 15-21 in Figure 24 showed strain level increased. The strain in compressive area changed to lower values, and the one in tensile area changed to higher values.

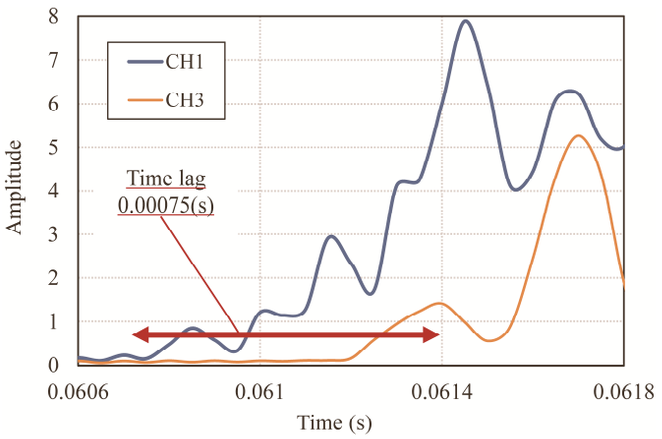

Figure 25. Captured waveform when PC tendon B4 broke

5.3 *Elastic wave*

Figure 25 shows the waveform obtained from the breakage of PC tendon B4 by loading. The time difference between the waves captured with ultrasonic probes CH1 and CH3 is calculated by a cross-correlation function. A wave velocity is calculated from that and it is approximately 2600 m/s. This result is different from the wave velocity obtained from the pre-experiment. Unlike the pre-experiment, it seems that the change in the wave caused by the propagation path has occurred because the position where the wave is caught was far from the breakage occurrence position. Moreover, the web thickness is thinner than that of the PC sleeper. It might be due to the change in the wave mode from longitudinal waves to surface waves immediately after the start of the wave propagation. The speed of surface waves is lower than that of longitudinal ones.

5.4 *Vibration characteristic*

5.4.1 *Data processing method*

The natural frequency in this paper is the dominant frequency obtained by fast Fourier transform of the experimental data.

The data gained in the experiment is processed in the following procedure regarding damping characteristics. First, the vibration waveform at the natural frequency in the vertical first order mode is extracted by applying a band pass filter around the natural frequency. Second, in order to obtain the accuracy damping vibration waveform, an autocorrelation function calculation is performed with data after the maximum amplitude of the extracted waveform. Third, the exponential attenuation curve is approximated by least square method using a maximal value of the acquired damping vibration waveform. Finally, the logarithmic decrement and damping ratio are obtained from Equation 3, 4 using the exponential attenuation curve.

$$\delta = \frac{1}{m} \cdot \ln \frac{a_n}{a_{n+m}} \tag{3}$$

where m = the number of cycles; and a_n = the amplitude of the nth wave.

$$\zeta = \frac{\delta}{2\pi} \tag{4}$$

5.4.2 *Natural frequency and damping ratio*

Figure 26 shows the processed data obtained from the experiment. A natural frequency slightly decreased as the number of PC tendon break increased. In contrast, a damping ratio tends to increase with increasing the number of PC tendon break. Both the natural frequency and the damping ratio are considerably changed at time 8th breaking of PC tendon, which result from the fracture of beam. A tendon break does not significantly affect the change of frequency characteristics unless all the PC tendons placed in the lowest rows break.

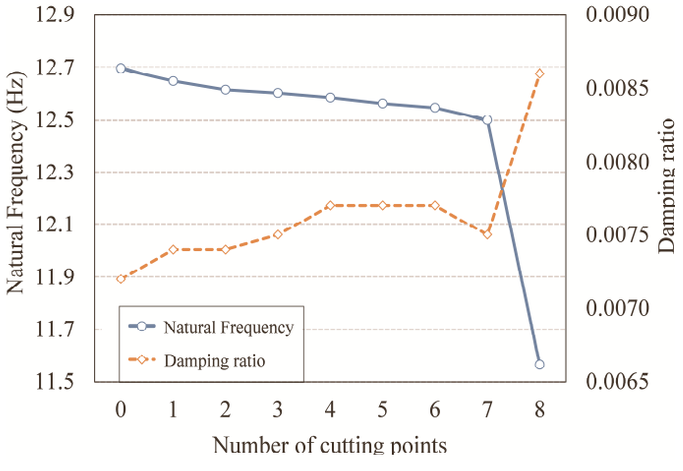

Figure 26. Damping characteristics

6 CONCLUSIONS

This paper described the structural behavior of PC beam in terms of tendon break. The structural responses were observed and evaluated by bending experiments using strain gauges, displacement meters and piezo electric sensors. The conclusions are summarized as follows.

(1) The bending behavior of the PC girder can be simulated by applying initial stresses to rebar elements, defining destructive energy to the concrete for tension behavior and perfect elasto-plasticity to the tendon.

(2) The stress distribution changes in the vicinity of the breaking point, whereas the influence on the global behavior is small, when tendons break. When tendon break occurs in the region where bending stresses are large, the bending stiffness reduces accompanied by crack inducing.

(3) Elastic waves caused by tendon break tend to propagate throughout the beam and can be captured by monitoring micro vibration of the beam surface.

(4) It is suspected that longitudinal waves are predominant in elastic waves resulting from the tendon break. However, it is necessary to consider the influence by the propagation path of the generated wave. Further work is needed to explore this effect.

(5) Frequency characteristics do not considerably change by tendon breaks except for the case that all the PC tendons placed in the lowest rows break. However, a natural frequency slightly decreases with increasing the number of PC tendon break. In contrast, a damping ratio trends to increase with increasing the number of that. In this experiment, results showed that the damping ratio increased by 20% when all tendons in the lowest part of PC related to the primary mode broke in addition to damage concrete.

Bridges Approach Slabs with Fibre Reinforced Polymers

M. Nasser Darwish, *F.ACI*
Faculty of Engineering, Alexandria Univ., Alexandria, Egypt

ABSTRACT:. Conventional steel reinforcing bars in concrete bridge approach slabs (BAS) are subject to high corrosion levels, and hence, fibre reinforced polymers (FRP) bars are their potential substitutes in aggressive environments, since they have higher resistance to aggressive exposures and corrosion. BAS seldom receive appropriate design considerations and are common sources of problems. Their behaviour is governed by soil-slab interaction, leading to varying relative stiffnesses which affect the straining actions especially under heavy loads, and where the moments are reduced with the reduction in rigidity. If neglected, this may lead to irrational designs. BAS are applications where the mechanical properties of FRP bars, i.e. high strength and low stiffness (rigidity), are suitable and advantageous. The BAS is designed as structurally reinforced with FRP bars adapting the principles of reinforced concrete strength design. FRP bars not only enhance strength but also durability. However, serviceability rather than strength requirements control the design. The inherent differences between FRP reinforced BAS and steel reinforced BAS are highlighted and some special considerations of BAS addressed.

1 INRODUCTION

Bridge concrete approach slab (BAS) are transition slabs laid on i mmediate approaches to a bridge generally with one end resting on wall/abutment. They are supposed to form gradual transition between concrete bridge slabs and adjacent concrete/asphalt pavements or embankments and to provide a smooth and structurally sound transition to the adjacent roadway pavement, and mitigate voids and excessive differential settlement between the bridge structure and the approach embankment. Conventional steel reinforcing bars in concrete bridge construction are often subject to high corrosion levels, hence, fibre reinforced polymers (FRP) bars are potential substitutes to steel reinforcement in aggressive environments. Similarly BAS with steel reinforcement suffer from high corrosion, in addition to other severe conditions, including loss of support, poor soil compaction, water ingress, drainage problems…etc.

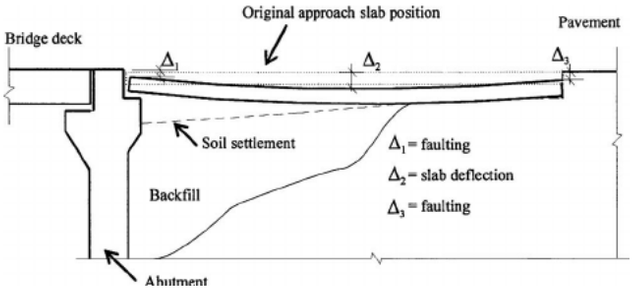

Figure 1. Sketch for bridge approach slabs (*internet BAS photo*)

There are several applications using FRP reinforcement in bridge construction mainly slab decks (eg. see ACI 440 2007), however, less in concrete pavements and slabs on grade (SOG) (ACI 325 2015, Choi et al. 2005, Darwish 2002, Walton et al. 2005), FRP dowels for transverse pavement joints (Shalaby et al. 2001) however, relatively fewer applications of FRP bars in BAS as standalone elements. The use of FR concrete in BAS (Caltrans 2008), and FP decks as replacement units for deteriorated BAS (Chai et al.) were reported.

FRP bars have higher resistance to aggressive exposures and corrosion, key aspects in determining the concrete cover to the reinforcement and tolerable crack widths, hence are potential substitutes to steel reinforcement in aggressive environments and potentially may extend service life. In addition, FRP bars are magnetically neutral (transparent), and hence can be used where electromagnetic neutrality is a requirement especially with the advent of the new smart/intelligent bridge and traffic systems and toll and loop detectors.

Although BAS are important structural elements however they seldom receive appropriate design considerations and are common sources of problems. They are supposed to be cast on uni form, well-compacted soils, and their end may be simply supported at the abutment or resting on a sl eeper slab/beam or just on the underlying grade, i.e. SOG. Adequate compaction under BAS is generally difficult in such restricted areas, and may not be fully achieved. Differential settlement mainly between the bridge end/abutment founded on a more unyielding foundation and the BAS founded on a soil/fill pro-

duces a "bump" in the roadway at the end of the bridge, i.e. sudden change in the slope grade of the BAS, rather than relative smooth transition between the bridge and approach pavement. This affects rideability and driving conditions, and may lead to further deterioration and cracking of the BAS with repetitive loads (Rajek, 2010), and BAS settlement constitutes a major problem (New Mexico Dept. of Transportation 2006).

In previous papers advanced concrete structural analyses of steel reinforced BAS was discussed (eg. Darwish 2016) and FRP reinforced SOG have been investigated (eg. Darwish 2002). In this paper FRP reinforced BAS are addressed and the inherent differences between BAS with FRP and those with steel bars highlighted. The BAS is considered as structurally reinforced with FRP bars adapting the principles of reinforced concrete design. FRP bars not only enhance strength but also durability. However, deflections rather than strength requirements control the design.

2 NUMERICAL IDEALIZATION

From a structural point of view for both cases of BAS: either reinforced with FRP or with steel bars, a typical BAS can be considered as supported on the bridge abutment at one end and on a sleeper slab/beam at its other end, or without the sleeper (Darwish 2016). The sleeper is supposed to reduce settlement and erosion due to water beneath the pavement. BAS can also be just SOG. BAS have been modeled as two way slabs assuming several boundary conditions (Rajek 2010, Thiagarajan et al. 2010) these range from:

- simply supported as a suspended bridge slab without accounting for the underlying soil support to account for any unexpected erosion beneath the slab or softening of soil underneath;
- SOG resting on one end on non-yielding supports, i.e. abutment, and with or without a sleeper slab/beam on the other end.
- SOG resting on the soil underneath.

Soil support underneath the slab can be modeled by using elastic springs (i.e. modulus of sub grade reaction proportional to the subgrade stiffness) although other soil representations (e.g. elastic half space) could be used. The underlying soil can be assumed with no voids (elastic springs over entire span); or with a percentage of voids due to washout or bad compaction (elastic springs over part of the span). Proposals to reinforce the underlying soil were suggested (Chen et al. 2016).

Several numerical idealizations have been adopted (see e.g. ACI325 2015, Darwish 2016). These include: linear Finite Element Method (FEM) and FE with partial soil support and idealizations with limited nonlinearities to model BAS. FEM with full material nonlinearities for SOG considering the concrete slab and reinforcement properties are few (Darwish et al. 1988, Laco et al. 2016). Analyses which consider both the reinforced concrete slab and underlying soil material nonlinearities are rare. Idealizations with material nonlinearities can help assess the actual factors of safety involved and help towards better design, as resulting displacements and loads provide bases for comparison with serviceability criteria derived from tests, practice and pertinent standards.

It has been shown (e.g. Darwish 2016) that assuming the BAS as simply supported beam over its entire length between the abutment and the sleeper, and neglecting the soil elastic support underneath the slab, produces high design moments leading to highly conservative and uneconomical designs. In turn, full soil support may be un-conservative, and the design as a SOG disregarding the abutments/supports seems to be conservative. Considering the far end of the BAS on a sleeper as non-yielding may lead to unconservative deflections. As expected accounting for elastic soil support produces smaller moments, and a reduction in slab thickness. Some design guidelines take into account the potential loss of soil support and void formation under the slab due to consolidation, poor drainage...etc. and provide for partial degree of support to the BAS, by using an effective span factor, less than the actual span e.g. sometimes considered about 0.70 of the suspended span. Several studies on the performance of approach slabs have been carried by researchers and transportation agencies (e.g. Thiagarajan, et al. 2010). As naturally expected the most conservative deflection practical idealized situation is for the case of a SOG, and for smaller values k, modulus of subgrade reaction, the differences increase, and cases approach each other for higher values of k (Darwish 2016).

BAS behaviour is governed by soil-slab interaction, leading to varying relative stiffnesses which affect the straining actions especially under heavy loads, and where the moments are reduced with the reduction in rigidity (Darwish et al. 1988, Losberg 1978). If neglected, this may lead to uneconomical thicknesses and irrational designs. Hence, BAS are applications where the mechanical properties of FRP bars, i.e. high strength and low stiffness (rigidity), are suitable and advantageous (Darwish 2002).

3 AIM & SCOPE

This paper aims at investigating the structural; design of BAS reinforced with FRP bars, based on treating the slab as a structural concrete SOG element applying the principles of reinforced concrete strength design and considering the reinforcement as structurally active to contribute to the load carrying capacity, similar to steel reinforced BAS. The beneficial characteristics of FRP bars in BAS are

utilized and the behaviour of FRP reinforced BAS reinforced are discussed. In addition, the differences between FRP and steel bars reinforcement in BAS are highlighted, and serviceability concerns discussed.

4 PROPERTIES OF FRP BARS

FRP bars are composed (ACI440 2007, Egyptian FRP Code 2005) of continuous high strength fibres embedded in a resin. Fibers are generally made with materials of relatively high modulus of elasticity and high ultimate strength, e.g. glass and carbon. Glass FRP (GFRP) bars are the least expensive among FRP bars. Nevertheless, they possess the lowest tensile strength, (f_{ult}), and modulus of elasticity, (E), in comparison to other FRP materials. In addition, glass fibers may be affected by the alkalinity inherent in the concrete if not properly protected by the surrounding resin matrix. Carbon fibers (CFRP) have high strength and stiffness; and low ultimate strain however may be more expensive than GFRP.

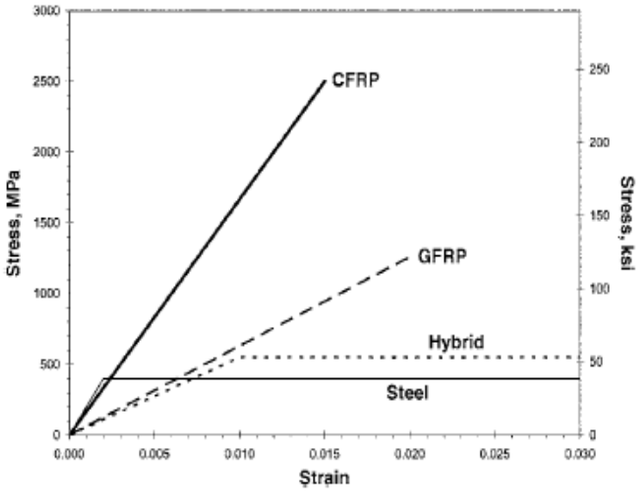

Figure 2. Typical stress-strain curves for FRP (ACI440 2007)

Other mixed breaded bars are available. Internal FRP bars are only considered here, and no ne ar surface mounted bars NSM, or FRP grid or grating systems discussed.

FRP bars are of anisotropic natures and may suffer from brittle fracture, and cannot generally be bent cold. Moreover, they suffer from lack of plastic behavior (i.e. are non duc tile), premature tendon rupture, low dowel resistance and have relatively poor shear strength in the transverse direction. The strength of FRP bars is time dependent and they may suffer creep rupture, hence limiting the sustained load, e.g. to 50-60% of the static short-term tensile strength, may be required. Besides, long-term strength characteristics for FRP bars need consideration (ACI 440 2007). FRP bars should also be checked for fatigue, serviceability criteria, cyclic, or sustained load combined with environmental effects, durability and long term performance. Improving the bond be tween FRP bars and the concrete enhances force transfer; increases the cracking moments; and reduces crack width. In flexural members reinforced with FRP bars, the tension stiffening effect (i.e. tension carried by the concrete between two cracked sections) is generally insignificant. There are inherent differences in behavior between steel and FRP bars. FRP bars have linear stress-strain diagram; and have higher tensile strength. However, their elastic moduli, (E), are generally lower than that of steel. Hence, FRP reinforced BAS will typically have larger deflections, larger crack widths, greater flexural strength, and less ductility behavior than those reinforced with steel bars. Consequently, deflection limits are an important parameter in design considerations. In addition, strength reduction factors or material resistance factors are generally lower than those for steel.

5 SOG WITH FRP BARS

Unlike steel, the elastic modulus of FRP is only slightly higher than that of concrete (especially for GFRP the modular ratio, $n=E_G/E_c$, is small (i.e., just above 1 f or high strength concrete) unlike that for steel, hence limited tensile stress can be transmitted from the concrete to the FRP bars, and most of the tensile load is absorbed by t he concrete. Generally when the tensile strength of the concrete is exceeded, cracks form and the cracking process continues until the cracks extend over most of the cross section and the neutral axis depth is much closer to the compressive end of the slab than in the case of steel. Hence, generally (Darwish 2002) i) a large portion of the cross section is subjected to tensile strains; ii) much larger curvatures and deflections are expected; iii) shear strength is reduced due to increased crack width and reduced size of the compression stress block; and iv) bond of FRP rods may be reduced. In addition, in FRP reinforced concrete flexural members, the transition from the uncracked section to the fully-cracked section may be more abrupt than when using conventional steel bars. However this is not the case for BAS due to presence of the underly-ing soil and membrane effects and, as such, transitions are gradual due to the soil elasticity. In addition, the cracking loads may be generally less than those calculated based on the section modulus of the transformed cross section due to the possible debonding of the FRP bars from the surrounding concrete.

The traditional “drag theory” used for calculating the required steel reinforcement for uniform temperature and shrinkage in BAS as SOG is not directly valid for FRP bars since they have different bond characteristics than steel bars and no plastic deformation. This equally applies to available guidelines for determining steel reinforcement for continuously reinforced concrete pavements and

minimum amount of steel reinforcement, e.g. the Yoder formula (Darwish 2002). The shrinkage and temperature effect of continuously reinforced concrete pavements CRCP reinforced with FRP have been studied and modifications to the formula were suggested (e.g. Choi et al 2005, Walton et al. 2005).

Generally modes of failure of flexural concrete elements reinforced by FRP bars include: i) shear failure of bars at a crack due to low dowel resistance; ii) flexural failures by rupturing of the reinforcement, however only for small amounts of reinforcement; iii) failure by slipping of the FRP bars due to loss of bond; and iv) crushing of the concrete in the compression region. However, in BAS, the membrane effects and the presence of the subgrade undermines the previous failures (Darwish 2002). FRP reinforced slabs will normally have wide cracking. The large depth and width of the cracks virtually diminishes shear resistance that could be provided along the crack/joint due to aggregate interlocking. Hence, the ability to transfer shear loads across joints (or cracks), and resistance to punching is less in BAS with FRP bars due to low dowel resistance of FRP bars and increased crack width. Estimating the load carrying capacity of and deflections of BAS are discussed hereafter.

The increase in crack width may not seriously affect FRP bars durability, however affects the durability of the concrete section and the ingress of aggressive factors and slab riding conditions. There is a decrease in GFRP durability with time, and its durability may be vulnerable on exposure to alkaline environment. Fire protection is generally not a serious issue in BAS with FRP bars since failures are not detrimental due to soil existence. Environmental reduction factors on FRP allowable stresses for the case of concrete section exposed to earth, should be applied (Egyptian FRP Code 2005) and long term performance assessed. The increase in strength with using FRP is modeartly effective in reducing the deflections and crack width realtive to steel reinforcement. The design of FRP reinforced SOG is generally governed by serviceability requirements rather than strength (New Mexico Dept. of Transportation 2006). Due to the lack of potential ductility plastic methods of analysis i.e. the yield line theory (as an upper bound solution), may not be totally valid for FRP reinforced concrete slabs. Besides, there may be a lack of moment redistribution in cases of FRP reinforced slabs thus requiring additional conditions when applying lower bound solutions (Darwish 2002).

6 STRUCTURAL DESIGN

From a structural concrete design point of view concrete FRP reinforced BAS can be treated similar to steel reinforced BAS (Darwish 2016), and regarded as typical SOG with special boundaries, subjected to heavy truck loads, along with other environmental loads. The conventional design of the SOG thickness is generally based on empirical methods or limited theory. These stemps from service load flexural concrete tensile stresses computed by elastic analysis with an allowance for shrinkage and temperature; or on practical guidelines. The basis is to design the slab as plain or very lightly reinforced concrete slabs relying on the flexural strength of the plain concrete (ACI 325 2015) which is completely disregarded in the design of most concrete structures (Losberg 1978). Reinforcement is generally placed to control the width of shrinkage and temperature cracks, and the amount of reinforcement is calculated by applying an arbitrary ratio to the gross concrete cross section area, based on temperature effects. The reinforcement used thus increases in direct proportion to the slab thickness, and its depth is arbitrary based on observed performance.

6.1 *Structurally Active BAS*

Structurally active reinforced concrete BAS are reinforced for structural action and designed assuming the slab to be cracked under wheel loads, and reinforcement provided and positioned according to concrete design requirements, i.e. to carry flexural and other tension forces and contribute to the load carrying capacity. The conventional "absence of crack" criterion will lead to a relatively thick slab. For the interior loading case, there is a prominent positive maximum moment (tension at the bottom of the slab) under the load in comparison with a small negative radial moment, Fig. 3.

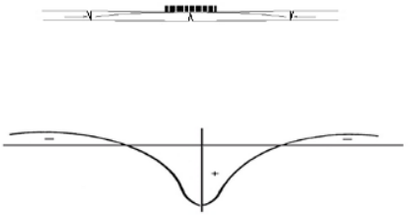

Figure 3. High positive & low negative moments under interior loading

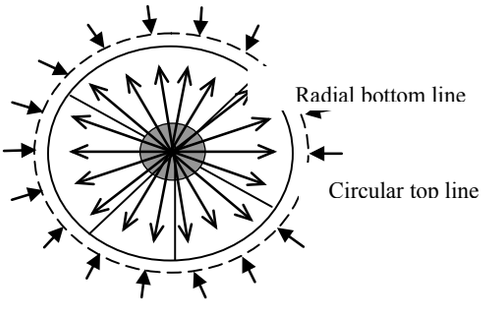

Figure 4. Bottom & top cracking lines (Losberg 1978)

The high positive moments from a co ncentrated load will require significant thickness, if tensile cracks are to be avoided. An aggravating situation is that the thicker and more rigid the slab is made, the higher the maximum moment will be (Darwish et al. 1988; Losberg 1978).

To apply the principles of reinforced concrete, the slab is designed to crack, and two way bottom reinforcement is provided to resist the tensile stresses caused by the positive peak moment, while the slab thickness is designed so that concrete in tension can resist the relatively low negative moment, Figure 3. Such design results in thinner slabs. This, in turn, will decrease the value of the positive moment peak, and the rigidity will further decrease as the bottom of the slab cracks.

7 BEHAVIOR OF ACTIVELY REINFORCED BAS

A typical behavior of a SOG under the interior loading case is linear prior to concrete bottom cracking, the effect of which is a reduction of the slab flexural rigidity. The occurrence of bottom cracking marks the start of the effectiveness of the reinforcement structural contribution. The deflection curves continue with no sharp jumps or kinks in the displacements corresponding to the occurrence of concrete cracking as all transitions are gradual and smooth, and continue even after concrete top cracking due to the soil elasticity (Darwish et al. 1988, Darwish 2002).

7.1 Design of Actively Reinforced BAS

The same principles for steel reinforced BAS (Darwish 2016) are applied for FRP reinforced BAS. A design envelope may be used for the estimation of the top cracking loads of actively reinforced SOG with bottom active reinforcement based of synthesis of nonlinear FE results. Details are found elsewhere (Darwish et al. 1988, Darwish 2002). It accounts for the reinforcement amount and position, concrete properties, and geometric section properties, besides load and soil characteristics. Only the interior loading case is mentioned here due to space limitations. The top cracking loads are related to the sum of positive and negative moment of resistances M^+, and M^-, respectively, and can be expressed as (Fig. 5):

$$(M^+ + M^-)/P = \psi\{a/l_{cracked}\} \qquad (1)$$

where:

M^+= positive ultimate moment, per unit width, provided by the bottom reinforcement= $A_s f_s (d - 0.50 a')$

A_s= area of bottom reinforcement,

f_s = stress in the bottom reinforcement at ultimate positive moment,

d= reinforcement effective depth,

a'= depth of equivalent concrete compressive rectangular stress block,

M^-= negative ultimate moment, per unit width, provided by top flexural concrete strength,

P= concrete top cracking load, P_{tc},

ψ= function relating $(M^+ + M^-)/P$ and a/1,

a= radius of loading area,

l= radius of relative stiffness, relates the slab stiffness to soil stiffness, (length)= $(D/k)^{0.25}$

D= flexural rigidity per unit width of the slab section, (force*length),

k= modulus of subgrade reaction,

l_{gross}= radius of relative stiffness, based on the gross section properties= $(D_{gross}/k)^{0.25}$,

D_{gross} = flexural rigidity per unit width of the gross section,

$l_{cracked}$= radius of relative stiffness, based on fully-cracked section properties, and

$D_{cracked}$ = flexural rigidity/ unit width of fully-cracked section.

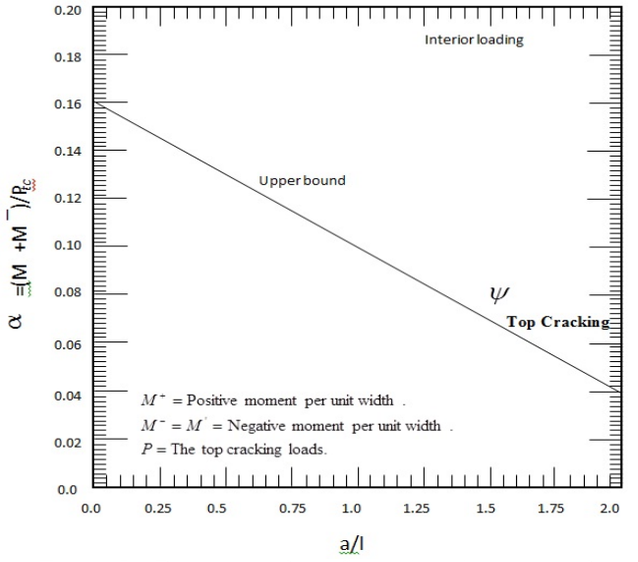

Figure 5. Design envelope for estimatiing top cracking loads (Darwish et al 1988)

The value a/1 is based on the fully cracked not the uncracked section properties.

7.2 Estimating Deflections

Estimating the deflections for FRP reinforced BAS with FRP is crucial regarding the serviceability criteria for loads higher than the cracking loads. Similar to deflections treatment in steel reinforced BAS, (Darwish 2016), coefficient η_1 (less than 1) is to be multiplied by t he deflection of the fully cracked slab based on elastic linear analysis, to estimate the typical deflections, for bottom reinforced slabs under interior loading. It is estimated by comparing deflections resulting from FE analysis at top cracking Δ' with those obtained under the same loads but applying linear elastic analysis of the fully cracked cross section, $\Delta_{cracked}$'.

The deflections for the fully cracked section are calculated at the center interior point, and represent the upper deflection limit. The lower bound for the slab deflection is the elastic deflection of the uncracked section. A typical value for the deflection coefficients at the top cracking load, η_1, is 0.60. For infinite slabs with predefined joints or cracks, with adequate load transfer, these coefficients seem to increase by approximately 20% (Darwish et al. 1988) more than for infinite slabs say 0.72. Similar approximate coefficients could be obtained for finite size slabs, following the same procedure. In essence the coefficients represents the effect of the contribution of other less stressed, less cracked sections to resist loads and decrease the overall deflection at a certain section. One can approximately estimate the slab deflections, in the nonlinear range, under external loads greater than the bottom cracking load, for infinite slabs with bottom reinforcement, under interior loading case, as follows:

-Calculate the bottom cracking load from linear analysis, P_{bc}, and the corresponding deflection, Δ_{bc}, based on the uncracked section properties. P_{bc} can be calculated from the elastic theory by equating the resulting moment M due to the load P, to the flexural cracking moment of the slab, $f_r\ h^2/6$. This may be expressed as (Darwish et al. 1988; Losberg 1978):

$$M = f_r (h^2/6) = P(1 + \upsilon) \{0.04901 - 0.07958 \ln (a/l) + - 0.0781 (a/l)^2 \} \quad (2)$$

for a/1*<1.0, where f_r is the concrete flexural tensile strength.

The deflection, Δ, for an infinite slab under interior loading, the deflection (e.g. Δ_{bc} at the bottom cracking load can be approximately expressed from elastic theory as:

$$\Delta_{bc} = \Delta = 0.03125 (4 - a/l) Pl^2/D \quad (3)$$

Estimate the top cracking load with the help of Fig. 5. Calculate the maximum deflection corresponding to that load, $\Delta'_{cracked}$, calculations based on the *fully cracked* cross section properties. The deflections can be calculated for a/l*=0, as:

$$\Delta'_{cracked} = \Delta = 0.125 Pl^2/D \quad (4)$$

- Using the displacement coefficient η_1 estimate the deflections at the top cracking load:

$\Delta'_{tc} = \Delta = \eta_1 \Delta'_{cracked}$

Δ' = Δ'_{tc} = deflection computed from FE, for the load causing top cracking

$\Delta'_{cracked}$ = deflection computed from elastic analysis for a fully cracked cross section, for the load causing top cracking ,

η_1 = coefficient for estimating deflection at top cracking load from the deflection of a fully cracked section, and

Such deflections and loads exclude the dead load effects .

-Estimate the deflection under the applied load assuming the deflection curve to be composed of linear segments. This can be expressed as

$$\Delta' = \Delta_{bc} + \{(\Delta_{tc} - \Delta_{bc}) (P - P_{bc}) / (P_{tc} - P_{bc})\} \quad (5)$$

where, P_{tc} and P_{bc} are the loads causing top and bottom cracking, respectively. Thus, the deflection, Δ at any load P could be calculated. The deflections under edge and corner loading conditions are generally larger than those under interior loading, and may control serviceability.

Since BAS are under reinforced sections, for steel bars, f_s is assumed equal to the yield stress, f_y. However, since FRP bars have linear stress-strain relationships up to rupture, the stress in the FRP reinforcement f_s, can be assumed to be approximately about 50% of its tensile strength due to time dependent effects and aggressive environment. In addition, the tensile strength of FRP bars cannot be fully utilized as it is accompanied by excessive deflections. The moment M^+ can be considered as a property of the section, its material, and reinforcement amount and position.

For an uncracked section, the gross moment of inertia, I_{gross}, for a plain concrete section does not practically differ from that of a reinforced concrete section. Therefore, the radius of relative stiffness, l_{gross}, is nearly the same for both sections, and the bottom cracking load; failure load, according to elastic analysis is practically the same regardless of the reinforcement amount, position and properties, in elastic analysis. In the design envelope the properties of the fully cracked section are used. The values of $l_{cracked}$ are smaller for FRP reinforced BAS than for steel reinforced BAS, as expected. Hence as can be depicted from the curve (Fig. 5) the top cracking loads for FRP reinforced BAS are higher than those for steel reinforced BAS, due to low elastic moduli of FRP bars. For small values of a/1 less than approximately 0.20, it is more likely that failure will be governed by punching shear rather than flexure, for either FRP or steel reinforcment.

8 SPECIAL CONSIDERATIONS

Prior to cracking BAS have the same behavior and practically the same bottom cracking loads regardless of the reinforcement type (FRP or steel) or amount (plain or reinforced), since linear analysis does not recognize the presence of the reinforcement or its effects in increasing the load carrying capacity. After cracking, FRP reinforced BAS exhibit greater reduction in stiffness than steel reinforced BAS and

hence have greater deflections. For slabs with FRP the top cracking loads are higher than for those with steel bars, as expected, due to the reduced stiffness of the FRP cracked slab, i.e. smaller $1_{cracked}$ value. However, this is accompanied by excessive deflections, Δ, that should be checked against serviceability and geotechnical limitations (Chen et al. 2016).

8.1 *Finite vs. Infinite BAS*

The nonlinear FE analysis for either SOG with FRP or with steel (Darwish 2016) is general and can account for all BAS sizes, infinite and finite, with any boundaries, and special conditions or loadings, however, this may be complex, hence simplified approaches may be needed. The presented approach referred to here was developed based on synthesizing data from FE results into simple charts for infinite SOG, however can be extended to finite size slabs. As expected, the most conservative deflection under a concentrated central load is the case of infinite SOG rather than finite ones, and for higher values of k, the differences in deflections decrease between the cases, and approach each other for higher k values-Coefficients greater than 1.0 can be developed to account for that (Darwish 2016). Hence for estimating the deflections for a BAS under bottom and top cracking loads, apply a coefficient (less than 1) when using $l_{cracked}$ for loads greater than the bottom cracking loads. In addition apply a coefficient (greater than 1.0) to account for finite size slabs (or slabs with predefined joints) relative to infinite size slabs. The effect of own weight, and edge loading should be considered. As superposition is not applicable in the nonlinear stages, hence for specific or special cases and combined loadings, full nonlinear finite element analysis may be resorted to.

8.2 Serviceability

For BAS serviceability criterion rather than strength generally controls the design. FRP bars are not subject to corrosion and the high corrosion resistance is independent of the cover thickness, hence conventional crack width limitations for that reason solely, are not applicable. Long term deflections of FRP reinforced concrete slabs should be considered, and there is need to limit GFRP bars strains under sustained loads due to potential failure from creep rupture and alkaline related deterioration. Temperature and shrinkage effects can be incorporated in the design procedure (e.g. Choi et al. 2005, Darwish et al. 1988). Practical tolerable crack widths were addressed (Choi et al 2005, Waldron et al. 2005). Designs of BAS based on settlement analysis have been reported (e.g. Seo et al. 2002, New Mexico Dept. of Transportation 2006). BAS should provide relative smooth transition between the bridge and approach pavement. However BAS typically experience uneven transition and differential settlement causing inconveniences and bumps adjacent to the bridge end piers and in the pavement at the bridge ends. Suggestions that a tolerable bump may have a slope or angular distortion of 1/200 for simply supported spans and for bump rating and indices were proposed (Seo et al. 2002). Some treat the bump at the end of the bridge as a standalone design issue with prevention as a design goal (New Mexico Dept of Transportation 2006).

9 CONCLUSIONS

Fibre reinforced polymers (FRP) bars are potential substitutes to steel reinforcement in concrete approach slabs (BAS). FRP are non metallic and possess magnetic transparency and unlike steel have higher resistance to aggressive exposures and corrosion, key aspects in determining the concrete cover to the reinforcement and tolerable crack widths. BAS behaviour is governed by soil-slab interaction, leading to varying relative stiffnesses which affect the straining actions under heavy loads, and where the moments are reduced with concrete cracking, and the decrease in flexural rigidity can significantly affect the stress distribution, reduce the maximum moments and increase deflections. If neglected, this may lead to uneconomical thicknesses and irrational designs. The mechanical properties of FRP bars, i.e. high strength and low stiffness (rigidity), are suitable and advantageous in BAS. The treatment of FRP reinforced BAS is similar to steel reinforced BAS, and both are reinforced SOG. The BAS is considered as structurally reinforced with FRP bars adapting the principles of reinforced concrete strength design, as employed for steel reinforced BAS. FRP bars not only enhance the strength but also durability. However, serviceability rather than strength requirements control the design. The inherent differences between BAS with FRP bars and those with steel are highlighted, and special features of FRP reinforced BAS addressed. Nonlinear concrete slab analysis can lead to utilizing beneficial material properties and to improved economical designs and full use of new materials, often disregarded in conventional analysis.

ABSTRACT: Recent catastrophic or unexpected structural failures in road and rail bridges (such as Stewarton rail bridge, Ayrshire, De la Concorde bridge in Canada and more recently the Italian concrete bridge near Lecco) have, in part or full, been attributed to concealed deterioration or deficiencies in one or many components. Defects are usually identified in the course of regular visual inspections carried out by a competent inspector, making an assessment on the condition of the visible components, with reference to appropriate guidelines provided in standard inspection manuals. Hidden defects present unknown risks to the overall integrity of the structure if not identified and rectified.

In recognition of these risks, members of the Bridge Owner's Forum in the UK initiated a project to develop a guide that provides recommendations for identifying, inspecting, designing and maintaining bridges with hidden components. Recently published by CIRIA, Arup and AECOM have collaboratively developed this guide, which the current paper provides a summary of findings from the guide. Translated into an Australian context, key concepts are discussed, such as defects in typical hidden components, proposed risk assessment techniques for management, and recommendations for the development of more targeted inspection and maintenance regimes (that may include health monitoring techniques) to critical areas. The paper also provides various design and planning recommendations for consideration in the preliminary evaluation phase.

1 INTRODUCTION

Bridge owners, operators and engineers including designers, assessors and maintainers all play key roles in bridge management. A core component of a bridge management programme is on-site examinations by a competent bridge inspector. These inspections are central to recording bridge condition and are used by bridge owners to ensure defects are identified and rectified within reasonable timeframes as well as identifying larger maintenance works. When coupled with a refined numerical assessment of capacity, the risk posed by a bridge and / or individual components to threatening safety can be better defined. Generally, this works well in Australia: there are few serious failures. However, amongst other items the success of the process is sensitive to the quality of the access available during the inspection. If an inspection does not include all elements since, for example they are hidden and not easily examinable, the adverse effects can be significant or in the worst cases catastrophic.

High profile cases in recent years such as at Stewarton, de la Concorde, Hammersmith and Boston Manor have bought the importance of hidden defects in bridge components to the forefront of bridge owners' focus. Prompted by these and other cases, the Bridge Owner Forum (BOF) identified the need to define good practice when inspecting, identifying and maintaining hidden bridge components.

BOF approached the publisher CIRIA to produce a new guidance document covering these areas. In December 2014, CIRIA procured the joint services of AECOM and Arup to write this report, recently published as CIRIA Guide C764 "Hidden Defects in Bridges – Guidance for Detection and Management" (Collins et al, 2017). Guidance is given to:

- Define the component that may contain a defect. Common defect types are described.
- Inspection guidance on
- Identification and maintenance
- Design guidance

This paper provides a brief summary of guidance provided in C764. Whilst this guide was written for a UK and Ireland audience, this paper has been expanded to provide an Australian context to this issue. The paper discusses what a hidden defect is, some examples where hidden defects have been instrumental in catastrophic structural failures, an overview of current practices in identifying and managing such defects and components, and then outlining potential solutions in how to manage bridges with hidden components.

2 EXAMPLES OF HIDDEN DEFECTS

2.1 *Definition of a Hidden Defect*

The key driver in a bridge inspection is to identify components that have defects. Defects are defined broadly as a detrimental action to a bridge component that:

> "*risks the ability of the bridge to be defined as meeting service level and safe for use criteria*"
> (Highways Agency, 2007)

Defects can be formed or become apparent at any time in the structure's life. Six primary sources have been listed as principal sources of defects:

- Inadequate design
- Naturally occurring damage
- Accidental or deliberate damage
- Material deterioration
- Reduced functionality of component
- Other sources such as poor design detailing

Usually, most components are visible or accessible to inspect and assess its condition. A hidden component is an element that would not usually be visually inspected as part of a bridge inspection i.e. to within touching distance using normal inspection techniques such as visual techniques and hammer tapping. Its obscurement may be due to design, deterioration, functionality of the component, or simply that an element may not be accessible at the time of the inspection (e.g. submerged piles).

Unfortunately, in some cases the time a defect is found is once the component has failed. In the case where a component is hidden or not visible, this presents a significant risk, particularly if it is a structure-critical member.

It is also important to consider untypical hidden defects and untypical hidden components. This may include unusual or bespoke detailing, accidental inclusion of temporary works, or any form or structure (intentional or otherwise) that may lead to a detrimental condition (such as water retention), and thus a compromise in the structural integrity of a component or the overall structure itself. A hidden component can also be a one that no one knows exists, but may cause a defect that is detected by non-visual means.

2.2 *Case Studies*

Case studies were collected for the CIRIA report to provide useful background reading as well as give a practical context to this topic. A short summary of five case studies is given below, two of which are Australian examples, and the rest are those that became central to forming the new guidance of the CIRIA report.

2.2.1 *Stewarton Rail, United Kingdom*

In January 2009, a train derailed as it crossed the Stewarton Rail Bridge, leaking various heavy fuels into the local waterways. There were no injuries or fatalities however the bridge had collapsed completely (Figure 1). The ensuing investigation demonstrated that the predominant cause of the collapse was due to a shear failure in two of the three main girders. The failure was initiated due to significant section loss (some complete) in the web plates, which were buried under ballast.

Figure 1. The Stewarton Rail Bridge after collapse

Prior to the collapse, concerns had been raised on corrosion to visible areas of the bridge. It was also noted that at defined locations there were areas under ballast that may be prone to severe corrosion and lamination leading to loss of section. Following this urgent defect report, the bridge owner inspected the main girder to assess the issues raised, suggest actions and recommendations. The full extent of the corrosion in buried areas was not identified in this inspection and no recommendations were raised to repair the defect

2.2.2 *Del La Concorde Bridge, Canada*

In 2005 the suspended span of a highway bridge over a dual carriageway collapsed, killing five people. Brittle failure to a half-joint detail had occurred (Figure 2). Whilst there were a number of contributing factors including leaking expansion joints, the root cause of failure was identified as inadequately fixed reinforcement. Half joint reinforcement detailing offers little redundancy to such defects. This hidden defect was exacerbated by: high stress concentrations focussed at re-entrant corners; the debris and moisture trapping nature of the joint's re-entrant corner and the difficulty of accessing the bearing shelf for inspection or maintenance.

Figure 2. Failure of De la Concorde bridge

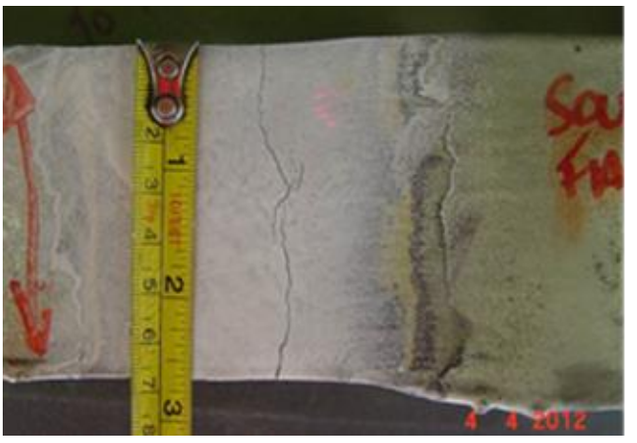

Figure 3. Crack in electro-slag weld, Boston Manor Viaduct

2.2.3 *Boston Manor Viaduct, UK*

The 1 km Boston Manor viaduct is in Brentford, West London (Wearne, 2014) (Nicholls, 2015) carrying the dual carriageway of the M4 motorway. Opened in 1965, its girders and trusses have over 600 electro-slag butt welds. Electro-slag welding is rarely encountered in bridgeworks: Boston Manor is thought to be the only electro-slag welded bridge on the UK trunk road network. Following concerns over the method's susceptibility to fatigue and brittle fracture, by the late 1970s the method was superseded.

As late as 2011's principal inspection, no cracks breaking through the surface of the paint system had been found. Aware of the historic issues of electro-slag welding, the Highways Agency (bridge owner) commissioned a numerical assessment of the welds. No issues were found. To verify the assessment, non-destructive testing (NDT) and material samples were taken in 2012. The rapid development of events was remarkable:

- Mid March 2012, start of NDT inspection.
- 22 March 2012, first crack in electro-slag weld identified.
- 23 March 2012, further cracks found and 17.5t emergency weight restriction imposed.
- 28 March 2012, increasing incidence of crack discovery: 7.5t emergency weight restriction imposed.

In total, 111 cracks were found in electro-slag welds (Figure 4). It was stated that the cracks would require remediating within a maximum of 250 weeks to avoid critical failures. A summer embargo on structural works was approaching around the London 2012 Olympic and Paralympic Games, during which all weight restrictions required removing. Work to remove cracks by grinding / burring started immediately. Just seven days before the embargo, the road was closed to all traffic due to the continued propagation of some cracks, meaning brittle fracture was a real possibility. The cracks were finally removed by burring under monitoring by thermal image detection. The bridge reopened 13 July 2012 to 7.5 tonne traffic

2.2.4 *Hornibrook Highway Bridge, Australia*

Located in an aggressive marine environment, the Hornibrook Highway Bridge was completed in 1935 as a privately commissioned construction project. It consisted of 294 spans, was 2684 m long and was the longest road viaduct across water in Australia when completed (Melchers et al. 2017). It was demolished in 2011 due to extensive deterioration in the timber superstructure and the reinforced concrete headstocks, however the majority of reinforced concrete piles were in remarkably good condition.

One exception to this was a pile that 'bent' whilst being extracted during the demolition process. Upon closer inspection, the cross-section of the pile showed that two of the four reinforcing bars was either completely or severely corroded, adjacent to rust staining along the failure plane. The remaining two bars were in good condition with no signs of deterioration. With the exception of a very fine transverse crack where the failure initiated, no rust staining or deterioration was observed on the external concrete surface.

Figure 4: Pile showing reinforcing bars in good and poor condition

2.3 *Bus Station Retaining Wall*

The bus station is partly set below ground level with secant pile walls in an arched form retaining the fill and roads as well as supporting the structural deck above the bus station. An unreinforced block wall acted as an architectural facing in front of the piled retaining wall. Inspectors noted that the block wall was often damp in one length of the wall. This observation was nearly a decade after the station had opened. Further investigations revealed that soil had been washed into the space between the piles and blockwall by groundwater. This in turn had caused a stormwater pipe to rupture and increase the water flow and hence rate at which soil was lost below the road. The block wall was acting as a retaining structure for which it was not designed, its curved shape providing the strength to prevent collapse. A large hole had formed below the adjacent road – the source of the material now in the void between pile and blockwork. Two potentially catastrophic hidden defects were identified; overloading and potential collapse of the block wall and formation of a large sinkhole in the road above.

Similar hidden sinkholes have been known to form in several situations including below the curved spill through surface protection at bridge abutments, at joints in stormwater culverts, and behind retaining walls, including bridge abutments, adjacent to rivers or stormwater channels.

3 CURRENT MANAGEMENT STRATEGIES

3.1 *Overview*

Responsibility for the management of bridge infrastructure rests with many different organisations and authorities worldwide. The management of their infrastructure is typically governed by a series of documents, guidelines, standards, specifications or technical notes. In some cases where organisations are small, have limited resources or are responsible for a small number of bridges in their network, these are often managed implicitly or on an individual basis. The following sections provide an overview of current bridge management practice in the UK and Australia in relation to hidden components.

3.2 *UK*

Typical bridge management practice for trunk roads is defined in the Design Manual for Roads and Bridges (e.g. BD 63 (Highways Agency, 2007)). For local roads, the document "Well Managed Highway Infrastructure – A Code of Practice" (UKRLG, 2016) is preferred. For the purposes of identification and mitigation of hidden defects, the approaches outlined in the two documents is similar. Bridge condition is recorded from a regime of inspections including general, principal, and special inspections. Inspections provide key information for all maintenance interventions, including decisions for monitoring or testing. However these guidance documents currently do not explicitly detail a regime for uncovering and inspecting hidden components for general or principal inspections.

The owner and maintainer of bridges on the British heavy rail network, Network Rail, operates inspections similar to the highways' authorities' inspections, conducting routine and detailed examinations of varying frequency and using a risk-based approach. Under this regime, it would not be usual practice to expose hidden components. Following the collapse of the Stewarton Bridge in 2009, Network Rail reviewed their inspection approach to incorporate hidden critical elements (HCE). This interesting, proactive work is detailed in the CIRIA guide and has resulted in intrusive inspection to approximately 4000 bridge spans. This has led to a programme of works, including bridge replacement and strengthening. HCE examination has now entered the regular cycle of bridge inspections.

In total, 111 cracks were found in electro-slag welds. It was stated that the cracks would require remediating within a maximum of 250 weeks to avoid critical failures. A summer embargo on structural works was approaching around the London 2012 Olympic and Paralympic Games, during which all weight restrictions required removing. Work to remove cracks by grinding / burring started immediately.

3.3 *Australia*

In Australia, a range of asset management documentation relating to bridges exists. From a high level perspective, Austroads provides several documents that presents collated information and best-practice summaries of bridge management practices in Australia. These guidance documents include:

- Guidelines for Bridge Management – Structure Information (AP-R252-04)
- Guide to Asset Management (currently being updated)
- Guide to Bridge Technology (currently being updated)

A deskstop study shows that all state road authorities have formal documentation that provide high-level asset management guidance for their infrastructure. In relation to bridges, various documents of varying levels of sophistication and depth exist to provide more specific guidance. Relating to the inspection of bridges, again most state road authorities have developed their own bridge or structure inspection manuals to govern the inspection requirements and outputs. Informal risk management regimes may also be in place for specific at-risk

components, such as halving joints or post-tensioned cables.

However it should be noted that only a handful of manuals specifically mention hidden components, and a lesser number to provide documented guidance for their management. With the exception of the Queensland Department of Transport and Main Roads (TMR), there are no publically available guidelines that provide risk management strategies for bridge managers/owners to identify, inspect and manage structure-critical components that are hidden or inaccessible. The following documents provide guidance on hidden defects:

- AS5100.8 (2017): Mentions the use techniques to inspect hidden areas in certain applications, such as timber bridge drilling or Ground Penetrating Radar for void detection. However guidance is minimal and provides no broader recommendations.
- Level 3 Inspection Criteria for Potentially Structurally Deficient Bridges" (TMR, 2016): identifies the "possibility of hidden distress" as a factor to be considered when assessing a bridge for an immediate risk to public safety.
- VicRoads Structure Inspection Manual (2014): some references made to hidden deterioration.
- Transport for NSW, Assets Standards Authority: released Technical Note TN 072 (2014) that identifies hidden structures, used by both road and rail authorities. They define hidden structures as "structures or components of a structure that are obscured in such a way that they are not readily visible" and state that "the examination of hidden structures is important to assure ongoing structural integrity". Some guidance is given to inspecting such components, but lacking in specifics.
- Structures Examination Engineering Manual (RailCorp, 2009): relates to the identification of defects that may be indicators of hidden components deterioration, such as "stain trails indicating hidden corrosion or working members"

In summary, there is currently minimal published guidance for bridge asset owners or managers to assist in identifying and developing strategies to manage hidden components and their defects. Risk management strategies dealing with items such as half-joints, hinges, post-tensioning cables or other special or low-redundancy hidden components are generally dealt with on a unique bridge or issue-specific case. Consideration should be given to this area, particularly relating to structural capacity.

4 PROPOSED MANAGEMENT STRATEGY

4.1 *Overview*

It is anticipated that the vast majority of bridge owners already have a bridge management approach from which the task of identifying at-risk structures can commence. Where a process does not already exist to do so, it is recommended that bridge owners mandate a new programme of managing hidden defects.

To formalise a process on how a bridge owner / operator / maintainer can manage the risks posed by hidden defects to their portfolio of bridges, the CIRIA report provides detailed guidance, largely based on the approach taken by Network Rail post-Stewarton. It is representative of a proactive approach.

An overarching risk management approach is recommended in the management of hidden defect in bridges. This is based on a process developed as part of the UK's bridge assessment processes (Highways Agency, 2015). A cyclical three stage process is recommended in the guide, which comprises the following steps:

- Understanding the risk features
- Implementing a targeted inspection regime
- Evaluation and implementation

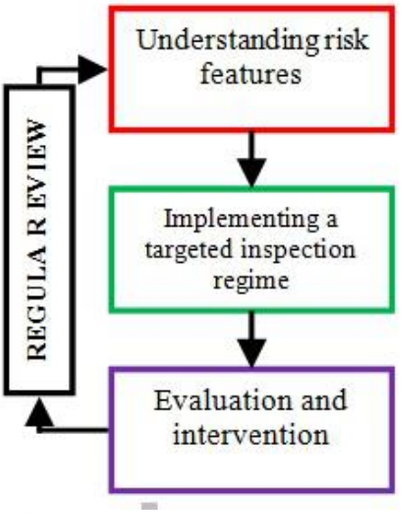

Figure 5: Simplified flow chart of suggested process for managing hidden defects

The process is shown in Figure 5 and is explored further in the following sections.

4.2 *Understanding the Risk Features*

This phase predominantly involves collating and reviewing existing information about a bridge in order to understand the criticality of a bridge and its components in isolation and as part of a network. It involves the following steps:

- Review of bridge inventory information
- Review of bridge componentry

– Identify component criticality to bridge.

It also involves the review of existing information pertaining to a bridge such as drawings, photographs, previous inspections and assessments, maintenance records, modification and construction records.

It is recognised that each bridge portfolio managed will be distinct, though there may be common features that can streamline management. Considerations towards structure redundancy, ductility, environmental conditions, bridge loading history and the impact of condition on the structural capacity of the bridge will be required in the overarching exercise of identifying and understanding risks associated with hidden defects.

An important aspect of this phase is to be asking "what is not recorded?" and "what cannot be seen", as this process can often lead to uncovering issues not previously explored that relate to hidden components.

Identification of critical components and the effect of their deterioration must be considered on a case-by-case basis by an experienced bridge engineer. Critical components may differ significantly between superficially similar bridges. Some examples of areas that may be more critical than others include:

– truss members where there is little or no structural redundancy
– half-joints
– post-tensioning st
– eel members in regions of high stress \main cables of suspension bridges.

The outcome of this process will be an understanding of which hidden components are present in the assets being managed and how critical their condition is to the safety of the structure. Bridges can then be prioritised based on their susceptibility to these defined defects. Note that this guide does not recommend a method for prioritisation, although this should be undertaken on a risk basis. It is recommended that prioritisation be undertaken by experienced bridge engineers.

The review from this phase will inform the second phase (i.e. the inspection regime) of this process.

4.3 *Targeted Inspection Regime*

Inspections are considered a core component of bridge management and are crucial to accurately determine risk. Hidden defects investigation could be either undertaken as a special/Level 3 inspection or worked into a current Level 2 inspection regime. The former should be considered where the risk of failure of a hidden component with significant consequences is likely to occur before the next inspection. This would be an interim measure until intervention works are undertaken. Where it is not possible to inspect all hidden components within the required cycle of Level 2 inspections those of greatest risk should be prioritized.

Thorough inspection is vital. The hidden defects inspector should actively search for and identify the likely cause of a defect. If the cause is not found or unclear, it is equally important that this is recorded for further investigation by others. The key distinction the CIRIA guide makes is for inspectors to ask "what can I not see?".

It is possible that an element that is in poor condition with widespread defects has no detrimental effect on the load carrying capacity of the structure. So, while recording condition is useful and important, there may be a disparity with what is of prime importance to the bridge owner, i.e. bridge capacity and management of risks posed to bridge users/third parties

4.4 *Evaluation and Intervention*

As in any bridge management regime, high quality inspections are only of value if they are accurately interpreted and remedial works enacted upon. This stage of bridge management is generally well recorded in existing guidance. Accurate interpretation may include consideration of how the identified condition of the hidden element effects bridge capacity: numerical assessment may be required. Then, if unacceptable risk remains, remedial works would follow that may include:

– Monitoring
– Load restrictions
– Further numerical assessment
– Component replacement
– Alternative load path provision
– Strengthening
– Bridge replacement
– Updating of emergency plans.

Residual risks should be highlighted and mitigated.

4.5 *Regular Review*

Risk posed by a hidden defect may change over time due to:

– Condition degradation
– Load changes
– Changes in load path
– Developments in structural understanding
– Cultural change in risk perception

It is hence vital that once the hidden defects programme is set up, it is regularly reviewed. This should include incorporation of intrusive works to

hidden areas as part of the established inspection regime.

4.6 *Final Comments*

Undertaking a hidden component inspection may require much pre-planning, intrusive works and disruption to bridge users.

Given the considerable efforts to facilitate the inspection, other works that could take advantage of this access could be considered.

If undertaken wholeheartedly, this is not a short exercise, however it does reduce the likelihood of unforeseen failures, such as those described in the case studies.

5 USE OF TECHNOLOGY

There is recent interest in use of technology, notably drones and photographic visual techniques to inspect areas of bridges that are difficult to access (McRobbie et al, 2014, Lovelace, 2015).

Where an area is difficult to access, initial inspection by drone may assist in identifying locations where thorough inspection is most needed. However, in general, inspection using technology should not be undertaken in place of principal inspections.

A rapidly developing area that may form an information source into the risk-based approach is Structural Health Monitoring (SHM). Bridge engineers have identified the potential for SHM to greatly assist in bridge management, and numerous existing bridges where hidden defects have been identified or are suspected have had SHM installed (Anderson et al, 2012). A SHM system:

- constantly samples instrumentation output during bridge operation, and possibly as early as during construction
- includes multiple structural components
- processes output to generate information that assists general bridge management
- allows access to historic data captured by SHM.

It is vital to understand that when retrofitting SHM, pre-existing damage is identified and recorded. Otherwise, only the rate of deterioration will be measured not an absolute measure of damage accrued.

6 DESIGN GUIDANCE

The above discussion outlines strategies for existing bridges. For new structures risks associated with hidden components and their defects can be mitigated at the design phase. This requires the designer to review the overall structure for areas where components may become hidden or difficult to inspect, understand the criticality of the hidden components, the processes that may result in defects at these hidden components and the opportunity to eliminate these hidden components. The review should also consider moisture traps or other mechanisms that may increase deterioration of a component.

The ultimate aim is to eliminate such components or issues, however this is not always be possible, for example piles will be in the ground and reinforcement embedded in concrete. Therefore, the designer should aim to provide a considered approach to mitigation of this risk. Other options is to allow for long-term monitoring strategies to be installed to either monitor the bridge (such as structural health monitoring, see Section 6 for further discussion) or to provide on-going mechanical support to eliminate the risk (e.g. dehumidification in post-tensioning applications or cathodic protection applications).

Beyond the specific guidance given in this section, the designer of a new bridge looking to avoid critical defects in hidden deck components is directed to Hendy and Iles (2015) and Soubry (2001).

7 CONCLUSIONS

Defective bridges may put the travelling public, those working on the bridge and third parties at risk. Where a defect is not known and if applicable, appropriate monitoring is not undertaken, the associated risk cannot be managed or mitigated appropriately. In severe cases this can lead to severe network disruptions and at worst, fatalities, as observed for the collapse of the Stewarton rail Bridge in Scotland in 2009. A brief review of current bridge management publications in the UK and Australia highlights the lack of guidance on managing bridges with hidden components.

Based on these failures and lack of guidance, CIRIA published C764 “Hidden Defects in Bridges – Guidance for Detection and Management”, which provides considerable detail on all the common bridge types and their possible hidden defects. Guidance is given to:

- Define the component that may contain a defect. Common defect types are described.
- Inspection guidance
- Identification and maintenance
- Design guidance

Similarly in Australia, such manuals and guidance have not been developed to account for uncovering, inspecting and managing hidden components and subsequent defects. With aging bridge stock ever more heavily used, effective management of hidden bridge components is going to increase in importance unless extensive actions are taken. Bridge owners, managers and inspectors are urged to consider this most important subject in their day-to-day work.

ACKNOWLEDGEMENTS

C764 was funded by Freyssinet, Welsh Government, ICE, Transport Scotland, Highways England, Transport Infrastructure Ireland, Network Rail, TransportNI, Environment Agency, Ramboll, Mouchel, Strainstall, Arup and AECOM. Report contents have been shaped by the project steering group including members from the sponsorship organisations. Permission to present report C764 from CIRIA is gratefully acknowledged.

Captain Cook Bridge Bearing Replacement

W Mengel, P Adams, W Hansford, J Spathonis
Queensland Department of Transport and Main Road

ABSTRACT: The Captain Cook Bridge is the most trafficked bridge in Queensland. The original DU Glacier and stainless steel sliding plates failed and were replaced in 1996-97. Routine inspections in July 2016 found that the PTFE sheet had extruded from the sliding bearings on the bridge's two main suspended spans at its southern end. Bespoke bearing designs were implemented in February 2017.

This paper discusses the innovative bearing design changes, how the replacement bearing design evolved, the jacking of the suspended spans, traffic control and strategies to allow the new bearings to be installed. This paper discusses the bearing design changes and a new sliding material, *Orkot TXMM®*. This was the first trial of Orkot in a bridge bearing in Queensland. As this material has a high allowable compressive stress, it not expected to extrude under a substantial increase in traffic loading. As part of the design changes, a new lateral restraint was installed.

1 BACKGROUND

The Captain Cook Bridge crosses the Brisbane River and provides the main arterial feed into Brisbane's CBD from the southern suburbs and Gold Coast region. The bridge was opened to traffic in 1972, and is currently the most trafficked bridge in Queensland, with an annual average daily traffic of 135,000 vehicles.

Captain Cook Bridge contains two separate 550m long bridges, one for each four lane carriageway. The five span, twin cell, variable depth, post-tensioned precast box girder forms the superstructure for each bridge. There are two 34m long suspended spans in each bridge spanning the cantilevers between piers 1 and 2, and piers 3 and 4 respectively — refer to Figure 1. The bridges, each with a kerb-to-kerb width of 13.4m, share common substructure foundations.

The suspended spans are supported on three bearings at each end, with fixed hinged bearings at one end, and sliding knuckle bearings at the other end. The original sliding bearings contained stainless steel sheet and a DU-Glacier bearing material. Inspections discovered that the sliding material had failed and the stainless steel sheets were discharging. They were subsequently replaced in 1996-97 with thicker 6mm stainless steel plates and 4mm thick glass filled polytetrafluoroethylene (PTFE) sliding material (Fong 2000). After 20 years of service, routine inspections in July 2016 revealed the extrusion of the PTFE sheeting from the sliding bearings on the southern Suspended Spans B — refer to Figure 2.

With the frequency of heavy vehicles and hauling expected to increase with the commencement of major construction activities in the CBD and planned high-rise developments, immediate action was required to prevent further deterioration of the bearings and potential structural damage to the bridge.

This paper will briefly discuss the bearing failure but will primarily focus on the bearing design, maintenance and logistical activities to jack the suspended spans, remove the old bearings and install the replacement bearings. Others have addressed the bridge dynamics and bearing loads in more detail (Hourigan 2017).

At the same time as work was progressing on the replacement of the damaged bearings, the project team also had to address other critical work on three access ramps on the adjoining Riverside Expressway.

2 SLIDING BEARING CHARACTERISTICS

All of the original Captain Cook Bridge bearings were specially designed hence are unique to this structure. These bearings consisted of an upper stainless steel plate, and a sliding material forming a low friction sliding surface. The low friction sliding material was confined within a recess in the top of a knuckle. The fulcrum of the base plate is curved (760mm radius) to allow the knuckle to rotate over the base plate. This arrangement accommodates deck rotations and sliding due to live-load induced deflections and thermal expansion. The sliding friction creates an overturning moment, causing a rotation about the transverse axis. The bearing stresses are redistributed so that the centroid of pressure is eccentric to resist the overturning moment. This results in a non-uniform stress distribution across the knuckle. This bearing behaviour is summarised in Figure 3 and was considered in the design of the new knuckles.

It was previously concluded (Fong 2000) that the original 1970's bearings failed because of the DU-Glacier plates' inability to tolerate non-uniform bearing stresses. A number of factors could have con-

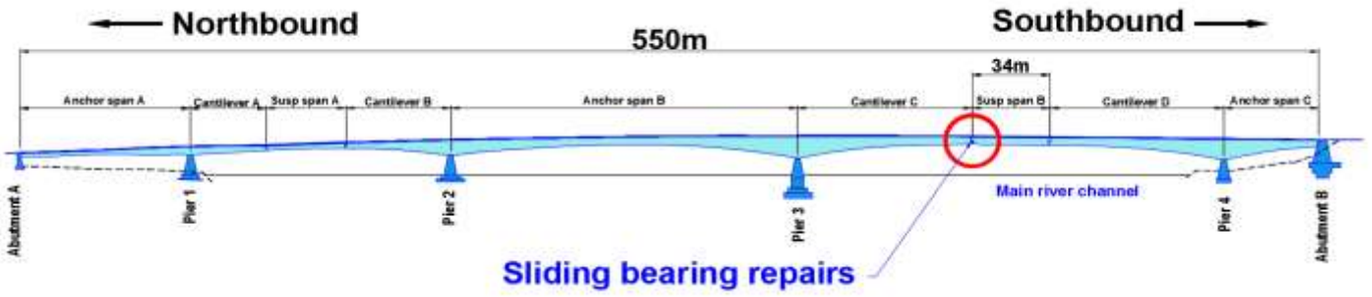

Figure 1 — Captain Cook Bridge – view looking downstream

Figure 2 — Extrusion of the PTFE bearing material

tributed to the current failure of the PTFE — refer to Figure 4. From a design perspective it is important that the PTFE is fully confined within a recess to prevent extrusion under high pressure. Factors that have influenced failure are:

2.1 Increased friction at the sliding interface due to contamination and wear of the PTFE and stainless steel plate– the seal disintegration may have contributed to this failure

2.2 High stress at the leading edge due to poor bearing geometry and high friction

2.3 Increased traffic loads and greater traffic density since last repairs

2.4 Inability of the bearings to adapt to lateral alignment changes due to transverse deck thermal movement and bearing wear

2.5 High leading edge stresses caused excess rotation and separation or very low pressure on the trailing edge allowing extrusion

2.6 Failure and degradation of the adhesive used to bond the PTFE to the knuckle.

Instrumentation installed around the bearing joints after failure and before replacement indicated a very lively bridge structure resulting in considerable knuckle rotation and sliding action. The aggregated sliding movement due to thermal expansion and contraction would be in the range of 1km over a 50 year period. However the sliding movement resulting from traffic weight induced deck deflection, including braking, is estimated to exceed 30km.

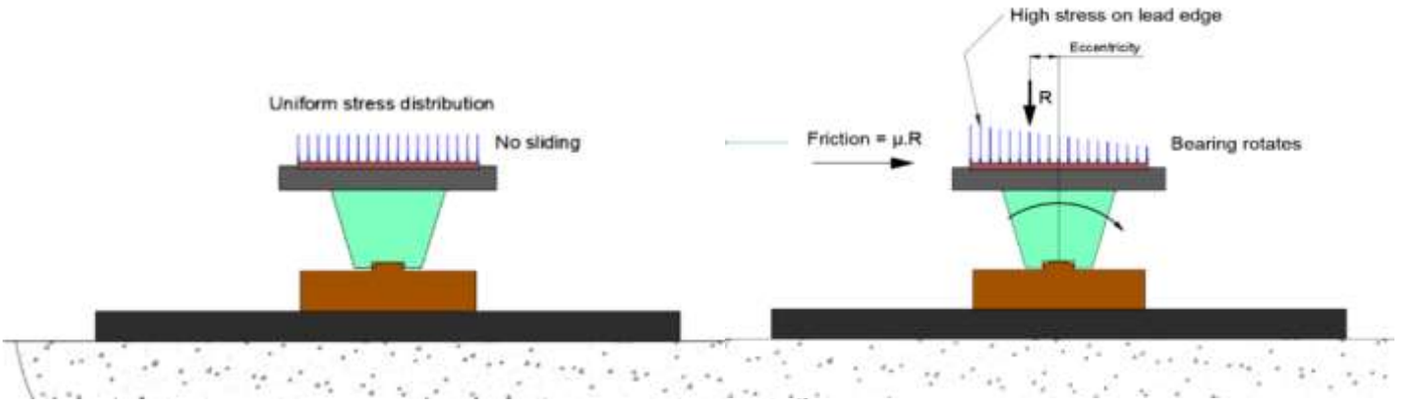

Figure 3 — Sliding knuckle static and dynamic characteristics

3 RECTIFICATION STRATEGY

The bearing rectification strategy had to be developed to allow the repair work for each structure to be completed in an 8 hour period without full traffic closure. A key objective was to minimise disruption to the traffic network into and out of the CBD.

The repair history showed that the two previous designs only lasted 20 years. Hence it would not be worthwhile duplicating what was already there as the PTFE had demonstrated that it extruded under the applied load conditions. The ideal solution would be to remove the existing bearing and replace it with an off-the-shelf spherical bearing. However due to the size of a spherical bearing, this would require removal of the bottom baseplate and grout. However, the tight time restraints and pressure to ensure that the work was carried out in the designated time, meant that the existing bearing base plate had to remain. A new design replacement knuckle required a similar configuration so that it could fit into the space available.

A mathematical analysis of the current rectangular bearing arrangement yielded the following relationship. (N.B. The formula for a circular bearing pad differs from a rectangular/square bearing pad)

$$(Peak\ stress)/(Uniform\ stress) = 1 + \mu.6.h/w$$

where μ equals the coefficient of friction (1)

Hence it can be seen that the stress amplification on the leading edge of the knuckle is influenced by the coefficient of friction and the rotating height to width *(h/w)* ratio — refer to Figure 3. A design was proposed whereby the geometry was improved considerably and a different sliding material was used. Two basic options for a suitable replacement were considered — a Maurer spherical bearing and Orkot TXMM® (Trelleborg 2014). The Maurer spherical bearing would not fit into the desired space unless significant additional work was carried out such as removal of the original baseplate and grout. Due to time constraints the project team decided that this was not an option. Also the EU approved sliding material patented by Maurer is not available as a separate component.

Figure 4 — Extruded PTFE from bearing

Because a timely decision had to be made to allow the detailed design to commence, the material selected for use was Orkot TXMM®. This material had not previously been used in this particular application in Queensland but is used extensively in critical applications within the marine industry. The Orkot family of products have been in use for over 60 years. It has very low frictional properties due to dispersed PTFE and MoS_2 and can be used without

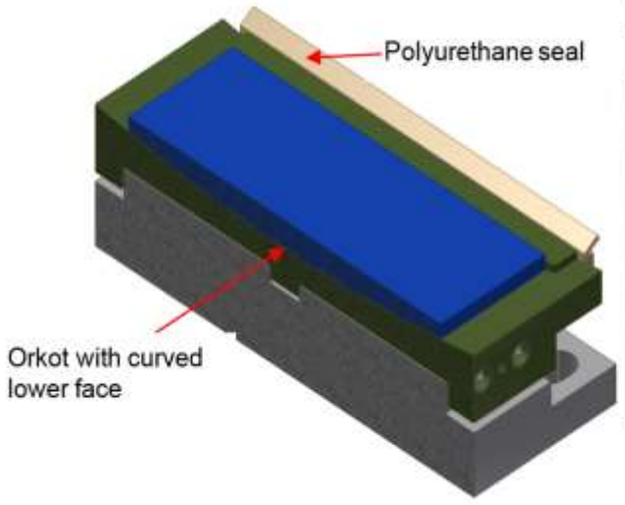

Figure 5 — Section through new knuckle

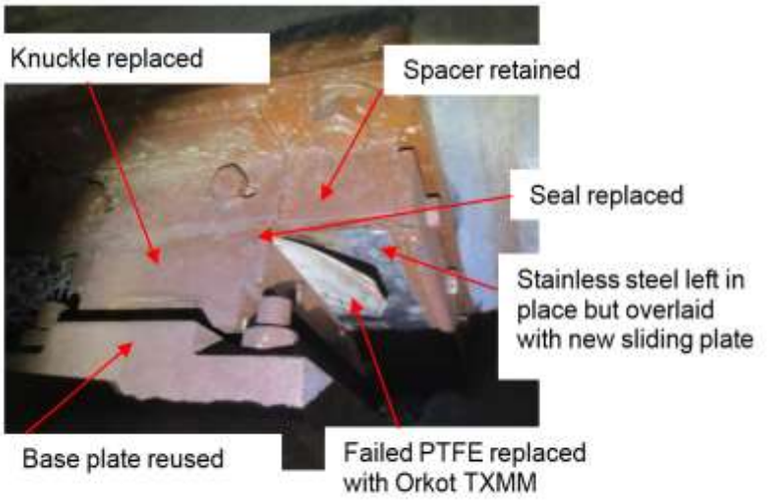

Figure 6 — What was replaced?

additional lubrication. It is superior to most other products on the market because of its high compressive strength of 280 MPa. Its high compressive strength is attributed to the laminated reinforced construction which prevents material flow under high compression forces. Other plastic materials can be used at high compressive loads but these materials must be fully confined on all sides with a small allowable running clearance (approx. 2mm). The Orkot manufacturer, Trelleborg, were very cooperative and supplied the required technical information to allow wear calculations to be performed. The design incorporated a high wear allowance. The Orkot material was manufactured to design specifications by Trelleborg in the United Kingdom.

A design was formulated which fulfilled the operational requirements. This design required that an existing thick spacer plate had to be removed and replaced with a thinner plate. The design team checked to see whether this was physically possible and found that some of these plates had been welded in place. The construction drawings did not show any welds! Because of the position of these welds, an alternative approach was required. It was thought that the welding may have been a fabrication error as not all plates had been welded.

Because of this issue, the design was further constrained. Further detailed investigation highlighted that the top and bottom halves of the current bearings may not be parallel. To counteract any misalignment, the bottom of the Orkot bearing had a machined radius so that the bearing material could self-align when installed. Ideally this radius should have been in the vicinity of 500mm but due to conflicting design requirements a radius of 1700mm was adopted. A number of different thickness stainless steel shims were on hand to pack below Orkot to compensate for different installed bearing heights. Figures 5, 6 & 7 show — a section through the new knuckle, what was replaced and the installed bearing.

The Captain Cook Bridge was designed in the late 1960's. The design was imperial and all fasteners were made with British Standard Whitworth (BSW) threads. Where necessary these BSW fasteners were interchanged with Grade 8.8 zinc plated Unified National Coarse (UNC) fasteners. When the bearings were manufactured in the early 1970's, the marking of hole positions would have been a manual process. There was a concern over the accuracy of the position of hole centres which had to be aligned with new components. To compensate for this, hole clearances in the new components were increased. Compressed air powered die grinders were available to enlarge holes where required (this was required in one instance). The compressed air was sourced from a compressor located on a truck on the bridge deck with associated lines fed through the expansion joint. The old bearings were measured under difficult conditions to ensure there was no gross variation in dimensions.

If the new bearings could not be installed for some unforeseen reason, the fall-back position was to remove the old knuckles, clean the PTFE recesses and install new PTFE replacement inserts. These PTFE inserts had already been sourced and cut to size and contained the same 25% glass. This would then allow the bridge to remain operational until any problems encountered could be resolved at a later date.

The original design allowed for the lateral restraining forces of each suspended span to be counteracted by the centre bearing whose lateral clearance dimensions were smaller than the two outer bearings. Because this lateral restraint design could be improved significantly and to remove this requirement from the revised bearing design, the project team decided to relocate the lateral restraint away from the centre bearing to one of the cells — refer to Figure 8. Irrespective of this decision, there is a requirement for a high vertical movement temporary lateral restraint to control the deck during jacking as the centre bearing (with its lateral restraint function) had to be removed. The new lateral restraint was fully adjustable so that running clearances could be set as well as the relative lateral position of the suspended span with respect to the cantilever. This new lateral restraint fulfilled two roles — a temporary restraint during jacking and a permanent restraint for normal operation.

Figure 7 – Installed replacement bearing before final lowering showing a strain gauge housing on the end of the knuckle

4 BEARING DESIGN SUMMARY

There were a number of design changes implemented (refer to Figure 6), all of which will contribute to longer bearing life, namely:

4.1 *Sliding material*

The traditional material used in applications such as this is PTFE. Because the PTFE with 25% glass failed previously this was replaced with Orkot TXMM®. The coefficient of friction of Orkot TXMM® is low and in combination with other mechanical properties led to the consideration that it will perform better in this situation than glass filled PTFE. Orkot contains dispersed PTFE, MoS_2 and the reinforced layers within Orkot provides the high load capacity. After considering a number of factors, it was decided that it was safe to use Orkot in a trial capacity and monitor its long-term performance.

4.2 *Sliding plate*

This is usually made from stainless steel because it is a relatively inexpensive material and is corrosion resistant. However it is soft and susceptible to abrasion and scratching. This was replaced with a ground and polished steel plate (grade K1042). The plate was coated with 50 µm of electroless nickel followed by 15µm combination of electroless nickel and PTFE. After electroplating the sliding plate was heat treated to achieve a high surface hardness. This surface treatment was selected because of its corrosion and scratch resistance and low coefficient of friction. The back of the plate was sand blasted and was retained in place with epoxy and screws.

4.3 *Knuckle material*

The previous knuckle was manufactured from mild steel. Because of the tighter dimensional design constraints this knuckle was more highly stressed than the previous design. The material selected was Bisalloy 80.

4.4 *Scraper seals*

The previous seals were made from rubber which was compressed against the stainless steel plate. This design failed as rubber has a relatedly short life span. Also as the rubber became worn, it lost is preload. This was replaced with a purpose made polyurethane seal (E93A hardness) which was deflected/sprung against the sliding plate to compensate for wear. Polyurethane is a very hard wearing material and has a long life expectancy in excess of 20 years. The seals can be easily replaced without disturbing the bearings.

4.5 *Greasing points*

Grease nipples were fitted to the new knuckles to allow the rocking area beneath the knuckle to be greased. The primary reason for this is to prevent moisture from entering this area and to prevent fretting corrosion which was present in the previous bearing design.

4.6 *Load monitoring*

Very late in the manufacturing process a decision was made to instrument the knuckles with strain gauges at both ends. A preferred solution would be to integrate a weighing system into the knuckle at the design stage. The new 'smart' bearing knuckles were calibrated prior to installation. The weighing system permitted monitoring during the installation works, and subsequently during service. However

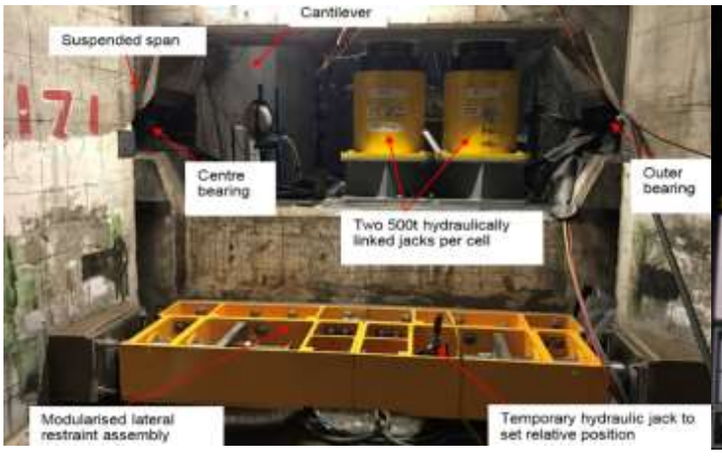

Figure 8 – View of lateral restraint and 500t jacks

Figure 9 – Jacking control console

because of their exposed position the strain gauges are susceptible to potential damage.

4.7 *Lateral restraint*

Removal of this function from the centre bearing reduced the side load and hence would increase the life at the knuckle/baseplate interface. It also fulfilled the lateral restraint role during jacking operations.

5 JACKING SYSTEM

The 800 tonne suspended span is supported on adjacent cantilever spans by halving joints with the cantilever spans providing the bottom diaphragm and the suspended span containing the top diaphragm. Four 500 tonne hydraulic jacks were used to jack the suspended span by approximately 27 mm – refer to Figures 8, 9, 10 & 11. Each 500t jack weighted 550kg. The hydraulic jacks are double acting with a lock ring incorporated on the outside of the main piston. The lock rings are manually adjusted as jacking progresses to ensure safety in the unlikely event of a hydraulic failure.

During bearing rectification works, the suspended span rested solely on these lock rings. The sizing of the hydraulic jacks is usually on the basis that the jack capacity should be more than twice the intended load to be lifted. In this case the total jack capacity was over four times the load. The sizing of these jacks was more about future-proofing the inventory of jacks.

At the base of each jack, a check valve and bypass valve is incorporated into the main lift circuit to protect against hydraulic circuit failure during lifting. However this check valve must be bypassed during lowering operations to allow the jack to retract.

The vertical movement of the jacks are controlled by a string potentiometer which produce 25 pulses per mm (Hansford 2011). Because the structure is heavily reinforced at the halving joint, it has a high transverse stiffness. Four independently controlled jacks could have been used however the loads in each jack would have varied widely because of the system tolerances. To overcome this, the hydraulic jacks were arranged in pairs. The load in each jack within a pair was identical. The computer system controlling the jacking operation was programed to control only two '1000t' jacks with the area of each '1000t' jack equal to twice the area of one 500t jack. The computer system automatically multiplies the programed jack area by the jacking pressure to display the jacking force of each jack pair.

The hydraulic hoses, air lines and control lines had previously been fed from inside the bridge through the expansion joint and attached to the outside of the bridge rails. The jack's hydraulic power unit, a 415 volt 3 phase diesel generator and an air compressor were mounted on a truck. At the commencement of repairs, this truck was moved into place and occupied one of the outside lanes. The hoses and lines tied to the outside of the bridge railing were quickly attached and jacking operations commenced with only minimal delays. In the days leading up to the jacking, a trial lift occurred where the bridge was raised by 1-2mm to generate full working pressure. The system integrity was verified and the hydraulic lines and jacks were checked for oil leaks.

Throughout the jacking operation, the deck crew were in constant mobile phone contact with the jacking crew inside the bridge. This allowed the deck crew to stop traffic during the raising and lowering of the suspended span. During jacking the deck crew would constantly check for potential binding of the finger joints.

6 OPERATIONAL ISSUES

The work inside the bridge cells was defined as a confined space. All personnel had to undergo the mandatory confined space training. The work space gases had to be constantly monitored as per regulations. All personnel had to undergo site specific

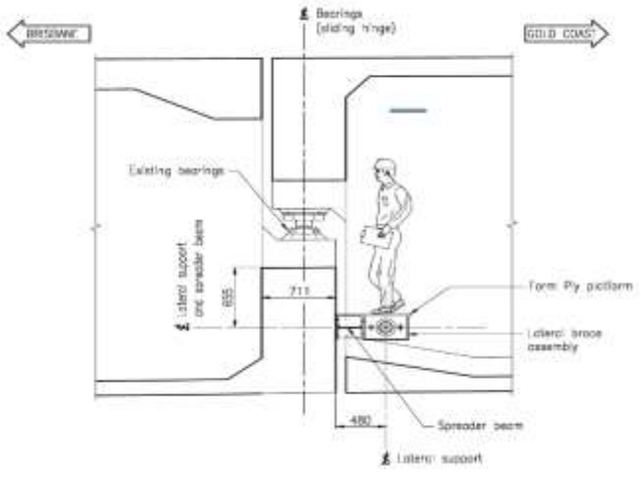

Figure 10 — Section through sliding hinge

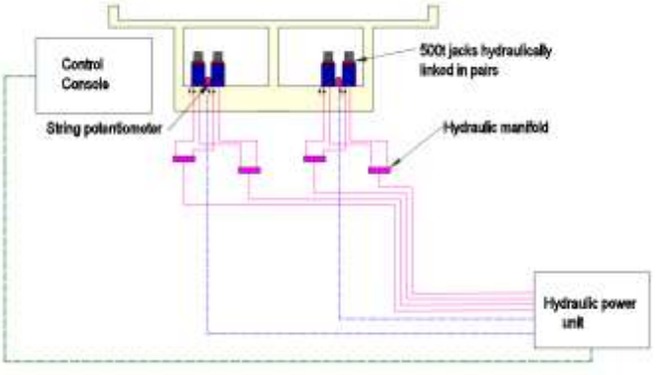

Figure 11 — Schematic of jacking system

safety induction training as well as prestart meetings.

All personnel working in close proximity to the hydraulic jacks and high pressure hydraulic lines were required to wear safety spectacles and protective gloves.

The January/February jacking times coincided with high summer temperatures. Although the work was performed at night, the concrete had not cooled down sufficiently and inside temperatures were still high. To improve the safety of working in the confined space, heavy plastic curtains were hung from the ceiling to cordon off a work area in each cell. Each work area was cooled by three portable self-contained air conditioning units. The hot air generated by the air conditioning units was removed by flexible ducts which led into the expansion joint gap. Although the temperature inside the cells was still high, potential heat stress was well managed. Bottles of cool water were available and mandatory work breaks outside the bridge were enforced.

7 PREPARATION ACTIVITIES

All activities that could be performed in advance were undertaken in the weeks leading up to the jacking. Where these activities included deck work this was carried out at night with single lane closures. The replacement bearings, lateral restraints, tools and material handling equipment were all purchased weeks before the deadline. The synchronised computer jacking system and cabling were repaired so that backup systems were available. Installation preparation activities included:

7.1 Erection of scaffolding to access the elevated entry door on the southern abutment

7.2 Cleaning of any vermin, dust and old equipment from inside the bridge

7.3 Erection of scaffolding inside the structure to allow horizontal access through the bridge cells

7.4 Installation of material handling conveyors

7.5 Installation of an electricity supply to the jacking point for lighting, air conditioning and power tools

7.6 Installation of steel spacers for the hydraulic jacks to transfer the jacking forces into the structure

7.7 Installation of four hydraulic jacks plus have a spare jack inside the bridge

7.8 Installation of all hydraulic hoses, air lines and jacking control lines with the outer ends tied to the outside of the bridge railings

7.9 Installation of the new lateral restraint

7.10 Removal of sections of the bridge deck railing over the expansion joint. This was replaced with a hinged section so that hand rails did not have to be removed on the jacking night

7.11 Ensure all required equipment, parts and tools were laid out on benches inside the bridge

7.12 Installation of air conditioners and hot air ducting

7.13 Undertake a trial jacking of the bridge to test the system for functionality and leaks

7.14 Days before the jacking, a full technical team briefing occurred inside the bridge at the workface describing the work, roles and responsibilities.

8 TRAFFIC CONSIDERATIONS

The dates of the two jacking operations were planned well in advance. The outbound structure was programmed to start at 8pm on Saturday 28 January continuing until 6am on Sunday 29 January 2017. This included a two hour contingency buffer. The inbound structure had similar jacking times on the Saturday 18 and Sunday 19 February 2017. The jacking times were planned not to coincide with major sporting events or entertainment events such as the *Adele* concerts which would generate large concentrated traffic flows.

Agencies such as Queensland Police Service and Brisbane City Council were advised of closure times. A decision was made not to broadly advertise the repairs as the project was to be treated as a normal maintenance activity. The police were engaged to assist traffic controllers in controlling traffic flow. During the repair period, only passenger vehicles and small single axle trucks (approx. 5t GVM) were permitted to cross the bridge. Large trucks had to bypass via alternate routes. The outside traffic lanes were channelled into the two centre lanes to ensure the load was distributed over the main box sections not the cantilevered wings. Additionally, the speed limit was reduced from 80km/h to 40km/h.

During the short period where the bridge was being jacked all traffic was stopped. After jacking had stopped and the jack's lock rings engaged, the low speed traffic was permitted to flow.

The jacking height was limited to 27mm. To prevent traffic running over the end of the expansion joint fingers, 25mm thick plywood sheets were temporarily nailed to the asphalt deck wearing surface.

9 CONCLUSIONS

After the bearing failures were discovered in July 2016, the following 6 months were occupied with the planning, design, manufacture and preparation prior to the installation of the replacement bearings. A number of components were changed to improve the life expectancy of the bearings. The changes included a new lateral restraint that was designed to replace the in-service operational lateral restraint, previously provided by the centre bearings. The design changes adopted and the attention to detail in the preparation work allowed the works to be completed well within the allocated timeframe.

Strain gauges were installed onto the new knuckles to allow the real-time, in-service monitoring of traffic and environmental loads.

Within one night, the bridge was jacked and bearing rectification works completed under live traffic. This resulted in minimum interference to one of the state's busiest transport routes.

The bearing rectification works were successfully completed on both suspended spans by February 2017. Regular inspections of the bearings will be undertaken in the future to monitor their performance and wear.

10 ACKNOWLEDGEMENTS

The authors would like to acknowledge the large collective efforts and spirit of cooperation of the numerous personnel associated with all phases of this project. Also acknowledged are the businesses who supplied, manufactured and tested the various components that were required for the project.

Reliability Assessment of Reinforced Concrete Pylons Subjected to Biaxial Bending

Ji Hyeon Kim & Hae Sung Lee
Seoul National University, Seoul, Republic of Korea

ABSTRACT: This paper presents the reliability assessment of reinforced concrete pylons for cable-supported bridges subjected to biaxial bending moment. The load contour method is employed to determine the strength of reinforced concrete pylons under biaxial bending. The failure surface defined by the load contour method is utilized as the limit state function in the reliability analysis. The load parameter and the strength parameter such as the material and geometric properties are considered as random variables. The most probable failure point and reliability index are calculated by the Hasofer-Lind Rackwitz-Fiessler algorithm with the gradient projection method for the advanced first-order second-moment reliability method. The reliability analyses of the pylon for cable-supported bridges in Korea are performed for the surface exponents of 1 and 2. The effect of the surface exponents and the comparison of the reliability index for uniaxial bending to that for biaxial bending are discussed in detail.

1 INTRODUCTION

A robust reliability assessment method of reinforced concrete (RC) columns subjected to biaxial bending is proposed by Kim and Lee (2017). The proposed method is utilized to evaluate a reliability level of rectangular sections for short columns in the study. The proposed scheme certainly plays an important role for code calibration procedure, in which the reliability indices for various real sections should be evaluated to set a target reliability index. The reliability levels of RC pylons need to be estimated accurately to determine a proper a target reliability index of a wind load-governed limit state for cable-supported bridges.

As a cross-section of the pylons for cable-supported bridges is usually designed as a hollow section, the section properties for internal forces have to be estimated based on the effective flange width considering the shear lag or determined by rigorous analysis. However, most design codes (AASHTO, 2012; KMOLIT, 2016a; KMOLIT, 2016b) state that the full compression flange width effect is valid for the capacity of a cross-section at the strength limit state. The scope of this study is to estimate the reliability index of an RC pylon for the strength limit state, and thus, the entire cross-section is valid to evaluate the strength of RC pylons.

This paper adopts the reliability assessment method proposed by Kim and Lee (2017) in order to estimate reliability levels of RC pylons for cable-supported bridges subjected to biaxial bending. The failure surface defined in the load contour method is provided as the limit state function for the reliability analysis. The minimization problem defined by the advanced-first order second-moment reliability method (AFOSM) (Haldar and Mahadevan, 2000) is solved by using the Hasofer-Lind Rackwitz-Fiessler (HL-RF) algorithm with the gradient projection method (Liu and Der Kiureghain, 1991). The axial force (P) - bending moment (M) interaction diagram (PMID) of a pylon under uniaxial bending is interpolated by using the cubic spline method as presented in Kim et al. (2015). The PMIDs about the principal axes of the section are used in constructing the load contour. The sensitivities of the limit state function required in the HL-RF algorithm are calculated through the direct differentiation method.

The reliability indexes and most probable failure points (MPFPs) of the pylon for cable-supported bridges in Korea are calculated in case that the surface exponents of the load contour are 1 and 2. The effect of the surface exponents are investigated through the reliability analyses. The reliability index of RC pylons subjected to uniaxial bending is compared to the reliability index under biaxial bending. It is demonstrated that the reliability index of a pylon for biaxial bending may become significantly lower than that for uniaxial bending depending on the surface exponent.

2 RELIABILITY ASSESSMENT METHOD

2.1 *3-dimensional PMID*

Kim and Lee (2017) adopts the load contour method proposed by Bresler (1980) in order to define the PMID of an RC column subject to combined axial and biaxial bending moment in the 3-dimensional axial force (P)-moments (M_y, M_z) space.

$$\Phi(\mathbf{F},\mathbf{B}) = \Phi(P, M_z, M_y, \mathbf{B}) = 1 - \left(\frac{M_y}{\widetilde{M}_y(P)}\right)^{\alpha} - \left(\frac{M_z}{\widetilde{M}_z(P)}\right)^{\alpha} = 0 \quad (1)$$

where $\mathbf{F} = (P, M_y, M_z)^T$, $\mathbf{B}$ is the surface parameter vector of the PMID, and α is the surface exponent that is determined by the strength characteristic of a cross section. M_y and M_z represents the y-directional and z-directional moments, respectively. $\widetilde{M}_y(P)$ and $\widetilde{M}_z(P)$ are the ultimate moment capacities for a given P in pure bending about the y and z direction, respectively. The surface exponent, α, determines the feasible region of the load contours that present the PMID in $M_y - M_z$ plane. The α of 1 indicates the lower limit of the columns strength and describes a straight line connecting the $\widetilde{M}_y(P)$ and $\widetilde{M}_z(P)$. The α of 2 denotes the upper limit of the column strength and the load contours are drawn as the ellipse.

The PMIDs of the column subject to the y and z directional uniaxial bending moment are expressed in terms of the axial force, respectively, and are defined in the $P - M_y$ plane and the $P - M_z$ plane as follows:

$$\Phi_k(P, \widetilde{M}_k, \mathbf{B}_k) = 0 \quad \text{for} \quad k = y, z \quad (2)$$

The subscript k indicates the direction of the uniaxial bending moment hereafter.

The limit state of an RC column is defined by the PMID given in Eq. (1) and described as $\Phi(\mathbf{F}_q, \mathbf{B}) = 0$. That is, $\Phi(\mathbf{F}_q, \mathbf{B}) > 0$ and $\Phi(\mathbf{F}_q, \mathbf{B}) < 0$ represent the safe and failure states of the RC column, respectively. $\mathbf{F}_q$ denotes the internal force vector. The relations between the internal forces and the external loads are assumed to be linear, although each external load component may have nonlinear load effects on an RC column.

$$\mathbf{F}_{q,0} = \begin{pmatrix} P_q \\ M_{q,y} \\ M_{q,z} \end{pmatrix} = \mathbf{C}_0 \mathbf{q} \quad (3)$$

Here, $\mathbf{C}_0$ and $\mathbf{q}$ are the load effect matrix and load parameter vector, respectively. Each column of the load effect matrix is composed of the load effects calculated in the structural analysis for the nominal value of the corresponding load component. The load parameter vector represents the statistical properties of the load components. The nominal values of the load parameters are given as 1, and the mean value of each load parameter becomes the bias factor of the original load component. The statistical distribution and coefficient of variation (COV) of each load parameter follow those of the original load component.

The surface parameters are determined based on the strength parameters representing the material and geometric properties of a cross section. The strength parameters of an RC column are conveniently written in one vector

$$\mathbf{s} = (s_j) = (f_{ck}, f_y, E_s, A_{gt}, A_{s,1}, \ldots, A_{s,m}, y_{s,1}, \ldots, y_{s,m}, z_{s,1}, \ldots, z_{s,m})^T \quad (4)$$

where f_{ck}, f_y, E_s indicate the compressive strength of concrete, the yield strength of the reinforcing bar and the Young's modulus of the reinforcing bar, respectively, and are included in the material properties. m, A_{gt}, $A_{s,k}$, $y_{s,k}$, $z_{s,k}$ denote the number of reinforcing bars, the gross area of a cross section, the area and position of the k-th reinforcing bar in the y and z direction, respectively. he position of a reinforcing bar is the distance from the extreme compression fiber of the cross section to the center of the reinforcing bar. The geometric properties consist of the area and position of each reinforcing bar and the gross area of a cross section.

The PMID of $P - M_k$ plane is composed of infinite sampling points, which represent the ultimate strength combinations of RC Columns. Kim et al. (2015) suggested the analytic form of the PMID in $P - M_k$ plane by introducing a piecewise cubic polynomial functions (Kreyzig, 2006). The polynomial function, called as the cubic spline, is used to interpolate two adjacent points as a piecewise continuous and twice differentiable function.

2.2 *AFOSM*

The strength parameters of an RC column, the load parameters are considered to be random variables. All random variables are assumed to be statistically independent to each other in this study. For the compactness of forthcoming derivations, the random variables are written in one vector, $\mathbf{X} = (\mathbf{q}, \mathbf{s})^T$. In case that all random variables are normally distributed and statistically independent to each other, the reliability index and corresponding MPFP are evaluated by solving the following minimization problem through the AFOSM (Haldar and Mahadevan, 2000):

$$\min_{\overline{\mathbf{X}}} \beta^2 = \left\|\overline{\mathbf{X}}\right\|_2^2 \quad \text{subject to} \quad \overline{\Phi}(\overline{\mathbf{X}}) = 0 \quad (5)$$

where β and $\|\cdot\|_2$ denote the reliability index and the 2-norm of a vector, respectively, while the overbarred variables indicate standardized random variables and $\overline{\Phi}(\overline{\mathbf{X}}) = \Phi(\mathbf{X})$. Since the limit state function is nonlinear with respect to the random variables, the minimization problem given in Eq. (5) is solved iteratively by the HL-RF algorithm with the gradient projection method (Liu and Der Kiureghain,

1991). The Rackwitz-Fiessler method (Rackwitz and Fiessler, 1978) is adopted for nonnormal random variables to estimate the equivalent normal distribution.

The sensitivity of the PMID with respect to the random variables is required for iteration procedures of the HL-RF algorithm. The direct differentiation method is utilized to compute the sensitivity of the PMID. Detailed formulations of the sensitivity for the PMID with respect to the random variables are derived in references (Kim et al., 2015 and Kim and Lee, 2017).

3 APPLICATIONS TO RC PYLONS

The reliability analyses are performed for the design sections of RC pylons for two cable-stayed bridges and one suspension bridge: The Incheon Bridge (IB), Busan Harbor Bridge (BHB), Yi Sun-shin Bridge (YSB), and New-millennium Bridge (NMB). Since the load combination under a strong wind condition without the live load governs the failure of the pylons, the dead and wind load effects are considered in the analyses.

The general view of the three cable-supported bridges and the longitudinal wind direction (WD) are presented in Figure 1. WD1 indicates the longitudinal wind direction acting on the left pylon to the right pylon, and WD3 designates the opposite wind direction of WD1. The front view of the pylons for the cable-supported bridges is illustrated in Figure 2, and the transverse wind directions denoted as WD2 and WD4 are indicated with the arrows at the top of each pylon in the figure. The transverse wind load is applied to both columns of a pylon simultaneously. Each pylon consists of two symmetric columns, and

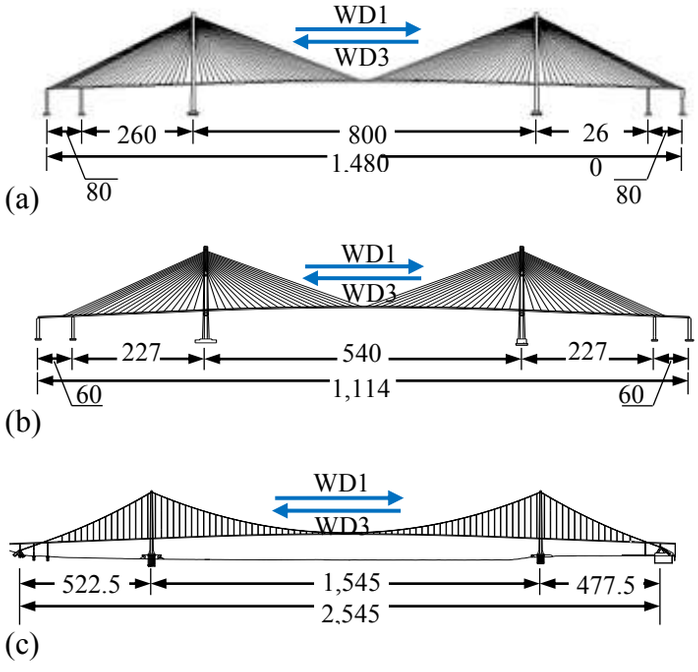

Figure 1. General view of cable-supported bridges and longitudinal wind direction: (a) IB; (b) BHB; (c) YSB (Unit: m)

the reliability analysis is conducted for the bottom section of the left column for a pylon marked with a dotted circle in Figure 2.

Figure 3 shows the geometry and arrangement of reinforcements of the cross-section at the bottom of the pylons. Since the member axis of each column of the pylons is inclined from the vertical line, the cross-sections shown in Figure 3 are projected to the plane perpendicular to the member axis and marked with a dotted line in Figure 2 for the reliability analysis. The inclined angle of the column and sectional properties of the bottom sections of the pylons are

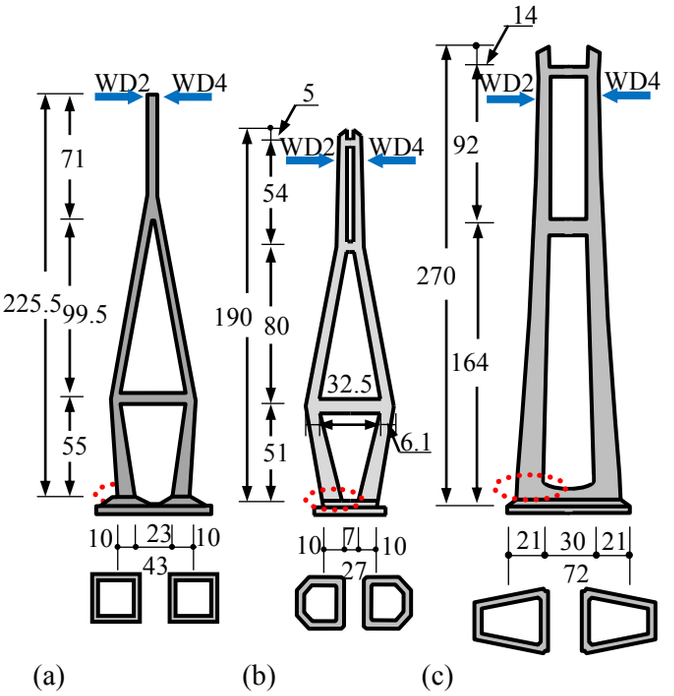

Figure 2. Front view of the pylon and transverse wind load direction: (a) IB; (b) BHB; (c) YSB (Unit: m)

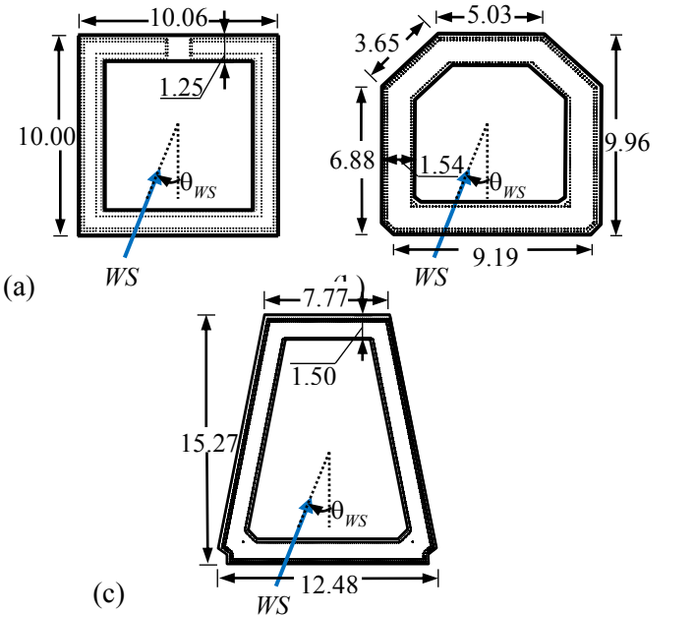

Figure 3. Geometry and rebar arrangement of the bottom section for the pylon: (a) IB; (b) BHB; (c) YSB (Unit: m)

summarized in Table 1. The nominal values of the compressive strength of concrete and the yield strength and Young's modulus of the reinforcements are also provided in the table. The reinforcement ratio of the cross-section where the lowest reliability index satisfies the target reliability index of 3.1 for $\lambda_{WS} = 1$, $\delta_{WS} = 0.3$ is quoted from Kim et al. (2017), and is summarized for the three bridges in the table.

The statistical parameters of the random variables are given in Table 2 and quoted from the previous works (Kim et al., 2015; Kim et al., 2017). DC_P, DC_G, DC_C, DW, and WS indicate the dead load due to the self-weights of the pylons, girders, cable members, wearing surfaces and utilities, and the wind load, respectively.

The load effects induced by each load parameters are calculated using a commercial program, and are presented in Tables 3 and 4 for the longitudinal and transverse directions, respectively. WD in parentheses refers to the wind load direction illustrated in Figures 1 and 2. The calculated load effects include a moment amplification effect in axial forces and bending moment due to the P-delta effect. In the tables, the compression depicts a positive sign. The positive bending moments in the longitudinal and transverse directions represent the clockwise action in Figure 1 and the counterclockwise action in Figure 2, respectively.

Table 1. Inclined angle of the pylons and sectional properties of the sections

Bridge	Inclined angle	A_{gt}	Rebar ratio	f_{ck}	f_y	E_s
	(°)	(m^2)	(%)	(MPa)	(MPa)	(GPa)
IB	6.18	36.16	1.84	45	400	
BHB	12.14	47.48	0.52	40	400	200
YSB	3.22	69.35	0.46	40	400	

Table 2. Statistical parameters of the random variables

The angle of attack of the wind load to the pylon, θ_{WS}, is indicated in Figure 3. The angle of $\theta_{WS} = 0°$, 90°, 180° and 270° correspond to WD1, WD2, WD3, and WD4, respectively. The angle of attack of the wind load varies from 0° to 360° while the nominal magnitude of the wind load is maintained constant. The effect of the surface exponent and the angle of attack on the results of the reliability analysis is investigated. For $\alpha = 2$, the reliability analysis is performed with an interval of 5° for the angle of attack of wind load. The interval for the angle of attack for $\alpha = 1$ is defined as 1° in order to clearly illustrate the discontinuity of the reliability indexes later on the figures.

The variations of the reliability indexes and the standard normal wind load at the failure point with the angle of attack for IB are presented in Figures 4 and 5, respectively. The variation patterns of the two figures are quite similar to each other, which implies that the wind load governs the failure of the pylon for the biaxial loads. The reliability levels of $\alpha = 2$ are higher than the target reliability level for all the angle of attack, which is exactly the same for the other bridges. The lowest reliability index of $\alpha = 1$ is calculated as 2.98 close to the WD2, which is 4% smaller than the target reliability index. Since the failure surface of the pylon is linearly interpolated in the case of $\alpha = 1$, the strength of the pylon for biaxial bending decreases sharply and results in a lower reliability level.

Figure 6 shows the nominal load effects and the failure points for IB with respect to $0^{\circ} \le \theta_{WS} \le 360^{\circ}$, which are marked with centered symbols every 5° or 1° in a counter-clockwise direction. The solid squares in the figure indicate the internal forces at ϕ = 0°, while the solid circles are associated with θ_{WS} = 90°, 180° and 270°.

The axial forces corresponding to each centered symbol are different, and the load effects are located on different M_Y-M_Z planes in 3D space. Since the dead and wind loads generate the bending moments in the opposite and same directions in WD2 and WD4, respectively, the position of a large circle constructed with black blank circles, which present the nominal load effects, is shifted above the axis of M_Y = 0. The results clearly show that the angles of attack for the failure points on the moment axes in Figure 6 exactly coincide with those where the discontinuities of α = 1 and are observed in Figures 4 and 5. The reliability index of the pylon is calculated for uniaxial bending corresponding to θ_{WS} = 0°, 90°, 180° and

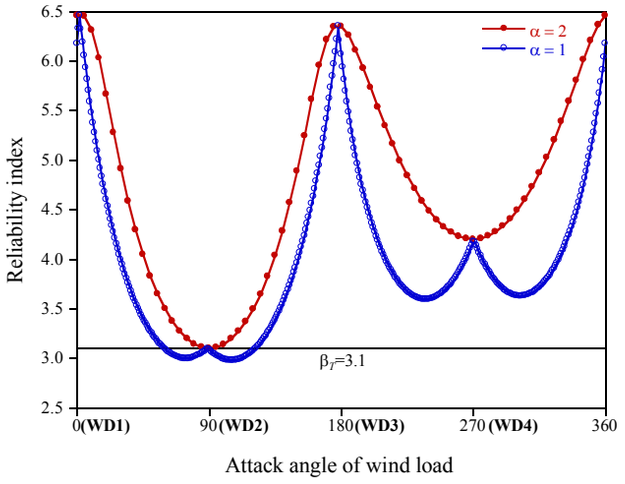

Figure 4. Reliability indexes of pylons for IB under biaxial bending

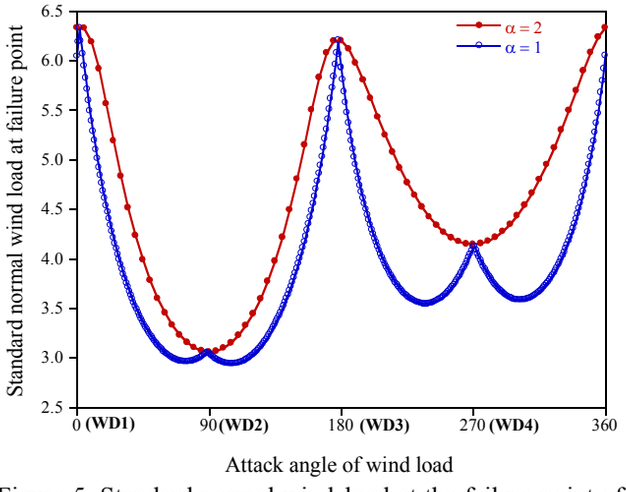

Figure 5. Standard normal wind load at the failure point of pylons for IB under biaxial bending

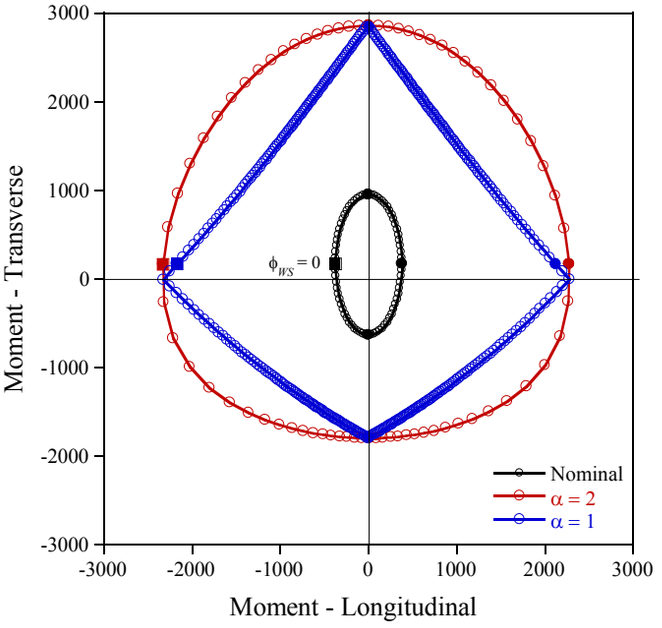

Figure 6. Nominal bending moments for IB

270° and is compared with that for biaxial bending in Table 5. The bending moments about the axis perpendicular to the wind load and the axial forces given in Tables 3 and 4 are considered for uniaxial bending. A slight difference in the reliability indexes between uniaxial bending and biaxial bending is caused by the biaxial moment due to the dead load.

Since the wind loads in WD2 and WD4 induce the tensile and compressive axial forces, respectively, the pylon under the load effects in WD4 exhibits a higher level of safety than that in WD2 even though the total nominal moment in WD4 is larger than that in WD2. This is because the moment capacity of a pylon decreases rapidly as the compressive axial force diminishes in the tensile failure region of the PMID. The longitudinal wind load yields a similar level of reliability indexes in WD1 and WD3. As in the transverse wind load case, the difference in the reliability indexes in WD2 and WD4 is caused by the opposite wind load effect on the axial forces of the pylons. However, the axial forces induced in the pylons by the longitudinal wind load are much smaller than those by the transverse wind load, which leads to a less significant difference in the reliability indexes between the two longitudinal

Table 5. Comparison of reliability indexes under uniaxial and biaxial bending for IB

Wind direction	Reliability index	
	Uniaxial bending	Biaxial bending (α = 2)
WD1	6.47	6.46
WD2	3.10	3.10
WD3	6.36	6.35
WD4	4.20	4.20

wind load cases in comparison to the transverse wind load case. The reliability index seems to be proportional to the distance between the nominal load effect and the failure point as shown in Figures 4 and 6. However, it should be noted that such a proportional relationship may not be valid according to the failure mode of a pylon depending on the load combination (Kim et al., 2015).

Figures 7 and 8 show the reliability indexes and the standard normal wind load at the failure point for BHB under biaxial bending, respectively. The comparison of reliability indexes for uniaxial and biaxial bending is presented in Table 6, and the nominal load effects and the failure points in M_y–M_z space are illustrated in Figure 9. The smallest reliability index is calculated in WD2 for both uniaxial bending and biaxial bending of $\alpha = 2$. However, the lowest reliability level of $\alpha = 1$ is calculated as 2.21 at $\theta_{WS} = 215°$, and the reliability indexes of $\alpha = 1$ decreases more rapidly in the range of $180^\circ \le \theta_{WS} \le 360^\circ$ than at $0^\circ \le \theta_{WS} \le 180^\circ$. The large biaxial moments are generated in the range of $180^\circ \le \theta_{WS} \le 360^\circ$ by the superposition of the bending moment in the longitudinal and transverse direction, and are very close to the failure surface of $\alpha = 1$. The combination of bending moments with a short distance to the failure surface yields a higher probability of failure.

The comparison of reliability indexes for uniaxial and biaxial bending is presented in Table 6. Since the ratio of bending moment due to the dead load to the wind load is apparently large in comparison with the other bridges (*vide* Tables 3 and 4), the failure points for biaxial bending exist within the quadrant and not on the axes. The reliability levels for uniaxial bending are a little bit higher than those for biaxial loads in WD1, WD3, and WD4 for $\alpha = 2$ as shown in Table 6.

The results of the reliability assessment for YSB are presented in Figures 10-12, and Tables 7. Discussions on the results of the YSB are similar to those of IB. For YSB the bending moments due to the dead and wind load are produced in the same

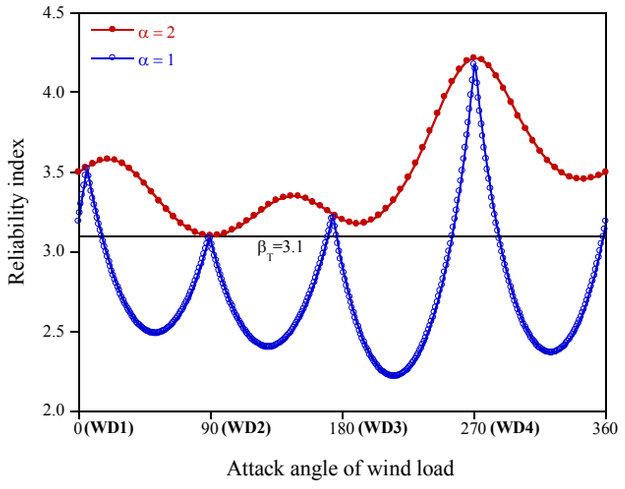

Figure 7. Reliability indexes of pylons for BHB under biaxial bending

WD4	4.27	4.22

transverse direction. Thus, the unions of the nominal load effects are positioned below the axis of $M_y = 0$ as shown in Figure 12. In the three bridges, the minimum reliability indexes for biaxial bending are lower than that for uniaxial bending by 4% to 28% and are summarized in Table 8. Therefore, even if a pylon secures a high reliability level for uniaxial bending, a significantly lower reliability level may result for biaxial bending, which depends on the surface exponent.

4 CONCLUSIONS

This paper presents the reliability assessment of RC pylons for three cable-supported bridges in Korea. The failure surface of RC pylons is defined by the load contour method. The load and strength parameters are considered as random variables. The reliability analysis is performed for the section of which the lowest reliability index secures a certain target reliability index. The surface exponents of the load contours are used as 1 and 2 in order to calculate the reliability index for the lower and upper limits of the strength.

The limit state of a pylon is mainly governed by the wind load. The reliability level for surface exponent of 1 is higher than the target reliability index of 3.1 for all angle of attack. The minimum reliability index under biaxial bending for surface exponent of 1 is reduced by 4-28% of the target reliability index. Since the reliability index for biaxial loads varies significantly with the surface exponent, most design codes specify the surface exponent as one in order to deduce conservative design. The precise surface exponent for a cross-section is required for more economical design.

Experimental research on shear behavior of rubber-ring perfobond connector

Y.Q. Liu, Y. Liu & F. Wang
Department of Bridge Engineering, Tongji University, Shanghai, China

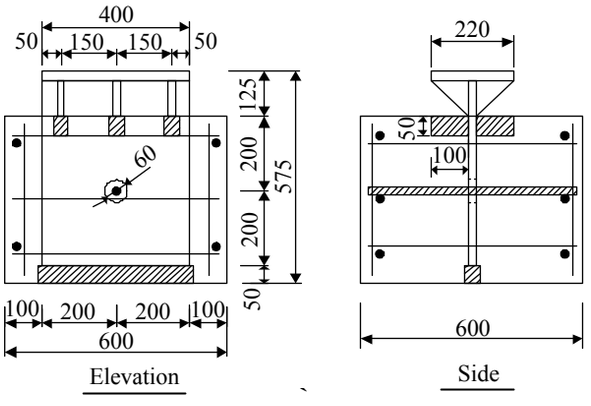
ABSTRACT: To mitigate the shear concentration of partial holes in groups, perfobond connector with an easy-installed rubber ring was proposed. Then nine modified push-out tests including four specimens with one hole and five specimens with four holes were conducted to reveal the shear mechanism of the rubber-ring perfobond connector. The presence and thickness of rubber rings, the number of holes and the arrangement of rubber rings were investigated in the tests. The test results showed that the failure of perfobond connector consists of four stages, including the damage of bond, the shear failure of concrete dowel in the hole, the tension-shear yielding and the failure of perforated rebar. The yield slip of perfobond connector can be increased by 260% to 745% by employing the rubber ring, which was related to the thickness of rubber ring and the deformation ability of perforated rebar. The presence of rubber ring which decreased the area of concrete dowel reduced the shear capacity by 15%. The strain difference of steel plate in adjacent rows was reduced by placing the rubber rings on the first and the fourth rows, indicating rubber rings could be utilized to alleviate the non-uniform shear distribution. Finally, the existing formulas of shear capacity based on previous modified push-out tests were evaluated.

1 INSTRUCTION

Perfobond connectors have the advantages of simple structure, easy installation, and excellent shear behavior and fatigue performance. In recent years, the application of perfobond connectors has been increased in the composite bridges, such as the interface of composite girders, the joint of hybrid girders and pylons, the anchorage zone of composite pylons and the anchorage joints between suspenders and girders, etc. Perfobond connector ensures that load is transferred efficiently between steel and concrete components.

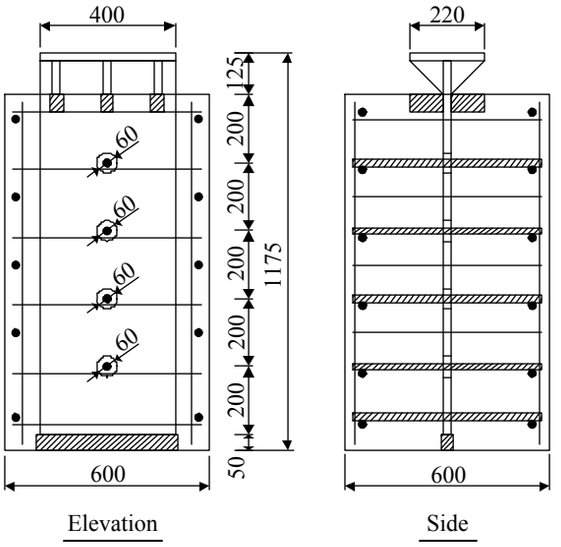
The shear behavior of perfobond connector was mainly studied by push-out tests. Yamadera et al. (1993) first proposed and carried out a modified push-out test. Then Wang et al. (2013) and Su et al. (2014, 2016) summarized the failure modes and the appropriate situations of different test methods. As perfobond connectors are increasingly employed in hybrid structures and anchorage joints, Zhang et al.(2007), Wang et al. (2014), He et al. (2016), Nakajima et al. (2016), Xiao et al. (2016) analyzed the effects of hole diameter, perforated rebar diameter, thickness of plate, concrete compressive strength and bond on the shear performance of perfobond connector by conducting modified push-out tests. Recently, scholars had begun to focus on the structural behavior of perfobond connectors arranged in multi rows and columns. Oguejiofor & Hosain (1994) suggested that increasing the number of holes can enlarge the shear strength of perfobond connector when the spacing between two adjacent holes is larger than 2.25 times hole diameter. Martins et al. (2010) and Vianna et al. (2013) carried out push-out tests respectively and found that the number of holes had only a small effect on the shear bearing capacity. Ahn et al. (2010) concluded that when the perfobond connectors were arranged in two columns, the average strength was 80% of the strength of a single connector.

In the hybrid structures joints and composite anchorage zones, some of the connections may have worked in the plastic stage, although the overall load does not reach the load carrying capacity of the structures. The shear of connectors is mainly related to the shear stiffness and the position in the group. Decreasing the initial shear stiffness or increasing the slip at the start of bearing shear can reduce the shear of connectors. Xu et al. (2014, 2016) decreased the initial shear stiffness of studs by using the rubber sleeves, which had a negligible effect on the shear capacity. Therefore, this paper presents a rubber ring used on perfobond connectors to increase the slip at the beginning of bearing shear. By setting the rubber rings to some of the holes in connector group, the shear of each hole may tend to be



uniform, and the composite behavior of joints would be optimized.

In this paper, modified push-out tests including four specimens with one hole and five specimens with four holes were conducted to study the shear behavior of rubber-ring perfobond connectors. The parameters investigated were the presence and thickness of rubber rings, the number of holes and the rubber rings arrangement. The failure modes, load-slip curves, load-strain curves of steel plate and perforated rebar were analyzed and compared. The shear mechanism of rubber-ring perfobond connectors was discussed. Finally, the existing shear capacity formulas based on modified push-out tests were collected and evaluated in comparison with the test results.



2 MODIFIED PUSH-OUT TEST

2.1 *Test specimens*

Fig 1 shows the configuration of specimens. To examine the influence of rubber ring parameters on the shear behavior, the irregular distribution of shear in the multi-hole specimens and the reasonable arrangement of the rubber rings in the joints, nine modified push-out test specimens were designed. The thickness of rubber ring of the four single-hole specimens was 0 mm, 2 mm, 4 mm, 6 mm, respectively. The position of rubber rings of the five multi-hole specimens was none, all the holes with the thickness of 4 mm, 1st and 4th hole with the thickness of 2 mm, 4mm and 6 mm, respectively. Detailed parameters are shown in Table 1.

(a) Single-hole specimens

(b) Multi-hole specimen

Figure 1. Specimen configuration.

Table 1. Parameters of specimens.

Specimen	d/mm	d_s/mm	n	t_r/mm	Position
PB	60	20	1	-	None
RPB-1	60	20	1	2	Hole
RPB-2	60	20	1	4	Hole
RPB-3	60	20	1	6	Hole
MPB-1	60	20	4	-	None
MPB-2	60	20	4	4	All holes
MPB-3	60	20	4	2	1st & 4th hole
MPB-4	60	20	4	4	1st & 4th hole
MPB-5	60	20	4	6	1st & 4th hole

The thickness and length of the steel plate were 20 mm and 400 mm. In the area between the top steel plate and the concrete block, stiffening ribs were provided to prevent the buckling of the steel plate during the loading process. 50 mm height of foams were mounted below the ribs to avoid the contact between the ribs and concrete block during loading. Similarly, 50 mm high wood blocks were placed at the bottom of the steel plates before pouring the concrete to remove the end pressure of steel plates. Since cohesive and frictional force existed in the actual structures, the specimens were not greased to reflect the real shear behavior of perfobond connectors in the joints.

2.2 *Rubber ring details*

A rubber ring including the inner ring and the wings on both sides of the steel plate was put forward to increase the slip of perfobond connector at the start of bearing shear. The outer diameter of the inner ring is the same as that of the hole, and the internal diameter is the outer diameter minus twice the thickness of the inner ring. The length and thickness of the wings are 10 mm and 4 mm, respectively, to

prevent the rubber rings from falling off during pouring concrete. The rubber rings with various thicknesses are shown in Fig 2.

Figure 2. Rubber rings with various thicknesses.

As the hardness of rubber rings is small, the installation only needs to compress the rubber ring into the hole manually, and then restore the geometry so that the outer surface of the ring and the hole wall contact. The installation process is simple and efficient.

2.3 *Material properties*

In the casting of concrete blocks, cubic and cylindrical specimens were fabricated to test the properties of concrete. The compressive strength of concrete cube f_{cu} and cylinder f_c was 52.1 MPa and 45.5 MPa, respectively. The cube splitting strength f_t was 4.6 MPa and the elastic modulus E_c was 40.6 GPa. The rubber employed in the test was natural rubber with the measured Shore hardness of 61 degrees. The tensile strength was 20.7 MPa, and the elongation at break was 549%.

The yield strength of the steel plate was 345 MPa. As the failure mode of specimens was the fracture of perforated rebar, the tensile tests of the fractured rebar of the single-hole specimens were conducted after demolishing the concrete blocks. The yield strength f_y and tensile strength f_u of each rebar are shown in Table 2.

Table 2. Rebar material properties.

Specimen	f_y /MPa	f_u /MPa
PB	438.3	562.3
RPB-1	413.8	560.7
RPB-2	470.7	581.6
RPB-3	508.0	617.9

2.4 *Test setup and instrumentation*

The specimens were loaded by using a servo hydraulic testing machine with a capacity of 20000 kN. The loading scheme referred to the Eurocode 4 (2005). Before the formal loading, five cyclic loading with the load range from 5% to 40% of the estimated ultimate strength were conducted since the load-slip curve had been stable after five cycles. Force control was utilized with the loading speed of 2 kN/s during the cyclic loading, while the formal loading used displacement control. Depending on the slip less or more than 3 mm, the loading speed was 0.2 mm/min or 0.5 mm/min. Lime cushion with the thickness of 2 mm was placed on the top and bottom of the specimens to avoid the emergence of a large eccentricity. Short rebars were welded to both sides of the steel plate and wrapped in foam to obtain the slip at the hole of perfobond connectors. The space below the short rebars was guaranteed to be not less than 50 mm. 2 and 8 LVDTs with a precision of 1/1000 mm were employed in single-hole and multi-hole specimens. The test setup and loading are shown in Fig 3.

Figure 3. Test setup and loading.

Strain gauges were mounted on the steel plate and perforated rebar to further explore the shear mechanism of rubber-ring perfobond connectors. Five strain gauges were vertically arranged on a horizontal section with a vertical distance of 60 mm from the center of the hole. The arrangement of steel plate strain gauges is shown in Fig 4.

Five strain gauges were arranged on each perforated rebar, including the upper and lower edges at the hole, the upper edge which was 40 mm from the center of the hole, the lateral sides which were 10 mm and 15 mm from the centerline, as shown in Fig 5. Wherein the strain gauges on the upper and lower edges were parallel to the longitudinal direction of rebar, while the strain gauges on the lateral sides were perpendicular to the axial direction.

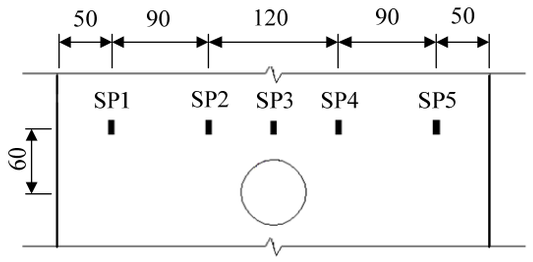


Figure 4. Strain gauges on steel plate. /mm

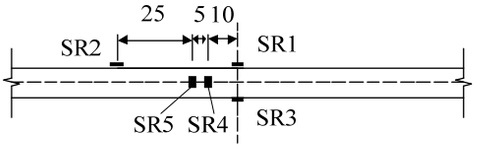

Figure 5. Strain gauges on perforated rebar. /mm

3 TEST RESULTS

3.1 *Failure modes*

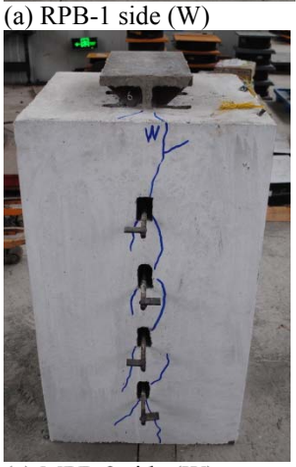

Fig 6 shows the crack distributions of concrete blocks. The crack sounds were heard when the specimens were loaded to about 70% bearing capacity, and the cracks appeared on both the top surface and the two lateral surfaces perpendicular to the steel plate. On the lateral surf aces parallel to the steel plate, no cracks were found in all the single-hole specimens, MPB-4 and MPB-5, while sim ilar vertical cracks appeared in MPB-1~3.

(a) RPB-1 side (W)

(b) RPB-1 top

(c) MPB-2 side (W)

(d) MPB-2 side (S)

Figure 6. Crack distributions on concrete blocks.

It could be seen from the shapes and distributions of cracks that the cracking was m ainly due to the failure of the bond between the steel plate and concrete. When the specim ens were loaded to the ultim ate bearing capacity, fracture sounds of perforated rebar were apparently heard.

Only the concrete at both ends along the length direction of the steel plate was cut to avoid breaking the actual shear planes. Then the concrete blocks were manually separated into two parts. Figure 7 shows the original shear plane for PB and RPB-2.

(a) PB shear plane

(b) RPB-2 shear plane

Figure 7. Shear planes of perfobond connectors.

As the slip increased, the concrete near the loading end was compacted, and the perforated rebar m oved toward the wall of the hole. The part close to the loading side of rubber ring was com pletely squashed. Both sides of the wings encountered large deformation and were sheared off. However, the lower part of the rubber ring rem ained intact and free from the concrete in the hole. The shear plane of the conventional perfobond connector was utterly vertical, while the shear plane of the rubber-ring perfobond connector form ed a sm all inclination with the steel plate surface. The rubber ring enlarged the span of the concrete dowel, resulting in a bending mode to some extent and the tensile cracking of the lower part of the concrete dowel. There were slip traces on the steel plate surface and concrete shear plane, indicating the existence of friction in the sliding process.

3.2 *Load-slip curves*

Fig 8 gives the load-slip curves of single-hole specimens, where the slip used the mean of the values measured by two LVDTs. The load-slip curve of the ordinary perfobond connector specimen PB included four stages. The initial phase of loading was a linear elastic stage with high stiffness, mainly relying on the bond between the steel plate and the concrete to resist the load. When the load increased to the cracking load V_c, the sounds of cracking were heard, which marked the end of the first stage. Followed by a rapid decline in bond, the load was mainly born by the concrete dowel and the perforated rebar, leading to reduced stiffness of the specimen. With the increase of slip, the shear failure of concrete dowel occurred, and the load reached the yield bearing capacity V_y. Although the concrete shear plane still retained the mechanical friction, the load in the third stage was mainly taken by the perforated rebar. As the slip grew, the load dropped to some extent. When the slip further increased, the shear plane of the perforated steel was in the strengthening stage, so that the load approximately linearly rose to the ultimate bearing capacity V_u. Then the perforated rebar was sheared off, and the load dropped sharply.

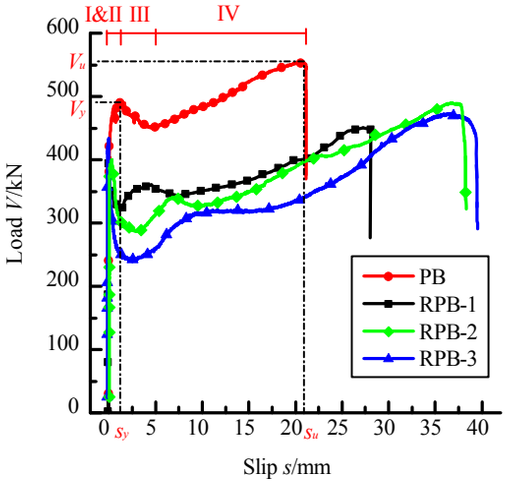

Figure 8. Load-slip curves of single-hole specimens.

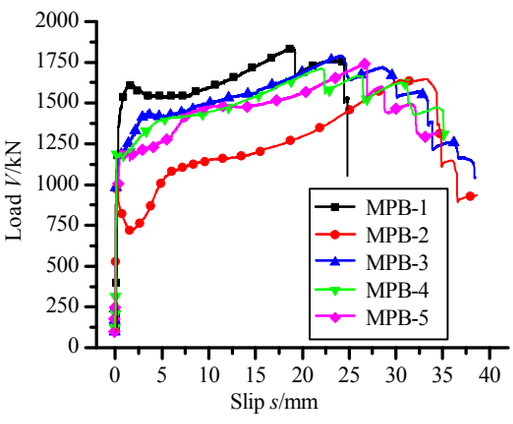
There were some differences between the load-slip curves of rubber-ring perfobond connector specimens RPB-1~3 and that of PB. Table 3 summarized the test results. Due to the rubber ring, fewer loads were carried by the concrete dowel in the first stage. The cracking loads of the four single-hole specimens were close to each other, indicating that the load in the initial stage was mainly supported by the bond. The load dropped dramatically with the growth of slip after the damage of the bond. As the increase of the rubber thickness, the yield bearing capacity V_y and the yield slip s_y reduced and grew, respectively. The main reason was that setting rubber ring diminished the area of concrete dowel, while the small stiffness of rubber improved the slip capacity of perfobond connectors. The third and fourth stages of RPB-1~3 were similar to that of PB. The ultimate slip s_u increased with the thickness of rubber ring, but the improvement was not evident when the thickness was greater than 4 mm. That was because there were limits on the deformation capacity of perforated rebar.

Table 3. Test results.

Specimen	V_c /kN	V_y /kN	s_y /mm	V_u /kN	s_u /mm
PB	401.2	491.7	1.12	555.2	20.69
RPB-1	394.4	357.5	4.03	447.8	28.10
RPB-2	392.0	339.7	6.82	489.4	36.79
RPB-3	421.2	316.0	9.46	472.6	36.66
MPB-1	1336.4	1607.5	1.42	1839.8	19.08
MPB-2	1064.2	1091.1	6.50	1647.0	33.24
MPB-3	1093.3	1437.1	3.46	1789.5	24.11
MPB-4	1172.9	1401.3	5.10	1711.7	22.11
MPB-5	1193.0	1436.8	7.77	1739.7	26.64

Compared to the ordinary perfobond connector, the yield bearing capacity of rubber-ring perfobond connector decreased about 30%. Since the failure mode was the fracture of perforated rebar, the ultimate bearing capacity reduced by 15.4%. The difference between ultimate bearing capacity and yield bearing capacity was related to the properties of perforated rebar. The yield slip grew by 260% to 745%, which was determined by the thickness of the rubber ring.

Fig 9 shows the load-slip curves of multi-hole specimens, where the slip was the average of values measured by the LVDTs in the first row. The overall trend of the load-slip curve of MPB-1 was similar to that of PB, and MPB-2 which used rubber rings on all of the holes was identical to RPB-2. Each specimen contains four perforated rebars, resulting in several sounds of the fracture of rebars and the multi-step ladder in the failure stage curves.



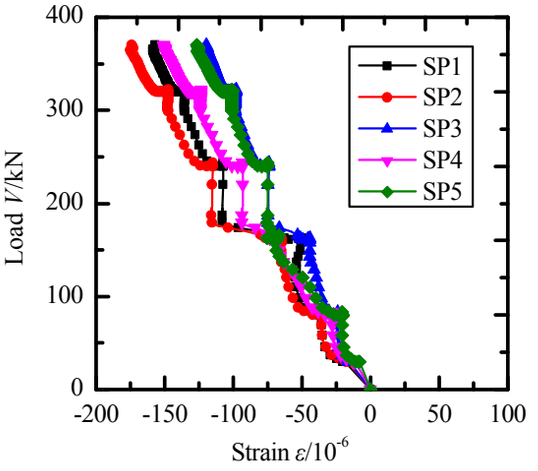


Figure 9. Load-slip curves of multi-hole specimens.

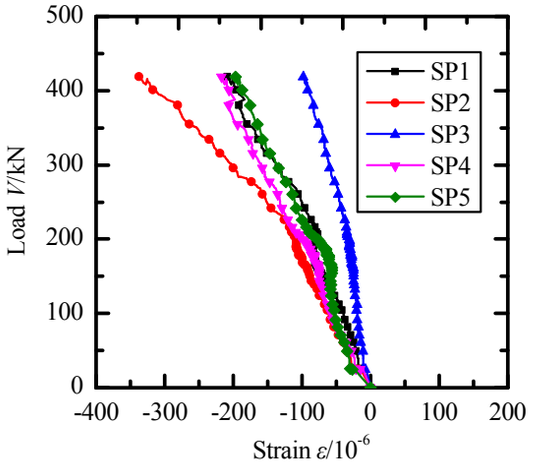
The rubber rings with different thicknesses were employed on the first and fourth holes in MPB-3~5. The cracking loads of these three specimens were close, which were less and larger than that of MPB-1 and MPB-2, respectively, indicating that concrete dowels were involved in carrying load at the first stage in the multi-hole specimens. As the middle concrete dowels could bear load when the bond was damaged, the load-slip curves of MPB-3~5 did not appear the sharp drop of load in that of RPB-1~3 and MPB-2. The larger thickness of the rubber made the more hysteresis of carrying shear of the hole, the smaller stiffness in the second stage and the higher yield slip. The yield bearing capacity and the ultimate bearing capacity of these three specimens were close, which were about 89% and 95% the yield and ultimate capacity of MPB-1, respectively because the area differences of the concrete dowel were relatively small and the failure mode was the fracture of perforated rebars. The ultimate slip of MPB-2 was greater than MPB-3~5 and MPB-1. The ultimate slip of MPB-4 was less than that of MPB-3, possibly due to the difference in material properties of individual perforated rebar.



3.3 *Load-strain relationship of steel plate*

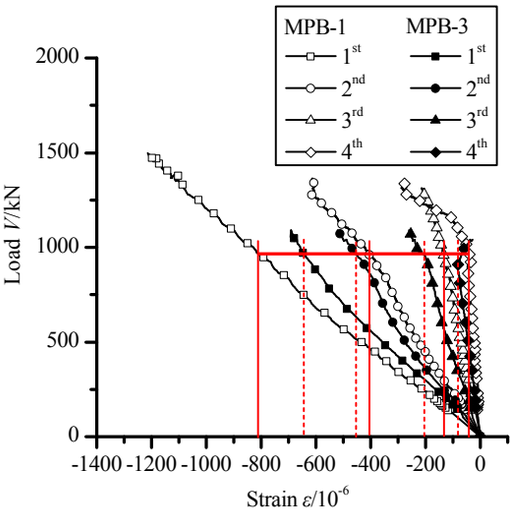
Fig 10 shows the load-strain relationships of each measuring point on the steel plate in PB and RPB-3. The full cross-section of the steel plate was compressed, and the vertical strain increased linearly with the growth of load. After the concrete block cracked, the slip increased rapidly resulting in the damage of most strain gauges. The measured strain of SP2 and SP4 whose horizontal distance from the center of the hole was 60 mm were relatively large, followed by SP1 and SP5. Due to the bond and friction, the vertical strain measured by SP3 which located in the centerline of the steel plate was minimal. The strain on both sides of the centerline was asymmetric.

The steel plate strain patterns in each row of the multi-hole specimens were similar to that of single-hole specimens. Fig 11 compares the steel plate load-strain relationship of each row between MPB-1 and MPB-3, where the strain took the average of SP2 and SP4. In the multi-hole specimens, the strain of the steel plate reduced gradually with the increase of the row number. Each curve was intercepted by the same load, and the horizontal distances of the adjacent intersections in the same specimen reflected the load magnitude between the adjacent holes. The steel plate strain of the first row in MPB-3 decreased by applying the rubber rings, and the horizontal distances of adjacent intersections were less than those of MPB-1, indicating that a reasonable arrangement of rubber rings could alleviate the local shear concentration.

(a) PB

(b) RPB-3

Figure 10. Load-strain relationships of single-hole specimens.



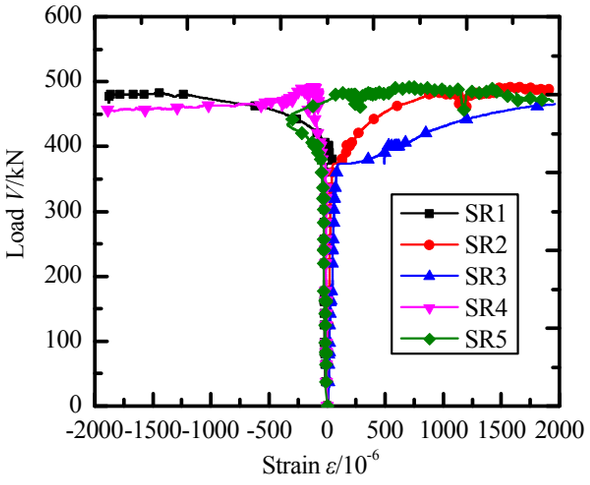


Figure 11. Comparison of load-strain relationships between multi-hole specimens.

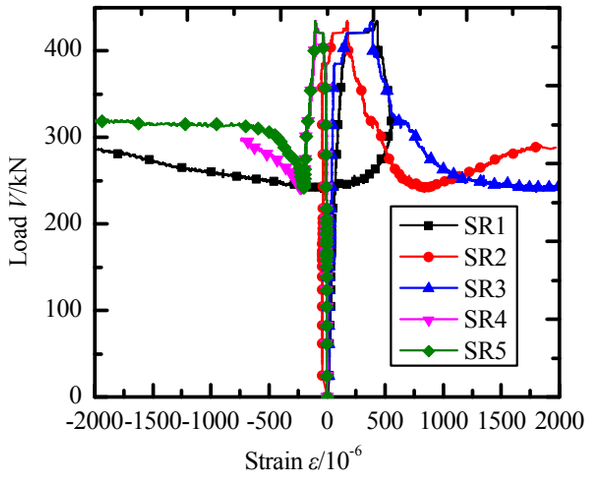

3.4 *Load-strain relationship of perforated rebars*

Fig 12 shows the load-strain relationships of perforated rebars. At the initial loading phase, the load was mainly resisted by bond and concrete dowel, re-

sulting in the small strain of perforated rebars. When the load reached the cracking load, the strain rose rapidly. The tensile strain of SR3 grew fastest. Then the compressive strain of SR1 and the tensile strain of SR2 increased, which showed the bending characteristics of perforated rebar. As the slip increased further, the strain of SR4 and SR5 rose. It was noted that SR4 was in compression while SR5 was in tension, indicating that the horizontal distance from the center of hole to the shear plane in PB was 10 mm to 15 mm. On the contrary, both SR4 and SR5 were in compression in RPB-3, indicating that the shear plane moved away from the centerline after setting the rubber ring.

4 EVALUATION OF SHEAR CAPACITY FORMULAS

4.1 *Existing formulas*

This paper collected the Formulas (1) to (5) of shear bearing capacity for perfobond connectors, which were based on the modified push-out test results.

Where A_c is the area of concrete dowel, A_s is the area of perforated rebar, A_{tr} and f_y' are the area and yield strength of transverse reinforcements, τ_b and A_b are the bond strength and contact area between the steel plate and concrete block, and t is the thickness of steel plate.

Zhang et al. (2007) proposed Formula (1) by regression of the test results of 31 specimens. The authors believed that the shear bearing capacity was mainly provided by the concrete dowel and perforated rebar. Tensile strength was chosen to calculate the shear bearing capacity. Wang et al. (2013) carried out the push out tests using horizontal loading, including 33 specimens and presented Formula (2) to calculate the shear bearing capacity. Where the coefficients α, β and δ are 0.9974, 0.1293 and 220 kN, respectively. The authors supposed that the transverse reinforcements had contributions to the bearing capacity, while the contributions of concrete dowel were ignorable. The bond was considered in the tests, but only the constant term δ was given in Formula (2).

$$V_u = 0.95\times(2A_cf_c)+0.94\times(2A_sf_u) \tag{1}$$

$$V_u = \alpha(2A_sf_u)+\beta(2A_{tr}f_y')+\delta \tag{2}$$

Wang et al. (2014) proposed Formula (3) based on three series of 24 groups of modified push-out test results, in which the shear bearing capacity was affected by the concrete dowel, perforated rebar and transverse reinforcements. Yield strength was used to consider the contributions of perforated rebar and transverse reinforcements. He et al. (2016) conducted 12 specimens of modified push-out tests to analyze the individual contribution of the bond, concrete dowel and perforated rebar. Then Formula (4) was put forward. Nakajima et al. (2016) studied the results of the 35 modified push-out test specimens and presented Formula (5). The authors believed that the shear bearing capacity was provided by the concrete dowel and perforated rebar, both of which were related to the thickness of steel plate.

$$V_u = 0.498A_c\sqrt{f_c}+0.255A_sf_y+0.065A_{tr}f_y' \tag{3}$$

$$\begin{cases} V_u = \tau_bA_b+1.06A_cf_{cu}+2.09A_sf_y \\ \tau_b = -0.022f_{cu}+0.306\sqrt{f_{cu}}-0.573 \end{cases} \tag{4}$$

$$\begin{cases} V_u = V_c+0.84d_sf_yd^{0.1}t^{0.8} \\ V_c = 0.15\alpha A_cf_c^{0.65}A_s^{0.43}t^{-0.5} \\ \alpha = 6.9d_s^{0.4}d^{-0.7} \end{cases} \tag{5}$$

4.2 *Comparison of formulas*

The calculated results by substituting the measured parameters in the experiments into Formula (1) to

(5) were compared with the ultimate bearing capacity obtained by the tests, as shown in Table 4. Although Formula (1) did not consider the bond, the overall error was minimal among the five equations. The reasons were that the contribution of concrete dowel was overestimated and tensile strength was used to consider the effect of perforated rebar. In Formula (2) and (3), different strengths of perforated rebar were used, and the difference of coefficients was substantial. The contribution of transverse reinforcements was taken into account in both equations, resulting in larger calculation results. Formula (5) was usable for a specific parameter range, which was not applicable when the diameter of perforated rebar was greater than 16 mm or the rebars and concrete with high strengths were employed.

Since Formula (4) took account of cohesive force, the calculation error of PB was small. The calculation errors of the specimens with rubber ring were about 20%. The possible reason was that the constraint effect of the steel plate on the concrete in the hole was significantly reduced, and the contribution of concrete dowel should be reduced in the shear capacity formula. On the other hand, the increase of slip capacity caused a decline in residual bond and friction. Therefore, the formula of the shear bearing capacity of rubber-ring perfobond connector needs to be further studied.

Table 4. Calculated results of each formula /kN.

Specimen	(1)	(2)	(3)	(4)	(5)	Test
PB	549	656	651	588	137	555.2
Error/%	-1	18	17	6	-75	
RPB-1	517	655	618	550	128	447.8
Error/%	15	46	38	23	-71	
RPB-2	500	668	651	569	142	489.4
Error/%	2	36	33	16	-71	
RPB-3	494	690	670	576	150	472.6
Error/%	5	46	42	22	-68	

5 CONCLUSION

The following conclusions could be drawn based on the investigations above.

(1) When the load reached the ultimate bearing capacity, the failure mode of both ordinary and rubber-ring perfobond connectors was the fracture of perforated rebar. The rubber ring enlarged the span of concrete dowel, resulting in the bending characteristic of concrete dowels.

(2) Compared to conventional perfobond connectors, the yield capacity of the rubber ring perfobond connector reduced by about 30% and the ultimate capacity decreased by 15.4%. The yield slip increased by 260%~745%, depending on the thickness of rubber rings.

(3) By applying the rubber rings, the strain differences of adjacent rows were diminished, indicating that a reasonable arrangement of rubber rings could alleviate the local shear concentration.

(4) The calculation errors of the shear capacity formula considering the contributions of the bond, concrete dowel and perforated rebar were small. The constraint effect of the steel plate on the concrete dowel was reduced by employing rubber rings.

Effect of Hinge-Type Connections on the Lateral Cyclic Behavior of a Prestressed High-Strength Concrete Pile

B. Lim & J. W. Kang

Y. J. Kim & H. Yoon
Korea Institute of Civil Engineering and Building Technology, Goyang, Republic of Korea

ABSTRACT: This paper presents the cyclic behavior of a prestressed high strength concrete (PHC) pile with hinge-type pile head connections designed for reducing the bending moment due to lateral loads. The PHC pile is a hollow cylindrical prestressed pile made by centrifugal compaction and is being increasingly used in the foundation of civil structures because of its good seismic performance and cost effectiveness. This study investigated the seismic performance of full-scale PHC piles with four head types. The pile specimens consist of a reference specimen with no pile cap, a hinge specimen with a pile cap on the head, a hinge specimen with a pile cap and reinforcing steel, and a hinge specimen with prestressing steel. The cyclic response of the four PHC pile specimens was obtained by quasi-static tests conducted with displacement-controlled lateral cyclic loadings. According to the test results, the PHC pile with a pile cap had the best lateral displacement capacity among the specimens. The other hinge specimens also showed good cyclic performance with only minor damages due to the reduced bending moment around the pile head, whereas the reference specimen with no pile cap exhibited severe damage. It was observed from hysteresis curves that the PHC pile with a pile cap had better bearing and energy dissipation capacities compared to the regular reinforced concrete pile. Design features of the PHC piles, experimental configuration, and the test results will be presented. The proposed head connections can be used to diminish the flexural damage of PHC piles due to ground motions.

1 INTRODUCTION

Prestressed High Strength Concrete (PHC) piles are characterized by excellent resistance to lateral and impact loads and large load carrying capacity owing to prestressing effect of tendons and high compressive strength of concrete. They are usually fabricated with a high strength concrete with the compressive strength of over 80 MPa, which is greater than the compressive strength of a regular prestressed concrete (PC) by at least 1.6 times. Thus, they have the advantages of less cracking due to hitting and high corrosion resistance (Aoshima *et al*., 2006). Furthermore, compared to PC piles, PHC piles allow the penetration of the hard middle layer and the implementation of long piles, and are usually cheaper than steel pipe piles (Hwang & Cho, 2005). Therefore, in the US and Europe, PHC piles are frequently used in deep foundation for bridges as well as for high-rise buildings.

Pile foundation must be designed to sufficiently endure vertical load and horizontal earth pressure, and effectively resist seismic load. Thus, the sufficient horizontal load bearing capacity of pile foundation is one of the key considerations for seismic design of structures. In fact, many earthquake damages due to insufficient horizontal load bearing capacity of piles have been reported across the world. On June 28, 1948, shear failure occurred on the independent footings of many buildings due to an earthquake of 6.8 magnitude in Fukui , Japan. In 1964, damages to pile foundations of various structures occurred due to liquefaction caused by the Niigata earthquake. Sugimura *et al*. (1981) evaluated the damages of existing piles due to the earthquake in Miyagi in 1978 and proposed a foundation design method to improve them. To investigate the causes of the damages of structures and pile foundations caused by an earthquake of 7.2 magnitude that occurred in KOBE, Japan in 1995, Mizuno *et al*. (1996) analyzed the damage patterns, soils, and environmental characteristics around the buildings and suggested an improvement of pile design. In 1989 in San Francisco, USA, the substructure and pile connections of the Oakland Bay Bridge were damaged seriously by an earthquake of 6.9 magnitude (Elgamal *et al*., 2008). To reduce these earthquake damages, it is critical to attain sufficient displacement ductility of piles. In particular, the design details of pile-footing connections have a large effect on the seismic performance of pile foundation because the cross-section

and stiffness of members change rapidly around the connection part. Depending on the method of reinforcing the connection of pile foundation, the stress concentration on the pile-footing connection can be mitigated in various patterns. Recently, active studies have been conducted to reinforce the connections of PHC pile and footing with infilled concrete and additional steel bars and to understand the horizontal behavior characteristics of pile systems. Larosche *et al*. (2014) performed an experiment to reinforce three connections of PHC piles and footings arranged in a row with infilled concrete, tie bars, and axial bars and apply the Joshua Tree seismic load which had occurred in California in 1992. Through this experiment, they evaluated the constrained stress of infilled concrete, the ductility of foundation, and the damages of piles, and proposed a footing design method. Bang *et al*. (2016) carried out a lateral loading experiment after arranging infilled concrete and reinforcing bars in the hollow parts of PHC piles and evaluated the bending moment, ductility, and energy dissipation capacity of pile connections. They also found that the behaviors of pile-footing connections depended on the insertion depth of piles, the number and location of longitudinal reinforcing bars. Yang *et al*. (2016) analyzed the load versus displacement curve, ductility and bearing capacity of piles according to the arrangement method of reinforcing bars in the connection between PHC piles and footings.

These reinforcement methods for the head of PHC files increase the bending stiffness of the footing connection, thus increasing the lateral displacement ductility of piles. However, this type of connection is expected to exhibit lower lateral displacement ductility than the connection of full hinge structure if the vertical load bearing capacity of a pile does not change. In this study, the pile head is made into a hinge structure by mounting a pile cap on the connection of PHC pile and footing. Then the increase in the lateral displacement ductility of pile and the decrease in the bending moment of the connection are evaluated. To this end, quasi-static lateral load tests were performed by producing a fully fixed specimen with no pile cap and with the pile-footing connection reinforced by infilled concrete, axial and lateral reinforcement bars, a full hinge specimen with a pile cap on the head pf PHC pile, a partial hinge specimen with the connection reinforced by axial and lateral reinforcement bars and with a pile cap on the pile head, and a partial hinge specimen with PC steel wires extended to the footing and with no infilled concrete.

This paper introduces the design characteristics of PHC pile connections and describes a quasi-static experiment method for evaluating the seismic performance of the connections. The seismic performance of PHC piles with the connection reinforced with a pile cap is presented by comparing the load versus displacement curves, fracture patterns, and energy dissipation capacity of the specimens to which four reinforcement methods have been applied.

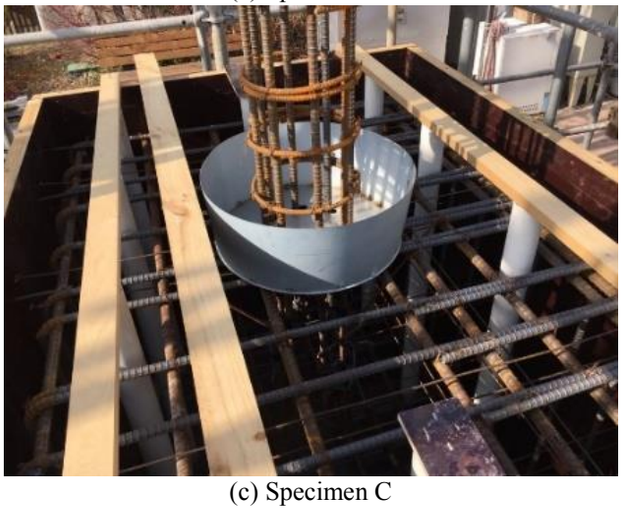
2 PREPARATION OF SPECIMENS AND EXPERIMENTAL METHOD

2.1 *Preparation of the PHC pile specimens*

PHC piles generally have a hollow cross-section and are fabricated using a centrifugal force to produce concrete with uniform characteristics. To produce high-strength concrete with 80 MPa or higher compressive strength, silica powders, high-performing water reducing agent, and a special admixture are added (Aoshima *et al*., 2010).

The PHC pile specimens used in this study comprise high-strength concrete with 80 MPa or higher compressive strength and nine PC steel materials with a 9.2mm nominal diameter. Their diameter, thickness and length are 500 mm, 80 mm, and 3500 mm, respectively. Specimens were produced by classifying these PHC piles into four categories depending on the existence of pile cap and the internal reinforcement method of footing connections. Figure 1 shows the PHC pile specimens of these four types. Specimen A is a fully fixed specimen with no pile cap and with the pile-footing connection reinforced by infilled concrete, axial and lateral reinforcement bars. Specimen B is a full hinge specimen with a pile cap on the head pf PHC pile. Specimen C is a partial hinge specimen with the connection reinforced by axial and lateral reinforcement bars and with a pile cap on the pile head. Specimen D is a partial hinge specimen with PC steel wires extended to the footing and with no infilled concrete.

Specimens A, B, and C were fabricated in a length of 3.5 m by applying one cutting method, which cuts the concrete and PC steels together for 5m long PHC piles produced in a factory. Specimen D was fabricated with nine PC steel bars at the end of the 3.5m long PHC pile exposed for 500 mm. The design reference compressive strength of the footing concrete and the infilled concrete of the hollow part of PHC piles is 30 MPa. The reinforcement bar of the infilled concrete in the hollow part of pile is D19 deformed bar with a yield strength of 400 MPa.



The pile cap mounted on the pile head of Specimens B, C and D have a crown diameter of 501 mm, a bottom diameter of 545 mm, a height of 201 mm, and a thickness of 1.2 mm. Figure 2 shows the dimensions of the pile cap.

Specimens	A		B		C		D	
	Pile	Footing	Pile	Footing	Pile	Footing	Pile	Footing
Dimension (mm)	Ø500-80	1500 × 2000	Ø500-80	1500 × 2000	Ø500-80	1500 × 2000	Ø500-80	1500 × 2000
Height (mm)	3500	1300	3500	1300	3500	1300	3500	1300
Prestressing bar	9-Ø9.2	-	9-Ø9.2	-	9-Ø9.2	-	9-Ø9.2	-
Longitudinal bar	8-D19	-	8-D19	-	8-D19	-	8-D19	-
Transverse rebar	D13@150	D13@150	-	-	D13@150	D13@150	-	-
Concrete strength (MPa)	80	30	80	30	80	30	80	30
Yield strength of longitudinal bar (MPa)	400	-	-	-	400	-	-	-

For all Specimens A to D, the PHC piles were inserted into the footing by a length of 100mm. The footing is a concrete block with a horizontal length of 1500 mm, a vertical length of 2000 mm, and a height of 1300 mm. The loading unit at the top is a concrete block with a horizontal length of 1500 mm, a vertical length of 1500 mm, and a height of 1200 mm. Eight D19 reinforcing bars were arranged in Specimen A and Specimen C for the reinforcement of infilled concrete. A laser riser was used to combine the footing top with the PHC piles accurately at right angle. Table 1 shows the dimensions of each specimen and the dynamic characteristics of materials. Figure 3 shows the schematics of the connections of the four PHC pile specimens.

2.2 *Quasi-static test*

To evaluate the seismic performance of the four PHC pile specimens with different connection details, a quasi-static test was conducted, which applied lateral load at the top end of the piles while applying an axial load. As shown in Figure 4, the piles were placed on the top of the footing and a loading concrete block was placed on the pile top. The long-term allowable axial load of 1400 kN was applied to the pile by an actuator in the axial direction and the pile was loaded laterally by an actuator supported on a reaction wall. The lateral actuator was connected to the loading unit of the pile at a height of 3000 mm above the pile bottom. The actuator applied the lateral load to the pile cyclically up to a displacement of 178.84 mm with a displacement control method that increases the lateral displacement in increments of 6.39 mm. Positive and negative loads were repeated in two cycles in each displacement step as shown in Figure 5.

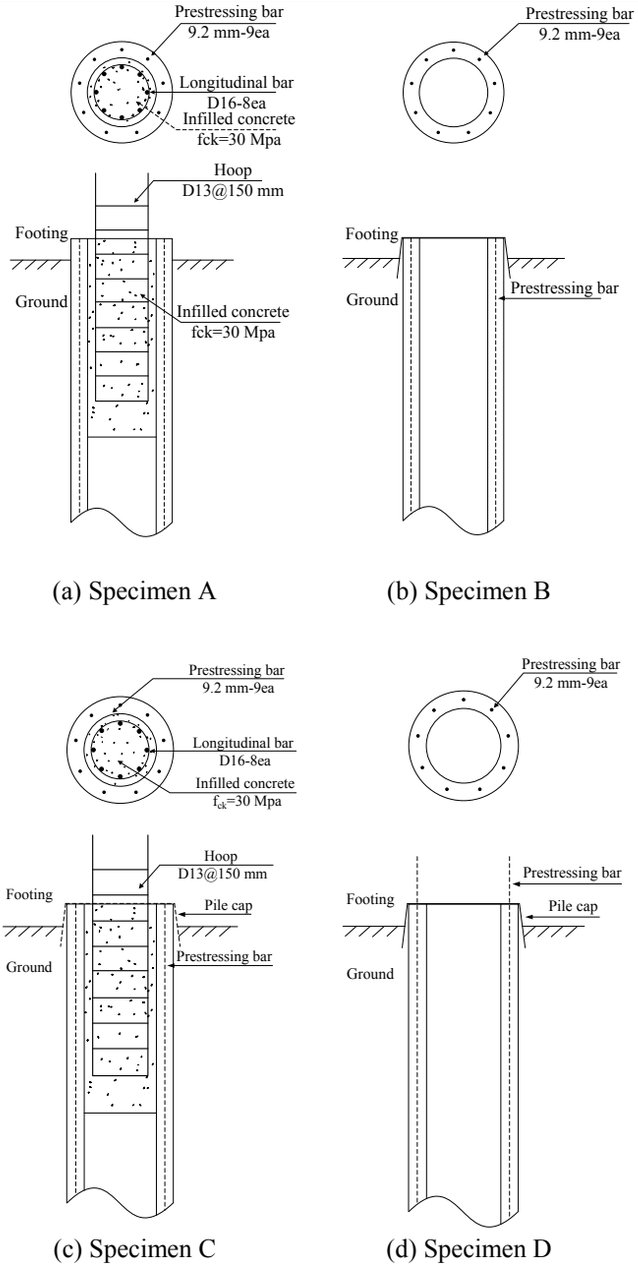

Figure 3. Schematics of the four PHC pile specimens.

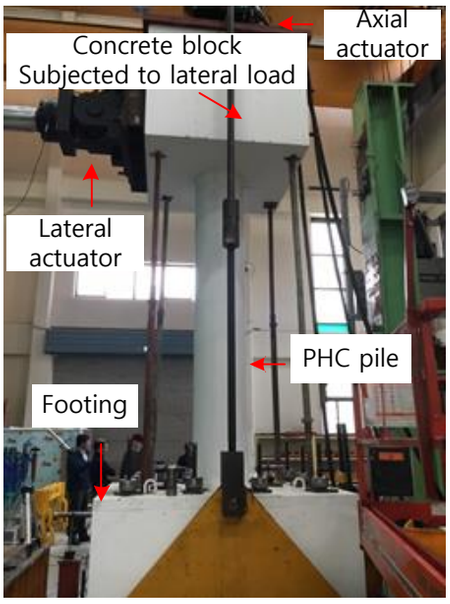

Figure 4. Quasi-static test setup with a PHC pile specimen.

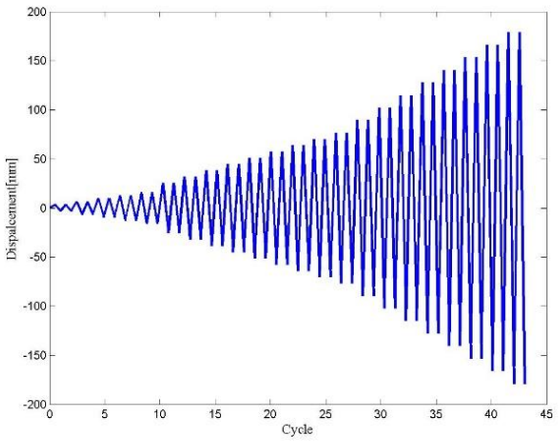

Figure 5. Cyclic loads for the quasi-static test.

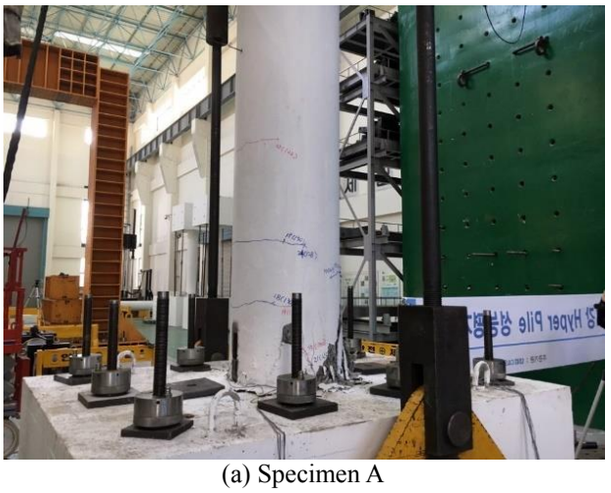
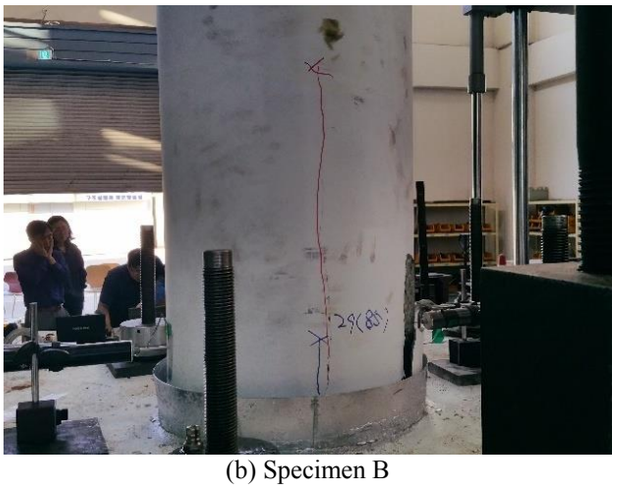
3 TEST RESULTS AND DISCUSSION

3.1 *Fracture patterns of the PHC pile specimens*



The quasi-static test was repeated until the four PHC pile specimens were fractured. Figure 6 shows the fracture patterns of these four PHC piles. In the case of Specimen A, initial flexural cracks were observed near the connection of PHC pile and footing at a lateral displacement of 44.72 mm. The flexural cracks progressed as the lateral displacement increased. Then longitudinal shear cracks occurred at a lateral displacement of 57.49 mm. As the lateral displacement of the specimen increased, the widths of flexural and longitudinal shear cracks increased. At a lateral displacement of 77.10 mm, the specimen reached its maximum load 135.77 kN, and the pile was fractured at a lateral displacement of 131.50 mm.

In the case of Specimen B whose connection to the footing is close to hinge, longitudinal cracks of the pile developed at a lateral displacement of 89.43 mm. There were no significant flexural cracks generated until then. Then it reached the maximum load of 98.98 kN at a lateral displacement of 149 mm.



In the case of Specimen C whose connection is reinforced with infilled concrete and rebars, longitudinal shear crack occurred earlier than flexural cracks as in the case of Specimen B. The lateral displacement at the development of the longitudinal crack was 51.10 mm. The width of the longitudinal cracks increased as the lateral load increased and the length of cracks increased toward the pile top. The cover concrete was spalled at a lateral displacement of 106.84 mm. Then it reached the maximum load of 140 kN at a lateral displacement of 120.3 mm. After reaching the maximum load, the PHC pile was fractured at a lateral displacement of 140.54 mm.

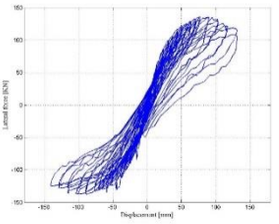
In the case of Specimen D, no significant flexural bending and longitudinal shear cracks were generated unlike the other specimens, and the cover concrete was separated at a lateral displacement of 173.75 mm. The specimen reached the maximum load of 114.32 kN at a lateral displacement of 173.75 mm. The separation of concrete from the surface of the PHC pile specimens seems to have been caused by the concentration of stress along the cracks at the connection of PHC pile and footing.

The results of this test showed that the displacement of Specimen D was greater by 2.25 times, 1.17 times, and 1.24 times than those of Specimens A, B, and C, respectively at the maximum lateral load. In other words, the lateral displacement ductility was large in the order of Specimens D, B, C and A. The reason that the lateral displacement ductility values of specimens B, C, and D were larger than that of Specimen A is that the PHC pile connection using a pile cap proposed in this study increases the lateral flexibility of the PHC piles. Specimens B to D with a pile cap showed some cracks in the connections and the body of PHC piles, but their lateral load bearing capacity did not decrease much until the end of test compared to Specimen A.

(a) Specimen A

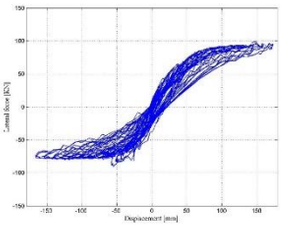
(b) Specimen B

(c) Specimen C



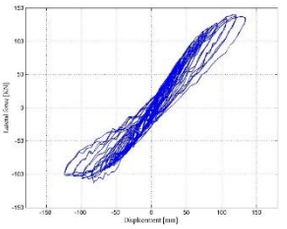
(d) Specimen D

Figure 6. Fracture patterns of the four PHC pile specimens.

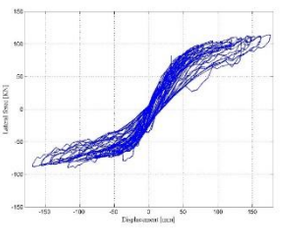


3.2 *Lateral load-displacement curves*

The yield load, peak load, and ultimate load of each specimen are shown in Table 2. Furthermore, the ductility ratio of each specimen was calculated by using the yield displacement and ultimate displacement at fracture.



As shown in Table 2, ductility ratios of Specimens A, B, C, and D are 2.15, 5.55, 3.16, and 5.37, respectively. Specimen A has the lowest displacement ductility due to the connection with the infilled concrete reinforced with tie bars and axial bars. Therefore, its lateral flexibility is relatively small compared to others. Specimen C shows a greater displacement ductility compared to Specimen A because a pile cap was mounted between the footing and pile, which improved lateral flexibility.



(a) Specimen A

(b) Specimen B

(c) Specimen C

(d) Specimen D

Figure 7. Hysteresis curves obtained from the quasi-static test of the four PHC pile specimens.

Table 2. Lateral load and displacement values at yielding, peak, and ultimate states of the four PHC pile specimens.

Specimens		A	B	C	D
Yielding state	P_y(kN)	125.13	58.59	68.88	68.36
	δ_y(mm)	57.40	30.30	41.25	32.35
Peak state	$P_{\max}$(kN)	135.77	98.98	140	114.32
	$\delta_{\max}$(mm)	77.1	149	120.3	173.75
Ultimate state	P_u(kN)	108.40	96.01	136.71	114.32
	δ_u(mm)	123.20	168.3	130.2	173.75
Ductility ratio	(δ_u/δ_y)	2.15	5.55	3.16	5.37

Specimen B shows a greater displacement ductility compared to Specimens A and C because the head was reinforced only with a pile cap with no tie bars and axial bars and the connection is close to a full hinge. Specimen D shows a similar displacement ductility as that of Specimen B because the PC steel wires do not greatly affect the bending stiffness of pile although the PC steel wires are extended from the pile to the footing.

3.3 *Viscous damping ratio*

The energy dissipation capacity is one of the items that should be considered to evaluate the seismic performance of structures. The dissipated energy of a structure can be expressed by an area surrounded by the load versus displacement curve. Figure 8 shows a schematic of the load versus displacement curve as well as the dissipated energy and maximum strain energy for a structure under cyclic loading.

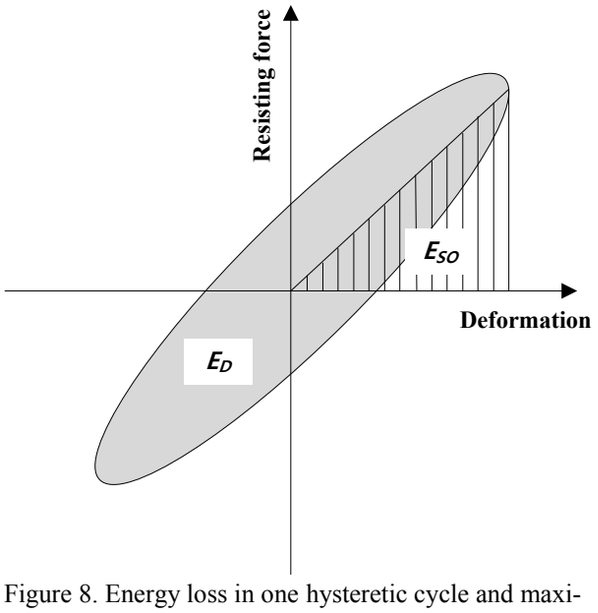


Figure 8. Energy loss in one hysteretic cycle and maximum strain energy.

In this figure, E_D denotes the dissipated energy in one cycle, and E_{So} denotes the maximum strain energy. The area ratio of E_D and E_{So} calculated through Equation (1) can be used to indicate the viscous damping ratio of specimens (Chopra, 2001).

$$\zeta = \frac{1}{4\pi}\frac{E_D}{E_{So}} \tag{1}$$

Figure 9 shows the viscous damping ratios of Specimens A to D calculated using Equation (1).

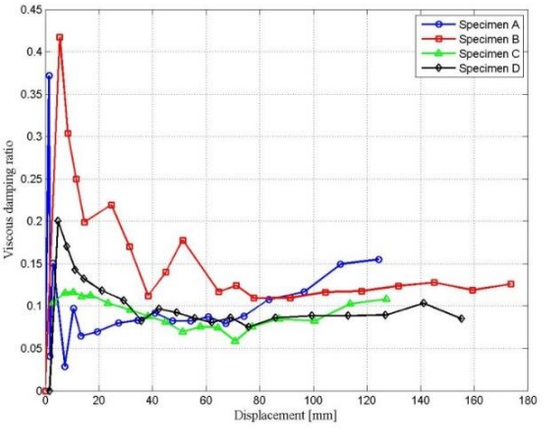

Figure 9. Viscous damping ratio of each specimen.

Among the specimens, B and D with large lateral displacement ductility showed large damping ratios in general. This is because Specimens B and D whose connection of PHC pile and footing is close to a full hinge have a larger energy dissipation capacity in lateral behaviors compared to Specimens A and C.

4 CONCLUSION

In this study, four types of PHC pile specimens were fabricated depending on the existence of pile cap and the internal reinforcement method of the footing connection. The load versus displacement curves recorded by applying repeated loads to the specimens were compared, and the fracture patterns and the viscous damping ratio of PHC piles were compared.
Specimens B and D exhibited larger displacements at the peak lateral load compared to Specimens A and

C. The descending order of ductility ratio of the specimens was B, D, C, and A. Furthermore, the comparison of viscous damping ratios of the specimens showed that Specimens B and D whose connections are close to a full hinge had a greater energy dissipation capacity than those of Specimens A and C. Based on these findings, applying the head reinforcement method of Specimens B and D to the PHC pile footing is expected to provide excellent seismic performance.

ABSTRACT: Seismic damage had shown that bearing damage was common in the actual damage of bridge structures. It was considered as the weakest part of seismic performance in bridge structure system. Based on 32m-span simply-supported girder railway bridges in China, considering the mechanical characteristics of two kinds of typical bearings, a precise nonlinear dynamic analysis model was established. The bearing damage index based on the displacement failure criterion was put forward, and then the vulnerability curves of two kinds of bearings under different damage states were formed by traditional reliability probability analysis method. The seismic performance of two kinds of bearings was compared and evaluated from the viewpoint of vulnerability. The results show that the vulnerability of the two kinds of bearings under different damage states is obviously different under earthquake. When the pier is low, the double spherical aseismic bearing has a good isolation effect, which effectively reduces the failure probability of the bearing components under different damage conditions. However, with the pier height increasing, the isolation effect gradually decreases, which indicates that for simply-supported bridges with high piers, the seismic performance of bearings cannot be improved by using it.

1 INTRODUCTION

Earthquake is one of the most serious natural disasters that mankind face, for it brings huge casualties and economic losses. Railway as the lifeline of earthquake relief work, the seismic damage of railway bridges not only causes huge economic losses, but also leads to indirect economic losses, for the secondary disasters such as traffic disruption will retard the relief work and hinder the post-disaster reconstruction.

The lesson of railway bridges' seismic damage is profound, and railway bridges have been destroyed in varying degrees in all previous violent earthquakes. The investigation of seismic damage in recent years shows that the damage of bearings is one of the most common seismic damage of railway bridges. As an important component connecting the superstructure and substructure of bridge, the bearing mainly plays the role of transmitting the reaction force from the superstructure and bearing the horizontal deformation. The research has showed that the bearing damage is very common in actual seismic damage of bridge structure, and it belongs to the vulnerable part of bridge structure (Wu 2012). Other superstructure damage such as the collision of adjacent beams or the longitudinal and transverse displacement of bridge, appears mostly after the failure of bridge bearing. Once the deflection exceeds the allowable value of the movable bearing, the bridge is tilted or the bearing falls. According to statistics, the bearing anchors of at least 19 rail bridges are cut in Tangshan earthquake in July 28, 1976 (Wang 2013). Therefore, it is necessary to study the seismic vulnerability of bearings.

Different requirements for bridge isolation design leads to different type of bearings adopted, and different types of bearings exhibit different mechanical characteristics under the action of the earthquake. In this paper two types of typical bearing for railway bridges are selected, namely spherical bearing and double spherical aseismic bearing. Based on the analysis of bearing capacity, a precise nonlinear dynamic analysis model is established. The bearing damage index is put forward according to displacement failure criterion and the vulnerability curves of these two types of bearings under different damage states are formed by traditional reliability probability analysis method (Howard 2001). The seismic performance of the two types of bearings is evaluated from the point of vulnerability, which provides a reference for seismic design of similar bridges.

2 MECHANICAL MODEL OF TYPICAL BEARINGS

2.1 *Overview of bridges and typical bearings*

In this paper, the prestressed concrete simply supported bridge with a span of 32 meters, which are most widely used and distributed in China, is taken as the research object. The bearing vulnerability under the conditions of different pier heights from 10 to 50 meters is studied. Two-piece prefabricated post- tensioned T-beam is used in the superstructure of the simply supported girder bridge. The full length of the beam is 32.6m with the calculated span of 32m and height of 2.5m, and the width of bridge deck is 4.9m. The main girder adopts C50 concrete, and the column pier adopts C40 concrete. Two types of bearings are considered which are respectively spherical bearing and hyperboloid spherical isolation bearing. The schematic diagram of the structure is shown in Figure 1.

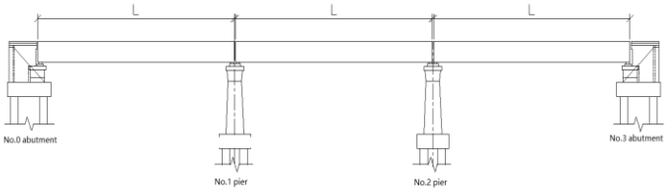

Figure 1. Diagrammatic sketch of calculation model of three-span simply supported girder bridge.

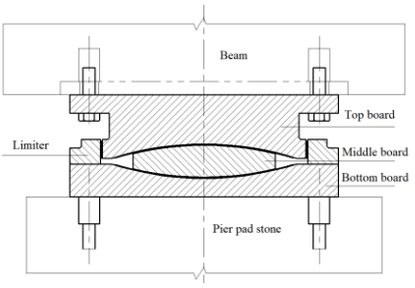
The spherical bearing is a kind of bearing developed on basis of pot rubber bearing. After years of development, its design theory, production and inspection technology have been mature. The advantages of the bearing lies in: ①the bearing parts are free of rubber material, so that the problems such as unmanageable rubber quality and rubber aging problem will not exist; ②the plane displacement and angle rotation of the bearing are provided by the sliding between plane friction pair and spherical friction pair, so the rotational resistance is smaller and the rotation is more flexible; ③the skateboard is made of the new sliding material which has high carrying capacity and good wear resistance, therefore it can effectively reduce the bearing size. Because of its unique advantages, it has been gradually applied to railway bridges.

The double spherical aseismic bearing is a new-type bearing formed on basis of the spherical bearing by using the large radius spherical friction pair instead of the plane friction pair and setting a shearing resistance device, whose structure is shown in Figure 2. Double spherical aseismic bearing works based on the friction pendulum principle. When the earthquake happens and the horizontal force exceeds a predetermined value, the shear pin and the safety screw of the limiter are cut and the horizontal limit constraint of the bearing is released, so the large radius spherical friction pair can slide freely horizontally. The earthquake energy is consumed gradually through that friction resistance and the structural period is prolonged, so the purpose of shock absorption and seismic resistance can be achieved. After the earthquake, the weight of the structure can form a restoring force that make the structure back to the original position.



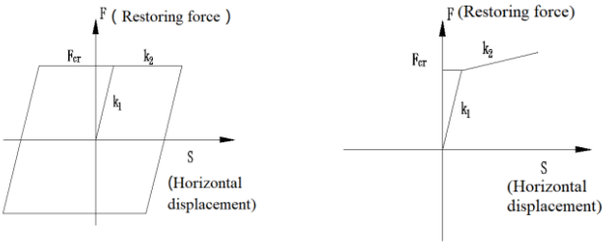


Figure 2. Structure of double spherical aseismic bearing.

2.2 *Mechanical Model of Bearing*

The horizontal stiffness of the bearing has great influence on the seismic response of the main structure of the bridge (Ye 2001) and longitudinal seismic wave input method is adopted to study the vulnerability of the bridge along the longitudinal direction, therefore, the mechanical properties of the bearing in the horizontal direction is mainly discussed in this paper.

In the conventional seismic response analysis, the restoring force-displacement models of the spherical bearing and the aseismic bearing are both bilinear. However, there are some differences between the two models, as is shown in Figure 3.

(a) Spherical bearing (b) double spherical aseismic bearing

Figure 3. Restoring force-displacement relationship of bearing.

The lateral force “F” is the horizontal seismic action of the bearing at a certain moment, and the lateral displacement "S" is the horizontal displacement of the bearing corresponding to the lateral force F at a certain moment. k_1 denotes the stiffness of the bearing before slipping, while k_2 denotes the stiffness of the bearing after slipping. F_{cr} means the horizontal sliding critical force of the bearing. The parameters comparison of the spherical bearing and the spherical aseismic bearing is shown in Table 1.

Table 1. Summary table of bearing parameters.

parameter	Spherical bearing	Double spherical aseismic bearing
F_{cr}	1.5e+05 (N)	3.0e+05 (N)
k_1	5.0e+06 (N/m)	1.0e+07 (N/m)
k_2	5.0e+01 (N/m)	1.7e+06 (N/m)

By comparing the parameters of the spherical bearing and double spherical aseismic bearing, it is found that the spherical aseismic bearing has a greater horizontal sliding critical force and pre-slip stiffness than the spherical bearing. The stiffness of the spherical bearing is almost zero after slipping, but the stiffness of the spherical aseismic bearing is still very large, which is about 0.17 times of the pre-slip stiffness.

2.3 *Establishment of Damage Index of Bearing*

To evaluate the vulnerability of bearings, the damage state of the structure must be determined and damage index should be quantified firstly. The research performed by Hwang, H, et al. (2001) has shown that the failure process of bridge structures can be described by 5 states, namely, undamaged, slight damage, Moderate damage, Extensive damage and complete destruction. There are many different criteria for determining the damage index of components. These criteria can be summarized as follows(Fan 1999): strength failure criterion, deformation failure criterion, energy failure criterion and deformation and energy double failure criterion. The damage degree of bearings is directly related to its deformation. In the general study, the deformation of bearings is used as an index to measure the damage degree. In this paper the maximum allowable displacement of 8160 spherical bearings and double spherical aseismic bearings at the longitudinal direction of the bridge is 30mm. The relationship between the damage degree and displacement of these two types of bearings is determined after referring to relevant data (Li 2012, Fan 2001), as is shown in Table 2. The displacement of 30mm, 45mm, 75mm and 150mm are taken as the demarcation points for slight damage, moderate damage, Extensive damage and complete destruction respectively.

Table 2. The relationship between the damage index and damage level of bearings for simply supported girder bridges.

Damage Level	Damage Index (mm)
Basically Undamaged	$D \leqslant 30$
Slight Damage	$30 < D \leqslant 45$
Moderate damage	$45 < D \leqslant 75$
Extensive damage	$75 < D \leqslant 150$
Complete Destruction	$D > 150$

3 STRUCTURE MODELING

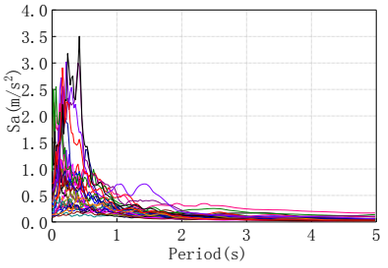
3.1 *Calculation model*

The finite element analysis model of three-span simply supported girder bridge is established by using OpenSees software, and the nonlinear time history analysis of the structure is carried out. As the main girder remains in the elastic state under the earthquake load and the actual seismic damage investigation also shows that the main girder will not be destroyed, the main girder is simulated with elastic three-dimensional beam element. As the pier is to withstand enormous earthquake force, it is usually allowed to be into plastic state in seismic code, so that a plastic hinge will appear in the expected location of piers to prevent the other components from being destroyed by utilizing the rotational energy dissipation of the plastic hinge. Therefore, the piers are modeled by elastic-plastic fiber beam elements. Pile-soil interaction is simulated by the equivalent spring element. The stiffness of the spring is calculated by the *m* method according to the Specification (Yang 2015). The bearing is simulated by the bilinear hysteresis model.

3.2 *Ground motion input*

Ground motion input is the basis for the structural seismic response analysis. The differences between the seismic excitations have great influence on the seismic response of structures. The uncertainty of ground motion leads to the uncertainty of the seismic response of bridge structure, so it is very important to select suitable earthquake wave records for structural vulnerability analysis. Generally, earthquake waves can be categorized into two types: measured earthquake wave and artificial earthquake wave. Based on an overall consideration of various factors, the measured earthquake waves are chosen as input.

At present, the measured Wenchuan earthquake waves are relatively comprehensive, and can really reflect the Chinese geological condition. According to the site type of the actual bridge, considering the strength and the integrity of earthquake wave records, 80 earthquake waves are selected as the original ground motion input for the nonlinear dynamic analysis of the bridge. The response spectra of the 80 earthquake waves and the average response spectrum are shown in Figure 4.



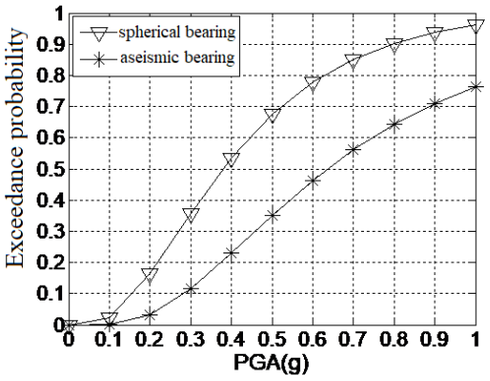


Figure 4. Acceleration response spectra of 80 ground motion records.

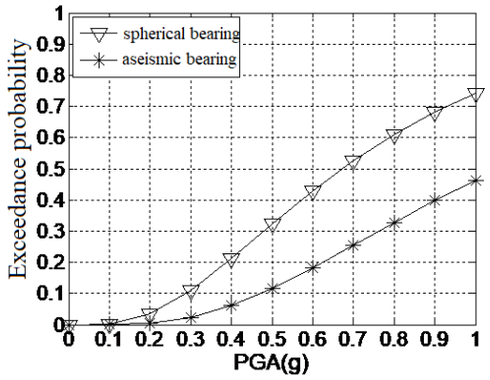
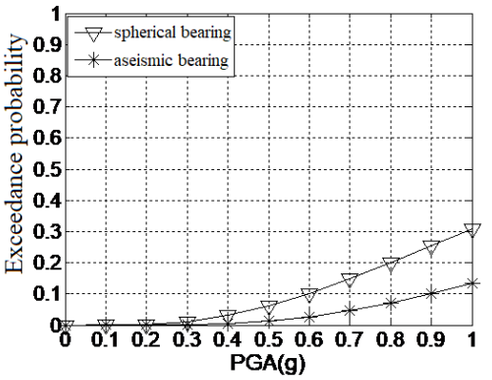
4 VULNERABILITY ANALYSIS OF BEARINGS



4.1 *Comparative analysis of vulnerability curves for two kinds of bearings*

In order to compare the seismic vulnerability of these two kinds of bearing components for 32m-span simply supported girder bridges with different pier height, the seismic vulnerability curves of the two kinds of bearings under different damage states are plotted in one graph, as shown in Figure 5 to Figure 9.



As can be seen from the above figures, (1) the seismic vulnerability of spherical bearing is larger than that of double spherical aseismic bearing under different damage states. (2) When the ground peak acceleration (PGA) is less than 0.1g, the vulnerability of the two kinds of bearings under Slight and Moderate damage states is very small. With the increase of seismic intensity (PGA), the seismic vulnerability of these two kinds of bearings increases and the deviation value of them also increases gradually. However, when the seismic intensity reaches a certain degree, the deviation value decreases gradually. (3) When the seismic intensity is 0.2g, the failure probability of the two kinds of bearings in the Extensive damage state begins to deviate. The failure probability of some simply supported girder bridge in the complete destruction state also begins to deviate, and the deviation value increases with the increase of seismic intensity index.

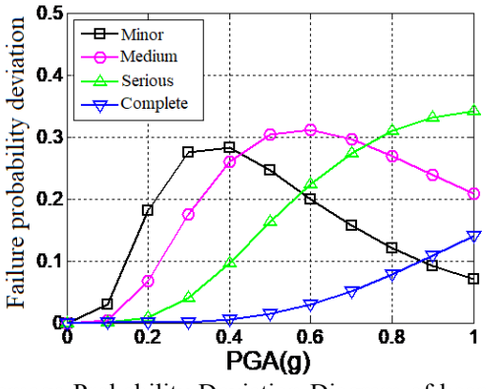
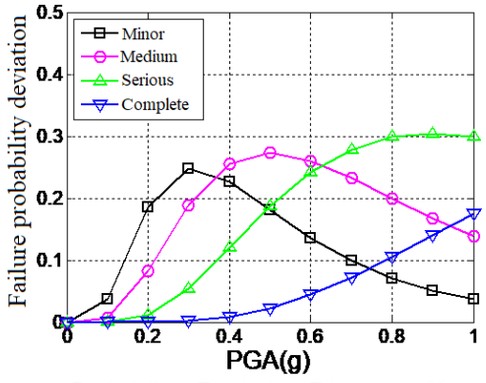
4.2 *Analysis of Seismic Damage Probability Deviation for Two Kinds of Bearings*



For further study on the failure probability deviation of these two kinds of bearings with different pier height, the trend that damage probability deviation changes with PGA for these two kinds of bearings is given, as is shown in Figure 10. In Figure 10, Slight, Moderate, Extensive, Complete stands for the Slight damage, Moderate damage, Extensive damage, complete destruction respectively.

As can be seen from Figure 10, (1) for all simply supported girder bridges with different pier height, the trend of failure probability deviations of the two kinds of bearings corresponding to Slight damage and Moderate damage state firstly increases and then decreases with the increase of PGA. (2) For simply supported girder bridges with different pier height, the damage probability deviation of bearings is inconsistent, and the range that the maximum deviation value occurs is also not the same. However, it can be seen that the damage probability deviation value decreases with the increase of the pier height, and the PGA corresponding to the maximum probability deviation value also gradually reduces. It indicates that with the pier height increasing, the effect of seismic mitigation and absorption of double spherical aseismic bearings is gradually decreasing. For example, under Slight damage condition, the maximum deviation value of damage probability of



bearing is about 30% and the corresponding PGA is about 0.5g for the simply supported girder bridge with 10 meters pier height, while for the simply supported girder bridge with 40 meters pier height, the maximum deviation value of damage probability of bearing is about 10% and the corresponding PGA is about 0.2g. (3) For the simply supported girder bridge with 10m~30m pier height, the damage probability deviation value of bearing components increases with the increase of PGA. When the seismic intensity is 1.0g, the damage probability deviation value of bearing for all simply supported girder bridge with different pier height reaches maximum. However, for the simply supported girder bridge with 40m~50m pier height, the maximum deviation value of bearing appears when the seismic intensity is 0.9g, and the maximum value is 4.99% and 1.12% respectively.

5 CONCLUSION

In this paper, the seismic vulnerability analysis of two kinds of typical bearings is carried out by taking the 32m-span simply supported girder railway bridge as the study object and the law of the failure probability of the two kinds of bearings with different pier height is discussed. Through comparison and analysis, the main conclusions are obtained as follows:

Under the action of earthquake, the failure probability of different bearings for railway aseismic bridge under different damage states is obviously different. Taking bearing deformation as the damage index, the theoretical vulnerability curves of two typical bearings are calculated, which provides reference data for the seismic design and reinforcement of the substructure of similar bridges.

When the pier height is small, the double spherical aseismic bearing has a good effect of seismic isolation, and it can effectively reduce the failure probability of the bearings in different damage states. But with the increase of pier height, the effect of seismic isolation gradually weakened. It indicates that for the simply supported girder bridge with high pier height, the spherical aseismic bearing doesn't work well in improving the seismic performance of the bearing components.

ABSTRACT: As from its construction, the Bosphorus Bridge underwent various retrofitting and repairment studies. The most critical one is the replacement of the inclined hanger ropes with vertical hanger ropes. The project is recently completed; however, the response of the bridge with vertical hanger is not estimated due to the lack of Structural Health Monitoring data. In this study, the effects of the vertical hanger arrangement on the bridge's response are aimed to be determined by making experimental data and numerical analyses. For this objective, finite element model of the bridge with inclined and vertical hangers are developed. Considering the modal analysis results, comparative study is conducted to identify the hanger replacement effects on the bridge. The outcomes reveal that the frequencies of the vertical deck modes of the bridge are changed as 10-25 % in terms of frequency. Thus, stiffness of the bridge in vertical direction is obtained to increase.

1 INTRODUCTION

Suspension bridges are special civil infrastructures among the transportation systems including long-span viaducts, tube tunnels, underwater systems etc. One of the distinguished side of the suspension bridges is the strengthening, maintenance, management and structural safety challenges mostly related to the post construction of them. Therefore, an efficient way to track the structural changes in these bridges is of crucial issue. In addition, the monitoring of these large-scale structures has certain challenges varying from the limited time to interruption in their operational functions during testing. The most effective solution to these difficulties is newly adopted approach of Structural Identification (St-Id), which contains Structural Health Monitoring (SHM) system to detect the changes/anomalies in the large-scale civil infrastructures (Catbas, Kijewski-Correa & Aktan 2013, Catbas, Susoy & Frangopol 2008). The general definition of SHM system made by Catbas, Kijewski-Correa & Aktan (2013) and Aktan, Catbas, Grimmelsman & Tsikos (2000) is to reliably make operational and performance prediction of large-scale infrastructure systems. Certain research and case studies in the literature were conducted on the long-span bridges by (Frangopol 2011, Frangopol, Saydam & Kim 2012, Fujino & Siringoringo 2011, Wang, Tao, Li & Zhang 2016, Wong & Ni 2009)

The Bosphorus Bridge shown in Figure 1 is firstly decided to permanently monitor after the critical hanger rope breakage event in 2004. Before this event, the bridge was identified many times; however, these aims were achieved with portable monitoring in the study of (Tezcan, İpek, Petrovski, Paskalov & Durgunoglu 1975, Petrovski, Paskalov, Stojkovichet & Jurokoviski 1974, Brownjohn, Dumanoglu, Severn & Blakeborough 989, Erdik & Uckan 1988).

Figure 1. The Bosphorus Bridge.

These studies were basically focused on the verification of the developed FE model of the bridge with the recorded experimental data on the basis of the dynamic response properties. With regard to the studies conducted through permanent SHM system of the bridge (Bas, Apaydin & Celep 2016a, 2016b, Bas, Apaydin, Ilki & Catbas 2017, Apaydin (2010), Apaydin, Bas & Catbas 2015, Erdik & Apaydın 2007and Kosar (2002). These studies are made on the bridge with the inclined hanger arrangement. After

the most comprehensive rehabilitation project for the Bosphorus Bridge recently finished in 2016, the effects of the hanger replacement form from inclined to vertical on the dynamic properties of the bridge are not investigated yet. In this study, this investigation is carried out by making a comparative study. For this aim, the FE model of the bridge having inclined hangers is updated through the SHM data obtained during the extreme wind event. Similar efforts are made for the bridge with the inclined hangers but, due to no SHM data in very limited time to obtain experimental data, only FE model of the bridge with vertical hanger is established considering all provisions given in the rehabilitation project. Then, the changes in the modal characteristics of the both model are compared to identify the effects of the hanger replacement on structural response of the bridge.

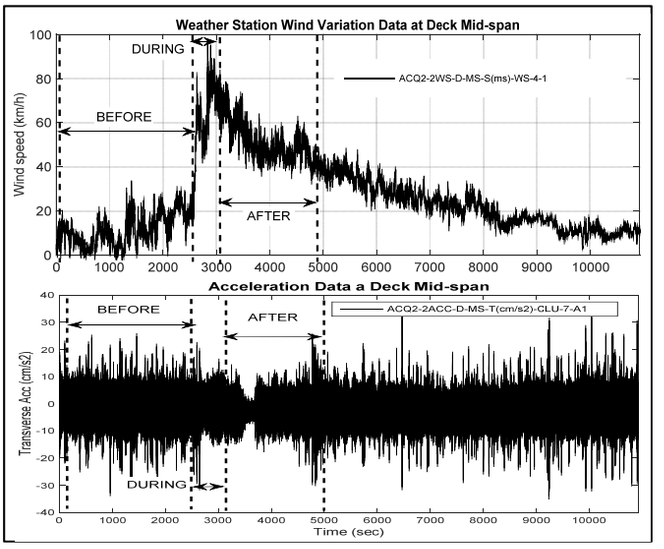

Figure 2. Wind speed variation and three time ranges: Before, During and After.

2 WIND VIBRATION CHARACTERISTICS OF THE BRIDGE USINH SHM DATA

2.1 *Extreme wind event*

Due to the location of Istanbul, strong winds is not usual for the bridges on the Bosphorus straits. However, the Bosphorus Bridge experienced a critical wind load in 2012, leading to larger displacement in transverse direction. During the event, wind speed reached from the average speed of 20 km/h to approximately 100 km/h within the short duration of 10 min. The variation of wind speed was recorded from the SHM system of the bridge. Figure 2 shows the sharp increase in wind speed obtained from weather station. According to site observations and bridge engineer's predictions, extreme wind load was forced the bridge to lateral direction. Data from the weather station sensors proved these statements. In Figure 3, wind speed was plot-ted against to wind directions in polar chart considering bridge's layout.

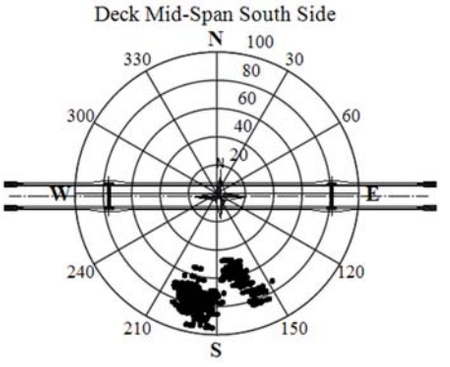

Figure 3. Wind speed-wind direction plot during the extreme wind event.

As shown in Figure 2, total wind duration is divided into three time ranges of Before, During and After. For model updating of the bridge, Before and After ranges are considered making utilizing structural identification (St-Id) approach. However, the bridge was in heavy traffic operation recording Before range data, which means to have higher noise content than After range. Thus, After range is regarded as ambient vibration data for modal characteristics identification of the bridge.

Developing bridge-based data analysis that includes filtering, averaging and windowing, the modal properties of the bridge are obtained utilizing fundamental FFT analysis as depicted in Figure 4. More details are also given in Table 1.

3 FE MODELS OF THE BRIDGE

In order to obtain more reliable outcomes, 3-D full-scale shell FE model of the Bosphorus Bridge with inclined hanger is established considering its as-built drawings given in (KGM 1973). General modeling considerations are given in Figure 5. All components of the bridge from towers, deck, portal beams and approach span are modeled with steel thin shell plate elements. The boundary conditions are considered as shown in Figure 5. Accordingly, 4121 points, 263 frame elements, 387 cable elements and 3996 shell elements are used for the Bosphorus Bridge with inclined and vertical hanger elements. The FE model of the bridge is demonstrated in Figure 6. Apart from the hanger replacement, the other retrofitting works including strengthening of the tower base section and damper placement on the expansion joints are also considered.

4 MODAL ANALYSIS AND MODEL UPDATING OF THE BRIDGE

The modal analysis of the FE model of the bridge with inclined hanger is first conducted and the results are given for the first five effective modes in Table 1. Besides, the first five modes and corresponding frequencies are depicted in Figure 7. Based on the percentage change in modal characteristics of the FE model of the bridge with inclined hanger, the FE model is resulted to be properly developed. Only difference in Mode-2 is seen to be high with percentage of 10 % in terms of modal period. These outcomes prove that the considerations for the established FE model are well determined and they are implemented reliably to the FE model of the bridge with vertical hanger.

5 EFFECTS OF THE HANGER REPLACEMENT ON THE DYNAMIC RESPONSE OF THE BRIDGE

Due to the lack of SHM data recorded from the bridge with vertical hanger in a very limited time as from the project completion date of 2016, the effects of the new hanger arrangement on the bridge response are identified with the developed FE model of the bridge with vertical hanger. For this aim, a comparative study is adopted and the results are given in Table 2. As expected, the frequencies and periods of the vertical modes of 1^{st} V_{asym}, 1^{st} V_{sym} and 2^{nd} V_{sym} are relatively changed. Based on modal frequencies, the bridge with vertical hanger has higher rigid vertical response than that with inclined hanger. In lateral modal vibration of the bridge, no variation is obtained. The reason for high rigidity in vertical direction is estimated to be direct connection of vertical hangers to the deck instead of vertical component of the inclined hanger. However, stress release is predicted in the deck of the bridge in longitudinal direction. Therefore, additional structural arrangement may be required. Besides, this study indicates that structural response of the bridge with vertical hanger will be changed under extreme events of earthquake, wind, traffic, marathon etc. due to the variation in the modal frequencies of the bridge. For instance, the frequency features of simulated earthquakes to be used for seismic analysis of the bridge should be adapted taking the new modal frequencies into account. Future work of the study is to verify these outcomes with SHM data and laboratory model of the bridge with vertical hanger.

6 CONCLUSION

In this study, the effects of vertical hanger arrangement on suspension bridges are obtained. For this aim, newly completed hanger replacement project for the Bosphorus Bridge is considered. The effects are specified with the comparative study on the modal properties of the bridge. First of all, wind vibration characteristics of the bridge with inclined hanger are determined dividing the SHM data into certain parts. These characteristics are then adopted for the modal validation of the 3-D full-scale FEM of the bridge. For this purpose, the FE models of the bridge with inclined and vertical hanger are established according to as-built project drawings. The FE model of the bridge with inclined hanger is updated with the SHM wind data; however, due to the lack of the SHM data for the bridge with inclined hanger, its FE model is not verified with experimental results. Therefore, the hanger replacement effects are investigated on the basis of the updated model with inclined and the model with vertical hanger. According to the comparative outcomes, the following points are obtained;

- As expected, the frequencies and periods of the vertical modes of 1^{st} Vasym, 1st Vsym and 2nd Vsym are relatively changed.
- On the basis of modal frequencies, the bridge with vertical hanger has higher rigid vertical response than that with inclined hanger.
- In lateral modal vibration of the bridge, no variation is obtained.
- The reason for high rigidity in vertical direction is estimated to be direct connection of vertical hangers to the deck instead of vertical component of the inclined hanger.
- Stress release is predicted in the deck of the bridge in longitudinal direction. Therefore, additional structural arrangement may be required.
- Structural response of the bridge with vertical hanger will be predicted to change under extreme events of earthquake, wind, traffic, marathon etc. due to the variation in the modal frequencies of the bridge.

Investigation of limit temperature span of continuous bridges considering track-bridge interaction

Y.H. Yan, D.J. Wu & Q. Li
Tongji University, Shanghai, China

ABSTRACT: This paper aims to study the limit span of continuous railway bridges without the setting of the rail expansion devices for continuous welded rail (CWR) on the bridges. The track-bridge interaction models are established for both three-span continuous bridges and continuous rigid frame bridges with different main spans. The additional stress of CWR on bridges and the relative displacement between the bridge and the rail are calculated under the effects of both train braking and temperature variation. The results show that the rail additional stress increases linearly with the increase of the temperature span. It is necessary to set up the rail expansion devices on three-span continuous bridges when the temperature span exceeds 220 m. The continuous rigid frame bridge can notably reduce the rail additional stress and thus a larger limit temperature span can be gained.

1 INTRODUCTION

For the continuous welded rail (CWR) on prestressed concrete railway bridges, the setting of the rail expansion devices can effectively reduce the interaction between the bridge and the rail, thus ensure the safety, stability and normal use of the track structure. The setting of rail expansion devices has its disadvantages at the same time, such as affecting the driving comfort, increasing the workload of maintenance and the construction cost (Esveld et al. 1995, Esveld 2001). Therefore, to determine the bridge span that it is necessary to set up the rail expansion joint has become a difficult problem for the design of the CWR on bridges.

The increase of span generally leads to the increasing of rail additional stresses and relative displacements between the bridge and the rail under the train braking and temperature variation (Railways, I. U. O. 2001). Many scholars have established the track-bridge interaction model of different structures by using finite element method, and the limit span of railway bridges to set up the rail expansion devices has been studied (W.S. Liu et al. 2013, Q.S. Wu et al. 2016). However, no unified conclusion has been reached so far.

To solve this problem, finite element models are established for track-bridge interaction analysis of both three-span continuous bridges and continuous rigid frame bridges with different span arrangement. Calculations are made on the additional stress of the CWR on bridges and the relative displacement between the bridge and the rail under both train braking and temperature variation. Finally investigation is conducted for the maximum temperature span of both continuous bridges and continuous rigid frame bridges without setting up the rail expansion devices.

2 COMPUTATIONAL MODELS

2.1 *Track-bridge interaction model*

Based on an actual railway bridge project, the track-bridge interaction models of three-span continuous bridges with span arrangements of 48m+64m+48m, 60m+100m+60m, 70m+125m+70m, 100m+160m+100m respectively are established. The main girder sections are box girders with single chest and room, which varies in height along the longitudinal direction. Fig. 1 presents the overall arrangement of continuous bridges, and the parameters of the concrete girders with different spans are listed in Table 1.

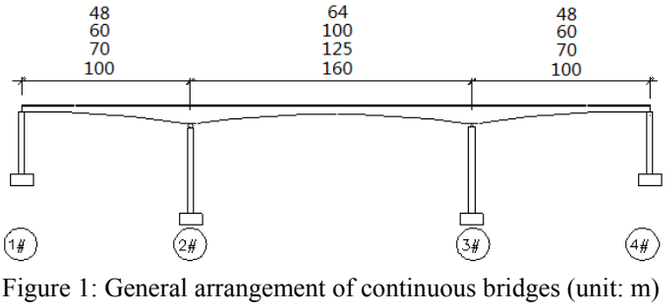

Figure 1: General arrangement of continuous bridges (unit: m)

Fig. 2 illustrates the finite element model for track-bridge interaction analysis. Beam elements were used to simulate the main girder, the rail and the rigid arms, linear spring elements were used to simulate the vertical, lateral and torsional rigidity of fasteners, and nonlinear spring elements were used to simulate the longitudinal resistance of the track. It is assumed that there is no rail expansion devices on the bridges.

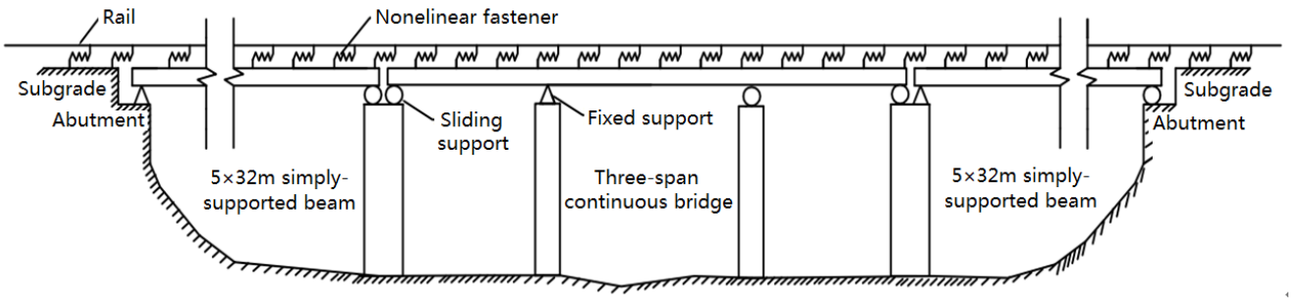

Figure 2: Track-bridge interaction model

Table 1: Parameters of concrete girder

Span arrangement (m)	Middle-span section		Support section	
	Area (m^2)	Height (m)	Area (m^2)	Height (m)
48-64-48	9.25	2.7	13.34	5.6
60-100-60	15.11	4.8	27.30	7.8
70-125-70	34.62	5.2	73.77	9.2
100-160-100	50.53	6.3	90.66	12.8

In order to take the adjacent structures into consideration, the simply supported beam and the subgrade on both sides of the continuous bridge are also modeled. Previous studies have shown that with the increase of span numbers, the maximum rail additional stress on the simply supported beam has largely converged when the span number reaches 5 (C.X. Yin 2000). And the length of the rail on the subgrade is set to 100m as recommended in the UIC code (Railways I. U. O. 2001). Therefore, the finite element model is considered as "100m subgrade + 5 ×32m simply supported beam + three-span continuous bridge+ 5×32m simply supported beam + 100m subgrade".

It is assumed that the horizontal force at the sliding bearing of simply supported beam is zero, and the horizontal force is borne only by the fixed bearing. The subgrade is assumed to be rigid and fixed. The longitudinal displacement at both ends of the rail is restrained to simulate the rail fastening-down zone. The longitudinal and vertical stiffness at the top of the pier is considered by linear springs at the corresponding positions. The model boundary conditions are shown in Fig. 3.

The type CHN60 rails and the type V fasteners are adopted in the design of CWR. The longitudinal resistance property of the track is determined according to China's "Code for design of railway continuous welded rail" (PRC, Ministry of Railways 2013), which considers two cases of both loaded and unloaded, as shown in Fig. 3.

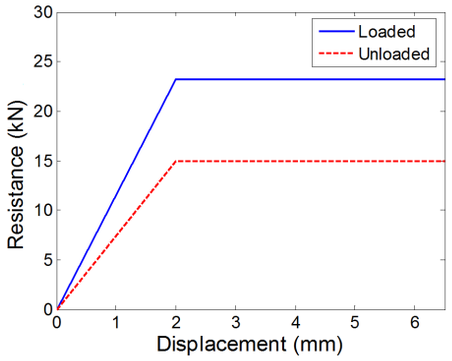

Figure 3: Longitudinal resistance relation curve

2.2 *Loads*

The analysis of the track-bridge interaction in railway bridges mainly includes the additional stress of CWR caused by train braking, temperature variation, deflection, etc (PRC, Ministry of Railways 2013). Among them, the additional stress of CWR caused by deflection are relatively small, so only train braking and temperature variation are considered in this paper.

2.2.1 *Train braking*

Scholars have done a lot of theoretical and experimental research on train braking (L. Lu et al. 2014). During the process of train braking, sliding and rolling frictions between the wheel and the rail are the main causes of braking force, which can be expressed as:

$$P_f = \mu mg \tag{1}$$

where P_f = train braking force, μ = wheel-rail friction coefficient, m = mass of the train.

The interaction between the rail and the bridge caused by train braking should be studied by dynamic methods, while many scholars have studied it by simply using static methods. It is found that the difference between the dynamic methods and the static methods is usually insignificant (Q.Y. Xu 2005). Therefore, the static methods are adopted in this paper.

The Chinese railway standard live loading are adopted in the calculation for vertical load of the trains (Fig. 4). The three-span continuous beam is fully loaded to simulate the train braking force. The wheel-rail adhesion coefficient is set to be 0.164.

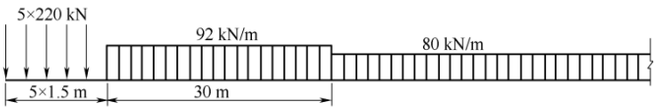

Figure 4: Computing graphs of China railway standard live loading

2.2.2 *Temperature variation*

According to China's "Code for design of railway continuous welded rail" (PRC, Ministry of Railways 2013) as shown in Table 2, the temperature difference between the concrete girder and the rail is set to 15℃ in this paper's calculation.

Table 2: Temperature difference of the beam

Beam type	Daily temperature difference of the ballasted track girders(℃)	Annual temperature difference of the ballastless track girders(℃)
Concrete girder	15℃	30℃
Steel girder	25℃	-

3 CALCULATION RESULTS

3.1 *Train braking*

Fig. 5 shows the distribution of the rail additional stress under different span arrangements. Table 3 lists the calculation results of the rail additional stress and the relative displacement between the bridge and the rail under train braking.

Table 3: The rail additional stress and the relative displacement between the bridge and the rail under train braking

Span arrangement of continuous bridges	Additional tensile stress (MPa)	Additional compressive stress (MPa)	Relative displacement between the bridge and the rail (mm)
48m-64m-48m	23.60	-20.88	2.43
60m-100m-60m	30.53	-27.61	3.41
70m-125m-70m	35.44	-33.65	4.26
100m-160m-100m	45.19	-41.36	6.21

As shown in Fig. 5, the rail additional tensile stress peaks at the left end of the three-span continuous bridge, while the rail additional compressive stress peaks at the right end of the continuous bridges with different span arrangements.

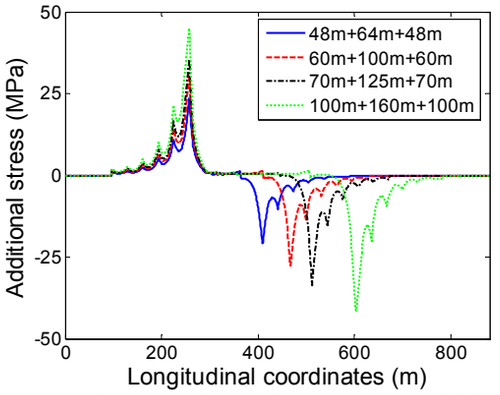

Figure 5: Distribution of the rail longitudinal additional stress under train braking

It can be noted from Fig. 5 that the distribution law of the rail additional stress under train braking with different span arrangements is basically the same. The additional stress at both ends of the three-span continuous bridge is larger compared with that in the middle section. The rail additional stress increases linearly with the increase of the span of the continuous bridge. When the length of the three-span continuous bridge is increased from 160m to 360m, the maximum value of the rail additional tensile stress under braking increases from 23.60MPa to 45.19MPa. And the relative displacement between the bridge and the rail increases from 2.43mm to 6.21mm.

3.2 *Temperature variation*

Fig. 6 presents the distribution of the rail longitudinal additional stress under different span arrangements when the temperature variation of the concrete girder is 15℃, and Table 4 lists the calculation results of the rail additional stress and the relative displacement between the bridge and the rail under temperature variation.

Similarly, the rail additional tensile stress peaks at the left end of the three-span continuous bridge, while the rail additional compressive stress peaks at the right end of the continuous bridges with different span arrangements.

Table 4. The rail stress and the relative displacement between the bridge and the rail under temperature variation

Span arrangement of continuous bridges	Additional tensile stress (MPa)	Additional compressive stress (MPa)	Relative displacement between the bridge and the rail (mm)
48m-64m-48m	30.20	-44.50	4.81
60m-100m-60m	30.54	-60.40	6.37
70m-125m-70m	30.61	-72.36	7.63
100m-160m-100m	30.78	-90.36	10.38

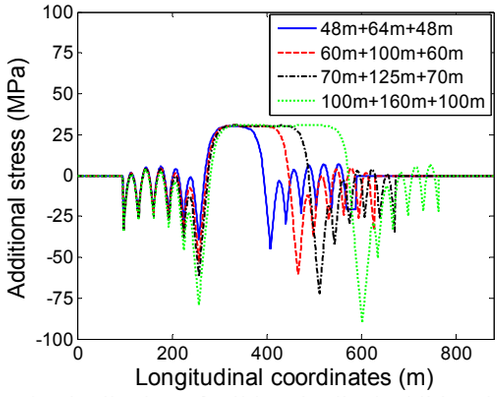

Figure 6: Distribution of rail longitudinal additional stress under temperature variation

It can be noted from Fig. 6 that for difference span arrangements, the distribution law of the rail additional stress under temperature variation is basically the same. Temperature variation induces the rail additional tensile stress on the continuous bridge, while induces the rail additional compressive stress on the adjacent simply supported beam. The rail additional compressive stress is larger at both ends of the simply supported beam, and is the largest at the end of the continuous bridge.

The rail additional compressive stress under temperature variation increases linearly with the increase of the span of the continuous bridge, while the increase of the rail additional tensile stress is not obvious. When the length of the three-span continuous bridge is increased from 160m to 360m, the maximum value of the rail additional compressive stress under temperature variation increases from 44.50MPa to 90.36MPa And the relative displacement between the bridge and the rail increases from 4.81mm to 10.38mm.

3.3 *Superposition of the effects of train braking and temperature variation*

It can be found from both Fig.5 and Fig. 6 that the rail additional stress peaks at the right end of the continuous bridge under both the train braking and the temperature variation, so the maximum rail additional stress can be obtained through the direct superposition of the train braking and the temperature variation.

It is found that the maximum value of the rail additional stress under both train braking and temperature variation is approximately linear with the temperature span of the continuous bridge (L.H. Cui et al. 2012). The temperature span refers to the distance between the fixed support and the most remote sliding support of continuous bridges. Fig. 7 illustrates the relationship curve between the rail additional stress and the temperature span.

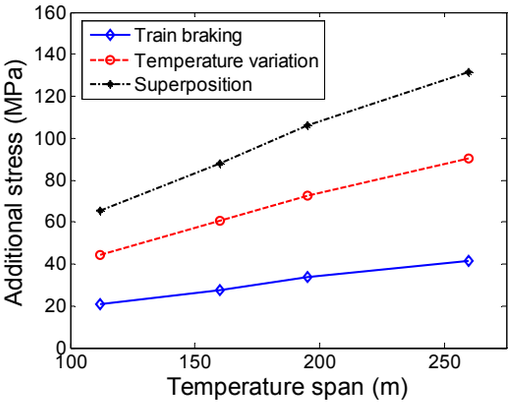

Figure 7: The change law of rail additional stress with temperature span of continuous bridges

It is found from Fig. 7 that the rail additional stress under both train braking and temperature variation increases linearly with the increase of temperature span of the continuous bridge.

According to China's "Code for design of railway continuous welded rail" (PRC, Ministry of Railways 2013), the rail stress should meet the following formula in the design of CWR:

$$\sigma_d + \sigma_t + \sigma_f + \sigma_z \le [\sigma] = \frac{\sigma_S}{k} \quad (2)$$

where σ_d = dynamic bending stress at the bottom of the rail, σ_t = maximum rail temperature stress, σ_f = larger value of the rail additional stress under both temperature variation and bending of the bridge, σ_z = rail additional stress under train braking, $[\sigma]$ = rail permissible stress.

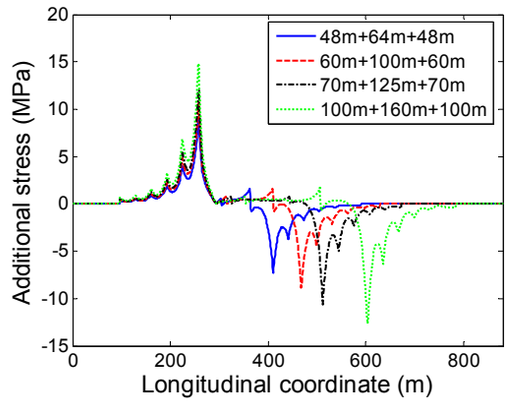
The permissible stress of the ordinary rail is 351MPa, and the dynamic bending stress at the bottom of the rail is set to 150MPa. The temperature stress is approximately 85MPa (PRC, Ministry of Railways 2013) which is calculated from the rail temperature difference, so the residual permissible additional stress value is 351-150-85=116 MPa. In

the fitting formula of the rail stress obtained above, let:

$$y = 0.4501x + 15.981 = 116 \quad (3)$$

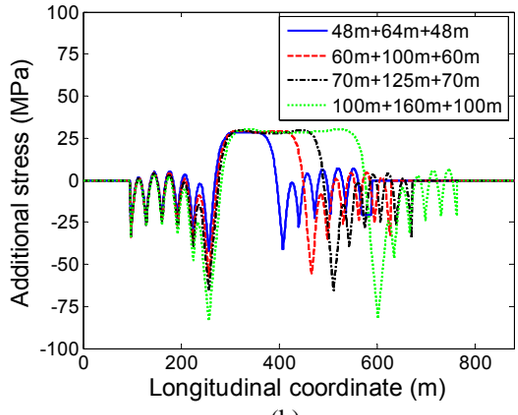
where x = temperature span of three-span continuous bridges (unit: m), y = rail additional stress (unit: MPa).

It can be solved that the value of x is 222.2, which means that it is necessary to set up the rail expansion devices on three-span continuous bridges when the temperature span exceeds 220 m. In general, the ratio of the side span to the middle span of the three-span continuous bridge is 0.4~0.6, so the limit range of the total length of the three-span continuous bridge is 310m~350m.



4 LIMIT SPAN OF THE CONTINUOUS RIGID FRAME BRIDGE

Due to its advantages of reasonable structure, convenient construction and smooth driving compared with the continuous bridge, the continuous rigid frame bridge has become one of the common bridge types of long-span bridges. For railway bridges, due to the large rigidity of continuous rigid frame bridges, the substructure will be allocated to greater stress in the track-bridge interaction. Therefore, the rail additional stress under load can be reduced, and thus the limit span of the beam bridge can be improved.



On the basis of finite element model of the three-span continuous bridges with different spans, the track-bridge interaction finite element model of three-span continuous rigid frame bridges is then established by changing the bearing constraint condition, in order to investigate the limit temperature span of continuous rigid frame bridges.

4.1 *Train braking and temperature variation*

The determination of train braking load and temperature variation is consistent with that of the above continuous bridges. Fig. 8 presents the distribution of the rail additional stress under both train braking and temperature variation independently.

(a)

(b)

Figure 8: Distribution of rail longitudinal additional stress under: (a) train braking; (b)temperature variation

It can be found from Fig. 8 that the distribution law of the rail additional stress on the continuous rigid frame bridge is consistent with that on the continuous bridge. The rail stress on the continuous rigid frame bridge is significantly reduced compared with that on the continuous bridge. The comparison of calculation results of these two different forms of bridge structure under both train braking and temperature variation is shown in Table 5.

It can be seen from Table 5 that there is little difference between the calculation results of these two different forms of bridge structure under temperature variation. However, the rail additional stress and the relative displacement between the bridge and the rail on the continuous rigid frame bridge are significantly reduced under train braking.

4.2 *Linear fitting results*

Similarly, the rail additional stress peaks at the right end of the continuous rigid frame bridge under both the train braking and the temperature variation, so the maximum rail additional stress can be obtained through the direct superposition. For the continuous rigid frame bridge, the rail additional stress is proportional to the length of the bridge, and the fitting curve is shown in Fig. 9.

Table 5: Comparison of calculation results between continuous bridges (CB) and continuous rigid frame bridges (CRFB)

Span arrangement	Train braking				Temperature variation			
	Additional compressive stress (MPa)		Relative displacement between the bridge and the rail (mm)		Additional compressive stress (MPa)		Relative displacement between the bridge and the rail (mm)	
	CB	CRFB	CB	CRFB	CB	CRFB	CB	CRFB
48-64-48	-20.88	-7.35	2.43	0.86	-44.50	-42.21	4.81	4.03
60-100-60	-27.61	-8.90	3.41	1.05	-60.40	-56.79	6.37	5.27
70-125-70	-33.65	-10.68	4.26	1.19	-72.36	-65.40	7.63	6.34
100-160-100	-41.36	-12.64	6.21	1.49	-90.36	-83.78	10.38	8.39

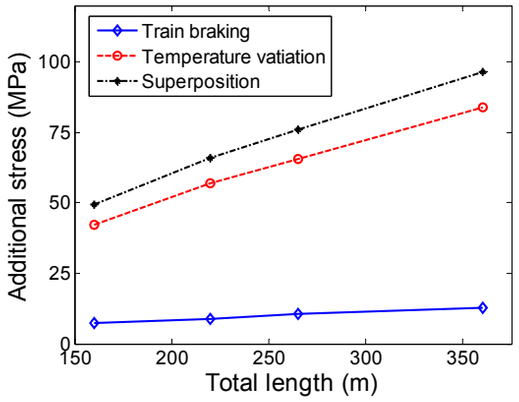


Figure 9: The change law of rail additional stress with bridge length of continuous rigid frame bridges

In the fitting formula of the rail stress obtained above, let:

$$y = 0.2322x + 13.633 = 116 \quad (4)$$

where x = total length of three-span continuous rigid frame bridges (unit: m), y = rail additional stress (unit: MPa).

It can be solved that the value of x is 440.9, which means that it is necessary to set up the rail expansion devices on three-span continuous rigid frame bridges when the total length exceeds 440 m.

It can be seen that the continuous rigid frame bridge can effectively reduce the rail additional stress, especially the rail additional stress under train braking. Based on track-bridge interaction, the limit length of the continuous rigid frame bridge can be raised from 310m~350m for the continuous bridge to 440m.

5 CONCLUSION

The track-bridge interaction of railway continuous bridges and continuous rigid frame bridges with different span arrangement is analyzed in this paper. The major conclusions can be drawn as follows:

(1) The rail additional stress at both ends of the three-span continuous bridge is larger compared with that in the middle section under train braking. The rail additional compressive stress reaches the peak values at the end of the continuous bridge under temperature variation.

(2) The rail additional stress and the relative displacement between the bridge and the rail increase linearly with the increase of the temperature span of continuous bridges.

(3) It is necessary to set up the rail expansion devices on three-span continuous bridges when the temperature span exceeds 220 m. The limit range of the total length of the three-span continuous bridge is 310m~350m.

(4) The continuous rigid frame bridge can effectively reduce the rail additional stress. The limit length of the continuous rigid frame bridge can reach 440m.

Code development for existing structures: influence of concrete strength statistics

B.L. Badimuena & S.M.C. Diniz
Federal University of Minas Gerais, Belo Horizonte, Brazil

ABSTRACT: Strengthening/ retrofitting of structures and infrastructures is a challenging and extremely relevant topic. One of the key tasks in the decision process over strengthening/ retrofitting or demolishing an existing infrastructure is its condition assessment and checking against expected performance rules, usually established in technical codes. However, the problem of performance evaluation of existing reinforced concrete structures is quite distinct from design of new ones. A question arises on the statistics of the concrete compressive strength to be used in the calibration of semi-probabilistic codes for existing structures. In this paper, Monte Carlo simulation is used in the determination of the probabilities of failure (and corresponding reliability indexes) associated to axially-loaded columns. Different scenarios are considered for the compound coefficient of variation, i.e. the one including statistical errors, size effects for the extracted cores, etc. The resulting safety levels for existing axially-loaded reinforced columns, assessed via ACI 562 Repair Code, are obtained and discussed.

1 INTRODUCTION

At present, strengthening/ retrofitting of structures and infrastructures is a challenging and extremely relevant topic. For instance, according to the 2013 ASCE Report Card for America's Infrastructure (ASCE 2013), one in nine of the US bridges are rated as structurally deficient, while the average age of the 607,380 bridges is close to 50 years. The Federal Highway Administration (FHWA) estimates that an annual investment of $20.5 billion is needed to eliminate the US bridge deficient backlog by 2028.

One of the key tasks in the decision process over strengthening/ retrofitting or demolishing an existing infrastructure is its condition assessment and checking against expected performance rules, usually established in technical codes. However, the problem of performance evaluation of existing structures is quite distinct from design of new ones. Design codes for new structures deal with uncertainties related to design and construction process; on the other hand, there is a change in the nature of such uncertainties, --from inherent to epistemic--, for a number of the variables affecting the existing structure performance.

In the case of reinforced concrete (RC) structures, concrete compressive strength is predicted from cylinder tests for a population of new structures, while in the case of an existing structure it is predicted from extracted cores of the actual structure. As such, a question arises on the statistics of the concrete compressive strength to be used in the calibration of semi-probabilistic codes related to existing structures.

In this paper, Monte Carlo simulation is used in the determination of the probabilities of failure (and corresponding reliability indexes) associated to axially-loaded RC columns. Different scenarios are considered for the compound coefficient of variation, i.e. the one including statistical errors, size effects for the extracted cores, etc. The resulting safety levels for existing axially-loaded RC columns, assessed via ACI 562 Repair Code (ACI 562 2013), are obtained and discussed.

2 EXISTING STRUCTURES VERSUS NEW STRUCTURES

The safety evaluation of existing structures is distinct from that related to the safety implementation in the design of new ones. While design codes for new structures allow for uncertainties in the design and construction processes, much of what was initially uncertain are no longer in the finished structure (Melchers 1999).

Nevertheless, even if existing structures undergo multiple investigations, some uncertainties in the main variables related to the structural performance will continue to exist. The determination of the actual values of various parameters (e.g. in situ concrete

compressive strengths, concrete modulus of elasticity, etc.) in the existing structure introduces uncertainty of its own. As such, similarly to the design of new structures, the current variability of the basic variables describing actions, properties of materials, geometry, and model errors related to existing structures must be taken into account. In this sense, realistic structural performance assessments can be established in probabilistic terms only.

A question of utmost importance is the definition of criteria for the assessment of the structural condition of a given structure. The following differences between the evaluation of new and existing structures must be taken into account in the assessment of structural performance (Diamantidis et al. 2012):

- Economic aspects – the additional costs necessary to increase the reliability of new structures are usually insignificant compared to those incurred for similar measures for existing structures;
- Social aspects - restrictions and relocations of users and the impact of loss of cultural values or inheritance do not influence the design of new structures;
- Principles of sustainable development - the reduction of waste and the recycling of materials are aspects that are much more significant in the case of the evaluation of existing structures.

In recognition to these differences between the assessment of structural performance of new and existing structures, new documents have been developed specifically for existing structures, while others are being revised in such a way to best address the problem of existing structures. For instance, while Chapter 27 in ACI 318 (ACI 318 2014) is dedicated to *Strength Evaluation of Existing Structures*, the ACI 562 Repair Code has been launched in 2013 specifically for existing RC structures. The 2020 fib-Model Code, an update of the current 2010 fib-Model Code (Féderation Internationale du Béton 2010) has been planned to be a single, merged structural code for new and existing structures.

3 EQUIVALENT CONCRETE COMPRESSIVE STRENGTH

Concrete compressive strength is an important variable in the design of RC structures. Based on semi-probabilistic design formats, current codes for design of RC structures deal with deterministic values in the design process in lieu of their random counterparts (Diniz 2008). In this way, the random variable "concrete compressive strength" is replaced by the "specified (or characteristic) concrete compressive strength", f'_c, in the limit states design of new structures.

The "specified concrete compressive strength", f'_c, is a well-established concept in the design of new structures and is based on a prescribed quantile in the corresponding probability density function (PDF) describing the random variable.

Considering that for the design of new structures the "specified concrete compressive strength" has fulfilled its function, the professionals are faced with the difficulty of defining an equivalent value for use in the equations of structural safety checks for the evaluation of existing RC structures. In defining an equivalent value, account shall be taken of the particularities of estimating the *in situ* concrete compressive strength. By introducing an "equivalent specified concrete compressive strength", the evaluation process resembles that of designing new structures to which the professionals are more accustomed, thus reducing the likelihood of errors related to the different verifications.

Although not an internationally agreed procedure, the "equivalent specified concrete compressive strength" has been adopted in a number of codes related to the evaluation of existing structures, e.g. ACI 562 (ACI 2013) and CAN/CSA S6-06 (CSA 2006). In the definition of the equivalent strength two issues must be dealt with: (i) the adjustment of strength results measured by cores; and (ii) the selection of appropriate quantiles to be used in the calibration of design codes for assessment of existing structures.

According to ACI 562 (ACI 2013), individual results are adjusted in such a way to take into account the most relevant influencing factors:

$$f_c = F_{l/d}\ F_{dia}\ F_{mc}\ F_d\ f_{core} \tag{1}$$

where $F_{l/d}$, F_{dia}, F_{mc}, F_d and f_{core} are the adjustment factors considering, the influence of the ratio height/diameter of the core, diameter, humidity and damage to the cores in the extraction procedure, and core strength, respectively. These coefficients are given in Table 9.1 of ACI 562. Statistical errors shall also be taken into account in the evaluation of the statistics of core strengths, considering the usual small numbers of cores extracted from the structure under investigation.

The criterion adopted by ACI 318 (ACI 2014) to define the specified concrete compressive strength, f'_c, considers that it corresponds to the tenth lower percentile of the compressive strength of the concrete obtained from cylinders tested at 28 days. In other words, the criterion adopted by ACI 318 stipulates that 1 in 10 test specimens will have a strength value lower than the specified strength.

According to ACI 214.4R (ACI 2010), several methods for converting in-place strength obtained from non-destructive tests to an equivalent value are based on a 10% quantile in the characterization of the *in situ* strength. However, a study by Bartlett & MacGregor (1996) has shown that in the finished structure, the specified strength represents approximately the 13% quantile for the *in situ* strength in the

case of walls and columns and approximately 23% for beams and slabs. The same study concluded that the value of the quantile associated with columns is more appropriate in the definition of an equivalent specified strength since column resistance is more sensitive to concrete compressive strength than beam or slab resistance. Therefore, any procedure that defines the specified strength for existing structures based on the 13% quantile of the *in situ* strength is more appropriate, while those assuming a 10% quantile is more conservative (ACI 214.4R 2010).

The procedure devised by Bartlett & MacGregor (1996) to specify the equivalent specified concrete compressive strength for existing structures considered the 13% quantile. Based on that procedure, ACI 562 (ACI 2013) and CAN/CSA S6-06 (CSA 2006) suggest Eq. 2 for the equivalent concrete compressive strength to be used in verification purposes of existing structures:

$$f'_{ceq} = 0.9 f_{cm} \left[1 - 1.28 \sqrt{\frac{(k_c V)^2}{n} + 0.0015} \right] \quad (2)$$

where f_{cm} is the mean resistance of cores, adjusted for size effects and humidity, V is the coefficient of variation of the cores strength, n is the number of extracted cores used in the estimation of the mean strength f_{cm} and k_c is a modification factor for the coefficient of variation of the cores strength, depending on the number of cores, given in Table 1.

4 RELIABILITY-BASES FOR RC EXISTING STRUCTURES

Among RC structural components, columns subjected to loads with small eccentricities are the most affected by concrete compressive strengths lower than those foreseen in the design process, or concrete variability superior to the reference value used in the calibration of the corresponding design code.

In addition, for the structural integrity of the structure, columns are those components whose local failure can lead to the overall failure of the structure. In this way, considering the importance of the concrete compressive strength in the column resistance and the importance of columns for structural integrity, the impact of actual concrete compressive strength on the reliability of existing RC columns shall be evaluated.

For the reliability assessment, --in addition to theoretical considerations related to the behavior of materials--, the relevant code recommendations are equally important and should be taken into account in the analysis. Relevant code recommendations considered in this work are those related to the behavior of the materials (concrete and steel), the determination of the load effects, and the procedure for estimation of the existing RC column resistance. To this end, ACI 562 (ACI 2013) and ACI 318 (ACI 2014) recommendations for axially-loaded RC columns are assumed herein.

4.1 *Performance function*

Considering the pertinent variables related to the problem at hand, the corresponding performance function used in the Monte Carlo Simulation (Ang & Tang 1990) procedure is given by:

$$M = \left[\alpha_c F_c \left(A_g - A_s \right) + F_y A_S \right] E_M - (G + Q) \quad (3)$$

where M is the safety margin, and the random variables F_c is concrete compressive strength, A_g is the area of the gross cross-section, F_y is the steel yield strength, G and Q are the dead and live loads acting on the column, respectively, and E_M represents the model error associated to column resistance estimation. The area of longitudinal steel, A_s, is taken as deterministic; the deterministic parameter α_c is taken as a function of the concrete grade. Further details are found in Badimuena (2016).

4.2 *Statistics of the load effects*

Figure 1 illustrates the procedure used in definition of the statistics of the load effects (mean dead load, μ_G, and mean live load, μ_Q), for the selected columns satisfying ACI 562 (ACI 2013) provisions.

In the computation of the design loads, S_d, from which the statistics of the acting loads may be defined, it is assumed that, design loads are equal to design column resistance, R_d, i.e. $S_d = R_d$ (Diniz & Frangopol 1997). Details about the structural configuration are given in the next section. For each assumed value of the mean concrete compressive strength, f_{cm}, the equivalent specified compressive strength is determined according to Eq. 2. In this study, two different values for the number of cores are assumed (three and eight); the corresponding k_c values are taken from Table 1.

In addition to the above information needed for the determination of the equivalent specified concrete compressive strength (n and k_c), Eq. 2 also calls for the coefficient of variation of cores strength. Therefore, two different values of the coefficient of variation, 5% and 10%, referred to herein as V_{master}, are considered (see Fig. 1). It is noted that the coefficient of variation associated to concrete compressive strength used in the calibration of ACI 318 for the design of new structures is 10% (Szerszen & Nowak 2003).

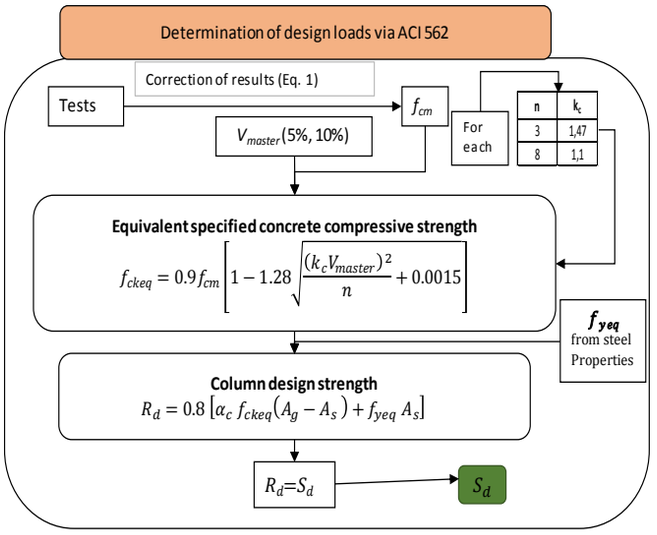

Figure 1 – Determination of design loads S_d according to ACI 562 (2013).

For a given RC column, based on the information presented in Galambos et al. (1982) for the dead load, G, and the live load, Q, and the corresponding design loads, S_d (as previously described), the complete statistics of these variables are defined. In this process, the ratio r between the mean dead load and mean live load is needed (see Fig. 2). In this study, the following values are assumed for this ratio: 0.5, 0.75, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, and 4.0.

4.3 *Statistics of material strengths*

Regarding the statistics of the random variable concrete compressive strength, F_c, for each value of the assumed mean strength, six different values of the corresponding coefficient of variation are considered. These values range from 5% to 17.5%; they have been selected in order to represent different scenarios for the variability of concrete strength in existing RC columns. The procedure for the generation of the PDF curves for the random variable concrete compressive strength, F_c, is summarized in Figure 3. For the random variable steel yield strength, F_y, PDF curves were generated according to ACI 562 recommendations and the statistics (bias factor and coefficient of variation) given in Galambos et al. (1982), as shown in Figure 4.

Each assumed value of the coefficient of variation of the cores strength, V, creates a resistance scenario for the analyzed column resulting in different PDF curve for the column resistance. The interaction between column resistance and corresponding load effects defines the reliability associated to each assumed scenario. As can be seen from Figure 5, the greater dispersion of the resistance curve the greater the probability of failure of the column.

5 DETAILS OF THE SELECTED COLUMNS

The selected columns correspond to two different cross-sections (rectangular, S1, and square, S2, see Fig. 6), four concrete compressive strengths (f_{cm} = 20, 30, 50 and 70 MPa), four longitudinal steel ratios (ρ_l = 1%, 2%, 3% and 4%). The characteristic steel yield strength is taken as 500 MPa for all columns. Details of the selected columns are presented in Table 2.

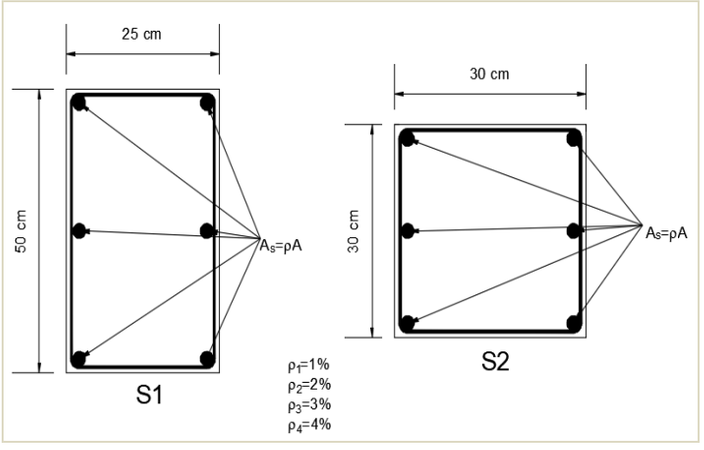

Figure 6 – Details of the columns cross-sections.

These columns were grouped in eight series (P1, P2, P3, P4, P5, P6, P7 and P8), each series representing a given cross-section and concrete compressive strength. For instance, series P4 correspond to S2 cross-section (square cross-section) and mean concrete compressive strength equal to 30 MPa. Each series contain four columns representing the four assumed longitudinal steel ratios. Additionally, for each combination of cross-section geometry, f_{cm}, and ρ_l (32 combinations), 9 load ratios are assumed (r = 0.5, 0.75, 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, and 4.0). In total, 288 short axially-loaded columns have been selected for analysis.

Table 2. Details of the selected columns.

Column	Cross section	f_{cm} (MPa)	f_{yk} (MPa)	ρ_l	A_s (cm²)
P1	S1	20	500	1%	12.5
				2%	25
				3%	37.5

				4%	36

6 RELIABILITY RESULTS

The reliability assessment was performed for the selected columns. As described in Section 4, it is assumed that the loads acting on the column follow ACI 562 (ACI 2013) recommendations. Eq. 2 used in the estimation of f'_{ceq} requires the coefficient of variation of the cores strength, V. As such, the information regarding the coefficient of variation used in the code calibration is needed. As presented in Section 4, two different values of V (V_1 = 5% and V_2 = 10%, referred to herein as V_{master}) are assumed. For each column, the assumed number of cores is taken

as 3 and 8, with the corresponding values of the coefficient k_c given in Table 1. This results in four different combinations of V_{master} and k_c, i.e. each of the 288 columns was checked for four combinations of V_{master} and k_c. Furthermore, while V_{master} represents the variability of the cores strength used in the calibration, the actual variability of the cores may differ from the values assumed in the calibration process. To account for the actual variability in the cores strength, the statistics of the column resistance are obtained considering 6 different values of the assumed measured strength obtained from cores (V = 5%, 7.5%, 10%, 12.5%, 15%, 17.5%).

Monte Carlo Simulation was used for the reliability assessment of each selected column for the ultimate limit state. The statistics of the basic variables used in this procedure are displayed in Table 3. Probabilities of failure (and corresponding reliability indexes) were computed for each column at a given scenario (V_{master}, k_c, and V). For each column in each scenario, a sample size of 10^6 is used in the simulation process. Considering the large volume of data that resulted from the investigation performed in this study, in what follows, only a few results are discussed and general results are highlighted.

Table 3. Statistics of the basic variables.

Mean	Coefficient of Variation	Type of distribution	Reference
Concrete Compressive Strength			
f_{cm}= 20, 30, 50, 70 MPa	5%, 7.5%, 10%, 12.5%, 15%, 17.5%	Lognormal	Assumed
Longitudinal Steel			
f_{ym} =572.5 MPa	10%	Lognormal	Assumed
Cross-Section Geometry			
B= 25 cm	2.2%	Normal	S1 (rectangular) JCSS (2001)
H=50 cm	2.8%	Normal	
B=30 cm	1.93%	Normal	S2 (square) JCSS (2001)
H= 30 cm	1.93%	Normal	
Model Error			
1.0	11%	Normal	Diniz & Frangopol (1997)
Dead Load			
See Figs.1 and 2	10%	Normal	Galambos et al. (1982)
Live Load			
See Figs.1 and 2	25%	Gumbel	Galambos et al. (1982)

Figures 7 and 8 present reliability indexes and probabilities of failure as a function of the load ratio r, respectively, for columns in series P3, and longitudinal steel ratio ρ_l= 1%. In these analyses, V_{master} = 0.05 and the number of cores is equal to 3. In these figures, for each group of bars corresponding to a given value of the load ratio, different results are obtained depending on the assumed variability of the measured strength obtained from cores. In Figure 7, two horizontal bars are shown as a reference. They correspond to the upper and lower values of the target reliability index (β_T, 3.8 and 3.1, respectively) suggested in the 2010 fib-Model Code (Féderation Internationale du Béton 2010).

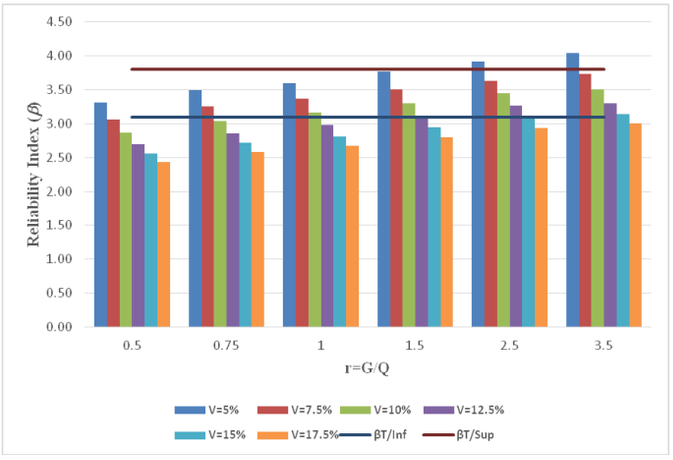

Figure 7 – Reliability indexes associated to columns in series P3, ρ_l= 1%, n = 3, and V_{master} = 0.05.

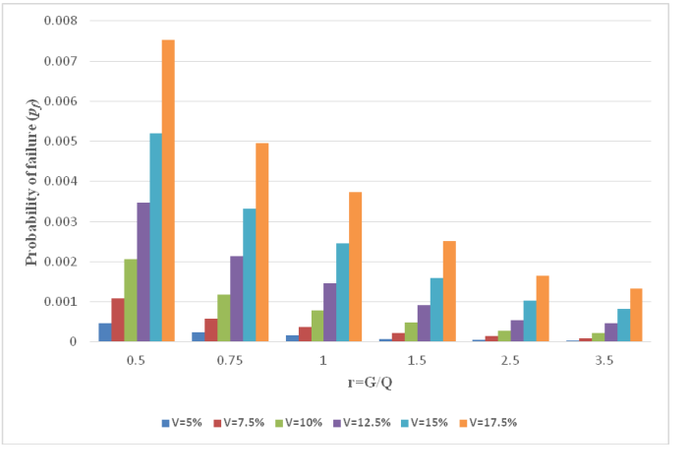

Figure 8 – Probabilities of failure associated to columns in series P3, ρ_l= 1%, n = 3, and V_{master} = 0.05.

It should be observed that reliability indexes can be easily obtained from the corresponding probabilities of failure. Additionally, in code calibration procedures, reliability indexes are frequently used as surrogate measures of the component reliability (e.g. Szerszen & Nowak 2003). However, it should be kept in mind that small differences in the range obtained for the reliability indexes translate in a much higher range in terms of probabilities of failure.

This is clearly seen by comparing the results displayed in Figures 7 and 8. For instance, when the load ratio, r, is equal to 0.5, the range in probabilities of failure is 7.5 x 10^{-3} - 4.6 x 10^{-4}, and the corresponding range in terms of reliability indexes is 2.43-3.31. In other words, while the highest probability of failure is about 16 times larger than the smallest probability of failure in the range, the highest reliability index is only 36% larger than the smallest reliability index in the range.

Figures 9 and 10 present reliability indexes and probabilities of failure as a function of the load ratio r, respectively, for columns in series P3, ρ_l= 1%, n = 3; however, V_{master} = 0.10. A comparison between Figures 7 and 9 (and Figures 8 and 10) shows a similar trend in both cases: (i) higher reliability levels are obtained as the load ratio increases, and (ii) decreased reliability as the concrete variability increases. It is also observed that an increase in the value of V_{master} used in the code calibration also increases the resulting reliability levels. This can be easily understood as a higher value of V_{master} translates into a lower equivalent concrete compressive strength, and consequently, more restrictive values of the loads that may act on the column.

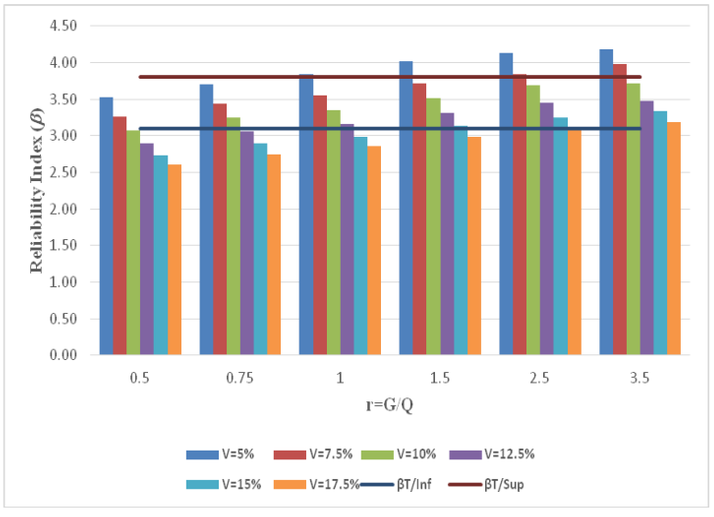

Figure 9 – Reliability indexes associated to columns in series P3, ρ_l= 1%, n = 3, and V_{master} = 0.10.

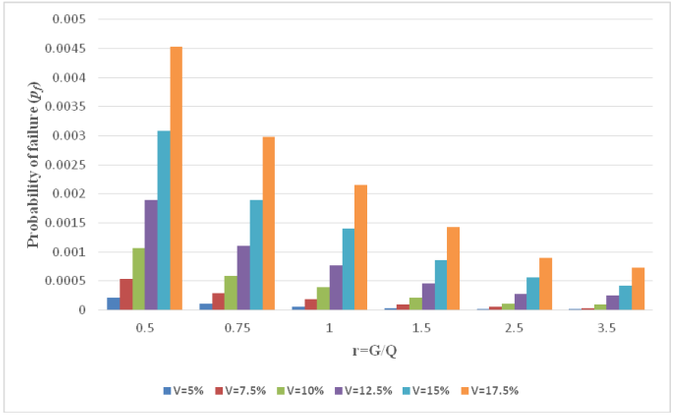

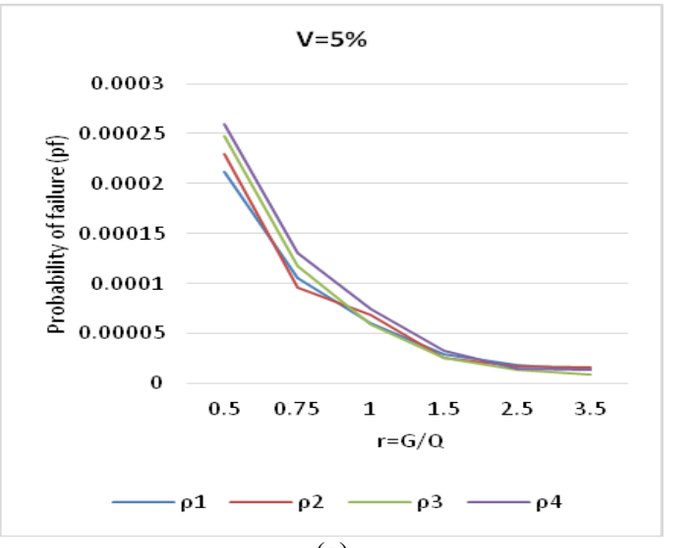

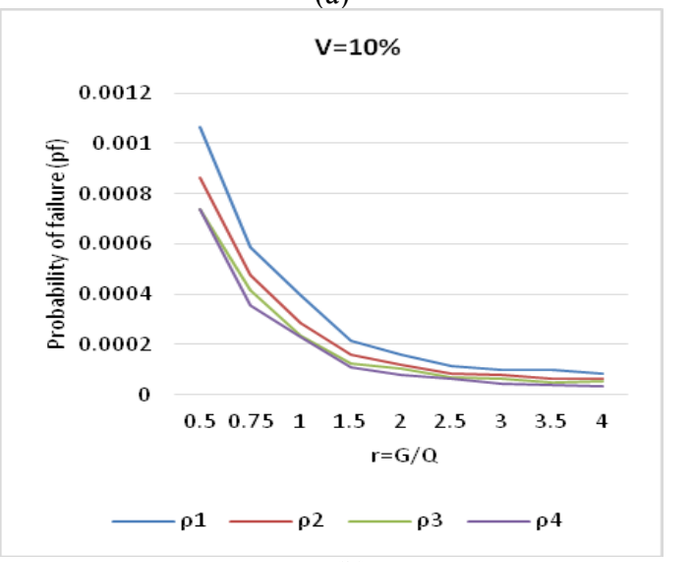

Figure 10 – Probabilities of failure associated to columns in series P3, ρ_l= 1%, n = 3, and V_{master} = 0.10.

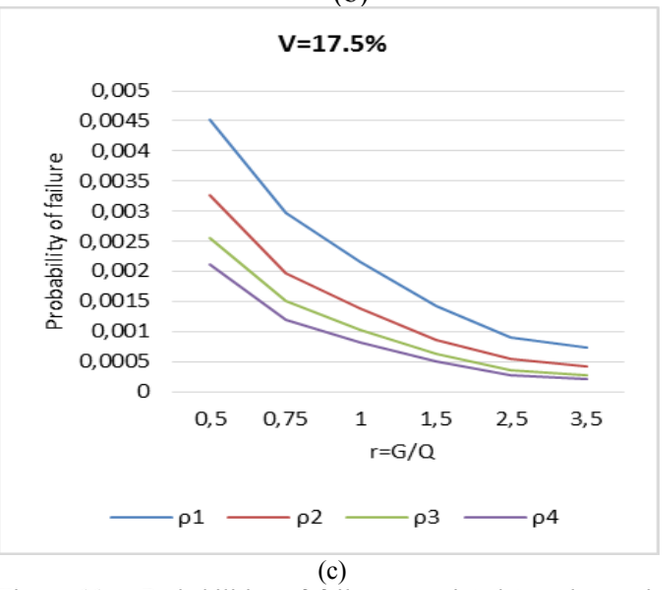

The effect of the longitudinal steel ratio on the column reliability is shown in Figure 11 (results presented in terms of the probability of failure).

(a)

(b)

(c)

Figure 11 – Probabilities of failure associated to columns in series P3, n = 3, and V_{master} = 0.10, for different values of the longitudinal steel ratio, ρ_l: (a) V= 0.05, (b) V= 0.10, (c) V= 0.175.

From Figure 11 it is seen that the influence of the amount of longitudinal steel is small for lower values of the coefficient of variation of the extracted concrete cores, V. However, this influence increases as this coefficient of variation increases, particularly for low values of the load ratio; see for instance Figure 11(c), which corresponds to V=17.5%.

7 SUMMARY AND CONCLUSIONS

In this study, the reliability levels associated to short, axially-loaded existing RC columns were assessed. These structural elements have been chosen since they represent the condition where the influence of the in situ concrete compressive strength would be the most relevant to the structural integrity.

It was considered that updated statistics are obtained for the in situ concrete compressive strength only. These updated statistics were obtained from information on strength of extracted cores adjusted for size effects and number of cores. The analysis corresponds to a snapshot of the safety margins at the time of the investigation; as such the time-dependent behavior of the materials involved, as often occurs in deterioration processes associated to RC structures, has not been taken into account.

Four different scenarios representing the combinations of V_{master} (used in the code calibration) and the number of cores were considered in the reliability assessment of 288 selected columns. Furthermore, for each column, 6 different values of the coefficient of variation of the extracted concrete cores, V, were assumed. Considering the large amount of data gathered in such analyses, only a few representative results were presented in the previous section.

It was observed that the coefficient of variation of the extracted concrete cores, V, has an important influence on the resulting reliability levels. This is particularly more evident when results are presented in terms of probabilities of failure. It is important to note that while for new structures the coefficient of variation of concrete compressive strength may vary in a small range, the coefficient of variation of the extracted concrete cores may fall within a much larger range.

Regarding the value of V_{master} used in the code calibration procedure, it was observed that an increase in such value increases the resulting reliability levels. It is observed that a higher value of V_{master} translates into a lower equivalent concrete compressive strength, and consequently, more restrictive values of the loads acting on the column and higher reliability levels.

Considering the range for the target reliability index suggested in the 2010 fib-Model Code (3.1-3.8), the resulting reliability levels violate such targets for a number of the selected columns in this study. This is particularly true for those columns representing a combination of smaller load ratios and higher coefficients of variation of the extracted concrete cores. Notwithstanding, it is important to note that there is still no consensus on target reliability levels for the assessment of existing structures.

Target reliability metrics for code calibration procedures of new structures are usually presented in terms of reliability indexes (e.g. Galambos et al. 1982, Szerszen & Nowak 2003). However, as highlighted in this study, small differences in the range of the reliability indexes translate in a much larger range in terms of probabilities of failure. Considering these significant differences, it is concluded that the assessment of important existing structures should be explicitly made in probabilistic terms.

Risk-based performance evaluation for concrete bridge deck repair

H. Huang & M. Liu
Relcon Infrastructure Management Inc., Denver, Colorado, USA

ABSTRACT: Repair of concrete decks has a significant impact on the total costs of a bridge repair and rehabilitation project. Therefore, it is important to establish a rational procedure and criteria for evaluating deck performance. This paper compares the evaluation procedures and performance criteria in the 2014 Canadian Highway Bridge Design Code with those in the Manual for Bridge Evaluation published by AASHTO in 2011. The fundamental differences between bridge design and evaluation have been identified, followed by a proposed evaluation procedure, where the risks related to the time-dependent uncertainties associated with concrete deterioration and the epistemic uncertainties in measurement and testing methods, including spatial variations, are considered. The proposed procedure is calibrated using a similar procedure for new structure design. More importantly, this paper emphasizes that new bridge design deals with group characteristics of future structures, while bridge evaluation addresses the status of individual elements in existing structures.

1 INTRODUCTION

Repair of concrete decks has a significant impact on the total costs of a bridge repair and rehabilitation (R&R) project. This is because a concrete deck is an important component in the structural system of a bridge, but it is also vulnerable to environmental attacks (*e.g.* extreme cold or hot weather, snows, winds and deicing salts) or increased heavy traffic loads. The amount of concrete materials in a bridge deck warrants an expensive construction for both new bridges and existing bridge R&R. Therefore, it is very important to establish a rational procedure and criteria for evaluating concrete bridge deck performance, particularly for bridge R&R projects.

1.1 *History of concrete bridge decks*

Before the 1920's, timber was used as decking for stone and steel bridges. By the 1930's, reinforced concrete was well established as a major building material. In March 1930, *Public Roads Magazine* published a paper of "computation of stresses in bridge slabs due to wheel loads" by Professor H.M. Westergaad of the University of Illinois as the foundation for modern design of concrete bridge decks. According to Item 107 from the 1994 National Bridge Inventory (NBI) published by Federal Highway Administration (FHWA) of the U.S. Department of Transportation, about 70% of the existing bridges in the U.S. have cast-in-place reinforced concrete decks, and about 90% of the total U.S. bridge deck areas are made of reinforced concrete.

1.2 *Functions of concrete bridge decks*

The primary function of a bridge deck is to deliver the reaction from vehicle tires to the bridge framing system that supports the deck. The additional functions of a concrete bridge deck include (a) proving a roadway to move; (b) distributing traffic loads to various supporting elements; (c) an important addition to the top flange of bridge girders behaving compositely with the framing members; (d) part of the stiffening system (*e.g.* horizontal diaphragms), particularly for torsion deformation; (e) acting as a slab structure when without a bridge framing system for a simple span bridge up to approximately 40 feet in length.

1.3 *Behavior of concrete bridge decks*

The responses of a concrete bridge deck subjected to wheel loads can be modeled as either a flexural member or a compression membrane having an "arching action". Making composite actions between the deck and the supporting floor system is a fundamental requirement for long-lasting concrete bridge deck construction. A lighter and composite bridge deck will provide economic and reliable solutions for both new bridge design and existing bridge R&R. Meanwhile, a concrete deck suffers wear, abrasion, and deterioration due to traffic contacts.

The steel reinforcement may also corrode. As a result, a concrete bridge deck usually contains a layer of special surface materials for better resisting traffic wear and abrasion, improving skid resistance and protecting the deck itself, while the steel reinforcement is often protected with epoxy-coating. For example, in Canada, the 90 mm (3.54 inches) asphalt layer with waterproofing system is used on top of concrete deck for protection.

1.4 *Causes of concrete deck deterioration*

There are many causes that are responsible for concrete deck deterioration. The most well-known cause is the deicing salts that dramatically increase the chloride-induced steel corrosion in a concrete deck. In fact, the root causes of concrete deck deterioration may be found in both design and construction, in addition to the operation phase of a bridge. For example, the concrete decks could be designed to be too thin or insufficient concrete cover over steel reinforcement. The supporting steel girders may be too limber, or more importantly, the concrete decks are not designed to composite with the steel girders. During the construction phase, the potential causes include, but are not limited to, dirty and reactive concrete aggregates, insufficient cement, too much water, excessive concrete placement temperature, incomplete consolidation, slow finishing, lack of uniform curing or concrete was too young when traffic was allowed. The poor design and lack of maintenance of deck drainage and expansion joints may also cause concrete deck deterioration.

1.5 *Performance evaluation of concrete decks*

The literature review on performance evaluation of concrete decks indicates that the relevant publications focus on two areas as the inspection techniques for condition assessment and the deterioration rates for remaining service life prediction. The current condition assessment is heavily relied on visual inspection at the top and bottom surfaces, particularly in the areas exposed to traffic or drainage. Although coring and/or nondestructive evaluation (NDE) may be used for condition assessment, if necessary, the current condition assessment on concrete bridge decks is considered to be subjective in nature. On the other hand, the deterioration rates of concrete bridge decks can be determined by either statistical modeling from bridge inventory database (*e.g.* the National Bridge Inventory, NBI) or time-dependent corrosion modeling with probabilistic initiation time, corrosion propagation rate or load models (Cady & Weyers 1984, Stewart & Rosowsky 1998, Oh et al. 2007). However, neither condition assessment nor determination of deterioration rates can provide the safety margin of an existing concrete deck due to lack of traffic loading information in the performance evaluation processes.

This paper compares the evaluation procedures and performance criteria for concrete bridge decks in the 2014 Canadian Highway Bridge Design Code (CSA Group 2014) with those in the Manual for Bridge Evaluation published by AASHTO in 2011. After then, the fundamental differences between a new bridge design and an evaluation of an existing bridge have been identified, followed by a proposed evaluation procedure, where the risks are related to the time-dependent aleatoric uncertainties associated with a stochastic process of concrete deterioration and the epistemic uncertainties in measurement and testing methods, including spatial variations.

2 BRIDGE EVALUATION CODES

The bridge evaluation code may be either a part of a design code for new structures (*e.g.* the *Canadian Highway Bridge Design Code* published in 2014) or a stand-alone manual such as the 2011 *AASHTO Manual for Bridge Evaluation*. In addition, the guidelines on condition surveys (*e.g.* the Ministry of Transportation Ontario (MTO)'s *Structural Rehabilitation Manual* published in 2007) are often used to perform field measurements.

2.1 *Canadian Highway Bridge Design Code*

Section 14 "Evaluation" of the 2014 *Canadian Highway Bridge Design Code* comprises the code requirements for evaluating an existing bridge in Canada, where the acceptable evaluation procedures include the ultimate limit states methods either using the load and resistance adjustment factors specified in Clauses 14.13 and 14.14 or the mean load method for the ultimate limit states specified in Clause 14.15.2.3. The load testing method specified in Clause 14.16 is also allowed for bridge evaluation. In addition, the serviceability limit states method shall be used in determining the load-carrying, stability, and load posting of masonry structures and bridges with excessive cracking, deformation, stress, or vibration. The other approved methods include the fatigue limit state specified in Clause 14.18.

The general bridge evaluation methodology in this Section requires (i) a condition inspection per Clause 14.6, (ii) determination of material strengths in accordance with Clause 14.7, and (iii) loads and load distribution in accordance with Clauses 14.8 to 14.11. The philosophy behind this general evaluation methodology is to maintain a consistent level of risk to human life for each element of the bridge (Allen 1992), in other words, the risks other than loss of a human life, such as the monetary loss of assets and the intangible loss of reputation, are not considered. The life safety criterion for the determi-

nation of the target reliability index (β) in bridge evaluation herein is related to the required evaluation level, expected warning of failure (*i.e.* brittle or ductile failure) and evaluation purpose (*i.e.* permit traffic or controlled vehicles). As a result, the β values ranges from 2.0 to 3.5 and the corresponding load factors and resistance adjustment factors are presented in Clauses 14.13 and 14.14, respectively.

For concrete bridge deck evaluation, a rapid method of evaluating the load carrying capacity is provided through Figures 14.4 and 14.5, based on NCHRP Report 292 (NCHRP 1987). The performance factor is set at 0.5 to ensure an adequate level of safety against a shear failure and intends to reflect the variations in the actual condition of the concrete deck. When the conditions specified for the rapid method are not satisfied, the resistance capacity of the concrete deck shall be determined per Section 8 of the 2014 *Canadian Highway Bridge Design Code* and expressed as an equivalent wheel load at the centerline of the span of the concrete deck. In addition, a resistance adjustment factor is introduced in Table 14.15 for all components that have no visible sign of defects or deterioration to fine-tune the resistance factors used in new bridge design. The bias coefficients and coefficients of variation (COV) of the resistance adjustment factors are presented in Table C14.6. The effects of defects and deterioration are discussed in Clause 14.14.3, where the uncertainties in determining the resistances of deteriorated or damaged materials at the critical member sections are recognized in general. However, no effort has been made to quantify these uncertainties.

2.2 *The Manual for Bridge Evaluation*

The Manual for Bridge Evaluation published by the American Associate of State Highway and Transportation Officials (AASHTO) serves as a standard and provides uniformity in bridge evaluation procedures and policies for the U.S. highway bridges. The first edition of *the Manual* was published in 2008 and the 2nd edition published in 2011 with 2011, 2013, 2014, 2015, and 2016 interim revisions (AASHTO 2011) is the current bridge evaluation code. *The Manual* replaces both the *Manual for Condition Evaluation of Bridges* and the *Guide Manual for Condition Evaluation and Load and Resistance Factor Rating (LRFR) of Highway Bridges* with any interim revisions before 2008 that were published by AASHTO. *The Manual* has been developed to assist Bridge Owners to meet the requirements in the National Bridge Inspection Standards (NBIS) with the eight sections, including (i) Introduction, (ii) Bridge Files (Records), (iii) Bridge Management Systems, (iv) Inspection, (v) Material Testing, (vi) Load Rating, (vii) Fatigue Evaluation of Steel Bridges and (viii) Nondestructive Load Testing, along with the nine illustrative examples in Appendix A. The load rating methods in Section 6 include the Load and Resistance Factor method, Load Factor method, and Allowable Stress method, and no preference is placed on any of these rating methods. Section 8 describes the field load test procedures for determining the live-load capacity of a bridge as well as for improving the confidence in the assumptions used in the analytical or computer modeling of the bridge.

For concrete deck evaluation, Section 6.1.5.1 states that the stringer-supported concrete decks and metal decks that are carrying normal traffic satisfactorily need not be routinely evaluated for load capacity. The bridge decks should be inspected regularly to verify satisfactory performance. This is because the primary structural action of concrete decks is not flexure, but internal arching or membrane action. There is significant reserve resistance capacity in concrete decks designed by the *AASHTO LRFD Bridge Design Specifications*, except for the heavily spalled and deteriorated concrete decks that may be required to check for punching shear under wheel loads. Nevertheless, Appendix A7 illustrates the procedure for reinforced concrete slab bridge design and legal load check, where the loads and resistance capacities are determined with Sections 4 and 5 of the LRFD design specifications, respectively. After then, the Rating Factor (RF) is calculated using the load-rating equations in Section 6A, considering the condition and system factors.

2.3 *Comparison of bridge design and evaluation*

It is clear that both Canadian and AASHTO bridge evaluation codes are based on the LRFD bridge design specifications. The target reliability index for bridge evaluation is generally smaller than that for bridge design, primarily due to economic considerations. The effects of the actual condition of a bridge component or system, including defects or deterioration, are taken into account with resistance adjustment factors in the Canadian evaluation code as well as condition and system factors in the *AASHTO Manual for Bridge Evaluation*. Similar assessment methodologies exist in other structural evaluation codes, specifications, regulations or guidelines worldwide. For instance, the UK Department of Transportation recommended implementation of bridge design codes with very few modifications for bridge evaluation (Micic et al. 1995). The American Concrete Institute (ACI) 318 *Building Code Requirements for Structural Concrete and Commentary* (ACI 318 2014) and ACI 562 *Code Requirements for Evaluation, Repair, and Rehabilitation of Concrete Buildings and Commentary* (ACI 562 2016) permit increasing the strength reduction

factor (*i.e.* phi-factor, ϕ) for assessment of existing concrete members from the design values as shown in Table 1 below. This has been justified by the improved reliability due to the use of accurate field-obtained material properties, actual in-place dimensions and well-understood methods of analysis. In fact, the increased ϕ values are directly caused by the reduced target reliability index (β).

The rest of this paper investigates the root causes of uncertainties (*i.e.* variations or deviations) in new concrete structures, including new concrete bridge decks, as well as the root causes of uncertainties in assessment of existing concrete structures. By comparing the characteristics of the uncertainties, the fundamental differences are identified, and the corresponding uncertainty treatments are suggested.

Table 1. Phi Factor ϕ in ACI 318-14 and ACI 562-16

Concrete Member	ACI 318 Design	ACI 562 Assessment	
Tension-controlled sections	0.9	1.0	1.0
Compression-controlled sections			
with spiral reinforcement	0.75	0.9	0.9
other reinforced members	0.65	0.8	0.8
Shear, torsion, interface shear	0.75	0.8	0.8
Bearing on concrete	0.65	0.8	0.8
Strut-and-tie models	0.75	N/A	0.8

3 ROOT CAUSES OF UNCERTAINTIES

In general, a phi-factor (ϕ) is used to account for the probability of understrength of a structural member due to variations of in-place material strengths and dimensions, effect of simplifying assumptions in the design equations among others (ACI 318 2014). The ϕ values also account for deviations of the actual strength from the nominal strength as well as the potential failure modes (*i.e.* brittle or ductile failure) and associated consequences of the failure (ASCE/SEI 7 2010). Therefore, a comprehensive understanding of the root causes represented by the phi-factor (ϕ) values is essential for the development of a rational evaluation procedure and performance criteria for existing structures.

3.1 *New concrete structures*

The phi-factors for new concrete structure design in ACI 318 were calibrated through a large database of construction material properties from North American industry including the Concrete Reinforcing Steel Institute, National Ready Mixed Concrete Association, Portland Cement Association, and Precast / Pre-stressed Concrete Institute (Nowak & Szerszen 2003). The root causes of uncertainties in new concrete structure design were identified as: (i) variations in construction material properties (*e.g.* compressive strength of concrete, yield strength of steel reinforcement, modulus of elasticity of concrete and steel reinforcement) during the producing and curing process; (ii) variation in component dimensions, locations of steel reinforcement, and moment of inertia, among other factors related to the fabrication process; and (iii) effects of simplifying assumptions in the design equations (*i.e.* professional factor). Thus, the resistance capacity R of a new concrete member is expressed as a product of the three factors M, F, and P as

$$R = Rn \times M \times F \times P \quad (1a)$$

$$R = \phi \times Rn \quad (1b)$$

$$\phi = M \times F \times P \quad (1c)$$

where Rn = nominal resistance, M = construction material properties parameter, F = fabrication factor, and P = professional factor. The statistical properties of M, F and P (*e.g.* the mean values m, the bias factors λ, and the coefficients of variation COV) were derived from either the large database mentioned above or previous studies documented in the available literature (Nowak & Szerszen 2003).

3.2 *Existing concrete structures*

Obviously, the uncertainties associated with the producing, curing and fabrication processes for new concrete members, represented by M and F, respectively, no longer exist in assessment of existing concrete members, but new uncertainties associated with the investigation procedure (dimension measurements and material properties tests) appear. The uncertainties represented by P will be the same only if the same simplifying assumptions are used in the design equations for assessment of existing concrete members, but the additional assessment equations associated with the measurement and testing process will add the new uncertainties. For example, Equation (6.4.3.1) of ACI 562-16 is a simplified expression to determine the equivalent specified concrete strength $f_{c,eq}$ from the core testing results as

$$f_{c,eq} = 0.9\,F_c\{1 - 1.28\sqrt{\frac{(k_c V)^2}{n}} + 0.0015\} \quad (2)$$

where F_c = average core strength as modified to account for the diameter, length to diameter ratio and moisture condition of the core per ASTM C42 procedures; k_c = modification factor per Table 6.4.3.1 of ACI 562-16; V = coefficient of variation of the core strengths; and n = number of cores tested. The corresponding uncertainties due to the assumptions in Equation (2) must be included in accurately determining ϕ for assessment of existing concrete members. In addition, Section 27.3.1.1 of ACI 318-14 requires "dimensions of members shall be established at critical sections". However, the critical sections of an existing concrete member vary for dif-

ferent load effects, such as moment, shear, and axial force, even if the load is identical and well known (*e.g.* a moving truck load on a concrete bridge for the potential failure mode of shear). In other words, the critical sections of an existing concrete member may not be identified before performing a field investigation. Thus, the uncertainties that the field investigation results may not represent the properties at the critical sections of an existing concrete member must also be included in accurately determining ϕ for assessment of existing concrete members. As a result, the resistance capacity R_e of an existing concrete member can be expressed as

$$R_e = Rn_e \times T_e \times P_e \times Cr_e \quad (3a)$$
$$R_e = \phi_e \times Rn_e \quad (3b)$$
$$\phi_e = T_e \times P_e \times Cr_e \quad (3c)$$

where Rn_e = nominal resistance of an existing concrete member, usually based on the average measurements from the field investigation or the nominal values in design codes, T_e = factor related to the field investigation procedures, including but not limited to construction-material property and dimension measurements, P_e = professional factor associated with an existing concrete member, and Cr_e = factor accounting for the fact that the field investigation results may not represent the properties at the critical sections of an existing concrete member. Obviously, the statistical properties of T_e, P_e and Cr_e should be completely different from those of M, F and P. However, only limited or no previous studies on T_e, P_e and Cr_e can be found in the available literature.

3.3 *Fundamental differences*

As stated above, the root causes of uncertainties in new concrete structure design and in assessment of existing concrete structures have been found to be completely different. More importantly, the characteristics of these uncertainties are compared in order to identify the fundamental differences represented by the corresponding phi-factors, which will result in the different uncertainty treatments suggested.

In decision-making theory, the characteristics of uncertainties can be categorized as either aleatory variability or epistemic uncertainty. The aleatory variability describes natural randomness and cannot be reduced by an increase in knowledge. It is very important to recognize that the aleatory variability represents the characteristics of a random process as a group, but not a property of individuals (*i.e.* each observation) in the group. On the other hand, the epistemic uncertainty is due to lack of knowledge or limited data, and may be eliminated with sufficient investigations. The epistemic uncertainty may be initially represented with the probability density function (PDF) as a prior distribution for Bayesian updating. The results of the Bayesian updating may be used for future performance prediction of an individual in the group.

Since M and F reflect the uncertainties in producing, curing, and fabricating new concrete members, M and F are the aleatory variability. This is because producing, curing, and fabricating new concrete members can be considered as a natural random process. P is an epistemic uncertainty as the uncertainties in P may be reduced or eliminated with sufficient investigations. Therefore, the phi-factor for new concrete structures represents a combination of the aleatory variability and the epistemic uncertainty. It should be noted that the phi-factor for new concrete structures is to account for the uncertainties in future structures. In other words, the resistance capacity of a future concrete structure does not exist at the time of design and construction. The actual resistance capacity of a future concrete structure will be different from the calculated one due to the natural randomness associated with the producing, curing, and fabrication processes. On the other hand, the actual resistance capacities at critical sections of an existing concrete structure exist at the time of assessment. The uncertainties in R_e are due to lack of knowledge (*i.e.* uncertainties associated with the investigation processes) or limited data. Although an investigation process itself can be considered as a natural randomness process, the aleatory variability associated with the investigation process only affects the associated results (*i.e.* our knowledge of the actual resistance capacities at critical sections), but does not affect the actual resistance capacities themselves. Therefore, all of T_e, P_e and Cr_e should be treated as the epistemic uncertainty. As a result, the fundamental differences between the phi-factors for new concrete-structure design and for assessment of existing concrete structures are found to be (i) the phi-factors for new concrete-structure design represent the group characteristics of a random process (*i.e.* a producing, curing, and fabrication process for new concrete members), and (ii) the phi-factors for assessment of existing concrete structures reflect the epistemic uncertainty that may be used for future performance prediction of an individual existing concrete member through Bayesian updating.

The uncertainty treatments for an aleatory variability are primarily dependent on the PDF for observations available, but the uncertainty treatments for the epistemic uncertainty may include but not be limited to: (i) Bayesian updating; (ii) the interval (minimum, mode, maximum) analysis from observations available or expert opinion elicitation (*i.e.* no additional information but the interval required); (iii) Dempster-Shafer evidence theory; (iv) fuzzy sets; (v) possibility theory; (vi) imprecise probability; (vii) logic trees with weights from subjective judgments; and (viii) adjustment factor approach. Furthermore, the uncertainty treatments for a combina-

tion of aleatory variability and epistemic uncertainty involve: (i) second-order probability; (ii) two-stage Monte Carlo simulations; and (iii) adjustment factor approach.

4 CODE CALIBRATION PROCEDURE

The values of the phi-factors for new concrete-structure design in ACI 318 were obtained from a rigorous design code calibration procedure (Szerszen & Nowak 2003), which includes the following five steps: (i) selection of the representative dimensions and reinforcement ratios for the structural concrete elements of interest; (ii) selection of the statistical models for loads and load combinations; (iii) selection of the resistance models; (iv) probability analysis using the component reliability index, β; and (v) determination of the values of the phi-factors for each of the design limit states, based on the calculated closeness to the predefined target reliability index, β_T. Ideally, a similar code calibration procedure should be applied to determine the values of the phi-factors for assessment of existing concrete members, where the general format of the limit state function is

$$g = R - Q \geq 0 \tag{4}$$

where g = safety margin; R = resistance capacity; and Q = demand in terms of load effect. When R and Q are treated as the random variables as shown in Figure 1, the probability of failure P_f is illustrated as the shaded area in Figure 2. The component reliability index β is calculated using the inverse standard normal distribution function Φ^{-1} as

$$\beta = -\Phi^{-1}(P_f) \tag{5}$$

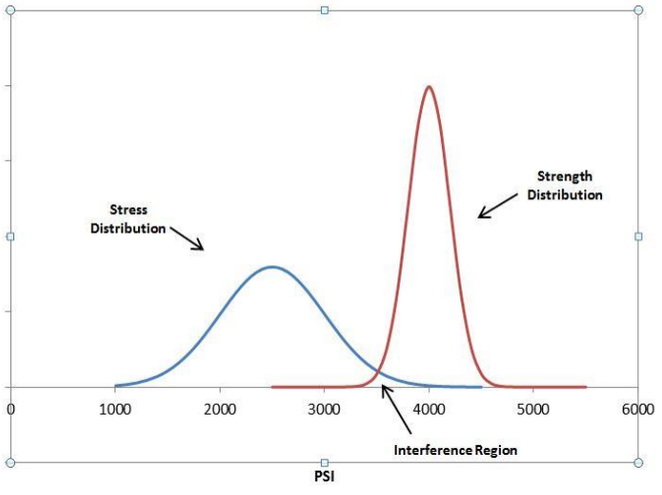

Figure 1: Random Variables R (Resistance) and Q (Demand)

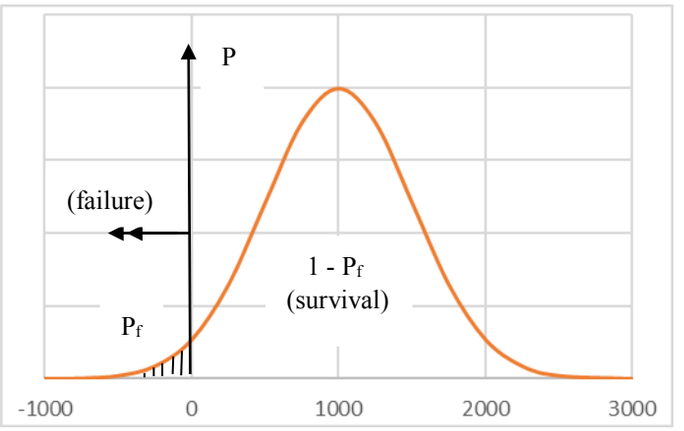

Figure 2: Probability of Failure P_f (the shaded area)

5 EXAMPLE

For each of the potential failure modes, R and Q for the different load combinations under consideration should be evaluated in order to accurately obtain the values of the phi-factors for assessment of existing concrete members. For example, for the potential failure mode of shear of a simply supported concrete beam, when the load combination only involves dead and live loads, the design equation can be expressed as

$$\phi_e R_{ne} = \gamma_D D_n + \gamma_L L_n \tag{6}$$

where γ_D and γ_L are the load factors for the dead and live loads, respectively. D_n and L_n are the nominal dead and live loads, respectively. The corresponding limit state equation is

$$g = R - Q = R - (D + L) = [(\gamma_D + \gamma_L (L_n / D_n))/ \phi_e] X_1 - X_2 - (L_n / D_n) X_3 \tag{7}$$

where the random variables X_1, X_2 and X_3 are R / R_{ne}, D / D_n and L / L_n, respectively.

Assuming the loading conditions for assessment of existing concrete members are identical to those for new concrete member design, ASCE/SEI 7-10 provides the statistical properties of the variables in Equation (7), as listed in Table 2. Thus, Equation (7) may be simplified as

$$g = 4.4 / \phi_e X_1 - X_2 - 2.0 X_3 \tag{8}$$

where the random variable X_1 in this case is a function of T_e , P_e and Cr_e that are related to the shear capacity of the concrete beam. The statistical properties of X_1 may be estimated as

$$\text{mean } X_1 = \text{mean } T_e \times \text{mean } P_e \times \text{mean } Cr_e \tag{9}$$

$$COVX_1 = (COVT_e^2 + COVP_e^2 + COVCr_e^2)^{1/2} \tag{10}$$

where the statistical properties of T_e , P_e and Cr_e (*i.e.* the mean values and COV) must be obtained from the Bayesian updating or other uncertainty treatments for epistemic uncertainty mentioned before.

Table 2: Statistical Properties of Variables in Equation (7) Based on ASCE/SEI 7-10

Variable	Value	Probability Distribution
γ_D	1.2	
γ_L	1.6	
L_n / D_n	2.0 (typical)	
X_2	Mean = 1.05 COV = 0.10	Normal
X_3	Mean = 1.00 COV = 0.25	Extreme Type I

It is emphasized herein that any statistical properties representing the group characteristics of a random process can only be used as a prior distribution for Bayesian updating in assessment of existing concrete members. Directly using the statistical properties representing the group characteristics in assessment of an individual existing concrete member may mislead the assessment outcomes. This is because the future performance of an individual existing concrete member can only be predicated by using the statistical properties updated from the field measurements that belong to the individual member. For example, the overall variability of in-place strengths that represents the group characteristics of a random process (*i.e.* a producing, curing and fabrication process for new concrete members) in Table 3.1 of ACI 214.4R-10 (ACI 214 2010) cannot be directly used without updating for assessment of an individual existing concrete member. Similarly, the within-test coefficients of variation in Section 7.1 of ACI 214.4R-10 and the repeatability in Section 3.2 of ACI 228.1R-03 (ACI 228 2003) must be updated for use in the assessment of an individual existing concrete member. These coefficients include, but not be limited to: 3.2% and 4.7% for the field coring tests by a single-operator and multi-laboratory operators, respectively, as shown in the precision statements of ASTM C42/C42M, 2.0% in ASTM C 597 for the ultrasonic pulse velocity measurement by one operator using different instruments or different operators using the same instrument, and 3.6% in ASTM C 873 for the three cast-in-place cylinders from the same batch.

As shown in Equations (9) and (10), the statistical properties of T_e, P_e and Cr_e are critical to determine the proper probability distribution of X_1. Thus, detailed studies of these statistical properties become necessary to correctly select the appropriate ϕ_e for various values of the target reliability index β_T. Advanced probability and statistical theories and techniques, such as propagation of uncertainty or error, autoregressive integrated moving average (ARIMA), and regression-Kriging, have a great potential in development of a rational procedure for the appropriate ϕ_e used in assessment of an individual existing concrete member. In absence of these detailed studies, the random variable X_1 is assumed herein to be a log-normal distribution with the mean value of 1.05 and the COV of 0.06. Table 3 summarizes the calculated probability of failure, P_f and corresponding reliability index β, through the 100,000 Monte Carlo simulations. The appropriate ϕ_e for the different values of the target reliability index β_T should be selected in accordance with the closest agreement between the calculated β and β_T. For example, if β_T is predefined as 2.5, ϕ_e should be 0.90. Similarly, ϕ_e should be 0.80, if β_T is assigned to be 3.0. Table 4 presents the sensitivity study results of X_1 (log-normal distribution) with different mean values and COV, where the calculated β is more sensitive to the changes of COV.

Table 3: Calculated Shear P_f under Dead and Live Loads

Assumed ϕ_e	0.80	0.85	0.90	0.95	1.00
Calculated P_f (%)	0.10	0.20	0.40	0.70	1.30
Reliability Index β	3.09	2.89	2.66	2.46	2.23

Table 4: Sensitivity Study Results of X_1

Assumed ϕ_e	0.80	0.85	0.90	0.95	1.00
Mean = 1.05, COV = 0.06	3.09	2.89	2.66	2.46	2.23
Mean = 1.05, COV = 0.15	2.66	2.46	2.26	2.06	1.84
Mean = 1.05, COV = 0.15	2.89	2.66	2.46	2.22	2.02

It should be pointed out that the Monte Carlo simulation results mentioned above are from only one load case of (1.2 Dead Load +1.6 Live Load), for purpose of illustration. The phi-factors for assessment of existing concrete members in Section 5.4 of ACI 562-16 and Section 27.3.2 of ACI 318-14 shall consider various load combinations as in ASCE/SEI 7-10. Thus, a rigorous code calibration process through multiple Monte Carlo simulations is required. Moreover, the assumption that the loading conditions for assessment of existing concrete members are identical to those for design of new concrete members needs to be validated, because the design life of a new concrete member is usually 50 years, but the remaining life of an existing concrete member may be much shorter than 50 years. More importantly, the load calibration process for new structures in ASCE/SEI 7-10 relies on the group characteristics of a random loading process, but the statistical properties of the loads applied to existing structures shall be updated to reflect the future loading prediction of an individual existing component. Finally, the target β_T for existing concrete members may be different from that for new concrete members because β_T is a function of various items (e.g. past structural behavior, engineering experiences, estimated construction costs and consequences of failure among others). β_T = 3.5 (*i.e.* $P_f \approx 0.023$ %) is

adopted for most of the components except for columns ($\beta_T = 4.0$) in new concrete structures, while the corresponding β_T for existing concrete structures is 2.5 (*i.e.* $P_f \approx 0.620$ %), primarily due to rehabilitation cost considerations.

6 CONCLUSIONS

This paper assessed the evaluation procedures and performance criteria for concrete bridge decks in both Canadian and AASHTO bridge evaluation codes, and determined that similar methodologies were adopted, where the bridge design specifications were modified with a reduced target reliability index, resistance adjustment factors, condition and system factors to represent the actual conditions of existing structures. Many other structural evaluation codes and specifications worldwide also implemented this approach. The further investigation on root causes of uncertainties in new concrete structure design and in assessment of existing concrete structures revealed that the phi-factors for new concrete structure design represented the group characteristics of a random process (*i.e.* producing, curing, and fabrication processes for new concrete members), whereas the phi-factors for assessment reflected the epistemic uncertainty that may be used for future performance prediction. The rigorous code calibration process through Monte Carlo simulations for assessment of existing structures was illustrated for only one load case (1.2 Dead Load +1.6 Live Load), where the statistical properties of the uncertainties in assessment of existing concrete structures (*i.e.* T_e, P_e and Cr_e) play a critical role for correctly selecting the appropriate ϕ_e for various values of the target reliability index β_T.

Although the routine load capacity evaluation is not required for concrete bridge decks, the statistical properties of T_e, Cr_e and P_e mentioned above may significantly affect the serviceability evaluation of the concrete decks. For example, the spatial and temporal variations of corrosion rates in a deteriorating reinforced concrete bridge deck were studied with structural health monitoring techniques (Marsh & Frangopol 2007). Furthermore, the field testing data indicated that the presence of heavy truck was an essential factor in the deterioration process of concrete decks (Szerszen & Nowak 2002). This is why the concrete spalling and potholes are often aligned with the traffic lanes. Therefore, the spatial variations on concrete bridge decks must be taken into account in the risk-based performance evaluation. This has been done in this paper by using an importance factor or a condition and system factor that is usually assigned to reflect actual conditions of the bridge decks. The advanced probability and statistical theories and techniques, such as propagation of error or uncertainty, autoregressive integrated moving average (ARIMA), and regression-Kriging, are expected to have a great potential in future development of such a rational procedure in safety assessment of existing concrete members.

Dr Robert Heywood
Director, Heywood Engineering Solutions, Australia

ABSTRACT: Bridge assessments can often feel like a maze for asset owners with the wealth of information available internationally on approaches to determine the appropriate heavy vehicle access management strategy. Throughout the world, heavy vehicles are operating on bridges at levels that exceed the assessed load carrying capacities of the bridges determined using design based ("standard") assessment procedures. The cost of strengthening these bridges is unpalatable and the consequences of restricting access are unacceptable. Inspections of these bridges in most cases indicate they are performing satisfactorily leading one to question the plausibility of the assessments. The key to unlocking the bridge assessment maze is to understand the inherent assumptions that underpin every form of assessment. An appreciation of the nature and type of assumptions then leads to a more informed position regarding actual risks, which ultimately provides the avenue to developed targeted management strategies for individual bridges and on a network-wide basis.

This paper aims to provide some guidance through the bridge assessment maze to empower the asset owner or manager to understand the requirements and outputs of bridge assessments. The paper begins by providing the distinction between design and assessment and then outlines current bridge assessment processes in Australia and selected international jurisdictions. A comparison of assessment assumptions is then presented to demonstrate the variability in assessment results that can in turn impact on the required management strategy and investment. The findings provide justification for the development of further guidance on the practical and reliable assessment of bridges.

1 INTRODUCTION

Maintaining road network access is a critical enabler of the economy and social functionality of any city or region, of which bridges play an important role. In this context, asset owners and managers are faced with the challenge of managing aging bridges in a safe and risk informed manner whilst balancing productivity and access demands.

Asset owners and managers often rely on the engineering profession to help them understand the risks associated with the ongoing management of their structures including providing advice on bridge capacity and access management. However some advice being received is often conservative, indicating a bridge is supposedly unfit for purpose, despite visual evidence to the contrary. The ramifications of a conservative assessment are more likely to lead to strengthening recommendations or access restrictions/diversions, both of which are unpalatable and unnecessarily costly.

This 'plausibility gap' between theoretical assessments indicating bridge capacities are unsatisfactory and satisfactory past performance has been discussed previously (Heywood et al. 2017, Shave, 2003), and fuels the debate surrounding the actual load-carrying capacities of existing structures. Add to this the wealth of data, technology, codes and methodologies that are currently available in relation to assessing existing bridges, it is no wonder asset owners often feel like they are lost in a maze of conflicting information.

It is the intention of this paper to provide some guidance through this maze to empower the asset owner or manager to understand the requirements and outputs of bridge assessments. The paper begins by providing the distinction between design and assessment and then outlines current bridge assessment processes in Australia and selected international jurisdictions. The key to unlocking the bridge assessment maze is to understand the inherent assumptions that underpin every form of assessment, the concept of which is explored through a comparative exercise. An appreciation of the nature and type of assumptions leads to a more informed position regarding actual risks, which ultimately provides the avenue to develop targeted management strategies for individual bridges and on a network-wide basis. These concepts are discussed and explored in the closing sections of the paper.

2 BRIDGE ASSESSMENT PROCESS

2.1 *Overview*

When determining the assessed capacity of a structure it is imperative that the differences between design and assessment are understood. Design procedures are typically conservative by nature, reflecting the need to future-proof new structures for their intended service lives. In contrast, the main task of bridge assessments is to ensure that the structure or parts of the structure do not fail under loading (Rücker et al. 2006). Shave (2003) states that the 'assessment of existing structures is a complex problem that presents different challenges and demands different expertise from design. Fundamentally it requires a deeper understanding of structural theory and, in particular, recognition of the true way structures behave as the ultimate limit state is approached'. Many international codes recognized this by adopting a reliability-based and risk-informed approach to help resolve the often conflicting demands of asset preservation and maintaining operation access where disproportionate expenditure associated with design reliability is unacceptable (Heywood et al. 2017).

Structures are designed to incorporate an operating margin (shown in yellow/red in Figure 1) between the calculated capacity and ultimately failure of a structure to allow for uncertainties in the loading, materials, design process and construction. Therefore, when undertaking an assessment with increased knowledge of the structure, its behavior and the loads it supports, it can be inferred that a smaller operating margin can be accepted when compared with accepting a new structure into service.

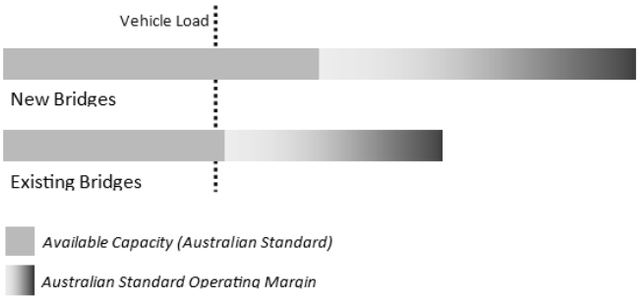

Figure 1: Operating Margins of new versus existing structure

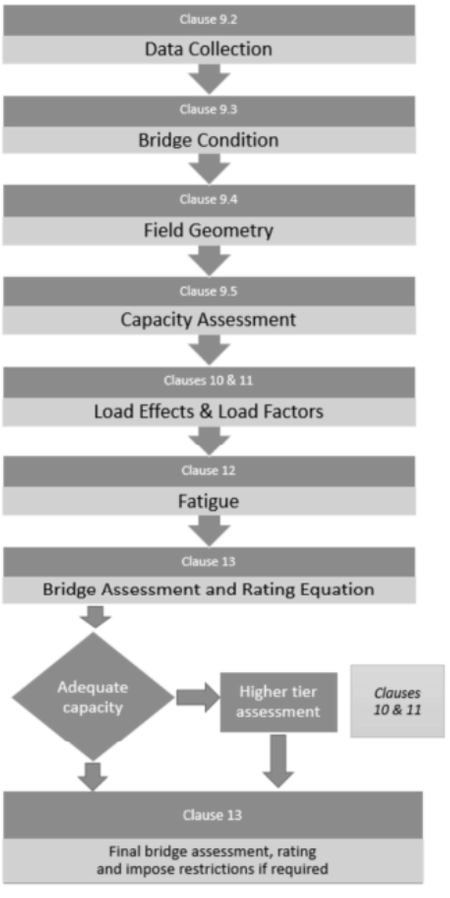
The consequences of a conservative assessment methodology may include the unnecessary and costly strengthening or replacement of an asset. This conservatism arises from the adoption of design parameters for assessment and often leads to a 'plausibility gap' between unsatisfactory theoretical assessments and satisfactory past performance (Heywood et. al. 2017) that needs to be explained. One approach to understanding the plausibility gap is the adoption of realistic, bridge specific assumptions that reflect the actual loading, material strength and behavior of a structure. International assessment standards are addressing the 'plausibility gap', by adopting 'reliability-based' and 'risk-informed' assessment methods (ISO 13822:2015). Many international codes have applied these principles to help resolve the often conflicting demands of asset preservation and maintaining access in circumstances where 'disproportionate' expenditure associated with design reliability is unacceptable.

2.2 *Australian Assessment Approach*

Bridge evaluations within Australia are currently assessed in accordance with requirements set out in the Australian Standard suite (AS 5100); in particular Section 7 (AS5100.7) Assessment (Standards Australia 2017). Part 7 of AS 5100 was introduced in 2004 to rate existing bridges. However, its guidance was predominantly based on design principles, as confirmed by the commentary, which states in Clause C4: "Rating of bridges is based on the same principles and philosophy as the design of new bridges, as specified in AS 5100.1" (Heywood et al. 2014, Ng 2017). The Live Load Factor (LLF) stated for use when assessing a bridge is 2.0 compared with a LLF of 1.8 used when designing for SM1600 loading as specified in Part 2 of AS5100 Australia Standards 2017).



The recently revised version of AS5100.7 (2017) aligns with international practice by presenting a hierarchical framework of increasing complexity to enable optimized outcomes of assessments in accordance with the network access and safety requirements (Ng 2017). This framework is illustrated in Figure 2. Initially the assessment process is still largely based on design principles with capacity reduction factors and load factors in keeping with AS 5100.2 with some reductions being allowed when certain conditions are met (Australian Standards 2017). For example, reductions to the Dynamic Load Allowance (DLA) can be made where speeds are restricted or the measured road roughness is lower than the recommended threshold. Reductions in LLF are allowed when network specific vehicles, such as cranes or heavy load platforms, or if Intelligent Access Program (IAP) monitoring is installed on a vehicle. These modifications are shown in Table 1.

Figure 2, shows that if a structure is deemed to be operating at reduced margins, a higher tier assessment may be undertaken. AS5100.7 permits the use of advanced analysis methods, field testing (such as proof and dynamic load testing), structural health monitoring, and the use of other standards and codes (with approval from the relevant authority) (Standards Australia 2017). There is no specific guidance to Engineers or authorities as to the specific process or assumptions that should be incorporated as a part of a higher order assessment. The most recent ver-

sion of AS5100.7, while providing more advice on assessment of structures, still does not provide sufficient information to adress the 'plausibility' gap between theoretical assessments and in service behaviour that authorities are searching for. For example, there are currently no provisions in AS5100.7 (2017) to account for the remaining service lives of structures, reliability methods, target levels of reliability (β), site specific loading or the use of probabilistic methods in alignment with ISO 13822 and ISO2394:2015 (Ng 2017).

Type of load	Live load factor
Pedestrian, cyclist path and maintenance traffic loads	1.5
Traffic load (road traffic)	
(a) SM1600	1.8
(b) T44	2.0
(c) MS18	2.0
(d) H20-S16	2.0
(e) Semi-trailer, road train, B-double	2.0
(f) Road train and B-double with IAP and on-board mass weighing	1.8
(g) Crane	1.6
(h) Volumetric (livestock, liquid)	1.6
(i) Heavy load platform	1.5
Centrifugal forces (all road traffic)	1.8
Braking forces (all road traffic)	1.8
Traffic load (general rail freight traffic)	1.6
Traffic load (specific rail freight traffic)	1.4
Centrifugal and nosing forces (rail traffic)	1.6
Braking and traction forces (rail traffic)	1.6

Table 1 Traffic Load Factors for the Ultimate Limit State

(Standards Australia 2017)

Figure 2. Overview of AS 5100.7 (2017) existing bridge assessment procedure (Ng 2017)

2.3 *International Assessment Approach*

International assessment standards, such as ISO13822 'Basis for Design of Structures – Assessment of Existing Structures' (ISO 2010) and ISO 2394:2015 'General principles on reliability for structures' (ISO 2015), are addressing the 'plausibility gap', by adopting 'reliability-based' and 'risk-informed' assessment methods. While these standards are not bridge specific, they provide both practical and higher order guidance dedicated to structural assessment that are useful for bridge assessment in order to close the plausibility gap. ISO 13822 mandates that a plausibility check must be undertaken stating that 'discrepancies between the results of structural analysis (e.g. insufficient safety) and the real structural condition (e.g. no sign of distress or failure, satisfactory structural performance) shall be explained'. The standard provides some general guidelines for the assessment of existing structures with a focus on the principles of structural reliability and the consequence of failure. It acknowledges that assessment procedures for existing structures are vastly different to design code requirements for new structures, and that current design codes may provide insufficient knowledge to complete such an assessment in a thorough manner.

ISO 13822 (ISO 2010) provides an overview of a number of methods available to verify the reliability of a structure in terms of safety and serviceability. These include:

- Reliability assessment – takes into account the remaining working life of a structure, the reference period and changes to levels of service, and associated external changes.
- Target reliability level – accepted predetermined criteria to verify the safety and serviceability of a structure.
- Limit states concept – both ultimate and serviceability states are to be assessed, with consideration of the local and global structural effects and ductility.
- Plausibility check – to conduct a critical review of any discrepancies between the results of the analysis and the real-life condition of the structure.
- Assessment based on past performance.

Another standard that is relevant to the assessment of existing structures is ISO 2394:2015 General principles on reliability for structures (ISO 2015). This international standard constitutes a common basis for defining design rules relevant to the construction and in the use of the wide majority of buildings and civil engineering works, whatever the nature or combination of the material used.

ISO 2394:2015 (ISO 2015) constitutes a risk and reliability-informed foundation for decision making concerning the design and assessment of structures. It provides comprehensive guidance to the assessment of structures from both reliability and risk per-

spectives as well as traditional approaches. Its assessment approaches include (Cl 4.4):

- semi-probabilistic (lowest level)
- reliability-based
- risk-informed (highest level)

ISO 13822 (ISO 2010) and ISO 2394:2015 (ISO 2015) provide a framework for advancing bridge assessment in Australia. As discussed in Section 2.2, the new revision of AS5100 Part 7: Bridge Assessment (Standards Australia 2017) takes steps to differentiate between assessment and design. It also states that ISO 13822 (ISO 2010) "may be applied to show that a bridge is safe, provided the original physical and structural integrity of the component under consideration has not been significantly altered and similar traffic conditions have prevailed over the last 20 years (Cl 10.6.1)". This is a simplification of the provisions of ISO 13822 (ISO 2010) which include a number of additional criteria including condition and no changes to the conditions of loading occur.

The American Association of State Highway and Transportation Officials (AASHTO 2011, 2014) and Canadian Highway Bridge Design Code (CHBDC) address the disproportionally high cost of increasing safety of existing structures by adopting reduced target reliability indices compared to the design of new structures. Table 2 highlights the differences in the target reliability index and the reference period, reflected in changes in live load factor, between the design of new bridges and assessment of existing bridges.

Table 2 highlights some significant differences between assessment and design:

- The target reliability indices and the reference periods are smaller for assessment compared with design.
- The margins are smaller and greater care is required. As a consequence other refinements are considered such as ductility, redundancy and inspectability (Canada) and truck traffic volume (USA). The Canadian approach accepts lower margins for elements that are ductile, redundant and inspectable but penalises elements that are brittle, non-redundant and uninspectable. The result is load factors that are generally smaller but can be larger than design load factors. The AASHTO MBE (AASHTO 2011) code accounts for it through a reduction in the capacity reduction factor (ϕ).

In summary, the USA and Canada adopt different standards for accepting new bridges into service which are higher than the standards for removing bridges from service. This approach, which has been used in Canada since the 1980s, is consistent with the risk-informed approach of ISO 2394:2015 (ISO 2015). While the current revision of AS5100.7 has made a step in the right direction in acknowledging the difference between assessment and design, engineers and asset owners are looking for further guidance to explain the 'plausibility gap'. By providing engineers a framework in which to explore the 'plausibility gap' and develop an appreciation for the assumptions and associated risk it will enable asset owners to manage their networks in a more strategic and risk targeted manner.

Design or Assessment	*Reliability index (β)*	*Reference period*	*Load factors*	*Comments*
Canadian Highway Bridge Design Code – CSA S6-14 (12)				
Design	3.5	75 years	1.70	Design LL > 'as of right' traffic
Assessment	2 to 4	1 year	1.40 to 1.77	Depends on ductility, redundancy and inspectability
American Association of State Highway Transport Officials (AASHTO)				
Design	3.5	75 years	1.75	AASHTO LRFD Bridge Design Specification (13)
Assessment (Routine commercial traffic – Operational)	2.5	5 years	1.40 ADTT < 100 1.65 ADTT = 1000 1.80 ADTT > 5000	AASHTO Manual for Bridge Evaluation (MBE) (14)

3 ASSESSMENT ASSUMPTIONS

3.1 *What is the capacity?*

An investigation was carried out by Collins (2015), where a thick slab beam was tested in shear to failure. Prior to undertaking the test, Collins invited 66 engineers from industry and universities to predict the failure load of the beam. A variety of codes were used by the participants and as can be seen in Figure 3, a vast range of answers were calculated from 300kN up to 4000kN. To put these shear capacities into perspective, the flexural capacity of the element was noted to be 2735kN. This leads the reader to question, which capacity is correct?

The beam failed at a load of 685kN. Based on the pre-test estimates provided, the majority of the predicted capacities were non-conservative as shown in blue shading in Figure 3. These results highlight that the assumptions used in an assessment are just as important to understand when making risk informed decisions as the result itself.

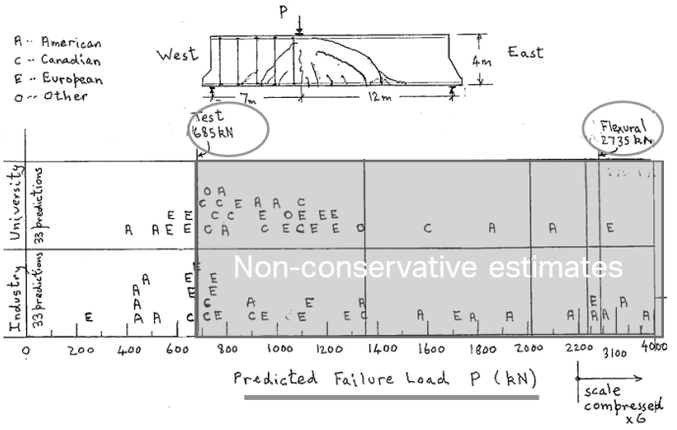

Figure 3: Load Failure Test Results (Collins 2015)

Without an appreciation of the assumptions by which a capacity of a structure is determined, asset owners cannot make informed decisions about the management of their structures.

To further illustrate the significance of assumptions, reviews of assessment outcomes have revealed a high degree of variability in results and a significant number of structures deemed as operating at reduced margins (Shaw et al 2014, Highways Agency 2003). The Queensland Department of Transport and Main Roads (TMR) undertook a review of over 500 bridge assessments and observed conservative and often erroneous results. The review determined that of the first 250 assessments, approximately 160 indicated that bridges were operating at reduced margins often contradicting the past performances of the structures. These low assessment results were due to conservative assumptions based on design practices and the use of inexperienced engineers leading to erroneous results (Shaw et al 2014).

A similar exercise was carried out by Parsons Brinckerhoff on behalf of the Highways Agency UK 10 years earlier (Shave 2003). A review of 294 bridge assessments was undertaken on structures deemed to be operating at reduced margins. The review analysed the reasons for the assessment failure and observed that the main contributing factors were:

- Increased loading
- Conservative analysis and assumptions
- Updates in standards/inappropriate use of standards
- Condition deterioration
- Design or construction errors

Both of these assessment reviews confirm that the assumptions used within an assessment are critical to the end result and that conservative design based assumptions can imply a structure is operating at reduced margins despite it still performing adequately. The results also imply that without a complete appreciation for the assumptions utilized within an assessment, the real risks cannot be understood and in turn managed.

To explore the impact of various assumptions and assessment approaches on assessment ratio, three investigations were undertaken:

- Code Comparison
- Assessment Methodologies
- Assessment Assumptions

3.1 *Limited Code Comparison*

In this section the shear capacity of prestressed concrete I girders are compared using the Canadian Highway Bridge Design Code and the 2004 and 2017 versions of the Australian Standard AS5100.

As discussed in Section 2.3, the CHBDC is one of the international standards that clearly differentiates between assessment and design parameters. It allows for a modification of the LLF based on the Reliability Index (β) and reference period. As shown in Table 3 this often results in a LLF less than that for design. However depending on the ductility, redundancy and inspectability of the element, it can result in an increase. Some of the other key differentiating assessment parameters between the Australian Standards and the CHBDC include:

- Material Factors – rather than use capacity reduction factors, material factors are applied to each individual material depending on the reliability of their properties.
- Dynamic Load Allowance – varies with relation to span. For spans <10m DLA = 0.4. For larger spans the DLA can be reduced up to 0.25.
- Special consideration for higher risk elements – provisions are included for higher risk elements (ductility, low redundancy, uninspectable) by increasing the LLF.

The above commentary by no means highlights all of the points of difference between the three codes. However, the abovementioned factors were used to compare the assessment of shear in pre-

stressed concrete I-girders using the three codes as shown in Table 3.

Table 3 Parameters for Prestressed Concrete I-Girders

Standard	LLF	DLA	Consideration of High Risk Elements	Method
AS5100.7 (2004)	2.0	0.4	No	Empirical
AS5100.7 (2017)	1.8	0.3	No	MCFT
CHBDC	1.8	0.25	Yes	MCFT

Note: MCFT = Modified Compression Field Theory

The following Rating Factor (RF) in accordance with the definition in AS5100.7 (2017) was used in the comparison:

$$RF = \frac{\text{Available bridge capacity for live load effects}}{\text{Live load effects nominated rating vehicle}}$$

Figure 4 illustrates the comparison between the Rating Factors for a particular prestressed concrete I girder superstructure when assessed using the three codes. The difference between the two Australian Standards highlights the difference between the truss analogy and Modified Compression Field Theory (MCFT) methodologies. Despite the differences in approach both indicate the bridge is operating at reduced margins.

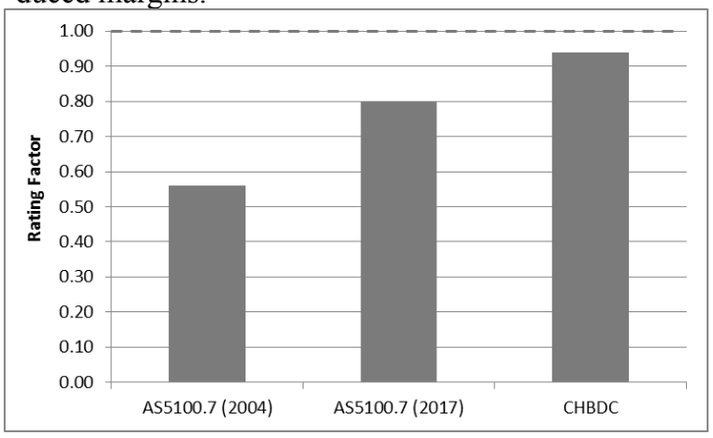

Figure 4 Rating Factor Comparison Prestressed Concrete I Girder Superstructure

The CHBDC is also based on Modified Compression Field Theory; however the capacity calculation is based on material factors compared with capacity reduction factors in the Australian Standards. This results in an increase of approximately 15% in the Rating Factor. The assessed structure showed no signs of overstress in the girders. The results indicate that there can be a significant variation in assessments when utilizing varying standards leading authority's to question their validity and which one is correct, if any. While all of the Rating Factors indicate the bridge is operating at reduced margins, the magnitude of the margin will influence the management strategy reinforcing the importance of understanding the assumptions behind an assessment.

This issue is not isolated to Australia with similar issues identified in USA (French 2010) and Germany (Teworte et al 2015). Moua et al (2017) investigated the impacts of assessment assumptions on the calculation of shear capacities of PSC-G bridges and concluded that the use of design based parameters was conservative for bridge assessments and that the use of higher order assessment methods was required to align with the in situ performances of the structures.

3.2 *Comparison of assessment methodologies*

The assessment of reinforced concrete deck slabs also tends to produce assessment results that are vastly different from the in service performances of structures. An investigation was undertaken to determine the variation in Rating Factor when various assessment methodologies and assumptions were used.

Three assessment methodologies/assumptions as applied to a bridge superstructure with a reinforced concrete slab deck with composite reinforced concrete kerbs, were investigated: elastic analysis; yield line analysis; and yield line analysis (including composite kerb). The comparison of the Rating Factors is shown in Figure 5.

The results indicate that if an elastic analysis approach to assessment is taken, the structure would be deemed to be operating at reduced margins (RF<1). The Highways Agency (2003) released a report stating that elastic analysis of concrete deck slabs can often lead to an inadequate assessment results. Concrete slabs have the ability to redistribute moments significantly prior to the formation of a failure mechanism and therefore an elastic analysis is rarely sufficient to prove that a slab is deficient in flexure.

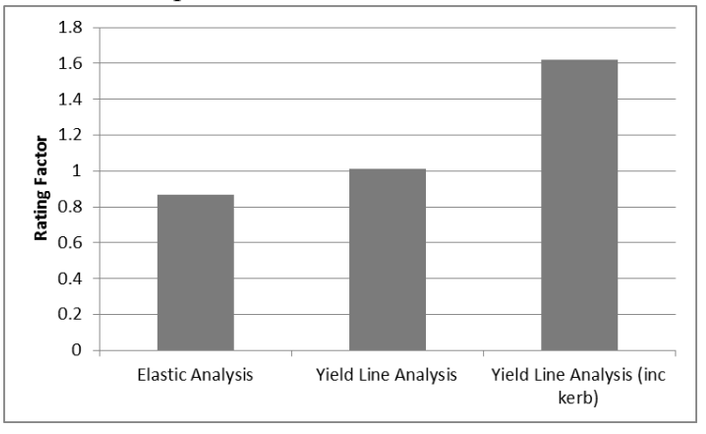

Figure 5 Rating Factor Comparison for Reinforced Concrete Deck Slabs

The yield line analysis indicated that the structure had adequate capacity – just. Whereas if the composite kerb was included, the results indicate the structure has sufficient reserve. The Highways Agency Report (2003) makes recommendations on an appropriate analysis methodology for reinforced concrete deck slabs. These results further build the case that the assumptions and risks associated with assessments must be understood in order to strategically and effectively manage structures on a network.

3.3 *Network Application*

An investigation of a group of 84 bridges was undertaken to compare the effects of assessment assumptions, and in turn investment decisions, across a network of structures. The sample of structures included bridges with prestressed concrete I girder and deck unit superstructures, and a variety of reinforced concrete substructures including portal frames and single columns. All assessed structures were deemed to be functioning satisfactorily based on their past performances under various different traffic scenarios.

The bridges were assessed at both Inventory and Operational Levels (Heywood et al 2017). At an Inventory Level, which is largely based on design parameters, 66 bridges had Rating Factors less than 1. When reassessed using Operational Parameters that reflected the existing life of the structure, condition, actual traffic loads and material properties and any higher risk elements, only 21 structures were deemed to be inadequate with RF <1.

The results once again reflect the importance of understanding the risks associated with the assumptions utilized in bridge assessments. Assessments based on parameters that better reflect the behavior of structures can provide a rational, risk-informed approach for the management of structures that have been deemed to have insufficient margins in accordance with Inventory Level assessments. Operational Assessments assist in explaining the plausibility gap between theoretical assessments and the in-service performance of structures. The use of operational bridge assessments can be used to inform investment and asset management prioritization. A Structure Management Plan should be put in place for operational structures to ensure the assumptions on which the assessment was based continue to align with the operation of the bridge.

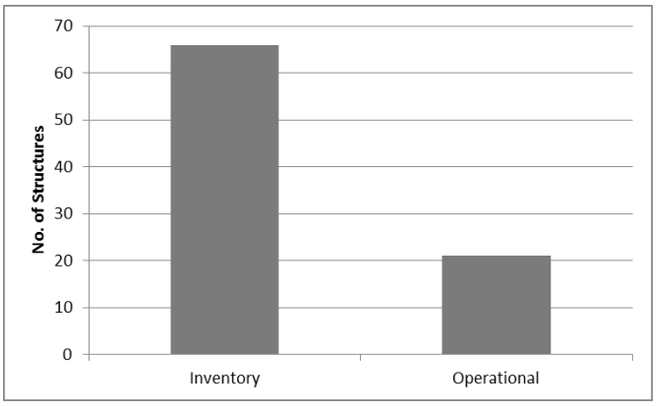

Figure 6 Number of Bridges with Rating Factors <1.0

4 DISCUSSION

The investigations outlined in Section 3 highlight the large variability in bridge assessment results based on the assumptions and methodologies underpinning assessments. Without an appreciation of these assumptions, it can leave asset owners questioning which assessments should be utilized for their management strategies. If conservative design assumptions or methodologies are applied, they can indicate that a significant number of structures are operating at reduced margins which don't correlate with the in-situ behavior of the structures, leading to a plausibility gap. International standards address this issue by applying a framework that allows assessors to include bridge specific assumptions that are based on observed bridge behavior and properties such as material strength. While the Australian Standard enables higher order assessments to be undertaken, there is no specific guidance to engineers or authorities as to the specific process or assumptions that should be incorporated.

It should be noted that higher order assessment does not necessarily indicate the need for refined assessment methods such as Finite Element Analysis (FEA). The investigations presented in Section 3 were undertaken without incorporating refined computer analyses. Assumptions that reflect the actual behaviors of the structures were used in the assessments. Where required, structural health monitoring or material testing can be undertaken to confirm these assumptions. While the use of FEA can be useful in certain circumstances and may indicate additional capacity, in simple elements such as a cantilever headstocks, no matter how refined the model, sufficient increase in operating margin will not be achieved if insufficient reinforcement has been provided in the original design.

When considering a framework for bridge assessments there are opportunities to learn from international experience and practice. Key items for consideration and further investigation include:

– A hierarchical, risk informed approach

- The adoption of a reliability-based assessment methodology
- Incorporation/guidance on the use of operational factors to reflect the actual behaviour of structures. This could include the use of material testing, actual vehicles based on Weigh In Motion (WIM)/Intelligent Access Program (IAP) data
- Consideration of higher risk factors including:
  - Redundancy
  - Inspectability
  - Ductility
- Guidance on appropriate factors to be used for infrequent vehicle assessments with increased control

Organisations, such as Austroads, have undertaken projects to investigate the various methodologies and processes adopted internationally for bridge assessments (Ng 2017). To ensure the ongoing credibility of the engineering profession more guidance is required to ensure bridge assessments results provide asset owners with a true appreciation of the risks associated with the ongoing management of their structures and networks. It is recommended that a supplementary guide be developed to complement AS5100.7.

5 CONCLUSION

Asset owners need to understand and, if necessary, refine the assumptions underpinning a capacity assessment of a structure. Assumptions which reflect actual, in-service behavior of a structure are more likely to result in realistic assessments than higher level analytical models such as Finite Element Analysis. By understanding the assumptions underpinning assessments, asset managers can make risk informed decisions when preparing their asset management strategies.

Bridge Risk Management: Credibility Gaps

P.S. McCarten
Queensland, Australia

ABSTRACT: Bridge asset managers are constantly facing significant challenges with aging bridge stocks, budget constraints and increased pressure from public scrutiny. The industry recognizes there are many technical and economic challenges associated with engineering and managing infrastructure systems. The reality that constructed systems perform differently than envisioned at planning, design, construction and operation phases in conjunction with the limited knowledge of constructed system behavior at different times and under different demand scenarios requires the Bridge Manager to apply a systematic risk based approach to developing maintenance, rehabilitation and replacement programmes.

In order to make good asset management decisions a Bridge Manager needs to:

- Understand the bridge management regime
- Have the knowledge and skills to challenge the code based design standards
- Have the ability to follow a systematic approach to investigating complex system problems
- Have the skills to identify the data (field and analytical) scope, extent and quality required to make informed decisions

For Bridge Asset Management Preservation Programmes to be adopted they must be recognized and accepted as credible by both the asset owner (Road Controlling Authority, RCA) and funding agency. A credibility gap occurs when there is a difference in expectation between the Bridge Manager and the approving agencies (in this Preservation Programme case the RCA and funding agency). Credibility gaps can occur in many aspects of bridge management and involve groups other than the RCA and funding agency, for example the freight industry and public community.

This paper provides an overview of bridge risk management and common credibility gaps and hence reinforces the need for good bridge asset management decision making. The recognition that bridge failures are continuing and with the average bridge age at failure being less than the normal design service life shows improvement in risk decision making is necessary.

1 INTRODUCTION

Bridge Managers have access to multiple tools to assist developing preservation and improvement programmes within a Road Controlling Authority (RCA) network. Bridge inventory and inspection data from both visual and special monitoring (e.g. structural health monitoring SHM) programmes is used with the analytical tools to develop maintenance, rehabilitation and replacement programmes to optimize network asset performance within the available budget. The analytical tools are also used in prioritizing network assets for more detailed assessments when the risks are determined to be significant – but what methods are used to quantify these risks?

Bridges under the responsibility of an RCA are generally public assets with budgets based on public monies. Bush et al (2011) recognized that while efficient application of current knowledge and learning is being achieved it may not be an effective use of effort and resources. Should sub-optimal outcomes result then it is contended there would be an adverse impact on the value of the public infrastructure. New Zealand Office of the Auditor General (NZOAG) and US Government Accountability Office (USGAO) audits confirm concerns in public spending identifying that:

- Bridge asset managers should move away from a maintenance and condition centric viewpoint to align with operational and strategic targets (USGAO 2008)
- Bridge engineers should deal with performance needs of an asset and provide the community with choices surrounding performance criteria (NZOAG 2004 and 2010)

- Bridge asset managers should move toward an advanced asset management approach

Advanced asset management is a process consisting of predictive modeling, risk management and optimized decision making to develop the required life cycle treatment options and long term funding predictions with clear links to delivered projects and strategic targets. Bush et al (2011) highlighted the importance of collecting complete, comprehensive and reliable data to define and report the linkage between bridge management and the wider strategic vision to ensure a sustainable and economic network is achieved.

McCarten (2012, 2014 and 2016) respectively set out the basic risk requirements, set out a performance measure regime which could be used to report the broader network performance and showed how more reliable performance measures could be achieved through a three level hierarchy of data collection, with:

Level 1 – qualitative

Level 2 – quantitative (based on as-built records)

Level 3 – quantitative (based on in-service performance records)

This paper focuses on risk but considers it in the wider context of the bridge management regime. The quality of the bridge risk decision making is also considered by making observations on 'credibility gaps' which suggest improvement may be required for Bridge Managers to maintain their role as trusted advisers to the RCA and wider community. This paper supplements the outcomes reported in the previous McCarten (2012, 2014 and 2016) papers.

2 BACKGROUND & DEFINITIONS

In order to understand bridge risk decision making it is necessary to understand the regime in which the risks are to be quantified and communicated. Most societies today have a degree of litigation, that is the tendency to take legal action to settle disputes. In litigious societies those making the risk decisions will be held accountable for their decisions. It is recognized those decisions will tend to be 'defensive' because the decision makers will be afraid of the cost, both monetary and reputational, if there is any possibility the decision taken could be inaccurate. Business sectors which consider they may be disadvantaged by bridge asset management decision making, e.g. the freight sector may consider decisions to downgrade a bridge load carrying capacity significantly and adversely impact their operations, and may pursue their right to challenge the decision making.

Bridge Managers and Bridge Engineers operating in a litigious regime will recognize the need for using high quality information, utilizing industry best practice and recognized assessment techniques to make the quality decisions expected by the RCA, industry and wider community.

Credibility is the quality of being 'trusted and believed' and relies on attributes of trustworthiness, reliability, dependability and integrity. Bridge Managers and Bridge Engineers must be credible to undertake their role as an adviser to the RCA.

A 'Credibility Gap' is defined as the apparent difference between what is said or promised by a representative of the government, large corporation or RCA and what happens or what is true. While the term first came into use in the 1960's and 70's with journalism, political and public discourse and was usually associated with skepticism about politicians it is now gaining wider use and is recognized in engineering and infrastructure management.

While it is clearly desirable to minimise the possibility of generating Credibility Gaps this paper will show that this outcome is unlikely for all gaps and Bridge Managers must manage them. Credibility Gaps will generally occur when the 'normal' bridge management and bridge engineering practices do not give the outcome expected by the RCA, industry and community.

This paper reviews bridge management systems and practices to identify likely and typical Credibility Gaps and provides suggestions for managing them.

3 MANAGING INFRASTRUCTURE SYSTEMS

Aktan et al (2013) have provided a comprehensive summary paper on managing complex engineering infrastructure systems. Civil engineering is a unique discipline as it is based on constructed systems while other engineering disciplines deal with manufactured products. Constructed systems are distinct in the way they are planned, financed, designed constructed and operated – especially with the uncertainties of as-built properties, loading, response and predicting changes in performance due to site specific conditions and environmental factors. The reality of how constructed systems actually perform can be significantly different from that envisioned by the designers, constructors and operators. It is recognized that each constructed system may perform differently at different sites even though the system is of a standard design.

The basic form for engineering and management of infrastructure systems is illustrated in Table 1 below.

Table 1: Performance Limit States, Hazard Event Exceedance Probability in the remaining Service Life (EP in SL), Criteria and Management

Limit State	EP in SL (%)	Performance Criteria	Lifecycle Asset Management
Utility & Functionality	100	Operational efficiency, safety & security; Robust and	Operational Management

		predictable lifecycle revenue stream	
Serviceability & Durability	>96	Effective and economical inspection, maintenance, repair & rehabilitation during lifecycle	Maintenance Management
Life Safety & Stability of Failure	20 - 60	Assurance of life safety, quick recovery of normal operations following a hazard (days-months)	Multi-hazards Risk Management
Safety at Conditional Limit States	<5	Minimise casualties, Protect escape routes, evacuation, search and rescue needs, Economic recovery (years)	Disaster response, Planning and Emergency Management

Table 1 shows the need to link the remaining service life EP for the limit state hazard events, the performance criteria for each limit state and the need for asset management throughout the lifecycle to ensure the performance requirements are met. It then becomes the responsibility of the Bridge Management team to either manage each bridge with compliance to the general Performance Limit States scheduled in Table 1 or to those specified by the RCA.

Bridge Managers are usually allowed the opportunity to adopt their own management strategy to achieve the specified performance requirements. While a wide range of management approaches can be adopted they are usually bounded by the following extreme strategies,

(a) Reactive approach to bridge management

(b) Proactive approach to bridge management

In many cases the RCA requirements will be set for a Bridge Management program which fixes the Bridge Inspection program and hence the use of the above strategies will be limited to either bridges requiring monitoring/special inspections or bridges identified with defects.

4 BRIDGE RISK MANAGEMENT

McCarten (2012) provided a comprehensive summary of bridge risk and risk assessment techniques from the basic definition with

- Likelihood considered to be the chance of something happening, often related to probability
- Consequence being the outcome of an event affecting objectives

The summary reinforced the need to implement risk management planning to obtain quality and extensive information on the fundamental issues:

- What can happen, how and why – by identifying the range of hazardous effects and the associated range of impacts on the structure response
- The possible consequences (in terms of impacts on objectives) and the factors influencing them
- The likelihood of the consequences and understanding what may affect the likelihood
- The effectiveness of controls in modifying the consequences or their likelihood
- The acceptability of the risk or the need for mitigation

Bridge management decision making is commonly based on using cost benefit analysis but this technique does not necessarily give high transparency for the risk decisions made.

The wider engineering industry has recognized the need to have transparency in risk decision making and provide guidance on industry and community acceptability. While there is still ongoing discussion and debate on the form and standards for risk management the representation given in Figure 1 below shows that generally accepted and in use.

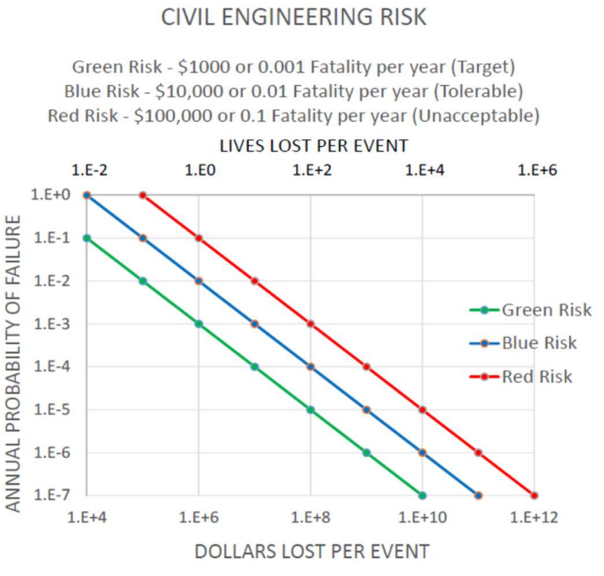

Figure 1. Civil Engineering Risk

Figure 1 has evolved from various studies including the following:

- the USACE to define acceptable risk for dam safety
- Baecher and Christian (2003) into geotechnical engineering risk
- Briaud et al (2013) into bridge scour risk

These studies have shown the risk representation and standards can be applied to various fields of civil engineering, but should they be applied to bridge management? This paper considers and reviews this proposition.

Figure 1 shows the generalized form for defining Civil Engineering Risk standards, recording target or acceptable [Green line], tolerable [Blue line] and unacceptable [Red line] risk standards. Figure 1 presents likelihood using 'Annual Probability of Failure' and consequences both in terms of 'Lives Lost per Event' and 'Dollars Lost per Event'.

While Figure 1 is used in this paper for discussion purposes for the application to a particular RCA calibration would be required, including:

- Adjusting the 'Dollars Lost per Event' to reflect the relevant currency
- Provide a method for adjusting the currency with time to ensure ongoing relevancy, and
- Calibrating the 'currency/life lost' ratio to meet jurisdiction requirements

Although Figure 1 has wide acceptance the presentation can be rationalized to take into account bridge management commonality and better fit bridge management decision making. Bridge hazards can be considered as likely, possible and extreme and relating these to repair, rehabilitation and replacement strategies is considered desirable. In this paper a well-managed bridge strategy will acknowledge extreme consequences (e.g. loss of life) are possible but this should not control basic decision making. More in-depth options analysis decision making would need to consider these consequences. The "Dollars Lost per Event" is the parameter that typically controls basic bridge decision making. In this paper it is assumed the bridge team is able to define and determine all direct costs associated with any repair/rehabilitation/replacement bridge strategy.

Over the last 20 years there has been significant research into methods and data requirements for determining the costs of bridge failure and the work of Wong et al (2005) provides a comprehensive summary of the direct and indirect costs that need to be determined. Wong et al (2005) developed methods for determining the cost consequences of both element and system failures for bridges, recognizing the differences between these bridge failure types, and identified there were deficiencies in the available information. The costs to be determined can be scheduled as below:

Direct Costs
- Bridge replacement (system failure)
- Bridge repair/rehabilitation (element failure)
- Access, traffic management and bridge removal (system failure)

Indirect Costs
- Traffic delay and diversion (element or system failure) during the bridge work
- Casualties (fatalities and injuries)
- Other costs, e.g. public enquiry/litigation, cost of reassessments of similar structures in the network (system failure), adverse public opinion and loss of morale

In this study it is necessary to determine the ratio of Total Cost/Direct Cost (TC/DC) for each event, recognizing the difference between an element failure and system failure event types, and irrespective of whether the event is planned (under a repair/rehabilitation/replacement program) or not. Wong et al (2005) investigated 9 case studies of bridges, with different materials, located in urban settings with relatively high levels of network redundancy (with many alternate routes available), bridges positioned over rail or road, and carrying relatively high traffic volumes (greater than 20,000 vpd along the road corridors). Based on the direct and indirect assumptions made in this study the Wong et al (2005) information suggests the following typical TC/DC ratios:

- Element failure 4.5 and 11.4
- Structural failure 41.5 and 49.8

Bridges in rural settings are typically located in a network with low level redundancy (low number of alternative routes), over waterways and carry relatively low traffic volumes and are expected to have significantly different TC/DC ratios. The Works Consultancy Services (1990) report determined actual direct costs of a bridge failure and assessed the indirect costs using the jurisdiction analysis method. Based on the assumptions in this study the Works Consultancy Services (1990) information provides a TC/DC ratio of 2.4 for the system failure. The bridge that failed was located adjacent to a small rural town (5,245 population) with limited network redundancy (the diversion cost was a significant proportion of the actual costs), the bridge was over water, bridge failure required temporary facility for utilities and pedestrian access (additional actual costs), and, the traffic volume carried on the bridge was low 3,217 vpd.

From the cases presented above there are clearly significant differences in the TC/DC ratio with these explained by the comments above. In this study the focus is bridge management decision making and it is considered both appropriate and realistic to use "lower bound" TC/DC ratios. The following TC/DC ratios have been adopted for the "lower bound"

- Element failure 2.5
- Structural failure 2.5

In adopting these TC/DC values it needs to be recognized the Direct Costs include all those necessary to complete the repair/rehabilitation/replacement, including:

- Actual physical works of the repair/rehabilitation/replacement
- Access works, including scaffolding, etc
- Temporary traffic management works, including diversion or shifting traffic routes through staged construction
- Temporary works removal, including diversions and the old bridge removal should a bridge replacement be required

It is also necessary to recognize that bridge management decisions involve financial expenditure and hence requires consideration of the 'true jurisdiction cost' of the indirect costs. In this study a sensitivity approach is taken to represent the jurisdiction perspective with an "upper bound" for decision making being TD/DC = 1.5. Based on this assessment the 'business as usual' tolerable risk guidance is given in Table 2 assuming the likely, possible and extreme bridge hazards have annual exceedance probabilities (AEP) of ≥ 20%, 3% and ≤ 0.5% respectively.

Table 2: Bridge Management Decision Making – Business as Usual
(Tolerable Risk $10,000 – Blue line)

Hazard	AEP (%)	"Dollars per Event" - Direct Cost	
		Maximum "Upper bound"	Element or System Failure "Lower bound"
Likely	≥ 20	$33,300	$20,000
Possible	3	$222,200	$130,000
Extreme	≤ 0.5	$1,333,300	$800,000

5 BRIDGE MANAGEMENT CREDIBILITY GAPS

The general definition of a Credibility Gap is presented above but in application to bridge management three different forms are identified. The forms are associated with different aspects of bridge management and are dependent on the 'degree of transparency' and 'level of communication' undertaken by the RCA or relevant stakeholder, e.g. funding agency. The three forms are given below:

1. Credibility Gap 1: Acceptance of the bridge maintenance or investment program. This gap is usually characterized by 'interest groups' within the community advising the investment program does not align with their expectations. Management of Credibility Gap 1 is focused on communications and consultation to ensure outcome expectations are better aligned
2. Credibility Gap 2: RCA bridge planning does not align with current practice. This gap is usually characterized by 'industry stakeholders'. An example of this gap is heavy haulage route planning where RCA information on route selection and strengthening requirements is based on theoretical analysis but industry practice based on actual usage suggests different outcomes, refer to Heywood (2016). Additional data collection, analysis and review, possibly with independent verification may be required to close the gap
3. Credibility Gap 3: RCA risk decision making does not align with government or community expectations. Three sub-types of Credibility Gap 3 occur with these defined by:
    a. Expected (Planned): 'Business As Usual' (BAU) bridge risk management. Bridge Manager and Bridge Management Team are required to know the assets, know the environment and associated hazards and manage the bridges accordingly. It is assumed the bridge service life is 100 years and hazards with 50% probability of occurrence in the service life (i.e. a 0.5% AEP of occurrence or 200 year return period event) should be managed
    b. Unexpected (Unplanned): Extreme event risk management. It is necessary to define the bounds of the BAU risk management to know whether the risks are extreme or not, and those used in this paper are given above
    c. Varying (Policy dependent): This Credibility Gap is essentially a subtype (a) but with uncertainty in assessing either the hazard or consequences and hence risk is poorly defined. Examples include lack of understanding the environment (e.g. seismic hazards (fault location and fault movement magnitude and likelihood) in some countries are not fully mapped and defined) or scientific evidence of hazards is not fully available (e.g. climate change). This reinforces the need for the Bridge Manager and Management Team to know the bounds of the BAU risks

Credibility demands are increasing with increasing traffic and freight demands and higher performance expectations. The case studies and discussions given

below focus on Credibility Gap 3 Sub-type (a) BAU bridge risk management.

6 CASE STUDIES

Four case studies are presented below providing different perspectives of bridge risk and failure issues before summarizing observations and detailed evaluations.

6.1 *General bridge failure analysis (2003)*

Wardhana and Hadipriono (2003) undertook analysis of over 500 bridge failures that occurred between 1989 and 2000 in the United States. The study found the failures related to design, detailing, construction, maintenance, materials and external event categories. The average bridge failure rate was 42 bridges per year and the average age at bridge failure was 52.5 years, with the range of ages from 1 year (during construction) to 157 years. The most frequent causes of bridge failure were attributed to floods and collisions, with floods (including scour) representing 53% of all failures. Bridge overload and lateral impact forces, from trucks, barges/ships and trains) constituted 20% of all bridge failures. The study reported that the design process was vulnerable to discontinuity or loss of the original design concepts. The mistakes, errors and omissions in the design process and the need for the bridge management team to be fully aware of the design concepts was emphasized. The study analysed the bridge type and bridge material to determine the numbers of failures of each. While the analysis did show that steel beam/girder and steel truss bridges constituted over 50% of all the bridge failures the study did not relate the numbers of bridge failures to the total numbers of each bridge type in the sample network studied nor relate the bridge failure category to the bridge type to determine the true vulnerability of each bridge and material type. The study recommended categorizing the failures as enabling (design or maintenance process), triggering (external event) and procedural (or management related) and suggested data for each should be collected and included into existing or new databases for future analysis. The study found that 11% of bridge failures were attributed to enabling causes with 85% to triggering causes. Further analysis showed 8% of the failures were maintenance related. The study reinforced the need for Bridge Managers to understand the triggering risks.

6.2 *General bridge failure performance (2014)*

Cook (2014) undertook analysis of over 100 bridge failures that occurred between 1987 and 2011 on a sample of New York State Department of Transportation bridges in the United States. The study followed the general method used by Wardhana and Hadipriono (2003) in respect to cause categorization but used the sample size to determine annual probability of failure estimates. The study also assessed conditional probabilities of collapse rates with consideration of the features used for the constructed bridges. The average bridge failure rate of 1/4,700 for the sample was verified by analyzing a further 6 samples before extrapolating to predict a total United States collapse rate of 128 bridges/years (95% confidence interval of between 87 and 222). The most frequent cause of bridge failure was attributed to floods and collisions, with floods (including scour) representing 52% of all failures. Bridge overload and lateral impact forces, from trucks) constituted over 30% of all bridge failures. The study recognized the sample may indicate failure trends specific to practices used in the sample region. The hydraulic data was analysed to check sub-category failure rates but the lack of clarity in the data limited this, it was considered that up to 80% of the hydraulic failures may be attributed to scour. The study found no significant reduction in collapse rate with enhancement of bridge design regulations. Although bridge age was a significant factor in maintenance and condition failures it was not significant in external event or triggered failures. Figure 2 below shows the distribution of bridge failures by age for the sample population.

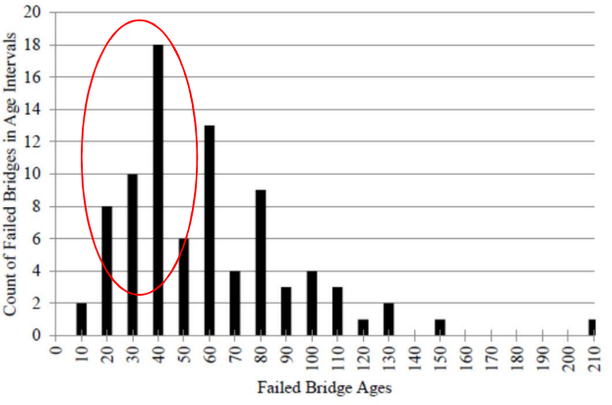

Figure 2. Distribution of bridge failures by age.

The average failure age is 54.8 years with a median of 50.5 years. The recognition that half the bridge failures have an age of less than 50 years, that hydraulic failures are common (with an average failure age of 47.9 years) and that the flood events that caused the failures are typically within the design standard range suggests there is room for improvement. It was noted that insufficient failure data was available to test the benefits of implementing under water inspections. The study report determined that by reducing the hydraulic failures by approximately 50% could reduce the annual total bridge failure rate by almost 30% and it is observed by addressing the failures highlighted in Figure 2 could improve the failure distribution and

the average bridge age at failure. The study concluded that more detailed information was required, on both causes and consequences, for future failure analysis and this requires a more robust data collection system that should be regulated or mandated at a federal level.

6.3 *Wairoa Bridge failure (1988)*

During Cyclone Bola (March 1988) the 56year old Wairoa Bridge failed with 6 of the 12 spans being washed away. The bridge provided SH2 access through the rural town of Wairoa (population 5,245) carrying traffic (AADT 3,217 vpd), pedestrians and the town main utilities. The replacement bridge was opened in December 1989 and a study of the failure costs was reported in Works Consultancy Services (1990). The costs took into account the initial 31km detour (March to June 1988) and the subsequent 12km detour in place through to bridge opening. While the new bridge direct costs amounted to $6.9M, other infrastructure costs (including both direct and consequential) amounted to $3.4M and when the additional road user costs were assessed the total cost of the bridge failure amounted to $18M. There was no loss of life associated with this bridge failure. The consequential costs were determined to be approximately 2.4 times the direct infrastructure costs. Hydraulic studies undertaken as part of the bridge replacement design showed the flow discharge experienced during the flood approximated 3% AEP event while the storm was assessed at a 1% AEP event. Even without correcting the dollars for time plotting these historic dollars and event probability range on Figure 1 shows the bridge failure falls beyond the 'unacceptable' red line. The bridge management industry needs to review this type of event to determine appropriate guidelines for managing the associated risks.

6.4 *Minneapolis I-35W Bridge failure (2007)*

In August 2007 the Minneapolis I-35W Mississippi River Bridge failed completely under peak hour traffic. The bridge (Wikipedia 2017) provided direct access to downtown Minneapolis, the University of Minnesota, area businesses and north suburban destinations for more than 140,000 vehicles per day. The bridge failure resulted in 13 deaths and 145 injuries and in any risk measure this is considered 'unacceptable'. The additional transportation costs associated with the failure due to detours (time and travel costs) were determined to approximate $400,000 per day and total $220M before bridge replacement, no cost has been put on the loss of human life. The economic impact of the bridge failure was estimated at $113,000 per day or $60M before bridge replacement. The replacement bridge cost was $234M. The technical review of the failure determined under sized gusset plates and renovations that reduced bridge strength and added extra bridge loading caused the failure. From ongoing inspection and rating the bridge was known to be structurally deficient. While the author is not aware of any failure probability assessment it clearly failed in the 40year service life and could be given a 0.5% to 3% AEP range. Plotting this event on Figure 1 clearly shows the event was 'unacceptable'. Due to the high profile of this failure the bridge management was put under close scrutiny and the duty of care and ethics of the team challenged and the litigation cases were substantial. The bridge management industry needs to review the decision making for this type of event to determine guidelines for managing the associated risks.

7 DISCUSSION

Bridge Managers need to show accountability and governance for the network bridge stock. In order to achieve this outcome informed decision making is required in all aspects of bridge management. Transparent and appropriate investigation, analysis and option assessment provides accountability for the processes. Credibility for the outcomes is tested when they are communicated to others. The paper has presented three types of credibility gap that may need to be managed. The Type One and Two credibility gaps can generally be addressed through comprehensive and transparent technical and communication processes. Type three, risk management, credibility gaps are starting to be recognized as the industry and community are being informed on the performance expected. Currently there are only a limited number of jurisdictions maintaining records of bridge failures and the standards for acceptable bridge risk management have not yet been set. Through the case studies of bridge failures and consideration of the Civil Engineering Risk the following potential credibility gap issues were identified:

1. Failure likelihood has been reported as 1/4,700 bridges, but should this be 1/6,000 or 1/10,000 to reflect the consequential costs to the community?
2. Failures typically occur during the bridge service life
3. Average bridge age considering all failures is 54.8 years, well below the design service life
4. Average bridge age for hydraulic failures is 47.9 years, well below the design service life
5. Specific bridge collapse failures show the consequential costs are significant and by most community measures are 'unacceptable', this is supported when the events are

plotted on the industry wide Civil Engineering Risk profile, Figure 1

6. There should be an industry agreed definition of bridge failure
7. Improvement in failure reporting and analysis is required to ensure informed decisions are made from the 'lessons learned'

It is recognized that managed bridge repair, rehabilitation and replacement limits the consequential costs and hence results in more acceptable bridge risk management. Examination of the bridge failure age distribution shows there is significant benefit in 'lessons learned' from the young bridge failures. Comparisons made to the industry developed Civil Engineering Risk profiles made in this study show it can provide a transparent basis for bridge management and the 'tolerable cost bounds' given in Table 2 could be used in decision making. It is recognized that should a bridge collapse occur then the event will most likely be 'unacceptable' and hence it is considered the RCA should encourage bridge managers to use a proactive preventive approach for bridge risk management to minimize the potential for extreme failures.

In order to manage the 'unacceptability' and consequences of extreme failures RCA's should be prepared. It is considered necessary for RCA's to have preparedness and emergency planning in place, with this involving ready access to temporary bridging facilities, trained and prepared recovery teams and emergency funding to manage the events. This study also reinforces the need to have high quality recording systems and emphasizes the seamless integration between bridge design and management teams.

8 CONCLUSIONS

It is concluded there is significant potential for credibility gaps in bridge risk management. To meet funding agency and community requirements for transparency and accountability it is suggested the industry wide Civil Engineering Risk be accepted for bridge management and the 'tolerable risk' profile be adopted for business as usual decision making. It is recognized that should bridge collapses occur the consequences will most likely be beyond the 'unacceptable risk' profile. To ensure credibility the RCA should encourage proactive preventive bridge management strategies be followed and preparedness and emergency planning be implemented. Jurisdictions must implement and maintain bridge failure reporting and regularly review and report on 'lessons learned'. Increasing traffic and freight demands on the road network in conjunction with increased expectations of performance reinforce the need for ongoing improvement in bridge risk management.

9 DISCLAIMER

The observations in this paper are those of the author and are presented to advance the topic in practice.

Codes and standard issues in assessing existing bridges

R. Pavan E. Siviero
AP&P srl, Italy

ABSTRACT: The assessment of existing structures adopting a specific code or standard is a technical procedure that is provided only in some nation. The possibility of harmonizing these type of procedure is needed in Europe, together with a completely new plan of infrastructural renewal. In this study new insight on this theme are provided, together with some code proposal for the new Eurocode era.

1 INTRODUCTION

Many existing bridges all over the world were not designed for the high service loads and the increased number of load cycles that they are exposed to today. Some bridges will have to be either strengthened or replaced in the next decades. Advancing their age, bridges could be subjected to a large variety of not designed actions or could also be not accurately maintained, leading to a particular state in which they need particular care and attention, in order to remain in service. Moreover, existing structures were not exempted from serious failures and engineers had regularly to suffer setbacks.
These setbacks contributed in many cases, however, to research and advancements in better understanding structural behavior and developing new theories (Kuhn et al. 2010). In these cases, the assessment procedures are needed.
The assessment of an existing structure aims at producing evidence that it will function safely over a specified residual service life. It is mainly based on the results of assessing hazards and load effects to be anticipated in the future, and of assessing material properties and geometry taking into account the present state of the structure (JCSS 2001). Guidelines for existing structures exist in a large number of countries. Thereby many countries have presented documents for particular categories of structures. In Canada, Germany, the Netherlands, Switzerland, UK and USA such guidelines have been prepared at a detailed level. In any assessment, the problem of fixing risk acceptance criteria is difficult since it must be compatible to codes for new structures (limit state analysis, safety factor format, etc.), and with national determined parameters (generally partial safety factor values) (Kuhn et al. 2010).

Figure 1. A multi span historical truss bridge.

As far as specific code and standards are not available, technical guide or pre-standard documents should be used. Moreover, procedures coming from evidenced based or field related experience, are quite extensively used also by bridge and infrastructures owner. Basing on past studies and research, a simplified approach has been developed by the author and applied in recent investigations of existing bridges. This approach is reported in the following paragraphs.

2 ASSESSMENT

2.1 *Ist level assessment*

The preliminary evaluation is the first level of investigation aiming at removing existing doubts about the safety of existing structures, adopting fairly simple methods and identifying critical parts or members in the structure. In order to identify critical members, it is necessary to carry out an intensive study of the available original design documents, along with a visual inspection of the structure and a photographic survey. The inspection procedure is of-

ten coded by infrastructural agencies manuals and procedures; however, at least the following points must be checked:

• The bridge construction is conforming to the original drawings and/or differences between as-built and drawings.

• Bridge modification during service (rehabilitation, strengthening, changes in the static system, etc.).

• Presence of any visual evidence of degradation (damaged expansion joints, supports, corrosion, cracks, vibration or loose rivets, collision, lack of structural members etc.).

Moreover, if available, inspection and maintenance reports can be used, and reference should be made to the evaluation report. The preliminary evaluation should include codes and recommendations analysis procedure where available, and conservative assumptions where information is lacking or doubtful. In this way, critical construction details can be identified.

2.2 *IInd level assessment*

The aim of the detailed investigation is to update the information obtained in other analysis by carrying out a refined assessment, especially for those members for which adequate safety was not confirmed by preliminary evaluation. At this stage a specialized consultant should assist. In this phase a FEM numeric model of the entire structure is developed. Based on the current code provisions, the structure should be recalculated and verification tables should report whether the structural members are safe or not. Concerning specific issues, such as the fatigue and seismic behavior of the bridge, detailed code provisions should be referred to. From this step-level investigation, non-destructive testing (NDT) could be used in order to characterize the basic material properties of the structure. The final report of the investigation should establish whether the structure is verified against specific issues and has sufficient static strength against actual loadings.

2.3 *IIIrd level assessment*

In case of key structures that have major consequences in terms of risks or costs related to a decision, a team of experts is needed in order to carefully check the conclusions and proposals reached in the last phase. Discussions and further assessments using specific tools can also be carried out to help reach decisions. At this level, on-site testing could be adopted in order to provide the dynamic identification of the structure, as reported in the following example.

2.4 *IVth level assessment*

This advanced level of investigation should be reserved for recurrent bridges along infrastructural nets, in which a rational procedure of analysis and intervention could help in determining if retrofitting interventions could be adopted, or if rational dismantling large scale operations are required. The procedure is based on a detailed survey of the existing bridge, a FEM analysis, a code verification procedure, NDT diffused sampling, and, based on these data on real scale testing of one case study structure, aims to determine the global static and cyclic behavior of the bridge. In specific cases, on-site dynamic identification could be performed. Concerning the fatigue assessment, in this case a LEFM investigation is required. Concerning seismic analysis, non-linear analysis is required. Specific material testing analysis should be performed dealing with the case analyzed. The advanced testing result should report on the various analysis performed, and should clearly state verification results indicating the specific retrofit needed for recurrent interventions. An advanced testing operation is reported in the following section, dealing with a recurrent existing bridge type in service along the railway lines.

2.5 *Assessment case studies*

As reported in the aforementioned step level classification, various stages of analysis could be adopted by bridge owners or managing agencies. Some examples have been developed by the author and could be found in detail in Pipinato (2016) the assessment of a new bridge is presented in order to evaluate different typologies of construction alternatives to gain different lifetime; while in Pipinato (2014) the assessment and rehabilitation of steel railway bridges using fiber-reinforced polymer (FRP) composites in the particular situation of the rehabilitation of metallic civil infrastructure using fiber reinforced polymer (FRP) composites is evaluated. The residual life of historic riveted steel bridges could be also assessed with an analytical approach or introducing an orthotropic steel deck design to extend the lifetime of plate and box girder bridge and viaducts, as explained in Pipinato et al. 2014 and in Pipinato (2014a). And however steel bridge exhibited in the past a wide amount of problems not evidenced in other bridges (Pipinato 2014b), for this particular type of structure a variety of technologies to repair and retrofit are available: this is the case reported for the fracture propagation and life cycle design of girders (Pipinato 2014c), or for advanced solutions of the corrosion protection (Pipinato 2014d). For network of bridges, however, an integrated solution has been presented in order to understand what is the possibility of prioritizing the bridge retrofit (Pipinato 2013a). A particular asset of bridges in

which the lifecycle assessment should be performed from the design stage is the case of long span bridges, where the traffic is represented also from exceptional moving loads and the consequent fatigue expected lifetime could fail in less than ten years from the construction stage if a correct detailing is not perceived (Pipinato 2013b-2013c-2010d); similar issues comes also from the original construction alternative choses, as demonstrated in Pipinato et al. 2012a. The particular case of fatigue sensitive materials of course is more recurrent in steel bridges where retrofit and assessment alternatives are in part applied (Pipinato 2012b), in part not well investigated, as is the case of coupled damages (seismic and fatigue, Pipinato 2012a,b, Pipinato et al. 2012c,d,e,f, Pipinato et al. 2011c,d). Wherever there is the possibility to investigate with full scale tests existing bridges, e.g. where managing agencies are interested to know the structural behavior of recurrent structures along their network, this could be an interesting occasion to understand how materials decay could influence the static and fatigue behavior of bridges: this is the case both of railway (Pipinato et al. 2011a,b, Pipinato 2011, Pipinato 2010b, Pipinato et al. 2010a,b,c,e Pipinato 2010, Pipinato et al. 2009, 2008a,b, Pipinato et al. 2007) and roadways (Pipinato 2010a). A particular and further subset is represented by monumental and large bridge structures (Pipinato and Modena 2010): in this case, a long and time-consuming but useful procedure should be performed, by evaluating al the assessment steps described before, in order to understand in detail the aforementioned problems that could influence the final retrofit design decision.

3 ESTIMATION OF KNOWLEDGE LEVEL AND CONFIDENCE FACTOR

The application of the aforementioned assessment procedures, lead to consequences in the structural analysis of the structure. Generally, as much information and tests have been performed onto the bridge, as much knowledge has been accumulated onto the structure, leading to more accurate data on the structural properties of materials, and on the structural behavior of the bridge itself. On the basis of this, a knowledge level listing could be drafted out, and consequently the so-called confidence factors could be applied, in a very similar procedure to the Italian existing standard for the assessment of existing buildings (Ministerial Decree, 2008).

3.1 *KL1-Knowledge level 1*

Geometry: the geometry of the structure is known or from a survey or from original drawings. In the latter case a visual survey is required to confirm the documentation. Collected data should be sufficient for developing a linear analysis.

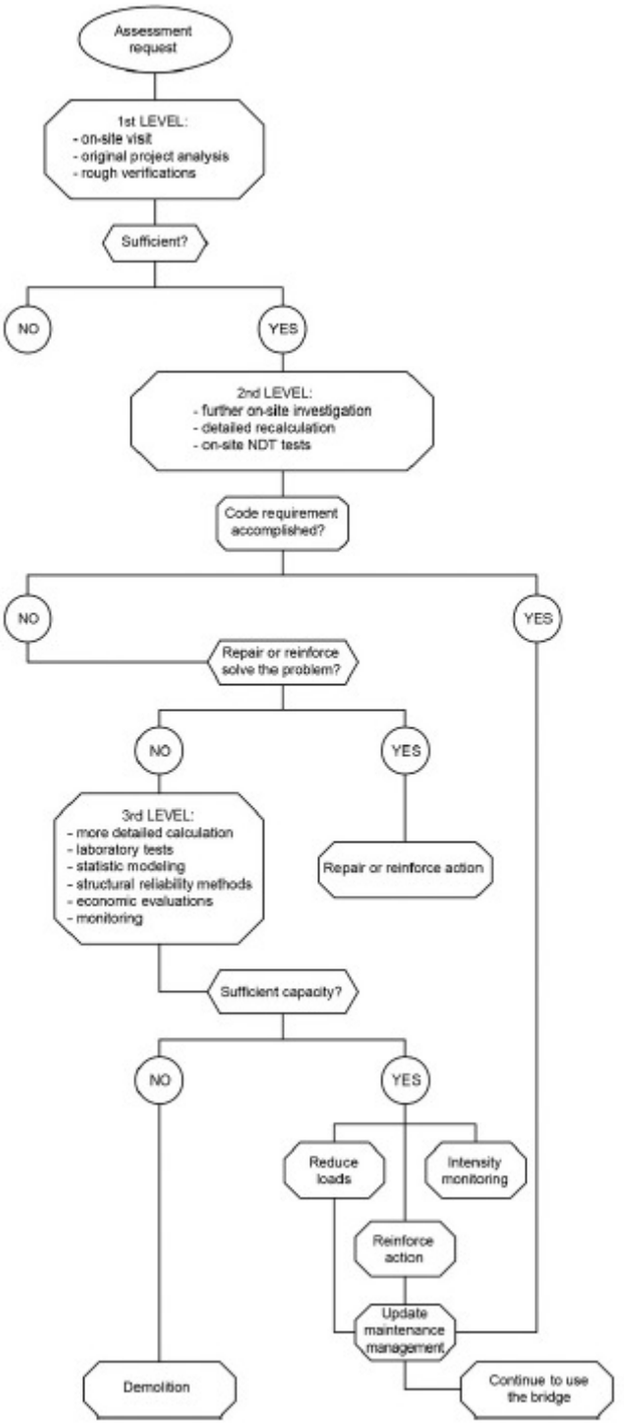

Figure 2. Step level assessment.

Structural details: details are not available from drawings and are designed according the practice of the construction age. A limited in situ verification is requested. Local resistance verification are required.
Materials property: material properties are not available, neither from the original documents, nor from original tests. Usual values of the practice are adopted, validated from limited in-situ tests.
Structural analysis type: The safety assessment in the case of limited knowledge is usually performed by static and dynamic linear analysis methods.

3.2 *KL2-Knowledge level 2*

Geometry: the geometry of the structure is known or from a survey or from original construction drawings. In the latter case a visual survey is required to confirm the documentation. Collected data should be sufficient for developing a linear or a non-linear analysis.
Structural details: details are available from original drawings or from not original construction documents. In this last situation, a limited verification of common details is performed. Local resistance verification are performed.
Materials property: material properties are available, from the original documents, or from original tests. Extensive in situ tests are performed to validate the original data whereas they are available from design and not from tests.
Structural analysis type: The safety assessment in the case of limited knowledge is usually performed by static and dynamic linear or non-linear analysis methods.

3.3 *KL3-Knowledge level 3*

Geometry: the geometry of the structure is known or from a survey or from original drawings. In the latter case a visual survey is required to confirm the documentation. Collected data should be sufficient for developing a linear or a non-linear analysis.
Structural details: details are available from original drawings or from original construction documents. Available data enable the implementation of a complete linear FEM model, performing local resistance verification, or the implementation of a non-linear model.
Materials property: material properties are available, from the original documents, or from original tests, or from an extensive in situ testing program. In the first case, limited in situ tests are developed to confirm the historical values; if the values obtained are minor than the original, an extensive in situ program is settled and performed. Available data enable the implementation of a complete linear FEM model, performing local resistance verification, or the implementation of a non-linear model.
Structural analysis type: The safety assessment in the case of limited knowledge is usually performed by static and dynamic linear or non-linear analysis methods.

3.4 *Confidence factors*

The confidence factor range should be calibrated according to the engineering knowledge level of the structure. Suggested values are in the following range:
- Confidence factor α: 1.30-1.35
- Confidence factor β: 1.20-1.25
- Confidence factor γ: 1.00-1.10

Although this procedure is suggested, it remains on the engineering choice of the structural engineer to establish the use of the confidence factor of the corresponding knowledge level, or in alternative, to use a lower confidence factor, when doubts arise from calculation. The confidence factor (CF) is considered a partial safety factor to be applied to the design strength in order to take into account for the lack of knowledge when analyzing existing structures:
$Fd = fm / (CF * \gamma m)$.

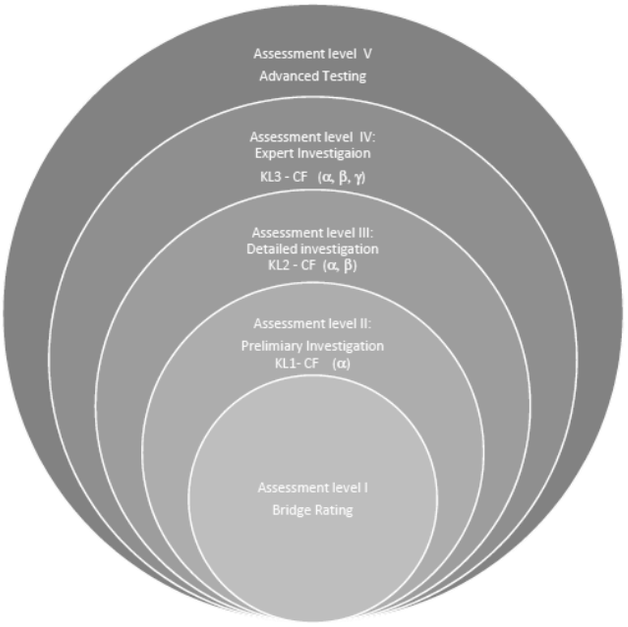

Figure 3. Step level assessment vs. knowledge level.

4 BRIDGE RATING

4.1 *United States of America*

The AASHTO LRFR Guide Manual is the first bridge load rating method in the United States to be based on modern principles of structural reliability and limit states design. The essential ingredients of a reliability-based design and evaluation include probabilistic models of the structural resistance and loads and a method for analyzing the reliabilities (or, conversely, the limit state probabilities) that are relevant to each bridge limit state. Such methods and tools have been applied to developing the AASHTO LRFD Specifications and the LRFR Guide Manual and are expected to be relevant also to improve rating methods for other countries. Details are available in the archival literature (Nowak, 1999; Moses, 2001).

4.2 *Australia*

Section 7 of the Austrian Bridge Design Standard provides rating guidelines with a commentary. The concept of rating is based on the limit state design philosophy and both serviceability and ultimate limit

states are considered. The ultimate action is defined as an action that has a 5% probability of being exceeded during the design life, which represents an average return interval of 2000 years; while the survivability action is defined as one having 5% probability being exceeded per year, corresponding to a return interval of 20 years.

4.3 *United Kingdom*

Document BD 21/01, Assessment of Highway Bridges and Structures, adopts a limit state format with appropriate partial safety factors for condition evaluation of most highway bridges except for cast iron bridges and masonry arch bridges. It is stipulated that bridges built after 1965 should normally be evaluated for serviceability as well as for the ultimate limit states; bridges constructed before 1965 do not need to be assessed for service limit states. Requirements for fatigue endurance however are not included in the standard and the reason stated is that the past stress history of each structure, which could profoundly influence fatigue limit checking, cannot generally be determined to the accuracy level required for assessment.

4.4 *Canada*

The GBSM (2012) is a reference document dedicated in particular for railway bridges. However, it shows a clear and easy procedure for the bridge analysis.

5 CONCLUSION

The assessment of existing structures adopting a specific code or standard is a technical procedure that is provided only in some nation. The possibility of harmonizing these type of procedure is needed in Europe, together with a completely new plan of infrastructural renewal. From the analysis of the documents presented, a review of existing assessment approaches and states rating practices have revealed a number of research issues that must be addressed for existing bridges evaluations (GDT 2009):

- -The bridge may contain archaic structural materials. Design documentation may be missing.
- -Material strengths in situ may be vastly different from the standardized or nominal values assumed in design. On the one hand, concrete strength can increase by as much as 150% beyond the 28-day standard basis due to continued hydration; on the other hand, the strength can deteriorate due to aggressive environmental attack from physical or chemical mechanisms. Failure to consider best estimates of strength and the time-dependent nature of the structural strength and stiffness invariably will lead to an erroneous estimate of in situ strength.
- - Analytical approaches to bridge evaluation usually (but not always) yield a conservative measure of actual load-carrying capacities [Bakht and Jaeger, 1990]. This conservatism is the result of assumptions made in the analysis regarding load sharing, composite action, support conditions and nonlinear behavior, in addition to differences in material strengths noted above.
- - Discrepancies among the different approved rating methods were noted. These discrepancies were confirmed by preliminary rating calculations performed on bridges. The reasons for these differences must be completely understood and addressed in developing new guidelines or codes.
- - Satisfactory bridge performance over a period of years of service provides additional information not available at the design stage. This information should be taken into account in designing in-service inspection programs and in making decisions regarding upgrading and rehabilitation.
- - Current condition assessment relies heavily on visual inspection. More quantitative models of structural deterioration have been developed but have yet to be incorporated in condition assessment procedures.
- - A test load must be a significant fraction of the expected maximum live load for the proof test to be informative and to lower subsequent risk.If the test load is increased to an informative level, the probability of damaging the bridge during the load test increases as well. This tradeoff between information gained and likelihood of damage must be part of the decision to load-test a bridge rather than relying on other rating methods.
- - Uncertainties in loads and resistances at the design stage are reflected in the safety factors (or load and resistance factors). At the evaluation stage, uncertainties can be either greater (e.g., due to deterioration) or less (measured properties; successful load test). These uncertainties must be identified and analyzed.

Horizontal Interface Shear Requirements for Precast Prestressed Concrete Bridge Beams with Slender Webs in Beam and Slab Bridge Constructions

ABSTRACT: All over the world precast prestressed concrete bridge beams are commonly used in small to medium sized highway and railway bridges, i.e. 20-50m spans. The majority of these bridges are built using I and U shaped precast prestressed concrete bridge girders with slender webs. When combined with a cast insitu deck slab they form a composite section that must be capable of resisting the horizontal shearing forces developed at the interface between the two elements. Interface shear requirements are generally more onerous than vertical shear when determining reinforcement ratios and this has become quite a contentious issue for bridge engineers in recent years with differing clauses in the design codes. This paper presents work which will form part of a PhD research project examining the performance of 6nr 3.3m long beams dynamically and statically tested using a four point loading set-up with varying reinforcement ratios crossing the interface. The interface roughness and concrete strength will not vary as the parameters chosen are synonymous with bridge construction. The study will also investigate the appropriateness for setting the cohesion factor c equal to zero for fatigue and dynamic verifications as per clause 6.2.5(105) of Eurocode 2 Part 2(2005). The aim of the research is to propose a minimum interface shear reinforcement equation for incorporation into Eurocode 2 Part 1-1(2004). It is recognised that a minimum percentage of reinforcement is required across the interface to prevent interfacial slip and brittle failure at loss of adhesion. Eurocode 2 Part 1-1(2004) does not presently include a minimum requirement.

1 INTRODUCTION

The research project examines the performance of 6nr 3.3m long prestressed concrete T-beams cyclically and statically loaded using a four point loading test similar to the research carried out by Kovach(2008). These beams are reinforced with prestressing strands, as the majority of bridge beams are prestressed. 3nr beams have 1nr 8mm stirrup crossing the interface and 3nr beams have no stirrups crossing the interface. The interface roughness and concrete strength does not vary as standard bridge practice in Ireland and the United Kingdom use a very rough surface finish and a C57/70 bridge beam mix with a C40/50 insitu top slab mix. The finish on the cast against concrete surface is a very important factor in calculating the interface shear strength. Eurocode 2 Part 1-1(2004) and the CEB-FIP Model Code(2010) classify the different applicable types of finishes into four categories, very smooth (cast against a steel or timber form), smooth (left as cast), rough (exposing the aggregate or raking the concrete) and very rough (shear key or indented concrete surface). Depending on the finish of the cast against concrete the two parameters, friction (μ) and cohesion (c) are then calculated. For the prestressed T-beams a very rough finish was used, this is an average of 3mm roughness when measured using a sand patch test. In terms of fatigue, the reasoning behind setting c equal to zero is to do with on-site issues such as dust, dirt and possibly laitance on the interface which is not cleaned off prior to the deck being cast. A more onerous reason behind setting the cohesion factor c equal to zero is the possibility of a breakdown of the interface over time as it is subjected to repeated loading and unloading during the lifetime of a bridge (120 years). The result of which amounts to an increase in interface shear reinforcement of approximately 20%. Since the introduction of the Eurocodes designers have been using the coefficient of cohesion based on clause 6.2.5 of Eurocode

Figure 1: Interface Reinforcement Close To Beam Ends Showing a Rough Surface Finish (Source Banagher Precast Concrete)

2 Part 1-1(2004) and using their own views on clause 6.2.5(105) of Eurocode 2 Part 2(2005) as there is not enough information in the code specifically for precast prestressed bridge beams with cast on deck slabs. Section 6.8 of Eurocode 2 Part 2(2005) states that a fatigue verification is generally not necessary for prestressed steel in regions where under the frequent combinations of actions compressive stresses occur at the extreme concrete fibres. The national annex to Eurocode 2 Part 2(2005) also contains a clause that if the slab acts compositely with the supporting beams or webs then the structural element does not require a fatigue verification. For the majority of bridge structures this is the case and thus can omit the designer from having to carry out a fatigue check. For a typical two span highway overbridge of twenty five meters per span the interface shear links when designed using the provisions of (Eurocode 2 Part 1-1(2004)) can be at less than 100mm centres, the width of the interface can be as short as 250mm so placing concrete in and around these links is quite difficult(see figure 1) let alone trying to achieve a very rough surface finish. The codes always specify a maximum stirrup spacing but a minimum stirrup spacing should also be considered. From industry experience 100mm is manageable anything less is extremely cumbersome in order to produce a high quality finished product.

2 RESEARCH OBJECTIVES

Two major objectives have been defined for this research study:

1. Carry out a the state of the art review on interface shear, particularly regarding static and dynamic loading and a comparison with other recognised bridge design standards.

2. Propose a minimum interface shear reinforcement requirement for Eurocode 2 Part 1-1(2004) based on the testing undertaken. It is recognised that a minimum percentage of reinforcement is required across the interface to prevent interfacial slip and brittle failure at loss of adhesion. Eurocode 2 Part 1-1(2004) does not presently include a minimum requirement. The proposal will involve a review of the main bridge design standards along with experimental testing as part of the project. Recent bridge projects in Ireland and the United Kingdom have used the CEB-FIP Model Code(2010) recommendations for minimum interface shear reinforcement.

3 PREVIOUS RESEARCH

3.1 *Shear Friction Theory*

The shear friction theory is used in all of the major bridge design codes, i.e. BS5400-4(1990), Eurocode 2 Part 1-1(2004), CEB-FIP Model Code(2010), ACI 318-14(2014) and AASHTO LRFD-BDS(2007) for designing the reinforcement required to cross the longitudinal interface between concrete members cast at different times. In this case a precast prestressed concrete bridge beam with a cast insitu top slab. Figure 2 shows a rectangular concrete block with a cracked interface which has also slipped, this is known as the saw-tooth model and was initially developed around 1960 to predict the longitudinal shear strength of concrete interfaces with the following four parameters considered:

1. Compressive strength of the weakest concrete
2. Normal stress at the interface
3. Shear reinforcement crossing the interface
4. Roughness of the interface substrate

Birkeland and Birkeland(1966) stated that the external shearing loads tend to produce a slippage of the member along an axis, usually at an interface. This slippage is resisted by friction resulting from the external clamping force. If reinforcement is present along the interface this reinforcement will provide an external clamping force on the concrete. This reinforcement has to be anchored on both sides of the interface for it to be effective. The reinforcement then becomes stressed in tension as a direct result of the slippage of the concrete, known as dowel action, this tension provides an external clamping force on the concrete resulting in compression across the interface and the shear stresses being transferred by shear friction.

The literature review identified several milestones of the shear friction theory from 1960 to the present date which are summarized in Table 1.

3.2 *Minimum Interface Reinforcement*

Currently Eurocode 2 Part 1-1(2004) does not have a provision for calculating the minimum percent-

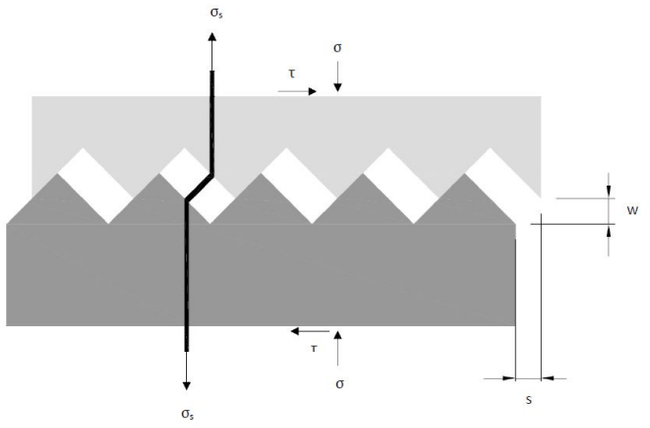

Figure 2: Shear Friction Theory

age of interface reinforcement required. BS5400-4(1990) and CEB-FIP Model Code(2010) have provisions for which the majority of bridge designers use. Hughes(1987) carried out several phases of testing to challenge the provisions of (BS5400-4(1990)). He came to the conclusion that they were conservative but should still be adhered to. Randl(2013) came up with an equation after performing extensive testing which was adopted in the latest version of the CEB-FIP Model Code(2010). Table 2 identifies the differences in the design codes in relation to the minimum percentage of interface reinforcement. It is clear further testing is required on this topic.

3.3 *Dynamic or Fatigue Verifications*

The general consensus amongst bridge designers is that clause 6.2.5(105) of Eurocode 2 Part 2(2005) is not required for short span highway and railway bridges. Reducing the coefficient of cohesion c to zero increases the amount of shear reinforcement crossing the interface to unmanageable levels. Figure 1 shows the end of a precast prestressed W beam with 12mm links at 100mm centres using a c value of 0.4 as per clause 6.2.5(2) of (Eurocode 2 Part 1-1(2004)). This is a very high ratio of stirrups, reducing c to zero would mean 12mm links at 80mm centres, an increase of 20%. Reducing c to zero also results in the design shear resistance of the interface without stirrups being equal to zero when designing to Exp(6.25) of Eurocode 2 Part 1-1(2004) or Exp(7.3-50) of CEB-FIP Model Code(2010), suggesting that the longitudinal shear stress capacity for concrete at the interface is neglected. According to Randl(2013) the shear resistance of concrete interfaces subjected to fatigue loading has not been investigated in a comprehensive way. Randl(2013) states that the most important thing to consider is will there be a crack along the interface. If the shear resistance of the interface is greater than the shear stress acting on it then the answer is unlikely and there is no requirement for shear reinforcement according to CEB-FIP Model Code(2010) and Eurocode 2 Part 1-1(2004). Chung and Chung(1976) were one of the first to carry out dynamic testing in 1976. They concluded that fatigue failure of the interface joint is not probable if the repeated load is not more than 55% of the ultimate static load or if the horizontal shear stress at the interface does not exceed $2.75N/mm^2$. Hughes(1987) carried out small scale push off tests, small scale RC T-beams and large scale precast prestressed M-beams in 1987 using both static and cyclical loading. He concluded that service stresses in bridgeworks tended to be $2.0N/mm^2$ and

that the cracking stresses of $3.0N/mm^2$, $2.5N/mm^2$ and $2.0N/mm^2$ for monolithic, roughened and rough as cast surfaces respectively proved that the interfaces would remain uncracked at service loads. Loov and Patnaik(1994) carried out tests on RC T-beams in 1994 the results of which proved that the stirrups are typically unstressed and ineffective until the horizontal shear stress exceeded 2.0MPa.This indicates the strength of an interface without stirrups. They did confirm that the stirrups became relatively effective when the shear stress reached 3MPa.

4 EXPERIMENTAL STUDY

4.1 *Specimens*

Each beam had a top flange width of 550mm and depth of 100mm. The web was 300mm deep and 150mm wide. The beams were 3300mm long with an effective span of 3050mm. The slab did not cover the entire length of beam, this was based on previous research by Loov and Patnaik(1994). They cited an issue with cracks forming between the support of the beam and the interface at a distance equal to the effective depth of the web section. The slab at the end of the beam provides restraint against interface slip and to correct this the authors suggested reducing the slab length to allow for the horizontal shear failure. The beams were overly reinforced for bending with 4Nr 12.9mm prestressing strands and overly reinforced for vertical shear with 10mm links at 200mm centres. 3Nr 10mm lacer bars ran longitudinally in the top slab. The beams were designed to fail in interface shear only.

The beams were split into two series, comprising of three beams each. A control beam was also manufactured in order to obtain its ultimate strength. Test series 1 beams had no reinforcement crossing the interface. Test series 2 beams had an 8mm stirrup at 400mm centres (0.15% bh = minimum steel as per (BS5400-4(1990))) crossing the interface to represent minimum interface reinforcement.

The varying parameters were the level of load and the ratio of reinforcing stirrups crossing the interface. The beams were poured with C57/70 grade concrete and the top slabs cast twenty eight days later with C40/50 grade concrete. The beams had a very rough surface finish in accordance with (Eurocode 2 Part 1-1(2004)) Section 6.2.5 (2).

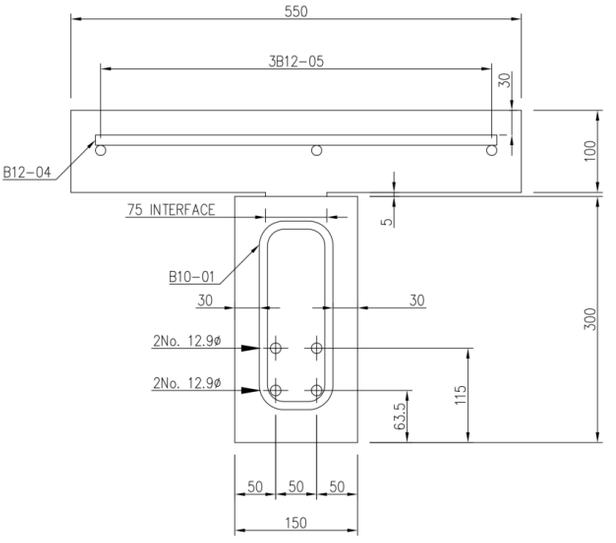

Figure 3: Prestressed TB1 Section

4.2 *Testing instrumentation*

Once the beams were positioned in the testing frame the instrumentation was installed. The instrumentation consisted of a hydraulic load cell and pump, two linear variable displacement transducers (LVDT's), four strain gauges attached to the outside face of the slab (SG1,2,3&4), two horizontal(SG8&9) and two vertical slip gauges(SG6&7). The instrumentation layout can be seen in figure 5 and is based on the work carried out by (Kovach(2008)).

4.3 *Cyclic Loading Procedure*

The beams were loaded with 16,800 cycles of load, the load cycle itself ranged between 150kN and 250kN as the ultimate strength of the beams was found to be in the region of 350kN and for fatigue purposes fatigue load model 1(FLM1) as per (Eurocode 1 Part 2(2002)) was used which corresponds to 70% of the ultimate load(LM1). The number of cycles was taken from Eurocode 1 Part 2(2002), it can

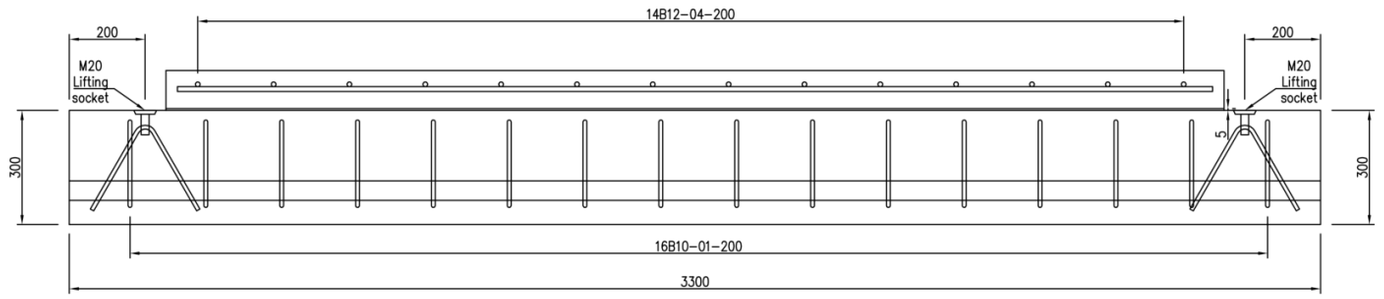

Figure 4: Prestressed TB1 Elevation

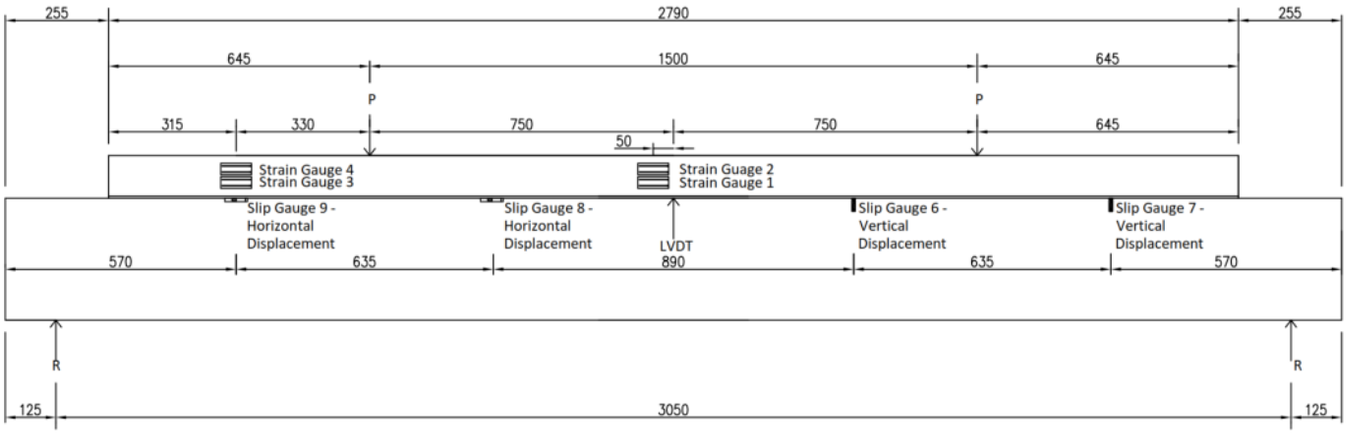

Figure 5: Phase 2 Instrumentation

be shown that two million commercial vehicles will cross the slow lane of a motorway bridge per year which equates to two hundred and forty million commercial vehicles during its lifespan. LM1 represents a vehicle weighing 600kN with four 150kN point loads dispersed through 400mm wide contact lengths. The test beams have 550mm wide top slabs and therefore can take half of a LM1 vehicle. From Table NA5 of Eurocode 1 Part 2(2002) the heaviest vehicle to use the bridge crosses it ten times per million crossings. The closest vehicle in weight to a LM1 vehicle crosses it seventy times per million crossings or 16,800 times during the life of a bridge. Clause 6.8.7 of Eurocode 2 Part 2(2005) states that Miners rule should be used to calculate the total number of cycles required. Using a minimum stress of 0.5MPa and a maximum stress of 4MPa the number of cycles was calculated at approximately 500,000 which is not practical for a laboratory test as it would take over 400 hours to perform.

4.4 *Test procedure*

The concrete beams were placed on a spreader beam which had 150mm wide x 250mm long x 50mm thick solid steel bearing pads to act as supports at the end of the 3.3m long concrete beam giving an effective span of 3.050m. The two point loads were applied using a steel spreader beam again fixed with 150mm wide x 250mm long x 50mm thick solid steel pads 900mm from the end of the concrete beam. The test setup can be seen in figure 5 and figure 6. All of the beams were subject to dynamic and static tests. The first beam that was tested was the control beam, PTB1-4 to see what the ultimate breaking load capacity was.

Figure 6: Phase 2 Test Set up Photo

5 EXPERIMENTAL RESULTS

5.1 *PTB1-1*

PTB1-1 was cyclically tested over three days prior to the static test. The cyclic test was ran from approximately 10am to 5pm and stopped when the lab was unoccupied over night. Following the cyclic test a visual inspection of the beam was carried out and the beam was found to be structurally sound, there were no signs of vertical shear or flexural cracks. The interface was uncracked even though gauge 9 read -0.71mm at maximum load during the cyclic test. This was put down to a faulty gauge as gauge 8 read -0.04mm and the vertical displacement gauges read 0.09mm and 0.01mm. It was unclear as to how a reading of 0.71mm was recorded. Therefore the gauges were all reset to zero for the static test. The beam was loaded in increments of 50kN with the test paused for inspection. There was no movement on any sensors until a load of 100kN was recorded. After 300kN all sensors were now giving values with sensor 7 the highest at 0.11mm. Noise was heard from the beam and the interface was starting to delaminate. The load was held for 5 minutes and sensors 8 and 9 were increasing but not rapidly. The load was increased and at 343kN delamination of the interface occurred. The horizontal slip gauges went from -0.09mm and -0.2mm to -1.09mm and -1.76mm respectively.

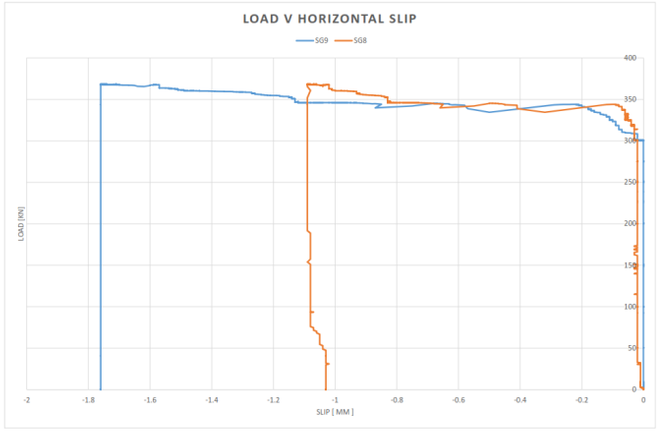

Figure 7: PTB1-1 Load v Slip

5.2 *PTB1-2*

PTB1-2 was statically loaded following a successful dynamic test. At 150kN all sensors started to signal movement albeit very slight. At 300kN vertical gauge 6 and horizontal gauge 9 both read 0.1mm and were steadily increasing. There were several vertical shear cracks clearly visible. These were the standard vertical shear crack running from load point to support. All of these cracks were on the right hand side of the beam where gauge 6 was located. At 317kN there were quite a lot of vertical shear cracks, with some in excess of 0.25mm. Gauge 6 was reading a vertical displacement of 0.9mm which was extremely large and showed delamination had occured. The beam was now carrying all of the load and the vertical shear cracks were excessive. All of the other gauges never read values greater than 0.1mm. It shows the brittle nature of an unreinforced interface where local delamination can materialise. The test was stopped at this stage as delamination had occurred and a failure of the prestressed beam was of no relevance to this study.

Figure 8: PTB1-2 Cracking at 300kN

5.3 *PTB1-3*

PTB1-3 was cyclically loaded for 16878nr cycles of load. The beam did not delaminate and was statically tested to failure. At 325kN gauge 7 started to steadily increase from 0.25mm upwards to 0.4mm whilst the load was held. Gauge 6 was holding well at 0.4mm and all of a sudden gauge 8 the horizontal slip gauge close to the midspan gave and went from 0.02mm to 0.82mm and at the same time gauge 6 went from 0.4mm to 0.69mm. The load was let off and the test stopped. Once delamination occurred at 325kN the beam acted alone and took the weight of the slab and all of the live load, vertical shear cracks opened up right away and were well in excess of 0.3mm. PTB1-1 failed at 343kN, PTB1-2 at 317kN and now PTB1-3 at 325kN. All failures were similar and consistant with each other which was very positive considering only 3nr beams were tested.

5.4 *PTB2-1*

PTB2-1 was statically tested after 16890 cycles of load were carried out. At 250kN the effect of the stirrups was already quite noticeable as the beam was considerably more stiff and composite as could be seen in the gauges. At 325kN the load was held and further visual inspections took place, slip gauge 9 reached -0.13mm and vertical shear cracks appeared on the beam. These cracks measured 0.1mm. Strain

Figure 9: PTB2-1 Cracks Underneath the Beam

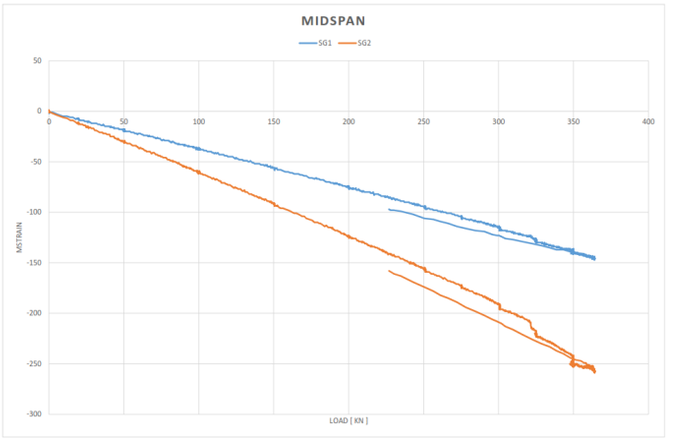

Figure 10: PTB2-1 End Strain

gauges 3 and 4 gave a slight spike and this represented the cracks occurring. The load was increased to 350kN which was not possible with series one beams. The load was held and the interface was still well intact apart from gauge 9 which had slipped to -0.23mm with more and more vertical shear cracks appearing. The load was held and the interface did not move any further. Flexural cracks were now also starting to appear. The cracks were now well in excess of 0.25mm and travelled under the beam and across the soffit as can be seen in figure 9. The load was increased to 364kN and held for 5minutes. This was the maximum load that the test rig was able to produce. The interface slipped again to -0.28mm as per gauge 9 but held well and did not increase any more under this load. Finally the load was withdrawn slowly and gauge 9 reverted back to -0.09mm. The effect of the stirrups, even though they only consisted of 1nr leg of 8mm bar at 400mm centres was quite impressive to see. Failure here was not an interface failure but a vertical shear and flexural one.

5.5 *PTB2-2*

PTB2-2 was statically tested after 17300 cycles of load were carried out, with no delamination of the interface. At 340kN the load was held and visual inspections took place, slip gauge 7 had moved approximately 0.1mm from the start of the test and vertical shear cracks appeared on the beam which represented a non composite member and a delamination of the interface even though visually it was not clear. These cracks measured in excess of 0.1mm. The load was increased to 365kN and held, the interface was still intact apart from gauges 7 and 9 which were slipping gradually. Gauge 7 had moved 0.2mm and gauge 9 0.3mm approximately so not much movement when compared to series one tests. The load was held for 5 minutes and the interface did not move any further.

5.6 *PTB2-3*

PTB2-3 was statically tested after 17708 cycles of load were carried out on the beam. At 325kN the load was held and visual inspections took place, slip gauge 7 had moved to 0.17mm and cracks were now visible on the beam. The flexural cracks near the midspan were 0.1mm and the vertical shear cracks at the beam end were 0.2mm. The load was increased to 365kN, the vertical cracking was now very excessive and spread down and under the web of the beam. The crack was in the order of 2mm. A prestressed beam failure was not wanted and so the test was stopped with a vertical shear and flexural failure cited. The interfaces of PTB2-1 at 364kN, PTB2-2 at 365kN and PTB2-3 at 365kN were still very much intact when the test was stopped. All failures were similar and consistant as per test series 1 beams.

6 CONCLUSIONS AND RECOMMENDATIONS

6.1 *Code Provisions:*

The test results prove that the provisions of the current bridge design codes are conservative and safe.

6.2 *Surface Preparation:*

Precast concrete manufacturers cast bridge beams internally and externally during all seasons. Trying to achieve a surface finish with high strength flowable concrete is extremely difficult. The method used in the experiments has been tested by Banagher Precast Concrete and works very well. In summary the beams are poured and finished. They are left rough as cast and after approximately 30 minutes the finishing foremen dash the tops with 8mm aggregate and clamp it into the concrete with a roughening tool. The beams are then covered and cured. When the beams are removed from the manufacturing line they are power washed and any loose aggregate is cleaned away. This method achieves an average roughness of 3mm which corresponds to a very rough surface as per (CEB-FIP Model Code(2010)).

6.3 *Minimum Links:*

At present there is no minimum interface links provision in (Eurocode 2 Part 1-1(2004)). Engineers are using the minimum provisions of (BS5400-4(1990)) and (CEB-FIP Model Code(2010)) for bridge beam

Table 3: Average Factor of Safety

Beam Type	Design Capacity	Stress @ 1st Interface Crack	Factor of Safety
PTB1-1	0.65	8.39	12.91
PTB1-2	0.65	7.76	11.93
PTB1-3	0.65	7.95	12.23

Table 4: Summary of Results

Type	Beam Age	Slab Age	Beam Str.	Slab Str.	Int. Links	Design Cap.	1^{st} crack stress	SR
PTB1-1	148	119	77.02	77.22	None	0.65	8.39	3.58
PTB1-2	168	139	77.02	77.22	None	0.65	7.76	3.24
PTB1-3	174	145	77.02	77.22	None	0.65	7.95	3.32
PTB2-1	188	159	77.02	77.22	1B8-400	1.17	7.95	3.49
PTB2-2	160	131	77.02	77.22	1B8-400	1.17	8.32	3.36
PTB2-3	178	149	77.02	77.22	1B8-400	1.17	7.95	3.20
Note: Age in days, Str. = Strength, Units of Strength in MPa, Int. = Interface, Cap. = Capacity. Units of Stress in MPa, SR = Surface roughness, Units of Surface roughness in mm								

designs. The testing carried out proves that these provisions are safe and can be used in practice. Prestressed bridge beams will always contain stirrups crossing the interface for vertical shear requirements. Once the surface is rough and stirrups are present no additional interface stirrups need be provided. This is the view of the panel of experts involved in writing the new version of (Eurocode 2 Part 1-1(2004))

6.4 *Dynamic or Fatigue Verifications:*

There were no interface cracks until an average shear stress of 8.03MPa. Comparing this to the design resistance for an unreinforced joint of 0.65MPa shows the merit of this research and proves that not enough testing has been carried out to validate the overly conservative approach of reducing c to zero for fatigue verifications. In reality all bridges are dynamically loaded as they are used by vehicular traffic. To reduce c to zero results in an uneconomical design. Further laboratory testing should be sought to disprove clause 6.2.5(105) of Eurocode 2 Part 2(2005).

Bridge Safety Assessment for Strength II Limit State in AASHTO LRFD Specifications

Hani Nassif & Peng Lou
Rutgers, The State University of New Jersey, Piscataway, New Jersey, United States
Paul Truban
New Jersey Department of Transportation, Trenton, New Jersey, United States

ABSTRACT: The AASHTO LRFD Bridge Design Specifications (AASHTO 2016) defines Strength II limit state for various agencies to consider the load combination relating to the use of bridges in the United States by owner-specified special design permit vehicles, evaluation permit vehicles, or both. However, the code calibration process, initially performed in 1994, was applied only to the Strength I Limit State (Nowak 1999). Additionally, the configuration and characteristics of permit vehicles vary from state to state. This study presents the comparison of load effects among design permit vehicles from different agencies. Then the design permit vehicle of New Jersey Department of Transportation (NJDOT) is assessed using five years of permit vehicle records. In comparison with the current AASHTO live load factor of 1.35, the averages of the bias ratios at the 75-year level are found to be 1.31, 1.23, and 1.16 for the positive moment, shear, and negative moment, respectively.

1 INSTRUCTIONS

1.1 *Background*

Overweight vehicles are commonly considered to affect both the structural safety and deterioration of bridge structures. AASHTO LRFD Bridge Design Specifications (AASHTO 2016) defines Strength II Limit State with a load factor of 1.35 for agencies to consider the load combination relating to the use of bridges by owner-specified special design vehicles, evaluation permit vehicles, or both. However, this limit state has never been calibrated. In the United States, Nowak (*1993,1994*) initiated the development of truck live load models based on truck survey data collected in Ontario in 1975. The results constituted the major development of live load models for Strength I limit state. In addition, although same live load factor of 1.35 for Strength II Limit State is currently used, the configurations of design permit vehicles vary from state to state. Therefore, the factored design load for Strength II Limit State varies from state to state.

1.2 *Objectives*

The design permit vehicle from each state usually represents the local permit vehicles. This study aims at assess NJDOT Design Permit Vehicle. A total of 208,487 Permit vehicle registration records from 2010 to 2015 were provided by NJDOT. Load extrapolation was performed in order to get the extreme 75-year loads.

2 PERMIT VEHICLES FROM VARIOUS AGENCIES

Figure 1 shows the ratios of load effect caused by NJDOT Design Permit Vehicle and HL93. The load effects include maximum positive moment in simply supported beam (Simple Span Moment), maximum shear force in simply supported beam (Simple Span Shear), and maximum negative moment in two equal span continuous beams (Continuous Negative Moment). The ratios of Simple Span Moment and Simple Span Shear are around 1.5 for different span lengths between 20 *ft* and 200 *ft*. For Continuous Negative Moment, the ratio is consistently under 1.5 except for 40 *ft* span, which is 1.7. Figure 2 shows the design or evaluation permit vehicles currently used by agencies including New Jersey, Pennsylvania, New York State, Wisconsin, and California. It is important to note that Wisconsin *(2017)* and Virginia *(2016)* do not have the requirement of Strength II Limit State during the design while they do require the evaluation of the permit load rating if permit vehicles is requested to operating on a bridge. On the other hand, the states, such as New Jersey *(2016)* and New York State *(2016)* not only require the Strength II Limit State but also require considering the design permit vehicles in the service limit states.

Some state DOTs developed their design permit vehicle based on the envelope of load effects created by issued routine permit vehicles. However, this does not share the same philosophy of reliability-based LRFD design. Figure 3 shows the design load effects of different design permit vehicles comparing to NJDOT Design Permit Vehicle in terms of Simple Span Moment, Simple Span Shear, and Continuous Negative Moment. Based on Figure 2 and Figure 3, Pennsylvania and New Jersey has similar design permit vehicles and therefore the design load effects created are close. California Design Permit Vehicle has lower design load for short spans and higher design load for long spans comparing to NJDOT. Due to the different configuration of design permit vehicles, the design live load varies significantly among the agencies.

3 DATA PROCESSING AND LOAD EXTRAPOLATION

3.1 *Statistics of permit vehicle records*

Figure 4 shows the permits issued by NJDOT for each month from September 2010 to July 2015. In

general, the average annual increase for the number of permits is 7.66%. Figure 5 shows the distribution of permit vehicle records based on the number of axles. The majority of permit vehicle records, about 94.1% of total records, are five, six, seven, and eight axles vehicles. Figure 6 shows the Cumulative Density Distribution (CDD) of the Gross Vehicle Weight (GVW) plotted in Normal Probability Paper (NPP) along with the approximated Generalized Extreme Value (GEV) distributions. The GEV distribution is found to be the best fit with the location parameter $\mu = 105.4$, scale parameter $\sigma = 21.28$, and shape parameter $\xi = 0.04526$. This indicates this can be best described as a type II extreme value distribution, also known as Fréchet distribution.

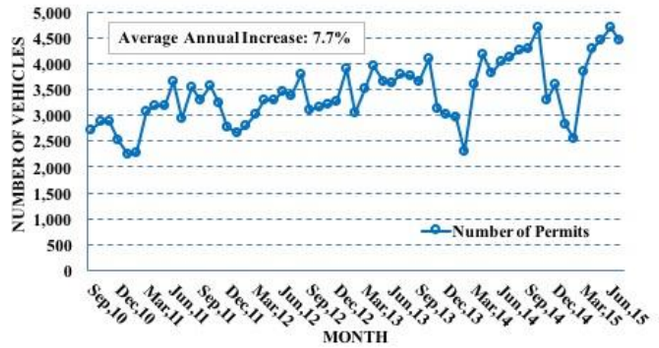

Figure 4. Permits Issued by NJDOT from 2010 to 2015

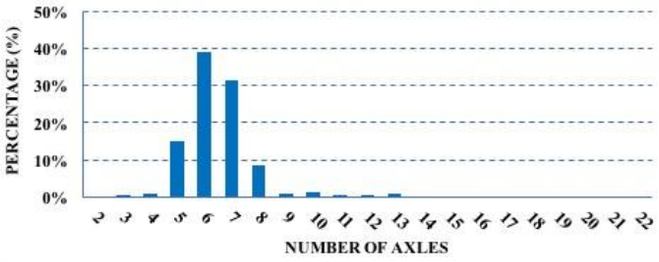

Figure 5. Number of Axles for Permit Vehicles

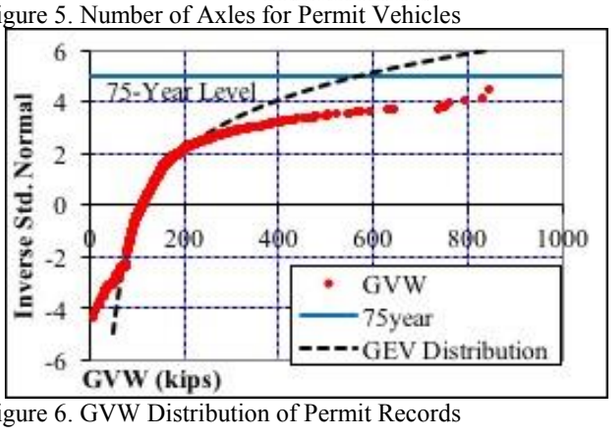

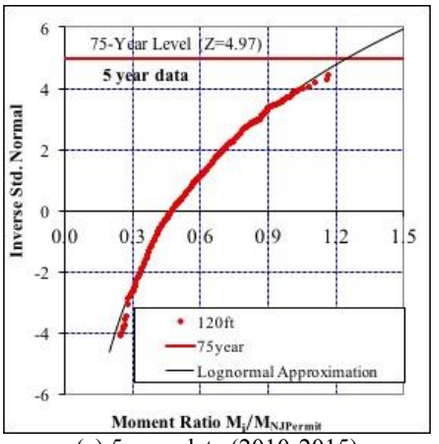

Figure 6. GVW Distribution of Permit Records

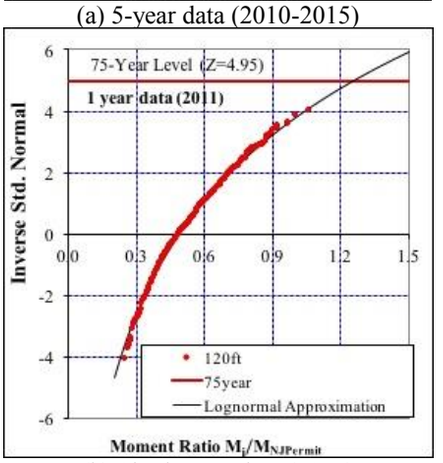
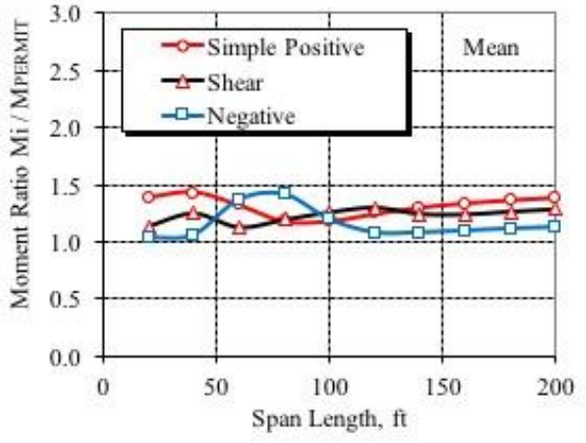


3.2 *Live load effects and load extrapolation*

The first step is to use Federal Bridge Formula to exclude the oversize vehicles from the database. In addition, there are about 0.25% of the records (516 records) that are heavier than 250 kips. These vehicles can be regarded as superload loads, which are distinguished from routine permits. However, when developing the design permit vehicles, one should not penalize all bridges for few extremely heavy superloads, which in some cases might even not be operated on the bridge network. Therefore, as the second step, only permit vehicles that are below 250 *kips* are considered for the load extrapolations. Then a total of 202,033 permit vehicle records are used to obtain the bias ratios, the load effects created by permit vehicle records over the load effect by NJDOT Design Permit Vehicle, of Simple Span Moment, Simple Span Shear, Continuous Negative Moment for span lengths ranging from 20 *ft* to 200 *ft*. For the load extrapolation method, lognormal approximation is used to predict the future 75-year maximum loads. This is different from GVW distribution, which is best described as type II extreme value distribution. The lognormal approximation method calculates the characteristic parameters of the lognormal distribution and plotted the distribution along with the bias ratios in NPP. This approach is found to be consistent, stable, and less sensitive to extreme loads. The coefficient of determination (R^2) is higher than 0.97 in every case.

Figure 7 shows an example of load extrapolation for Simple Span Moment of 120 *ft* span length using five-year data and single year data. It can be seen that the lognormal approximation fit the entire data very well. In addition, the extrapolated results are very close using either five-year data and single year data. This means the extrapolation method is effective and consistent over time.

(a) 5-year data (2010-2015)



(b) Single year data (2011)

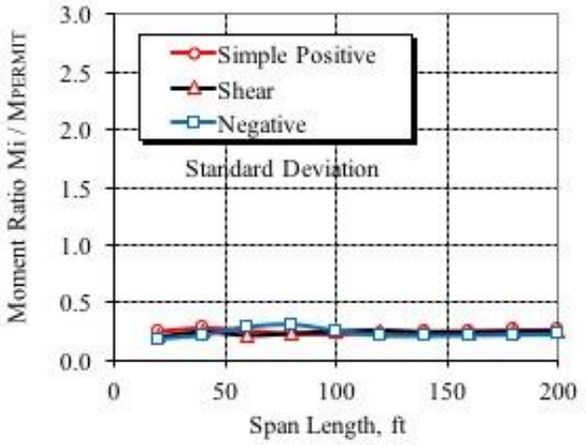


Figure 7. Load effect extrapolation (120 *ft* Simple Span Moment)

4 STATISTICAL PARAMETERS FOR THE STRENGTH II LIMIT STATE IN AASHTO LRFD

Figure 8 gives the mean and standard deviation of bias ratios for the predicted 75-year maximum loads for different span lengths. For New Jersey design permit vehicle, the means and standard deviation (STD) of bias ratio are consistent for different span lengths. This means the current NJDOT Design Permit Vehicle represent the local permit loads well and there is no need to change the configuration of the design permit vehicle. If the load extrapolation results in inconsistent over different span lengths, a new configuration should be proposed to represent the permit load better. The average value of the bias ratios at 75-year level is 1.31, 1.23, and 1.16 for the Simple Span Moment, Simple Span Shear, and Continuous Negative Moment, respectively. Considering the current live load factor, 1.35 for design permit load, in Strength II limit state, NJDOT Design Permit Vehicles gives close bias ratios based on the results. In addition, it is found that the coefficient of variations (CoV), which is about 20%, is higher than previous calibration works.

(*a*) Mean of Maximum 75-year load

(*b*) Standard Deviation of Maximum 75-year Load

Figure 8. Bias Ratio of predicted 75-year maximum loads to NJDOT Design Permit Vehicles

5 CONCLUSIONS

This study presents a study of the validation of Design Permit Vehicle for NJDOT Structural Design Manual. Permit vehicle registration records are used to perform live load extrapolation. The average value of bias ratio at 75-year level are found to be 1.31, 1.23, and 1.16 for Simple Span Moment, Simple Span Shear, and Continuous Negative Moment, respectively. The results are within the current live load factor, 1.35, for Strength II limit state.

Large skewed bridge for high speed trains. Northwest of Spain

C. Jurado (Ph. D., M. Sc., B. Sc., MBA)
Polytechnic University of Madrid, (Spain) / Ingecal Ingenieros, S. L., Madrid, Spain.

ABSTRACT: During the years 2008 to 2010 it has been constructed in Spain the new railway line of high velocity trains, which will connect Valladolid with the northwest of Spain.

One of the first phases comprises the connection of provinces Valladolid and León with a train of 220 km/h of speed. The section Río Cea-Bercianos del Real Camino with 10.5 Km of length comprises 5 great viaducts from 36 to 442 meters with an inversion of 22 million Euros and it will cross the provinces of Valladolid and León in direction to Galicia on the Northwest of Spain.

The present paper exposes the project and construction of one of the most singular viaducts in this phase which crosses above the existing motorway M-31, with a very acute angle of 20º. The solution has been a skew bridge called in Spanish terminology "in pergola" with a length of 153 m.

1 THE SPANISH INFRAESTRUCTURE PLAN 2000-2020

Spain has undertaken with the assistance of European funds a tremendous effort to overcame its deficiencies in transport and infrastructures. From the end of eighties until the mid of the nineties, it has took with Germany the first place in the European Union (EU) in the percentage of Gross Domestic Product (GDP) allocated to investment in transport infrastructures.

From the threshold of 0.5-0.6% of GDP in the mid-eighties it has gone to values of around 1.7-1.8% in the last years (figure 1).

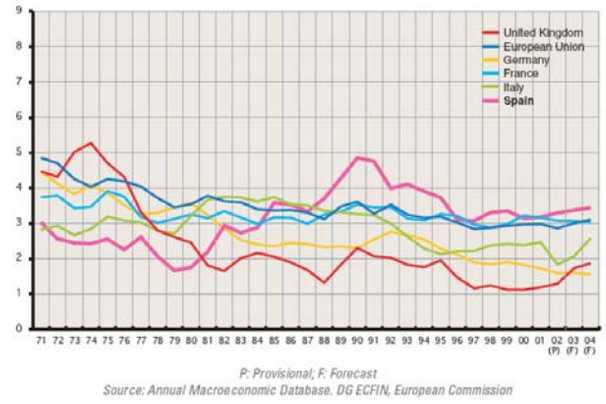

Figure 1. Trends in Public Investment by countries in EU (%GDP)

The Spanish Infrastructure Plan 2000-2020 projects to connect all the provinces with the centre of Spain with high velocity trains. The cost of the Plan will be about 114.2 thousand million Euros. The finance will be public and private. By the year 2020 all the capital of province will be connected by train with less than four and a half hours from Madrid, in the centre of Spain (figure 2).

Figure 2. Spanish Infrastructure Plan 2000-2020

In the year 2020 the 90 % of population of Spain will be to less than 50 km from a new station of high velocity railway net, so in the year 2020 the net of high velocity trains will be in Spain 10.000 kilometers.

2 INTRODUCTION

During the years 2008 to 2011 it has been constructed in Spain the new railway line of high velocity

trains (HVT) that will connect Valladolid with León in the northwest of Spain (figure 3).

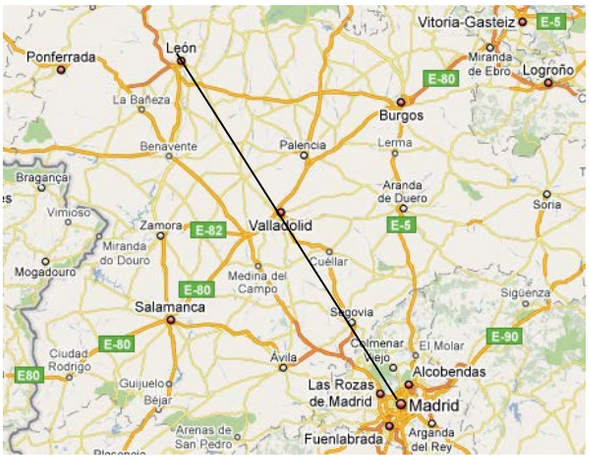

Figure 3. New railway line Madrid-Valladolid-León

This part of the Spanish Infrastructure Plan will cost 200 millions of Euros with a length about 183 kilometers. The speed will be about 220 kilometres per hour, but the railway platform is prepared to reach 350 kilometres per hour.

The connection between Palencia and Leon comprises 122.20 km and in the middle of it is the phase of Río Cea-Bercianos del Real Camino with a length of 10.5 kilometers (figure 4)

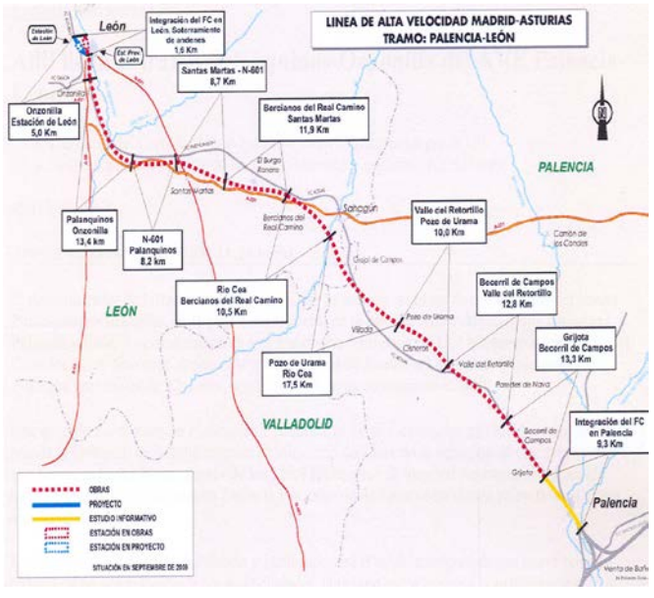

Figure 4. New line of High Velocity Trains. Section between Palencia and León (122,20 km)

The present paper exposes the project and construction of one of the most singular bridge in the section of Río Cea - Bercianos del Real Camino, from Palencia to León, which crosses over the existing motorway M-31. The solution of the bridge has been made a skew viaduct called "in pergola" with a length of 153 m and with a width of 14.5 m.

3 THE PROJECT

The phase Río Cea-Bercianos del Real Camino, passes near Sahagún's municipal area and the total length of platform of high speed reaches 10.5 km.

The work begins, approximately to 3 km to the south of the population of Sahagún, in the P. K. 55+100 of the informative study (300+000 P.K. of the project of construction), following with direction Northwest with a length of 10.501,635 m, up to the P. K. 65+587 of the informative study and to 0.6 km to the north of the population of Bercianos of Real Camino.

Between the kilometre point of 300+000 and the 310+500 which is the total length of the section it has been projected five great viaducts from 36 m to 442 meters and six bridges over the line of high velocity trains, to maintain the permeability for people and animals.

In the table 1 there is a resume of the five great viaducts in this phase Río Cea-Bercianos del Real Camino.

Table 1. The five viaducts included in the section of HVT Río Cea-Bercianos del Real Camino

Designation	P.K. BEGINING	P.K. END	TOTAL LENGTH (m)	STPANS DISTRIBUTIONS (m)
Viaduct over Cea river	300+072	300+188	116.00	35.50–45.00–35.50
Viaduct over Valle stream	300+861	300+897	36.00	36.00
Viaduct over Santiago road	306+501	306+943	442.00	32.00+3x41.00+50.00+5x 41.00 + 32.00
Viaduct over Coso stream	308+824	308+976	152.00	34.00–2x42.0–34.00
Pergola over A-231 motorway	308+980	309+133	153.00	76.50 + 76.50

The most singular viaduct between the five last ones in the fifth called "Pergola over the A-231 motorway" with a length of 153 meters (figure 5)

The project of the viaduct was made by the author of this paper, with a three-dimensional model of finite elements using the program SAP2000N, that it includes all the parts of the structure, such as: foundations made with piles (4,500 m of piles), mat foundations tying the piles, pillars, and the superstructure comprising a prestressed concrete slab, and the complete abutments.

The model of finite elements made consists of 8,806 nodes, 6,366 FRAME elements and 2,326 SHELL elements and the number of hypothesis studied was 1,306 with static and dynamic situations.

In view of the great obliquity of the crossing of the new railway line of high speed over the existing motorway A-231 which connect the provinces León and Burgos, with a very acute angle of 20 º, turns out to be necessary the disposition of retaining walls of great length in the zone of the acute angles North in the abutment E-1 (side Palencia), and South in the abutment E-2 (side León).

The deck is solved by means of a lightened slab of constant height of prestressed concrete, with a height in the axis of the deck of 1.52 meters and 1.0 meters in the edges.

The pillars of the viaduct have circular form, with diameters of 0.9 and 1.1 meters. Their heights are approximately equal and around of 6 meters.

The abutment 1 (low P. K.) is very singular and it is determined by the presence of the Viaduct over Coso stream immediately before, so it was necessary to arrange a unique abutment for the two structures, that allow in one side to dispose the support of the Viaduct over Coso stream and on the other side the support of the Pergola (figure 6)

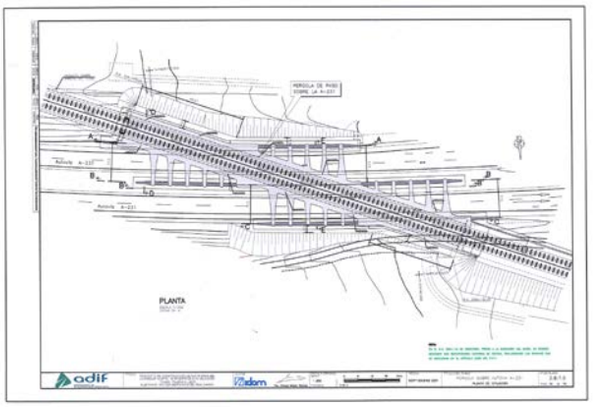

Figure 6. Pergola over A-231 motorway

The Abutment 2 is conventional with walls of containment of lands to avoid inundating the motorway A-231 (figure 7)

The foundation is deep trying to look for the rocky stratum. The abutments are founded by means of piles of 1.0 and 1.2 meters of diameter, whereas the intermediate pillars need piles of 1.0 and 1.5 meters of diameter. In the abutments where are the prestressed nerves of the deck, the foundation is solved by means of piles of 1.0 meter of diameter.

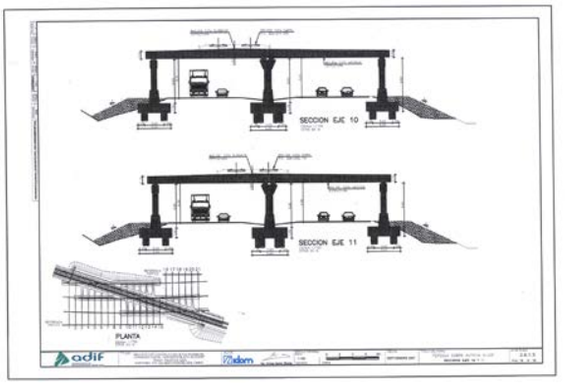

Figure 7. Transversal section of the Pergola viaduct

The soil under the structure is constituted by the next layers:

- Anthropic landfills with a maximum of 4.00 meters (called QXP).
- Tertiary sediments until the depth investigated of 30 meters, composed by:
  - Clay and slightly sandy clay (called TMA1)
  - Clayey lime (called TMA2)
  - Sand and limed sand (called TMA3)

So the foundation of the Pergola must be deep with piles of 1.20, 1.50 and 1.80 meters of diameter, which must be fixed at least 6 diameters in the materials with consistency or compacity hard and very hard.

In the figure 8 it must be seen the geological section of the soil in the transversal direction to the Pergola.

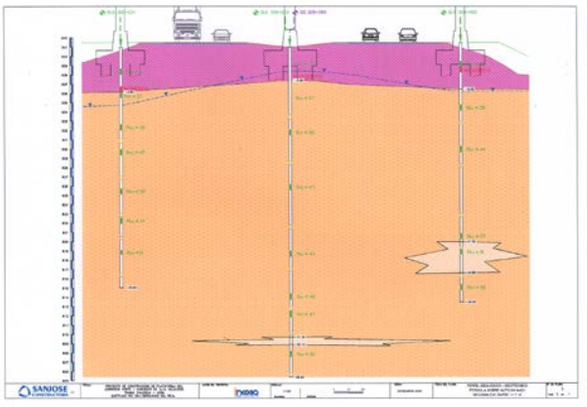

Figure 8. Geological transversal section to the Pergola viaduct

For the project of the pergola on the highway A-231 there has been generated an integral three-dimensional model that includes all the elements of the superstructure and of the infrastructure, such as:

- 16 piles of 1.00 m of diameter and 20 m of length in abutment E-1
- 48 piles of 1.20 m of diameter and 22 m of length in abutment E-1
- 24 piles of 1.00 m of diameter and 20 m of length in central pillar
- 16 piles of 1.50 m of diameter and 20 m of length in central pillar
- 16 piles of 1.00 m of diameter and 20 m of length in abutment E-2

- 48 piles of 1.20 m of diameter and 22 m of length in abutment E-2
- Slabs of foundations
- Abutments
- Prestressed deck, etc.

All of this constituted a complete three dimensional model of the whole structure that comprises 8,806 nodes, 6,366 FRAME elements and 2,326 SHELL elements (figures 9 and 10).

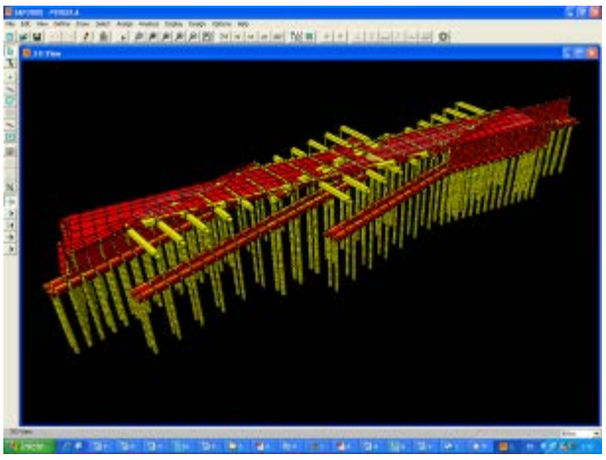

Figure 9. Three Dimensional Finite Element Model of the Pergola from the NE

This model permits to obtain all the responses of the Pergola such as moments, shears, axial forces, etc. in all the elements (figure 11).

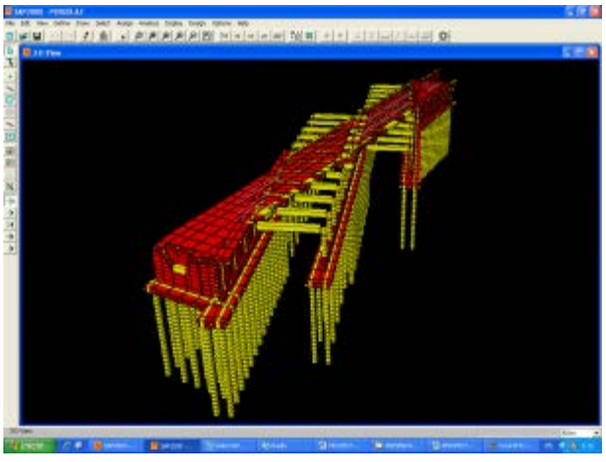

Figure 11. Transversal flexural moments in SHELL elements

4 CONSTRUCTION OF THE STRUCTURE

The structure is now under construction and the process of this was:

- First construction of piles.
- Second making the walls and the pillars (figure 12).
- Third the abutments (figure 13).
- Four the upper slab, etc.

In order to construct the prestressed upper slab it was necessary to cut one of the senses (two lanes) of the highway and to deviate the traffic temporarily for the other sense (two lanes), in order to scaffold one of the parts of the viaduct without any risk for the traffic, and to prestress the slab of the deck (figure 13)

Figure 12. Construction of central pillars (September 2009)

Figure 13. First phase of deviation of highway A-231 (November 2009)

5 CONCLUSIONS

As a conclusion it was projected a very singular Pergola viaduct by means of a three dimensional model of finite elements, which comprises all the parts of the infrastructure and the superstructure taking in consideration all static and dynamic loads by means of 1,306 with static and dynamic load combinations. The viaduct was finished in 2010.

Repair and Retrofitting of Bridges – Present and Future

Harminder Singh
Associate Technical Director. Arcadis Australia Pty Ltd., Australia

ABSTRACT: Bridges are being constructed around the world and are increasing the number of assets to be maintained in the future. Since the Roman Empire to Victorian Era, the bridges are being constructed of timber, stone, masonry to the modern era of constructing the bridge with Glass-Fiber Reinforced Plastic materials. From stone masonry to concrete and steel, the bridge of each material type has different durability level, maintenance issues, repair and retrofitting requirements.

The modern bridges being constructed are more durable and lower life cycle cost. Now the focus is more on the environmental aggressivity in which the structure is being constructed and take adequate preventive measures at the design stage. The old structures before the 1980s have a lot of repair and retrofitting requirements. With the increasing load of traffic and the requirement to accommodate more number of lanes per bridge, it is a challenge for bridge engineers to check the structure to the lowest factor of safety, thus avoiding the widening of bridges in some cases and contributing to the long-term sustainability.

To overcome the challenges for the optimum use of bridges, the paper suggests the way forward for inspection, monitoring and asset management. With the BIM becoming more popular, it has also discussed about the requirement of single database of bridge assets where all the inspections, current and new assets information can be centrally located. The requirements for the assessment and repair of structures is discussed and the way forward for 3D printing for repair of concrete bridges. The paper also discusses about the various standards available for bridge maintenance in different countries. In the end, the critical discussion is presented about the future of bridges and repair requirements and the latest materials available to explore for use in structures to avoid major repair and maintenance in the future.

1 CONDITION AND ASSESSMENT OF BRIDGES

1.1 *Deterioration of Bridges*

There are different reasons for deterioration of structures and depending upon the location there are different factors lead to degradation of structures. In the coastal regions, the main reason of deterioration is saline environment where the air borne salts affects both the steel and concrete structures. For structures in high earthquake zones, the main attention is on designing the structures that can sustain in the high ground movement forces. Although the structures are designed for these transient forces but still in high intensity earthquakes, the structures have some cracking or minor damage that can lead to change in stress distribution and initiate the deterioration. The main reasons for deterioration of structures are:

a) Environmental aggressivity
b) Change in traffic need and live loads
c) Physical damage due to vehicle overloading and collision
d) Scouring, settlement, ship impact and earthquake
e) Steel structures – fatigue loading and corrosion
f) Substandard construction
g) Stray Currents
h) Fire

With the increase of traffic demand, every major road and bridges across the world requires to be widened or la ne rearrangement required to cater for the future traffic requirements. This requires the widening of bridges or some of the pedestrian path removed to accommodate new lane arrangement and change the load distribution in the structures. The impact of widening is more on skew and curved bridges where the load distribution changes quite significantly. With the special vehicles are to be accommodated on the bridges that have much heavier axle lo ads than the previously designed live loading so the fatigue check for residual life should help in understanding whether the bridge will be suitable for future demand.

The focus now is more on designing the structures that can sustain in the various impact situations either from rail, vehicles, ships etc. This requires the structures to design for higher collision loads in advance to cater for possible collision situation. But during the actual impact the force transferred to the structures could be higher than the designed forces that impacts the foundation. Post collision, the checking of bridge suitability to open for traffic, the foundation of the structure is often overlooked for any possible effects. In the other events like scouring of foundations, it is

important to check the foundations for excess scoring beyond the design requirements. The collapse of Malahide Viaduct, Ireland in 2009 (Figure 1) provides an example where the scouring lead to the collapse one of the bridge span when the commuter trains were few seconds away from the viaduct.

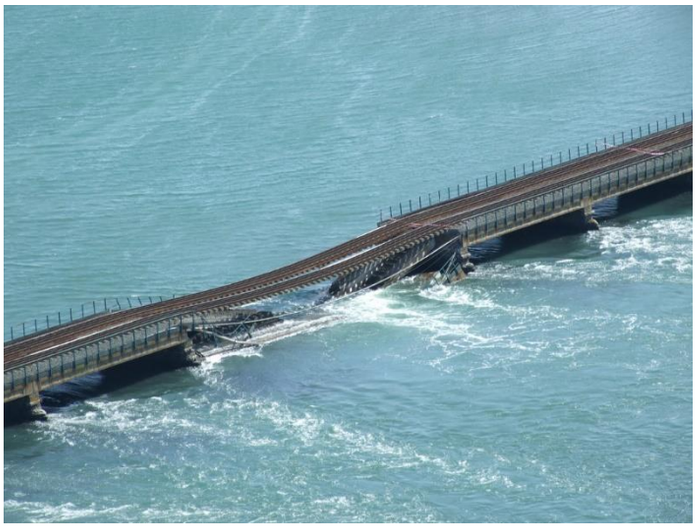

Figure 1 Lessons to be Learnt from Malahide Viaduct

The design of structures in the earthquake environment requires a careful detailing for the required ductility of the structural members. The 1995 Great Hanshin earthquake where the Hansin Expressway (Figure 2) collapsed due to low ductility of the substructure. Now the more focus is on the design that helped the structure to behave more elastically during the earthquakes.

The recent fire event of Greenfell Tower in London reminds the requirement for use of fire proof materials for bridges as well. With the more architects and urban designers involved in planning of bridges so the trend now is more towards amalgamating the structures to the surrounding environment by giving an eye-catching experience rather than 'concrete' view experience. It is to check that the cladding and some of the materials being used on shared path bridges are fire proof and these types of events can be avoided in the infrastructure sector.

1.2 *Bridge Inspection*

1.2.1 *Current Practice*

It is a normal practice worldwide to undertake the general inspection of structures every 2 years and detailed inspection within touching distance every 5 years. This frequency of inspection can be increased in case during the previous inspection the structure is found in bad condition or of significant importance. With the reducing budget of different local authorities, there is an impact on the spending for inspection and condition monitoring. The delayed inspections can further delay the repair of the structures significantly and sometimes become the reason of failure. The current practice of physical inspection of bridges helps in deciding the condition rating of different bridge components that can be used in the load rating and strengthening design (if required). However, the current system does not provide the comparison of all the available information based on the previous and current photographs and inspection reports.

Figure 2 Limited Ductility Lead to Collapse of Hanshin Expressway

1.2.2 *Latest Inspection Techniques*

With the advancement of technology, the inspection with drones has a huge opportunity for the future. In some of the sectors like high rise buildings this technology has already being used but it is still in the budding stage. The drone inspection is especially useful for bridges over creeks and rivers depending on the span of the bridge where a lot of temporary works are required for detailed inspection that can save the cost of temporary works. The bridge over railways are a very big candidate for drone inspection where the

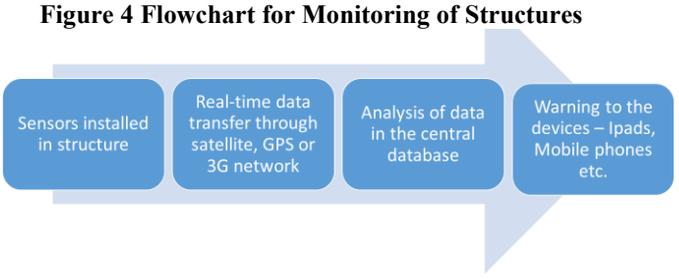
small windows of access during rail closure can be used for inspecting the bridge quickly. The close images can be taken with the drones while maintaining the required gap from the structure. It is expected that the drone inspection can help in reducing the requirement of detailed. The little change can help in saving budgets for local authorities and can be used for the bridge maintenance works.

Figure 3 Drones are Huge Contributor for Inspection

1.3 *Early Detection System*

For medium to long span bridges and the bridges of significant importance, it is more prudent to monitor the structures remotely than inspecting at regular intervals. It helps in providing the real-time information of the structural behavior and gives an advanced warning if the distress is beyond the safe limits. The monitoring of concrete bridges could involve checking the vibrations, stress and strain levels with sensors at prominent locations along the structures. The data can be fed remotely into the centrally located database where the outputs can be generated in real time and can provide advance warnings.

The structures in the high earthquake zone also requires as real-time monitoring so that in any event of exceedance of movement that can lead to distress in structure, the traffic can be slowed down or stopped completely. Also, it will help in pinpointing the distress location and understanding the repair or refurbishment requirements.



As a cheaper alternative, Moire tell tales by Bill Harvey Associates can be installed for checking any movement and cracking in structures. They have an accuracy of 0.1mm tell tales and images can be taken by drones from the distance and any movement can be checked from images later. With the drones, there is no need to access every tell t ales physically and drones can be helpful to record the data.

.

1.4 *Monitoring System*

Now with the architects involved in the planning of bridges it is a trend to provide more longer and slender structures where the serviceability could be a major concern. It is more prudent to install the sensors permanently for the life time monitoring of structures. For the normal situation, the system will be neutral and in case of any distress it can provide immediate warning to asset owner about the possible problem. These days the advanced system can provide the alerts on the mobile phones or IPad to several people in the monitoring team. If there is a frequent warning or significant warning the emergency inspection or mitigation can be planned. With this system, most of the bridges would not require frequent inspections. The savings from remote inspections can used for installing this system on other bridges. Most of the bridges have major defects in the superstructures. The sensors can be installed at the strategic locations along the span that follows the process shown in Figure 4 and hierarchy of bridge monitoring for future is as per Figure 5.

Figure 4 Flowchart for Monitoring of Structures

Digital Image Correlation is a 3D, full-field, non-contact optical technique to measure contour, deformation, vibration and strain on almost any material. The technique can be used for many tests including tensile, torsion, bending and combined loading for both static and dynamics applications. The method can be applied from very small (micro) to large testing areas – and the results are readily comparable with FEA results or strain gauges. The possibility of use of this technique in bridges should be explored further.

1.5 *Bridge Management System*

One of the point author advocate the use of asset management system where the real-time database of structural assets can be maintained for structures. The real-time monitoring system as discussed before can be connected to the asset management system that can provide real time alerts. The physical inspection data and photographs can be directly fed into the system where the automatic inspection reports can be generated that can save a lot of time and budgets to use for other automation activities.

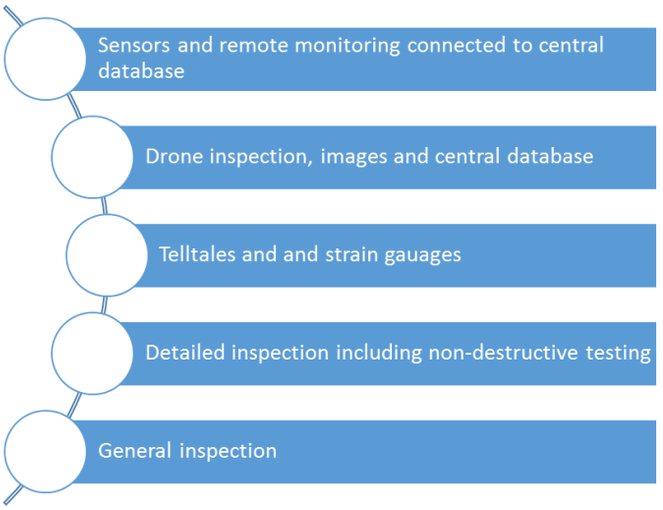


Figure 5 Proposed Hierarchy for Monitoring of Structures

The inspection data from drones can be fed into the system that can become the single source of all information. With the BIM becoming a norm for current and future projects, it is a challenge to the bring the existing assets in the BIM environment and its integration with the asset management system. To make the single source of all information, the existing assets can be digitized using drones and the 3D models can be used for asset tagging, tagging of inspection photos, recording and comparing defects and finally if there is any upgradation or widening required the same model can be used for providing the existing structural information. The as-built drawings and information of each bridge can be digitized and tagged to the model. Initially the cost will be high however at a later date the cost will offset by less manual data management, no data loss and less frequent inspections with higher confidence level in the available information. Drones can take 3D pictures, connect to the central system and compare with the previously inspected photographs. Any difference between previous and current photographs can help in identifying the possible distress where the mitigation can be planned.

2 ASSESSMENT OF BRIDGES

2.1 *Current Practice and Way Forward*

It is a normal practice to undertake the need based approach for bridge assessments. The requirements of bridge assessment could trigger by anything like due to change in traffic demand and other transient effects. The new vehicle load can significantly impact the structure that can deteriorate the condition of bridges. The assessment can also be due to widening of bridges where the study is required to check the existing structure for new distribution of forces. The main reasons that bridges require an assessment are:

a) Significant deterioration of structure due to age and other reasons
b) Increase in vehicle loading that require re-assessment of bridges in the network
c) Assessment of structure after significant natural event like earthquake, cyclone etc.
d) Accidental event – road or rail collision, ship collision etc.
e) Widening of existing structure

In most of the assessments it is found that there is significant reserve capacity in structural members that can eliminate the strengthening requirements. With the proposed real time monitoring system, the structures can be checked quickly under controlled conditions for new vehicle loading. The system can help in reducing the requirements of detailed assessment or improve the confidence level. For some of the initial sample bridges, the site results can be compared with assessment results to gain confidence and later the system can be solely used for checking the bridge suitability for increase in traffic demand.

2.2 *International Standards*

There are many standards available worldwide that provides a useful information for assessment and strengthening of structures.

European Standard EN 1504 has 10 parts that covers the complete lifecycle of structures from protection and repair of reinforced concrete. The standard also includes the test methods for material properties, specification for the key repair materials, including coatings, mortars, bonding agents and injection materials.

BA 32/90 is one of the UK standard for bridge assessment and repair of concrete structures that is in use for a long period. With the implementation of Eurocodes few years ago, this standard is still being used in conjunction with EN1504 and provides a useful initial information about bridge inspection and repair. The standard also covers the requirement of principal and special inspection.

ACI 562-16 is the latest standard available from American Concrete Institute which is now integrated with the ACI 318 requirements. The standard helps in understanding and identifying the unsafe structures and strengthening requirements. It is a performance based standard that provides the flexibility in the assessment and repair design process and identifies the

provisions to improve performance of the repaired structures.

3 REPAIR AND RETROFITTING

3.1 *Repair Requirements*

It has been rather disappointing to find out that only 75% of repairs survive 5 years. 25% of repairs survive 10 years and only 5% survive 25 years. There is a lot of research work undertaken on the repair of structures that bring out several products from different companies for improving the long-term durability of repairs. It is found that the failure of expansion joint and bearings are one of the significant reasons for deterioration of bridges. Now the integral bridges are more common for small to medium span structures that eliminates the maintenance requirements. The inspection of integral structures is much easier than the previous structures with bearings that have smaller parts and difficult to access for inspection.

The maintenance work of bridges has the following influence and constraints

a) Financial constraints and funds availability
b) Technical knowledge and knowledgeable staff
c) Number of assets and their importance to the public
d) Capability to organise effective quality assurance measures
e) Management methods

Serviceability failure can sometimes lead to deterioration of structures that includes cracking, spalling, shrinkage and deflection. This can happen due to poor workmanship, use of poor material, improper cover, concrete placement and other reasons. The serviceability is now a part of the design of structures and more focus is on the durability. These days with the scarcity of land more projects are being delivered in the brownfield sites where there is potential presence of a hazardous substance, pollutant, or contaminants. The environmental aggressivity is being checked in the design stage and appropriate steps are being taken in the design by providing adequate protection to structures.

3.2 *Decision for Repair and Retrofitting*

For a typical bridge in the urban environment or on a freeway there is limited opportunity to repair or replace the structure as the disturbance to the community is significantly high and thus limit the options to upgrade the structure. There are several reasons for repair of bridges discussed in the previous sections. It is also important to understand whether the residual life of structure is sufficient that warrant the decision making of whether the structure should be repaired or replaced. The typical example of collapse of 35W Bridge (Figure 6) in Minneapolis, USA where the existing bridge was even substandard for construction loads. The bridge was also rated as fracture critical, meaning that the failure of just one vital component could cause the whole bridge to collapse.

The conventional system in practice is to undertake the load rating and provide the residual capacity of different components of the bridge. The detailed inspection of the bridge that also includes the destructive and non-destructive investigations provides the condition assessment that help in selecting the factors based on the condition assessment. The inspection on site can provide the useful information about the level of strengthening requirements.

The condition factor and load rating help in decision making for strengthening. The process of decision for maintenance works generally follows the process as per Figure 7.

Figure 6 Collapse of 35W Bridge in Minneapolis, USA

During assessment and strengthening the serviceability and fatigue requirements should also be checked that later in the life of structure could become a main governing criterion for deterioration of concrete structures. However, this practice still provides a suc-

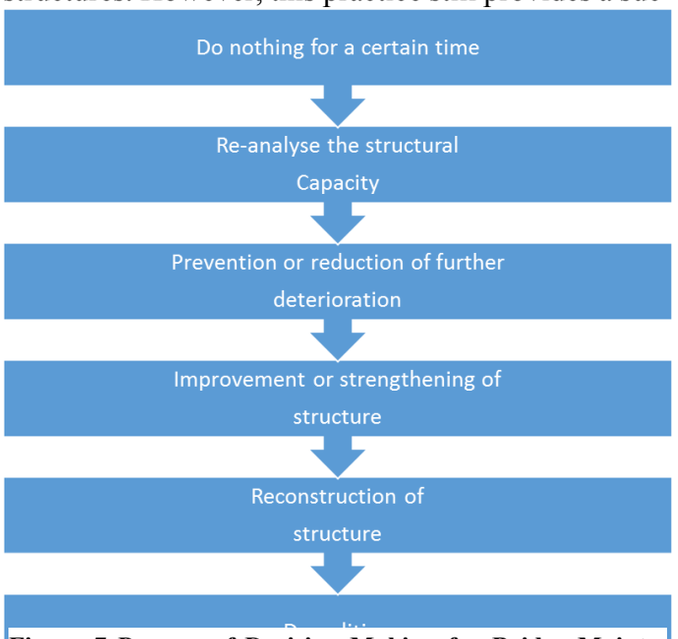

Figure 7 Process of Decision Making for Bridge Maintenance

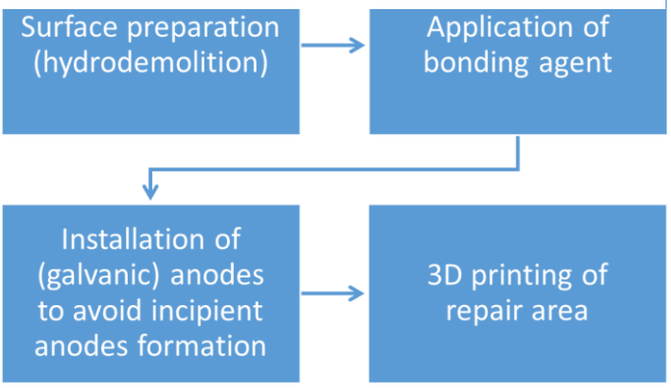
cessful outcome and the bridges strengthened with this method have successfully delivered the right outcome.

Other factors that could affect the decision making for repair of bridges are:

a) Residual life
b) Serviceability requirements
c) Fatigue requirements
d) Further deterioration possibilities after repair
e) Foundation condition
f) Future demand of bridge use
g) Exceptional forces – like earthquake, change in weather



3.3 *3D Printing for Concrete Structures*

3D printing of structures is getting popular across the world and recently the 3D printed bridge for cyclists was completed in the Netherlands. The main benefit of 3D printed material is that the optimum material can be used in different parts of the structure thus avoiding the need of prismatic shapes where the same section is continued to the support because of the formwork simplicity and making simple shapes.

The similar 3D printing can be used for the repair and rehabilitation of structures. The suitability of this process depends upon the substrate strength. As the material is deposit in the required shape so there will be careful surface preparation required alongwith the bonding agent for adhesion of new material with the substrate. With the use of 3D printing for repair there is no formwork required and the repairs can be completed quickly without significant temporary works. With the smaller nozzles, the material can be deposited around the reinforcement that avoids the shadow formation which is commonly a problem with sprayed concrete. The flowchart for repair and strengthening with 3D printing is in Figure 8.

With the bigger nozzles, the 3D printing can also be used for strengthening of structures. The flexible fibers like polypropylene can be used to reduce shrinkage and increase the strength. The ready-mix materials available these days has a quick gain in strength that can help in open the structure for traffic sooner. The addition of micro fiber reinforcement can help in improving the tensile strength of concrete and avoiding additional reinforcement in some cases. The material can be made more workable by adding superplasticizer and retarder so there is blockage of nozzles during 3D printing.

Figure 8 Process of Repair/Strengthening with 3D Printing

4 DURABLE MATERIALS FOR CONSTRUCTION

While planning for the maintenance of existing structures it is also important to make the future structures more durable so they require less maintenance and improve the service life. With the new research available it is the time to incorporate these new materials in greater use.

4.1 *Self-Healing Concrete*

Materials are now developed to a level that the durability of the structures has increased significantly. In the concrete structures, there is a discussion going on for the use of self-healing concrete. The self-healing concrete can repair its own crack work based on the bacteria that can survive in green and hardened concrete for more than 200 years. They get activate when the water or moisture enter cracks and they start producing limestone the can close the gaps within

concrete. It is expected the crack upto 0.8mm can be repaired with the self-healing bacteria.

4.2 *Ultra-High Performance Concrete*

Ultra-High Performance Concrete (UHPC) with compressive strength ranges between 120 to 150 MPa is being encouraged to use across the world. The UHPC includes fine sand, silica fume, ground quartz, high range water reducer, an accelerator, steel fibers, and water. The Australian Standards already allow to use concrete grade upto 100 MPa however it is still not in the range of UHPC. With the use of fiber reinforced concrete the normal concrete can reach upto to the ultra-high strength.

4.3 *Fiber Reinforced Polymer Composites*

Fibre-reinforced polymer (FRP) is a composite material made of a polymer matrix reinforced with fibers. FRP composites have been included in new construction and rehabilitation of structures through its use as reinforcement in concrete, bridge decks, modular structures, formwork, and external reinforcement for strengthening and seismic upgrade. The applicability of FRP reinforcements to concrete structures as a substitute for steel bars or prestressing tendons has been actively studied. FRP reinforcements offer several advantages such as corrosion resistance, high tensile strength, lightweight and ease of handling. The most serious problems with FRP reinforcements are the lack of plastic behavior and the very low shear strength in the transverse direction. The AS5100.8 provides the guidelines for strengthening of bridge structures using FRP composites.

4.4 *Weathering Steel*

Other innovative material quite common but seldom used in Australia is Weathering Steel. It is becoming common in the Europe to use this material because of the benefit of low maintenance and low life cycle cost. Although the initial cost is slightly high but considering the cost of initial protective coating and maintenance cost for 20 years this comes out cheaper than the conventional steel. Also, there is a significant focus on the urban designs so these bridges built with weathering steel (although provides an ugly appearance and feels like the bridge is crumbling) can be covered with urban cladding panels of any shapes and sizes.

4.5 *High Strength Steel*

The Australian Standards and other international standards now allow the steel grade up to 700MPa that help in reducing the amount of steel required for the structure. The high strength steel can be combined with UHPC discussed above where the high strength of concrete can help in balancing the internal forces in the section. Another option is to prestress the deck or steel section that can help in improving the overall resistance of the section.

5 FUTURE OF BRIDGES AND REPAIR REQUIREMENTS

There is an indiscriminate mining across the world for construction and there is already a shortage of construction materials and alternative ways are being invented to use different materials. Sand, which is a basic ingredient of concrete found shortage and number of middle eastern countries are buying sand from overseas. The abundant sand available in the deserts cannot be used because of it quality and suitability. There is 40bn tons of sand and gravel is used per year all around the world.

The onus is on the engineers to consider sustainability as part of their design. There is a great demand to reduce the section sizes of structures that helps in reducing the overall self-weight and foundation sizes. There is a need to use innovative materials, high strength materials as discussed in the section above that can help in contributing to sustainability.

Recently the world first modular glass fiber reinforced plastic footbridge was installed in the UK. The bridge design with name of 'Pedesta' is developed by Arup alongwith the Mabey Bridge. The modular bridge is expected to be of particular interest to the rail industry, providing a safer alternative for quick installation.

With the more durable materials and strict quality control in place for the new structures, the need of repairs is expected to reduce in the future. The integral structures are becoming more popular that is helping in eliminating the maintenance requirements.

The bridges constructed in the 20th century are still a challenge by maintaining them well can help in and avoiding the reconstruction and attaining sustainability in the long term. These bridges are the main point of attention for planning, maintenance and prolonging the service life. In most of the cases and especially the arch structure can sustain more than 100 years of design life.

BIM is expected to be an integral part of the asset management system where the existing structures model can be used for asset tagging and other purposes. The planning for inspection, repair and upgradation can be planned from the single system and can become a common data environment for all type of works. The early detection system and monitoring system as discussed before can be linked with this asset management system, plan inspection with drones and connect to real time monitoring of the structures. So the future lies in how to maintain and prolong the life of existing structures, remote monitoring of structures, construction of the new structures sustainably using minimum materials.

6 CONCLUSIONS

There are a number of new materials available that has already helped in improving the construction quality but still the challenge lies with an open question about how to manage the existing structures. It is expected that the remote monitoring and drones will become integral part of asset management system and existing available system can be digitized and fed into the management system which can become a single source of all current and new assets. The BIM process will become a part of larger asset management system. There is a need to use less and high strength materials that contribute to the sustainable future.

7 ACKNOWLEDGEMENT

The author would like to thanks his family for their support while writing this technical paper. The author would also like to thank the Arcadis Civil Structures team for their motivation to write this paper.

ABSTRACT: This paper proposes the displacement coefficient, R_d, for bridge column subjected to near-fault earthquake. R_d is defined as a ratio between ultimate displacement and elastic displacement. 142 pulse-like ground motions are utilized to perform the nonlinear time history analysis with constant ductility from 1 to 6. This study investigates the R_d in four aspects, including (1) signal processing method, (2) orientation of the velocity, (3) hysteretic models, and (4) number of the ground motions. The analytical results are compared with the regulations specified in AASHTO 2011. For a structure with typical displacement ductility of 4, compared to the analytical results, the R_d in AASHTO 2011 is overestimated within the period of 0.5 second, and underestimated between 0.5 and 4 second. Therefore, the revised formulation of R_d is proposed, which could be suitable for the bridge considering the near-fault effect in Taiwan.

1 INTRODUCTION

1.1 *Background*

Taiwan is located at the boundary between the Philippine Sea Plate and Eurasian Plate. The present converging rate is around 80 mm per year (Yu et al. 2001). In this convergence, the Philippine Sea Plate lies beneath to the north of Taiwan, while the Eurasian Plate in southern Taiwan is hidden under the Philippine Sea Plate toward east of mainland. Such a complicated activities of the plate caused the frequent earthquakes and orogeny in Taiwan. In addition, those activities also caused numerous active faults. According to the latest distribution map of active fault announced by Central Geological Survey in 2012, there are 20 Type 1 active faults and 13 Type 2 active faults, both of which have been activated in the past 10,000 and 100,000 years, respectively. These faults lie on the north-eastern and south-western direction, and most of the faults are reverse fault, while some faults are strike-slip fault along the eastern and western direction. The Shanchiao fault near the Taipei city in Taiwan is located in the tensile stress zone, which is a normal fault.

On September 21, 1999, a devastating earthquake with 7.3 magnitude on the Richter scale is called Chi-Chi earthquake. Chi-Chi earthquake caused different levels of damages to thousands of bridges in the central of Taiwan. Approximately 20 percent of the bridges suffered different damage levels, and 26 bridges were considered severe damage. It has been confirmed that due to the fault crossing or ground surface rupture near the bridge site, the superstructures were fallen from the collapsed piers in nine bridges, including Shi Wei bridge, Dong Fong bridge, Pi Fong bridge, Chang Gung bridge, Wu Xi bridge, Ming Chu bridge, Tong Tou Bridge, Long Men Bridge, and Li Yu Bridge along the Chelungpu fault.

Taiwan is a narrow island, so the numbers of people live near the near-fault region within 10 kilometers are accounted for 8.6 million. Any earthquake like the Chi-Chi earthquake occur again will induce another disaster. Therefore, it is necessary to initiate research works on near-fault earthquake and its impact to the infrastructure.

1.2 *Research Process*

Figure 1 illustrates the procedure of this study. There are seven steps, from selection of input ground motions as the first step to the proposed formula of R_d in the final step. The details of each step will be explained in the following sections. Section 2 is characteristics of near-fault ground motion. Section 3 is the signal processing of the time history. Section 4 is engineering parameters. Section 5 is analysis method. Section 6 is analytical results. Section 7 is proposed formula of R_d.

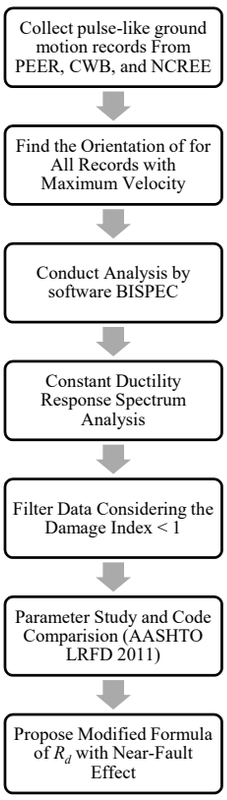

Figure 1: The procedure of research

2 CHARACTERISTICS OF NEAR-FAULT GROUND MOTION

When the fault was moving, the area closing to the ruptured fault was named near-fault area. It could be observed that there were some special characteristics for strong ground motion in the near-fault area. Thus, in seismic engineering, it was given a specific name called "Near-Fault Ground Motion".

2.1 *Peak of High-Strength Ground Motion and Acceleration response spectrum*

The seismic energy would dissipate during the process that seismic waves were traveling along the route of itself, and peak of ground motions and spectral accelerations would also degrade since that process. However, the ground motions which were near the fault provided a limit route to make the seismic energy to dissipate. As a result, the ground motions near the fault had higher peak value of ground motion, and acceleration response spectrum with different period than far-filed fault.

2.2 *Special Acceleration response spectrum in space distribution*

Near-fault ground motions had the characteristics including hanging wall effect and rupture directivity effect. Both of these characteristics caused the special difference of acceleration response spectrum in the space distribution comparing with the far-filed earthquake.

2.3 *Hanging Wall Effect*

The definition of hanging wall effect is that there are two stations located at both side of the inclined fault where are on the hanging wall and footwall position respectively. And the distance from the rupture surface are the same. When the fault was moving, it could be recorded the larger value of the ground motion on the station located in the hanging wall. The reason is that the station on the hanging wall position situated the radiative direction of seismic waves when the fault was moving. Therefore, it can sustain more strong seismic waves in this position.

2.4 *Rupture Directivity Effect*

The S wave superposed along the rupture direction of fault and caused the energy of seismic waves gradually increase along with the development of rupture of fault. This phenomenon was named rupture directivity effect. By the practical information and related predictable model could realize that the major reason to make the area of local low-frequency in acceleration response spectrum become larger, the larger earthquake magnitude is, and the smaller the frequency of the response spectrum amplification is. Since the accumulation of energy in the process when fault was rupturing hence the amplification along the rupture line of fault was positively correlated to the distance from station to epicenter (Spudich et al. 2014).

2.5 *Characteristics of Special Displacement of Ground Motion and Ground Velocity Time History*

2.5.1 *Permanent Ground Displacement*

The strong magnitude earthquakes caused by the activities of fault usually followed deformation of ground. Therefore, it produced the permanent ground motion in the areas where were near the fault. Even though there were no the situations that fault ruptured to the surface of the ground in the small magnitude, it could always observe the same deformation of ground for the same earthquakes in the areas where was near the epicenter.

2.5.2 *Velocity Pulse*

According to the results of rupture directivity effect and permanent ground displacement, it could be found there were some velocity time histories along with velocity pulses of single frequency and velocity pulses single direction recorded by several stations near the fault (Mavroeidis & Papageorgiou. 2003). These pulses would cause the low-frequency acceleration response spectrum to amplify, and these special velocity time histories would also lead to the increment of demand for nonlinear structural seismic design.

3 SIGNAL PROCESSING OF THE TIME HISTORY

This study collected the ground acceleration records from the Central Weather Bureau (CWB) in Taiwan, Pacific Earthquake Engineering Research Center (PEER), and National Center for Research on Earthquake Engineering (NCREE) in Taiwan to conduct nonlinear dynamic time-history analysis.

3.1 *The Central Weather Bureau in Taiwan (CWB)*

CWB set up hundreds of strong motion stations in Taiwan since 1991 and it has collected a lot of ground motion records. Most of the data belong to far-field records, where the near-fault data was primary collected from the Chi-Chi earthquake. The raw data are recorded by the strong motion stations and released by CWB after converting to an ASCII format. However, the acceleration time history downloaded from the CWB are without correction and the baseline usually drifts dramatically after the integration to velocity and displacement.

3.2 *The Pacific Earthquake Engineering Research Center (PEER Center)*

Chou et al. (2008) described the processing procedure of PEER strong motion database. Except for the baseline correction, PEER Center removed the instrumental response. In addition, a cosine taper was also adopted to revise the acceleration to zero in the start and the end of the acceleration to make the accelerations more smoothly in the two ends. However, in the processing procedure, PEER Center used a causal butterworth band-pass filter to the time history. This filter eliminated the permanent displacement for the seismic records.

3.3 *National Center for Research on Earthquake Engineering in Taiwan (NCREE)*

The processing procedure for NCREE mainly had two stages. Firstly, they used the re-mean to make baseline correction. The original acceleration records usually have small shifts in baseline, so the shift needed to be deducted and the baseline shift is the mean value of the first several seconds of pre-event noise before P-wave arrival. Second, the data collected from NCREE used the two points method (Iwan et al. 1985) to perform re-trend. The process was to remove the shifting of the baseline. During the earthquake, the seismograph might tilt when it met a strong shake. Therefore, in the acceleration time history, during the period of the strong shake, a box-like signal was mixed. An inclined line can be seen in the integrated velocity time history, and a least square method was used to find the slope of this inclined line between selected points. Then, the slope was corrected and the inclined line was back to the datum line. This way can reserve the permanent displacement.

4 ENGINEERING DESIGN PARAMETERS

Figure 2 shows the lateral force and lateral displacement relationship of one linear elastic system and one elastic perfect plastic system.
These two systems can be related by three engineering design parameters. R represents the force reduction factor. R_d is the displacement amplification factor, and C_y is the yielding strength factor. R, R_d, and C_y can be presented as function of displacement ductility, μ. μ is the ratio of the maximum displacement and yield displacement in elastic perfect plastic system. When μ is increasing, the plastic deformation of the structure would become more obvious. In this study, the major engineering parameter discussed is the displacement amplification factor R_d with respect to the constant value of displacement ductility μ.

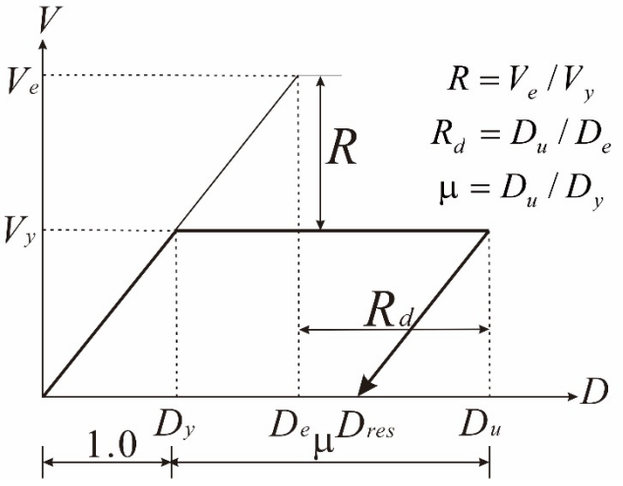

Figure 2: Force – Displacement Relationship

4.1 *Hysteretic Model*

4.1.1 *Elastic Perfect Plastic Model (EPP Model)*

Elastic Perfect Plastic Model (EPP model) is showed in Figure 3. EPP model is suitable for steel structure with an apparent yielding strength, and the corresponded hysteresis loop is well saturated. It is assumed the ratio of post yielding stiffness to elastic stiffness is zero.

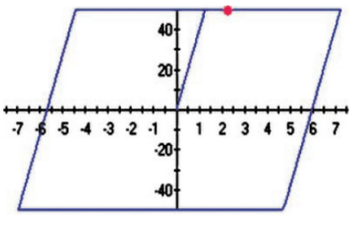

Figure 3: EPP Model

4.1.2 *Modified Clough Model (MC Model)*

Figure 4 shows a typical hysteresis loop for Modified Clough Model (MC Model). For a new design bridge column, it is expected to have a ductile failure. This

model is capable of describing the hysteresis behavior of reinforced concrete column member with sufficient lateral reinforcement. Obviously, the ratio of post yielding stiffness to elastic stiffness is zero for both EPP and MC models in this study for the reason of simplicity.

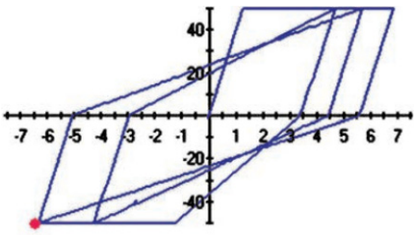

Figure 4: Modified Clough Model (MC model)

4.2 *Displacement Magnification Coefficient, R_d*

R_d is a ratio of displacement to measure the gap between ultimate displacement of a nonlinear system and elastic displacement of a linear system with same structural period. R_d is used to estimate the ultimate displacement by introducing a factor to amplify the displacement obtained from a linear elastic system. The definition of R_d can also be found in FEMA-440 (ATC 2005), FEMA-P695 (ATC 2009), and AASHTO Guide Specifications for LRFD Seismic Bridge Design (AASHTO 2011). In this study, only the regulations in AASHTO for bridge are discussed. The formulas in AASHTO are shown as follows:

$$R_d = \begin{cases} \left(1-\frac{1}{\mu_D}\right)\frac{T^*}{T}+\frac{1}{\mu_D} \geq 1.0 & \frac{T^*}{T} > 1.0 \\ 1 & \frac{T^*}{T} \leq 1.0 \end{cases} \quad (1)$$

in which

$$T^* = 1.25T_S \quad (2)$$

$$T_S = \frac{S_{D1}}{S_{DS}} \quad (3)$$

S_{D1} = Spectral response acceleration parameter at a period of 1 sec

S_{DS} = Spectral response acceleration parameter at short periods

According to the hypothesis that elastic system and elastic-perfect-plastic system have the same displacement, but it is not valid for short-period structures which may have an inelastic behavior. As a result, it can use R_d to adjust the elastic displacement for short-period structures. The formula for R_d defined that R_d is > 1 when the period of structures, T, is less than the characteristic ground motion period, T^*. The character μ_D in AASHTO is the same as μ in this study. There are different μ_D for various seismic design categories, SDC, in AASHTO. For bridges in strong earthquake region, μ_D may be taken as 6 for maximum local member displacement demand.

5 ANALYSIS METHOD

This study utilized BISPEC (Hachem 2013) to conduct nonlinear time-history analysis for a single degree of freedom (SDOF) system. The SDOF system is assumed to be an important bridge and located at a site which is near the Chelungpu fault in Taiwan. The analysis results are presented by constant displacement ductility μ to establish the relationship between structural period, T, and R_d. The structural period was from 0 to 10 sec, and the ductility μ was in a range of 1 to 6.

5.1 *Selections of Pulse-Like Time Histories*

This study collected pulse-like time histories from Strong Ground Motion Database of PEER with different types of faults, such as strike slip, normal, and reverse faults. The total number of records selected is 142. In order to reduce number of time histories, 39 records in the event of Chi-Chi earthquake were reserved. Eventually, 31 records applied to this study because those records are duplicated records for the comparison purpose used by NCREE to verify the signal processing process.

It could also be found the major fault type in Chi-Chi earthquake is reverse fault. Based on the code requirement, it is required to use seven ground motions for nonlinear time history analysis. Therefore, seven stations with tremendous velocity pulse are further selected, such as TCU052, TCU063, TCU065, TCU068, TCU075, TCU102, and CHY101, respectively. The raw data without signal processing of these seven stations can also be downloaded from CWB of Taiwan.

5.2 *Orientation of Maximum Velocity*

In general, the ground accelerations can be measured by accelerometer in two perpendicular horizontal directions and one vertical direction. However, it is not guaranteed that the signal with maximal velocity can be just recorded in the earthquake event. There is a need to reproduce a combined signal from two horizontal components corresponding to the velocity records at an angle to achieve the maximal velocity. For all 142 records, the specific angle has been found. Therefore, not only two individual horizontal components but also the combined component which contains the orientation of maximum velocity can be applied to the following constant spectrum analysis.

5.3 *Response spectrum*

As mentioned, PEER, CWB, and NCREE used the different methods to perform signal processing. CWB and NCREE reserved permanent displacement of the ground surface, but PEER eliminated the permanent displacement. Although the scope of this study is to focus the structural period within 10 sec, it is needed to investigate the permanent displacement by conducting the response spectrum analysis to acquire the average value of the 7 major records. Meanwhile, the difference in acceleration and velocity response spectrum within the period of 50 second were also compared by using records selected from PEER, CWB, and NCREE, respectively.

5.4 *Damage Index*

According to Bozorgnia and Vitelmo (2002), if the damage index (DI) is of 0, the system presents an elastic response. However, if DI is greater than 1, the system is about to be collapsed. Therefore, the structural response should be further examined whether the corresponding value of DI is greater than 1.0. Once DI is larger than 1.0, the system at a specified displacement ductility is failed. In this case, the results can't be included to be averaged with other results in same condition.

5.5 *Code Comparison*

It is expected that the analysis process is very time-consuming due to large amount of cases. The total number of the cases to be analyzed is about 511,200 by multiplying 142 motions, 3 signal processing methods, 2 hysteresis models, 6 displacement ductility, and 100 intervals of the period. As a result, some important parameters should be determined to reduce the number of cases. The analytical results will be discussed in four different aspects: (1) signal processing methods, (2) orientations of the records, (3) hysteretic models, and (4) numbers of records, respectively. In the end, the analytical results under these four criterions would be also compared with the current design requirements from AASHTO, so that to find the difference between analytical results and code values.

6 ANALYTICAL RESULTS

When dealing with the data in the following sections from 6.1 to 6.3, 7 records form PEER with the event of Chi-Chi earthquake will be selected to perform the analysis to obtain the global trend of R_d, But the suitable number of ground motions still need to be investigated in section 6.4. Moreover, for those 7 records, the orientation is in the east-west direction because the acceleration records have more notable pulse-like signal in this direction than in the north-south direction. In addition, the EPP model, as a standard model, is adopted to conduct the analysis for the comparison purpose.

6.1 *Signal Processing Methods*

Figure 5 indicates the acceleration response spectrum, velocity response spectrum, and displacement response spectrum by using the data from PEER, CWB, and NCREE, respectively. It can be observed the acceleration response spectrum and velocity response spectrum displayed duplicated results. But, a notable difference can be found on the displacement response spectrum when the structural period exceeds 10 sec, and it became more obvious between 30 and 50 sec. As a result, it is assumed the permanent displacement should be considered, and the signal should be specially processed to preserve the long duration component for the structure with long period, such as 10 sec. Otherwise, for conventional structure with the period less than 10 sec, there is no need to make special signal processing to include the permanent displacement in the spectrum analysis.

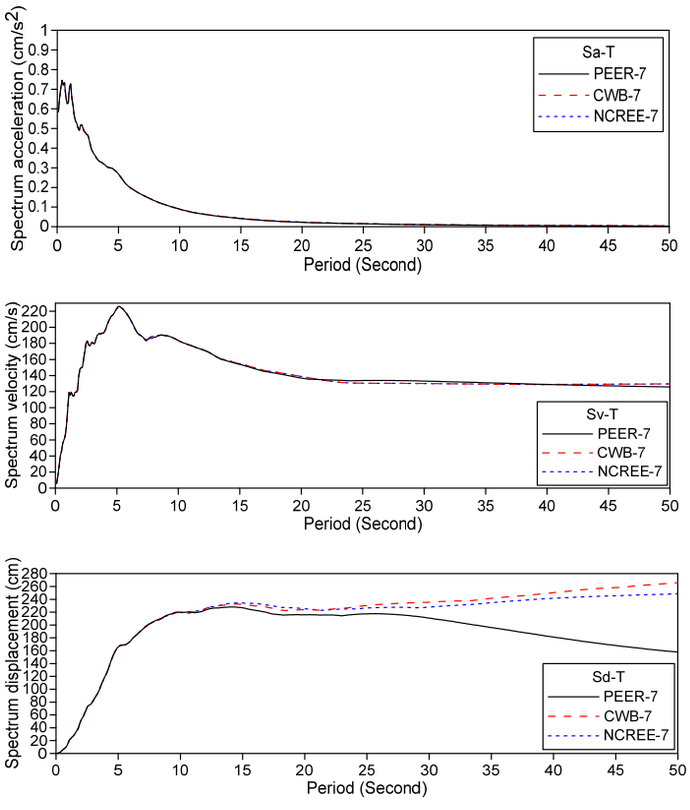

Figure 5: Spectrum analysis analyzed by data from three research institutions

Figure 6 shows the results of R_d analyzed by data given from CWB, PEER, and NCREE. In general, the analysis results for PEER, NCREE, and CWB are similar when μ is increased from 2 to 6. When μ is 2, and the period is within 0.5 sec, the R_d given by the code is close to 5. However, the analysis result just reaches 1.5. After the period of 5 sec, both code value and analysis result have almost same values. For μ is changed from 3 to 6, the code value is about two times

of the analysis result within the period of 0.5 sec It indicates the ultimate displacement of the structure may be overestimated based on the code regulations, particularly for structure with short period to obtain a conservative value of ultimate displacement. On the other hand, for the case with larger μ and the period is between 1 and 4 sec, the analysis result became slightly higher than the code requirement. It was more apparent when μ is increased from 4 to 6. Besides, the analysis results of R_d are smaller than the code values after the period of 4 sec for all cases with different μ.

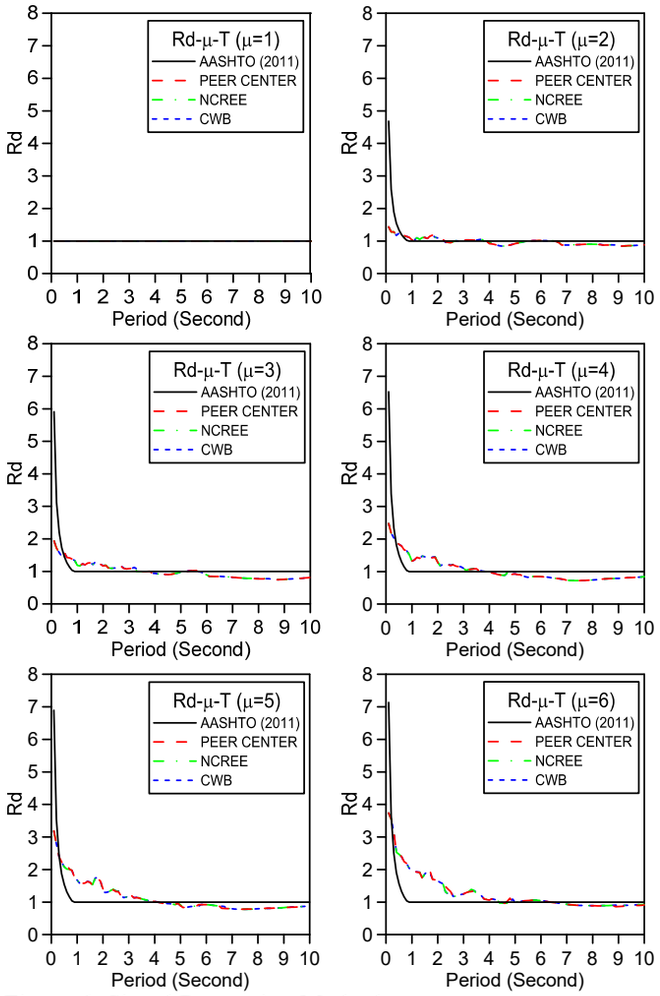

Figure 6: Signal Processing Methods

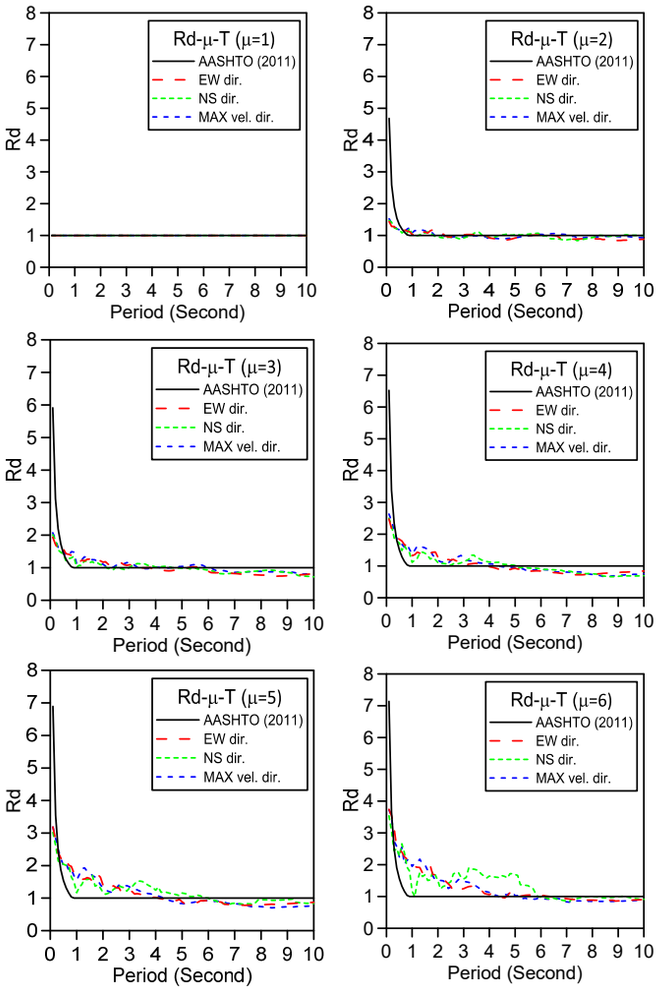
6.2 *Orientations of the Maximum Velocity*

Figure 7 shows the results of R_d analyzed by data with respect to west-eastern, north-southern, and maximum velocity direction. Overall, within the period of 0.5 sec, the values of R_d from AASHTO are double or triple than the analysis results if μ is in the range from 2 to 6. Though the trend of analytical results is similar, the results with maximum velocity direction is still slightly larger than the data with other two directions. The major difference between code requirement and analytical results can be found in the range of 0.5 to 4 sec. Before 4 sec, the analysis results exceed the code value; on the contrary, after 4 sec, the analysis results are gradually less than the code value. It is more obviously for the results with μ from 4 to 6. Besides, the analysis result are mildly fluctuated in the case of north-southern direction if μ is 5, and it becames more distinct if μ of 6 can be expected.



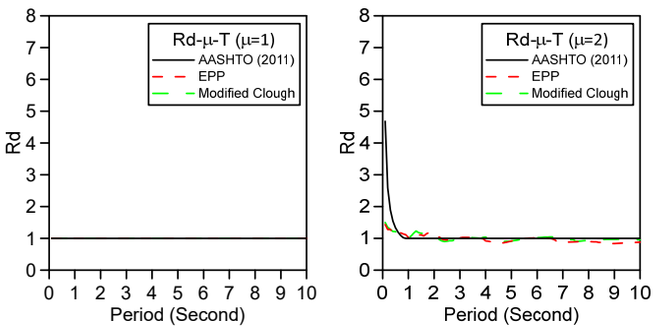


Figure 7: Orientations of the Records

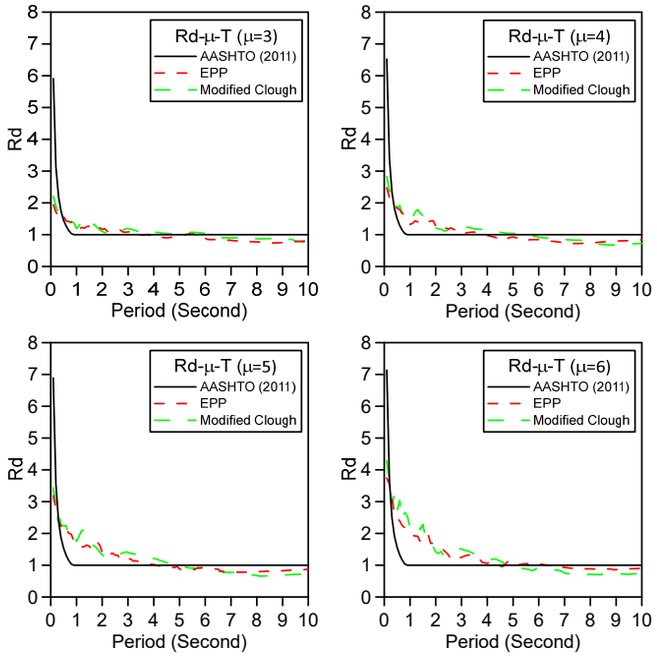
6.3 *Hysteretic Models*

Figure 8 illustrates the results of R_d analyzed by data based on two kinds of hysteretic models. The results showed no obviously difference between these two models when μ is changed from 2 to 6. And the entire trend of the analysis results is quietly similar to the results mentioned above, such as the signal procession methods and orientations of the records.



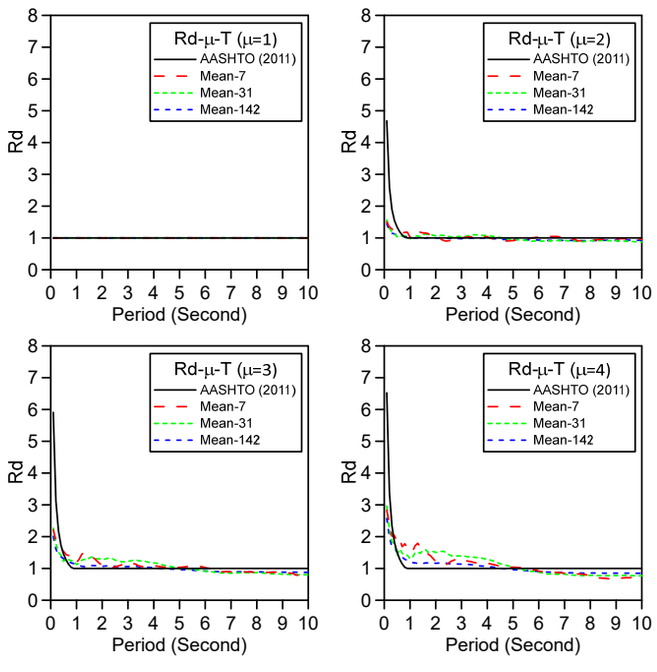


Figure 8: Hysteretic Models

6.4 *Numbers of Ground Motions*

Figure 9 indicates the results of R_d with respect to the three different numbers of ground motions: 7, 31, and 142 sets. Basically, when μ is increased from 2 to 6, the overall trend of the analytical results is very similar to the data mentioned from section 6.1 to 6.4. The code requirement gives higher value of R_d in short period than the one obtained from nonlinear time history analysis. Periods at 0.5 sec and 5 sec are two typical periods. It can be found, the analytical results are higher than the code value if the period is between 0.5 and 5 sec. After 5 sec, the analytical results are smaller than the code value as 1. In addition, results resulted from the average of 31 ground motions dominate the response as an envelope curve, if the structural period is located in the range of 1.5 sec to 5 sec.

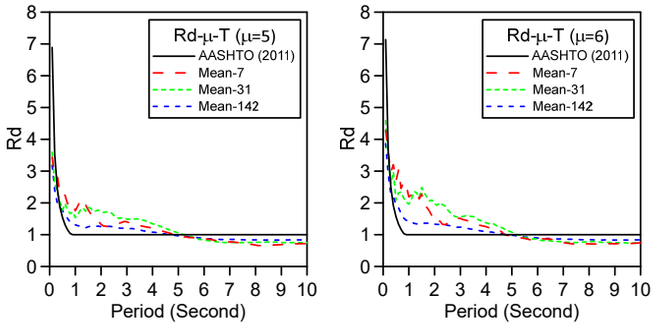

Figure 9: Numbers of Records

7 PROPOSED FORMULA OF R_d

Based on the previous discussions, in order to obtain the modified formula of R_d, the structural responses were determined by the following requirements. Total of seven pulse-like ground accelerations records in Chi-Chi earthquake were selected from PEER directly, and the time history records were adjusted to follow the orientation of maximum velocity. The Modified Clough model was applied to simulate the response of RC bridge column.

In the process of finding the proposed formula, this study referred to Miranda (2000) introducing the exponential relation in the nonlinear regression analysis. Unfortunately, the analytical results in medium and long period of this study can't be successfully described by the expression of exponential formula. Finally, the formula for structural subjected to near-fault earthquake are proposed in Eq. 2. Figure 10 illustrates the comparisons between the proposed formula and the analytical results, as well as the values obtained by AASHTO. The proposed formula can be divided into three segments according to the corner period T_0^M. Within $1.2T_0^M$, the proposed R_d has a linear inverse relation with period but is proportional to ductility. For the transition segment between $1.2T_0^M$ and $7.5T_0^M$, the proposed R_d is gradually decreased until reaching a constant of 1.0 at period of $7.5T_0^M$.

$$R_d = \begin{cases} 0.5+0.03\mu\left(10+\dfrac{1}{T}\right) & T<1.2T_0^M \\ 0.4\times\left[(0.3-0.2\mu)T+(1+\mu)\right] & 1.2T_0^M \le T \le 7.5T_0^M \\ 1 & T \ge 7.5T_0^M \end{cases} \quad (2)$$

in which

$$T_0^M = \frac{S_{M1}}{S_{MS}}$$

S_{M1} = Spectral response acceleration parameter at a period of 1 sec adjusted for site class effects

S_{MS} = Spectral response acceleration parameter at short periods adjusted for site class effects

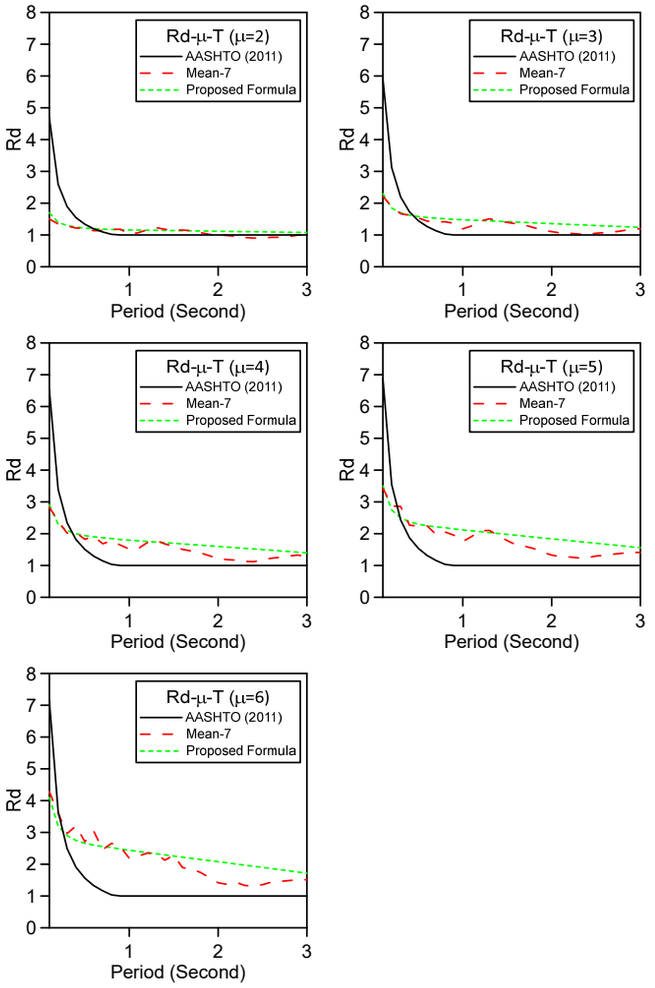

Figure. 10: Results of Proposed Formula

8 CONCLUSIONS

This study is a preliminary research on the issue of displacement-based performance assessment for bridge considering the near-fault effect. Major contribution is to propose the modified formula of displacement amplification factor R_d and structural period T within 3 second as well as constant displacement ductility μ from 1 to 6. The near-fault effect is considered by selecting the ground acceleration records with pulse-like signals from PEER. The nonlinear time history analytical results were presented to compare the displacement amplification factor suggested by AASHTO. It is found the analytical results gave a relative smaller displacement demand if the structure period is shorter around 0.5 sec, but have higher expected displacement for structural period is in the range of 0.5 and 5 sec. Consequently, the modified formula was proposed in this study and has a good agreement with the analytical results. In practical use, the engineers can easily carry out the performance check by multiplying the R_d and elastic response as a displacement demand, and compare it to the displacement capacity. Further research is therefore needed to address the R_d due to far-field earthquake to compare the difference.

The Condition of Padang's Bridges after 2009 Earthquake Disaster

Masrilayanti, Ruddy Kurniawan, Nidiasari & Nurhamidah
Andalas University, Padang, Indonesia

ABSTRACT: The city of Padang, the capital of West Sumatra, Indonesia, has many of bridges, but it seems that the government is not paying attention to the data archieve of the bridges in a proper way. Yet, archiving is very important since doing in a good way will give positive benefits to the societies. In 2009, Padang was hit by a massive earthquake that caused so much structural damage to infrastructure, including bridges. After almost ten years of the earthquake, bridges condition in Padang were analyzed by using two methods, BMS 1993 (Indonesian Provisions) and FHWA (USA). This paper describes the condition of the bridges in Padang City after 8 years of the 7,9 Richter Scale shocking earthquake so that it can be determined whether it needs to give retrofitting or not to the bridges by priority scale. Three main bridges in Padang City were screening and analyzed using FHWA, namely Simpang Haru Bridge; Kuranji Bridge; and Marapalam Bridge. The results show that although by visually assessment with BMS Standard the condition of the bridges are good enough, using FHWA procedure finds that Marapalam Bridge has the highest priority to be retrofitted.

1 INTRODUCTION

1.1 *Padang as the risk region of disaster*

Padang is known as the capital city of West Sumatera, Indonesia. It lies on Sumatra 's west coast and has a beautiful scenery cause this province has hills, beach, valleys and lots of rivers. Padang consists of eleven districts, and every districts has their own characteristics and vulnerable cases of disasters.

Almost all of disaster types for tropical country are available in this city, such as earthquake, lanslides, or floods. Padang has a long history of earthquakes. This city stands under a dangerous two plates, namely Indo-Australian and Eurosian Plate. In addition, Padang region also has lots of volcanoes so that it can induce earthqukes as well.

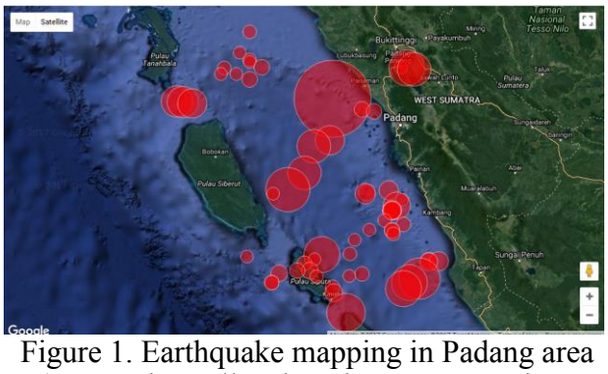

Figure 1. Earthquake mapping in Padang area (source: https://earthquake-report.com/)

In 2009, Padang was hit by a huge 7,6 RS earthquake. That earthquake caused many people lost, lots of houses and building collapse, and thousand of people death. Local government stated that around 130.000 house were severe damage, 60.000 houses were moderately damage and about 70.000 houses were slightly damage. In addition, bridges and road also had damage. However, since the epicentrum was about 70 km under the sea, the tsunami did not occur after the earthquake.

1.2 *System of Bridges Archiev*

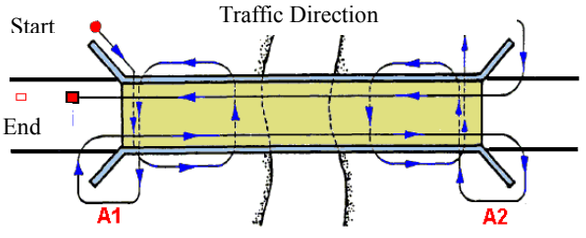
There are three types of street or highway in Indonesia, namely; National Highway, Provincial Highway and Regional Highway. National Highway is a street built by the government to connect provinces. Provincial street is a street which located in a province to connect cities in a province, whereas regional street is a street or road which connecting districts within the city.

1.3 *Highway classification in Indonesia*

There are three types of street or highway in Indonesia, namely; National Highway, Provincial Highway and Regional Highway. National Highway is a street built by the government to connect provinces. Provincial street is a street which located in a province to connect cities in a province, whereas

regional street is a street or road which connecting districts within the city.

1.4 *Purpose of the research*



Research purposes are to obtain the condition of the bridges around Padang City by using BMS Standard, and to have the information of the bridges regarding their urgency to retrofitting. Retrofit should be conducted by a properly method. Caterino et al (2014) stated that the requirements of strengthening arises not only from deficiencies of the primary elements but also from the insufficiency of structural elements.

Thus, repairing activities of the bridges will focuses to the bridge's rank under its very condition. It is hoped that some arguments that the bridges retrofitting has been based on location priority will not happen anymore.

2 RESEARCH METHODOLOGY

The methodology of the research is mainly visual survey and analysing by using BMS Standard and FHWA-HRT-06-032 2006.For BMS Standard, about 236 bridges have been surveyed and marked by using BMS Standard. Then several bridges among them were analyzed by using FHWA procedure to get the information relating to their priority of retrofit.

Visual survey has been done by searching the overall condition of the bridge. Terms to be surveyed are: surface, pavement, piers, abutment, girder, truss, seating, plants or grass which are on the bridge's elements. Procedure to conduct the survey can be seen from the figure below.

A1 = Abutment 1
A2 = Abutment 2

Figure 2. Survey direction

For analysing by using FHWA Standard, the rank of the bridges can be obtained. The rank of the bridges aims to conduct the priority of the bridges to be retrofitted. The rank comes after evaluating the bridges by considering the screening proccess, asses the vulnerability of the bridges, and performance level of the bridges under earthquake. Out put will be 0 to 100, which informs that higher the rank, more vulnerable is the bridge.

3 BRIDGES SAFETY CONDITION AFTER HUGE EARTHQUAKE

3.1 *BMS Standard*

BMS stands for Bridges Management System and was released by Indonesian Government in 1993 in order to obtain a positive evaluation and maintenance of the bridges in Indonesia. BMS standard has 6 level of bridge's condition as can be seen in the table below:

Table 1. The marking value of BMS Standard

Condition	Meaning
0	The bridge is still new and no remarkable damages
1	Very little damages are found and not give any effects to the structures of the bridge
2	There are a few damages and it needs to be observed in the future of time
3	There are some damages and likely to be more serious in 12 months
4	There are serious damages and need to be fixed immediately
5	The bridge cannot be used anymore

Source: BMS Standard, 1993, Indonesia

The mark 0 to 5 are obtained by accumulating the evaluation marks of the bridge in several element conditions, those are: strength of the structure element, the damage of the elemen, the effects of the damages, and the function of the element.

After analyzing the bridge under BMS standard, the results is that commonly the condition of the bridges is good as can be seen from the graph below.

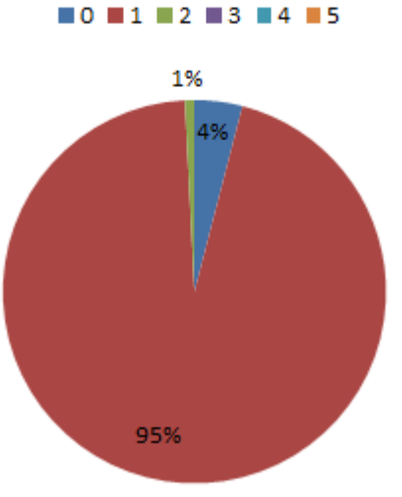


Figure 3. The distribution of BMS Standard marks on the bridges in Padang City (source: own research result)

3.2 *FHWA Standard*

FHWA stands for Federal Highway Administration and its tasks are to analyze, maintenane and arrange the evaluation of highway and its structures in USA. For this study, the regulation used are FHWA-HRT-06-032 2006 Part 1 which focuses on subject to bridge and its substructure. It evaluates the condition of the bridges by analyzing the seismic retrofit category (SRC) of the structures. The purpose of this evaluation is to obtain the bridge rank which defines how urgent the bridge to be retrofitted in order to overcome the earthquake or other disaster in the future.

To define the seismic retrofit category, it needs to find the anticipated service life (ASL) of the bridge. Anticipated service life is the remain age of the structure by reducing its age now to the year when it has been built.

There are three kinds of ASL relating to anticipated service life as can be seen in the table below:

Tabel 2. Categories of Anticipated Service Life

Service life category	**Anticipated service life**
ASL 1	0 - 10 yrs
ASL 2	11-40 yrs
ASL 3	> 40 yrs

Source: FHWA-HRT-06-032

Performance level is the performance of the bridge to overcome earthquake. Performance level can be obtained by considering the importance of the bridge's function, ASL value, and the kinds of ground moving due to earthquake. Classification of performance level can be seen in the table below.

Table 3. Classification of Performance Level

EARTHQUAKE GROUND MOTION	BRIDGE IMPORTANCE And SERVICE LIFE CATEGORY					
	Standard			**Essential**		
	ASL 1	**ASL 2**	**ASL 3**	**ASL 1**	**ASL 2**	**ASL 3**
Lower Level Ground Motion 50% probability of exceedance in 75 years; return period is about 100 years.	PL0	PL3	PL3	PL0	PL3	PL3
Upper Level Ground Motion 7% probability of exceedance in 75 years; return period is about 1000 years.	PL0	PL1	PL1	PL0	PL1	PL2

Source: FHWA-HRT-06-032

After obtaining the value of performance level, the earthquake dangerous level should be analysing by considering the intensity of ground vibration on the rock and its amplification on the soil layers above. There are several categories of this level as written in the table below.

Table 4. Hazard Level regarding the intensity of ground vibration.

HAZARD LEVEL	$S_{D1} = F_v S_1$	$S_{DS} = F_a S_s$
I	$S_{D1} \leq 0,15$	$S_{DS} \leq 0,15$
II	$0,15 < S_{D1} \leq 0,25$	$0,15 < S_{DS} \leq 0,35$
III	$0,25 < S_{D1} \leq 0,40$	$0,35 < S_{DS} \leq 0,60$
IV	$0,40 < S_{D1}$	$0,60 < S_{DS}$

Source: FHWA-HRT-06-032

Other terms that should be considered are vulnerability rating, seismic hazard rating and then bridge rank.

Vulnerability can be obtained by visual analyzing of the bridge. Bridge should be observed visually by evaluating its column, abutment, and liquifaction factors.

The values of FHWA range for bridges' rank lies between 0 to 100. 100 value means the condition of the bridge is urgent and need to be retrofitted as soon as possible. 0 value means that the bridge is not urgent and do not need to be repaired.

4 BRIDGES SAFETY FOR MITIGATION OF DISASTER

Three bridges are analyzed using BMS 1993 and FHWA namely Simpang Haru, Kuranji, and Marapalam Bridge. The first is located in Andalas Distric, the second is in Kuranji District, and the third is in East Padang District.

4.1 *Simpang Haru Bridge (Bridge I)*

Simpang Haru Bridge is a two spans precast concrete bridge and has been used by the people in the city for more than 25 years. The bridge is arranged in two single spans and the total length is

60 meters. The condition of the bridge overal is good, only has some cracks on the trotoar, plants on around the abutments and piers.

This bridge has been renovated in 2010 after the huge earthquake came hit Padang City. It suffered a quite critical damage due to the earthquake however it does not cause the bridge to collapse.

From the picture it can be seen that overal condition of the bridge is good. A small grass plant is on the piers of the bridge. The main girder is fine, however it needs to re-paint the bridge in order to get good aesthetic.

Figure 4. Simpang Haru Bridge (source: own research collection)

Thus by using BMS standard analysing, it can be said that the bridge is under condition 1. It means the bridge is safe and comfort for traffic and people.

Meanwhile, evaluation using FHWA results in 19,8. The value arrives from the condition of the bridge which is still good except of the plants around it. The bridge was built in 1992 and has routine maintenance from the local government. However, the urgency of the bridge is quite high since it lies on a crowded population area.The value 19,8 means that this bridge is not having high priority for retrofitting.

4.2 *Kuranji Bridge (Bridge II)*

The second bridge Kuranji bridge is a composite bridge and built in around 1992. The bridge is aranged in a continous two spans. BMS standard resumes that the bridge is also in condition 1. The photograph of the bridge can be seen in the figure below.

Figure 5. Kuranji Bridge (source: own research collection)

From the figure it can be described the overall condition of the bridge. Things to be considered are the condition of the pier foot, as due to the people activity around it, scouring could be a serious problem in the future. However, the bridge is just having an annualy maintenance from the local government such as painting, reinforcement, and re-surface. Thus it reform the bridge in a positive way.

For the second analysis (FHWA procedure), the value is 6,04. It comes from the condition of the bridge is quite good, no critical damages on the bridge, the age of service is 25 years old. Meanwhile, the urgency of the bridge is essential, which means the bridge is high urgent to be used for the population. The bridge also has a regular maintenance so that its condition is fair enough.

4.3 *Marapalam Bridge (Bridge III)*

Figure 6. Marapalam Bridge (source: own research collection)

The last bridge to be analyzed is Marapalam Bridge, located in East Padang District. It is a three spans prestressed bridge, and was built in 1995. Analyzed with BMS 1993, the mark of the bridge is 2 which means the bridge needs to be considered evaluated in 12 months ahead. However, no important damage can be visualized. The bridge also has a routine yearly maintenance such as painting, surface checking, and abutments. Only some cracking at the

abutment and some wild plants or grass are seen around the piers cap and the abutment as can be seen from the Figure 7.

Second analysis describes a different result because it gives mark as 66,4 rank of the bridge. It means this bridge has the highest priority among the three bridges. Visually BMS survey decides this bridge has nothing to be seriously afraid of relating to bridge performance, however analysis with FHWA regulation resumes on the contrary.

The problem with this bridge is that this structure does not have bearing on its support. The main girder is putting down directly to the seating as can be seen from the figure below. For FHWA analysis, bearing has a potential effect in calculating the bridge's rank. How bearing is used play an important role in assessing the performance of the bridge under earthquake load. If the bearing used is vulnerable to the earthquake load, the value of bridge's vulnerable is also high.

Figure 7. Plants and cracking on the Marapalam Bridge (source: own research collection)

From the Figure 8 below, it can be seen that main girder is directly attached to the support of the bridge. This condition could yield structure to have a great displacement when earthquake attacks. Thus, after analyzing the bridge, the result says that this bridge has the highest priority to be retrofitted among the three bridges.

Figure 8. The condition of Marapalam Bridge support (source: own research collection)

5 CONCLUSION

Analyzing the bridges under Bridge Management System (Indonesian provision), gives a positive results that mainly the bridges are in good conditions. The range is also small from 0 – 5 which means cannot implify the urgency of the bridges to be retrofitting in properly priority.

Meanwhile, using USA regulation to analyze the bridge relating its priority to have retrofitting, gives a clearer consideration. The range is far from 0 to 100, thus the bridges can be evaluated in a more specific mark.

From the three bridges assesments, the results are saying that Bridge III (Marapalam Bridge) is getting the highest mark, that is 2. Meanwhile Bridge I and II have the same mark in 1 condition. So it needs more asessment to choose which one of these two bridges should have a more priority to be retrofitting.

On the other hand, FHWA regulation gives the highest bridge rank to Bridge III since it has 66,04 point. It concludes that Bridge III should have the first priority to be repaired or retrofitting. Bridge I is the second and the last priority goes to Bridge II.

6 AKNOWLEDGEMENT

The authors wish to express their gratitude to Kemenristekdikti, (Indonesian Ministry of High Education and Research Department) for the precious financial support so that this research could be conducted, as stated in Research Project No: 059/SP2H/LT/DRPM/IV/2017.

Advanced Nonlinear Finite Element Modelling of Reinforced Concrete Bridge Piers

E.P.G. Bruun, A. Kuan, G.T. Proestos, E.C. Bentz, & M.P. Collins
Department of Civil Engineering, University of Toronto
Toronto, Ontario, Canada

ABSTRACT: Severe cracking was observed on the flexural tension face of a reinforced concrete hammerhead bridge pier cap. Determining the cause and severity of the damage was complicated by the geometry of the piers, which influenced the strut-and-tie mechanism. A tapered end cap raised questions about the development of the tension reinforcement in the chord, while a hexagonal pier column meant that the effective area of the compressive strut was uncertain. Depending on the assumptions made, widely different estimates of the ultimate capacity were reached by traditional calculation methods. Therefore, to accurately assess the safety of the bridge piers, a series of analyses were performed using VecTor2 – a nonlinear finite element analysis program (NLFEA) developed at the University of Toronto. A parametric study was conducted by varying the effective width of the piers and the amount of reinforcement engaged, and the factored strength of the pier was obtained using a novel procedure. This paper concludes that using 2-D NLFEA in a discerning manner allows engineers to understand complex 3-D situations.

1 INTRODUCTION

1.1 *Background*

Despite the development of simple and powerful tools to assess the strength of reinforced concrete structures, hidden complexity often makes determining the strength of even a simple structure a nontrivial task. Consider the following structure shown in Figure 1, which is a typical pier supporting a multi-span bridge in Canada. A recent inspection noted the presence of several vertical, and some diagonal, cracks, and it was concluded that strength of the pier needed to be determined to evaluate the overall safety of the structure. At a first glance, the structure appears to be a straightforward cantilever, suitable for a 2-D analysis using a strut-and-tie model. Looking more closely, the geometry of the pier complicates matters considerably through the section. The width of the bearing pad suggests that shear lag effects may be significant; when combined with the taper on the hammerhead and supporting column, it is not clear how much of the concrete section is effectively utilized. It is also not clear if all of the flexural reinforcement can be utilized, due to the anchorage detailing of the various layers of steel, as well as the aforementioned shear lag effects. When considering all of these factors, using simple code-based procedures is difficult.

Nonlinear finite element analysis (NLFEA) is a powerful tool for understanding overall structural behaviour given various geometric and material complexities. Specifically in the case of reinforced concrete, NLFEA allows engineers to consider effects such as post-cracking concrete tensile stresses, compression softening, bar development and crack slip among other things.

While NLFEA is appropriate for predicting the actual strength of a structure, it may also be necessary to verify that a structure has adequate capacity within a Load and Resistance Factor Design (LRFD) framework. For example, this may be needed when performing a code-based evaluation of an existing structure. However, it is problematic trying to assign a representative resistance factor to the predicted strength from an NLFEA output, since the associated resistance factors for concrete and steel are different, and guidelines for doing this currently do not exist.

Using the hammerhead pier structure as a case study, this paper describes a procedure for simplifying the complex geometry and evaluating the strength of these piers using VecTor2, a 2-D NLFEA program developed at the University of Toronto, which uses the Disturbed Stress Field Model (DSFM) (Vecchio 2000) as its theoretical foundation. A method is then described to obtain the factored strength of the pier for evaluation using an LRFD framework.

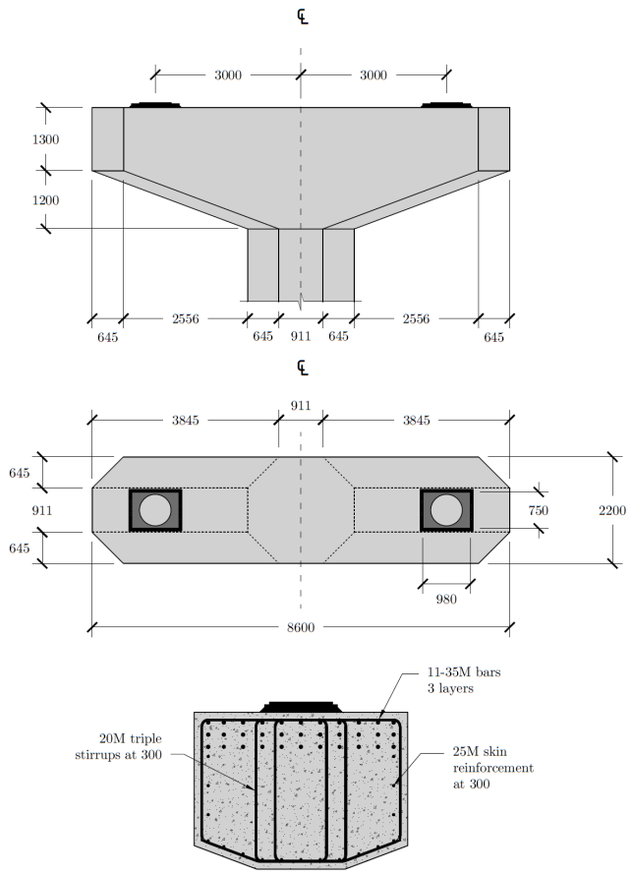

Figure 1. Elevation (top), Plan (middle) and Cross Section (bottom) of full hammerhead pier

1.2 *Description of Nonlinear Finite Element Analysis Methodology*

An analysis of the bridge pier was performed using a VecTor2, a 2-D finite element analysis program which is based on the DSFM. The DSFM, an advanced reinforced concrete material model based on the Modified Compression Field Theory (Vecchio 1986), is a smeared rotating-crack model which is formulated to consider tension stiffening, compression softening, and crack slip (Vecchio 2000). As the DSFM is capable of predicting the complete load-deformation behaviour of reinforced concrete elements, the full response of the hammerhead piers can be obtained from a VecTor2 model. Equally useful is the ability to calculate important parameters at any load level, such as the stresses and strains in the concrete and steel, crack patterns, crack widths and crack slips. Various other numerical models are implemented to complement the DSFM and allow for additional effects to be considered, such as tension softening, bond slip amongst others. VecTor2 uses 4-node rectangular elements for reinforced concrete materials, and 2-node truss elements for discrete steel reinforcement.

While a 3-D nonlinear finite element analysis based on the DSFM is possible to perform, it is a challenging task because a compatible preprocessor and postprocessor do not currently exist. In addition, the prohibitively large computational time needed to perform a full 3-D analysis currently makes nonlinear 3-D analysis of such a large structure impractical. Thus, a 2-D approach was used instead. To account for the aforementioned 3-D effects, a parametric study was performed to understand the sensitivity of the structural behaviour to varying model parameters. The key variables investigated were the effective section width and effective quantity of longitudinal reinforcement.

2 MODELLING PARAMETERS

The following subsections will outline the input parameters for the models created for this study. Conservative assumptions were made if precise information was not available.

2.1 *Model Mesh*

Due to symmetry, only half of the pier cap was modelled, using the centreline of the column as the vertical boundary. Figure 2 shows the schematic breakdown of the VecTor2 mesh used in the analysis, where the regions are described as follows:

Region A: The column base, which is further subdivided to represent the varying width as a result of the column taper. This region remains the same throughout all of the various VecTor2 models, as the column is not being directly investigated. The modelling assumptions for the column are discussed further in Section 3.1.

Region B: The connection point of the cantilever, which is further subdivided to allow for the out-of-plane width of the cantilever to be adjusted. A key part of this study (Sec. 4.2) is investigating how the effective width of the cantilever influences the capacity of the pier.

Region C: The cantilever portion of the pier cap with a constant thickness throughout. This region is also adjusted to account for the effective width of the pier (Sec. 4.2).

Region D: The end portion of the pier cap cantilever with a constant thickness of 911 mm. This region remains the same throughout all of the various VecTor2 models, which is a conservative assumption based on the minimum thickness of the column at its connection to the cantilever. The reasoning for this decision is discussed further in Section 3.3.

Region E: The baseplate spreading the applied load into the structure, with dimensions based on the assumptions discussed in Section 3.4.

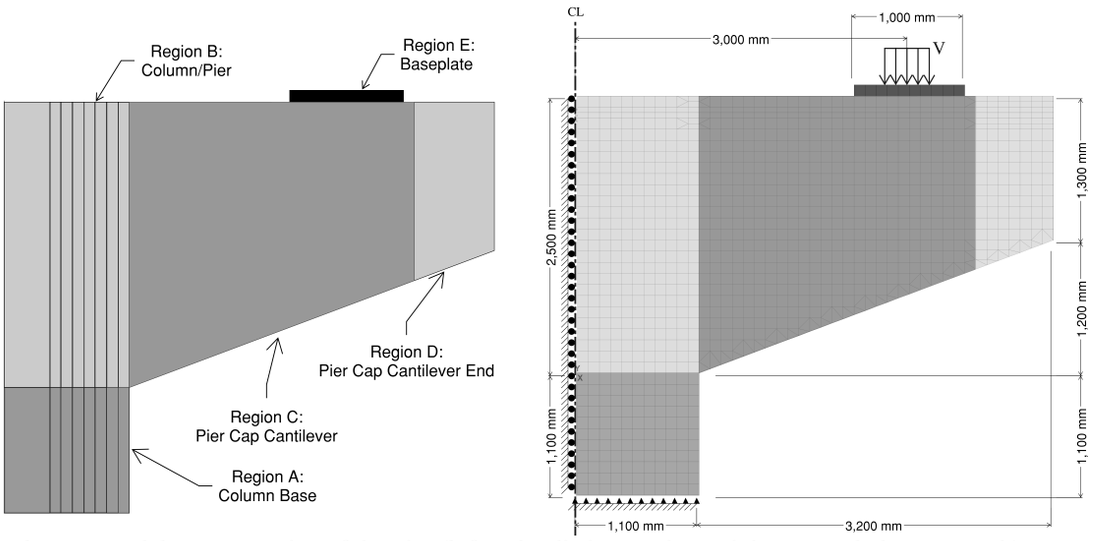

Figure 2. Finite element model representative of the pier (left = the distinct regions, right = actual element mesh)

To realistically represent the flow of forces in the structure, a portion of the pier column was also modelled (1100 x 1100 mm stub), with the horizontal boundary representing the base of the stub. Rollers were placed along the vertical boundary to allow for the development of horizontal reactions (moment couples) along this face, and pins along the horizontal boundary to represent the transfer of the applied shear force into the column. A summary of these boundary conditions is shown in Figure 3

Since VecTor2 makes use of relatively simple linear isometric elements, the element size was chosen to be 100 mm x 100 mm (XY-plane) in order to get a fine enough strain profile describing the structural behaviour through the depth of the pier. The irregular geometry of the column was modelled using elements of varying individual thickness (into the page).

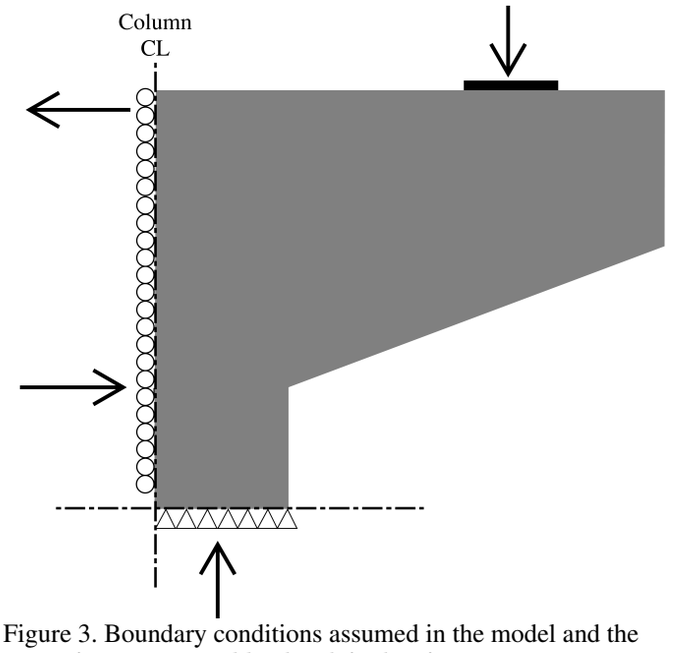

Figure 3. Boundary conditions assumed in the model and the approximate structural load path in the pier

2.2 *Material Properties*

The material properties were chosen according to the to design specifications, with $f'_c = 35$ MPa and $f_y = 400$ MPa. The Hognestad parabola was used to model the pre-peak stress-strain behaviour of the concrete, and a bilinear model was used for the steel.

2.3 *Steel Reinforcement*

The main flexural tension reinforcement was modelled as three layers of discrete elements across the top of the pier cap. To investigate the effect of varying levels of effective reinforcement on the capacity of the pier cap, the quantity of steel per layer ranged from 7000 $\frac{mm^2}{layer}$ (7 – 35M) to 11000 $\frac{mm^2}{layer}$ (11 – 35M).

Skin reinforcement and stirrups were distributed over the pier by averaging the steel over the concrete material in the region.

It was found that including the beneficial effects of the compression reinforcement did not lead to significant changes in the load-deformation behaviour of the piers. Thus, the analyses were performed without including discrete compression reinforcement in the finite element model.

2.4 *Applied Loading*

The bridge loading on the pier was distributed over a 500 mm width onto a 1000 mm wide base plate representative of the bearing details discussed in Section 3.4. In the analysis, the total load was incremented by 200 kN per load stage until ultimate failure.

3 IMPORTANT FINITE MODELLING ASSUMPTIONS

To account for the complexities caused by the geometry of the hammerhead piers, the following modifications were made to the 2-D model in order to capture the effects of the real 3-D structure.

3.1 *Pier Column Taper*

As shown in Figure 4, the tapered edges of the pier column were represented as discrete steps with a width of 100 mm (to match the typical element mesh size). Each step represented a 200 mm decrease in the overall width, although the final step was set to 911 mm to match the real minimum end width.

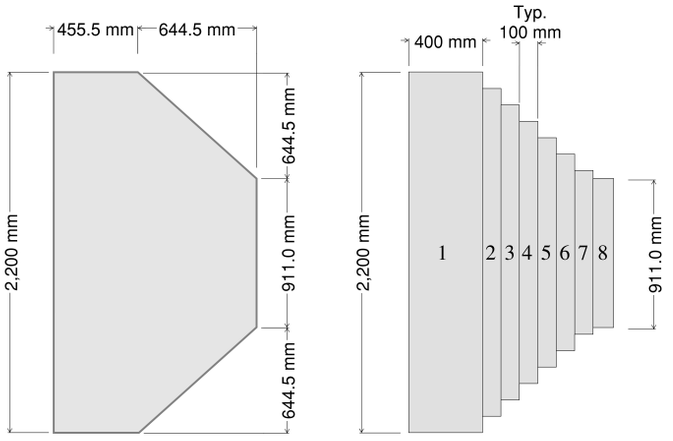

Figure 4. Cross-section of the pier half-column (left = as-built, right = model approximation)

The reinforcement in the pier column was represented as smeared throughout the slices, based on the resulting ρ_s from the as-built reinforcement as shown in Figure 5.

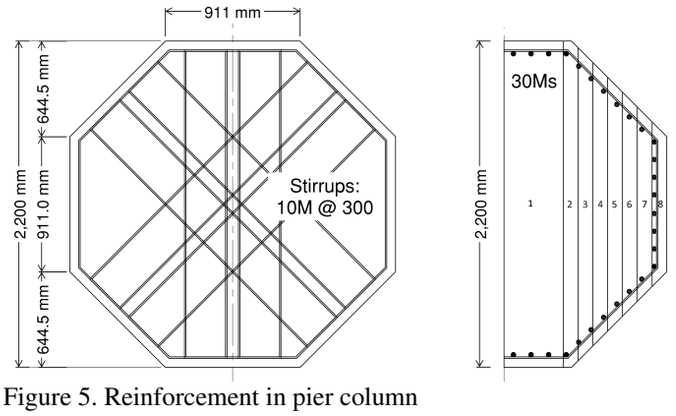

Figure 5. Reinforcement in pier column

3.2 *Pier Cap Chamfers*

As shown Figure 6, The cross-section of the pier cap cantilever was simplified to a rectangle, omitting the slight chamfer at the bottom edges and cap ends. The structural impact of this simplification was deemed minimal with respect to other parameters, such as out-of-plane effective width of the compressive strut or effective quantity of longitudinal steel.

3.3 *Pier Cap Ends*

In all the models the tapered portion at the end of the pier cap was omitted leaving only the minimum 911 mm constant width section (Fig. 7). This is a conservative but valid assumption since the region is not critical for the load carrying S&T mechanism, while the effect that this region has on the anchorage of the bars is handled explicitly when considering the development lengths of the reinforcement bars (Sec. 3.5). The variable W_{eff} refers to the effective width of the pier cap set as a parameter in the various models.

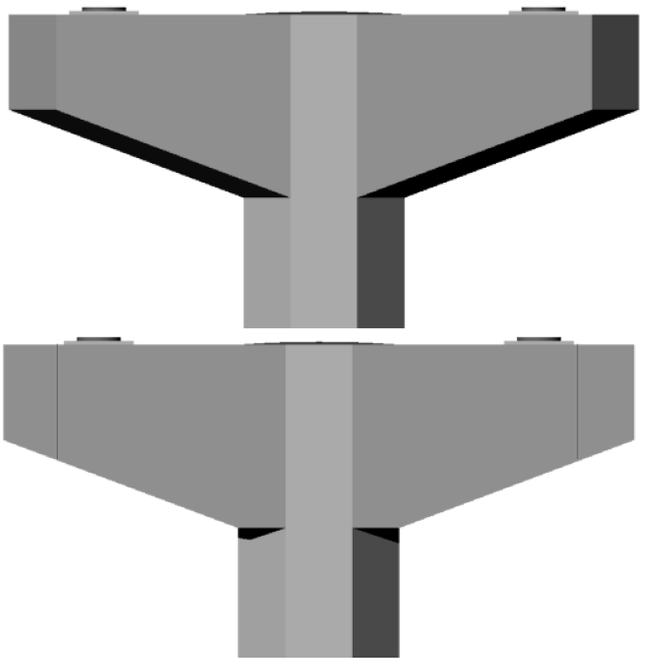

Figure 6. As-built (top) and simplified (bottom) pier cap profile. Note the uniform hammerhead thickness.

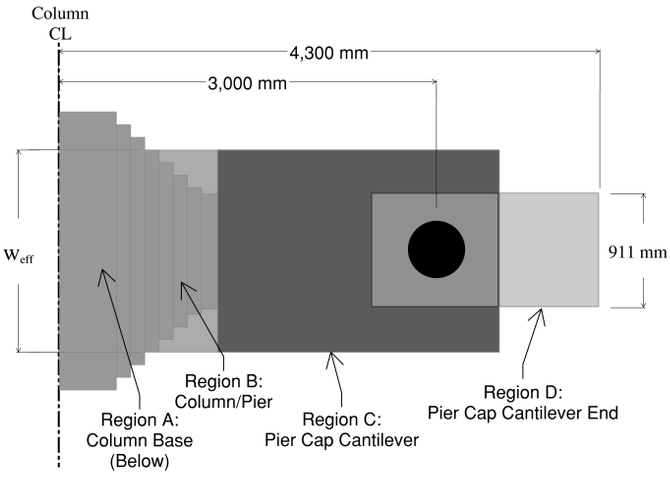

Figure 7. Plan view of pier cap showing simplified end portion

3.4 *Applied Load Bearing Area*

The pot bearing base plate is listed as 980 x 750 mm, with the bearing area further increased by 50 mm of grout at 45 degrees between the bottom of the plate and the top of the pier cap. The load is transferred through the pot plate, which has a diameter of 650 mm. As a conservative simplification, the base plate is modelled as stiff 1000 mm x 850 mm area, with the load distributed over a 500 mm width (Fig. 8).

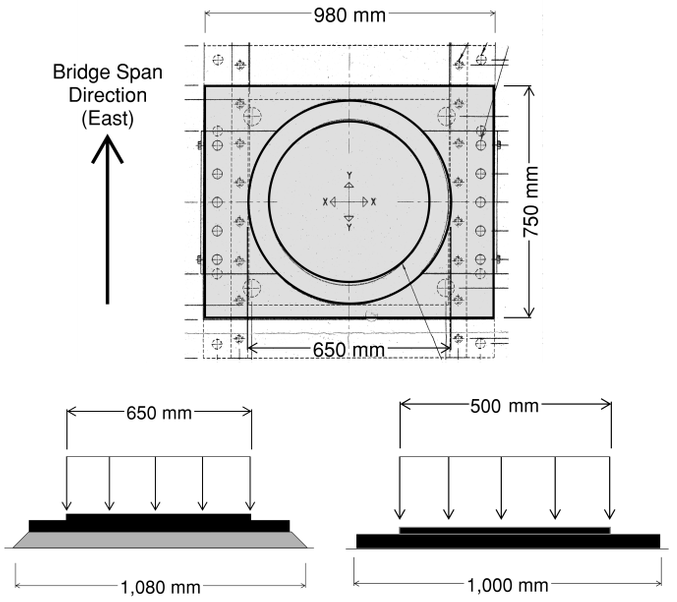

Figure 8. Plan view of pot bearing (top), with the actual (bottom left) and modelled (bottom right) loaded areas

3.5 *Reinforcement Bar Anchorage*

The longitudinal reinforcement in the pier cap was made up of mostly straight deformed bars, only the middle five bars had standard hooks at the end. While the taper at the pier ends was not modelled explicitly, its effect on the development of individual longitudinal bars was accounted for using the methodology described in this section. For example, since the outer bars were cut off closer to the column centreline due to the taper, their full development also occurred closer to the column and past the center of the applied load (Fig. 9) - ideally all the bars in an S&T chord should be detailed so that full development is achieved before this point.

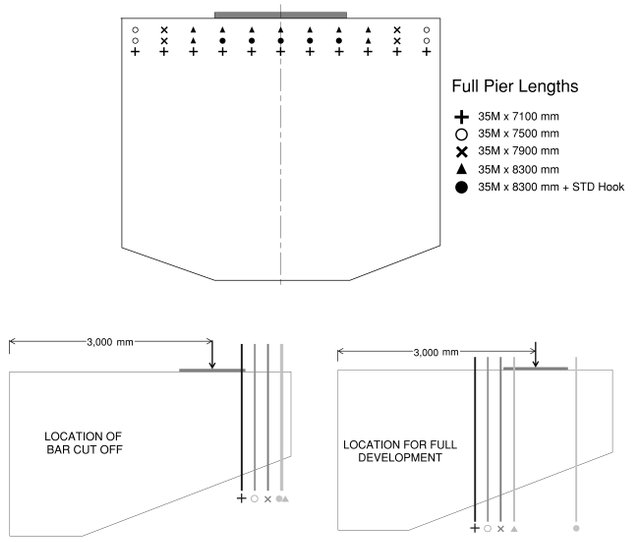

Figure 9. Cross-section of pier cap showing the 35M bars (top), where the cutoff points (bottom left) and full development points (bottom right) are shown for each type of bar

The axial force capacity of the top chord, accounting for incomplete anchorage, was then determined along the length of the cantilever. This capacity was compared to the demand in the longitudinal reinforcement from a sample VecTor2 model (in this case $W_{\text{eff}} = 1,200\,\text{mm}$, $A_s = 11,000\,\text{mm}^2$/layer) at around the peak load stages (Fig. 10). The anchorage was found to be adequate (i.e. capacity $>$ demand), especially when considering that the loads recorded in this model were significantly higher than the actual applied loads on the structure.

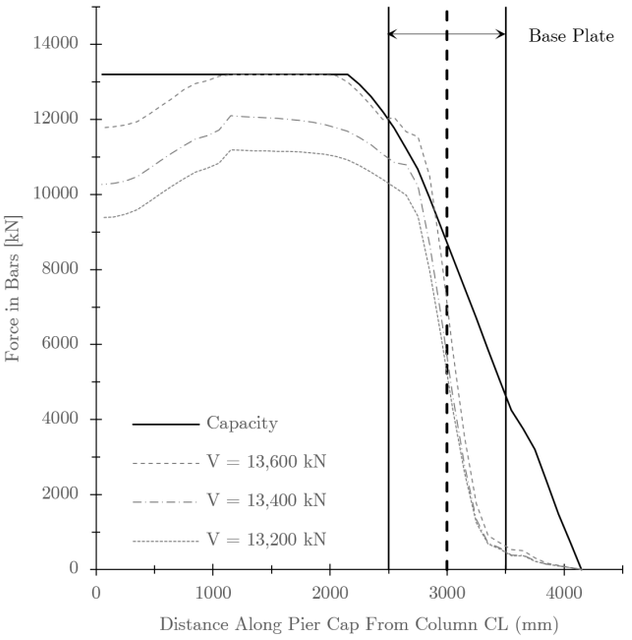

Figure 10. Demand on longitudinal tension reinforcement at applied loads ($W_{\text{eff}} = 1200\,mm$, $A_s = 11000\,\text{mm}^2$/layer)

4 ANALYSIS RESULTS

4.1 *Establishing the Parametric Study*

A total of 40 analyses were performed to obtain a comprehensive understanding of the behaviour of the hammerhead pier. The effective width of the structure was varied between 911 mm, the width of the thinnest section of the pier, up to the full width of 2200 mm (Fig. 12). Similarly, the quantity of steel included in the numerical model varied from a minimum of 7-35M bars per layer to the actual 11-35M bars per layer. This was done to account for the ambiguity in the number of bars that would be engaged by a load bearing area smaller than the full width of the pier.

4.2 *Results of Parametric Study*

Figure 11 compiles the results of all 40 analyses, with the ultimate nominal shear capacity being shown for the various widths and reinforcement quantities. It is apparent from the two plots that increasing the section thickness and quantity of reinforcement leads to gains

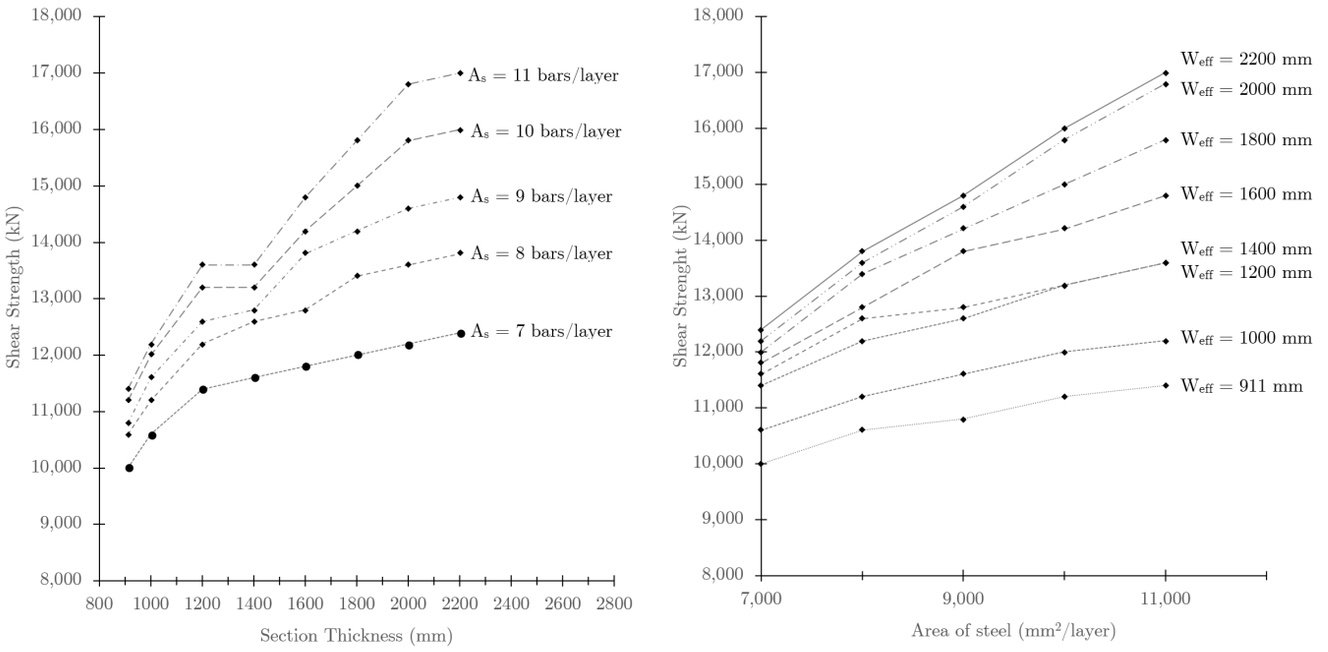

Figure 11. Influence of section thickness (left) and quantity of reinforcement (right) on ultimate capacity of pier

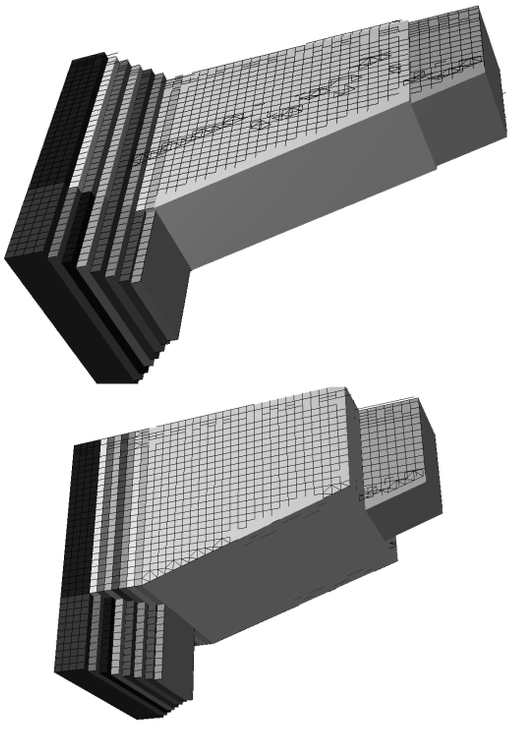

Figure 12. Effective width of pier cap varied from 911 mm (top) to 2200 mm (bottom)

in strength. Broadly speaking, increasing the thickness of the pier as well as the amount of steel led to proportionate gains in capacity. Generally, increasing the quantity of steel tended to provide larger gains in ultimate strength than increases in the thickness of the cross sectional area, which suggest that the amount of steel plays a major role in determining the strength of the structure. This was more pronounced in the analyses of the thicker sections, which benefited more than the thinner sections from additional steel in the tension chord.

5 DISCUSSION

5.1 *Failure Modes*

As VecTor2 is able to predict the complete load-deformation behaviour of the hammerhead pier structure, the failure mode can be understood by analyzing the element stresses and strains at failure. Figure 13 shows how the progression of failure events occurs as the effective section width is increased while maintaining the same amount of steel. If the effective section width is very thin relative to the quantity of reinforcement, then crushing of the concrete at the base of the pier occurs prior to yielding of the longitudinal steel. This can be seen in Figure 14. As the section gets larger, this pattern of events reverses and the steel yields followed by crushing causing failure.

5.2 *Integration of Results with an LRFD Framework*

Per the requirements of the National Building Code of Canada (Canadian Commission on Building and Fire Codes 2015), the factored strength of the structure must exceed the demands of the applied factored loads. The factored shear strength of the pier is thus obtained using the expression:

$$V_r = \phi_c V_c + \phi_s V_s \geq V_f$$

Where $\phi_c = 0.75$ and $\phi_s = 0.90$ are the strength reduction factors for concrete and steel accordingly (S6 Code Committee 2014). While this expression is straightforward for use with simplified design expressions, it is difficult to obtain the factored strength if the analysis is performed using NLFEA. Simply reducing the concrete cylinder strength and the steel

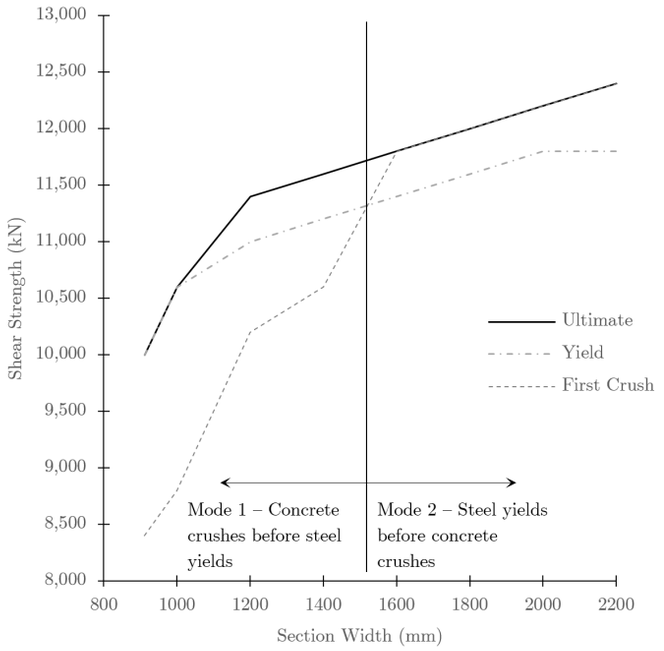

Figure 13. Influence of section width on shear strength. $A_s = 7000\,mm^2$ per layer)

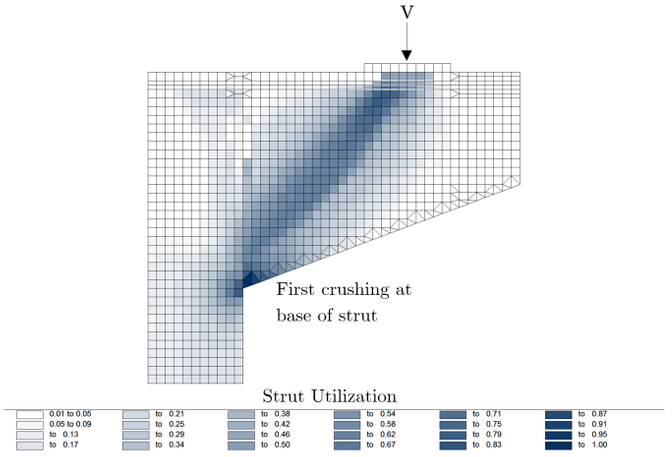

Figure 14. Crushing at the base of the pier

yield strength in the model by the corresponding resistance factors is not appropriate, as doing so would result in fundamentally changing the failure mechanism of the structure.

The approach taken in this study draws inspiration from the the ACI 318-14 code's provisions for flexural design (ACI Committee 318 2014). According to these provisions, the ultimate strain in the longitudinal reinforcement can be checked at failure to classify the failure mechanism. For tensile strains greater than 0.005, the failure is said to be governed by the tension failure of the longitudinal reinforcement. Conversely, strains less than 0.005 are a mixed failure mode where the crushing of the concrete has an influence on the ultimate factored flexural capacity. When applied to the VecTor2 analysis, the maximum strain in the flexural reinforcement was checked to determine whether the failure was clearly governed by yielding of the steel. An appropriate resistance factor obtained from the Canadian Highway Bridge Code was then applied (S6 Code Committee 2014). If the capacity of the analyzed structure is clearly governed by the behaviour of the steel, multiplying the ultimate load by the steel resistance factor of 0.90 is an appropriate way to obtain the factored strength. If crushing played a role, then the factored strength was obtained by multiplying the peak load by the concrete resistance factor of 0.75.

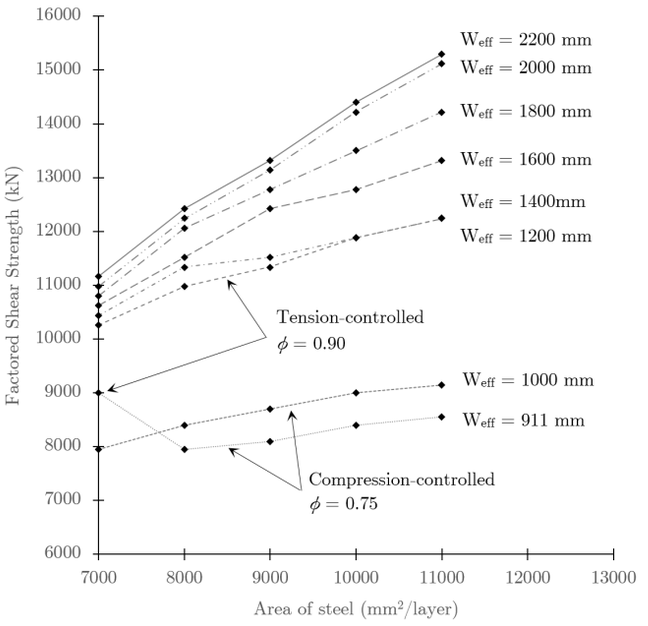

Figure 15. Factored shear strength of the pier

$$V_r = \begin{cases} \phi_s V_{ult} & \text{if } \varepsilon_s \geq 0.005 \text{ at failure} \\ \phi_c V_{ult} & \text{otherwise} \end{cases}$$

It should be noted that this analysis procedure is conservative for mixed failure modes where crushing occurs shortly after yielding, since the resistance factor used is either 0.75 or 0.90. Realistically, there should be a smooth transition where mixed failure modes which are controlled by both tension and compression are treated using a blended resistance factor which lies somewhere between 0.75 and 0.90.

Figure 15 shows the factored strength of the piers following an interpretation of the analysis results. In almost all cases, the ultimate strength is governed by yielding of the flexural reinforcement, with the exception of the thinnest possible section width (911 mm) or just slightly larger (1000 mm). The transition from tension-governed to compression-governed failure modes makes the spread of possible factored strengths particularly large, with the most conservative estimates of the factored strength being almost half the value of the most optimistic case, where all of the reinforcement and the full width of the pier are effective. When assessing the actual piers in question, it was determined that even with the most conservative assumptions, the structure was able to carry the required design loads.

5.3 *Crack Pattern Comparison*

As the purpose of the numerical modelling was to verify the safety of the cracked hammerhead pier, the crack pattern predicted by VecTor2 was compared against those seen in the actual piers. Figure 16 shows the predicted crack pattern of a typical analysis when the structure is carrying 50% of its maximum capacity, as well as a representative load-displacement plot which characterized almost all of the analyses. While the pier is heavily cracked, with predicted crack widths of up to 1.5 mm, it is quite far away from failing. All of the analyses performed predicted that the load causing first cracking was a small fraction of the ultimate strength, and well below the predicted service loads.

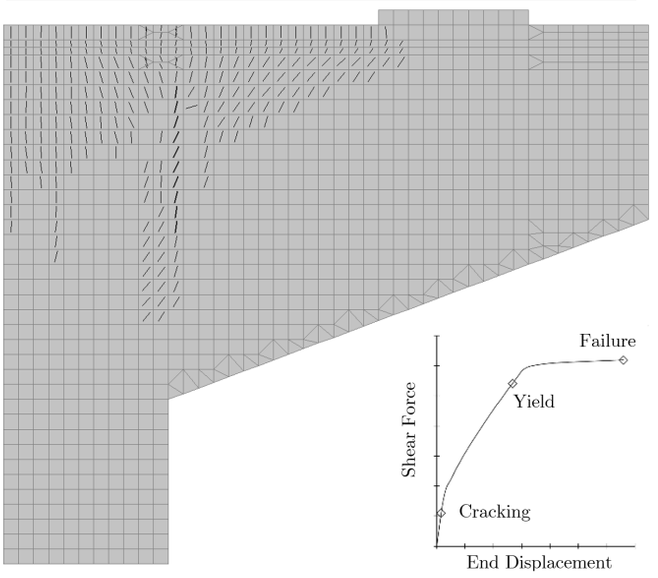

Figure 16. Typical crack pattern at 50% of member capacity

6 CONCLUSION

Nonlinear finite element analysis is a key part part of the modern structural engineer's toolbox when conducting an assessment of an existing structure which may be in distress. As shown from this case study of a cracked hammerhead bridge pier structure, the behaviour of seemingly simple structures can be complicated by subtle geometric features. In situations such as these, it is appropriate to turn to NLFEA to better understand the fundamental behaviour of these structures.

VecTor2, a 2-D NLFEA program based on the DSFM, was used to assess the piers. An extensive parametric study was performed to account for possible 3-D effects in the structure. The variables explored were the effective section width of the piers and the quantity of longitudinal reinforcement used, and the their effect on the piers' strength and failure mode were examined.

A simple procedure for using these NLFEA results within a LRFD framework was proposed, which assigns a representative resistance factor to the member's capacity by considering the strain in the longitudinal reinforcement at failure. While this method was used to obtain the factored strength for an existing structure, it is general enough to be used for designing new structures.

While a comprehensive 3-D nonlinear analysis to analyze reinforced concrete structures remains impractical for everyday use, the methodology discussed in this paper hopefully provides the practising engineer with a stronger foundation on which they can exercise their judgment when evaluating existing structures.

ABSTRACT: This paper focuses on the dynamic analysis of a stone masonry railway bridge under seismic loading. The simulation of the bridge structural behaviour is based on a 3D finite element model which includes the bridge components like piers, arches, spandrel walls, infill and foundations as well as the track components that are the rails, sleepers and ballast, both modelled using homogenous elements and elastic materials. Synthetic series of acceleration are used to represent the action of 5 earthquakes based on EC8. The structural modelling allowed to represent the bridge linear response in face of seismic actions aiming to evaluate the evolution of the dynamic effects in terms of deformations and stresses indicating an overall good behaviour.

1 INSTRUCTION

Arch bridges represent the most common typology of bridges in the European network of railway infrastructures, according to the survey carried out by the railway owners, representing 41% of the total inventoried bridges (Olofsson *et al.*, 2007). From these, 35% are over 100 years old, 62% have arch spans shorter than 10 m, 5% have spans larger than 40 m and 33% are made of stone (Bell, 2004).

The representativeness of this bridge typology and the increasing demands on weight and speed loads has been concerning the scientific community and the bridge owners to enhance the structural assessment of these bridges and to improve itself their condition state.

The assessment of the structural response and vulnerability to earthquakes is therefore of major importance to implement adequate management plans to guaranty the safety conditions of these bridges in the case of a seismic event.

The structural system of railway stone arch bridges is composed by the principal components, namely arches, spandrels and piers, formed in structural masonry, usually with regular (and large) stone blocks and (thin) mortared joints. Between the spandrels and above the arches, infill material is placed, usually also made up of stone and mortar (mixed with cement) but using stone blocks smaller and less regular those of the main components; this ends up as a more mortared material leading to an infill material similar to a poor concrete, as it is the case of Côa bridge according to documents of the bridge design (REFER, 1944).

The structural behaviour of stone masonry arch bridges is mainly controlled by the strength mechanisms and interaction between structural elements, as well as the mechanical behaviour of constituent materials; all these issues contribute for load transmission due to weight and traffic, foundation settlements and for the response to vibrations induced from traffic and earthquakes.

Regarding the global structural response under the most common loading (self-weight and traffic) two main mechanisms are activated according to the distinct bridge behaviour in the longitudinal and transverse directions (Gilbert, 1993). Under heavy loading, likely to approach failure conditions, the former is characterized by arch hinge mechanisms (see Figure 1a) resulting from transmission of vertical loads across the infill; the latter, mainly influenced by the interaction between infill, spandrels and arches, the bridge structural behaviour, is related with the transmission of horizontal pressures and the way how they are reacted namely characterized by out of plane mechanisms on the spandrels (see Figure 1b) and/or longitudinal cracking in the arch (Costa *et al.*, 2018).

During an earthquake, the development of the arch hinge mechanisms (joint opening by tensile failure) may came aggravated by additional vertical impulses due to the seismic action on the bridge, causing the collapse of the bridge as it seems to be the case of the bridge under river Claro shown Figure 2, due to Chile earthquake in 2010.

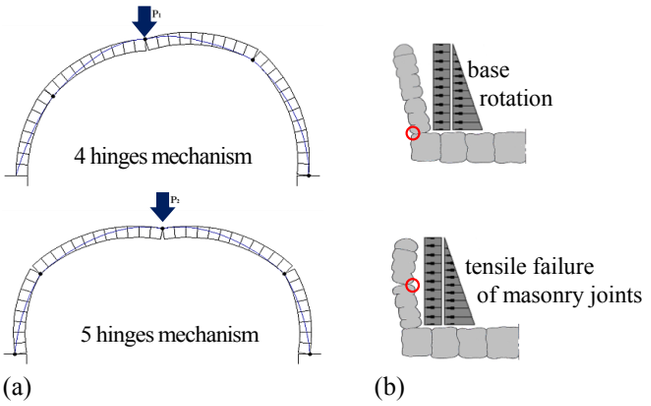

Figure 1. Failure modes: (a) arch hinge mechanisms and (b) out of plane of the spandrels.

In the transverse direction of the bridge, the out of plane mechanisms on the spandrels (rotation and sliding with joint opening by tension failure, shear failure or lack of equilibrium) may be aggravated by additional horizontal impulses, leading to the bridge collapse as the case shown in Figure 3 due to Umbria-Marche earthquake, Italy, in 1997.

Figure 2. Bridge collapse due to Chile earthquake in 2010 (http://revistaepoca.globo.com/Revista/Epoca/foto/0,,36940564,00.jpg).

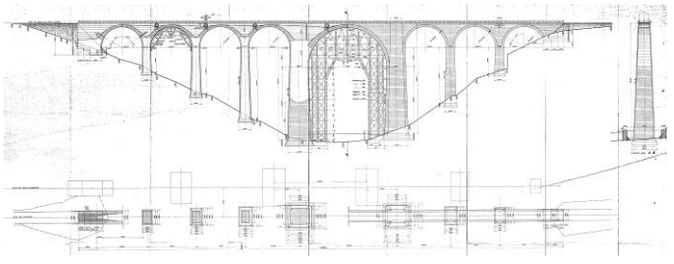
Figure 3. Bridge collapse due to Umbria-Marche earthquake in 1997 (Resemini & Lagomarsino, 2004).

The bridge failure mechanisms due to dynamic effects of the seismic action depend on the characteristics of the earthquake and foundation soil, as well on the dynamic characteristics of the bridge (vibration modes, frequencies and damping) and the capacity of the structure to resist cyclic loading (particularly dependent with the limited capacity of masonry to resist cyclic loads, when not confined and the with degradation of the stiffness characteristics of the masonry filler as deformation increases).

The bridge vertical and longitudinal vibration modes are likely to influence the dynamic amplification on the arch mechanisms due to the effect of the vertical component of the seismic action while the bridge transversal vibration modes are expected to influence the dynamic amplification in the transverse mechanisms due to the horizontal component of the seismic action.

2 CASE STUDY

The analysis of the structural behaviour of the Côa bridge under the railway traffic loading was the focus of a previous study which resorted to test techniques and numerical models that also allow the study of the bridge under dynamic actions. Because it is a large structure, the analysis involved a great complexity associated with the characterization of the constituent materials and the geometry of the bridge itself. The dynamic characterization of the structure was also carried out based on modal identification by performing ambient vibration tests on the bridge, briefly referred to in this paper. Taking benefit of the already updated structural model of the Côa bridge, a seismic analysis of the bridge was carried out to evaluate its structural response and vulnerability to earthquakes. The main results of this analysis are presented and discussed in this paper, seeking to find out to which extent the effects of seismic action affect or condition the structural bridge behaviour.



The Côa bridge, illustrated in Figure 4, was built in granite stone masonry in the late 1940s to replace an existing steel bridge over the Côa river in Beira Alta line of the Portuguese railways (REFER, 1944).

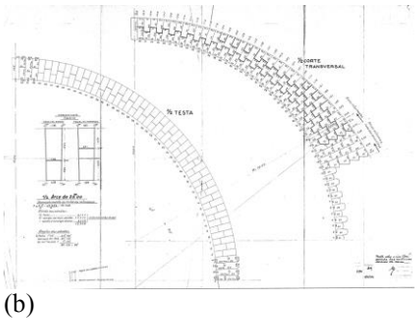


Figure 4. Côa bridge (at the right side) and piers and abutments of the replaced bridge.

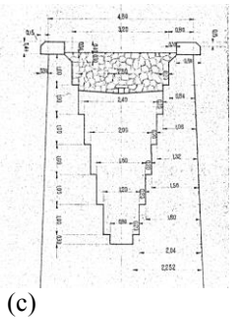
The total length of the bridge is approximately 238 m, with 4.8 m width and supports one single-track. The bridge is formed by eight arches, one with a span of 38 m and the others with 20 m, which are supported onto seven piers and two abutments. The maximum height difference between the foundation and the pavement is approximately 56 m. The bridge also features thickness variation with height and also on the piers in the longitudinal direction. Figure 5 shows some drawing details of the bridge design.



The arches consist of several ring segments with variable thickness. The foundations and external layer of the piers are made of regular stone masonry and the interior zone is filled with masonry consisting of irregular stones mixed with cement and mortar (called infill masonry). In the two highest piers, which support the larger arch span, the interior zone has distinct materials: from the foundation up to 18 m height it is made of regular stone masonry blocks, while the remaining zone consists of infill masonry.

(a)

(b)

(c)

Figure 5. Côa bridge design drawings: (a) elevation, (b) arch detail and (b) cross section (REFER, 1944).

The arches and piers support two spandrel walls with variable cross section composed of regular stone masonry. The backfill enclosed between them and the upper surface of the arches consists in infill masonry at the lower zone while the upper zone consists in dry stone material seated on a waterproof membrane with 9 cm thick. The railway track is formed by bi-block sleepers and UIC60 rails resting on about 50 cm thick ballast layer, placed above the backfill and delimited by sidewalks also in granite stone. At each side of the bridge there exist parapets made of puddled iron.

3 BRIDGE NUMERICAL MODEL

3.1 *FE model*

For the numerical modelling of Côa bridge a three-dimensional model based on the finite element method was developed in CASTEM software (CEA, 2011). This model, which FE mesh is shown in Figure 6, corresponds to an existing calibrated model already used to perform dynamic analysis under railway loadings resorting to ANSYS software (Jorge *et al.*, 2016). Common operations of output-input of FE meshes were carried out between software to perform subsequent analyses.

The arches, piers, spandrel walls, backfills, foundations, ballast and sleepers are modelled by tetrahedral finite elements. The rails are modelled by beam finite elements.

The boundary conditions were established using rigid supports to fix the node displacements at the foundations' base.

The mechanical properties of bridge materials are shown in Table 1.

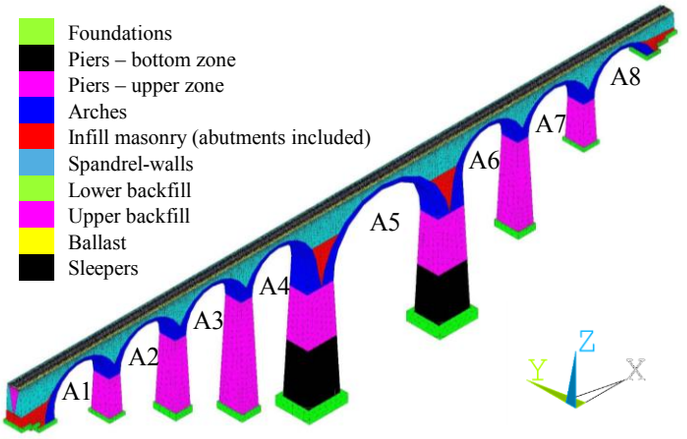


Figure 6. FE numerical model of Côa bridge.

Table 1. Mechanical properties of the calibrated materials.

Element material	Elastic modulus	Unit weight
	GPa	kN/m^3
Regular masonry	18.33	24.25
Infill masonry	13.49	24.25
Lower backfill	3.45	21.25
Upper backfill	0.34	19.60
Ballast	0.15	20.00
Sleepers	36.00	28.35
Rail	210.00	77.00

The elastic material properties and boundary conditions were adjusted to obtain numerically the dynamic characteristics measured in-situ. The assigned material properties were also based on bridge design data and on observations resulting from visual inspections on the bridge, as well as on the results obtained from material testing performed in other stone masonry structures (Arêde *et al.*, 2017 and Costa *et al.*, 2015).

3.2 *Modal analysis*

Figure 7 shows the values of the first ten natural frequencies and corresponding mode shapes. The modes 1 to 4, 6, 7, mainly involve movements of the bridge in the transversal direction. The other modes are refereed to movements in the vertical and longitudinal directions.

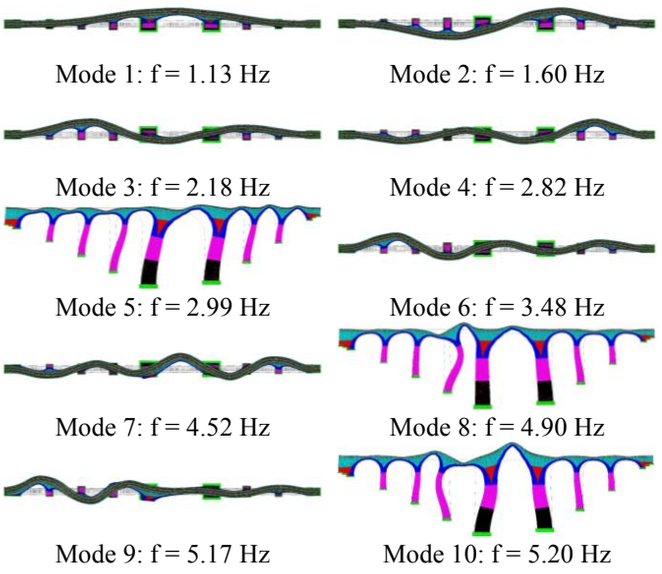

Figure 7. Numerical frequencies and mode shapes of the calibrated Côa bridge model.

3.3 *Model calibration*

The numerical model calibration was based on the bridge experimental modal properties, identified from measurements obtained in ambient vibration tests through the application of the Enhanced Frequency Domain Decomposition method, available at ARTEMIS (2009) software.

Figure 8 illustrates the configurations of the seven identified modes, including the average values of frequencies and damping coefficients. The analysis of the figure allows identifying modes associated to the transversal bending of the deck with very good definition. A detailed description of the bridge modal identification can be found in Jorge *et al.*, (2016).

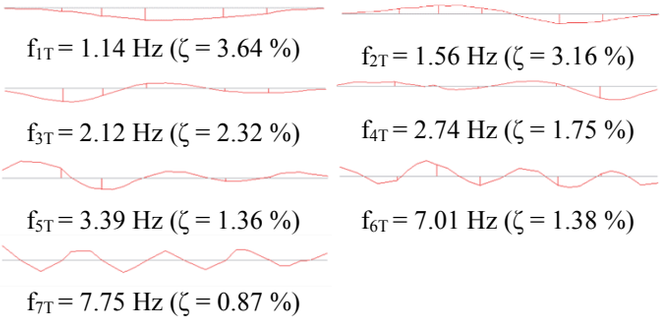

Figure 8. Experimental modal configurations for Côa bridge.

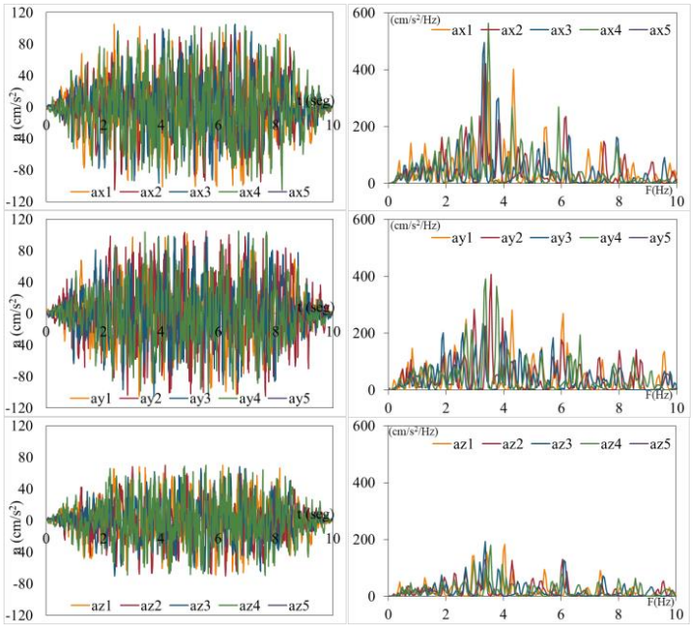
A sensitivity analysis and an optimization process using the modal pairing criterion based on modal assurance criterion (MAC) proposed by Allemang (2003), allowed to identify deviations between experimental and numerical values below 5% for all frequencies and all MAC values are higher than 0.90 (Jorge *et al.*, 2016).

4 SEISMIC ANALYSIS OF THE BRIDGE

4.1 *Methodology*

Due to the size of the structure a simplified methodology of analysis was adopted by considering the dynamic bridge response in the elastic regime. For material like masonry this is not the most suitable option, particularly if safety assessment is the focus. However, the present study mainly aims at obtaining response parameter estimates that allow understanding the structural behaviour trends when seismic action is included, rather than achieving very accurate response simulations.

The seismic analysis of the bridge was performed by integrating the dynamic equilibrium equations in the time domain, using the Newmark method implemented in the CAST3M software (CEA, 2011), under the seismic action simulated by artificial time series of ground accelerations as described in the next section. The Rayleigh damping matrix was adopted, based on the values of the two first calibrated frequencies. The integration time step was taken as 0.02 s, which was found appropriate and compatible with time series resolution.



4.2 *Seismic action*

The seismic action was characterized by synthetic accelerograms (see Figure 9), artificially generated to match the response spectrum defined according to Eurocode 8 (NP EN1998-1, 2010) and the respective National Application annex. Figure 9 shows the 15 (5x3) time series of accelerations and the corresponding power spectral density plots.

The seismic load represents an earthquake of moderate magnitude at a small focal length and duration of 10 seconds, commonly referred as a near-field earthquake (EC8-NA type 2 seismic action). Seismicity was considered adequate for the bridge location (seismic zone 2.4) with soil class A (rock) and design peak-ground acceleration (PGA) of 0.1g, defined with an importance factor of 1 consistent with a bridge case of importance class II and a return period of 475 years.

It should also be noted that, the acceleration time series correspond to the design value of the seismic action PGA (NP EN1998-1, 2010), for which the corresponding effects do not have to be further fac-

tored by any safety factor in the context of combinations with other actions.

Figure 9. Synthetic accelerograms in longitudinal, transverse and vertical directions: (a) time series and (b) spectral power densities.

5 RESULTS AND DISCUSSION

5.1 *Bridge response under the dead load*

The results of the linear static calculation, corresponding to the bridge behaviour under dead loads, are shown in Figure 10 in terms of the deformed configuration. The corresponding maximum values of the longitudinal-x, transverse-y and vertical-z displacements are summarized in Table 2. The results of the maximum and minimum principal stresses in each mesh zone are also included.

Regarding the maximum (absolute) values of the displacements and the principal stresses in the area of the arches and piers, it was verified, as expected, that they occur essentially in the arch 5 (the central on) and adjacent piers 4 and 5; these maximum values are also summarized in Table 3. The arch vertical displacement corresponds to about 1/6800 of the span and the horizontal displacements of piers are negligible (around 1/49000 of its height).

It is noted that the maximum tensile values in the arches' masonry are compatible with current values of tensile strength of the stone, although not necessarily the same for the masonry assemblage; on the other hand, the maximum compressions in the masonry have values usual in this type of stone masonry structures, well below the respective compressive strength. It is noteworthy that in the bridge design documents a reference to 57.85 MPa was found for the compression strength obtained on samples of granite stone used in the bridge (REFER, 1946).

5.2 *Bridge response under the self-weight and the seismic action*

The maximum values of the linear dynamic bridge response under seismic action and self-weight are summarized in Table 4 for each bridge element in terms of the maximum effects of the five earthquakes considered in the analysis (in line 2 for each element). The values in Table 4 also refer the results of the bridge response considering the load case of the bridge dead load (in line 1 for each element).

In order to obtain final values, ultimate limit state combinations were considered according to the Eurocodes, for which the loading combinations included in Table 4 are as follows: $S_G = G_k$ (line 1); $S_E = G_k + E_d$ (line 2); where G_k represents the characteristic values of effects of the dead load while E_d corresponds to the design (absolute maximum) values of the earthquake effects. According to the previously mentioned, these values correspond directly to the results of the application of the accelerograms considered in the analysis. Table 4 also includes (in line 3 for each element) the ratio Δ (absolute value) of values obtained from the seismic analysis to those obtained only with the dead load.

Table 4. Result variations due to seismic action (maximum of the 5 earthquakes): Principal stresses and displacements.

Mesh Zone	*Load case*	σ_1^+ MPa	σ_3^- MPa	*dx* mm	*dy* mm	*dz* mm

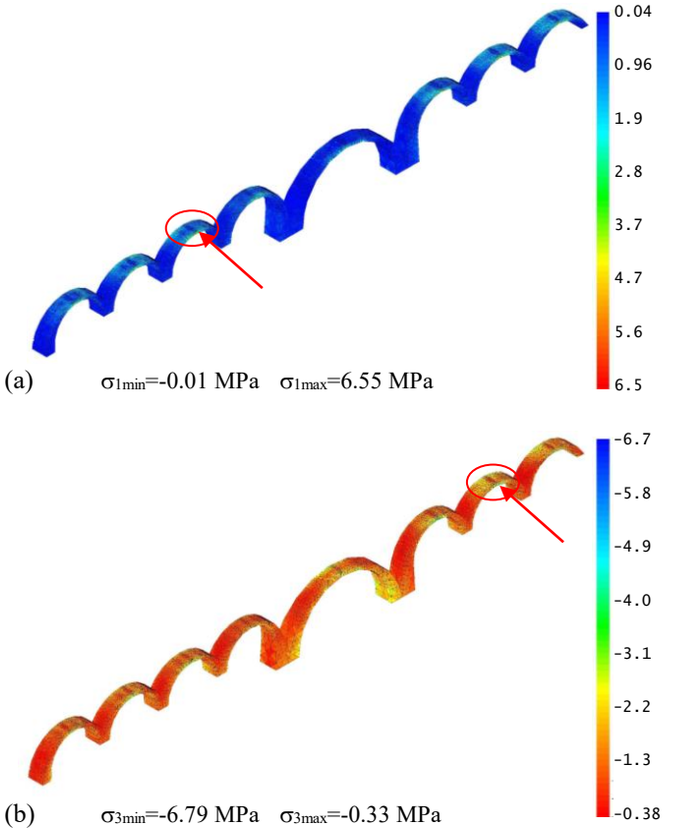
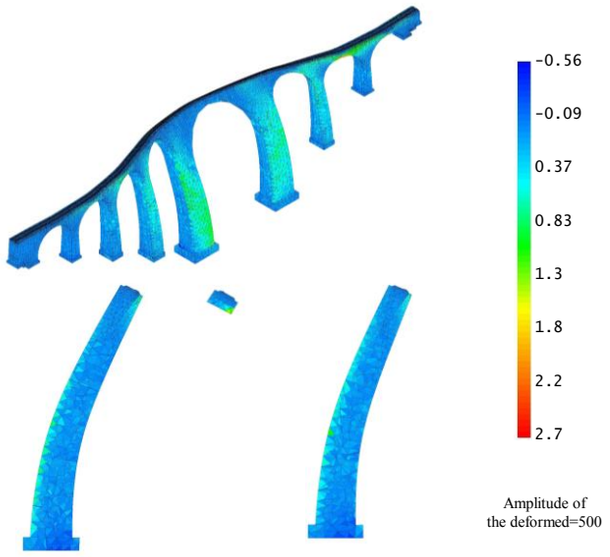
Considering the results of the linear seismic analysis ($S_E = G_k + E_d$), for the peak values of the principal stresses, with respect to the results obtained with the dead load case ($S_G = G_k$), it is clear that the influence of the seismic action assumes relative significance, with a maximum increase ratio of 32.93 and 5.21, respectively for the maximum principal stresses (tension) in the piers upper zone and the minimum principal stresses (compression) of the lower backfill.

The large increase in the maximum principal stresses (tension), particularly in the arch zones where the maximum positive value of the principal stress was obtained, evidences the need to adopt a nonlinear material modelling for masonry, since, as fragile material, the capacity of the masonry to accommodate tensile stresses is limited. Nevertheless the maximum values of tension are confined to a restricted area as shown in Figure 11, where the distribution of maximum values of principal stresses are shown in the arch zone, for load cases with earthquakes 3 and 2, in Figure 11a and b, respectively.

The minimum values of the negative principal stresses (compression) are also located in the arch zone, which are still compatible with the usual values found for the masonry strength.





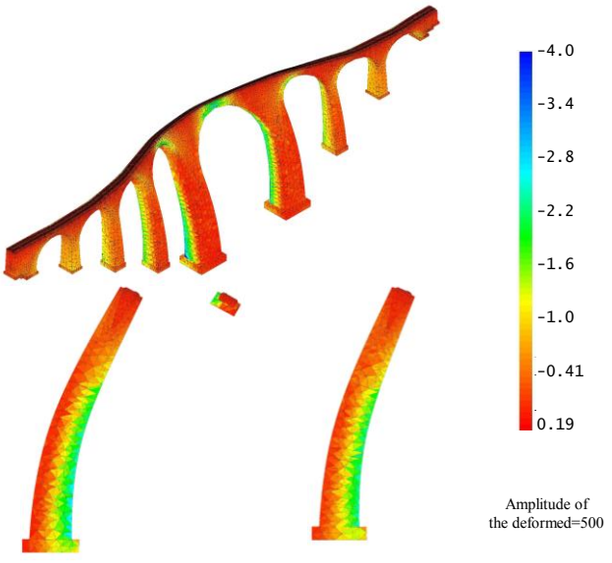


Figure 11. Principal stresses in the arch zone for the combination $G_k + E_d$: a) maximum and b) minimum.

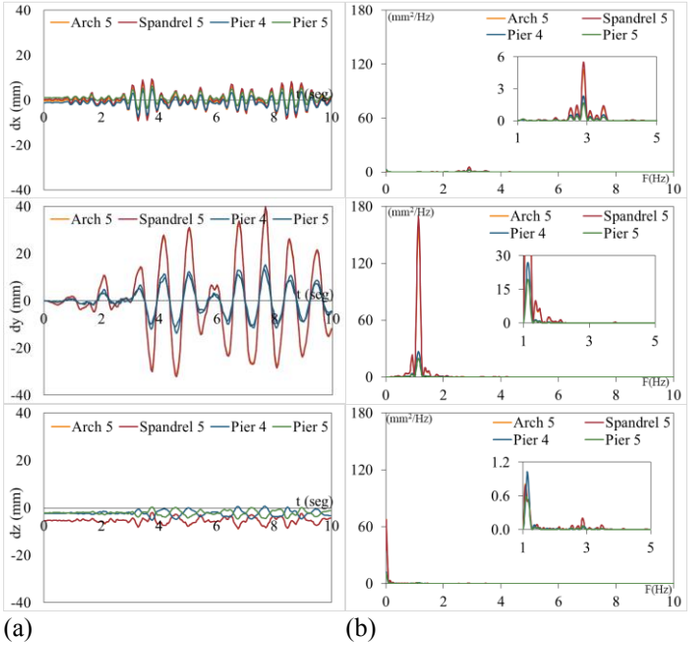
The distributions of the maximum and minimum principal stresses in the deformed configuration of the bridge are shown in Figure 12 for the load case $G_k + E_d$. The figure includes a 3D view and three transverse sections through the ½ span of the principal arch 5 and the adjacent piers 4 and 5. The plots correspond to the step of analysis when the maximum transversal displacement in the principal arch (arch 5) is found considering the earthquake 4.

With respect to displacements, as expected, the influence of seismic action is very significant in the horizontal directions, particularly in the transverse one (*dy*) as shown in Table 4 by the increment ratios up to +241.68 in the transverse displacements of elements located in the bridge upper zone (piers upper zone, arches, backfill and spandrels). Lower increase is found in the vertical displacements.

(a) σ_{1min}=-0.58 MPa σ_{1max}=2 MPa



(b) σ_{3min}=-4.01 MPa σ_{3max}=0.22 MPa

Figure 12. Principal stresses plots in the deformed configuration of the bridge for the combination of seismic action and self-weight: a) maximum and b) minimum.

However, despite these high relative increments, the absolute values of bridge displacements are rather modest. In fact, it is noteworthy that the maximum vertical displacement for the seismic action (with self-weight) recorded in the arch 5 and is only 8.87 mm, which corresponds to about 1/4280 of that arch span. Also, the maximum absolute values of the transverse and longitudinal displacements are, respectively, 38.42 mm and 9.87 mm (corresponding to 1/1350 and 1/5670 of the bridge height), which are values clearly acceptable for an arch with 38 m span and bridge piers with 56 m total height.

The displacements' evolutions in arch 5, adjacent piers 4 and 5 and spandrel 5 in the nodes where the maximum (extreme) absolute values were found, for the action of earthquake 4 plus the bridge self-weight, are plotted in Figure 13a. The corresponding power spectral densities are shown in Figure 13b.

The analysis of the peaks shown in the plots of power spectral densities relative to displacements in Figure 13b allows verifying that the corresponding frequencies in x- and y-direction are coherent with frequencies of the bridge vibration modes involving the maximum modal amplitudes in the same direction (where 1.13 Hz is the first transverse mode frequency and 2.99 Hz corresponds to the first longitudinal mode). Although not perceptible in Figure 13b, for the z-direction a peak is also found near the frequency of the 1st vertical mode (f_{1V}=4.9 Hz) but the peaks with higher energy are found for frequencies near to 1.13 Hz and 2.99 Hz, thus indicating a correlation with the amplitude of vertical components in 1st transversal and 1st longitudinal modes of the bridge.

Figure 13. Displacements of the principal arch and adjacent spandrels and piers in nodes with extreme values: (a) time history responses and (b) spectral power densities.

6 CONCLUSIONS

The structural response of the bridge indicates an overall good behaviour in face of seismic actions. In fact, the values found attest to the stiffness and strength capacity of the structure, with maximum longitudinal, transversal and vertical displacements (*dx*, *dy*, *dz*) in the zone of the principal arch of about 10, 40 and 10 mm, respectively, for which *dx* and *dy* correspond to about 1/5200 and 1/1300 of the bridge

height and *dz* corresponds to 1/3800 of the principal arch span. Moreover the masonry stresses obtained in the compression domain are compatible with the material strength and the maximum tensile stresses are observed in a small restricted area.

The analysis of the bridge displacements' time histories and their spectral power densities also allowed verifying, for transverse and longitudinal displacements, the proximity between the frequency values of the power spectral density peaks and those of the bridge vibration modes with higher amplitudes in the same directions (f_{1T}=1.13 Hz and f_{1L}=2.99 Hz); for the vertical displacements, the peaks are also found for frequency values close to the first longitudinal and transverse modes' frequencies, rather than to the first vertical mode. This fact is coherent with the higher aggravation of effects of seismic action in longitudinal and transverse directions (when compared with the effects of the dead load), indicating higher amplification effects in the horizontal directions than in the vertical one. Those results are also in agreement with the higher acceleration values that characterize the accelerograms in longitudinal and transverse directions than the vertical ones.

Finally it should be noted that the model used at the local level, may not be able to fully translate actual behaviour. In fact, by considering elastic materials there are some phenomena that are not represented in the used model and that can condition the obtained results, among which the most important are the aspects related to the non-linearity of the masonry behaviour in the tension domain and the degradation of the connections between masonry blocks due to the cyclic loads' action. In this context, it may be necessary to modify and adapt the used material constitutive models to ensure that seismic actions may or may not affect the local behaviour, particularly of the arches. Therefore as future developments for this study it is expected to use more adequate constitutive nonlinear models which should also allow taking in account other modelling conditions representing more severe scenarios of seismic events and bridge vulnerability.

Despite the adopted modelling shortcomings, still useful indications were obtained concerning the impact of seismic action in this kind of structures, namely concerning the locations and order of magnitude of stress and displacements aggravations likely to occur in the bridge structure.

Centre for Environmental Safety and Risk Engineering, Victoria University, Victoria, Australia

ABSTRACT: Rapid expansion of urbanization has led to the increased vulnerability of infrastructures to bushfires and wildfires. Australian, bridge inspection manuals recommend a level 3 type of investigation as a post-bushfire bridge evaluation. Fire/structure interactions are dependent on fuel quantity, geometry, fuel characteristics, ambient conditions and structural characteristics. Given the scant research on wildland urban interface (WUI) fire, this research presents a numerical modeling approach of WUI fire with Fire Dynamic Simulation (FDS) software, utilizing the parallel computing facility. A domain size of 56m length 10m wide and 25m height with a uniform 200mm mesh resolution, that includes different fuel geometries and a bridge structure, were modeled in the analysis. The maximum temperature of the 12mm thick steel web and concrete bottom surface are around 350C and 115C respectively. Initial results show that there is no considerable strength degradation nor concrete cracking nor spalling. However, some dehydration of the concrete and reduction of Young's modulus in steel by 25% was observed. However, the strength degradation of steel up to 400C is limited. Further research is recommended to assess the cumulative effects on a structure when exposed to recurrent WUI fire events.

1 INTRODUCTION

Australia is one of the most bushfire-prone countries in the world. Annually, 'disaster-level' bushfires cost Australia an average of $77 million(*Total cost of bushfire* 2004). Total natural disasters cost in Australia is expected to increase from $9 billion to $33 billion by the year 2050 according to the Australian Business Round table for Disaster Resilience. Researchers have shown the potential influence of climate change on to the more severe and longer fire seasons around the globe (Flannigan, Mike et al. 2013). A warmer world means longer fire seasons and more drier fuels (Flannigan, M, Wotton & Marshall 2016). Meanwhile, the rapid urban sprawl and population decentralization in recent decades that have increased the size of the wildland urban interface (WUI) resulting more communities and infrastructures vulnerable to bush and wild fires (Massada et al. 2009).

Especially the bridges in bushfire prone areas can be exposed to extreme fire conditions depending on the availability of quantity, type and condition of vegetative fuel and the ambient conditions. Timber bridges are the most vulnerable form of structures in the face of a bushfire. Even though no bridge failure has been recorded in other types of bridges most of the bridge inspection manuals in Australia usually recommend a level 3 types of investigation on bridges as a post bushfire bridge evaluation process (Vicroads 2014).

There is a lack of research to understand the different fire exposure levels of bridges located in a WUI. This research paper presents the results of few case studies of an ongoing work designed to assess the thermo-mechanical performance of existing composite steel girder bridges exposed to most rational fire events covering a range of fuel and environmental conditions. Research results can help to predict the isolated and cumulative effects on a structure when exposed to recurrent WUI fire events in the future.

2 RESEARCH METHODOLOGY

This research is designed to understand the extreme effects that can be expected on to a bridge structure subjected to WUI fires given different environmental and fuel conditions. Numerical simulation of the WUI fire is accomplished using Fire Dynamic Simulator (FDS) software. FDS is a computational fluid dynamics (CFD) model of fire-driven fluid flow. FDS is capable of simulating interactions among atmosphere, fuel, and fire. 56m long and 10m wide and 25m high domain that contains different fuel geometries and a bridge structure is simulated. A 10m length portion of

a 25m long and 11.5m wide composite steel plate girder bridge with 5 numbers of girders is modeled to represent a typical bridge structure. Temperature development of the structure is monitored using Adiabatic Surface Temperature (AST) computing devices attached to various locations of the bridge. The thermal analysis is carried out using general purpose finite element software ABAQUS. The aim is to understand the effect of fuel characteristics and environmental factors that can potentially change the fire behavior on to the thermal response of the bridge. The fuel materials of WUI fires can be broadly categorized in to two groups: fine fuel (material less than approximately 5 mm diameter) and coarse fuel (larger material). This study is limited to the modeling of fine fuel in both ground and elevated forms. Future investigation will be extended towards coarser fuel to complete the spectrum of fuel grading.

3 WUI FIRE CHARACTERISTICS

Vegetative fuels and fires in a wildland setting can be categorized as surface, or crown types. Fallen twigs, leaves, barks, branches, grasses, and shrubs less than 1.8m tall are the examples of surface fires(Mell et al. 2007). The fires in elevated vegetation in trees are referred to as crown fires.

The fire-fuel interaction in a WUI involves gas generation by solid fuel pyrolysis, the subsequent combustion of the fuel gases, and the resulting heat flux back to the solid fuel, driving continued pyrolysis and fire spread along the fuel bed.

Fire danger ratings have been established to indicate the vulnerability and the severity of potential grass and wildland fires depending on atmosphere conditions. Increased fire danger rating levels, such as the McArthur (Noble, Gill & Bary 1980) are associated with fire weather conditions such as high temperatures, high curing (drying of vegetation) rate, low relative humidity (RH) values and in particular high wind conditions. For burning vegetation that contains moisture increases its ignition time and decreases the rate of flame spread. The stronger wind forces the hot fire plume closer to the downwind fuel bed, increasing both the radiative and convective heat fluxes. This process leading to a faster fire spread in higher winds (Mell et al. 2007).

Fireline intensity, defined as the heat release rate (HRR in kW) of the fire front divided by the effective length across the spreading direction. The HRR is the most important input for conducting CFD simulations of fire (Moinuddin, KA et al. 2011). Therefore, the fireline intensity (kW/m) is one of the most important factors that decide the fire-structure interaction in a WUI setting. Fireline intensity has a strong correlation with the fuel availability and the rate of spread of the fire (Cruz et al. 2015). Higher fuel load (ton/ha) normally results in higher fireline intensity and consequently has greater impact on a structure. This research looks in to effects of wind speed and fuel loading in WUI settings in terms of three case studies.

4 MODELLING OF FIRE DYNAMIC IN WUI

Both wildland and WUI fires are very difficult to study with full-scale repeatable experiments in the field due to their expense, safety implications, and variations in atmosphere, terrain, and fuel conditions. As an alternative to this problem, practical predictions of wildland fire spread have been accomplished through "operational" mathematical models based on empirical correlations for wildland fuels. They fail, however, when the fire spreads to the built environment where the empirical correlations may no longer apply (Evans, Rehm & McPherson 2003).

Fires where strong fire-atmosphere interactions occur, such as crown fires, routinely strain the credibility of the empirical fire spread models (Mell et al. 2007). Moreover, there are many fire behavior problems, of increasing relevance, that are outside the scope of empirical and semi-empirical models. This paper describes the development of a three-dimensional, fully-transient, physics based, computer simulation approach for modeling fire spread through surface and elevated fuels in a WUI.

Although the NIST's FDS tool was initially developed to study building fires, its use is extended to study WUI fire problems. The FDS model has the capacity to utilize data including the local topography, infrastructures, ignition and burning characteristics of vegetative fuels, and meteorological conditions to provide a time dependent simulation of fire spread in a WUI setting. FDS is a computational fluid dynamics (CFD) model of fire-driven fluid flow. It includes sub models for fluid flow, combustion, heat transfer, and thermal degradation of the vegetative fuel. The combustion is modeled by a 'mixed-is-burnt' fast chemistry model. Turbulence is treated with large-eddy simulation (LES) approach. The simulation results in a three-dimensional, time-dependent, prediction of fire behavior. Both convective and radiative heat transfer between the gas phase and the vegetation is accounted.

4.1 *Parallel computing*

Characterizing the wildfire dynamics and its impact on structures requires observation and modeling accounting for a very wide range of length scales ranging from fine scales representing fine fuels to scales of importance in the WUI in the problem by rational means of aggregation. So, the computational cost is very high. To solve a system of large equations a feasible high-performance computing facility is often required.

In FDS the parallel MPI (Message-Passing Interface) implementation is designed for running on distributed memory systems, e.g. a computer cluster. MPI is used to execute FDS as a parallel job on a distributed memory system in terms of mesh dividence. During this research, a high Performance Computing (HPC) system Spartan operated by Research Platform Services (ResPlat) at The University of Melbourne is used in conjunction with the MPI version available in FDS (Melbourne 2017).

4.2 *Fuel characteristics*

4.2.1 *Surface fuel*

Table 1. Vegetation parameters for grass

Parameter	Value
Vegetation bulk density	2.5 kg/m3
Vegetation height	1.0m
Vegetation moisture content	6.3%
Vegetation Surface to Volume Ratio (SVR)	9770m-1
Vegetation element density	440kg/m3
Maximum Mass loss rate	0.4 kg/s
Vegetation Drag Coefficient	0.125
Emissivity	0.9
Air temperature	35 $°C$

Figure 1. Typical grass land with around 2.4kg/m2(Johnson 2002)

Figure 2. Appearance of grass with 5 to 15% moisture content and 80% to100% cured (Johnson 2002)

A significant variation of the fuel characteristics can be expected over a land scape scale; however, this study idealizes the problem to a uniform fuel bed. Table 1 summarizes the fuel parameters used to represent the grassland. Many of these input parameters can be considered to be in which a large variation would not be expected among different kinds of grass, such as the heat of combustion of the fuel, char fraction, element density, and emissivity. For other properties are considerably based on the environmental conditions or specific plot of land.

For vegetative fuels, the surface-area-to-volume (SAV) ratio is an important parameter that measures the available fuel surface area for heat and mass transfer and production of combustible vapors (Bartoli et al. 2011; Beer 1993). Representative value of SAV ratios of grass used in the analysis is based on the grass species, *Eriachne burkittii* (kerosene grass) that is reported by Cheney (Cheney, Gould & Catchpole 1993)

Grass curing is another important parameter that is a measurement of grass 'greenness' and is related to the percentage of dead grass in a land. Curing is dependent on seasonal conditions such as rain, temperature and is also dependent on plant species and land type. As grasses cure, moisture content decreases. Grassland fire danger rating index (GFDI) Mark 3 stipulates fuel moisture is a function of curing, air temperature and relative humidity (Cruz et al. 2014). Plant moisture acts as a heat sink and thus influences fire behavior by increasing the specific heat required for the fuel to combust (Johnson 2002). As plant moisture decreases, fire intensity, potential ignitability and fire spread rate. [13,15,20-22]. Figure 1 and Figure 2 provides a visual estimation on the grass fuel load, curing and fuel moisture condition that is used for the present. In FDS, fuel moisture, air temperature and relative humidity are provided as input variables.

Note that an emissivity of 0.9 is characteristic of wildland vegetation (Evans, Rehm & McPherson 2003) (P.G Jarvis 1976) so the assumption that a fuel element is a perfect absorber is reasonable.

A linear degradation model is used to model the pyrolysis process of grass (Morvan & Dupuy 2004).

4.2.2 *Elevated fuel*

Table 2. Thermo-physical parameters used to model the elevated vegetation

Parameter	Moisture	Vegetation	Char
Thermal conductivity (W/m.K)	2.0	2.0	2.0
Specific heat (kJ/kg.K)	4.148	1.2	1.2

Density (kg/m3)	1000	514	300
Reference temperature (C)	100	200	350
Reference rate	0.002	0.0005	0.0002
Heating rate (C/min)	1.6	1.6	1.6
Heat of reaction (kJ/kg)	2500	418	418

Table 3. Fuel grading used for the elevated vegetation modelling

Parameter	Value
Foliage	
Diameter	0.5mm
Length	50mm
Bulk density	2.0 kg/m3
Small round wood	
Diameter	1mm
Length	100mm
Bulk density	0.4kg/m3
Medium round wood	
Diameter	2mm
Length	100mm
Bulk density	0.3kg/m3
Large round wood	
Diameter	3mm
Length	100mm
Bulk density	0.5kg/m3

Understanding the processes involved in transition from surface to crown fires, and assessing fire risk in the wildland–urban interface (WUI) is very important. A basic building block of elevated fuel is a single tree. There are only fewer published data on thermo-physical properties of elevated vegetation when compared to grasslands. Among the few, the Douglas fir tree experiments reported by NIST laboratory provides valuable information on material properties that can be used for numerical modelling. During the current work the information published in the NIST experiment (Mell et al. 2009) is taken as the basis for defining the fuel properties. In FDS, Lagrangian particles can be used to represent vegetation as sub grid scale objects in the analysis. A "simplified" Arrhenius degradation model is used to model the pyrolysis of the tree vegetation. The solid fuel is assumed to be comprised of 87.7% vegetation and 12.3% moisture. The incident heat flux first evaporates the moisture component of the fuel and then during the pyrolysis process, reaction produces 74% pyrolysate and 26% of solid residue char. The pyrolysate ($C_{3.4}H_{6.2}O_{2.5}$) starts the combustion process when sufficiently mixed with free oxygen in the atmosphere and produces CO2, CO, H_2O and soot. Table 2 summarizes the thermo-physical parameters of each constituent used in the analysis. Fuel present in Douglas fir trees can be graded in to different length scales and these are modeled by modifying the properties of the fuel particles. Table 3 summarizes the geometric properties of four types of fuel gradings which constitute a tree: small, medium and large round wood in the modeled as small cylinders.

4.3 *Atmospheric conditions*

4.3.1 *Domain BCs*

The inlet of the domain is simulated with an atmospheric wind profile. The right and left-hand sides of the domain are simulated as periodic boundary conditions while other boundaries except the ground, which is a no slip surface, are kept open at a constant pressure. As a result the simulated domain becomes just one segment of an infinite number of identical segments (Linn et al. 2012).

At the inflow boundary for the duration of the simulation, the dependence of the ambient wind with height above the ground, z, is defined to follow a power law (Figure 3). At the same time magnitude of the cross-wind velocity is assumed to remains zero.

$$u = u_0 \left(\frac{z}{z_0}\right)^p \quad (1)$$

A typical atmospheric wind profile can be represented of the form equation 1. It should be noted that z_0 is not at the ground, rather some height where the reference wind speed u_0 is measured, like an elevated weather station. It is assumed that the ground is located at $z = 0$ (McGrattan et al. 2013)

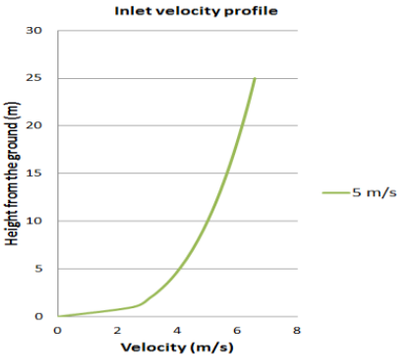

Figure 3:Inlet wind velocity profile, 5m/s, measured at 10m from the ground

4.4 *Adiabatic Surface Temperature (AST)*

Adiabatic surface temperature is a practical tool to express the thermal exposure of a surface to fire. The concept of AST was introduced by Wickström et al. in 2007 (Wickström, Duthinh & McGrattan 2007). AST is the temperature of a hypothetical perfect insulator exposed to the same heating (fire) conditions as of the real surface and that can be used for transferring data from fire models to thermo-mechanical models. Utilizing the AST helps to reduce the data flow in to the structural models by eliminating the dependency of the surface temperature on the net heat flux.

5 HEAT TRANSFER ANALYSIS

Heat transfer mechanism from the fire zone to boundaries of the girder is mainly through convection and radiation, while conduction is the main mechanism for heat transmission within the bridge assembly. For thermal analysis, temperature dependent thermal properties for steel, namely conductivity, specific heat and thermal expansion, were provided as input into ABAQUS. These properties are defined according to the Euro code 2 and 3 (EN 1993, 2004).

The heat transfer analysis of the steel girder is carried out using 8-nodes quadratic heat transfer brick elements available in ABAQUS, DC3D8, (Systèmes 2013). This element is well suited for the discretization of the structural domain and subsequent three-dimensional, steady state or transient thermal analysis of the system.

5.1 *Material properties*

The thermal and mechanical properties of structural steel and concrete are assumed to vary with temperature in accordance with Eurocode 2 and 3 (EN 1993, 2004). A material constitutive model recommended by Eurocode 3 is used to represent elevated temperature steel stress strain behavior in the model validation step. The degradation of the yield strength and Young's modulus at the elevated temperature is also taken as per the Eurocodes.

5.2 *Heat transfer model validation*

The general thermo-mechanical analysis procedure used in the investigation was validated by applying the similar procedure to model a reliable experimental results produced by Wainman and Kirby (1988) on a composite steel beam exposed to an ISO 835 standard fire (Figure 4). To represent the condition inside the furnace, during the heat tranfer analysis, coefficient of thermal radiation of 0.7 and convective heat transfer coefficient of 25kW/m^2 are used in the analysis.

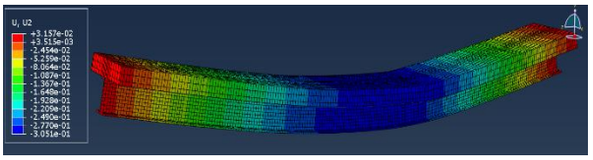

Figure 4: Vertical displacement response of the FE model of the composite steel beam

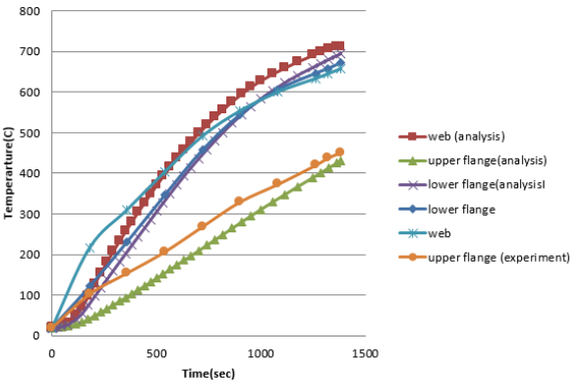

Figure 5.Temperature development of the selected points of the system, comparison of FE and test results.

Figure 5 and Figure 6 show the comparisons of predicted steel temperatures and the mid span deflection with that of measured in the fire test respectively. Measured temperature development of various location of the structural system and mid-span vertical deflection of the composite beam exposed to the ISO 834 fire are seen to be in close agreement with the FE predictions throughout the fire period. Overall, predicted temperature from the analysis is well comparable with measured data from the test.

6 RESULTS AND DISCUSSION

Model 1

Bridge structure is placed 32m away from the inlet boundary at the left-hand side. The grass strip starts 6m away from the away from the left side boundary. This allows the fire front to approach a quasi-steady heat release rate and rate of spread before reaching the bridge.

The wind velocity 10m above the ground is taken as 2m/s in this model, representing fairly mild conditions. Mesh size of the domain is maintained as a uniform 200mm spacing. As it was found that 250mm grid is sufficient to get grid-converged simulation (Moinuddin, KAM, Sutherland, D, Mell, W. 2017). The wind speeds used in the analysis is such that the fire-atmosphere interaction resulted a plume dominated fire. A predominantly vertical velocity field and a vertical flame and soot distribution can be seen in Figure 7 and Figure 8 respectively. The average fire spreading rate, estimated from visual representation of moving isosurfaces of HRR in Figure 9, is ≅ 0.3m/s within the entire domain.

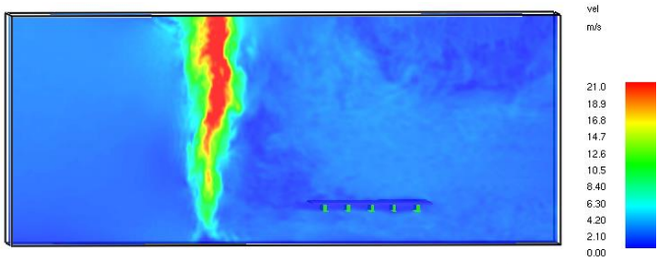

Figure 7. Wind velocity on the middle plane of the domain including the dominant fire plume.

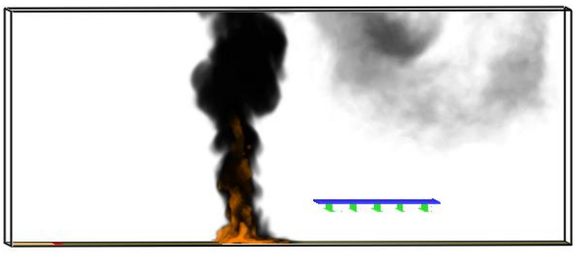

Figure 8.Fire plume and soot generation

After initializing the fire, the fireline intensity approaches a more or less a steady state value around 8000kW/m. Once the fire front enters under the bridge, initially plume dominated fire starts to bend as a result of the overhead physical obstruction. This increases the radiation energy transferred to the fuel bed in front of the fire front which in turn results an intensive burning and increased fireline intensity.

The adiabatic surface temperature of the structure was measured at the bottom surface of the concrete, mid height of the web and the flange bottom of each girder. A total of sixty-six AST measuring devices are used to monitor the bridge surface temperature. The average temperature development of each component is calculated using the results. Maximum AST reaches the value of 1200C (

Figure 10). Peak temperature resident time is very short and is about 30S.

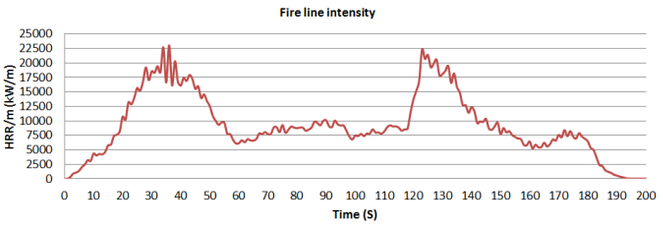

Figure 9. fireline intensity (hrr/unit length)

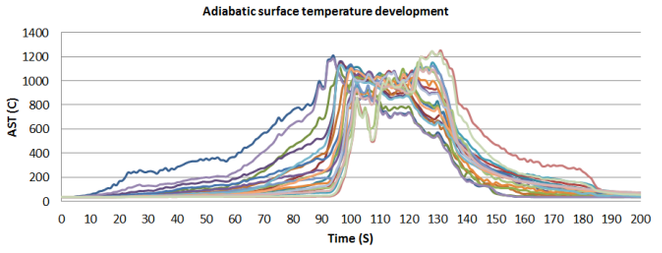

Figure 10. Adiabatic surface temperature development of the structure

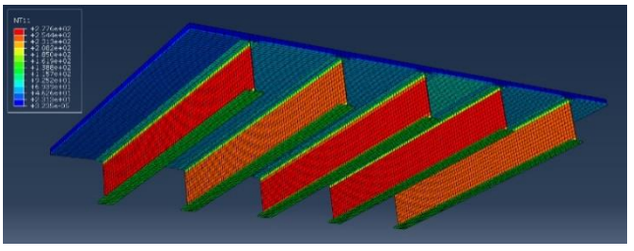

Figure 11. Temperature development of the heat transfer model in Abaqus FEM

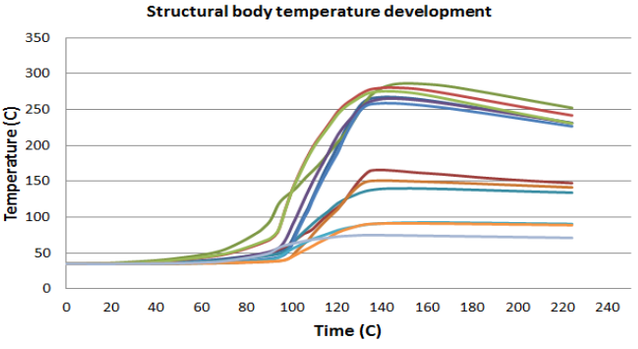

Figure 12. Body temperature development of the system

The temperature development of the structure can be grouped in to 3 categories. Relatively lesser thickness of the web results a highest temperature development that reaches around 300C. The bottom flange temperature development is around 150C. The concrete bottom surface temperature barely reaches 100C.

Model 2

In general, simulations of wild fires require models for both the fire-fuel interaction and the fire-atmosphere interaction. Second model is developed to understand the influence of wind speed on to the fire atmosphere and structure interaction. Cheney et al. (1993) has noted that the wind directly influencing fire spread is the net wind at the flame zone, not the wind measured remote from the fire. Wind speed of the model 1 is parametrically changed to achieve the model 2. The wind speed increased to 5m/s altered the fire-atmosphere interaction from a more plume dominated fire to a wind dominated (also known as boundary-layer mode) fire (Figure 13).

The higher wind forces both the flame and the hot fire plume closer to the downwind fuel bed (Figure 14), increasing both the radiative and convective heat fluxes. vapors at a rate dependent on the incident heat flux from the flame. The flame grows as the combustible vapors burn, which then creates a feedback mechanism for fire spread as the flame preheats additional unburned fuel ahead of the flame. As this process continues, the flame front progresses towards the unburned fuel. This is the process leading to a faster fire spread in stronger winds. For both wind speeds, radiation is the dominant heat transfer mechanism. The average rate of fire spread is increased to ≅ 0.6m/s. That in turn results a less residence time under the bridge even though the fireline intensity is increased (Figure 15) compared to the low wind speed case. As a result, even if the adiabatic surface temperature reaches to 1200C it results only lesser temperature development on the structure (Figure 16). The highest temperature 200C is recorded in the web of the structure. The concrete bottom surface temperature stays well below 100C (Figure 17).

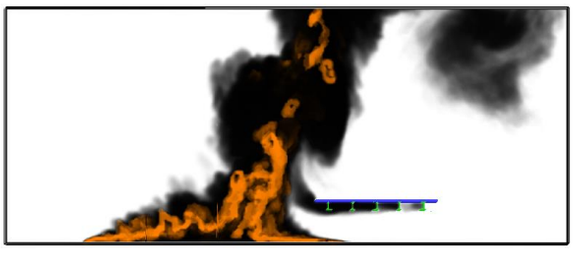

Figure 14. fire plume and soot generation

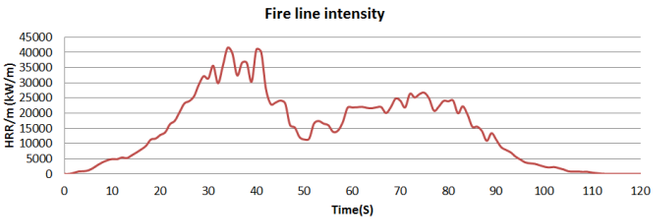

Figure 15. Fireline intensity (hrr/unit length)

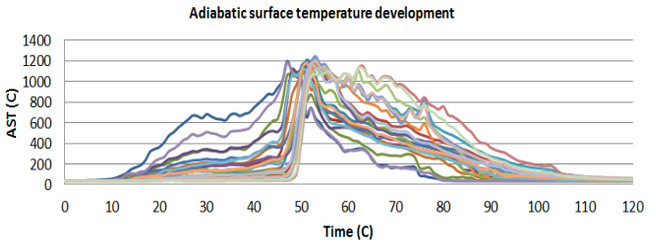

Figure 16. Adiabatic surface temperature development of the structure.

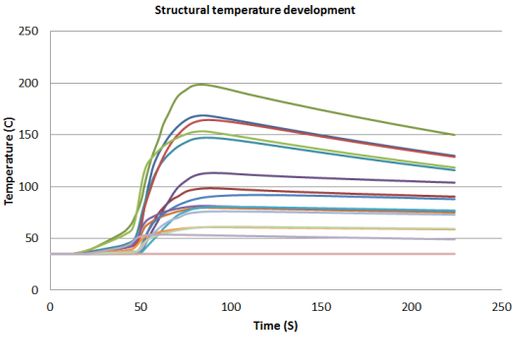

Figure 17. Body temperature development of the structure

Model 3

It has been identified that fires spreading in elevated vegetation are often more intense than fires spreading through surface vegetation such as grasslands(Mell et al. 2009; Miyanishi 2001). As a result, they are more difficult to suppress, produce higher heat fluxes and smoke. Such wildland fires can pose a serious threat to wildland–urban interface communities.

Model 3 is developed to understand the bridge-fire interaction where there is more elevated fuel load presents in the vicinity (Figure 18).

The domain size and the position of the structure is kept the same as the model 1 and 2. However the line of ignition was brought 11 m away from the bridge to reduce the computational cost. Five number of 4 m height and 2.0m diameter conical shape tress are introduced to the domain in two rows with 3 in front row. Wind is taken as 2m/s. Table 2 and Table 3 summarise the thermo-physical properties and the fuel gradings used to represent the elevated fuel.

The presence of more fuel in the vertical form has increased the fireline intensity from 8000kw/m to a maximum of 30000kW/m close to the bridge (Figure 20). Relatively low wind velocity give rise to a nearly vertical flame front (Figure 19). The average fire front progress rate is on average is the same as the Model 1(≅ 0.3m/s). The adiabatic surface temperature reached 1400C in some parts of the bridge (Figure 21). Introduction of the elevated vegetation along with the surface fuel increased the amount of fuel present around the structure. This has caused more than 50C temperature rise of the web when compared to Model 1.

7 CONCLUSION

Fire-structure interaction on a bridge located at a wildland urban interface is investigated in the form of three case studies. Temperature development of the various elements of the bridge system is taken as the primary output. The maximum temperature that is experienced by a structural element is used predict the degradation of the material strength parameters and possibility of the cracking of concrete.

Fireline intensity and the rate of spread are the most influential factors that affect the structural temperature development. Lower wind velocity in the domain tends to support a plume driven fire front with low intensity and slow progress. This type of fire tends to create higher temperature development of the structure due to the increased residence time of the flame front. In contrast, higher background wind velocity results a high intensity fires with a high rate of spread, however, such fires cause lower temperature development of the structure because of the lower residence time of the fire under the bridge. The presence of elevated fuel around the structure causes the highest temperature development (observed in these simulations) in the structure compared to the surface only fuel conditions.

Initial analysis results show the temperature developments of the structural components could not lead to a residual strength degradation of steel nor the cracking nor spalling of the concrete (Arioz 2007). This is mainly due to the less flame residence time that did not allow the temperature to build within the structure. However, the presence of elevated vegetation increases the risk significantly. The steel Young's modulus value decreased by 25% while the strength degradation of steel up to 400C is limited (BS 2005). Further parametric studies are needed to draw clear conclusions. Parametric studies are necessary to identify further critical fuel geometries around a bridge. These research results will in future help to predict the isolated and cumulative effects on a structure when exposed to recurrent WUI fire events.

Joint irregularity in the seismic behavior of highway bridges

M.C. Gómez-Soberón, A. E. Gómez-Benítez & R. J. Aguirre-Eligio
Materials Department, Universidad Autónoma Metropolitana, Ciudad de México, México

ABSTRACT: Taking into account previous studies of bridges with irregularity in the superstructure or in the substructure, new models have been generated with irregularity in both systems. The group of studied bridges presented degrees of curvature between 0 and 180 °, each 30 °, and ratios of the extreme to the central span length of 1:0.25, 1:0.50, 1:0.75, 1:1.25, 1:1.50, 1:1.75 and 1:2.00. The irregularity, considering both systems, is analyzed by changing the length of an extreme or central pier in percentages of ± 0.25%, 0.50% and 0.75%. Models with joint irregularity have been analyzed elastically using a database of 53 accelerograms registered in the most seismic hazardous zone of Mexico. Dynamic analyses were developed to evaluate the maximum responses obtained with the elastic analyses, mainly in displacements or mechanical elements, grouped by statistical quartiles. The quartiles obtained with different irregular configurations only in the superstructure, were compared with those found for different irregular joint configurations. Recommendations were generated for bridges with joint irregularity.

1 INTRODUCTION

The superstructure of a bridge is considered irregular if it has curvature or if it is skewed; also if it presents changes of stiffness in elements in the spans. On the other hand, the irregularity of the substructure of a bridge is defined when there are variations in length, or differences in resistances or stiffness in their piers (Gómez & Salas, 2012).

During a bridge design process, its regular or irregular condition is generally determined to define the simplified method of analysis to use, which helps to model the structural behavior as close as possible to reality. The AASTHO (2012) regulation suggests unimodal, multimodal and step-by-step methods of analysis, depending on the importance and regularity of the structure and the seismic zone. In addition, it sets limit values such as ratios of curvature or stiffness between adjacent spans and between piers of the same bent or adjacent bents. This classification only considers to group bridges as regular and irregular. The recommendations of AASTHO (2010) emphasize that the maximum relationships can occur between the rigidities of the piers and girders. Simple and similar classifications are made in other design codes, such as Caltrans or Eurocode. Therefore, it is necessary to evaluate the influence of certain irregularity conditions in the seismic behavior of bridges, to propose recommendations for their analysis, design, inspection and maintenance.

Several studies have been developed concerning the analysis of the response of irregular bridges subjected to seismic load, with single irregularity, either in the superstructure or in the substructure. In recent studies about irregularity of the substructure (e.g. Tehrani & Mitchel, 2010; Isakovic & Fischinger, 2000 and Kappos *et al*., 2005), different irregularity conditions presented different influence on the seismic behavior of the bridges. In the case of columns with irregular substructures, there are significant variations in the demand of deformation of them, concentration of shear forces in short elements, variation of the demands of ductility and greater participation in higher modes, as Moehle & Eberhard (2000); Kappos *et al*. (2005) and Isakovic & Fischinger (2008). Experimental studies show that the energy absorbed by an irregular bridge is concentrated in the shorter piers (Tehrani & Mitchell, 2010). This cause, in some cases, systems with insufficient levels of security, as Calvi *et al*. demonstrated (Tehrani & Mitchell, 2010).

Nowadays, curved bridges are becoming more common, but they have a complex distribution of compressive and torsional stresses, which generates large demands on all their components. There are several studies that have analyzed the behavior of curved bridges, such as Seo & Linzell (2013), which

show that these structures are more susceptible to seismic load than straight bridges.

Gómez & Salas (2012) analyzed bridges with irregular substructure, while Gómez & Pérez (2013) studied bridges with irregularity in the superstructure. In these last two works, the analyses were based on the same type of viaduct regular bridge, with three or four spans and single piles per bent. This present work continues these previous studies, combining models with irregular superstructure with those with irregular substructure to form models with joint irregularity. This study intends to verify how much the vulnerability of structures with joint irregularity changes.

2 ANALYSIS MODELS

2.1 *Regular models*

The bridge model used to represent the regular structure is the same used by Gómez & Salas (2012) and Gómez & Pérez (2013). The structure has four or five spans of 50 m each, with three single piers by bent of 14 m high. The superstructure consists of an unicellular box section with a roadway of 14 m and a height of 2.3 m. The piers have a box section of 1.4 m by 4 m of external transverse dimensions. Figure 1 shows the general dimensions of the bridges and the transverse dimensions of girders and piers.

In the previous studies, different forms of connection between girders and piers were analyzed, but as these authors demonstrated (Gómez & Salas, 2012; Gómez & Pérez, 2013) for the obtained results there is no difference between one and the another option. Therefore, only continuous bridges are analyzed in this work, with a unique girder and releasing the longitudinal moment between girder and piers.

2.2 *Irregular bridge models*

Based on the model of Figure 1, irregularity models were constructed in the superstructure and substructure. The models with irregularities in the superstructure have curvatures between 0º and 180º, every 30º, or present changes in the relationship between the extreme span length with respect to the length of central span in ratios of 1:0.25; 1:0.50; 1:0.75; 1:1.25; 1:1.50; 1:1.75 and 1:2.00. The models with irregularity in the substructure have extreme or central piers with lengths of ±0.25, 0.50 and 0.75 the original length of the elements.

The models with joint irregularity were formed taking the models with irregularity in the superstructure and inserting the substructure conditions of irregularity. Figure 2 shows schemes of curved bridges, with changes in the length of the extreme spans and with changes in the length of a central pier (the change of the length of an extreme pier was also studied). Consequently, the models with joint irregularity are a combination of the models shown in Figure 2.

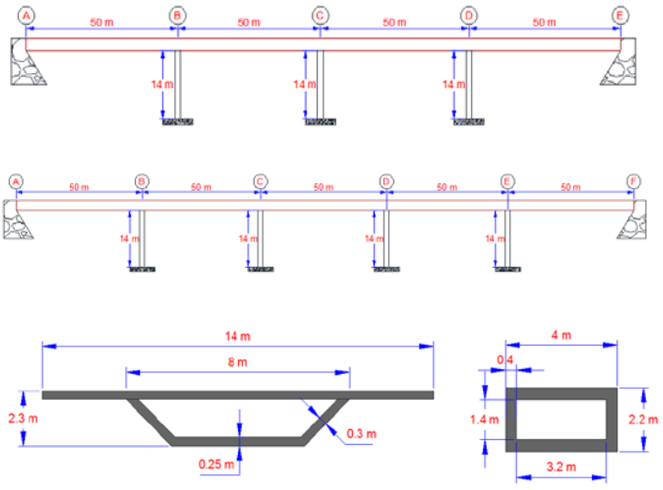

Figure 1. General regular bridge dimensions and elements transverse dimension.

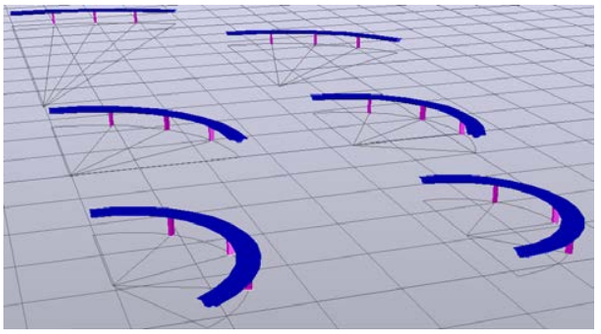
3 SEISMIC LOAD

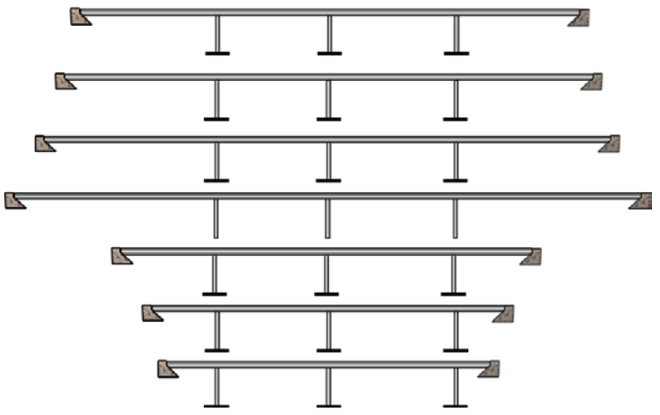
Regular and irregular structures were subjected to seismic load characteristic of one of the most hazardous seismic zone in Mexico (BMSF, 2000). For this, 53 three-component accelerograms were selected (although only the two horizontal components were applied), obtained in the Mexican States of Colima, Michoacán and Guerrero. The selection of accelerograms was based on the earthquake magnitudes or on the maximum soil displacements, velocities or accelerations.

Figure 3 shows the response spectrums for the greater horizontal component of the 53 accelerograms, considering 5% of critical damping. As it is observed in this figure, most of the records have peak spectral coordinate in periods lesser than 0.5 s, although the earthquake database has important diversity.



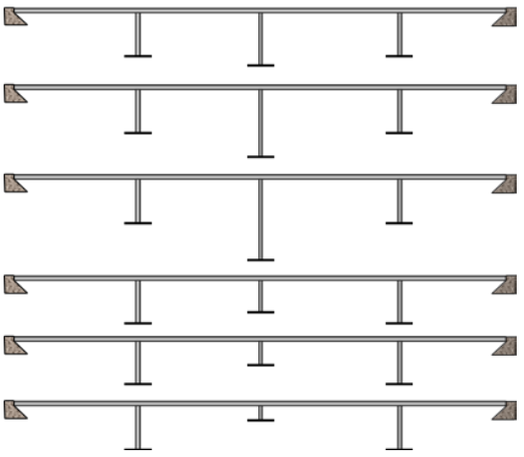
Greater horizontal component of the records is applied in the transverse direction of bridges, to produce the most unfavorable condition. The vertical component has not been considered; however some works show that it could be important for certain combinations of the dynamic properties of structure and soils, e.g. bridges located near the epicenter of an earthquake.

4 SUBSYSTEM ELASTIC RESPONSE



4.1 *Substructure irregularity*

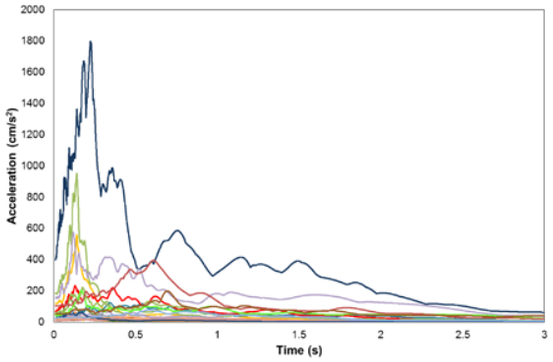
The bridge models with superstructure or substructure irregular conditions were subjected to the 53 ac-



celerograms and elastic responses were captured, obtaining the maximum displacements and mechanical elements, although only the results of the maximum transverse displacements are discussed here, specifically in node C of Figure 1, in the structure elevation scheme.

a) Curved

b) Superstructure girder irregularity



c) Substructure irregularity, central pier modification

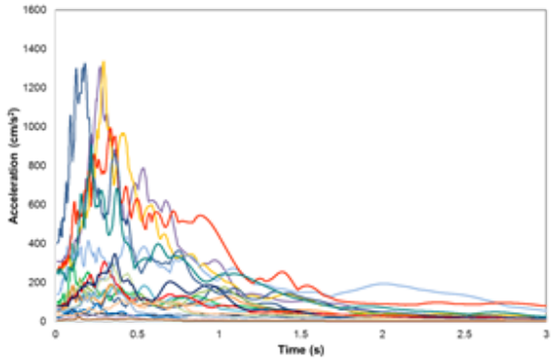


Figure 2. Schemes of bridges with single irregularity, in superstructure system (a and b) and substructure system

Elastic analyzes were performed with SAP 2000 program. In the studied models, the effect of soil-structure interaction was not considered, so the piers of the bridges are embedded in the base. In addition, elastic springs with transverse and rotational stiffness were used to simulate abutments and bearings.

Maximum displacements are used to define the normalized differences, between regular and irregular responses, as it is shown in equation 1. The normalized difference is organized from minor to the greater, in order to determine the statistical quartiles (25%, 50%, 75% and 100% of the values), with which the tendencies of variation for different irregular conditions of bridges are determined.

a) Colima and Guerrero states spectrums

b) Michoacán state spectrums

Figure 3. Elastic spectrums for the Colima and Guerrero (a) and Michoacan (b) states.

$$D_n = \frac{R_{IR} - R_R}{R_R} \quad (1)$$

where R_{IR} and R_R are irregular and regular responses, respectively.

For models with irregular substructure, the authors (Gómez & Salas, 2012) compared their dynamic properties, finding that the first two modal forms are similar, therefore it was defined that the changes in the responses were mainly associated with the irregularity variations themselves. Figure 4 shows the normalized differences of the maximum transverse displacements of the central node for the studied bridges, when the length of the central column is changed. In this figure, and in others of this work,

the horizontal axis represents the values of the normalized difference, indicating each line the changes for every substructure irregular condition; lines indicators represent each of the four quartiles. Figure 4 shows that the increase of the central column length produces more variation than the decrease of it. That is, the range of the normalized differences is greater when the length of the central pier is larger than that of the adjacent column, compared when this length is smaller. Thus, when the length of the central pier is less than 75% of the adjacent pier, the changes of the normalized differences are similar for all accelerograms; but when the length of the central pier is 75% larger than the adjacent pier, the normalized differences are greater.

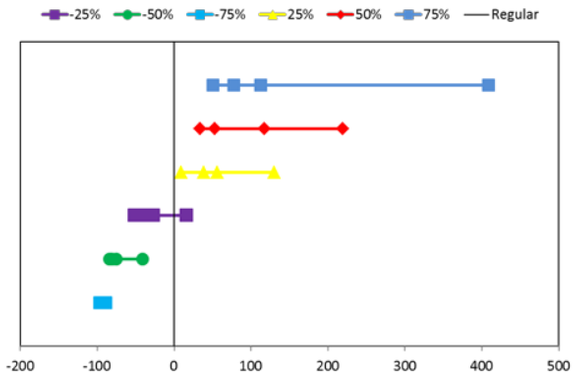

Figure 4. Normalized differences for bridges when the length of the central pier is changed.

Figure 5 shows the normalized differences in the maximum transverse displacements when the length of an extreme pier is changed. As it is observed, the trends are similar to those commented for Figure 4. However, when the central pier length is changed, more variations are recorded than when the length of the extreme pier is modified. For example, when the length of the central pier changes 75% (Figure 4), the normalized differences in the transverse displacement are similar to the values obtained from the normalized differences when the length of the extreme pier is changed only by 25% (Figure 5). From Figures 4 and 5 it is possible to conclude that a bridge is more vulnerable when the central pier has variation in its length, compared to structures that have piers close to the abutments, with the same variations.

4.2 *Superstructure irregularity*

The bridge models were subjected to the same seismic load and again the normalized differences of the transverse maximum displacements were obtained (Gómez & Pérez, 2013). Figure 6 shows the normalized differences organized by quartiles for the curved models. It is observed that, for greater change in the angle of curvature of the bridge, the results show greater dispersion up to 90º, and less dispersion for larger angles.

Figure 7 shows the normalized differences by quartiles for models where the length of the extreme span is changed. In this figure, it is observed that the greater the change in the length of the extreme piers, in relation to the length of the other spans, the greater dispersion in the normalized differences. Also, there is greater dispersion when the length is reduced than when it increases. Thus, it can be affirmed that bridges with extreme spans greater than the centrals, are more vulnerable.

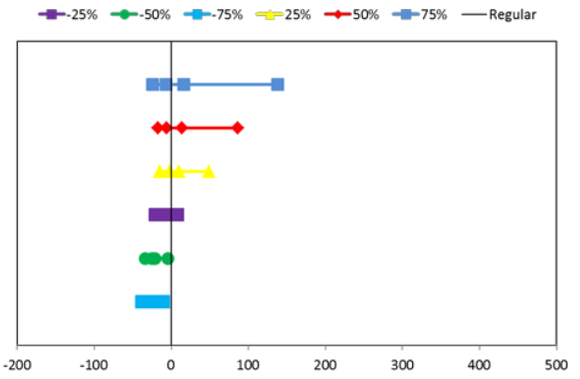

Figure 5. Normalized differences for bridges when the length of the extreme pier is changed.

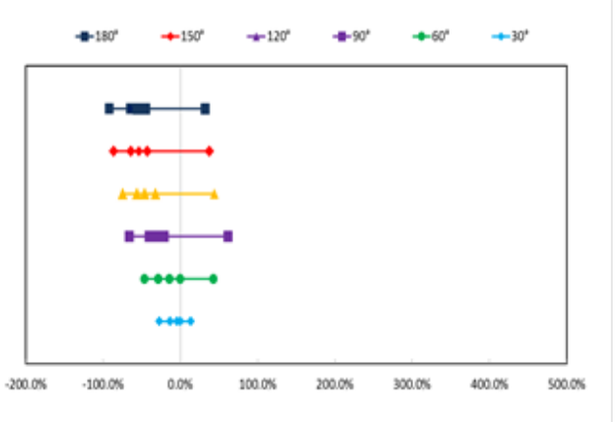

Figure 6. Normalized differences for curved bridges.

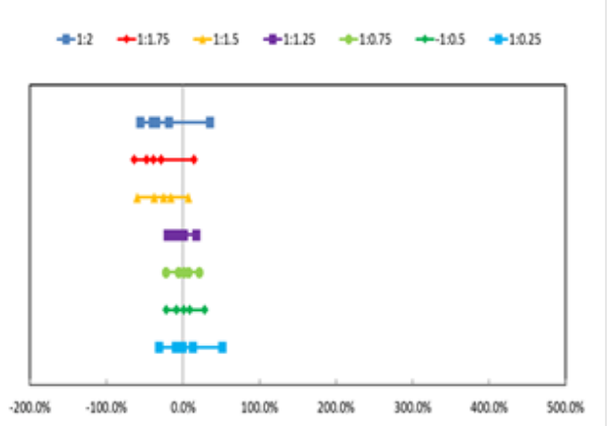

Figure 7. Normalized differences for bridge where the extreme span length is modified.

5 JOINT IRREGULARITY

For superstructure irregularity models were modified changing the lengths of the central pier and an extreme pier in percentages of ± 25%, 50% and 75%. In these models, elastic analyses were performed with the 53 accelerograms of Figure 3, and the normalized differences of the transverse maximum displacements were obtained with equation 1, they are also organized in quartiles. Figures 8 to 13 show the normalized differences of the maximum displacements of models with degrees of curvature of 30º, 60º, 90º, 120º, 150º and 180º, respectively, and with changes in the length of an extreme pier. For models with degrees of curvature of 120º or greater (Figures 11 to 13) minimal variation is observed when the irregularity of the substructure is included; while for bridges with lower degrees of curvature greater dispersions occur when the length of the extreme pier changes, especially for the case of bridges with a 30º curvature (Figure 8), which is the most common case of real curved bridges.

For bridges with changes in the length of the extreme spans and with changes in the length of the piers, the quartiles of the normalized differences were also determined. Figures 14 to 20 show the normalized bridge differences with changes in the ratio of the end-to-center span length from 1:2.0, 1:1.75, 1:1.50, 1:1.25, 1:0.75, 1:0.50 and 1:0.25, respectively. In these figures, and in the analyses where extreme pier is modified, it is observed that greater dispersions are generated in the models with joint irregularity when the length of the central pier is modified, compared to the dispersions obtained when the length of the extreme pier is modified. Also, greater dispersions occur when the length of the piers grows.

In general, a smaller length of the extreme spans, greater negative values of the normalized difference are obtained. So, the response of regular models is greater than that of irregular ones, although there is greater dispersion; and, therefore lower prediction and greater vulnerability. The variation of the fourth quartile is still not linear as it is assumed in many preliminary inspection methods and as it was found in models with irregularity only in one subsystem.

Comparing joint irregularity models with those with irregularity only in one subsystem, it is observed that in general there are greater dispersions in the first models, making the bridges with joint irregularity more no favorable and more vulnerable. When the length of the extreme pier is changed, this is less evident than when the length of the central pier is changed.

6 CONCLUSIONS

Although bridges have been studied with irregularity in their superstructure or substructure, parametric studies of bridges with joint irregularity have not been studied. That is the reason why this work analyzed bridges that show irregularity in both superstructure, considering curved systems (between 30º and 180º, every 30º) and with variation in the length of the extreme gaps (in ratios of 1:0.25, 1:0.50, 1:0.75, 1:1.25, 1:1.50, 1:1.75 and 1:2.00 with respect to the original length) and substructure, varying the length of some piers in percentages of ± 25%, 50% and 75%. For these models, elastic analyzes with a database of 53 earthquakes registered in the Mexican States of Colima, Michoacán and Guerrero were developed. From the results of analysis, the normalized differences between the responses of regular and irregular models, of the transverse maximum displacements are determined and grouped by quartiles to show trends of variation for each degree of irregularity.

From the results, it is observed that for curved bridges, the modification of the length of a pier generates greater dispersions if the structure has small angles of curvature, especially 30º. F or angles of curvature greater than 90º, no s ignificant variations are observed when the length of the piers is changed, compared when only the irregularity of the superstructure is considered.

For the models that have variations in the length of the extreme spans, in relation to the length of the central spans, when the length of one pier is modified (originally all equal), greater dispersions are generated. The ranges of the normalized differences are greater when the length of the central pier is changed than when this dimension varies in the extreme pier, as it occurs in the analysis of bridges

with irregularity only in the substructure. There is greater dispersion in the normalized differences as the length of the extreme span decreases, with respect to the initial length. In addition, there are greater dispersions when the length of the central pier is increased than when it is smaller than the original one. Not significant changes are observed when the length of the extreme piers changes.

As in the case of bridges with irregularity only in the substructure or only in the superstructure, in bridges with joint irregularity it is shown that the relation between the percentage of change of the length of piers and the variation of the normalized difference is not linear as it is assumed in all methods of preliminary inspection.

Linking seismic resilience into sustainability assessment of limited-ductility RC bridges

A. Y. Al-Attraqchi, M. J. Hashemi, R. Al-Mahaidi & P. Rajeev
Department of Civil and Construction Engineering, Swinburne University of Technology, Melbourne, VIC 3122, Australia

ABSTRACT: Sustainability addresses the environmental, economic, and social impacts distributed over the life of a structure. However, in sustainability assessment of a structure, often ordinary events such as normal operation or maintenance actions due to ageing effects are considered and the resilience of the structure to devastating disasters that emphasizes on structural performance and recovery under extreme events is often ignored. Recent experience from natural and man-made hazards, however, highlights that extreme events, particularly earthquake, could affect with a large magnitude, the environmental, economic, and social aspects of our built environment. This study aims to systematically integrate the seismic-resilience into the sustainability assessment of a limited-ductility RC bridge. Sustainability metrics include repair cost, downtime, and environmental impacts and they are computed by consecutive hazard, structural response, damage, and loss analyses in accordance with the performance-based earthquake engineering (PBEE) methodology. Multi-axis substructure testing (MAST) system at Swinburne was used to realistically capture the three-dimensional response of the column, from elastic range to collapse. The data collected from the experiments were then used evaluate the damage-states of the column and quantify the associated seismic-repair sustainability metrics.

1 INTRODUCTION

1.1 *Sustainability*

Sustainability is defined as a set of economic, environmental and social conditions, in which all of society has the capacity and opportunity to maintain and improve its quality of life indefinitely, without degrading the quantity, quality or the availability of natural, economic and social resources (ASCE, 2013). Accordingly, sustainable development of structures aims to achieve a reasonable balance between the environmental, economic and social impacts distributed over the life-cycle of a structure (Willard, 2002). In sustainability studies, however, only the 'ordinary' events such as construction, normal operations, maintenance actions due to ageing effects and deconstruction are considered and the resilience of the structure that emphasizes on the impact of structural performance and recovery under 'extreme' events are often ignored (Bocchini et al., 2014). This could be due to the fact that ordinary events will certainly occur, while extreme events may be rare or never occur during the service life of a structure. However, worldwide experience from recent natural and man-made hazards, have shown that poor structural performance could lead to significantly high environmental, economic and social impacts, which highlights that the goals of sustainability cannot be achieved without considering the resilience of structures (Bocchini et al., 2014, Frangopol and Soliman, 2016, Rodriguez-Nikl, 2015, Asprone and Manfredi, 2015). Particularly, earthquake is a hazard with severe long-term consequences on civil structures that ranges from direct and indirect economic losses due to repair or reconstruction; to social effects such as disruption of structures functionality; and environmental impacts such as energy consumption and carbon dioxide emissions due to subsequent repair/replacement, among others (Gencturk et al., 2016, Hossain and Gencturk, 2014, Dong et al., 2013). Therefore, there is a need for a unified framework, in which structural resilience to extreme events, especially seismic hazard, is integrated into sustainability assessments.

This study aims to systematically integrate seismic-resilience into sustainability assessment of a reinforced concrete (RC) bridge. The quantification of sustainability metrics is applied only to the bridge piers, which is the focus of this paper. Sustainability metrics were computed by successive completion of the hazard, structural response, damage and loss analyses in accordance with the performance-based earthquake engineering (PBEE) methodology (Moehle and Deierlein, 2004). Performance of bridges is therefore integral to the evaluation of

transportation network performance under high intensity earthquake scenarios. Also, Multi-axis substructure testing (MAST) was used to realistically capture the three-dimensional response of the columns, from linear-elastic range to collapse. The data collected from the experiments were then used to probabilistically evaluate the damage-states of the column and quantify the associated seismic-repair sustainability metrics.

1.2 *PBEE framework*

The performance-based assessment framework established by the Pacific Earthquake Engineering Research Center (PEER) is used to assess the seismic vulnerability of the bridge structure. The framework performance assessment is divided into four analysis phases, which are seismic hazard analysis, response analysis, damage analysis, and loss analysis. The product of each analysis is then integrated using a total probability theorem.

The PBEE procedures require the prediction of the seismic capacity of structures which is then compared to the local seismic demand. It produces an interface of the expected level of damage for a given level of ground shaking. In order to estimate the structural response under seismic loads, Vamvatsikos and Cornell (2002) proposed a computational-based methodology called incremental dynamic analysis (IDA). The IDA method gives a clear relationship between the seismic capacity and demand. It involves performing nonlinear dynamic analyses of the structure under a suite of ground motion records, each is incrementally scaled to several intensity measure (IM) levels. The structure is pushed all the way from elastic to inelastic and to the final global dynamic instability (collapse). The IDA curves relate the seismological intensity measures (IM), such as peak ground acceleration (PGA) to the response quantities in terms of the engineering demand parameters (EDP), such as the maximum deflection or drift of the structure. Another common method used is the multiple strip analysis (MSA) method (Jalayer and Cornell, 2009), which is used to quantify the distribution of the structural response, EDP, over a range of earthquake shaking intensities, IM. The final results are quantitatively modelled and then integrated into a probabilistic risk analysis procedure in a suitable format to be integrated with a seismic hazard curve in order to calculate mean annual frequency of exceeding a certain capacity damage limit-state.

1.3 *Multi-Axis Substructure Testing*

Multi-Axis Substructure Testing system in the Smart Structures Laboratory at Swinburne provides a powerful tool for investigating the effects of earthquakes, hurricanes, and other extreme loading events on large structural components using hybrid simulation testing (Hashemi et al., 2015). A sophisticated 6-DOF control system is used utilizing eight high-capacity hydraulic actuators that enable application of complex multi-directional deformation or loading schemes to structural components. The system can be used for performing quasi-static test or hybrid simulations.

Evolved from pseudo-dynamic testing (Nakashima, 2001, Mahin and Shing, 1985), hybrid simulation is a versatile and economically viable experimental technique to evaluate the dynamic performance of large civil structures (Nakashima et al., 1992). According to a report developed by the US earthquake engineering community in 2010, hybrid simulation capabilities are a major emphasis of the next generation of earthquake engineering research (Dyke et al., 2010).

The bridge model is calibrated based on experimental multi-axis results of a limited ductility reinforced concrete column that was tested under cyclic quasi-static procedure.

2 PBEE METHODOLOGY

2.1 *Quantification of seismic hazard*

The first step of the performance-assessment framework is to quantify the seismic hazard at the site. This is usually done using the probabilistic seismic hazard analysis (PSHA), which was first proposed by Cornell (1968). The method considers the earthquake sources, the distance to the fault, uncertainties in earthquake size, location and ground motion intensity and using a total probability theorem to quantify the probabilistically distribution of the shaking intensity of the site. By using the results of the PSHA, ground motions can be selected to represent the seismic hazard at the site. However, in this study, PSHA has not been performed, instead a suite of 44 (two records from 22 earthquakes) ground motions were chosen based on the ATC63 project by FEMA (FEMA, 2009). The selected ground motions originate from severe seismic events of ranging in magnitude between 6.5 and 7.6 and closest distance to the fault rupture larger than 10km. Thus, only strike–slip and reverse sources are considered. Table 1. lists the details of the ground motions.

2.2 *Response analysis*

Nonlinear dynamic response analysis is used to quantify statistical distribution of the structural response for different ground motions at increasing intensities. Incremental dynamic analysis (IDA) and multiple stripe analysis (MSA) are used for studying the structural response. The maximum drift value at each intensity measure is recorded to generate the IDA plots. By employing MSA, the mean of the lognormal drift values and the lognormal standard deviation are calculated at each stripe. These discrete data points are then fitted by a power-law model as shown in Eq. 1a and 1b.

$$\mu_{EDP|IM} = a(IM)^b \quad (1a)$$

$$\beta_{\ln EDP|IM} = c(IM)^d \quad (1a)$$

where $\mu_{EDP|IM}$ is the mean of the EDP and $\beta_{lnEDP|IM}$ is the lognormal standard deviation.

Multi-Axis Substructure Testing system was previously used as an advanced testing technique for studying the behaviors of a reinforced concrete column under quasi-static testing (Hashemi et al., 2017). The experimental results validate the collapse behavior of the columns in the numerical model.

2.3 *Damage states*

Damage states (DS) are defined based on the damage levels corresponding to the repairs necessary to bring the facility back to original state. They could be based on the structural or non-structural components damages due to the engineering demand parameter. Components are combined into performance groups that are affected in a similar manner by the EDP. In this study, only one performance group is used that corresponds to the damage of the columns. A sufficient number of damage states should be defined for each group to describe the range of possible damages at different levels of structural response.

The damage threshold limit states are obtained from the pushover curve as recommended by (Gencturk, 2011). In this study, the three limit states are the initial yielding drift, the drift corresponding to ultimate strength, and the collapse drift point. Further, uncertainties in the capacity to account for modelling errors and variation in material properties of these limit states are approximated by applying a 0.35 lognormal standard deviation to each limit state (Gencturk, 2011). The probability of being in a damage state given EDP is calculated from the limit states fragility curves based on Eq. 2. Next, the probability of being in a damage state given IM is calculated on Eq. 3.

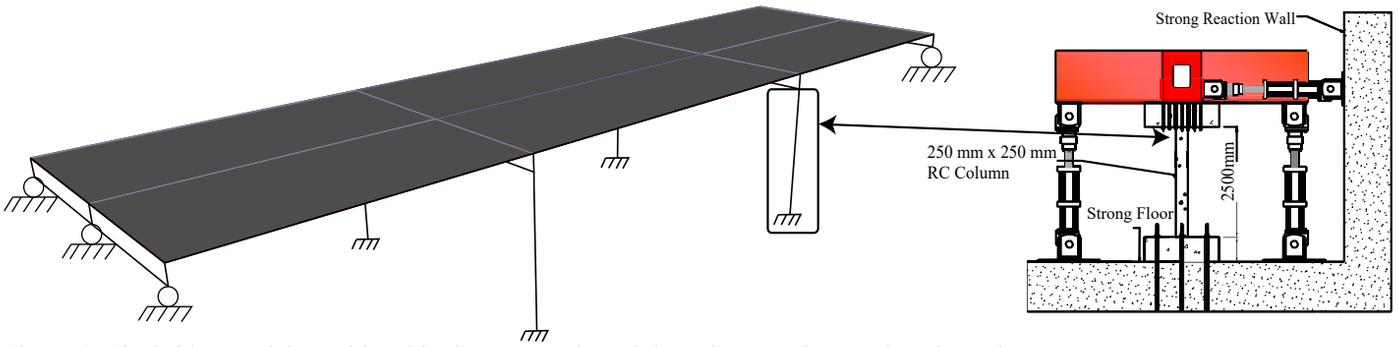

Figure 1. The bridge model considered in the case study and the column under quasi static testing.

$$P_{DS_i|EDP} = \left\{ \begin{array}{c} 1 - F_{DS_1}(EDP) \\ F_{DS_i}(EDP) - F_{DS_{i+1}}(EDP) \\ F_{DS_n}(EDP) \end{array} \right\} \text{for } 2 \le i < n \quad (2)$$

where F_{DS} is the fragility curve of exceeding EDP of a damage state, $P_{DS|EDP}$ is the probability of being in a certain damage state given EDP, and n is the number of the damage states.

$$P_{DS|IM} = \int_0^\infty P_{DS|EDP} f_{EDP|IM} \, dEDP \quad (3)$$

where $P_{DS|IM}$ is the probability of being in a certain damage state given IM, and $f_{EDP|IM}$ is the probability density function of EDP given IM, which is computed based on the IDA curves.

2.4 *Loss analysis*

The decision variable (DV) is the final step of the PBEE methodology. In this study, it is used to represent the economic, social, or environmental variables. There are many ways of expressing the losses as discussed in detail in (Moehle and Deierlein, 2004), in this paper the losses are defined as a constant value. A decision variable is defined for each damage state and the variable value given IM is based on Eq. 4.

$$\mu_{L_R|IM,NC} = \sum_{DS} \int_0^\infty \mu_{L_R|DS} P_{DS|EDP} f_{EDP|IM} \, dEDP \quad (4)$$

where $\mu_{LR|DS}$ is the mean loss DV corresponding to the DS and $\mu_{LR|IM,NC}$ is the mean of repair losses given IM and conditioned on no collapse.

A common approach is to split the equation into collapse case and non-collapse cases. By assuming mutually exclusive and collectively exhaustive events of collapse and no collapse, the mean of total seismic losses of the structure conditioned on the seismic intensity measure IM is described by Eq. (5).

$$\mu_{L_T|IM} = \mu_{L_{NC}|IM,NC}(1 - P_{C|IM}) - \mu_{L_C|C} P_{C|IM} \quad (5)$$

where $\mu_{LNC,IM}$ is the is the mean loss DV given IM for the non-collapse damage states, $\mu_{LC|C}$ is the mean collapse loss given collapse (note that the collapse loss is independent from IM), $P_{C|IM}$ is the collapse probability given IM.

The loss assessment converts the DSs to their consequent DVs. In this paper, four DVs are used, including the repair cost (related to economic aspect), downtime (related to social aspect), energy consumption and carbon dioxide emissions (related to environmental aspect).

3 BRIDGE CASE STUDY

3.1 *Model*

This bridge has three spans that are 10, 15 and 10 m long, for a total structure length of 35 m. It has integral bents with two columns per bent having a clear height of 5 m. The bridge is chosen to represent an average typical three-span bridge. The finite element model is developed using OpenSees (McKenna, 2011). The superstructure components are aggregated into one deck component and they are modeled as elastic elements. The bents are modeled using displacement based elements.

The columns were modelled using beam-with-hinges elements, of which the nonlinear behavior is assumed to occur within a finite length at both ends based on distributed plasticity. The plasticity model follows a peak-ordinated hysteresis response based on the Modified Ibarra-Medina-Krawinkler (IMK) (Ibarra et al., 2005) deterioration model of flexural behavior. The columns are calibrated based on previous quasi-static cyclic experimental results on a half scale specimen (Hashemi et al., 2017). The test was conducted by applying a constant axial load equal to 8% of the column's ultimate load carrying capacity, followed by imposing bidirectional lateral deformation reversals in displacement control that follows the hexagonal orbital pattern suggested in

FEMA 461 (Agency, 2007). This plasticity model was chosen because it is capable of capturing the important modes of deterioration that participate in side-sway collapse of RC structures. Explicit modelling of beam-column joints and bar-slip effects are not included since they are considered not necessary for performing collapse modelling of RC frames, according to FEMA-P695 (FEMA, 2009).

There are several methods for modelling the abutments. The first is just by modelling them as rollers, which is acceptable for multiple bridge spans since the effect of the abutments is minimum. In this paper, rollers are used to focus on the columns behavior as they resist the lateral forces. Other methods include considering the abutment-soil interaction and modelling it as a combination of linear springs based on material parameters recommended by Caltrans seismic design criteria guidelines (Caltrans, 2013).

3.2 *Results and discussion*

Dynamic time history inelastic analyses were carried out for the 44 selected earthquake records using OpenSees (McKenna, 2011). Prior to performing the IDA, pushover and cyclic analyses were conducted to check the static capacity of the structure and to determine the damage limit states, Figure. 2 shows the pushover and cyclic curves for a single column. The damage states were defined based on drift values corresponding to the yield point of the pushover curve, the pushover ultimate strength value, which are 1.0%,2.5%, respectively. As for collapse, it was defined based on the drift value corresponding to 5% drop in strength of the first cycle envelope, which corresponds to a drift of 5.0%. The two damage states are summarized in Table 2.

Table 2. Definition of damage states and the repair activities

States	Drift	Description	Repair Activity
DS0, no damage	< 1.0%	No/slight damage due to hairline cracks	No repair
DS1, NC	> 1.0% < 2.5%	Small flexural cracks Longitudinal rebar yielding	Epoxy injection to open cracks Repair/replacement of damaged cover concrete
DS2, NC	> 2.5%	Longitudinal rebar buckling Longitudinal rebar fracture Crushing of core concrete	Concrete removal and placement Epoxy injection of any cracks wider than 0.3mm Reinstatement of damaged concrete with a suitable repair mortar Wrapping of the column with CFRP

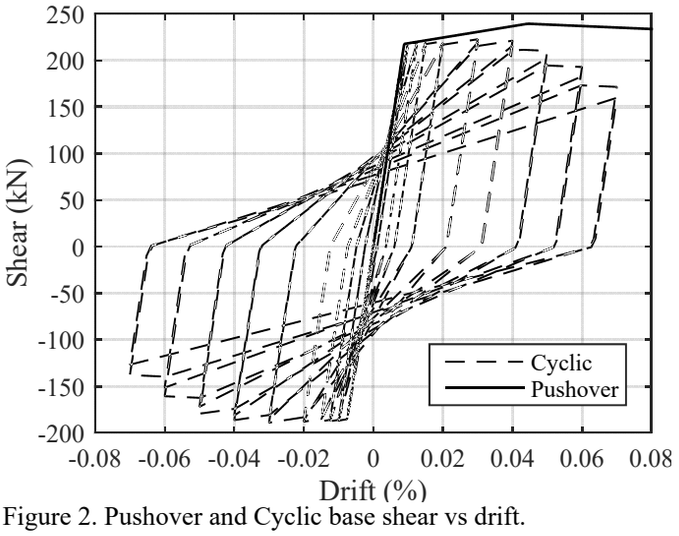

Figure 2. Pushover and Cyclic base shear vs drift.

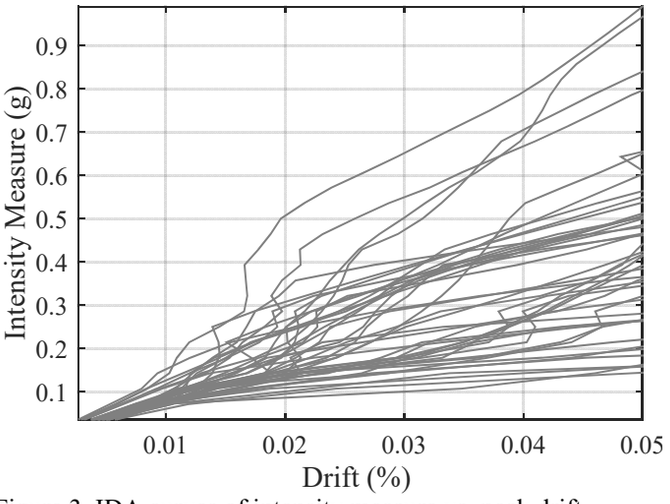

Figure 3. IDA curves of intensity measure vs. peak drift.

The data obtained from the IDA computations generate the IDA curves, as shown in Figure. 3. The IDA data are first processed from the beginning to the IM level where 50% (22 ground motions) of the data points are still available. Then, the median and standard deviations are fitted to generate a continuum of fragilities over the whole range of IM. Also, the global collapse probability is calculated from the IDA plots based on the 5% drift criteria, as shown in Figure 4. The area under the plot is collapse and area above the plot is no collapse. Fragility curves for damage states are shown in Figure 5. To illustrate the information contained in the fragility curves, consider the following example. If the drift value equals 2%, the conditional probability that a column is considered to have experienced minor damage or worse is 97.5%, to have a major damage or worse is 25.7%. Therefore, by the mathematics of set theory the probability of being in DS0 (no damage), DS1, and DS2 is 2.5%, 71.8% and 25.7%, respectively, as explained in Eq. 2.

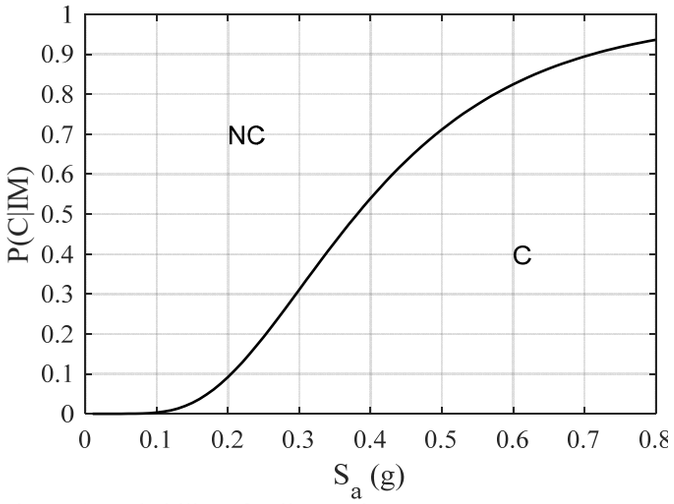

Figure 4. Probability of collapse given IM.

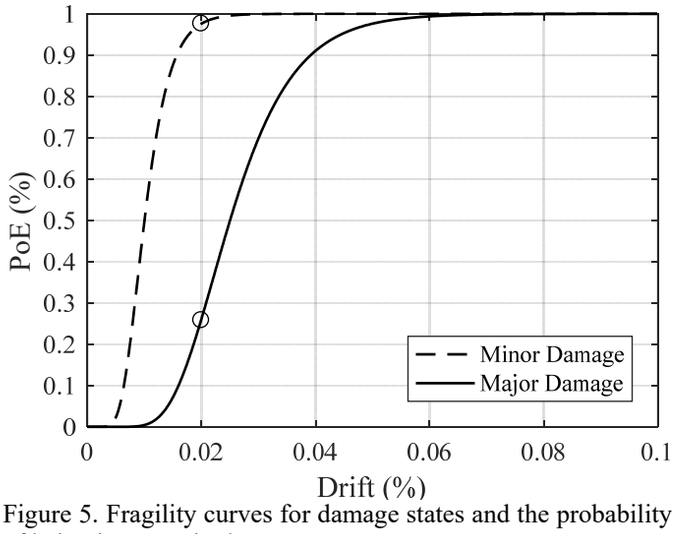

Figure 5. Fragility curves for damage states and the probability of being in a certain damage state.

By using Eq. 3, the probability of exceeding a damage state given the intensity measure was computed and it was used for the calculations of the loss decision variables in the next stage.

Finally, the expected losses for the structural repairs of the four decision variables for each damage state are summarized in Table 3. The mean structural repairs are based on the probability of exceeding the corresponding damage states (DS1 and DS2) given IM conditioned on no collapse.

Figure 6 shows the expected economic loses conditioned on seismic intensity. Economic viability is usually the main factor which governs the choice of repair type, as cost is usually the main driving force in any project. In order to quantify the cost of each repair activity, cost estimates were assumed, however ideally, they should be based on real estimates if available. The use of FRP for repair and rehabilitation of earthquake-damage structures can be considered as a cost-effective and time-saving alternative to replacement. It has been demonstrated that CFRP repairs can be used to rehabilitate an earthquake damaged RC column and return it to its initial collapse resistance capacity (Hashemi et al., 2016).

Figure 7 shows the expected social loses conditioned on seismic intensity. Social impacts deal with the consequences of the seismic repairs on the bridge functionality. The seismic repairs may cause disruption to public and reduced bridge capacity. Therefore, the repair downtime was considered as the social impact. Downtime is defined as the period between the occurrence of a seismic event and the completion of repair efforts and resuming operation. The repair downtime has two components, namely, the 'repair time', which is the time needed for the repair process and the 'mobilization time', which is defined as the time lag between the seismic event and the beginning of repair process. Unlike the repair, mobilization time could vary as it depends on activities such as inspection, damage assessment, consultations with professional engineers, financing, etc. (Mitrani-Reiser, 2007).

For the case study column in DS_2, the mobilization of one week was expected for site inspection, non-destructive testing, ordering materials, etc. Also, it was estimated that one day should be sufficient to complete the repair of the column. For the collapse state, a mobilization time of 30 days was allowed for the planning of reconstruction, which included: site inspection, preparation of a design and rectification procedure, engaging a contractor, ordering materials, etc. Similarly, the downtime for the other DSs was quantified as shown in Table 3.

Environmental impact assessment evaluates the repair activities in terms of the inflow (resource consumption) and outflow (hazardous effects of emissions) that influences the eco-system and human health. In this study the energy consumption and carbon dioxide (CO_2) emissions were considered as the input-output flow of the seismic repair in terms of the environmental impacts.

The energy consumption associated in the production and fabrication of repair materials such as repair mortar, FRP and epoxy is referred to as the material embodied energy in MJ/kg and are presented in Table 3 for the various materials used in the repair, based on data from Mara et al. (2014).

The total carbon emissions in $kgCO_2/kg$ for the respective materials used in this study are presented in Table 3 based on Mara et al. (2014). Figure 8 and Figure 9 show the environmental losses due to energy consumption and carbon emissions, respectively, conditioned on the seismic intensity.

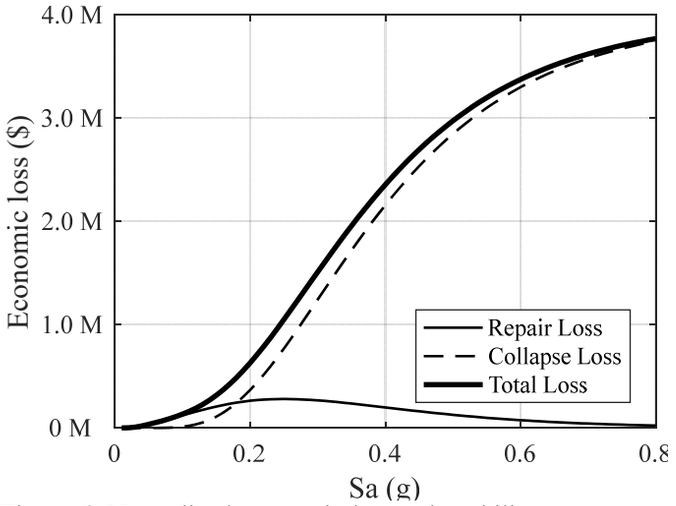

Figure 6. Normalized economic loss vulnerability curves conditioned on seismic intensity.

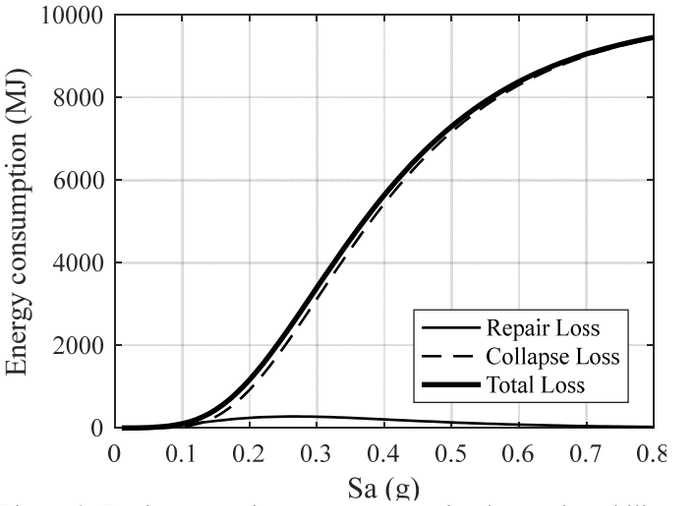

Figure 8. Environmental energy consumption loss vulnerability curves conditioned on seismic intensity.

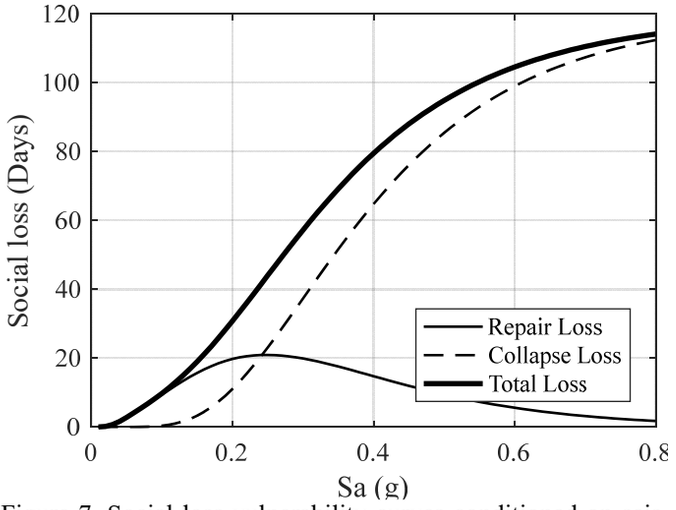

Figure 7. Social loss vulnerability curves conditioned on seismic intensity.

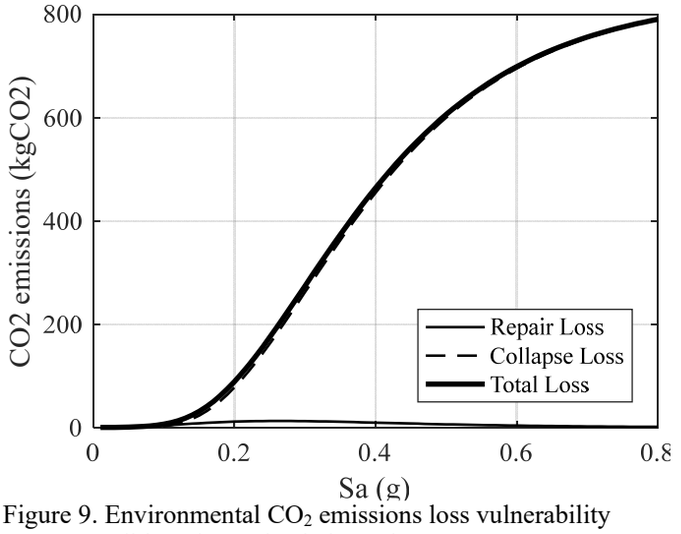

Figure 9. Environmental CO_2 emissions loss vulnerability curves conditioned on seismic intensity.

Table 3. Risk -based sustainability assessment of seismic repair

Damage States	**Economical**		**Social**		**Environmental**	
	Repair	Cost ($)	Repair Downtime		Energy consumption of repair materials (MJ)	CO_2 emissions of repair materials ($kgCO_2$)
			Repair Time (days)	Mobilization Time (days)		
DS_0		0	0	0	0.0	0.0
DS_1	Epoxy	100,000	1	7	19.2	1.8
DS_2	Concrete Epoxy CFRP	500,000	7	30	537.4	23.8
Collapse	Reconstruction	4,000,000	90	30	10067.8	842.7

4 CONCLUSION

A unified framework for sustainability assessment of structures is presented. This framework adopted the PBEE methodology to incorporate seismic-resilience into life-cycle sustainability assessment for RC bridges. Three out of the PBEE modules are presented, namely, structural response analysis, damage assessment, and loss assessment due to economic, social, and environmental factors. It is possible to incorporate the sustainability assessment in the design procedures to anticipate the cost, environmental and social impacts in the use phase of the structure so that it can be reduced by adopting a more resilient design. This can reinforce the necessity of incorporating structural damage and loss assessment in sustainability quantification procedure for seismic regions.

Study on Impact Behavior of Piers Subjected to Vehicle Collisions

R. W. Li & D. Y. Zhou
Research Institute of Structural Engineering and Disaster Reduction College of Civil Engineering, Tongji University, Shanghai, China

ABSTRACT: Vehicle collision with reinforced concrete (RC) pier is one of the leading causes of viaduct failures. Therefore, impact behaviors of RC pier are of significant importance for viaducts safety. However, previous experimental impact studies were concentrated on impact behaviors of RC beam, few experimental studies on impact behaviors of RC pier was conducted. In this paper, a series of impact tests were conducted to study the reinforcement ratio and impact velocity effects on the impact behaviors. The impact test results showed that a high reinforcement ratio led to a high impact resistance that reducing the total displacement, residual displacement and energy absorption capacity, and a high impact velocity increased the total displacement, peak impact force and energy absorption capacity. Difference between the impact behaviors and the corresponding static behaviors was discussed, the results of which showed that the failure modes were both shear failure while the crack patterns were different.

1 INTRODUCTION

Reinforcement concrete (RC) piers have been widely used all over the world. These RC piers are under the threat of vehicle collisions, which makes bridges under high risk of collapse. A statistic investigation (Harik et al. 1990) showed that 15% of viaduct failures were caused by truck collisions in the period of 1951-1998. A similar study (Cook 2014) showed that 19.6% of viaduct failures were due to vehicle collisions over a 25-year period. These viaduct failures were mainly triggered by pier failure subjected to vehicle collisions. Because of high peak effect and short impact duration of impact loading, the pier failure induced by vehicle collision is distinguished from that by earthquake ground excitation. Therefore, much attention was directed to impact behaviors of the RC pier to ensure bridge safety in practice.

Most previous experimental studies on the RC pier were focused on their seismic performance, but only a few experimental studies on their impact behaviors were conducted. Many researchers conducted the traditional falling weight impact tests of RC beam to simulate the impact process of RC pier under vehicle collision. For example, studies carried out by Kulkarni & Shah (1999), Kishi et al. (2002) and Saatci & Vecchio (2009) reported the t the high strain rate effect on impact response of RC beams, the impact behavior of RC beams without stirrups and the shear mechanisms effect on impact behaviors of RC beams, respectively. Additionally, other researchers (Sukontasukkul & Mindess 2003, Cotsovos et al. 2008, Fujikake et al. 2009, Bhatti et al. 2009, Shakir et al. 2016) also conducted falling weight impact tests to study the impact behaviors of different beam. It is found that conclusions and finding obtained from these studies may not be directly used to RC piers since the failure modes and boundary conditions between these two structural members are different. Therefore, it is required to conduct horizontal impact tests on the RC pier to study its impact behaviors and failure mode, which is critical for establishment of design method for the RC pier under impact loading.

In this paper, a series of horizontal impact tests were carried out to investigate the impact behaviors and failure mode of RC piers. Moreover, the reinforcement ratio and the impact velocity effects on the impact behaviors were analyzed. Besides, post-impact damage of the RC pier and difference between impact test results and the corresponding static test results were also discussed.

2 TEST PROGRAM

2.1 *Test specimens*

Figure 1 showed the schematic view of five specimens, with four impact test specimens and a static one. All the tested specimens were 1500 mm in height with a rectangular cross section of 240 mm × 300 mm.

Table 1. Reinforcement and stirrup arrangement of each specimen

Test method	Specimen number	Reinforcement ratio (Diameter of reinforcement) mm	Stirrup ratio (Diameter of stirrup) mm
Static loading	BP-1	1.4% (8 D12)	5.6‰ (D6 @100)
Impact loading	BP-2	1.4% (8 D12)	5.6‰ (D6 @100)
	BP-3	3.1% (8 D18)	5.6‰ (D6 @100)
	BP-4	4.7% (8 D22)	5.6‰ (D6 @100)
	BP-5	1.4% (8 D12)	5.6‰ (D6 @100)

Cube compressive strength of concrete was 42 MPa. Three reinforcement ratios were employed as 1.4% (8D12), 3.1% (8D18) and 4.7% (8D22). Stirrup ratio was 5.6‰ (D6@100). The yield strengths of the rebars, i.e. D12, D18 and D6 were 484 MPa, 495 MPa and 519 MPa, respectively. The detailed information of rebars arrangement were illustrated in Figure 1.

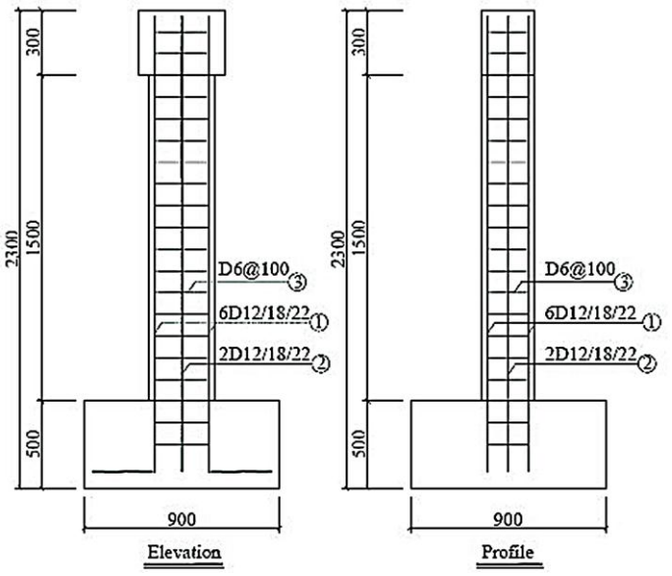

Figure 1. Schematic view of the tested specimens (unit: mm)

2.2 *Preparation of specimens*

For the static test, an MTS actuator was used to load specimen BP-1. Distance between the impact point and the bottom of specimen BP-1was set as 400 mm. The top of the specimen was designed to prevent the horizontal displacement and rotation, and the bottom was fixed on the floor. For the impact test, a simplified impact vehicle that was made of Chinese mild steel (Q235) with a mass of 1580 kg was used to load the specimens, which was shown in Figure 2. Velocity of the vehicle ranged from 0 m/s to 9 m/s. The impact point and boundary condition of each impacted specimen were the same as those of the static test.

Horizontal displacement at the impact point in the static test and the impact test were measured by displacement sensors. Contact force between the vehicle and the specimen in the impact test was measured by a dynamic load cell. The displacement at the impact point and impact force data were collected by a data acquisition system.

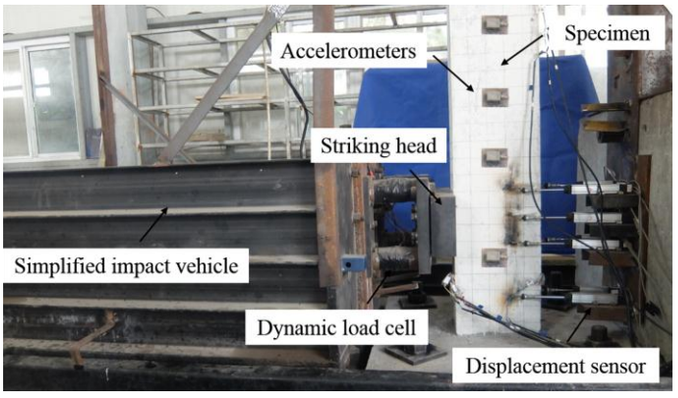

Figure 2. Schematic view of impact test

3 STATIC TEST RESULTS

3.1 *Failure mode*

Figure 3 showed that specimen BP-1 exhibited the shear failure with a principal diagonal shear crack. The principal diagonal shear crack initiated at the impact point and propagated downward with an angle of approximately 45 degrees. Moreover, it is found that several relative small diagonal cracks were respectively generated from the impact point downward and upward with angles ranging from 15 degrees and 45 degrees. Consequently, the final crack pattern of specimen BP-1 was ladder-shaped (see Figure 3).

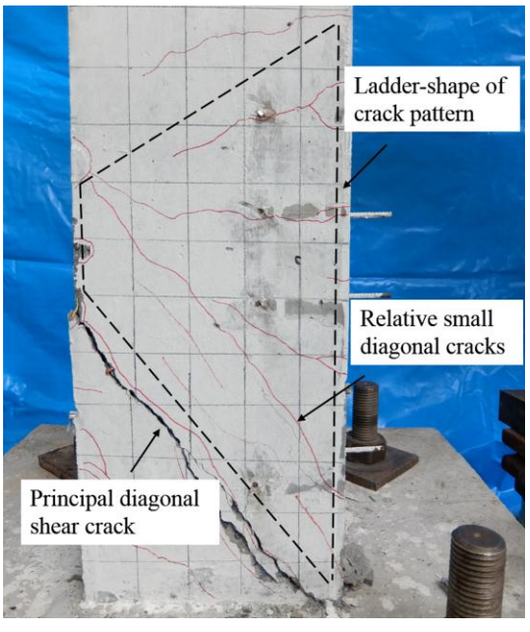

Figure 3. Failure mode of specimen BP-1

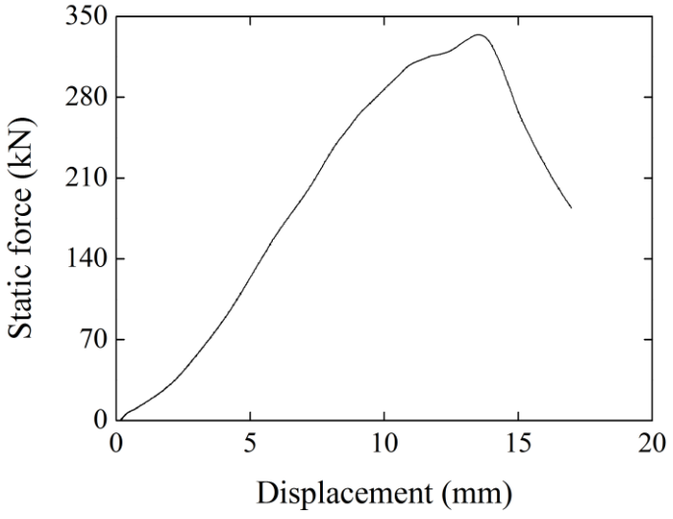
Table 2. Experimental results of the tested specimens

Test method	Specimen number	Impact velocity	Maximum force	Maximum displacement	Energy dissipation capacity	Failure mode
		m/s	kN	mm	kJ	
Static loading	BP-1	-	340	16.9	3.3	
Impact loading	BP-2	4.0	723	32.9	9.7	
	BP-3	4.0	703	25.9	8.9	Shear
	BP-4	4.0	705	21.3	7.8	
	BP-5	4.4	942	30.3	11.2	

3.2 *Load-displacement curve*

Figure 4 showed the load-displacement curve of the specimen BP-1 obtained from the static test. As illustrated in Figure 4, the maximum static force was 340 kN and the maximum horizontal static displacement at the impact point was 16.9 mm, and Both of which were listed in Table 2. Table 2 also presented the energy absorption capacity enveloped by the load-displacement curve of the static results, which was 3.3 kJ.



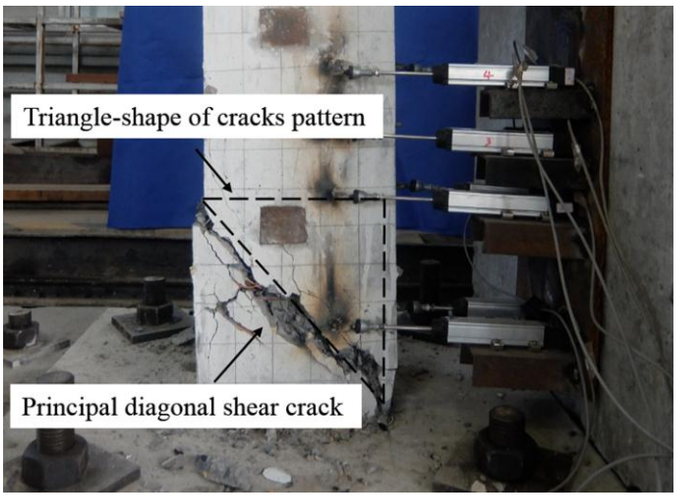


Figure 4. Load-displacement curve of specimen BP-1

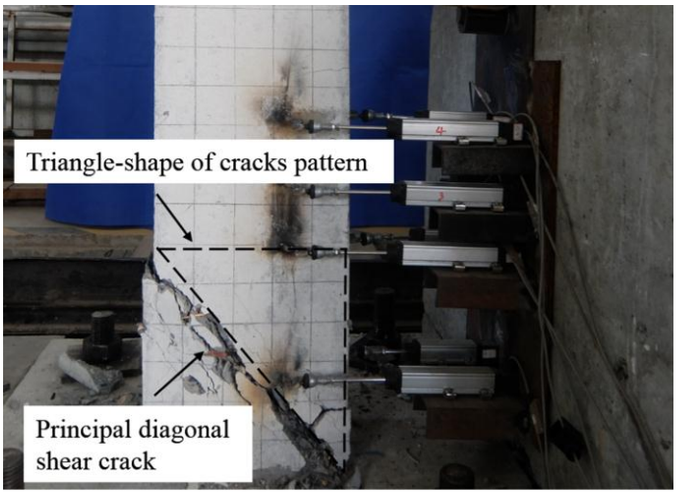

4 IMPACT TEST RESULTS

4.1 *Failure mode*

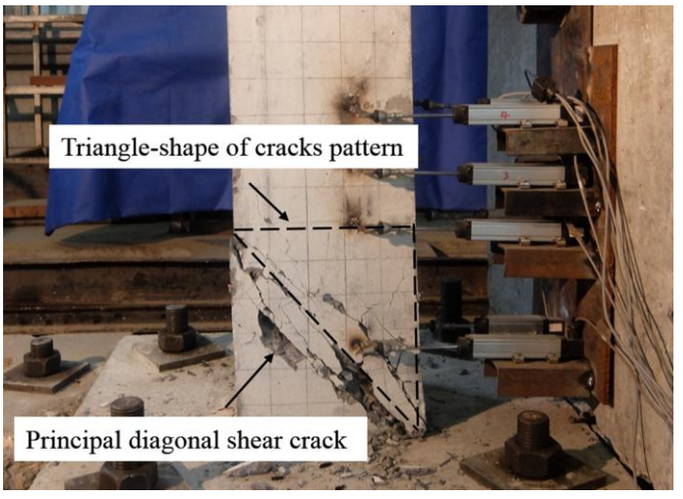

Figure 5 showed failure mode of each impacted specimen. As illustrated in Figure 5, all the impacted specimens failed in the shear pattern with a principal diagonal shear crack at the impact point. It is found that all the specimen sections were penetrated by the principal diagonal shear crack along an angle of approximately 45 degrees. Besides, there was no obvious diagonal cracks parallel to the principal diagonal shear crack appearing close to the impact point and the bottom of the specimen. Consequently, the final crack pattern of each impacted specimen was triangle-shaped (see Figure 5).

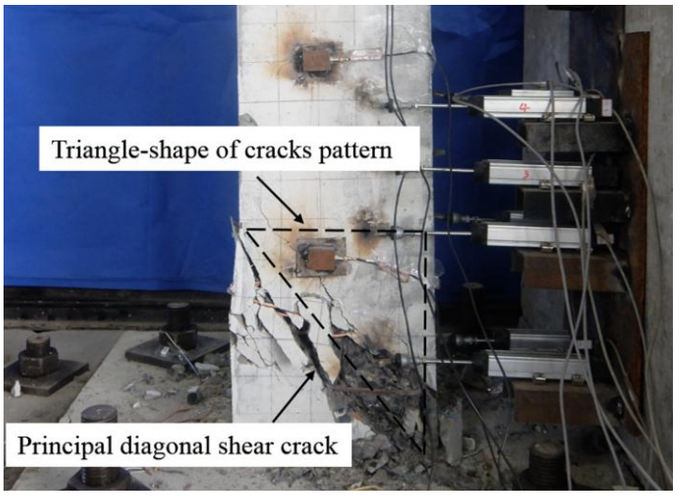

(a) Failure mode of specimen BP-2

(b) Failure mode of specimen BP-3

(c) Failure mode of specimen BP-4

(d) Failure mode of specimen BP-5

Figure 5. Failure mode of each impacted specimen

4.2 *Displacement time history*

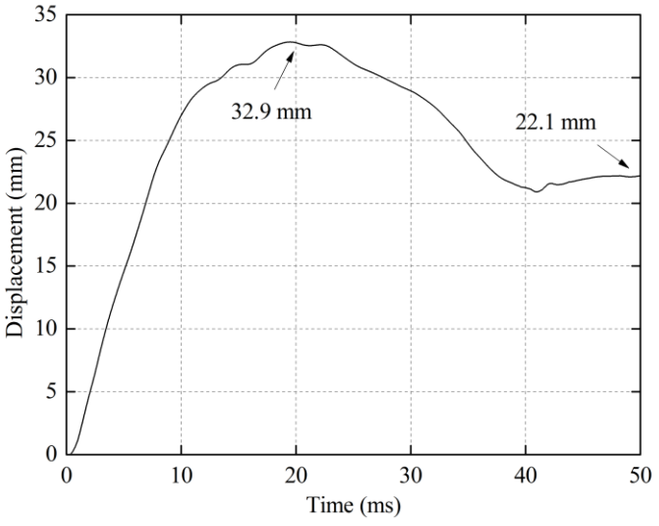

Figure 6 showed the displacement time history of each impacted specimen, and Table 2 presented the corresponding maximum values. As illustrated in Figure 6, it can be seen that a high reinforcement ratio improved impact resistance of the RC pier that reducing the total and residual displacement at the impact point. Comparing specimen BP-2 to BP-3 and BP-4, the maximum displacement was respectively reduced by 21% and 35%, and the residual displacement was respectively reduced by 32% and 52% as the reinforcement ratio increased from 1.4% to 3.1% and 4.7%. This is mainly owing to the improved RC pier stiffness with the high reinforcement ratio. Figure 6 also revealed that the total displacement increased with the increase of impact velocity. Comparing BP-3 to BP-5, the maximum displacement for an impact velocity of 4.0 m/s was 25.9 mm, and it increased by 17% (30.3 mm) for an impact velocity of 4.4 m/s. Additionally, it is found that ratio of the residual displacement to the total displacement increased from 50% to 65% as the impact velocity increased from 4.0 to 4.4 m/s. It can be explained that a higher impulse corresponding to a higher impact velocity can trigger more severe damage and plastic deformation of the RC pier and further result in a higher ratio of the residual displacement to the total displacement.

4.3 *Impact force time history*

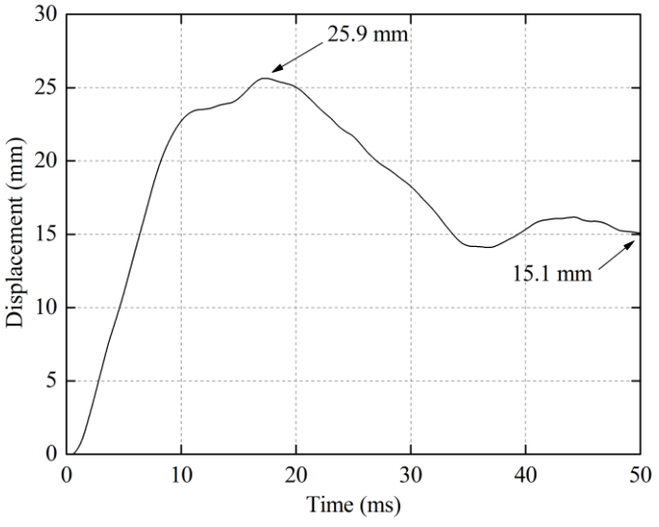

Figure 7 showed the impact force time history of each specimen, and Table 2 presented the corresponding peak values. It is found that the impact force time history can be divided into two phases. In the first phase, the impact force sharply increased to the peak value. This phase was defined from the zero of time to the end of the peak. This sudden increase occurred to obtain local acceleration of the impacted specimen, which was caused by vehicle collision. Duration of this phase was almost the same in all the impact tests, i.e. time ≤ 1.5 ms. In the second phase, the impact force gradually attenuated from the peak to zero. This phase finished with the complete failure of the impacted specimen. Duration of this phase was also almost the same in all the impact tests, i.e. time ≤ 28.5 ms.

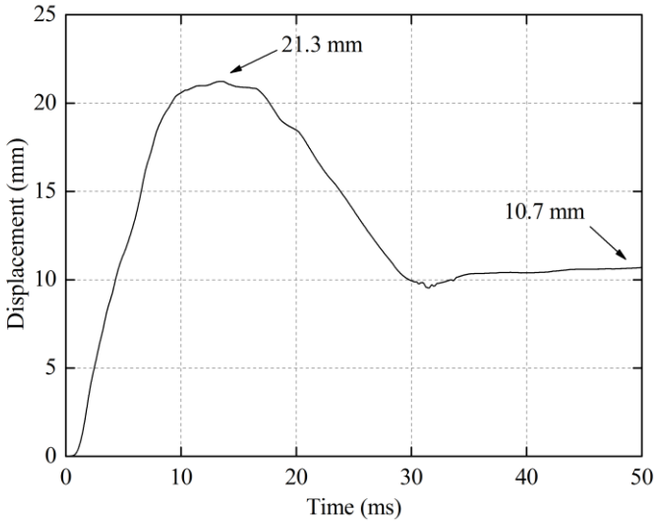
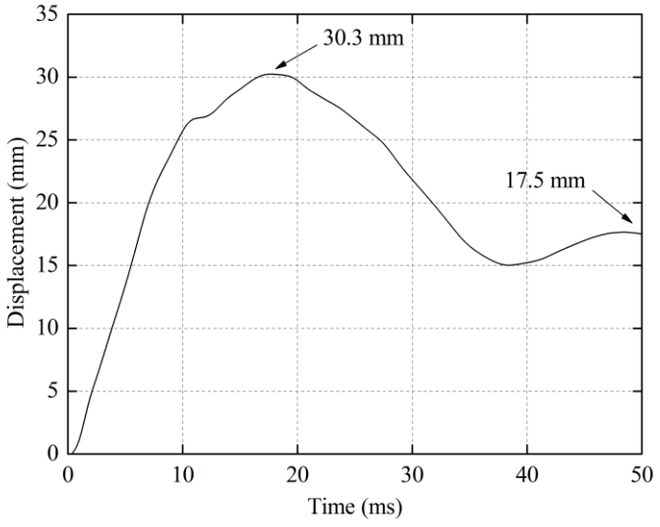
As illustrated in Figure 7, it can be seen that the peak impact force was independent of the reinforcement ratio. The peak impact force was almost 700 kN when the reinforcement ratio increased from 1.4% to 3.1% and 4.7%. This is because the contact stiffness between the impact vehicle and the RC pier was unchanged, as a result of the constant value.



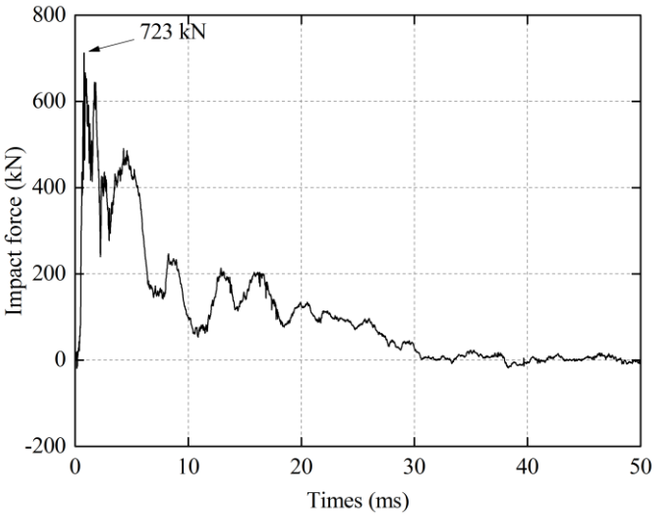
Compared BP-4 to BP-5, it is found that the peak impact force increased with the increase of the impact velocity. The peak impact force for an impact velocity of 4.0 m/s was 704 kN, and it was increased by 34% (942 kN) for an impact velocity of 4.4 m/s. This is because that a higher impulse induced by a greater impact velocity can lead to a larger peak impact force.



(a) Displacement time history of specimen BP-2

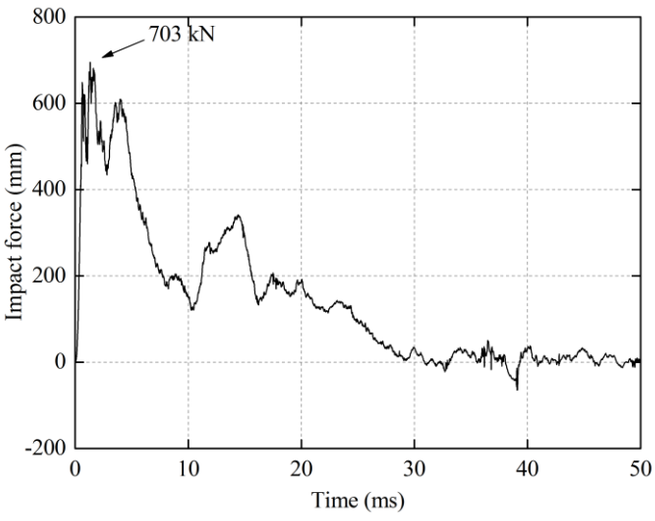
(b) Displacement time history of specimen BP-3

(c) Displacement time history of specimen BP-4



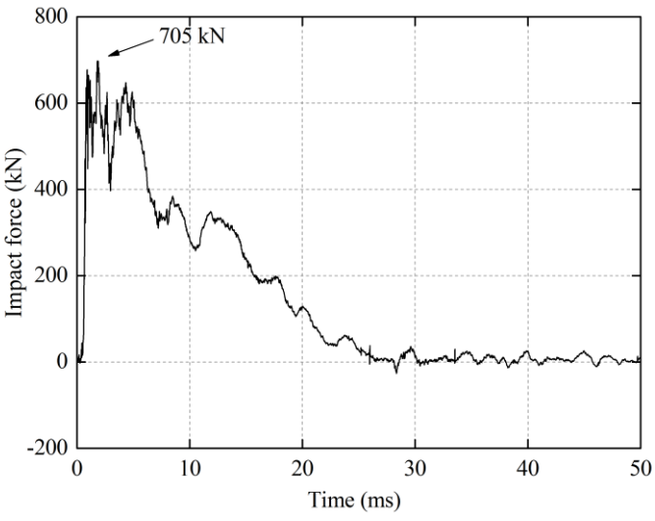
(d) Displacement time history of specimen BP-5

Figure 6. Displacement time history of each impacted specimen

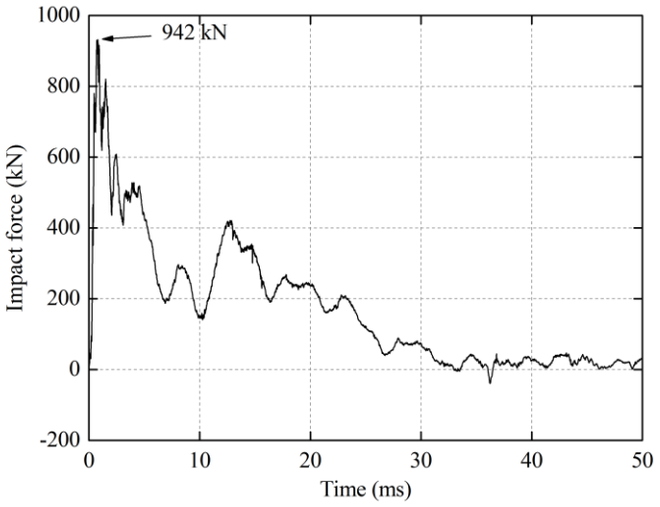


4.4 *Energy absorption capacity*

Figure 8 showed the load-displacement curve of each impacted specimen, and Table 2 listed the corresponding energy absorption capacities. Comparing BP-2 to BP-3 and BP-4, it can be seen that the energy absorption capacity was significantly affected by the reinforcement ratio. The energy absorption capacity was respectively reduced by 8 % and 12% as the reinforcement ratio respectively increased from 1.4% to 3.1% and 4.7%. It can be explained by the fact that the total displacement was reduced by the increased reinforcement ratio and the improved specimen stiffness that leading to a low energy absorption capacity.



As illustrated in Figure 8 (c) and (d), it is found that the energy absorption capacity increased with the increase of the impact velocity. The energy absorption capacity increased by 26% for the reinforcement ratio of 3.1% as the impact velocity increased from 4.0 to 4.4 m/s. This is because a greater total displacement and impact force were induced by a higher impact velocity, as a result of a greater energy absorption capacity.



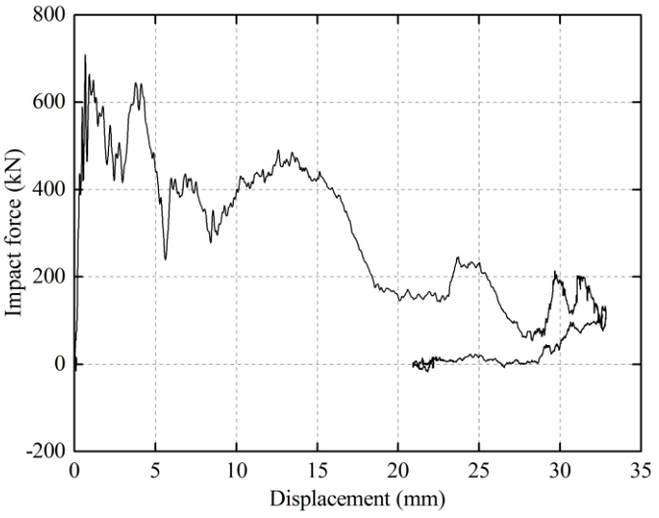
(a) Impact force time history of specimen BP-2

(b) Impact force time history of specimen BP-3

(c) Impact force time history of specimen BP-4

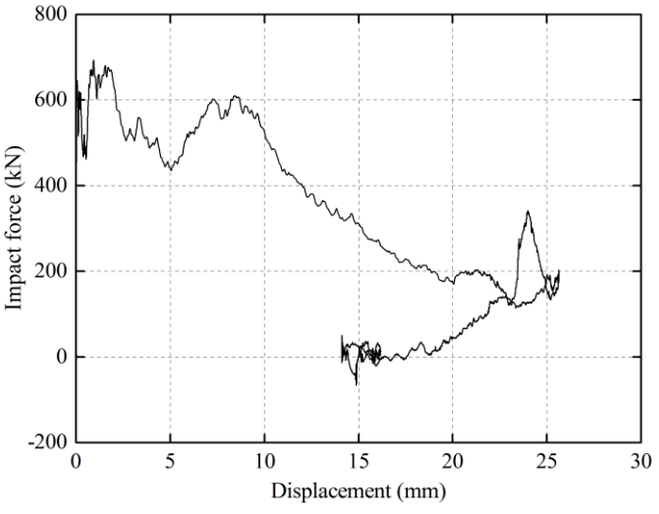
(d) Impact force time history of specimen BP-5

Figure 7. Impact force time history of each impacted specimen



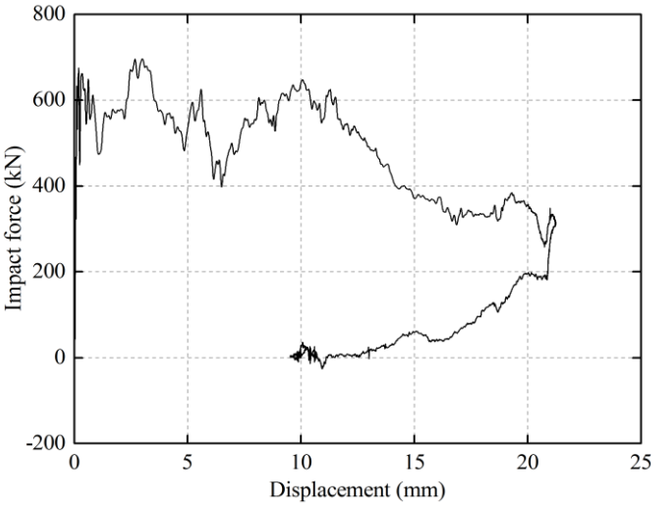
4.5 *Post-impact damage*

Figure 5 also showed the post-impact damage of each impacted specimen. In all the impact tests, the specimen reached the failure condition with the residual resistance provided by the reinforcements. As illustrated in Figure 5, it is found that the damage decreased with the increase of the reinforcement ratio. In BP-2 case, the principal diagonal crack was characterized with broken concrete, fractured stirrups and a large width at the impact point. In BP-3 and BP-4 cases, width of the principal diagonal crack was reduced. This is because that the residual resistance of the specimen was improved by a higher reinforcement ratio.



Compared to BP-3, it can be seen that the crack width of BP-5 became wider, more concrete spalled and stirrups were fractured. It can be explained by the fact that a greater amount of kinetic energy induced by a greater impact velocity of the vehicle was transferred into internal energy of the specimen, as a result of a more severe damage.

4.6 *Discussion*



According to the above analysis, crack patterns varied between the static test results and the impact ones, although all the specimens exhibited the typical shear failure mode. Crack pattern of the static results was ladder-shaped, while those of the impact results were triangle-shaped. Moreover, several small diagonal cracks were observed close to the loading point in the static results, while there is no similar diagonal cracks appearing in the impact results. This is because that there is enough time for the high stresses in the rebars to transfer into the neighboring concrete and rebars after the formation of the principal diagonal shear crack in the static test, resulting in several small diagonal cracks forming close to the loading point. However, the impacted specimens had no enough time to respond to the rapid change of the impact loading, so that the high stress was mainly concentrated at the impact point.

5 CONCLUSIONS

In this paper, four impact tests were conducted to study the reinforcement ratio and the impact velocity on effects the impact behavior of RC pier. A static test on the same RC pier was also conducted to compare with the corresponding impact test results. Main conclusions were summarized as follows:

(1) The impact test results showed that a high reinforcement ratio enhanced the impact resistance that reducing the total and residual displacements and energy absorption capacity. The maximum displacement was respectively reduced by 21% and 35%, and the residual displacement was respectively reduced by 32% and 52% as the reinforcement ratio increased from 1.4% to 3.1% and 4.7%. The energy absorption capacity was also respectively reduced by 8% and 12%.

(2) The impact test results showed that the impact force and the total displacement increased with the increase of the impact velocity. The peak impact force and the maximum displacement respectively increased by 34% and 17% as the impact velocity increased from 4.0 to 4.4 m/s, and meanwhile the ratio of residual displacement to total displacement increased from 50% to 65%. Besides, the energy absorption capacity increased by 26% for the reinforcement ratios of 3.1% when the impact velocity increased from 4.0 to 4.4 m/s.

(3) In all the impact tests, the post-impact condition revealed a shear-type damage characterized by the principle diagonal crack starting from the impact point to the bottom of the specimen. The damage was reduced by increasing the reinforcement ratio and increased by increasing the impact velocity.

(4) Comparison between the static test results and the corresponding impact test results showed that the failure modes of RC piers under both static loading and impact loading were shear failure, while the crack patterns were different. The crack pattern of the former was ladder-shaped, while the latter was triangle-shaped.

ABSTRACT: Existing reinforced concrete bridges are not typically designed to sustain the significant hydrodynamic forces resulting from river floods, tsunamis and hurricane waves. Particularly, there is an urgent need on vulnerability assessment and risk mitigation techniques for non-ductile bridges. For this purpose, a method for developing fragility functions is proposed in this research that relies on the nonlinear static analysis to estimate the global damage of bridge structures. The fragility functions consider the uncertainties both in the capacity in the form of material properties and the demand in the form of drag coefficient, and examine the ability of inundation depth, flow velocity and momentum flux to provide a reliable indication of the damage experienced by a non-ductile four-span bridge. The results showed that the velocity plays an important role as an intensity measure in the fragility analysis of non-ductile bridge structures.

1 INTRODUCTION

The damage of bridges during natural hazards leads to significant economic and social losses due to their vital role in emergency evacuation and post-disaster recovery (Mosqueda et al., 2007). Flood hazards such as tsunamis and wave surges have been reported among the major causes of bridge collapse in the United States (Wardhana and Hadipriono, 2003). In addition, the significant damage of bridges during hurricane Katrina in 2005 and Queensland floods in 2011 and 2012 has raised concerns on the resilience of existing bridges (Padgett et al., 2008, Pritchard, 2013). Current bridge design guidelines and retrofit strategies are not sufficient to withstand the extreme flood forces. In general, bridge response and failure mechanisms vary widely depending on the deck type, super- and sub-structure connectivity and applied forces. Ataei and Padgett (2012, 2015) and Ataei et al. (2010) investigated the unseating failure of simply supported decks under storm surges. The researchers reported that the bridge displacements and wave forces are among the most important parameters to be considered in vulnerability assessment. Salem et al. (2014) modelled the deck unseating failure of a bridge damaged by Tohoku tsunami in 2011 using applied element method. The researchers reported that the amount of trapped air plays significant role in the damage of bridge. Furthermore, Ataei and Padgett (2013) extended their investigation to include mapping the global response of bridge with the individual elements capacities in bridges with strong connection between deck and substructure.

Probabilistic modelling provides a practical tool to estimate the failure of bridges within an inventory given an intensity measure. The use of fragility functions for floods was first introduced by Koshimura et al. (2009a) using statistical models of field data. However, empirical fragilities have a number of drawbacks. The two main drawbacks are that they are specific to particular structures and/or area, and they suffer from lack of accuracy due to their dependency on visual observations (Koshimura et al., 2009b, Suppasri et al., 2011, Dias et al., 2009). Si-

hombing and Torbol (2015) estimated fragility curves by calculating the hydrodynamic forces through simulated tsunami waves. However, such method is computationally expensive considering the large number of models needed for fragility curve as well as it is limited to tsunami waves characteristics. This initiates the need for more practical schemes for fragility estimates that can capture the complete structural response of structures and do not require large computational cost.

Analytical models that adopt simplified patterns of flood load have recently been proposed (Attary et al., 2016, Petrone et al., 2017). The structure is usually subjected to incremental lateral static loads until failure in a process called "pushover", which is commonly used in earthquake engineering. It provides an indication of the capacity and demands of structures such as drifts, plastic deformations and element forces. Pushover analysis assumes that the structure undergoes the same mode shape throughout its dynamic time-history (Krawinkler, 1996). Several studies have been recently reported on the use of pushover analysis for generating fragility functions of building structures subjected to tsunami forces. The studies by Macabuag and Rossetto (2014) and Macabuag et al. (2014) showed that the load distribution has a significant effect on the pushover curve of the structure. The researchers also recommended further investigation of the application of tsunami in the post-peak stage and the use of a real-time history forces (Macabuag et al., 2014). This work was later extended by Petrone et al. (2017) to examine different discretization methods for tsunami applied loads. The study showed two main findings: first, tsunami loads should be discretized into constant number of point loads, and the variable height load-controlled pushover is more accurate in terms of the prediction of drift demands (Petrone et al., 2017).

Flow depth has been the most commonly adopted intensity measure in empirical fragility curves, as it is easy to measure in post-disaster field surveys. However, other parameters have also been reported to contribute to the magnitude of flood forces, such as flow velocity, momentum flux and acceleration (Nanayakkara and Dias, 2016, González et al., 2009, Løvholt et al., 2014). This implies that the use of flow depth as the only intensity measure can lead to a scatter in fragility data. In addition, most flood forces are directly related to the flow depth and velocity (ASCE, 2013, Attary et al., 2016). The use of momentum flux (hu^2) has recently been proposed as an intensity measure that combines both flow velocity and inundation depth (Park et al., 2014). In theory, the momentum flux has a linear relationship with the hydrodynamic forces, and hence, it can provide better correlation with the magnitude of force combining two intensity measures. However, the recent study by Attary et al. (2016) revealed that the accuracy of momentum flux can be affected by the magnitude and location of resultant force of the uniformly distributed tsunami load. Hence, an intensity measure called the kinematic moment of momentum flux was introduced to consider the effect of inundation depth on the force, which showed less scatter compared to other intensity measures (Attary et al., 2016). Moreover, Nanayakkara and Dias (2016) represented the tsunami force as a pressure distribution, in which the velocity was considered as a function of the flow depth.

However, limited research has been documented on the use of probabilistic risk assessment models for bridges subjected to significant hydrodynamic forces. Bridge structures have different topologies and modes of failure compared to other frame structures. Hence, the recently proposed fragility functions cannot be considered a reliable basis for assessing the vulnerability of bridges in flood-prone regions. The aim of this paper is to provide a preliminary study on the generation of fragility functions of reinforced concrete bridge subjected to flood hydrodynamic loads. The work presented in this paper examines the reliability of static nonlinear pushover analysis methods in risk assessment of non-ductile reinforced concrete bridges. In addition, the use of different intensity measures, i.e. flow velocity and momentum flux is studied. This research paves the way towards the implementation of practical analytical methods on the vulnerability assessment of bridges susceptible to collapse under extreme forces.

2 BRIDGE STRUCTURAL MODEL

A typical four-span reinforced concrete box-girder bridge is selected from the study by Li (2008). The bridge has an overall span length of 120 m and width of 8 m. Figure 1 shows the overall view of the bridge and the main details. As can be seen from the figure, the substructure consists of three main piers of equal height of 11 m, and two abutments of 1 m height. The box girder superstructure height is 1 m. The overall diameter of piers and concrete cover thickness are 1.2 and 0.08 m, respectively. The bridge three-dimensional (3D) model was developed using the Open System for Earthquake Engineering Simulation (OpenSees) (Mazzoni et al., 2006). The superstructure was represented by line elements located at its centroid. The elements had equal lengths of 7.5 m divided by nodes, while piers were modelled using twenty equal elements of 0.5 m length. The abutments and superstructure portion of piers height were modelled using a single element. Rigid elements were used for the superstructure centroid elements since the deck remains elastic throughout all loading phases of bridge.

The piers were modelled using displacement-based nonlinear beam column elements with four integration points to provide accurate distributed plasticity model. Single rigid elements were used for the abutments and superstructure portion of piers. The geometrical transformation was performed in the model using linear method for the superstructure elements. The P-Delta transformation was used for piers to capture the reduced capacity resulting from the additional bending moment induced on piers by the gravity loads at large displacements. The bridge was assumed to be fixed to the ground floor at all piers, while the abutments were allowed to move in the z-direction together with the elastic elements of piers.

The cross-section of elements of concrete was modeled using fiber approach, while layer approach was used for modelling the steel reinforcement. The concrete uniaxial stress-strain relationships were modelled using zero tensile strength Kent-Scott-Park and Karsan-Jirsa approaches (Karsan and Jirsa, 1969). The effect of confinement provided by the steel stirrups was considered in defining the materials properties of core concrete. The unconfined and confined concrete mean (μ) compressive strengths are 32 and 35 MPa, respectively. Both confined and unconfined concrete material models have an elastic modulus of 26 GPa. The steel spirals have a diameter of 0.02 m and were assumed to have a pitch of 0.5 m. The piers were reinforced with 20 longitudinal steel bars with a diameter of 0.03 m. The steel reinforcement was modelled using hysteretic model with mean elastic modulus of 208 GPa. The mean yield and ultimate strengths of steel were 500 and 530 MPa, respectively.

The torsional stiffness of piers was kept significantly large to prevent any premature torsional failure. The bridge masses are mainly contributed by the superstructure, whereas piers masses were found to be only 2.5% of the total bridge mass, and were, hence, neglected. The masses were distributed over the span nodes based on tributary elements. The fundamental period of vibration of the bridge was about 0.75 s. The gravity loads were calculated from the superstructure self-weight and other permanent objects on the bridge, and they were distributed along the bridge span nodes.

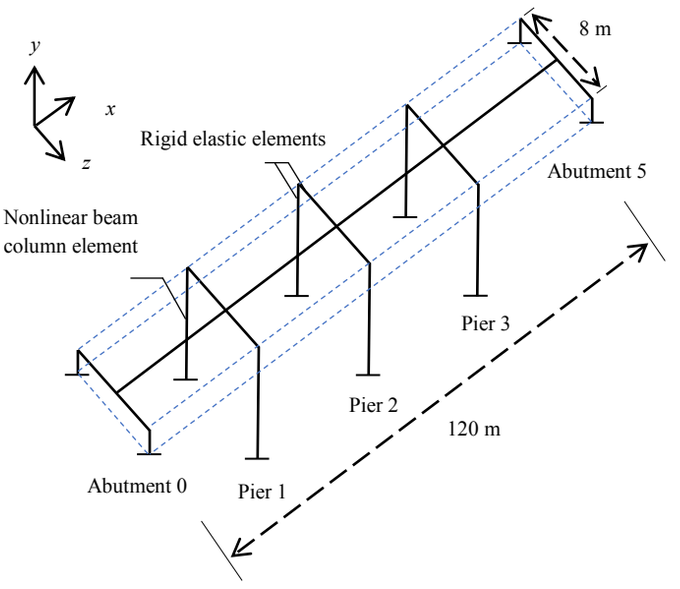

Figure 1. Bridge model main details.

3 FLOOD LOADING

River floods or tsunamis usually occur in the form of surging surface that does not have wave heights like the coastal hurricane storm surges. This eliminates any possible contribution from the wave height to the force. Thus, the forces that result from the flow are summarized as follows: hydrodynamic forces, hydrostatic forces, impulsive impact forces, buoyant forces and debris impact forces.

The hydrodynamic forces are the drag forces developed through the interaction between the structure and moving water. The hydrostatic forces generally occur due to the imbalance of hydrostatic pressure in both sides of bridge due to the accumulation of debris at one side, which results in different water depths (Zevenbergen et al., 2012). Impulsive impact force results from the air pockets that generate at the moment the water hits the structure (Douglass et al., 2006), and it is often expressed as 1.5 times the magnitude of hydrodynamic force (Ramsden, 1996). Buoyant forces form due to the displaced water by the bridge deck, and it can be significant if the air is entrapped between girders (Robertson et al., 2007). Debris impact forces usually depend on the moving objects that hit the structure, and vary widely depending on the type and amount of debris in the flood.

In this research, only the hydrodynamic forces are considered, as they dominate the tsunami and flood forces, and they can be estimated using the following equation:

$$F = 0.5 C_d \rho u^2 h b \quad (1)$$

where, C_d is the drag coefficient, ρ is the flood water density (1200 kg/m^3), u is the flow velocity, h is the

flow depth and b is the width or diameter of pier. Several patterns have been proposed for the distribution of flood forces on vertical objects. This ranges between triangular, trapezoidal and uniform patterns (Macabuag and Rossetto, 2014, Macabuag et al., 2014, Petrone et al., 2017). For simplicity, uniform pattern is used in this research as shown in Figure 2. The other distribution patterns will be investigated in future research.

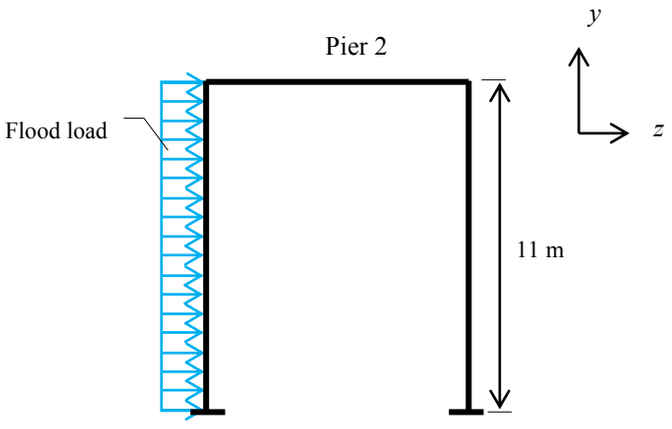

Figure 2. Distribution of flood load on bridge piers at full inundation.

4 FRAGILITY ANALYSIS

4.1 *Uncertainty of capacity and demand parameters*

The response of bridge subjected to flood load is sensitive to several parameters, either in flood forces or structural model. In this research, the concrete compressive and steel yield strengths follow a lognormal distribution with a standard deviation (v) of 0.4 and 0.3, respectively. The higher standard deviation of concrete is attributed to the large variability of its constituent materials properties. The flood density and steel and concrete elastic moduli were assumed to be deterministic. Table 1 summarizes all demand and capacity parameters used in the analysis. Uniform distribution was adopted for the drag coefficients with a range of values between 1.25 and 1.75 for circular columns or piers (ASCE, 2013).

Table 1. Capacity and demand parameters

Variable	**Type of distribution**	**Parameter used in distribution**
Concrete compressive strength, f_c'	Lognormal	v = 0.4, μ = 32 MPa
Concrete elastic modulus, E_c	Deterministic	-
Steel yield strength, f_y	Lognormal	v = 0.3, μ = 500 MPa
Steel elastic modulus, E_s	Deterministic	-
Drag coefficient, C_d	Uniform	Range = 1.25 to 1.75
Flood water density, ρ	Deterministic	-

4.2 *Methodology for development of fragility curves*

The adopted method for developing preliminary fragility functions for bridge is shown in Figure 3. The uncertainty in the structure parameters is first considered by generating random variables of f_c' and f_y. Ten random variables were generated using Latin Hypercube Sampling (LHS), giving a total of 100 structural models. The capacity curves from the model with mean values of f_c' and f_y is then obtained. Figure 4 shows the capacity curve obtained from the mean f_c' and f_y. The drift ratios are used as the engineering demand parameters (EDPs) for damage assessment, since the structure is subjected to lateral loads. In addition, it is assumed that the structure undergoes severe damage after exceeding the ultimate strength. As can be seen in Figure 4, the drift ratio corresponding to the peak strength of the mean capacity curve was found to be 0.0057 (at 10731 kN), and it is taken as the limit state of the fragility function. Although in reinforced concrete design the member is assumed to have structurally failed when it exceeds its ultimate strength (Nawy, 2000), such assumption does not give a clear indication on the amount of damage that the bridge experiences in the post-yield stage. However, for the sake of illustration of the methodology of fragility functions, this assumption is adopted in this research. Future research will address the use of different damage states of the structure, where more realistic time-history loads are applied in the inelastic deformation phase. The velocity was selected to have a maximum value of 10 m/s, and it was incremented by 0.5 m/s. The flood forces at the full inundation depth and 20 ranges of velocities are then computed with the ten random variables of C_d, which gives a total of 200 forces. A Froude number (Fr) limit is set to 2.0 in order to remove the unrealistic combinations of inundation depth and velocity (Foytong et al., 2013, Foytong et al., 2015). The drift ratios corresponding to the calculated flood forces are obtained and compared against the limit state. The cumulative probability of the drift ratios that exceed the limit state is finally obtained at each intensity measure.

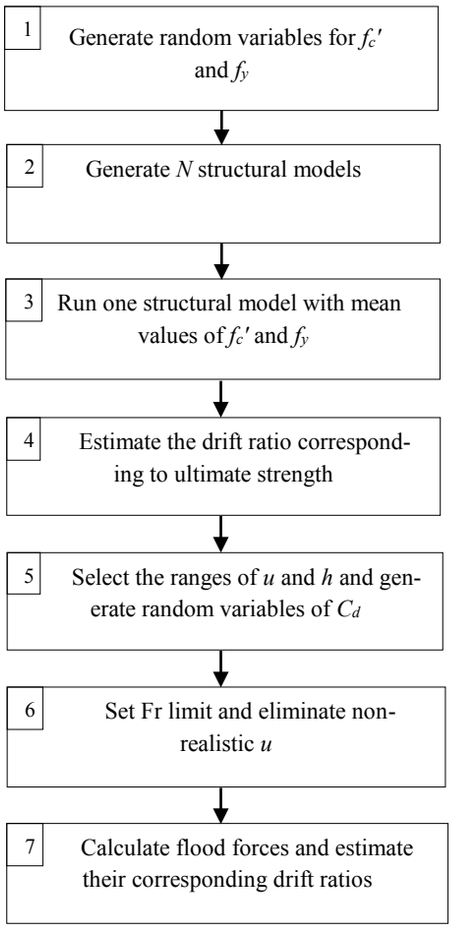

Figure 3. Methodology adopted for developing fragility functions for bridges under flood forces.

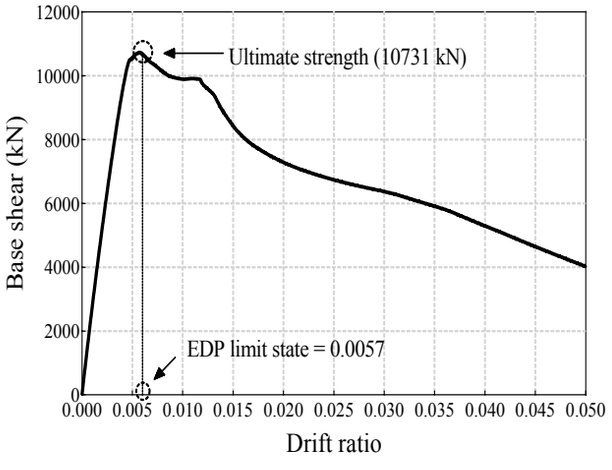

Figure 4. Capacity curve of the structural model from mean f_c' and f_y.

5 RESULTS AND DISCUSSIONS

The fragility curves were developed by adopting the method discussed in the previous section. Figure 5 shows the fragility of the reinforced concrete bridge at all velocity levels and full inundation. The figure shows that the transition zone representing the damage in bridge starts at velocity value of 4 m/s. The bridge had a high probability of collapse (up to 0.9) at velocity of 10 m/s, which corresponds to Fr value of 0.96. This shows that reinforced concrete bridges can be susceptible to collapse at relatively low Froude numbers compared to the threshold value of 2.0 given from past tsunami and flood events. In addition, Figure 5 indicates that velocity, as an intensity measure, has significant effect on the scatter of the fragility results. Such effect is ignored in most of the currently published fragility curves that adopt the inundation depth as the only intensity measure. For example, with the increase in inundation depth during tsunami or flood, at every single inundation and with the current range of velocities, the bridge exhibits different probabilities of failure.

As discussed earlier in this paper, the scatter of cumulative probability resulting from different intensity measures can be reduced by introducing intensity measures that combine both the velocity and inundation depth. As an example, Figure 6 presents the fragility curve using momentum flux (hu^2). In this method, one intensity measure is usually incremented while the other is implicitly increased through incrementing the momentum flux. As can be seen in Figure 6, the transition zone starts earlier compared to Figure 5, which highlights the significance of incorporating the inundation depth for providing better prediction of the bridge damage. However, the data provided in Figure 6 cannot be used to draw clear conclusions as they are extracted from only one depth. Hence, future research will provide further investigation of the effect of using methods that combine both intensity measures on the accuracy of fragility functions.

6 CONCLUSIONS

This research proposes the first methodology to develop analytical fragility curves for bridges subjected to tsunamis and floods. To illustrate this method, a reinforced concrete box-girder bridge, which suffers from lack of ductility, was modelled and subjected to hydrodynamic load. The method addresses the global lateral deformation of bridge through nonlinear static pushover analysis. The piers drift ratios were taken as the engineering demand parameters for assessing the damage of bridge. The probability of exceeding the limit, taken as the drift corresponding to the ultimate mean strength, was estimated for all flood scenarios. The two commonly used intensity measures, i.e. inundation depth and velocity were also addressed. The fragility functions of bridge at different velocities were developed at the full inundation depth. In addition, the use of momentum flux as a combination between the two common intensity measures was discussed. The method presented in this research enables fast scanning of the vulnerability of bridges in flood-prone areas. Future research will focus on integrating this method with complex failure modes that involve the superstructure, which was simplified as a rigid elastic element in this study. Further investigations are also needed on the different methods for application of loads as well as more realistic time-history flood loads.

7 ACKNOWLEDGEMENTS

The significant help from Ali Y. Al-Attraqchi (Department of Civil and Construction Engineering, Swinburne University of Technology) with OpenSees simulations is gratefully acknowledged. Also, specials thanks to Professor Riadh Al-Mahaidi (Department of Civil and Construction Engineering, Swinburne University of Technology) for his support towards this research. The financial support towards this research provided to the first author for his doctoral study by RMIT University, Australia in the form of RMIT PhD International Scholarship is gratefully acknowledged.

Dynamic response of an isolated bridge under basic pulse-type ground motions

M.H. Tsai & Z.Y. Jiang
Department of Civil Engineering, National University of Science and Technology, Pingtung County, Taiwan

ABSTRACT: Parametric studies on the dynamic response of a typical isolated bridge under three pulse-type ground motions were carried out in this study. The analysis results indicated that similar peak structural responses were induced under the three pulse motions. The peak isolator displacement could be effectively reduced as the stiffness ratio lied between 0.2 and 0.3. Seismic response of the isolated bridge under twenty pulse-like near-field and ten far-field earthquake records were compared with the pulse response. The analysis results indicated that for the considered range of the post-yield stiffness ratio, the mean-plus-one standard deviation response under the near-field seismic motions with scaled pulse period varied from 70% to 82% of that under the one-cycle Type-A pulse motions. Hence, the one-cycle Type-A pulse can be used as a pseudo-near field ground motion for the extreme seismic demand under pulse-like near-field earthquakes.

1 INTRODUCTION

From several major seismic events in the past decades, it is known that near-field (NF) earthquakes usually contain long-period pulses in the ground motions. The 1999 Taiwan Chi-Chi earthquake revealed that a major characteristic of the NF ground motions is the pulse-like velocity waves, which may be more destructive than their peak ground accelerations (PGA) for some structures (Makris & Chang 1998, Loh 1999). Chopra & Chintanapakdee (2001) compared the spectral characteristics of single degree-of-freedom (SDOF) systems under NF and far-field (FF) ground motions and indicated that the former may induce a larger strength demand with the same ductility factor. Since seismically isolated structures usually feature the lengthened structural period, they may be more vulnerable than non-isolated structures under the NF ground motions. Shen *et al*. (2004) combined a recorded seismic ground motion with different pulse functions to evaluate the effect of NF earthquakes on a seismically isolated bridge. Dicleli (2006) conducted a comprehensive numerical study to investigate the influence of characteristic strength and post-yield stiffness ratio of lead-rubber bearings (LRBs), PGA, pulse period, and cycle number of pulse motions on the NF seismic responses of an isolated bridge model. They indicated that the isolated bridge had larger dynamic response as the pulse period was approximate to the isolation period. Larger post-yield stiffness and characteristic strength of LRBs were suggested to reduce the displacement demand under NF ground motions. Jangid (2007) proposed a force function to find the optimum yield strength for LRBs of seismically isolated buildings under NF earthquakes. A yield strength ratio of 0.10~0.15 was suggested in the study. NF and FF seismic story drifts of two building models isolated with LRBs of varied post-yield stiffness ratio, isolation period, and characteristic strength were compared by Providakis (2008). Karalar *et al*. (2012) conducted sensitivity analysis and nonlinear time-history analysis to develop parametric equations for obtaining the optimum characteristic strength and post-yield stiffness of LRBs for isolated bridges located in NF regions.

The unique characteristic of the pulse-like NF ground motions implies that they may be represented with simplified or equivalent pulse functions. Several equivalent pulse functions were proposed to produce the approximate structural response under the pulse-like NF ground motions. Makris & Chang (2000) investigated the consistency between some recorded NF ground motions and three proposed pulse-type functions featuring different ground movement mechanisms. Eight simple pulse functions characterizing the effects of either the fling step or forward directivity were proposed by Xu & Xie (2006) to evaluate the relationships between pulse amplitudes and period for different pulses. He & Agrawal (2008) proposed an analytical velocity pulse model observed from NF ground motions for systematic design and assessment of seismic protective systems. Amiri *et al* (2008) used three pulse-type models to simulate the NF earthquake records

and the structural responses of three multi-story steel buildings under the pulse-type motions and the actual NF ones were compared. Sehhati *et al*. (2011) investigated the effects of NF ground motions on three different multi-story shear buildings and evaluated whether the simplified pulses are capable of representing the NF effects. Their analysis results revealed that the pulse-like ground motions may induce larger ductility demand and dispersion in structural response. Meanwhile, the proposed equivalent pulse model could capture the NF seismic response as the ratio of the pulse period to the fundamental structural period was in the range between 0.5 and 2.5.

From the literature review, it can be assured that the post-yield stiffness of the isolators is a key parameter in the NF seismic response because it is directly related to the extent of resonance between the isolated bridges and the pulse-like ground motions. Due to the uncertainties in the fault-rupture mechanism, the seismic demands of the pulse-like NF ground motions can vary significantly with earthquake events and are not easy to precisely predict. It could be more efficient in practical design of the isolated bridges against the NF seismic excitations if the maximum seismic demands can be roughly estimated by using some simple or equivalent pulse functions. Therefore, the peak dynamic responses of a typical isolated bridge subjected to pulse-type ground motions and twenty pulse-like NF seismic excitations were compared in this study. A bridge model was constructed to simulate the seismic response of the isolated bridge located in southern Taiwan and then used to carry out a parametric study for the peak dynamic response of the isolated bridge under three basic pulse motions proposed by Makris & Chang (1998). They may be regarded as the simplest pulses among those proposed simplified or equivalent pulse functions and thus easier for engineering applications. Moreover, the seismic responses of the bridge model with isolators of different post-yield stiffness ratios under twenty pulse-like NF and ten FF earthquake records were obtained. They were used to verify the effect of the post-yield stiffness ratio on the structural response and evaluate the validity of the pulse motions for the probable peak dynamic demand on the isolated bridge under pulse-like NF seismic motions.

2 BRIEF REVIEW OF THE ISOLATED BRIDGE

The isolated bridge is located at the Formosa Freeway in the Gia-Yi area of southern Taiwan. It is a three-span continuous bridge, as shown in Figure 1. Two LRBs were installed on each column bent and PTFE coated RBs were used at the abutments. The LRBs on the column bents can move in both the longitudinal and transverse direction, while the transverse movement of the RBs is restricted by shear keys at the abutments. This bridge was designed in 1990s. At that time, the design PGA was 0.33g and an important factor of 1.35 was used. This means that the designed PGA is approximate to 0.45g. The design displacement of the LRBs is 12.5 cm and the resulting equivalent damping is 18%. Also, it has an effective period of 2.04 sec in the longitudinal direction and 0.85 sec in the transverse direction due to the end restraints. The design dead load and live load for each LRB is 9006 kN (918 tf) and 1608 kN (164 tf), respectively. The design seismic force is 1348 kN (137 tf). Hence, the LRBs have effective stiffness equal to 10791 kN/m (1100 tf/m) and an energy dissipation capacity of 175.6 kN-m (18 tf-m).

Figure 1 The typical isolated bridge

3 NUMERICAL MODELING OF THE ISOLATED BRIDGE

After the construction of the bridge, the Central Weather Bureau (CWB) of Taiwan installed twenty-four accelerometers on the bridge to monitor the seismic response. In 1999, around one month after the Chi-Chi earthquake, an earthquake with a magnitude of 6.4 hit the Gia-Yi area. A finite element model for the bridge was constructed by using the SAP2000 program to simulate the bi-directional seismic response of the isolated bridge under the Gia-Yi earthquake. The superstructure, which is composed of continuously varied-depth box girders, and the bridge piers were modeled as beam-column elements. Total weight of the superstructure is about 42438 kN, including the live load. The LRBs on the pier tops were simulated by isolator elements, which exhibit bilinear hysteretic behavior in the horizontal directions and linear elastic behavior in the vertical direction. The RBs at the abutment were modeled by the frictional sliding type isolators with an initial lateral stiffness equal to that of the rubber layers and zero after slippage occurs. The coefficient of friction was assumed as 0.06 for the PTFE sliding surface.

In order to determine the bilinear parameters for the isolator elements, the elastic stiffness, yield strength, and post-yield stiffness were determined from the cyclic loading test results of the LRBs, as shown in Figure 2. With the characteristic strength, cyclic energy dissipation, and maximum displacement directly obtained from the test results, the associated yield displacement, elastic and post-yield stiffness, and yield strength were calculated. Since

the bearing displacement under the Gia-Yi earthquake was small, the parameters of the smallest test displacement were used in the simulation. However, very poor simulation results were obtained. Because the LRB was tested at a very low frequency, it was believed that the rate effect could play a role in the bearing parameters.

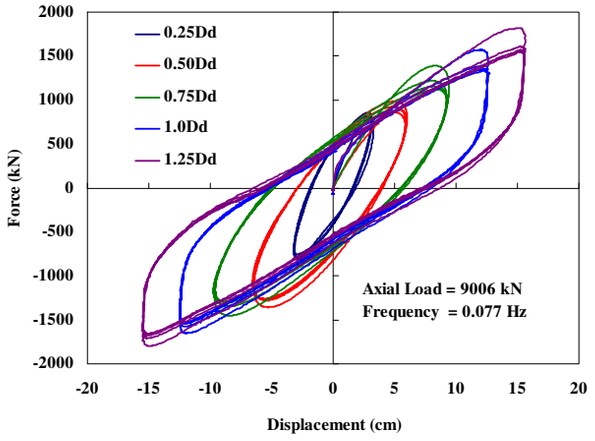

Figure 2. Cyclic loading tests of the LRBs

After several trial-and-error tuning, a better simulation result was obtained as shown in Figures 3a and b. Under the bi-directional excitation, longitudinal response had a better simulation result. The final determined parameters revealed that a high post-yield stiffness ratio was necessary for the simulation. The root-mean-square error of the acceleration time histories is 11.8% and 15.8% for the longitudinal and transverse response simulation, respectively. Since the isolated bridge was partially restrained in the transverse direction, this study was focused on its longitudinal dynamic response under pulse-type ground motions.

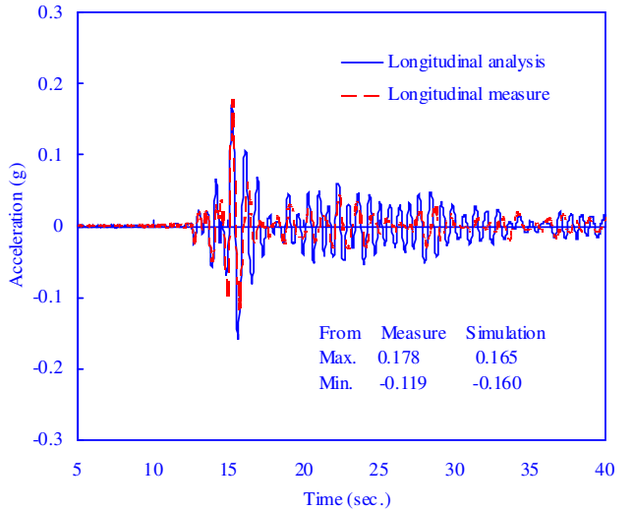

Figure 3a. The longitudinal simulation result

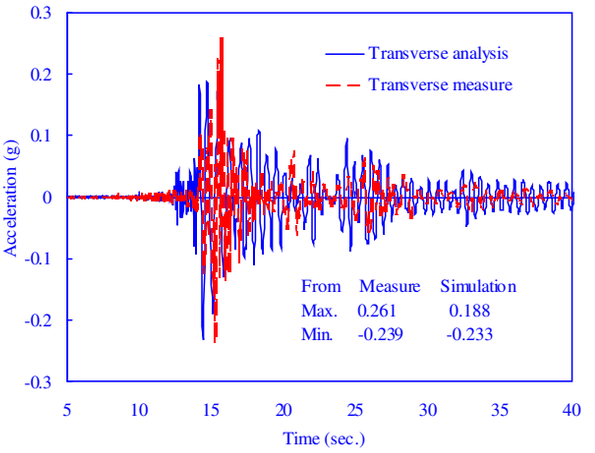

Figure 3b. The transverse simulation result

4 PEAK RESPONSE UNDER PULSE GROUND MOTIONS

The three basic types of pulse ground motions used in this study are the Type-A, Type-B, and Type-Cn functions proposed by Makris & Chang (1998). Their pulse ground accelerations are respectively expressed as

$$\ddot{u}_A(t) = \frac{\pi V_p}{T_p}\sin(\frac{2\pi t}{T_p}) = A_p \sin(\omega_p t), \quad 0 \le t \le T_p \qquad (1)$$

$$\ddot{u}_B(t) = \frac{2\pi V_p}{T_p}\cos(\frac{2\pi t}{T_p}) = B_p \cos(\omega_p t), \quad 0 \le t \le T_p \qquad (2)$$

$$\ddot{u}_C(t) = \frac{2\pi V_p}{T_p}\cos(\frac{2\pi t}{T_p} + \varphi) = C_p \cos(\omega_p t + \varphi), 0 \le t \le cT_p \qquad (3)$$

In the above expressions, A_p, B_p, and C_p are the corresponding PGA and T_p is the pulse period. Also, V_p is approximated to the peak ground velocity (PGV) and $\omega_p = 2\pi / T_p$. $c = (n + 1/2 - \varphi/\pi)$, is the multiplier of pulse duration for Type-Cn and n represents the cycle number. The Type-A, Type-B, and Type-Cn pulses represent fling-step ground motions, ground motions with forward directivity, and cyclic pulse ground motions, respectively.

Nonlinear time-history analyses of the isolated bridge model under the three pulse motions with a PGA of 0.5g were carried out. The pulse period T_p was varied from 0.5 to 14 seconds and three different numbers of cycles, namely one, two, and four, were considered. Different stiffness ratios, α, ranging from 0.05 to 0.5 were used in the parametric study to evaluate its influence on the pulse response. A period ratio defined as T_p / T_d, where T_d is the isolation period calculated with the post-yield stiffness of the LRBs, is introduced for the following discussion of analysis results. The peak acceleration and displacement at the deck center were collected to evaluate the effects of the period ratio, pulse type, cycle number, and post-yield stiffness ratio on the

dynamic response of the isolated bridge. Figures 4a-d show the peak structural acceleration and displacement responses with stiffness ratios of 0.05 and 0.45 under the 1-cycle pulse motions. The corresponding response under the scaled 0.5g Gia-Yi earthquake is also included in the figures for comparison. It is seen that the structural response was significantly enlarged under the pulse motions. Although the three types of pulse were proposed for different mechanisms of ground movement, they appear to have similar peak responses, especially near the resonant region of $T_p/T_d = 1.0$. As the stiffness ratio decreased from 0.45 to 0.05, it is observed that the acceleration response was moderately reduced, while the displacement response was significantly increased.

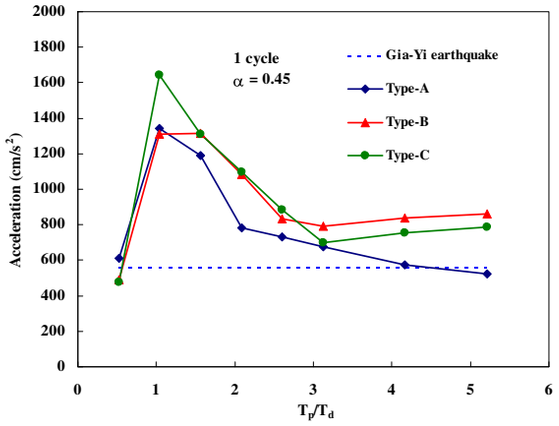

Figure 4a. Comparison of peak accelerations (α=0.45)

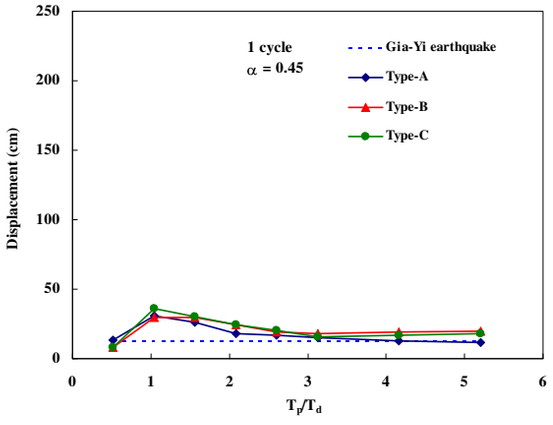

Figure 4b. Comparison of peak displacements (α=0.45)

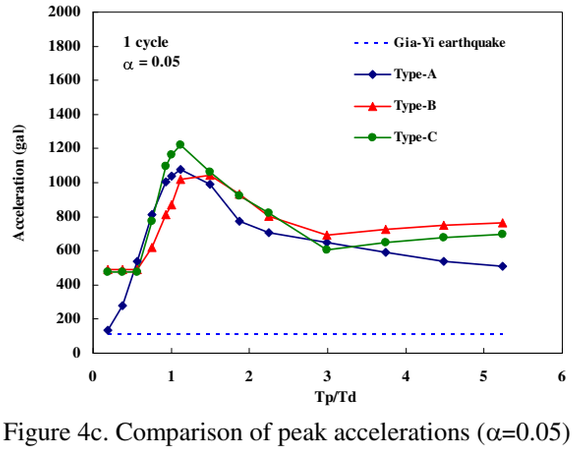

Figure 4c. Comparison of peak accelerations (α=0.05)

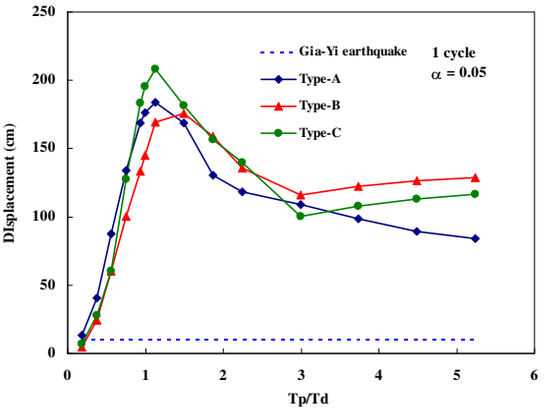

Figure 4d. Comparison of peak displacements (α=0.05)

In fact, irrespective of the stiffness ratio, the consistency of the peak structural response under the three pulse motions increases with the cycle number. Since the Type-Cn pulse is the one inducing the largest demand, it is used for the remaining discussion in this section. Figures 5a and b present the effect of period ratio and cycle number on the structural response. It is seen that the maximum response occurs in the resonant region where the period ratio is approximate to 1.0. The cycle number only takes effect at the resonant region. The resonant region approximately ranges from $T_p/T_d = 0.75$ to $T_p/T_d = 1.5$.

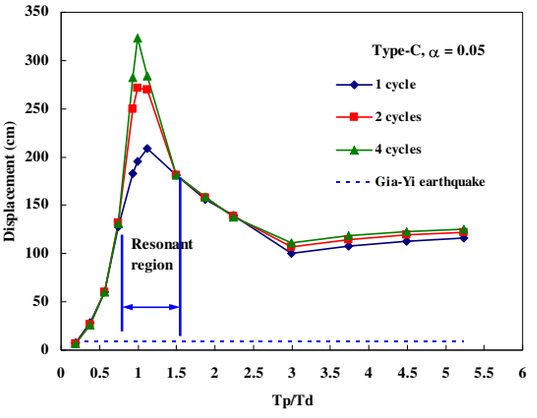

Figure 5a. Effect of period ratio and cycle number on peak displacements (α=0.05)

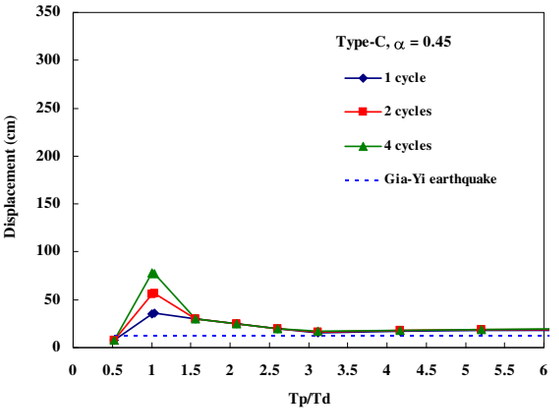

Figure 5b. Effect of period ratio and cycle number on peak accelerations (α=0.45)

The benefit of increasing post-yield stiffness ratio of the LRBs can be more pronounced as shown in Figures 6a and b. The figures show the variation of the peak deck acceleration and displacement with the post-yield stiffness ratio for the Type-Cn pulse motions. It can be seen that the displacement was effectively reduced as the stiffness ratio increased from 5% to 25%. When the stiffness ratio increases even further, the benefit to the displacement reduction becomes marginal. However, the acceleration response may generally increase with the stiffness ratio as expected. Even though, it is interesting to note that the increase in peak acceleration is less significant under the one-cycle pulse motions than under the multi-cycle pulse motions. Similar results were obtained for the Type-A and Type-B pulse motions, which are not shown herein.

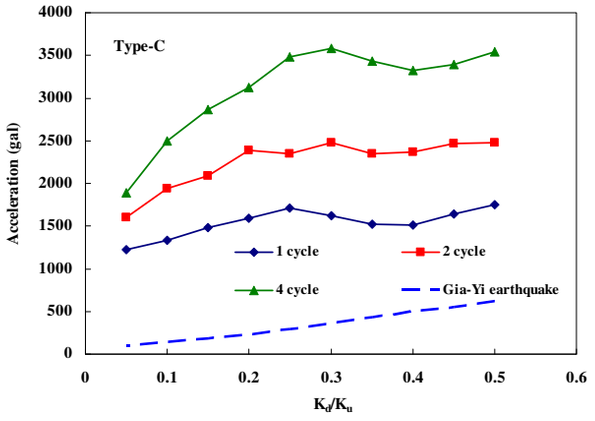

Figure 6a. Variation of the peak deck acceleration with the post-yield stiffness ratio

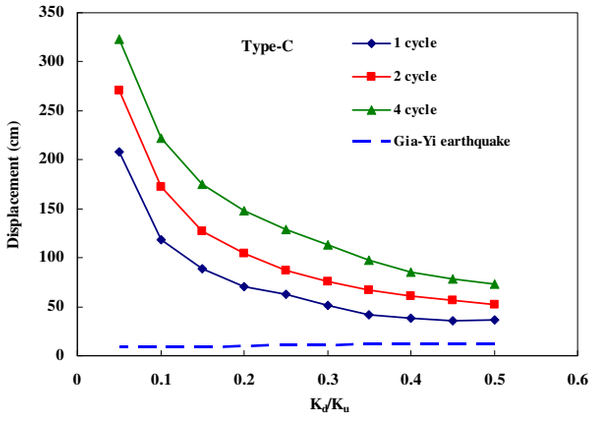

Figure 6b. Variation of the peak deck displacement with the post-yield stiffness ratio

5 PEAK RESPONSE UNDER NEAR-FIELD AND FAR-FIELD SEISMIC GROUND MOTIONS

From the analysis results of the isolated bridge under the pulse ground motions, it is known that the peak displacement could be significantly reduced and the peak acceleration moderately increased as the stiffness ratio of the LRBs was increased from low to medium values. The peak response occurs at a period ratio in the vicinity of 1.0. Also, they may increase moderately with the cycle number of the pulse ground motions. In order to understand the consistency between the pulse and seismic response of the isolated bridge, twenty pulse-like NF earthquake records were selected from the studies of Avsar & Özdemir (2013) and Baker (2007) for the seismic response analysis of the isolated bridge. Ten FF seismic ground motions were also selected from Avsar & Özdemir (2013) for comparison. All the seismic records were scaled to have a constant PGA of 0.5 g. Figures 7a and b show the 5%-damped individual and average response spectra of the NF and FF seismic records, respectively. It is observed from the figures that the NF ground motions have larger spectrum values than the FF ones in the medium-to-long period range. Hence, larger seismic response under the NF ground motions can be expected for the isolated bridge.

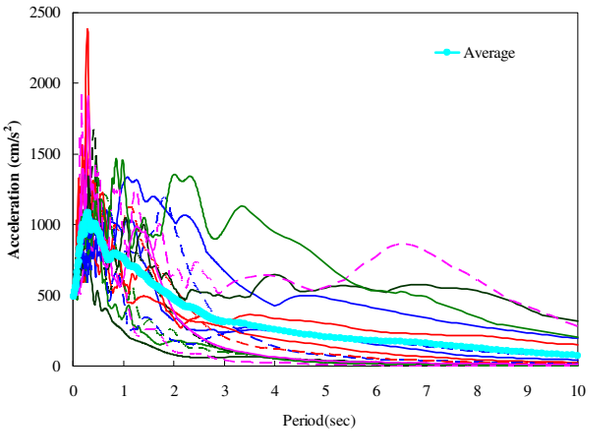

Figure 7a. The 5%-damped individual and average response spectra of the NF seismic records

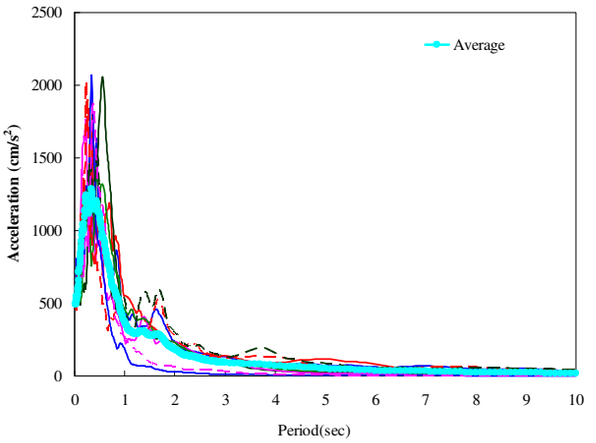

Figure 7b. The 5%-damped individual and average response spectra of the FF seismic records

Figures 8 and 9 present the peak structural response of the isolated bridge model with varied post-yield stiffness ratio under the pulse-like NF and FF seismic records, respectively. The mean (μ), mean-plus-one standard deviation (μ + σ), and mean-minus-one standard deviation (μ - σ) of the struc-

tural response are also indicated in the figures. It is apparent that the NF earthquakes induced significantly larger response than the FF ones. In general, the mean displacement and acceleration responses under the NF earthquakes are around 2~3 times of that under the FF earthquakes. It is interesting to note that the effect of increasing the post-yield stiffness ratio on the displacement response is more significant for the NF than the FF earthquakes, as shown in Figures 8a and 9a. As the ratio was increased from 0.10 to 0.25, the reduction in the mean displacement response was 30% for the NF earthquakes but only about 18% for the FF ones. Meanwhile, the amplification in the mean acceleration response was about 57% for both the NF and FF earthquakes in this range, as shown in Figures 8b and 9b. Variations of the mean and the mean-plus-one standard deviation curves show that the reduction in displacement and amplification in acceleration response are moderate as the stiffness ratio is larger than 0.25. A tradeoff between the displacement reduction and acceleration amplification should be determined if the LRBs are the only energy dissipation device against the NF earthquakes.

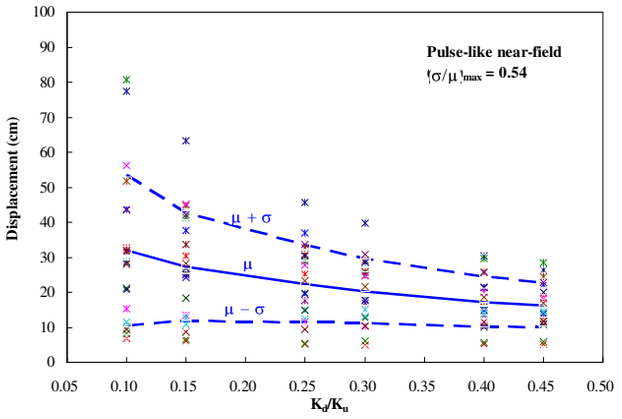

Figure 8a. Peak displacement response under the NF seismic records

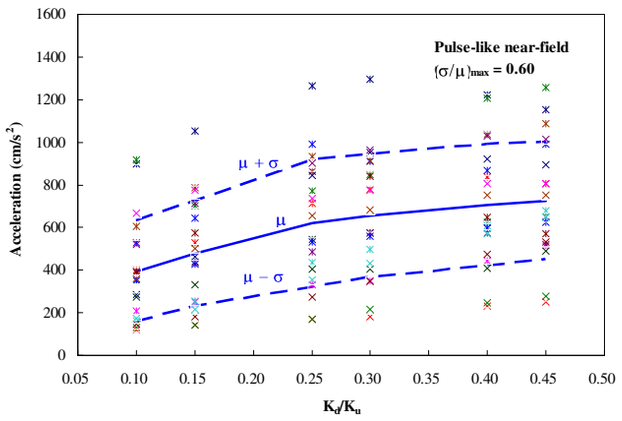

Figure 8b. Peak acceleration response under the NF seismic records

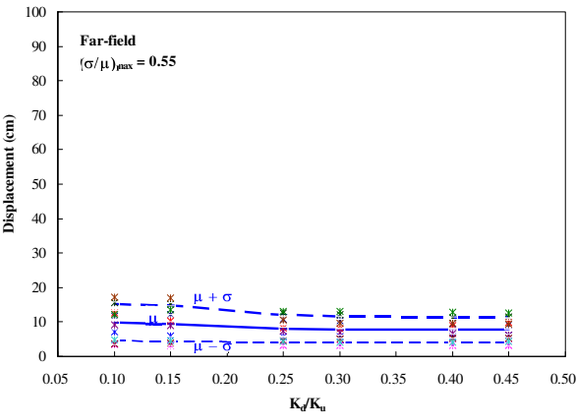

Figure 9a. Peak displacement response under the FF seismic records

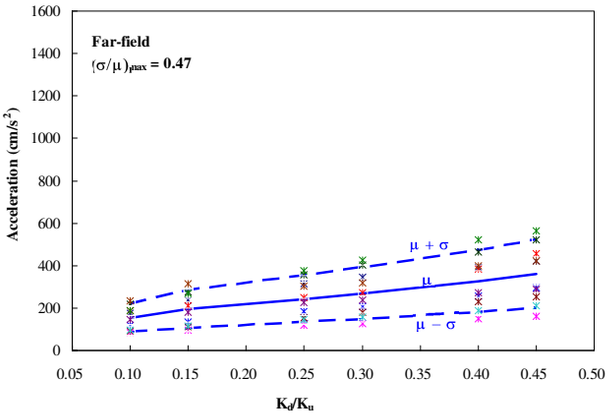

Figure 9b. Peak acceleration response under the FF seismic records

In a previous section, the influence of the period ratio on the peak structural response of the isolated bridge with LRBs of various post-yield stiffness ratios were investigated for the three pulse ground motions. It was shown that the peak response occurs as the isolation period is close to the pulse period. In order to understand if similar conclusion could be made for the pulse-like NF ground motions, the pulse period of the twenty NF ground motions were scaled to each specified pulse period and nonlinear time history analysis was conducted for the isolated bridge model with LRBs of different post-yield stiffness ratios. However, the peak displacement response under the NF ground motions with scaled pulse periods generally increases with the period ratio for each stiffness ratio, as shown in Figures 10a-d. The main reason for this apparent difference in the variation trend is that the pulse ground motions contain only a single frequency, while the NF seismic excitations have a wider range of frequency contents. Hence, even though the pulse period is away from the isolation period, there are still remaining seismic waves with periods close to the isolation period (Bake 2007). Nevertheless, increase in the peak displacement with the pulse period becomes moderate as the period ratio is larger than 2.0.

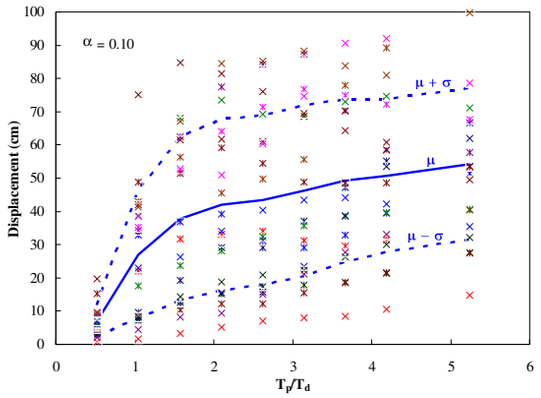

Figure 10a. Peak displacement response under the NF ground motions with scaled pulse periods (α= 0.10)

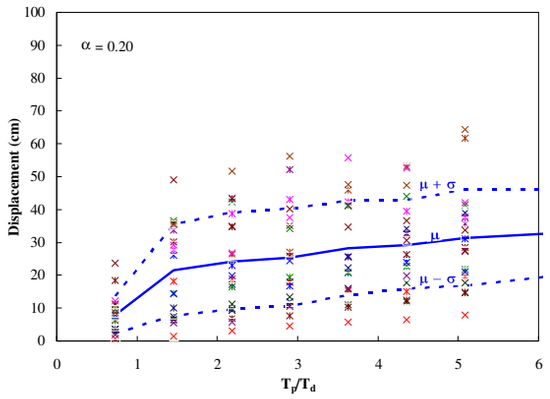

Figure 10b. Peak displacement response under the NF ground motions with scaled pulse periods (α= 0.20)

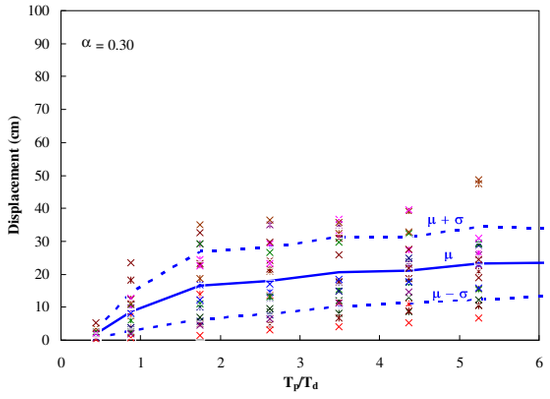

Figure 10c. Peak displacement response under the NF ground motions with scaled pulse periods (α= 0.30)

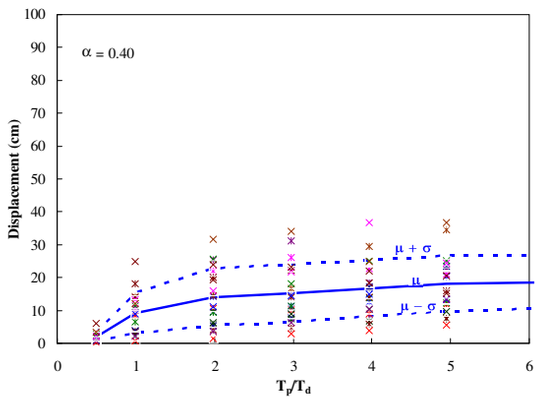

Figure 10d. Peak displacement response under the NF ground motions with scaled pulse periods (α= 0.40)

At last, figures 11a and b present the variation of the mean-plus-one standard deviation response of the peak displacement and acceleration with the post-yield stiffness ratio of LRBs, respectively, under the NF seismic motions with scaled pulse periods. It is seen that the increase of peak structural response gradually reduces with the increased pulse period. The corresponding response curves of the isolated bridge model under one-cycle excitations of the three pulse motions are also included in the figures. Apparently, the one-cycle pulse response is larger than the mean-plus-one standard deviation response under the pulse NF seismic excitations. The latter response generally varies from 70% to 82% of the pulse response under the one-cycle Type-A motions in the considered range of post-yield stiffness ratio. This implies that the one-cycle Type-A pulse may be an appropriate ground motion for the extreme seismic demand under pulse-like NF earthquakes. Because of its simple mathematical expressions, the peak structural response of an isolated bridge under the one-cycle Type-A ground motion with pulse period equal to the isolation period can be easily obtained.

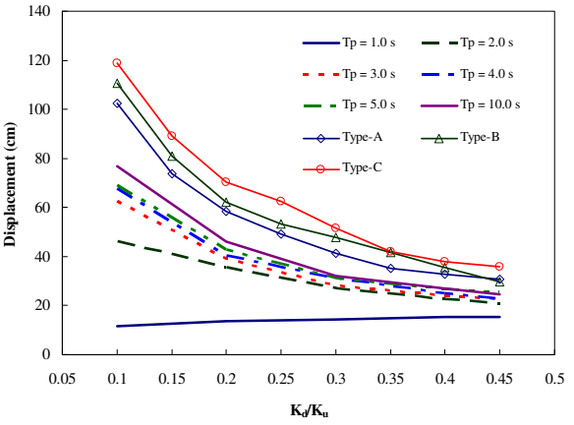

Figure 11a. Variation of the mean-plus-one standard deviation of peak displacement with the post-yield stiffness ratio of LRBs

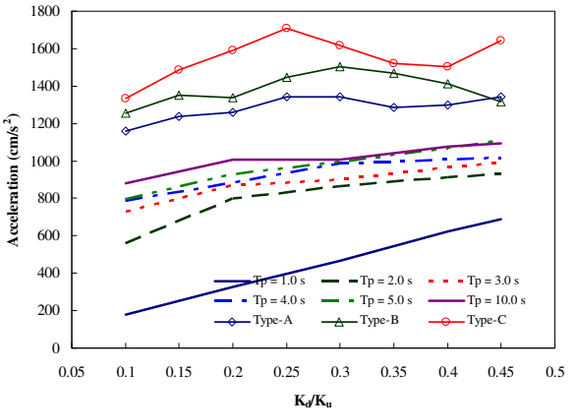

Figure 11b. Variation of the mean-plus-one standard deviation of peak acceleration with the post-yield stiffness ratio of LRBs

6 CONCLUSIONS

A typical seismically isolated bridge model with LRBs was constructed and verified with measured acceleration time histories under an earthquake event. Dynamic responses of the isolated bridge model under three types of pulse ground motion with various pulse periods and cycle numbers were investigated. The analysis results revealed that the three pulse motions have similar structural demands, especially as the cycle number increases. The pulse response depends on the pulse-to-isolation period ratio T_p/T_d. Peak displacement and acceleration response occur around the period ratio of 1.0. From the peak structural responses of the isolated bridge model with LRBs of various post-yield stiffness ratios, it was realized that the peak displacement decreases with increased stiffness ratio. However, an opposite trend was induced for the peak acceleration. Even though, it was observed that an optimal stiffness ratio exists in the range between 0.2 and 0.3 for reducing the peak displacement response.

In order to evaluate the consistency between the pulse and seismic structural response, twenty pulse-like NF and ten FF earthquake records were used for the seismic response analysis of the isolated bridge. The analysis results indicated that the effect of increasing the post-yield stiffness ratio on the displacement response is more significant for the NF than the FF earthquakes. Variations of the mean and the mean-plus-one standard deviation curves show that the reduction in displacement and amplification in acceleration response are moderate as the stiffness ratio is larger than 0.25. Moreover, seismic response of the isolated bridge model with LRBs of varied post-yield stiffness ratio under the twenty NF ground motions with scaled pulse periods was obtained. Different from the variations under the pulse motions, the peak displacement response under the NF ground motions with scaled pulse periods generally increases with the period ratio. Nevertheless, the increase in the peak displacement with the pulse period becomes moderate as the period ratio is larger than 2.0. A comparison between the structural response under the pulse-like NF and the one-cycle Type-A pulse ground motions revealed that the mean-plus-one standard deviation response of the former varied from 70% to 82% of the latter for the considered range of the post-yield stiffness ratio. This implies that the one-cycle Type-A pulse could be used as an appropriate ground motion to estimate the extreme seismic demand of the isolated bridge with LRBs under pulse-like NF earthquakes.

Research on Seismic Performance of Self-Compacting Concrete Bridge Columns

Zhiqiang Wang, Hongliang Duan, Hongyi Wei, Jieli Yang & Xianfeng Sun
Tongji University, Shanghai, China

ABSTRACT: Using self-compacting concrete to cast the bridge pier can improve the placeability of the concrete, reduce the labor costs, and achieve convenient green construction. Due to there is relatively lack of the research on mechanical behavior of self-compacting concrete columns and little design criterion or manual can be followed, self-compacting concrete is used less in actual bridge engineering in China. The quasi-static tests of self-compacting concrete bridge columns were performed to study the seismic performance in this paper. Based on practical engineering background, two specimens of concrete bridge column, with self-compacting concrete (SCC) and normally-vibrated concrete (NVC), were conducted in 1:3 scale ratio. The main objective of this research is to evaluate the influences of concrete material on the seismic performance of bridge columns. The failure modes, ultimate strength, hysteresis loops, skeleton curves, ductility and residual displacement of columns are presented and analyzed. The quasi-static test results show that, compared with normally-vibrated concrete column, the displacement ductility and energy dissipation capacity of self-compacting concrete column is insufficient. For the failure mode, plastic hinge is formed at the bottom of normally-vibrated concrete column. The height of plastic region is about 30~50cm for normally-vibrated concrete column. The self-compacting concrete column shows similar damage form; the height of plastic region is about 20cm. Nevertheless, due to poor bonding performance of self-compacting concrete, the stripping between longitudinal reinforcements, stirrups and concrete is discovered.

1 INTRODUCTION

Among the high-performance materials which are actively developed and popularized in the construction industry in the world, self-compacting concrete can be used to improve the concrete workability, reduce the labor cost and realize the convenient green construction. Many scholars have studied the compressive performance of SCC columns, and different factors that influence the static and compressive mechanical behaviors of SCC columns are discussed [1~4]. Nevertheless, the research on the seismic performance of self-compacting concrete is merely a few from researchers abroad, and the domestic research is close to the blank. Furthermore, the seismic performance of self-compacting concrete members is studied in building industry initially [5~6]. Due to the lack of research on mechanical properties of self-compacting concrete columns and the design criteria that can be followed, the application of self-compacting concrete in bridge construction is limited, and it is mainly confined to the concrete filled into steel pipe in concrete-filled steel tubular arch bridges. In order to use self-compacting concrete piers in seismic regions, it is necessary to develop the experimental study on the piers with self-compacting concrete, and to investigate the seismic performance and damage mechanism of self-compacting concrete piers, thereafter providing reliable basic research results.

2 EXPERIMENTAL PROGRAM

2.1 *Test specimens*

Two cast-in-place column specimens are designed in this paper. The specimen 2# is a cast-in-place self-compacting reinforced concrete column, which is used to study the seismic performance and damage mechanism of bridge piers. Specimen #1 is the cast-in-place (CIP) reinforced concrete column, which is designed as the benchmark.

The columns of specimens are 3.2m in height with the rectangular cross-section of 0.5m×0.53m. The footing of dimension 1.6m×1.6m×0.6m, is used to anchor the specimen to the strong floor of the lab. The dimension of the column cap is

0.9m×0.5m×0.4m. The effective loading height is 3.4m. The shear span ratio of the specimen is 6.42. Figure1 shows the geometric sizes of the two columns.

The materials used are C40 concrete, hot-rolled plain bar with nominal yield strength of 235MPa (HPB235), the concrete of the 1# specimen is normally-vibrated concrete, and the 2# specimen is self-compacting concrete.

The longitudinal reinforcements of specimen consist of ten 20mm-diameter hot-rolled ribbed bars (HRB400) and fourteen 8mm-diameter supplementary plain bars(HPB235). The nominal yield strength of hot-rolled ribbed bar and hot-rolled plain bar is 400MPa and 235MPa respectively. Detailed reinforcement arrangement is shown in Figure 2.

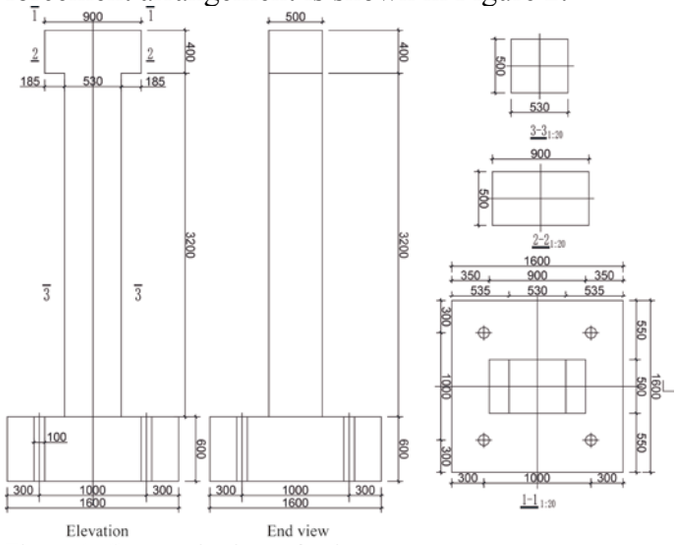

Figure 1. Geometric sizes of columns.

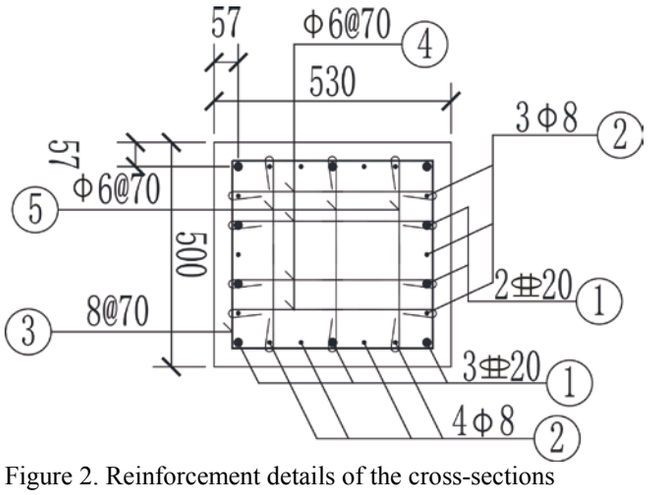

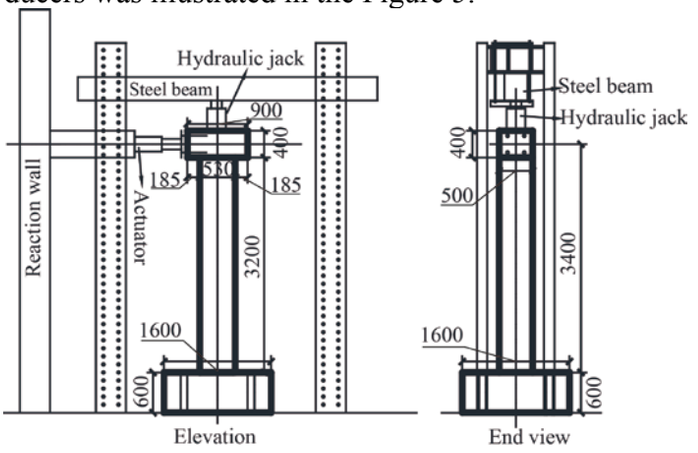

Figure 2. Reinforcement details of the cross-sections

2.2 *Loading and measurements*

The quasi-static cyclic loading experiment was conducted under displacement control. Figure 3 illustrates the test set-up for the cyclic loading test. Both the two specimens were subjected to a combination of axial load provided by a vertical actuator and repeated lateral loads applied by a hydraulic actuator mounted on the reaction wall. The displacement-controlled test was conducted on the basis of applied deformation levels, as shown in Figure 4, which were initiated by 2mm, and subsequently increased to 5mm, 10mm, 15mm, 20mm, 25mm, 30mm, 40mm, 60mm, and were finalized at failure. The maximum stroke of the actuator was ±250mm and each displacement was applied twice.

Global behavior of the specimens was estimated by measuring lateral displacements through displacement transducers and lateral force by a load cell of the actuator. The distribution of displacement transducers was illustrated in the Figure 5.

3 TEST RESULTS

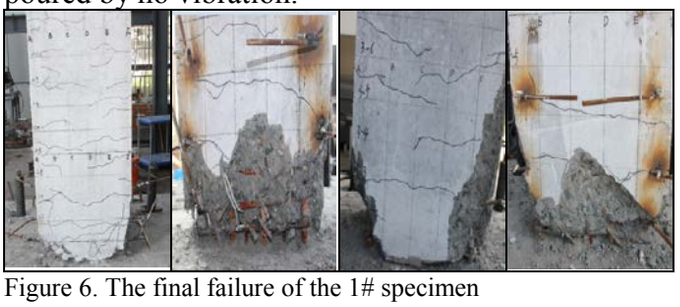
3.1 *Specimen damage and failure*

The performance level of bridge can be divided into five stages [7], which includes I: cracking, II: yielding, III: initiation of local mechanism, IV: full development of local mechanism, and V: strength degradation.

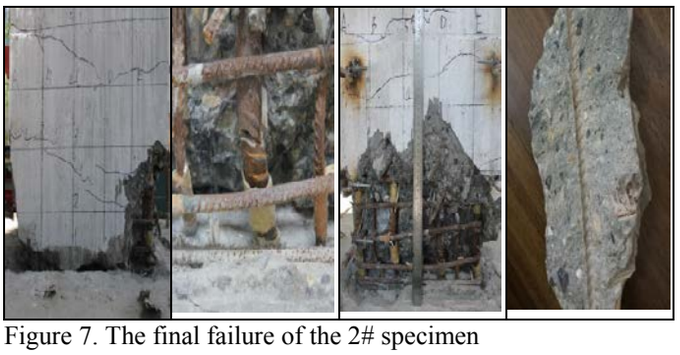
According to the above five stages, damage state and performance level of the two specimens are described as follows:

Level I initiated at the time when the column top displacement of 1# specimen and 2# specimen was 5mm and 10mm respectively. The hair-like cracks began to emerge, but they closed up after unloading.

The damage Level II was achieved when the top displacement of the 1# specimen and the 2# specimen pier reached 25mm and 20mm respectively. Corresponding to the 1# specimen, there were many bending cracks along the column, and a number of cracks extended to the side faces. The crack spacing was relatively uniform, about 15~20mm, the crack width was of 0.04~0.28mm.The crack width at the bottom of column was around 1mm. Crack still closed up after unloading. The measured value of the crack spacing in the 2# specimen was 20mm, and the width was 0.04~0.30mm.



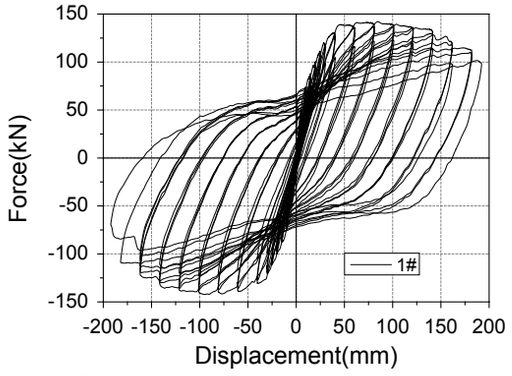
When the top displacement of 1# specimen and 2# specimen pier was 60mm and 80mm respectively, the piers reached the level III. At this time, corresponding to the 1# specimen, columns arose series of flexural cracks and diagonal cracks. The width of the fracture was 0.1~0.8mm, and multiple horizontal cracks closed up through cross section under the positive and negative load. The crack width of the column bottom was of 5~9mm, with a trend of column foot concrete to shed. The 2# specimen damage was similar to the situation. The crack width along the column was 0.1~0.42mm, with 3mm cracks at the bottom.



Level IV was when the corresponding loading displacement of the 1# specimen was 120mm, the concrete cracks of 1# specimen were staggered at a height of 15cm from the top surface of footing. In the course of the 10cm height above the platform, the concrete protective cover was peeled off and had a tendency to continue to flake. The crack width at the bottom of the column exceeded 10 mm. When the loading displacement reached 100mm, the 2# specimen was damaged as above. The concrete protective cover was peeled off at a height of 15cm from the footing. The crack width was more than 10mm.

When 1# specimen's load displacement achieved 160mm, the specimen carrying capacity reduced to 85% of the maximum load, reaching the level V of strength degradation. A large amount of concrete around the bottom fell out, and the width of the crack at the bottom measured about 20 mm. For the 2# specimen, the specimen carrying capacity reduced to 85% or less of the maximum load at the stage of 140mm displacement.

The final failure of the 1# specimen was shown in Figure 6. It can be observed that the destruction area was mainly concentrated in the column bottom. The height of plastic region was about 30~50mm. The longitudinal reinforcements buckled (one of the bars was fractured), and the stirrups bulged outward.



As shown in Figure 7, the 2# specimen was damaged in the same way with the height of plastic region about 20mm. Additionally, from the shed flake of the concrete protective cover, it could be observed that column longitudinal reinforcements and stirrups had complete separation interface to self-compacting concrete, providing inferior bonding performance. It might result from the self-compacting concrete poured by no vibration.

Figure 6. The final failure of the 1# specimen

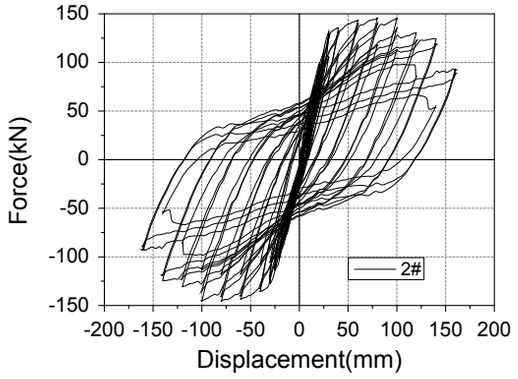


Figure 7. The final failure of the 2# specimen

3.2 *Evaluation of experimental results*

3.2.1 *Hysteresis curve*

(a) 1# Specimen

(b) 2# Specimen

Figure 8. Load-displacement relationship

The load-displacement relation of all specimens (Figure 8) reveals that the two specimens were in the elastic stage under the lower load. With the increase of the loading displacement level, the nonlinear phenomena such as the cracking of the concrete and the yield of the steel were gradually occurring. The hysteresis loop enlarged, and energy consumption increased. In general, both specimens showed flexible failure. Compared to the self-compacting concrete column, the ordinary vibrated concrete column had relatively plump hysteresis loops and slow intensity degradation throughout the test.

3.2.2 *Skeleton curves*

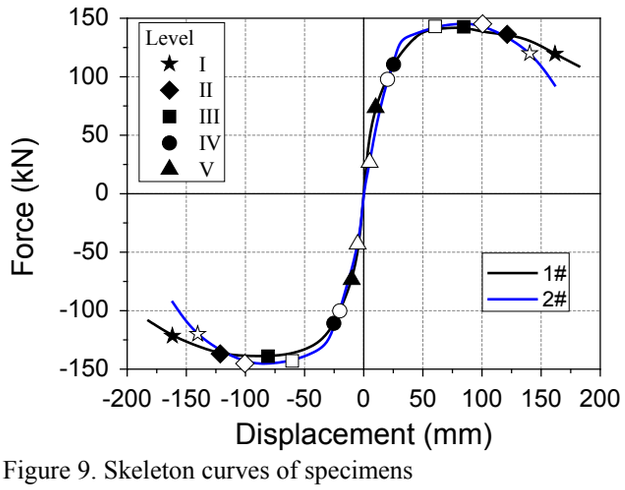

Figure 9. Skeleton curves of specimens

The skeleton curves of the two specimens is similar. In the early stage of loading, compared with the ordinary vibrated concrete specimen, the self-compacting concrete specimen was the earlier to crack and the stiffness was relatively small. When the displacement was loaded up to 80mm, both of the columns reached the ultimate carrying capacity. Then the carrying capacity began to decline. The ordinary vibrated concrete pier showed a gentler strength attenuation and a relatively good ductility.

3.2.3 *Drift*

The strength of the 1# specimen reduced to below 85% at 160mm loading, corresponding to the drift ratio of 4.71%. The strength of the 2# specimen decreased to 85% under 140mm loading with 4.12% drift ratio.

3.2.4 *Ductility*

The ductile coefficient calculated by the general yield bending moment method is shown in the table 1 below. On the whole, the self-compacting concrete column had relatively worse ductility compared to ordinary vibrated concrete pier.

Table 1. Ductility of the specimens

	Spec. #1	Spec. #2
Δ_y (mm)	21.7	25.2
Δ_u (mm)	158.7	140.6
μ	7.3	5.6

3.2.5 *Residual displacement*

The residual displacement at different load levels for all specimens is shown in Figure10. The specimen's relationship curve of the residual displacement was very close. At the initial loading, the specimen remained elastic as a whole. After unloading the specimen can be restored to the initial state and the residual deformation was close to zero. With the increase of the loading displacement, the specimen damage occurred and the residual deformation increases gradually.

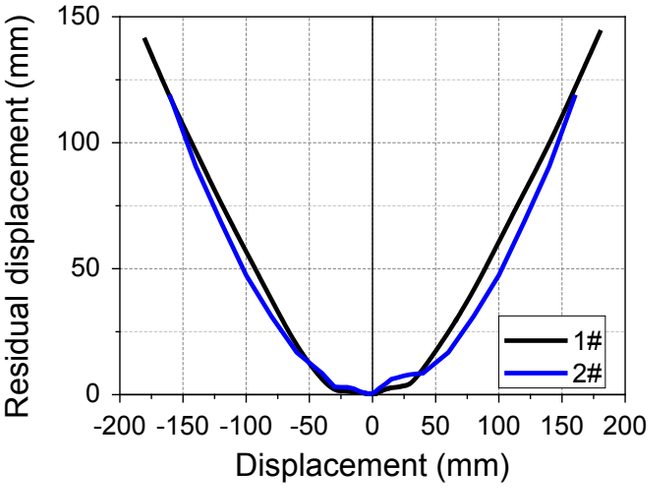

Figure 10. Residual displacement of specimens

4 CONCLUSIONS

In order to research on Seismic Performance of Self-Compacting Concrete Bridge Columns, a quasi-static cyclic loading experiment was conducted. Based on the results, the following conclusions can be drawn:

When the top displacement of the 1# and 2# specimen reached 160mm and 140mm respectively, the specimen carrying capacity reduced to 85% or less of the maximum load.

The failure of the two specimens was shown as flexible damage. Destruction mainly concentrated in the bottom of the column. A large number of concrete protective cover peeled off and core concrete crushed. Longitudinal reinforcements buckled and stirrups bulged outward. The height of plastic region of the 1# specimen was about 30-50mm. Correspondingly, the one of the 2# self-compacting concrete column was about 20mm.

The bonding performance of the self-compacting concrete was inferior. The stripping between longitudinal reinforcements, stirrups and concrete is discovered.

Comparison of hysteresis curve and skeleton curve, the normally-vibrated concrete column had relatively plump hysteresis loops and slow intensity degradation throughout the test.

The self-compacting concrete column had relatively worse ductility compared to normally-vibrated concrete column.

The residual displacement of the self-compacting concrete column and normally-vibrated concrete column was basically similar.

ABSTRACT: In order to evaluate the seismic performance of typical continuous rigid railway bridge with high pier under the action of near fault ground motion in western China, the vulnerability analysis of this type of bridge is carried out by using kernel density estimation method (KDE method). Considering the uncertainty of ground motions and bridge parameters, a model sample database is generated. The seismic response of the bridge is obtained based on the time-history analysis of the model sample database on the OpenSees platform. A bridge vulnerability analysis method based on KDE is proposed, in which the curvature ductility ratio and relative displacement are respectively considered as pier and bearing damage indexes. The longitudinal and transverse vulnerability curves of the structure are calculated and then the vulnerability distribution characteristics of the pier is studied deeply by this method. The results show that the failure probability of bearing is the highest among all the bridge members. It is also observed that the damage is mainly concentrated on the top and bottom of high pier under strong near fault ground motions. Further more, the established vulnerability curves can be used to evaluate the seismic performance of long span bridges with high pier, as well as to provide the basis for seismic risk assessment, seismic damage diagnosis and retrofit policy in transport system.

1 INTRODUCTION

In recent years, with the rapid development of traffic network in the west of China, a large number of railway lines have emerged in the western region. To cross the complex terrain, high mountains and deep valley areas, long span bridges with high pier are widely used, among which the multi-span continuous rigid frame railway bridge with high pier is more common. The increase of the pier height and span brings many technical problems about seismic design for railway bridges in this area. At the same time, the seismic activity in the western region of China is frequent in recent years, which makes the bridge operation safety being seriously challenged.

Since the beginning of 21st century, with the basic framework of probabilistic method for seismic design and evaluation based on performance put forward by the Pacific Earthquake Engineering Research (Mackie 2005), the seismic vulnerability curve has gradually become an important mean to evaluate the seismic performance of structures. At present, the study of seismic vulnerability has been deepened into various fields of traffic lifeline engineering. Bridge is an important hub of traffic lifeline system, therefore it is the key object of seismic vulnerability research.

Seismic vulnerability analysis methods generally include empirical method, test analysis method, and theoretical analysis method (Dong 2016). In recent years, due to the lack of real bridge seismic data in many areas, the theoretical vulnerability analysis of bridge has been more widely and deeply studied by scholars in various countries. Danusa (2012) conducted seismic vulnerability analysis for five common types of bridges in Quebec, Canada. Siqueira et al. (2014) made a design for strengthening and repairing a three-span continuous girder bridge in Quebec, Canada and established the seismic vulnerability curves of the bridge before and after the reinforcement. Noori et al. (2015) carried out the vulnerability analysis of the typical simple supported girder highway bridge in the central and eastern area of the United States, and studied the influence of the parameters (including the longitudinal inclination angle and the pier height) on the vulnerability of the bridge. Mosleh et al. (2016) established a probabilistic seismic demand model for a 32 meter-span simply supported girder bridge built in Iran in the 1990s and studied the seismic performance of the bridge under near fault and far field earthquakes. However, most of the above vulnerability analysis research work is aiming at the common regular bridges (such as simply supported bridge, medium and small span continuous girder bridge) and single bridge component (such as piers, bearings, etc.). For the western region of China, the vulnerability research for the railway long span

rigid frame and continuous girder bridge with high pier is few.

Based on this, the typical irregular rigid frame bridge in western China is taken as the study object in this paper. Considering the uncertainty of ground motion and bridge structure parameters and using the KDE based bridge vulnerability analysis method (Dong 2016), the vulnerability curve of the bridge structure is established and the seismic vulnerability character of the bridge structure is analyzed. And then the seismic performance of the typical railway bridge structure is evaluated, which provides the basis for the seismic design and post-earthquake damage identification of the bridge.

2 KERNEL DENSITY ESTIMATION BASED BRIDGE SEISMIC VULNERABILITY ANALYSIS METHOD

Seismic vulnerability refers to the probability that the damage degree of structures exceeds the specific damage state under the action of a certain intensity of earthquake (Nielson 2005). The calculation formula of seismic vulnerability probability for bridge components is as follows (Chen 2012):

$$P_f(IM,C)=P[\ D\geq C\ |IM\ ] \tag{1}$$

Where C represents the seismic response demand value of bridge components; D represents the capacity of bridge components to resist the seismic action; IM represents the ground motion intensity value; P_f (IM,C) indicates the probability that bridge components reach a specific damage state under the effect of earthquake with the intensity value of IM.

Carrying the conditional probability density function $f_{D|IM}$ of the seismic capacity of bridge components into the formula (1), then the vulnerability probability formula can be written as:

$$P_f(a,C)=P[D\geq C|IM=a]=\int_C^{+\infty} f_D(c|IM=a)dc \tag{2}$$

According to the theory of probability and statistics, the calculation formula of probability density function for seismic capacity of bridge components is:

$$f_D(c|IM=a)=\frac{f_{D,IM}(c,a)}{f_{IM}(a)} \tag{3}$$

Where $f_{D,IM}(\cdot)$ is the joint probability density distribution function of seismic capacity and ground motion intensity. The $f_{IM}(\cdot)$ is the edge distribution function of IM. Other symbols mean the same as above. If $f_{D,IM}$ $(\cdot)$ and $f_{IM}(\cdot)$ are known, the damage probability of bridge components can be calculated by using the formula (2), thus the seismic vulnerability curve of bridges can be established.

In order to establish the vulnerability curve of bridge components, taking N sets $\{(IM_i,D_i),\ i=1,\cdots,N\}$ of earthquake intensity data and the maximum response data obtained by time history analysis as the basis, the calculation formulas of the joint probability density function and edge distribution function of bridge structures are derived by introducing the kernel density estimation method (Rosenblatt 1956).

Firstly, the single parameter case for the random variable X is discussed, assuming that the X variable has n sample points $\{x_1,\cdots,x_n\}$. As can be seen from the definition of kernel density estimation, the kernel density estimate for the probability density distribution function is:

$$\hat{f}_h(x)=\frac{1}{nh}\sum_{i=1}^{n}K(\frac{x-x_i}{h}) \tag{4}$$

Where h represents the bandwidth parameters and $K(\cdot)$ represents the kernel function. The current commonly used kernel functions are uniform kernel function and Gaussian kernel function which can be seen for detailed function forms (Duong 2004). The results show that when the calculated sample points are sufficient, the accuracy of the evaluation results will not be affected no matter what type of the function is chosen. Therefore, the Gauss kernel function is used as the kernel function in this paper, namely $K(x)=\varphi(x)=\exp(-x^2/2)/\sqrt{2\pi}$. Carrying it into the last equation gives:

$$\hat{f}_h(x)=\frac{1}{nh}\sum_{i=1}^{n}\varphi(\frac{x-x_i}{h}) \tag{5}$$

Wand and Jones (1995) have discovered that the optimal bandwidth parameter of the formula (5) is $h^*\approx 1.059\sigma\cdot n^{-0.2}$, where σ is the standard deviation of X. The results show that the value of h will directly affect the correctness of the evaluation results. The seismic edge distribution function with the intensity of IM can be evaluated by using the formula (5), i.e., $\hat{f}_{IM}(a)$ is estimated by the intensity of N sets $\{IM_i,i=1,\cdots,n\}$ of ground motion records.

$$\hat{f}_{IM}(a)=\frac{1}{nh_{IM}}\sum_{i=1}^{n}\varphi\left(\frac{a-IM_i}{h_{IM}}\right) \tag{6}$$

The following discussion is about the multivariate random variables $\boldsymbol{X}\in \mathrm{R}^d$. D represents the dimension. If the n variables $\boldsymbol{X}=\{\boldsymbol{x}_1,\cdots,\boldsymbol{x}_n\}$ are known, the variables $\boldsymbol{x}_i(i=1,2\ldots,n)$ are independent of each other and there are m sample points in each variable $\boldsymbol{x}_i$, then the kernel density is estimated as follows:

$$\hat{f}_X(x)=\frac{1}{n|\boldsymbol{H}|^{1/2}}\sum_{i=1}^{n}K\left(\boldsymbol{H}^{-1/2}(x-x_i)\right) \tag{7}$$

Where $\boldsymbol{H}$ denotes the bandwidth matrix and belongs to the symmetric positive definite matrix. $|\boldsymbol{H}|$ denotes the determinant of the $\boldsymbol{H}$ matrix.

By introducing the standard normal kernel function of the multivariate parameter variable into Eq. (7), the kernel density estimation is solved as follows:

$$\hat{f}_{\boldsymbol{X}}(x)=\frac{1}{n|\boldsymbol{H}|^{1/2}}\sum_{i=1}^{n}\frac{1}{(2\pi)^{d/2}}\times\exp\left[-\frac{1}{2}(x-x_i)^{T}\boldsymbol{H}^{-1}(x-x_i)\right] \quad (8)$$

Where $(\cdot)^{\mathrm{T}}$ denotes the transpose of the matrix. Research carried out by Duong (2004) found that for the multivariate parameter variables, the complete type bandwidth matrix, which can be calculated using the smooth cross estimation method (Duong 2005), is usually used to estimate the kernel density when the correlation between the variables is unknown. Then, the time history analysis for the bridge under the action of n groups of earthquakes is carried out, and then the maximum dynamic response and the ground motion intensity $\{(IM_i, D_i),\ i=1,\cdots,n\}$ are extracted. The joint probability density function of the bridge component can be calculated by using the formula (8):

$$\hat{f}_{D,IM}(c,a)=\frac{1}{2\pi n|\boldsymbol{H}|^{1/2}}\sum_{i=1}^{n}\exp\left[-\frac{1}{2}\begin{pmatrix}c-D_i\\ a-IM_i\end{pmatrix}^{T}\boldsymbol{H}^{-1}\begin{pmatrix}c-D_i\\ a-IM_i\end{pmatrix}\right] \quad (9)$$

The formula (9) and (6) are substituted into the formula (3) to calculate the probability density function $f_D(c|IM=a)$ of the seismic capacity of bridge components. Next the integration is performed for solving the formula (2). Finally, the seismic vulnerability probability of the bridge members is:

$$P_f(a,C)=P[D\geq C|IM=a]=\int_{C}^{+\infty}f_D(c|IM=a)dc$$
$$=\frac{h_{IM}}{2\pi|\boldsymbol{H}|^{1/2}}\frac{\int_{C}^{+\infty}\sum_{i=1}^{n}\exp\left[-\frac{1}{2}\begin{pmatrix}c-D_i\\ a-IM_i\end{pmatrix}^{T}\boldsymbol{H}^{-1}\begin{pmatrix}c-D_i\\ a-IM_i\end{pmatrix}\right]dc}{\sum_{i=1}^{n}\varphi\left(\frac{a-IM_i}{h_{IM}}\right)} \quad (10)$$

The seismic damage probability of bridge components can be calculated by adopting formula 10, and then the bridge vulnerability curve can be established.

3 ENGINEERING EXAMPLES

3.1 *Engineering overview and finite element simulation*

The typical high-speed railway long span irregular rigid frame bridge with high pier in western China is selected as the research object in this paper. The span of the main bridge is arranged as 101m + 192m + 101m. The superstructure of the bridge is prestressed concrete box girder with variable cross-section, and the beam adopts C55 concrete. The height of the beam ranges from 6.9m to 13.2m and the width of the beam is 10.3m. The design value of the second stage dead load of bridge deck is 95kN/m. All piers of the bridge adopt rectangular hollow sections. The 2# pier of 74m height and 3# pier of 78m are rigid piers, and the 4# pier of 58m height is the cantilever pier. The longitudinal movable bearing at 0# abutment adopts spherical bearing whose type is TJGZ-LX-Q9000-ZX-e150-0.2g, while the longitudinal movable bearing at 3# side pier adopts spherical bearing whose type is TJGZ-LX-Q9000-ZX-e100-0.2g. The layout of the whole bridge is shown in Figure 1.

The finite element model of the full bridge is established by OpenSees software. The superstructure is simulated by beam element, considering the dead weight, the second stage dead load and the train load. The pier is modeled by fiber element, to which the constitutive models of steel and concrete are assigned. The concrete uses the Kent-Park constitutive model (Kent 1971). The value of constitutive model for ordinary concrete is based on Code for design of concrete structures (GB50010-2010), and the value of constitutive model for constrained concrete is calculated by Mander model (Mander 1988). The constitutive model of steel is determined by Giuffré-Menegotto-Pinto model (Menegotto 1973). The bearing is modeled with a bilinear spring element, and the abutment is modeled with a built-in zero length element with the material characteristics given in OpenSees. The effective stiffness and passive earth pressure of the bridge are solved according to California Department of Transportation, Caltrans Seismic design criteria. Six spring elements are used for equivalent simulation of bridge pile foundation. The full bridge calculation model is established by OpenSees Software.

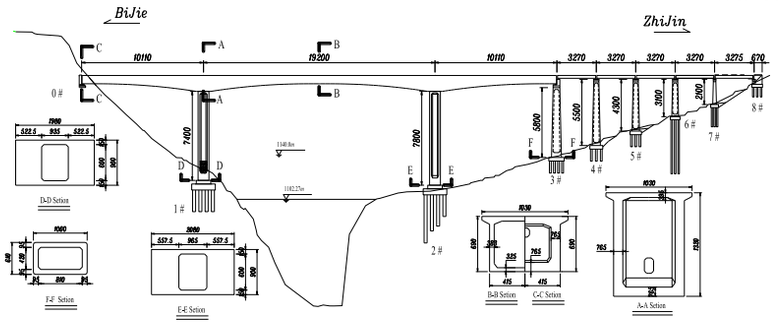

Figure 1. Schematic diagram of full-bridge layout (Unit: cm).

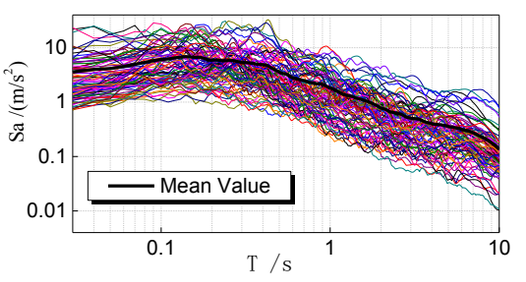

Figure 2. diagram of response spectrum characteristic.

3.2 *The uncertainty of ground motion*

As the bridge is located in Sichuan area, the measured ground motions of this area should be used for the time history analysis as far as possible to ensure that the calculated results are in accord with the actual engineering. Therefore, the measured ground motion records of Wenchuan earthquake in 2008 is chosen for the seismic vulnerability analysis in this paper. Based on the comprehensive consideration of the ground motion intensity and the integrity of measured data, 100 ground motion records from 40 observation stations in Sichuan province are selected. Figure 2 shows the acceleration response spectra and the mean spectra for each ground motion. Amplitude modulation of 100 ground motions is carried out, and then 10 PGA grades from 0.1g to 1.0g are obtained with the amplitude modulation step of 0.1g. Finally, 1000 sets of seismic analysis samples are generated.

3.3 *The uncertainty of bridge model parameters*

Because the structure is always affected by various factors (such as raw materials, construction technology, external disturbance and so on) in the construction process, randomness exists in the material property, component mechanical behavior and load effect. The above factors will affect the seismic performance of bridge structure itself, therefore, the uncertainty of above factors should be considered when conducting the vulnerability analysis. Pan (2007), Tavares (2012) and Mehdizadeh (2014) have studied the key parameters that affect the seismic performance of bridges, including the strength of steel and concrete, concrete density, the second stage dead load and bearing friction coefficient. According to the characteristics of the bridge in this paper, combining with the above scholars' research results, the key parameters and their distribution characteristic values considered in model bridge are given in Table 1. Parameter samples of the bridge model are generated by using Latin hypercube sampling method on the key parameters in Table 1, and then the analysis sample library of the bridge is formed. In view of the calculation scale and the selected sampling method, 1000 tests are used to generate 1000 bridge model samples in this paper.

Table 1. Uncertain parameters of model bridge and their distribution.

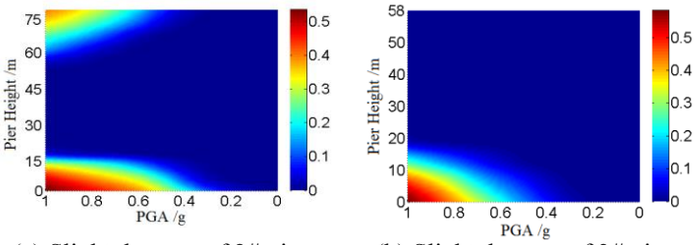
model parameter	Distribution type	mean value	variation coefficient
peak strength of C40 core concrete/MPa	Normal distribution	36.8	0.15
peak strength of C35 core concrete/MPa	Normal distribution	34.3	0.18
Steel yield stress/MPa	Normal distribution	400	0.06
Concrete density/ $Kg \cdot m^{-3}$	uniform distribution	2500	0.2
Steel hardening ratio	Lognormal distribution	0.02	0.25
Second stage dead load/$(kN \cdot m^{-1})$	Normal distribution	95	0.03
friction factor of bearing	Lognormal distribution	0.02	0.30

3.4 *Damage index of bridge structures*

In this paper, the long span rigid frame continuous girder bridge with high pier and is taken as the research object. The piers are very high and the height difference of the piers is very obvious (the maximum height difference reached 50.05m). In order to establish the vulnerability curve of long-span irregular bridge with high pier, it is necessary to make clear the damage index for the vulnerable parts of bridge. However, the selection and calculation method for reasonable damage indexes have been studied by Dong (2016) according to the characteristics of long span continuous rigid frame bridge with high pier. Based on the above literature, the cross section curvature is chosen as the damage index for the pier, and the relative displacement of bearing is chosen as the damage index for the spherical bearing. The specific damage index calculation method is described by Dong (2016). Due to the limited space, Table 2 only gives the calculation results of damage indexes in longitudinal direction.

Table 2. Uncertain parameters of model bridge and their distribution.

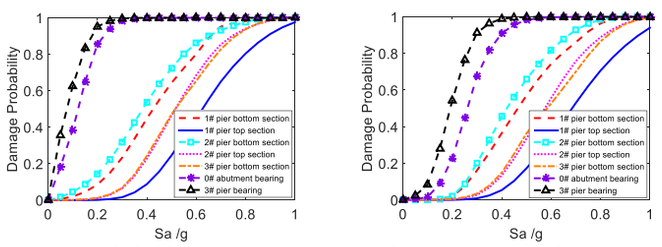
Damage state	position of section curvature/m^{-1}					Bearing member relative displacement/*mm*	
	1# pier bottom	1# pier top	2# pier bottom	2# pier top	3# pier bottom	0#abutment bearing	3#pier bearing
Slight damage	0.000405	0.000185	0.000400	0.000178	0.000460	150	100
Moderate damage	0.000468	0.000311	0.000462	0.000307	0.000545	300	200
Extensive damage	0.001280	0.001190	0.001270	0.001160	0.001480	600	400
Complete damage	0.003980	0.003830	0.003965	0.003821	0.004470	900	600



3.5 *Seismic vulnerability analysis of bridge structures*

3.5.1 *Seismic vulnerability analysis of the whole pier*

In order to study the vulnerability distribution of the whole pier, the vulnerability nephogram is used for analysis by referring to the method proposed in literature (Dong 2016). Namely using formula (8) to calculate the vulnerability curves of each element of the pier, and the vulnerability nephogram of the whole pier is plotted based on these curves. The vulnerability nephogram of each pier under longitudinal and transverse seismic action are shown in Figure 3 and Figure 4.



Based on the analysis of Figure 3, it can be seen that under the action of longitudinal earthquake, the bottom area of 3# pier is most likely to be slightly damaged. With the increase of PGA, the damage area extends from the bottom of the pier to the top gradually. The bottom and the top of 1# and 2# pier are easy to be damaged, and the damage area gradually develops from the two ends to the center with the increase of PGA. Therefore, the vulnerability of the pier at the bottom section and the top section should be focused on when conducting the seismic vulnerability analysis for railway irregular continuous rigid frame bridges.

It can be seen from Figure 4, under the action of transverse earthquake, the seismic damage is easy to occur in the bottom area of 1#~3# pier. Therefore, when the horizontal seismic vulnerability is conducted, the vulnerability of the bottom section of the pier should be paid attention. The above analysis results are consistent with the actual seismic damage.

（1） the results of longitudinal direction

(a) Slight damage of 1# pier (b) Slight damage of 2# pier

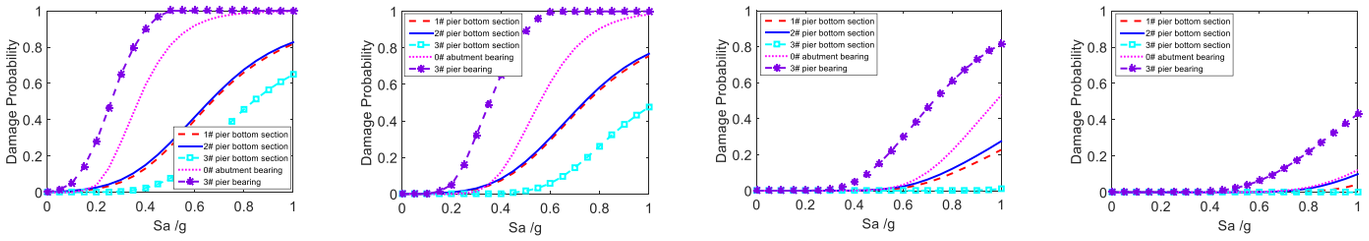

Figure 4. Vulnerability nephogram of piers under the transverse earthquake.

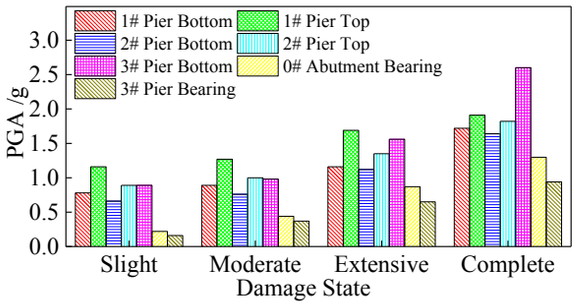
3.5.2 *Vulnerability analysis of each dangerous part of the bridge*

Based on the results of Section 3.5.1 and the actual damage, it is shown that for the long span continuous rigid frame bridge, the rigid piers (the bottom and top area) and the bearing are the most vulnerable components of the bridge. Seismic damage of the side pier is relatively small, and the seismic damage is mainly concentrated in the bottom of the pier. Therefore, when conducting the seismic vulnerability analysis for each dangerous component, the vulnerability of the parts such as the top and bottom section of 1#~2# pier, the bottom section of 3# pier, the bearing of 0# abutment and the bearing of 4# pier is the focus in this paper.

Using the KDE based seismic vulnerability analysis method proposed in this paper, the seismic vulnerability curve of bridge components can be generated. In this paper, the longitudinal and transverse seismic vulnerability curves of the bridge are established, and the strength index Sa are selected as the strength index of ground motion.

Figure 5 shows the longitudinal and transverse seismic vulnerability curves of each vulnerable part. It can be seen from the figure that the vulnerability curve of each part has similar shape and the damage probability increases with the increase of Sa. Under the action of earthquake, the bearing of 4# pier is the most vulnerable, followed by the bearing of 0 # abutment. And the last one is the bottom section of 1# pier. Using these generated vulnerability curves, the damage probability of each vulnerable part under the action of ground motion with different intensity can be evaluated, which can provide guidance for the seismic design optimization, bridge reinforcement scheme design, bridge reinforcement priority evaluation and economic loss evaluation after earthquake.



(a)Slight damage (b) Moderate damage (c)Extensive damage (d) Complete damage

（2） the results of transverse direction

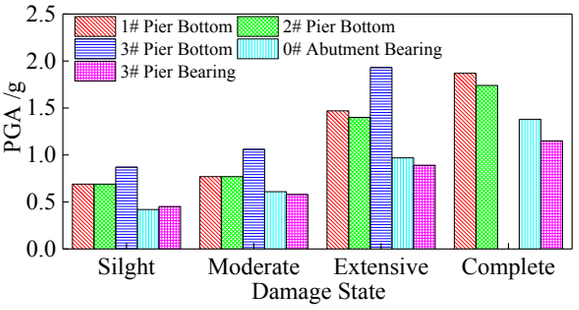


Figure. 5 Seismic vulnerability curves of different vulnerable positions.

3.5.3 *Comparative vulnerability analysis for each vulnerable component*

In order to reflect the seismic vulnerability of each component visually, the histogram of PGA median value for each vulnerable component corresponding to four damage states is given in figure 6. (If the median value of PGA is larger than 3.0g, the probability of seismic damage is very small and the graph is not plotted.)

(a) the result of longitudinal direction

(b) the results of transverse direction

Figure 6. Comparison of the median values of PGA for typical bridge members.

It can be seen from Figure 6, for the long span railway bridge with high pier, the bearing is the most vulnerable parts of the bridge and rigid piers are more prone to be damaged than other cantilever piers. The seismic vulnerability law of each component of irregular long span rigid frame bridge with high pier is more complicated compared to that of regular bridges. The geometrical irregularities, high order modes and other factors of the structure lead to the irregularities of the seismic response of piers, which makes the obvious difference in vulnerability of each pier. And the vulnerability distribution of each component has some differences in different damage states, while the seismic vulnerability distribution of each component for regular bridges has a certain law (Dong 2016 and Siqueira 2014). The uncertainty in the vulnerability distribution of long span continuous rigid frame bridge with high pier and the existence of a plenty of similar bridges in the western region both contribute to the seismic vulnerability research of typical railway continuous rigid frame bridges.

4 CONCLUSIONS

In this paper, the seismic vulnerability of the typical high-pier and long span continuous rigid frame railway bridges is analyzed by using vulnerability analysis method based on KDE. The main conclusions are as follows:

The characteristics that the damage probability of each element of piers varies with the peak acceleration value can be expressed intuitively by the vulnerability nephogram. In addition, the vulnerability nephogram can reveal the damage evolution process and the failure probability of the whole pier and reflect the vulnerability of the whole pier intuitively. Therefore, it is recommended to analyze the vulnerability of the whole pier by using the vulnerability nephogram.

The result of longitudinal seismic vulnerability of each dangerous component shows that for the pier members, they have a good seismic performance under the action of the design earthquake. The rigid pier is more prone to be damaged than the cantilever pier under the action of the earthquake with the same intensity. For the bearings, under the action of the design earthquake, the bearing members are prone to be damaged slightly and moderately, but hardly seriously or completely. In addition, by comparing the vulnerability of each component, it is found that the bearing is more prone to be damaged than the pier, which indicates that the bearing is the most vulnerable part among the bridges' dangerous components.

The result of transverse seismic vulnerability of each dangerous component shows that under the action of the design earthquake, almost all the piers and bearings will hardly be destroyed completely, and they have certain seismic performance. By comparing

the vulnerability of each component, it is found that the bearing is still the most vulnerable part.

Research on the influence law of central buckle on long-span suspension bridge's dynamic and seismic performance

L.P. Liu, Y. Liu & Y. Li
School of Transportation Science and Technology, Harbin Institute of Technology, Harbin, China. 150090

ABSTRACT: Based on an actual bridge project, three suspension bridge models with different kinds of central buckle were established on Finite Element Analysis model. The influence rule of central buckles on the long-span suspension bridge's dynamic and seismic performance was conducted by modal analysis and dynamic time history analysis. In terms of bridge's dynamic performance, it is found that the central buckle increases the overall stiffness of suspension bridge, impacts on the antisymmetric vibration mode significantly, and restrains longitudinal floating modes effectively. Besides, the rigid central buckle can make main cable's vibration modes in advanced. In the aspects of bridge's longitudinal seismic performance, the central buckles reduce the main girder longitudinal displacement and increase both main girder and main cable in the middle of span's internal force with these effects of the rigid central buckle increasing. The results also show that the central buckles make little influence on the displacement and internal force of bridge's other section. In the transverse direction, only the set of rigid central buckle increases the main girder's mid-span shear force, and doesn't influence on the displacement and internal force of the other parts. The research can provide some useful suggestions and references for the similar long-span suspension bridge structures' design.

1 INTRODUCTIONS

Setting central buckle at mid-span reasonably is an effective measure to improve rigidity of suspension bridge. Menkveld (2001) and Gimsing (2011) have analyzed the influence of central buckle on the New Tacoma Bridge. Since 1950s, central buckle has developed many derived forms. Viola (2005) has summarized them into three following kinds, 1) rigid buckle: jointing girder with main cable in a relatively fixed connection form at mid-span, such as triangular truss. 2)flexible buckle: establishing longitudinal restraints between girder and cable at mid-span with one or more pairs of inclined suspenders. 3)connecting girder and cable directly at mid-span.

Peng and Shao (2013) have deduced the differential vibrational equation of continuous suspension bridge with central buckle. The result shows that frequency of antisymmetric torsional mode is increased owing to the main cable's antisymmetric additional cable force near the central buckle. Wang et al. (2006a, 2006b) have drawn the following conclusions through studying on the dynamic performance of suspension bridge. Compared with short suspenders, setting central buckle results in improving structural stiffness. And the frequencies of vibration modes are increased in different degrees especially the modes of cable vibrating. Zou et al. (2009) have drawn the following conclusions through research on the effect of central buckle on the dynamic performance of three-tower ground-anchored suspension bridge. Firstly, the 1st vertical bending vibration mode is affected significantly. And some other vertical bending vibration modes are also affected fairly significantly. Secondly, due to the setting of central buckle, frequency of the antisymmetric torsional mode is increased obviously, lateral bending vibration frequencies are also increased, and mode of cable vibration is delayed. Thirdly, impact of central buckle on antisymmetric lateral bending vibration modes in single span is greater than that on symmetric vibration modes. By analyzing the effect of central buckle on dynamic performance of self-anchored suspension bridge, Li and Wang (2013) have concluded that bridge structure's displacement and internal force are affected slightly in elastic stage, whereas they are restrained greatly in elastroplastic stage. Zheng et al. (2009) have studied the influence of central buckle on long-span suspension bridge's deflection distributing law under live loading by Virtual Beam Method. It is the difference of longitudinal displacement constraints of central buckles on main cable that leads to the difference of deflection envelopes. Yang et al. (2008) have concluded that

difference from traditional two-tower suspension ones, the design of three-tower suspension bridges with central buckle may face many problems including the too high structural stress, the complexity of construction, connection and design. Structural responses of self-anchored suspension bridge with central buckle subjected to moving loads and effect of central buckle on overall stiffness of suspension bridges are also researched by Song et al. (2010). Wang (2013) has studied the central buckle's impact on the driving comfort and the vehicle-bridge coupled vibration. Ding (2002), Waisman (2011) and Ivana (2012) have analyzed the role of flexible central buckle and its long-term dynamics.

Setting central buckles in suspension bridges is a two-edged sword. The vibration periods of structure are reduced, so vibrational displacement of structure under excitations is decreased and the bending effect of vibrating short suspenders is mitigated. While some members get increased internal force demanding larger sectional design size. It increases the amount of materials consumption and structural weight. Structure's safety and reliability should be ensured through accurate static and dynamic analysis when central buckle is applied on long-span suspension bridge.

Model characteristics and time-history analysis of a suspension bridge over Yangtze River is conducted. The influence law of different forms of central buckle on seismic performance of long-span suspension bridge are discussed.

2 STRUCTURE AND MODEL

2.1 *Project overview*

The single-span suspension bridge adopts a simply supported structure system with two hinges. It is a fully enclosed, two-way and six-lane expressway bridge with 1490m main span and 470m side span. Seismic fortification intensity of the structural site is 7 degrees. Main cable is made of parallel galvanized high-strength steel wires whose cross-sectional area is 0.5155m^2. In completion state, theoretical design sag of main cable is 149.605m, rise span ratio is 1/9.96 and center distance of the two cables is 34.3m. Longitudinal horizontal distance of suspenders is 16.1m (the ones nearby towers is 20.5m away from the center line of bridge tower). As shown in Figure1, rigid central buckle is installed in the middle of main span to connect girder and main cable rigidly. The central buckle is a triangular truss whose vertical and inclined members are welded by wide-flange beams. And the upper and lower parts of the truss are connected by high-strength bolt group during the installation process. The main beam is closed flat steel box girder, 36.3m wide (comprising wind nozzle configuration) and 3m high. In the tower position, the main beam is supported on sliding bearing set on the crossbeam of tower. Gravity anchorage is adopted.

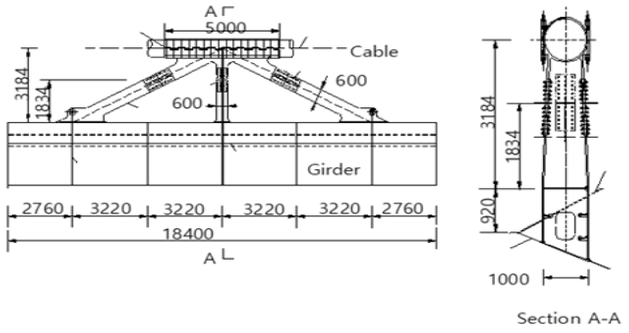

Figure 1. Diagram of the rigid central buckle (/mm)

2.2 *Modeling*

Finite element model of the bridge structure is established according to bridge design parameters by ANSYS Software. And girders are taken as spine beam model. They are simulated by 3D asymmetric variable section elastic beam element BEAM44. While main tower is simulated by 3D elastic beam element BEAM4, and main cable and suspender are simulated by 3D tension-only spar element LINK10.

The actual deck system is a closed all-welded flat streamlined steel box girder, while single-girder spine beam is used to simulate it. And the girder's stiffness and mass are satisfied. Stiffening girder is discreted as beam elements between two suspenders. Girder and suspenders are connected by massless rigid arm. Beam elements' rigidity is equal to stiffening girder's one, while beam elements' density is used to the equivalent one.

Simulation of cable system: main cable discretized according to the lifting points of suspenders is simulated by 3D spar element LINK10. Under competition state, main cable's initial strain is considered as element initial strain. And stiffness owning to gravity is also taken into account. Similarly, suspender is simulated by LINK10 and elements' initial strain is also considered. For mid-span rigid central buckle, diagonal and vertical bars are taken BEAM44 to simulate. For flexible central buckle, LINK10 is adopted.

Simulation of bridge tower: the suspension bridge's main tower consists of pillar and beam and is mainly subjected to axial compression under constant load. Main tower is simulated by beam element BEAM4 and the initial strain is taken into account.

Simulation of boundary condition: the subordinative relationship exists between the lower beam's displacement of main tower and the girder's translations in the bridge's transverse and vertical direction, and rotation in the longitudinal direction. The other three degrees of freedom, including one rotation and

two translations are not bounded. Two ends of main cables are treated as consolidation. Two main towers and the ground are consolidated.

Dimensional finite element model is established as shown in Figure 2.

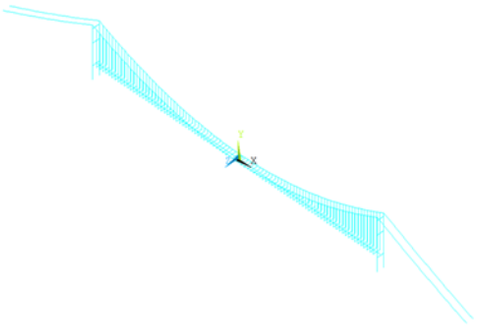

Figure 2. Three-dimensional finite element model of the suspension bridge

3 STRUCTURAL MODAL ANALYSIS WITH DIFFERENT FORMS OF CENTRAL BUCKLE

3.1 *Dynamic characteristic of suspension bridge ınstalled rigid central buckle*

The first 200 orders natural frequencies and mode shapes of this suspension bridge installed rigid central buckle are solved using Method of Block Lanczos. The first 20 orders natural vibration characteristic parameters are listed in Table 1.

Table 1. First 20 order vibration characteristics of the suspension bridge with rigid central buckle

Order	Frequency/Hz	Mode
1	0.04902	Symmetric lateral bending
2	0.08830	Antisymmetric vertical bending
3	0.12309	Antisymmetric lateral bending
4	0.12468	Symmetric vertical bending
5	0.17091	Symmetric vertical bending
6	0.18760	Antisymmetric vertical bending
7	0.21966	Cable's vibration
8	0.21974	Cable's vibration

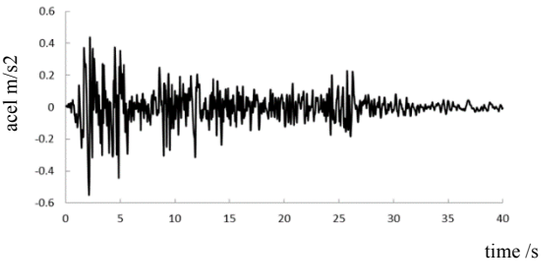
20	0.26690	Side cable's vibration

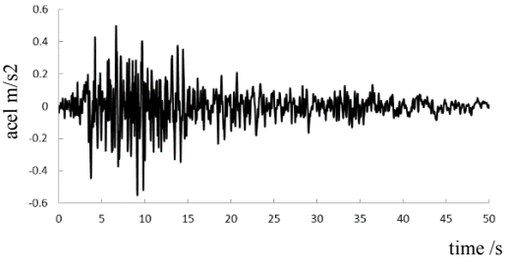
We can draw some laws from the suspension bridge's dynamics behavior listed in tables 1-3.

(1) After installed the central buckle, the structural stiffness of the suspension bridge is increased, the value of stiffness and frequency of the flexibility model is less than the increase in rigid one.



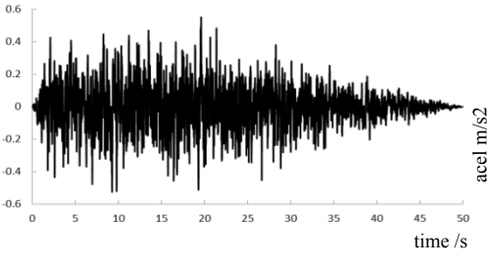
(2) Both the flexible central buckle and the rigid one have much more influence on the antisymmetric vibrating modes than on the symmetric ones, and both can restrain the longitudinal vibrating mode of suspension bridge.

(3) The setting of the rigid central buckle reduces the order of vibrating modes with the cable's vibration, makes the modes emerging in lower frequency. But the effect of flexible central buckle isn't so obvious.



4 DIFFERENT CENTRAL BUCKLES INFLUENCE ON SEISMIC PERFORMANCE

4.1 *Seismic wave data*



According to the site condition, two natural seismic waves and one artificial wave are used as inputting excitation. The three time-history-acceleration curves are showed in Figure 3.

a) El-Centro seismic acceleration time history

b) Taft seismic acceleration time history

c) Artificial seismic acceleration time history

Figure 3. Curves of seismic acceleration time history

The seismic precautionary intensity of the zone is 7 degrees on the Richter Scale. And design parameter of ground motion is 0.15g. The peak acceleration value of the seismic wave is adjusted to 0.55m/s^2 when performing the structure's seismic time-history response analysis under frequent earthquake action.

4.2 *Structural response under earthquake action in longitudinal direction*

Under earthquake action in longitudinal direction, the suspension bridge's structural responses with different modes of central buckle are conducted. The structural modes include bridge structures with rigid buckle, flexible one and none. Table 4 and 5 summarize the information of different central buckle's influence on structure.

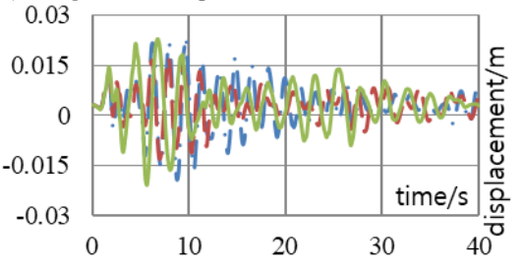
Under the earthquake action of El-Centro seismic wave, time-displacement and time-force curves with different forms of central buckle are plotted in Figure 4.



Some conclusions can be drawn from the above results, 1) the girder's longitudinal displacement decreased after installation central buckles. Among them, the rigid ones' impact is the most. But they have less effect on the longitudinal displacement of main cables and towers. 2) Longitudinal internal forces of girders and main cables increase obviously. As previous case, the rigid central buckle has the biggest influence.

	Stress/MPa	Taft	522	522	522
	Stress/MPa	Artificial	522	522	522

Some conclusions can be drawn from the above results, the transverse shear force increases much with the bigger rigid central buckle. But the flexible central buckle has the less affect.

5 CONCLUSION

The paper analyses the behavior of suspension bridge with three different central buckles, and some conclusions can be drawn.

1)The structural rigidity of suspension bridge can achieve increment by installing central buckle. In which, the rigid one has the most noticeable effect. The structural frequency increases obviously. The rigid central buckle has a great influence on the anti-symmetric torsional vibration mode of long-span suspension bridge, which can effectively restrain the longitudinal floating vibration mode. At the same time, it makes the vibration mode of the main cable in advance.

2)Under earthquake, the setting of the rigid central buckle makes the longitudinal displacement of the girder decreasing, and its mid-span force increasing. But the flexible central buckle has less influence on the tower's force. While in the transverse direction, the rigid one only caused the shear force in the middle span of the girder increasing. And it has less influence on other section's internal force and displacement.

AYALA BRIDGE, retrofitting of an historic steel bridge in Manilla (Philippines)

Vanessa BUCHIN-ROULIE, Nicolas KACZKOWSKI, Alexandre GROS, Fabien TESSON
Freyssinet International, Rueil-Malmaison, France

ABSTRACT: Ayala Bridge, in the center of Manilla, is a steel arch bridge built in the 1950s. It is comprised of 2 simply supported steel bridges constructed with 3 trusses connected together. The bridge has to be retrofitted for conformity to new codes (traffic and seismic). The retrofitting solution designed by Freyssinet was chosen because of its economy when considering both deck and foundations: it consists of minimizing the current seismic loads on piers and abutments, to get them lower than actual loads seen in the past under historic seismic and typhoon. Longitudinally, the 2 decks are linked together and extended with beams and new piles: the overall structure is working as a frame. Transversally, some seismic devices are placed. The overall steel structure is then strengthened using additional steel profiling and prestressing. Major parts of the work has been done with no traffic interruption at all.

1 INTRODUCTION

Ayala Bridge is one of the major bridges located in the center of Manilla (Philippines) over Pasig River. As a strategic axis (20 000 vehicles per day), its closure needed to be reduced to a minimum. It is comprised of 2 independent steel arch bridge of 61,6 meters (south span) and 73,8 meters (north span), constructed with 3 trusses connected together [Figure 1]. Transversally, the deck is composed of a concrete slab supported by stringers beams. The deck of 25,9 meters width supports 4 traffic lanes each of 3,05 meters and 2 sidewalks.

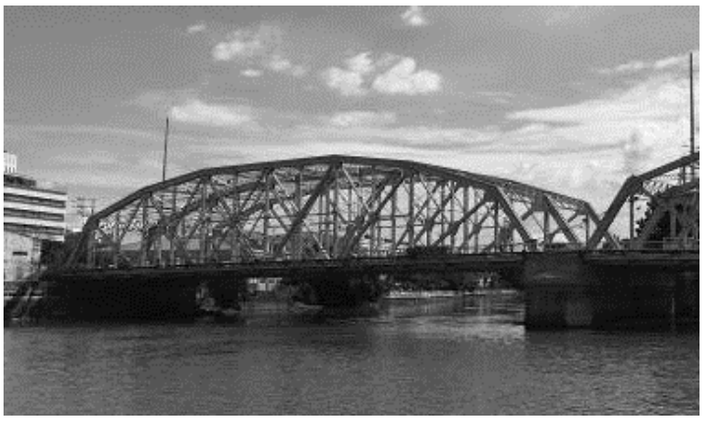

Figure 1. Global view of Ayala Bridge

Each bridge is fixed on piers and free on the abutments longitudinally, and fixed on piers and abutments transversally. The bearings are located under each arch.

The buried part of the concrete pier and abutment is about 2/3 of the total height. Piers and abutments are placed on driven timber piles.

In 2009, the bridge was declared as a historic legacy and landmark by the National Historical Institute, and consequently, should be preserved for posterity.

Rehabilitation and retrofitting of Ayala Bridge should be done in accordance with AASHTO 2002 regarding traffic loads including seismic action.

2 SURVEY AND INVESTIGATIONS

A full diagnosis of the present state of the bridge was done prior to any design work. The aim was to determine the current condition of the structure (steel trusses, bearings, deck, concrete structure), get essentials data to complete the design (confirmation of as built sections), and to check assumptions taken at tender stage regarding the soil capacity.

At this stage, a global geometry inspection of the steel structure are done with a 3D laser scanning technology in order to get the current configuration of trusses members and connecting nodes (with rivets and gusset plates).

For the assessment of inherent material properties and existing conditions, the steel materials are tested

in order to define its grade, strength, weldability, corrosion state and residual thickness. Regarding the concrete, carbonation and chloride content are defined as well as the location of rebar and its diameter. Compressive strength with samples and concrete homogeneity with ultrasonic pulse velocity are also measured to evaluate the quality of the existing material.

Soil investigation consists of cone penetration tests to evaluate the soil bearing capacity. Friction sleeve and vane tests are used to determine soil cohesive strength. CTP piezocone test is added to measure the pore water pressures to aid checking the risk of liquefaction.

Various laboratory investigation with samplings have been done to determine density, sieve analysis, Attenberg's limits and organic content.

The conclusion of tests done on the superstructure is that the steel structure and concrete deck are relatively well preserved, except in some areas located under the deck concrete structure that are extremely corroded. On the other hand, soil characteristics appeared to be poor compared to assumptions taken at tender stage. The retrofitting solution needed then to be adapted to real soil capacity.

If the investigation is correct regarding the substructure and superstructure, a huge risk existing on the wooden pile capacity is identified.

3 DESIGN OF THE RETROFITTING SOLUTION

3.1 *Re-design of the actual bridge*

In order to mitigate the lack of information regarding the wooden piles, the bridge was re-designed with the highest earthquake or typhoon felt since 1950.

The analysis of the existing bridge using FE model with software SAP 2000 allowed us to define the maximum reactions on piers and abutments under traffic loads given by the code used at construction time and existing earthquake or typhon felt since 1950. The stability of piers and abutment were then checked using Plaxis software taking into account soil and structure interaction [Figure 2]: different soil layers are modelized in order to obtain the maximum efforts in the piles. Wooden piles demand were then checked, with seismic action already felt since 1950 and compared to their capacity.

Due to a significant increase of the seismic action to conform to the AASHTO 2002 code, it was not possible to keep the bridge in its actual configuration (overloading of pier foundation and abutment would require significant strengthening). A new solution had, therefore, to be developed by Freyssinet.

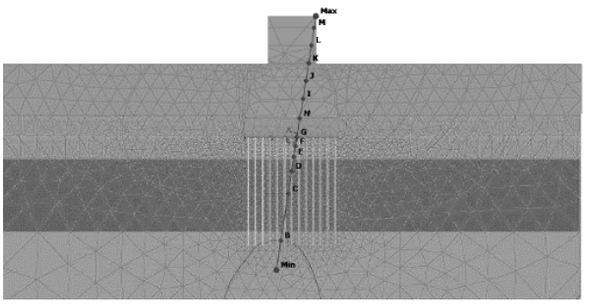

Figure 2. FE model of piers with soil-structure interaction

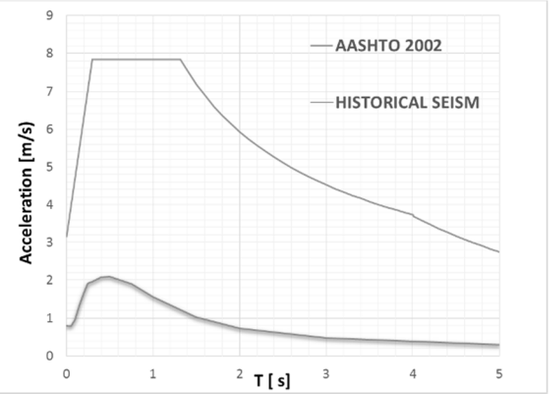

Figure 3. Comparison of AASHTO design spectrum and historic seism spectrum previously experienced by the bridge

3.2 *Seismic retrofitting*

The global behaviour of the bridge is critical for the existing foundations. The chosen retrofitting solution aims at minimizing the loads on the piers and foundations, calculated with current seismic codes, to reduce them to lower than the actual loads seen in the past on the structure under historic seismic or typhoon conditions.

Longitudinally, the two concrete decks are connected together with a continuity slab and extended using ground concrete beams, approach slabs and additional piles [Figure 4]. Indeed, the major longitudinal seismic effect is an axial load. The existing pier and abutments are self-stable when they are surrounded by soil but become unstable under an additional horizontal longitudinal seismic effort. The approaches on ground beams (length 25 meters) and 2 meter diameter pile (length 20m) will support the longitudinal seismic actions. Besides this, in order to minimize the effect on the pier and abutments, the bridge is placed on isolators. The overall structure is then working as a frame, with small impact on the actual foundations. Particular attention was paid to connection of the ground beam to the abutment and to the new piles.

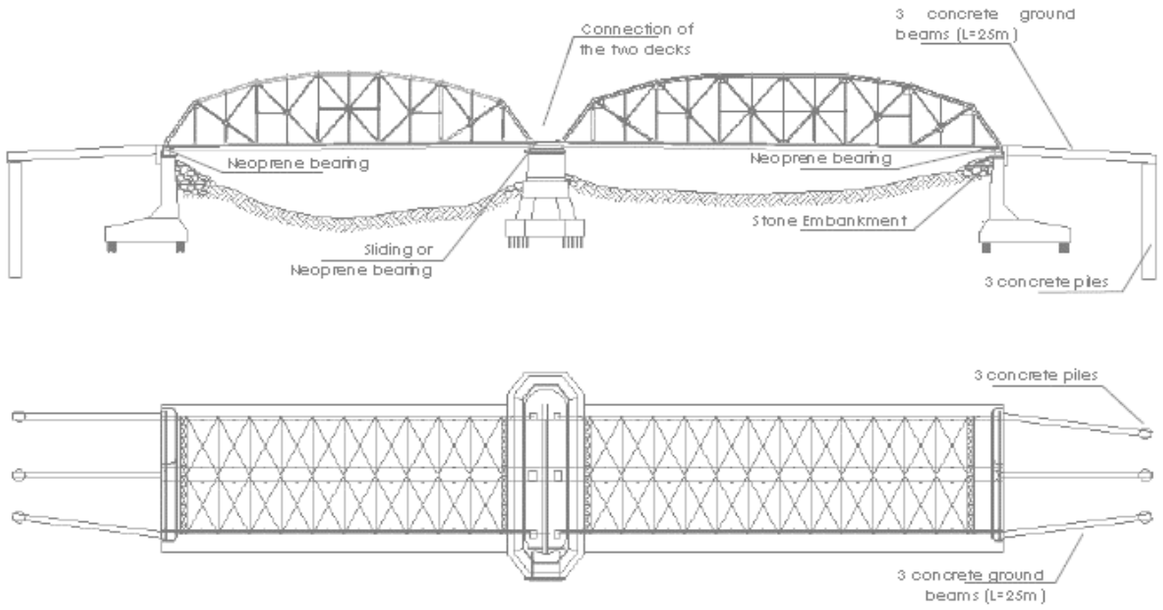

Figure 4. Global view of Ayala Bridge

Transversally, Fluid Viscous Dampers (FVD) are used simultaneously with isolators or High Damper Rubber Bearings (HDRB) to dissipate energy. Lateral stability under service loads is insured thanks to stop fuses [Figure 5]. These seismic devices are used to increase the overall damping and to ensure integrity of the bridge during and after an earthquake. They have low resistance to slow displacement (thermal variation) and become active during seismic motion [Figure 6]. In case of Ayala Bridge, FVD was chosen in order to comply with the past maximum loads seen by the pier [table1]. The overall seismic protection system was designed iteratively.

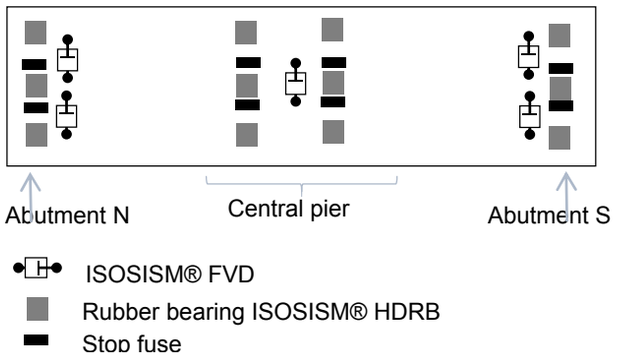

Figure 5. Layout of the bridge for transversal retrofitting

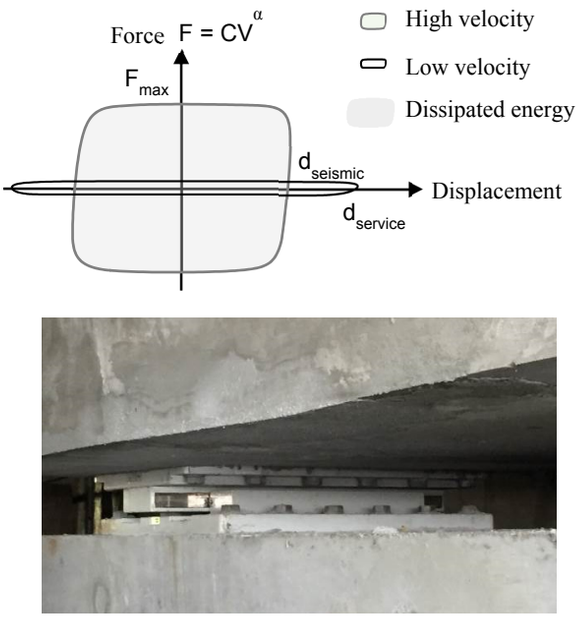

Figure 6. Fluid Viscous Dampers: Behaviour law and picture of FVD installed on pier

Table 1. Comparison of horizontal transversal effort on foundations

Fy	**South abutment [kN]**	**Central pier [kN]**	**North abutment [kN]**
Existing bridge	4063	13884	5125
Already seen typhoon/seism	3656	3656	3656
Retrofitted bridge	3200	2550	3150

Substructures are not completely embedded in the ground (around 2/3 of their height is embedded). Due to high seismic action at ground level and despite reduced longitudinal horizontal efforts, the abutments appear to be unstable whereas the pier remains stable. Considering that buried Substructure are self-stable under earthquake, the retrofitting solution consists, for the north abutment, in placing additional stone revetments on the embankment in front of the abutment [Figure 7]. This solution could not be applied to the south abutment, due to the depth of the river bed. Indeed, the stone embankment would have defined a slope that would have had an impact on the ship channel. To ensure stability of south abutment, 18 soil nails each of 25 meters long (capacity 800 kN) were required to be placed along the abutment [Figure 8].

Figure 7. Embankment for north abutment

Figure 8. Soil nails dispatched along north abutment

3.3 *Concept of the bridge strengthening*

The whole structure was checked using a 3D model on SAP 2000. All steel profiles were checked according to AASHTO 2002 code. This strengthening solution was chosen due to its economy in terms of work and materials.

The strengthening solution consists of adding a T profile welded on the top chord and on top of the transverse beam (to mitigate transversal effects) [Figure 9 and Figure 10].

Specific top nodes of the steel truss have been detailed to provide a proper connection between top chord and the top transverse strengthening members by taking into account the existing riveted gusset plates [Figure 11].

The bottom chord was strengthened by adding a straight centrally mounted prestressing cable placed inside the profile of each truss in order to balance extra-tension.

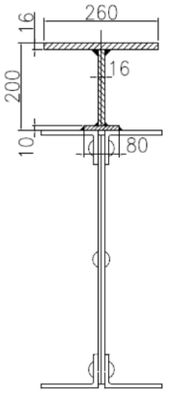

Figure 9. T profile welded on transverse beam

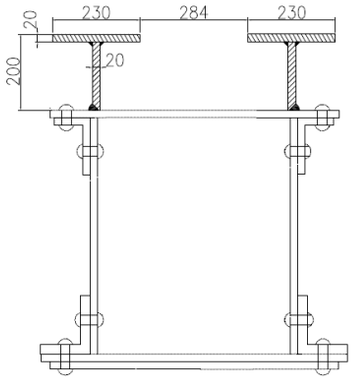

Figure 10. T profiles welded on top chord

The longitudinal rebars placed in the existing concrete slab appeared to be discontinuous at each crossbeam. In order to ensure the global function of the concrete slab during transversal seismic event, it was necessary to recreate this continuity by pouring a new slab (connected to the old one) on the top of the existing one. Finally, the full steel structure was sandblasted, restored locally as required to protect using a long-term corrosion protection system [Figure 12].

Figure 11. Example of node strengthening

Figure 12. View of the top chord being protected

4 JACKING OF THE BRIDGE

The bridge had to be jacked up of 70 cm in order to respect the required clearance regulation. The jacking was done prior to the retrofitting works, using a portal frame placed at each arch extremity with associated strand jacks [Figure 13. The connection of the cable to the deck structure was made with bespoke designed lugs fixed to the bearing pin [Figure 14]. The whole span was lifted simultaneously. After jacking, the approaches were adapted to suit the new bridge elevation.

Only jacking operations were done with traffic interruption. All other operations were done with full traffic or limited traffic (2 lanes instead of 4) on the bridge.

Figure 13 Bridge during jacking operation

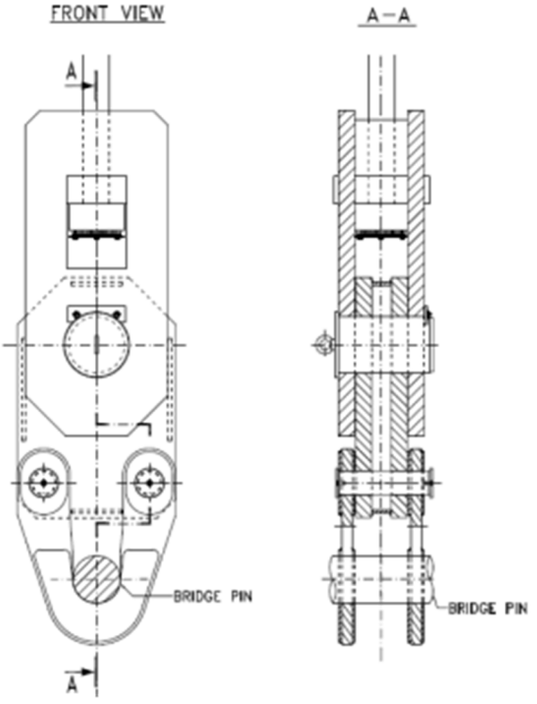

Figure 14 Lifting lugs

5 CONCLUSION

In this paper, we present an innovative solution designed and applied by Freyssinet on the Ayala Bridge in Manilla (Philippines). The technical solution consisted of reducing the load to the foundations using dampers and isolators (transversally) and an extended structure to support seismic loading (longitudinally).

One of the key elements for success in such project has been the need for the preliminary inspection to be as exhaustive as possible. Finally, this paper is presented to enable the reader to develop a full and comprehensive understanding of the different problems to be solved when considering any number of given/ chosen repair techniques.

Orthotropic steel bridge deck study with UHPFRC cold composite overlay

L. Duan, T. O. N. Houankpo & C. S. Wang
Engineering Research Center for Large Highway Structure Safety of Ministry of Education, Chang'an University, Xi'an, China

E. Brühwiler
Laboratory MCS, École Polytechnique Fédérale de Lausanne (EPFL), Lausanne, Switzerland

ABSTRACT: This paper propose that steel bridge deck reinforced by UHPFRC (ultra-high performance fiber reinforced concrete) overlay on deck plate with cold composite design method. Sustainable and reliable composite design between steel plate and UHPFRC is a significant factor to ensure expected structural performance of steel and UHPFRC composite element. Test and numerical analysis were carried out to study behavior of steel bridge deck with UHPFRC composite overlay adopting cold connecting, including casting UHPFRC layer directly on steel plate, adopting gluing stub, and gluing corrugated steel plate connector, respectively. In experimental study, series of UHPFRC and steel deck plate composite specimens were fabricated and tested considering different composite ways. It was analyzed the stress state and the relative displacement between UHPFRC layer and steel deck plate. Results from test study indicate cold connecting corrugated steel plate connector was an optimal composite design method. Calibrated by test result, FE model was established for steel bridge deck with UHPFRC composite layer. It was analyzed the interface behavior between UHPFRC and steel deck plate, and also the stress reduction level of fatigue details in steel bridge deck. Learn from FE analysis study, UHPFRC composite overlay design method could improve local rigidity obviously and also reduce stress range at typical fatigue detail in steel bridge deck.

1 INTRODUCTION

Orthotropic steel bridge deck was characterized with large capacity, low dead load, fast factory prefabrication, etc. Thus, it was applied in lots of large span bridges, especially cable stayed bridge and suspension bridge. During the long-term service stage, if without efficient and in-time maintenance strategies, the structural performance of bridges would degrade due to couple action of increasing vehicle loads, environmental corrosion, material performance degeneration, occasional overloading problem, or other unpredictable factors, which reduce existing service life and threaten bridge safety obviously. Learn from engineering experience, problems of fatigue cracking and overlay durability on steel deck plate are two typical problems found in orthotropic steel bridge deck.

For fatigue problems in steel bridge deck, several researchers have been carried out fatigue tests for orthotropic steel deck in order to study the fatigue performance at different fatigue details and the welding methods (Tsakopoulos & Fisher 2005, Wang et al. 2012, Wang et al. 2016). Fatigue cracking has generally been found at four typical fatigue-sensitive regions in orthotropic steel bridge deck due to low stiffness, welding defect, residual stress and so on, especially in heavy traffic lanes (Connor & Fisher 2012, Wang et al. 2012). Fatigue cracks at deck plate are the most severe ones in typical fatigues, because the deck has a large deflection under wheel load to produce large transverse bending moments. With increasing knowledge for orthotropic steel bridge deck, the thickness of deck plate is increasing from 12mm in early design to 20mm in complicated detail nowadays in design. However, it is not an economical way to achieve rigidity by increasing deck plate thickness.

The durability problem of overlay on steel deck plate was caused by increasing traffic intensity influenced directly above and complicated environmental effector. There are typical three kinds of overlay for steel bridge deck, including traditional mastic asphalt, thin epoxy resin surfacing impregnated with granules and reinforce high performance concrete (RHPC) layer. The thicker mastic asphalt overlay has relative greater stiffness or rigidity than the epoxy resin overlay. The fatigue cracks in deck plate have been detected in orthotropic steel bridge structure either with a thick asphaltic surfacing or with a thin epoxy layer. Compared with mastic asphalt overlay, RHPC layer has greater stiffness without increasing dead load. Learn from engineering experiences, typical overlay damages include overlay fatigue cracking, local failure, track, delam-

ination, etc. Compared with overlay performance in concrete bridge, overlay in steel bridge have a relatively short service life, since they usually carry great local deflection and is vulnerable to fatigue cracking and local failure (Walter et al. 2007). For example, it was found pavement damage and fatigue cracks in steel bridge deck for Van Brienenoord Bridge in the Netherlands (Jong, 2007); there was obvious pavement local damage of Mafang Bridge in China, because of less rigidity, heavy vehicle volume and vehicle amount (Li et al., 2015).

In order to improve structural performance and extend service life, researchers have devoted to study improved design methods and effective reinforcement methods for orthotropic steel bridge decks. For example, several reinforcement methods were proposed and studied, like applying gusset plate, using high performance concrete overlay layer, special types of asphalt concrete, gluing hard wood beams, filling troughs with polyurethane, bonding second steel plate and so on (Kolstein 2007, De Jong 2007).

Ultra high performance fiber reinforced concrete (UHPFRC) shows relatively high compressive strength, high tensile strength, high compactness and good workability (Makita & Brühwiler 2014). It was encouraged the method of applying UHPFRC layer on steel deck plate by cold connecting (epoxy bonding) shear connector. In this method, a composite layer of UHPFRC increases the rigidity and leads to wider distribution of concentrated wheel loads, leading to a significant decrease in fatigue relevant stresses and local deformation. Instead of welding connectors on deck plate, cold bonding connectors can avoid new fatigue vulnerable detail introduced in welding process. Thus, the method realize an UPPFRC-steel bridge deck composite system, which can enhance pavement performance and improve the local rigidity.

The interface behavior between the UHPFRC layer and the steel deck plate was an important factor to achieve effective UHPFRC-steel bridge deck composite system (Duan et al. 2015). This paper focus on sustainable and reliable composite design study between steel deck plate and UHPFRC. Both test study and numerical analysis were carried out to explore interface behavior and effective shear connector designs. In experimental study, UHPFRC and steel deck plate composite specimens were fabricated and tested considering different composite ways, including without shear connector design and gluing corrugated steel plate shear connector. Calibrated by test result, FE model was established for orthotropic steel bridge deck model with UHPFRC composite layer in Abaqus software. It was analyzed the interface behavior between UHPFRC and steel deck plate, and the stress reduction level at fatigue details in steel bridge deck.

2 RESEARCH BACKGROUND

Effective composite design between UHPFRC overlay and deck plate can ensures overall load carrying behavior of UHPFRC – orthotropic steel bridge deck composite system, thus improving pavement performance and reducing stress range at fatigue sensitive detail of orthotropic steel bridge deck. Several researchers have devote to overlay composite design with orthotropic steel bridge deck. Generally, this composite design can be achieved by welding shear connectors, like stubs, curved rebars, L or T shape steel plates, welded steel mesh or steel plate with holes (PBL). Since new fatigue detail will be introduced during fabrication stage when adopting the traditional welding for connectors, it is explored to glue connectors with epoxy resin. The study at Adhesion Institute at the Delft University of Technology was focused on three possibilities: prefab overlay glued on steel deck by a wet two-component epoxy paste adhesive; casting on a wet two-component epoxy paste adhesive; placing overlay in a dry two-component epoxy paste adhesive with shaked in aggregates (Buitelaar & Braam 2004).

Shao focused on reactive power concrete (RPC) material exploration and RPC overlay design on steel bridge deck, in order to reduce stress at fatigue sensitive details of orthotropic steel deck. Learn from series of experimental and numerical results, the thin RPC pavement can effectively eliminate the risk of fatigue cracking in steel deck (Shao et al., 2012). The compact reinforced reactive powder concrete (CRRPC) was explored and applied to strength deteriorated asphalt overlays and to strengthen orthotropic steel deck (OSD) bridges, and the FE analyses and fatigue tests had found that the thin CRRPC layer reduced the vehicle-induced stresses in the steel bridge deck significantly (Cao et al. 2015).

By using the FE analysis, Walter (Walter et al. 2007) had modeled the connection between the overlay (cement concrete) and underlying steel deck by using an 8-node interface element available in DIANA software, together with a user-supplied constitutive model. Based on force-slip relationship and in order to study the interface between concrete and steel beam, springs elements had been used by Lin to simulate the shear stud connector between the concrete and steel beam (Lin et al., 2013). Experimental tests and numerical analysis had been concluded by Dieng (Dieng et al., 2013). In order to model the interface behavior between the UHPFRC overlay and steel deck in orthotropic steel deck bridge, he used the Coulomb's law and Coulomb's friction model developed in MSC. Marc (MSC. Marc Volume A, 2005).

3 EXPERIMENTAL STUDY

3.1 *Test program*

Experimental study is conducted for UHPFRC and steel deck plate composite beams considering different composite effects, in order to study the composite structural behavior and find out optimal composite design method. In this paper, two simple supported specimens with loading (F) at mid-span were designed to study the bending behavior of specimens. The loading device is shown in Figure 1.

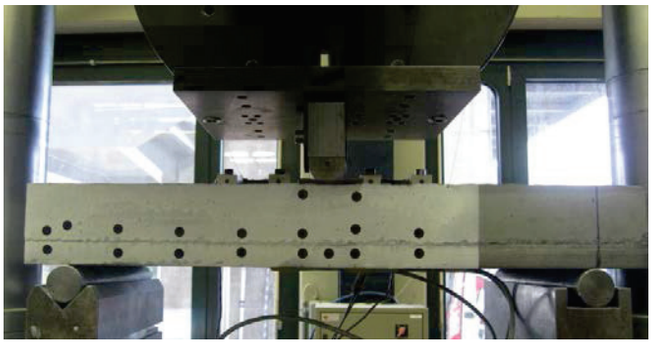

Figure 1. Applied load setup.

The span length of specimens were 420mm, and the width were 200mm. The thickness of steel plate was 20mm and the thickness of UHPFRC layer was 40mm. For specimen 1, the top surface of steel plate cleaned and shot blasted, epoxy is brushed on entire span length and aggregate is put on this epoxy interface, and then UHPFRC layer was cast. For specimen 2, after shot blasting steel plate, epoxy is brushed on entire span length, two connectors are glued at each half span, and then UHPFRC layer was cast. Figure 2 shows corrugated steel plate shear connectors glued on steel plate, which were fabricated by 4mm steel plate.

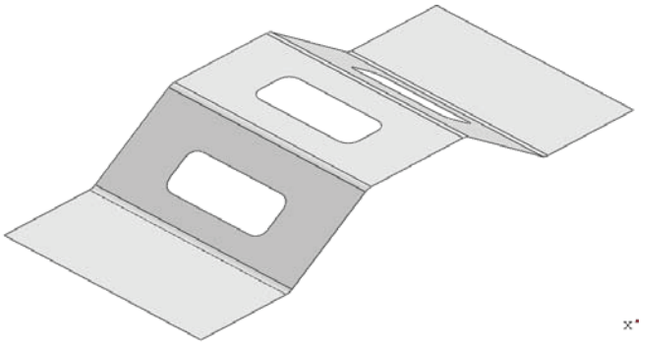

Figure 2. Corrugated steel plate shear connector.

3.2 *Test result analysis*

Specimens 1 and 2 have the same geometrical dimension, but different composite effect. The bending behaviors were described by force and steel strain at mid-span relationship, shown in Figure 3. Learn from Figure 3, at initial loading stage, specimen 1 has an early capacity reduction, which is caused by stably development of delamination between UHPFRC and steel under relatively weak composite design. The ultimate capacity of specimen 1 is controlled by interface composite effect. For specimen 2, there is a hardening stage, since greater shear resistance is supplied by composite interface by glued connectors. Thus, composite design effect, especially before steel plate yielding, is a significant factor to enhance structural rigidity.

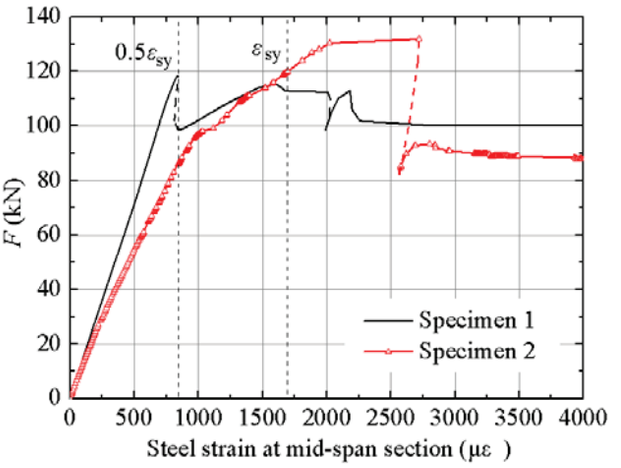

Figure 3. Force and steel strain curves.

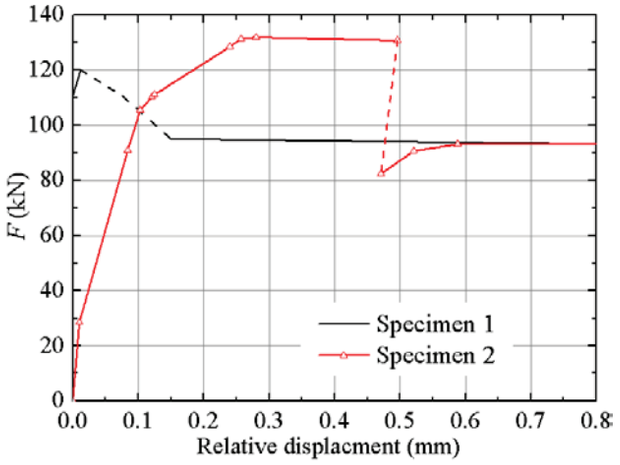
In order to describe interface effect between UHPFRC layer and steel plate, relative displacement between UHPFRC and steel flange is measured at one end of specimens during loading procedure. Figure 4 shows force and relative displacement at one end of specimen. Learn from Figure 4, specimens 1 with epoxy gluing interface have greater rigidity improvement, which supplies even shear resistance along all span length. The relative displacement between two layers is always about zero before ultimate capacity. The ultimate capacity of specimen 1 is controlled by interface composite effect. For specimen 2, there is a bi-liner force and relative displacement curve before steel plate yielding. Before tensile elastic limit strength of UHPFRC, specimen 2 has no relative displacement, since specimen 2 with two connectors has sufficient shear resistance. When loading beyond tensile elastic limit strength of UHPFRC flange, there is a stable relative displacement increase in specimen 2. As steel plate is yielding, deflection in specimen 2 are increasing nonlinearly, which accelerates interface failure. Then the ultimate capacity is controlled by composite interface failure, like connector glue area sudden failure. After failure of connector glue surface, there

is a drop of capacity for specimen 2, and then specimens turn into a platform stage.



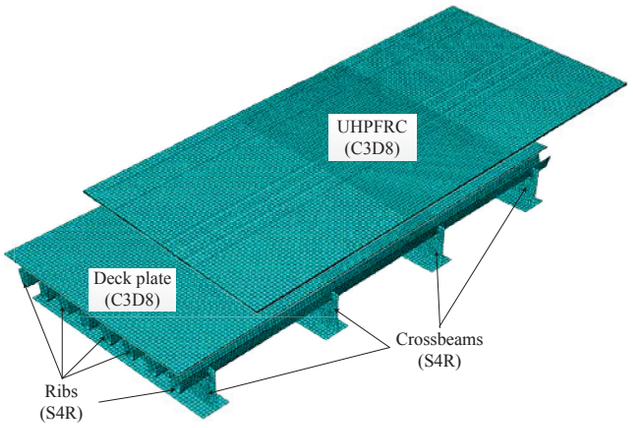


Figure 4. Force and relative displacement curves.

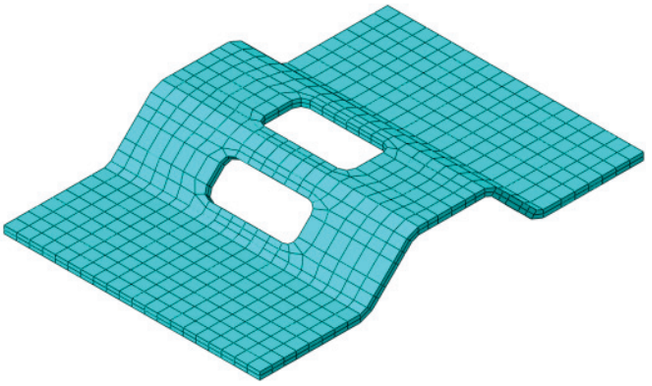
For specimen 1 and 2, the bending procedure can be described by four stages. Firstly, mid-span section is in elastic until attaining compressive strength of UHPFRC. The relative displacement is almost zero in this stage. Secondly, the mid-span section gradually turns into partial elastic until steel plate yielding. After steel plate yielding, the displacement grows quickly with force increasing slowly. Thirdly, as strain increasing obviously, crack is propagating through thickness of UHPFRC flange quickly, reducing effective section area. As crack propagating in UHPFRC flange, interface cracking is also quickly developed. Fourthly, the specimen attains ultimate capacity, which is controlled by interface delamination or resistance of mid-span section. After ultimate capacity, plastic hinge is formed at mid-span region and specimen turns into a platform stage.



4 FINTE ELEMENT ANALYSIS

4.1 *Model establishment*

Typical full scale orthotropic steel deck model was selected from a suspension bridge for numerical analysis. The FE model consists of a UHPFRC layer, deck plate, longitudinal ribs, and cross beams. The FE model was 10.2 m long, 4.8 m width and 0.972 m high, shown in Figure 5. The thicknesses of deck plate, longitudinal rib and cross beam were 16 mm, 8 mm, and 10 mm, respectively. The dimension of longitudinal rib is 300mm (width) × 280mm (height) × 8mm (thickness). The FE model contains 8 longitudinal ribs with center distance of 600 mm. In longitudinal direction, the model has three spans of 3.0 m +3.0 m + 3.0 m. The thickness of UHPFRC layer above deck plate was 40 mm. Two kinds of composition effects between UHPFRC layer and deck plate were considered, including no shear connector and epoxy bonded with corrugated steel plate shear connector. The bonded corrugated steel plate connector had been modeled on the orthotropic steel deck bridge. In the FE model, 4 mm corrugated steel plate connector (shown in Fig. 5(b)) and 2 mm epoxy adhesive were taken into account in order to be uniform with experimental studies.

(a) Steel bridge deck segment with UHPFRC overlay.

(b) Simulation of corrugated steel plate connector.

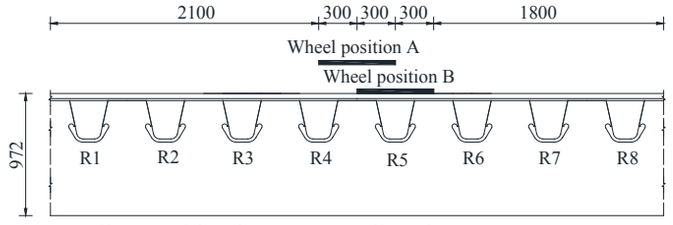


Figure 5. Establish of FE models.

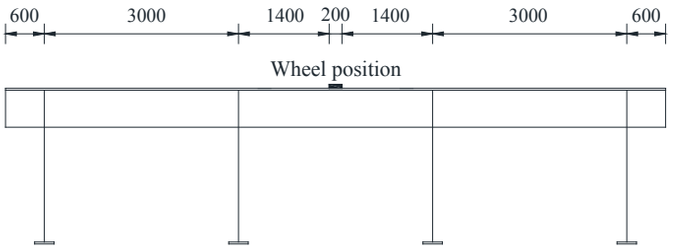
In sofeware of Abaqus, Figure 5(a) shows the meshing of the different elements, such as solid elements eight-node brick elements with reduced integration (C3D8R) were used for the UHPFRC layer and deck plate, and four-node doubly curved shell element with reduced integration (S4R) was used for the crossbeams and ribs.



In this model, steel grade of Q345q (with nominal yield strength of 345MPa) was used for steel bridge deck. For steel grade of Q345q, the Young's modulus of Q345q is 206GPa, the Poisson's coefficient is 0.3, and the ultimate tensile stress is 424.35MPa. Both compressive and tensile properties of UHPFRC were considered in FE analysis. The compressive yield strength of UHPFRC was 128MPa, and the Young's modulus was 50GPa. The elastic tensile strength of UHPFRC was 6.8 MPa, and the Young's modulus was 50GPa. The ultimate tensile strength of UHPFRC was 9.3MPa. The

Young's modulus of the epoxy resin is 12.3 GPa and the Poisson coefficient is 0.34.

One wheel tire contact area (600× 200mm) for fatigue vehicle type 3 was adopted for static loading, according to the " Specification for Design of Highway Steel Bridge" (JTG D64-2015) in China. The loading position is shown in Figure 6. The deck plate supported on several longitudinal ribs had similar behavior with continuous beam under wheel loads. In Figure 6(a), two loading positions (position A and position B) for wheel loading were considered to achieve maximum position moment and negative moment, respectively. In Figure 6(b), wheel loads were located at mid-span section of middle span length.

(a) Loading position in transvers direction.

(b) Loading position in longitudinal direction.

Figure 6. Loading positions (unit: mm).

4.2 *Interface simulation*

The bonded interface behavior between corrugated steel plate shear connectors and steel plate UHPFRC was modeled by the friction method described by contact friction finite elements of Abaqus library (Houankpo, 2016). The kinematic method used in simulation consists to define the contact without penetration and friction conditions at the different nodes. This method using the Mohr-Coulomb's friction law allowed approaching the real behavior of the interface. According to the Figure 7, forces and relative displacements allowed to express the contact variables behavior at the nodes. The normal displacements with corresponding forces components (Un, N) and tangent displacements with corresponding forces component (Ut, T) can used to explain the conditions of contact friction.

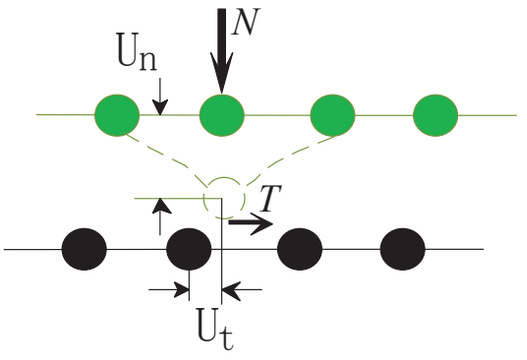


Figure 7. Contact variable in Coulomb's friction law.

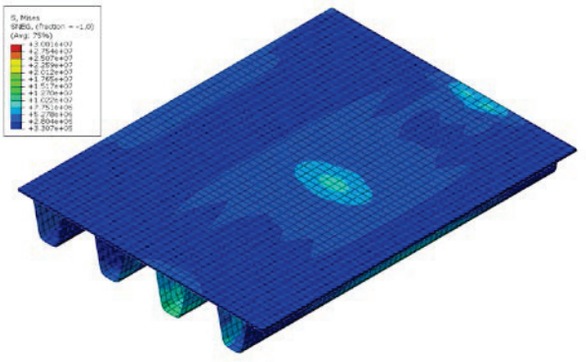
The contact without penetration condition can be expressed as:

$$\left(U_n \geq 0 \ \textit{and} \ N \geq 0\right) \Rightarrow U_n N = 0 \tag{1}$$

The friction condition is:

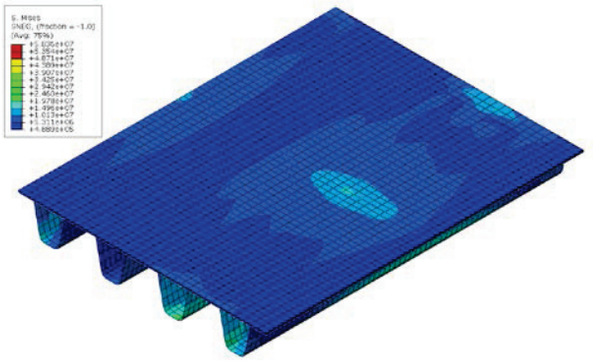
$$\left(U_t > 0 \Rightarrow -\overline{T} = \mu \overline{D}\right) \text{or} \ \left(U_t > 0 \Rightarrow -\overline{T} < \mu \overline{D}\right) \tag{2}$$

where $\mu = \frac{T}{N}$ is the friction coefficient and $\overline{D} = \frac{\overline{U_t}}{\left|\overline{U_t}\right|}$.



4.3 *Results analysis*

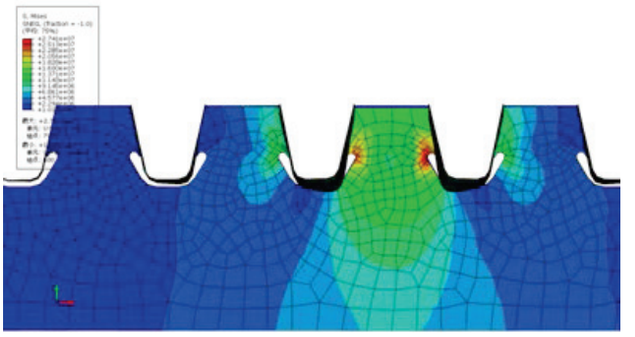
4.3.1 *Local stiffness analysis*



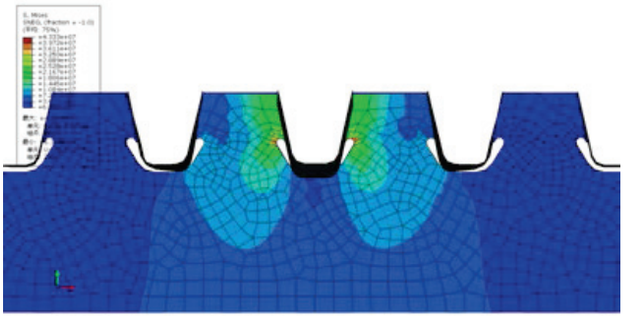
Learn from analysis results for the two models, deflections of deck plate were compared for local stiffness analysis, and the stresses at typical fatigue sensitive details were also compared. For the loading case A (shown in Fig. 6(a)), the deflection at bottom of deck plate between rib 4 and rib 5 were 0.49mm and 0.02mm for FE models with and without connector, respectively. The local stiffness of the deck plate increase 92% when adopting corrugated steel plate shear connector (cold bonding shear connector). The interface shear stresses under loading position were 6.8MPa and 2.33MPa. The shear stress at bottom of UHPFRC layer had been decreased about 66% because of contribution from composite design. The stresses at rib to deck plate detail were 98.89MPa and 43.53MPa for models with and without composite design (shown in Fig. 8(a)).

For the loading case B, the deflection at bottom of deck plate under rib 5 were 0.59mm and 0.14mm for FE models with and without connector, respectively. It can be noted that the stiffness of the pavement-deck plate system with bonded formed steel plate had been improved about 86.31%. The deflection at

the bottom of the rib5 had improved 50.3% if adopting composite effect. The stresses at rib to deck plate detail were 56.2MPa and 9MPa for models with and without composite design (shown in Fig. 8(b)). The normal stresses calculated at the free edge of crossbeam were 92.72 MPa and 52.27 MPa respectively, which contribute a lot to stop fatigue crack initiation and propagation.



(a) Loading postion A.

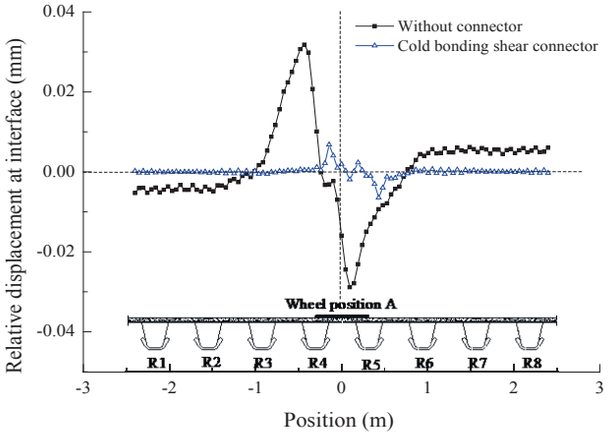


(b) Loading postion B.

Figure 8. Stress at rib to deck details.

For the FE model without shear connector, the calculated maximal stresses at free edge cutout of crossbeam were 36.68 MPa under loading position A and 43.33MPa under loading position B. Figure 9 shows stress distributions at free edge cutout of crossbeam for models for the FE model with colding bonding shear connector. These stresses value at free edge cutout of crossbeam had been reduced 26.40% and 30.76% respectively for the loading case A and B, respectively.

(a) Loading case A.



(b) Loading postion B.

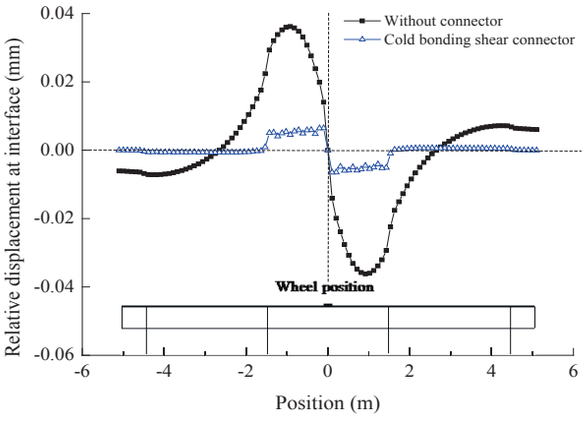


Figure 9. Stress at cut-out rib to crossbeam details.

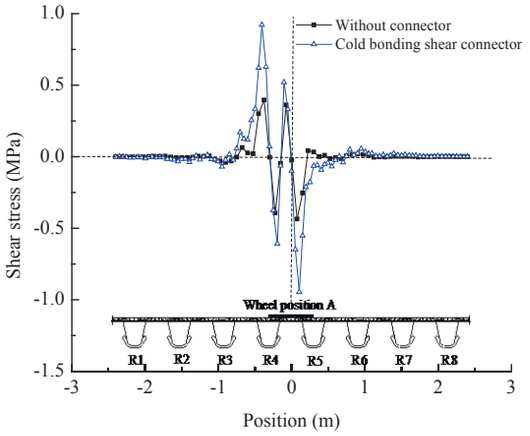
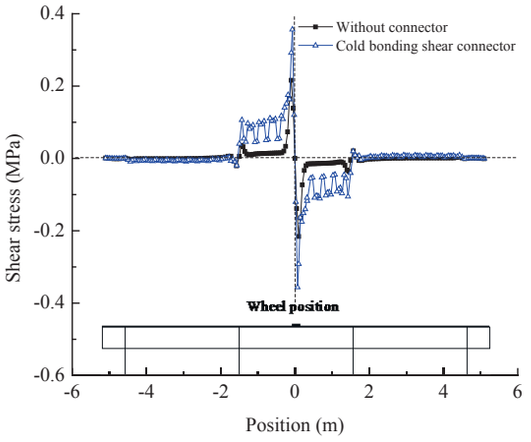
4.3.2 *Relative displacement analysis*

Under loading position A, the relative displacement between UHPFRC layer and steel deck plate was analyzed. As shows in the Figure 10(a), the relative displacements were anti-symmetrically distributed along the transverse direction of cross section. For FE model without shear connector design, the maximal relative displacement was 0.36 mm around the wheel attaching surface, which this maximal relative displacement for FE with cold bonding shear connector was 0.06 mm. This difference of relative displacement would be more obvious with loading level increase. Figure 10(b) shows that the relative displacements distribution along the longitudinal direction. Learn from Figure 10(b), this relative displacement distributions between UHPFRC layer and steel bridge deck plate were also anti-symmetrically with the wheel loading position. The cold bonding shear connector had improved the composite action for UHPFRC layer and steel bridge deck system effectively by limiting relative displacement at interface.



(a) Transversal direction.



(b) Longitudinal direction.

Figure 10. Relative displacement at the interface of UHPFRC layer and steel deck plate under loading position A.

(a) Transversal direction.

(b) Longitudinal direction.

Figure 11. Shear stresses at the interface of UHPFRC layer and steel deck plate.

The shear stress at the interface between UHPFRC layer and steel deck plate was comparatively analyzed under the loading position A, shown in Figure 11. Learn from Figure 11(a), the interface shear stresses were anti-symmetrically distributed along the transverse direction of cross section. For FE model without shear connector, the maximal shear stress was 0.44 MPa around the wheel attaching surface, which maximal shear stress for model with cold bonding shear connector was 0.91 MPa. This difference of shear stress would be more obvious as loading level increase. Figure 11(b) shows the shear stress distribution along the longitudinal direction. FE analysis results revealed that the cold bonding connectors had a maximum shear stress of 0.36 MPa under the wheel attaching surface. It can be concluded that the cold bonding shear connector can ensure the composite action of the UHPFRC-steel bridge deck system by enhanced its shear resistance of the interface.

5 CONCLUSIONS

This paper is focused on orthotropic steel bridge deck composite with UHPFRC layer by cold bonding shear connector. Bending tests were conducted for steel and UHPFRC composite beams with different composite design ways, including epoxy gluing UHPFRC layer and bonding corrugated steel plate shear connectors.

(1) Learn from test study, composite design between steel and UHPFRC is an important factor affecting structural rigidity. Cold bonding corrugated steel plate shear connectors adopted in test study was proved to be an efficient composite design method.

(2) Finite element model was established by software of Abqus for two orthotropic steel bridge deck model with UHPFRC layer, considering no shear connector and cold bonding shear connector respectively. Learn from comparative analysis results, steel bridge deck and UHPFRC layer composite system can improve load rigidity of steel bridge deck and decrease stress level at typical fatigue details, which proved the effective composite ways of bonding corrugated steel plate shear connectors

Effect of Diaphragms on the Exterior Girders during Bridge Construction

F. Hraib, L. Hui, R. Hindi
Department of Civil Engineering
Saint Louis University, St. Louis, MO, United States

ABSTRACT: During the construction of bridges, both live and dead loads play a critical role in the safety of the construction and the future serviceability of the bridges. Loads from screed machine and the fresh concrete weight can cause deflection of the overhang and excessive exterior girders rotation. The bridge permanent diaphragms keep the girders stable during construction, and they can potentially reduce the rotation as long as they are spaced properly. The main purpose of this study is to examine the effect of the spacing between diaphragms on the rotation of the exterior girder. Finite Element models were developed using SAP2000 software to simulate bridges with different diaphragms spacing. The results show that reducing the distance between diaphragms by 40% can decrease the rotation of the exterior girders by more than 60%. It also shows that the location of the screed machine along the span is very crucial.

1 INTRODUCTION

Construction of bridge superstructures is a very critical stage that if it is not carefully taken into consideration with the corresponding construction loads, many issues and deficiencies can occur during construction and the service life of the bridge may reduce. The lack of attention to loads and details during construction might result in significant instability of the structure and even failures of the bridges (Helwig and Yura 2012).

The overhang part of the deck slab is usually defined as the horizontal distance between the center line of the exterior girder and the edge of the bridge deck. The purpose of the overhang is to outspread the deck slab in the transverse direction which increases the deck's width without adding more girders. During construction, the overhang is subjected to loads from the fresh concrete weight, the screed machine weight, construction live loads and the weight of form work (Ashiquzzaman et al. 2016). The overhang formwork is often supported using steel brackets that rest on the web of the exterior girder, which creates torsion moments on the exterior girders as shown in Figure 1. These moments can lead to vertical deflection of the overhang and rotation of the exterior girder during construction (Clifton and Bayrak 2008). Hence, as the concrete is not hardened yet, and because of the deflection of the overhang formwork, a non-uniform deck slab thickness is expected in the transverse direction after the concrete is hardened. Also, as the steel brackets rest on the exterior girder, the girder can be subjected to excessive rotation and local buckling that may lead to reduction in the girders resistance and poor rideability in the future (Ashiquzzaman et al. 2017; Clifton and Bayrak 2008; Fasl 2008).

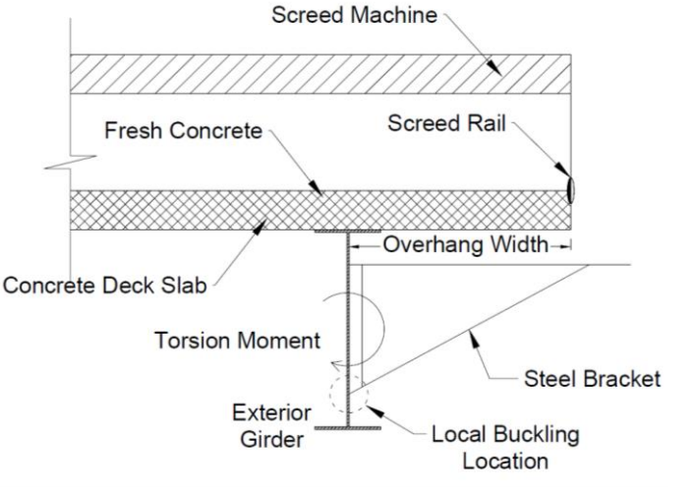

Figure 1. Overhang Definition and Exterior Girder Torsion Moment.

Permanent transverse bracing systems, represented by diaphragms or cross-frames, are designed to resist lateral forces during the service life of the bridge and assure stability of girders during construction. They also can resist the torsion moments in exterior girders from loads during the construction. However, these systems are not designed for loads during construction, and contractors tend to add temporary bracing systems to reduce the rotation of exterior girder. Common temporary bracing systems used now a days are timber blocks, diagonal and transverse ties and temporary cross-frames (Ashiquzzaman et al. 2016). The rotation of exterior girder is highly dependent on the geometry and the structural properties of the bridge superstructure (Ito et al. 2002; Schilling 1988).

The main purpose of this study is to examine the effect of the spacing between the bracing members on the rotation of the exterior girder. Finite Element models were developed using SAP2000 software to simulate bridges with different diaphragms spacing. The location of screed machine loads along the span of the bridge is examined as well to understand its effect on the girders rotation during construction. The study is concerned only with multiple span non-skewed steel girder bridges with steel diaphragms.

2 REFERENCE BRIDGE AND FE MODEL

In order to study the effect of diaphragms spacing, a reference bridge is selected as a benchmark. A three span field instrumented bridge was chosen for this study. Figure 2 shows the plan view of the reference bridge with its geometrical properties. It shows that the bridge superstructure consists of three W30x124 steel girders along three spans of 15.16 m (49`- 9``), 24.5 m (80`- 4``) and 15.16 m (49`- 9``). The girders spacing is 2.13 m (7 ft) with an overhang width of 94 cm (37 in) on each side. The original bridge is skewed by 3.8 degrees, but the skewness can be neglected in this study as it is very small and out of the scope of the research.

The diaphragms locations and spacing are also shown in Figure 2. C12x25 sections are used as diaphragms at all required locations in the reference bridge. The bridge is subjected to the fresh concrete load and the screed machine loads because they have the most effect on the rotation of the exterior girder. The weight of the concrete is taken based on the thickness of the deck slab that equals to 20 cm (8 in). On the other hand, the screed machine weight is distributed through 4 wheels on each overhang. The wheels weigh 340 Kg (750 lbs) each, and spaced at 61 cm (24 in), 122 cm (48 in) and 61 cm (24 in) from each other.

Finite Element (FE) models were developed using SAP2000 to simulate all bridges in this study. The FE model used has been verified with the field experimental results during construction (Ashiquzzaman et al. 2016). Figure 3 shows the finite element model of the reference bridge with the FE elements used for each corresponding member of the bridge's superstructure. Thick shell elements were used for both the girders and diaphragms while frame elements were used to model the steel brackets. The fresh concrete weight on the overhang part of the slab was simulated as point loads at the middle of each steel bracket, while the concrete in the internal bays is transferred to the edges of girder flanges as point loads along the span of the bridge. Finally, the screed machine loads were represented by point loads moving along a steel rail modeled using frame elements resting at the edge of the deck overhang. The rotation values are recorded at the middle of the web of the exterior girder along the span of the bridge for all models used in this study to assure consistent comparison of the results.

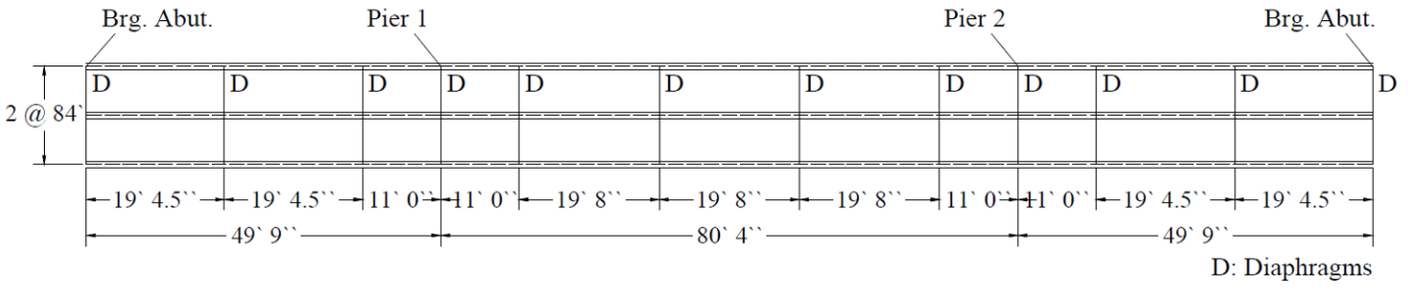

Figure 2. Reference Bridge Geometry.

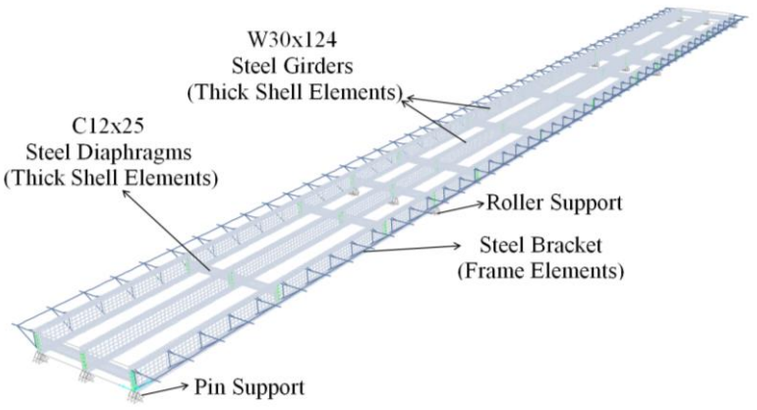

Figure 3. Finite Element Modeling.

3 DIAPHRAGMS SPACING EFFECT

In order to examine the effect of diaphragms spacing on the rotation of exterior girders, the number of diaphragms in the second span of the bridge has been ranged between 2, 4, 6 and 8. Only even number of diaphragms has been chosen in order to keep the middle of the span free in rotation, where it is expected to get the maximum rotation. The diaphragm spacing is then changed in the first and the second span in correspondence with the changes in the middle span. The diaphragms section was kept the same (C12x25) throughout the study in order to compare the results consistently. Figure 4 shows the diaphragms positioning and spacing for each case.

Figure 5 shows the rotation values at the middle and 1/3 of the second span for each case. The results show that increasing the number of diaphragms, which corresponds with reducing the diaphragms spacing, leads to significant reduction in the rotation of exterior girder. Increasing the number of diaphragms from 2 to 4, which parallels with diaphragm spacing of 8.2 m (26`- 10``) and 5 m (16`- 4``), respectively, reduces the rotation of exterior girder at the middle of the span by more than 60%.

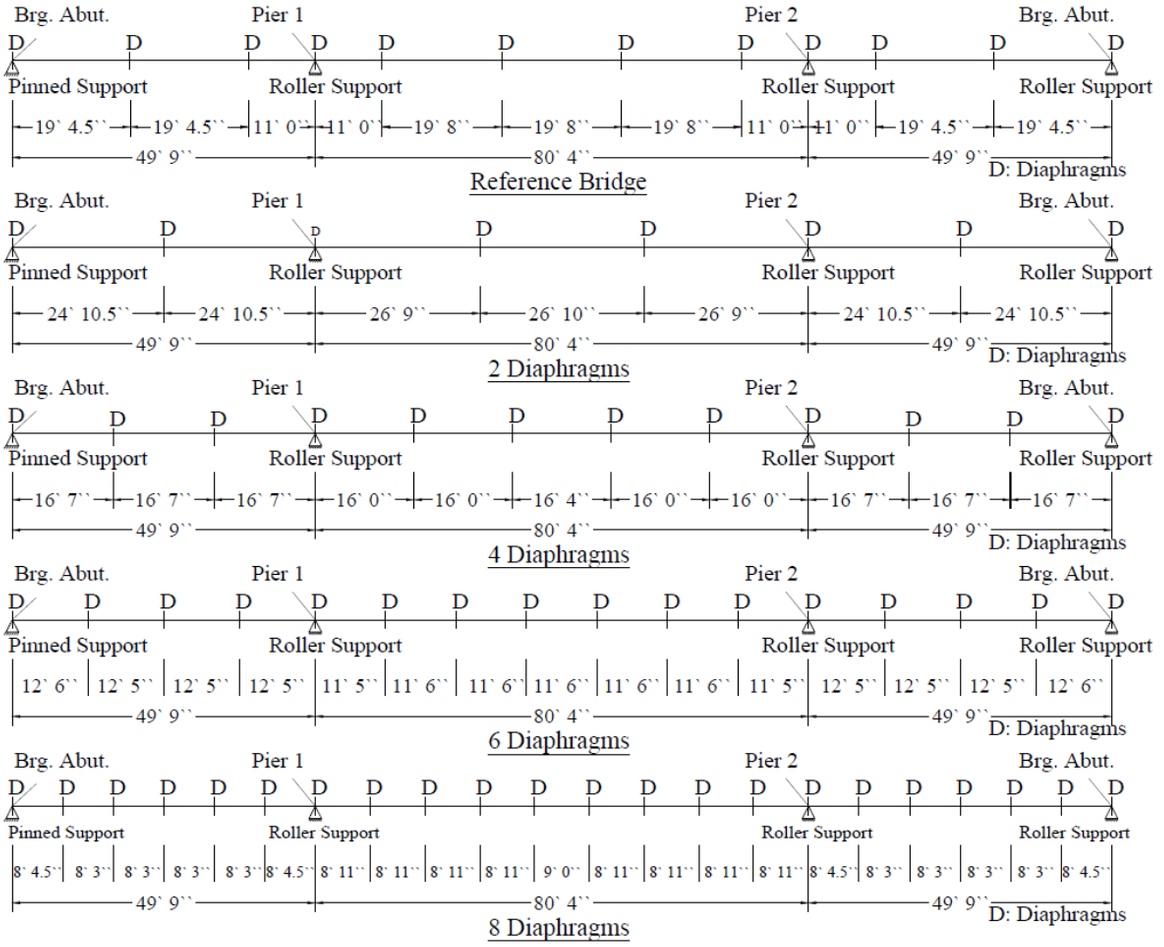

Figure 4. Diaphragms Positioning and Spacing.

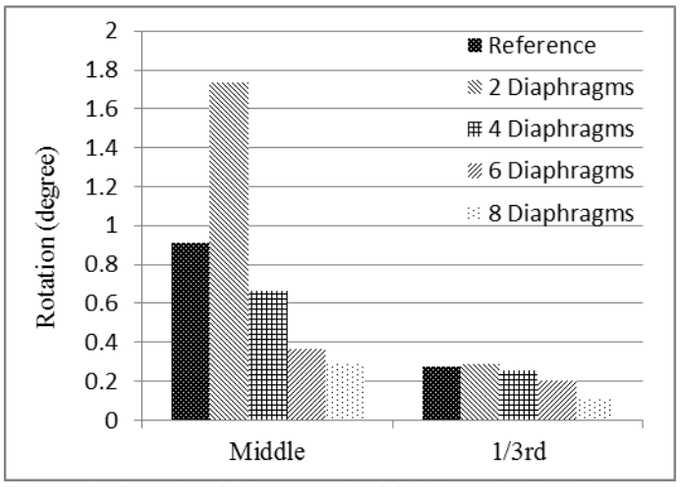

Figure 5. Rotation Values at the Middle and 1/3 of Second Span.

As Illinois Department of Transportation (IDOT) suggests that the maximum vertical deflection in the overhang during construction should not exceed 3/16 inches (IDOT 2012), the rotation of the exterior girder in the bridge in this study is limited to 0.29 degrees (0.005 rad). However, the rotation did not drop below IDOT limit until reducing the diaphragms spacing to 2.74 m (9 ft) by using eight diaphragms at the middle span. This confirms that the ratio between the unbraced length (B) and the diaphragm depth (D) is a very significant indicator (Ashiquzzaman et al. 2016). When B/D ratio dropped to below 4 in this specific bridge, the unbraced length changed to 2.74 m (9 ft), and as a result the rotation decreased to 0.29 degrees (0.005 rad).

The number of diaphragms at the second span of the reference bridge is four, with a maximum diaphragms spacing of 6 m (19`- 8``). However, compared to the bridge with 4 diaphragms at the second span, equally spaced at 5 m (16`- 4``), Figure 6 shows that even with the same number of diaphragms along the span, the maximum rotation is reduced by 27% just by rearranging the diaphragms locations in the reference bridge. This is because repositioning the diaphragms resulted in consistent and smaller diaphragms spacing along the span length.

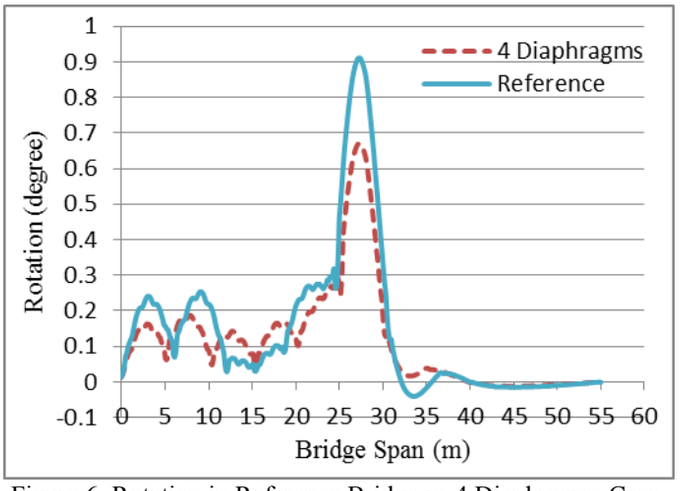

Figure 6. Rotation in Reference Bridge vs 4 Diaphragms Case.

4 SCREED MACHINE POSITION EFFECT

During the construction, the screed machine moves along the span of the bridge in order to finish the deck slab concrete surface. In this study, the machine loads and the corresponding concrete load has been simulated to move along the span of the reference bridge. The loading starts at Pier 1 and ends at the middle of the second span, where the loads were moved in the longitudinal direction of the bridge with 0.6 m (2 ft) step as shown in Figure 7.

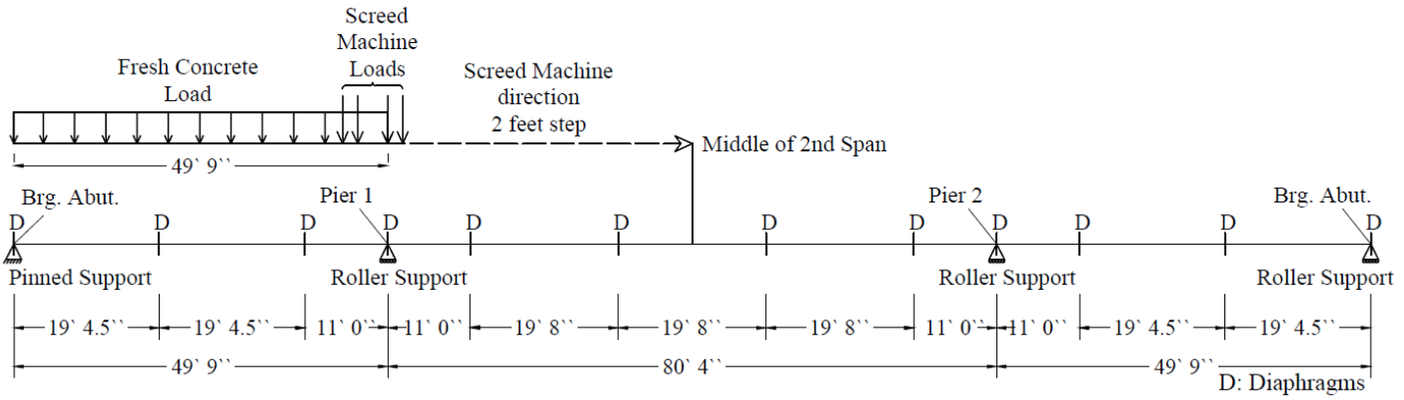

Figure 7. Screed Machine Movement along the Second Span

Figure 8 shows the rotation values in the exterior girder at the middle of the second span versus the location of the screed machine load. The results show a significant increase in the rotation when the load is exactly at the middle of the span. This is because the middle of the span is free to rotate and the screed machine locates exactly at half distance between 2 diaphragms that resist the rotation. It also can be noted that rotation starts to peaks up when the screed machine reaches the second diaphragm where the girder is free to rotate after that location. On the other hand, the results show that along the second span, the rotation of the exterior girder follows a pattern complies with influence line concept. The exterior girder is braced laterally by the diaphragms. Therefore, the girder can be looked at as a continuous beam supported by diaphragms and subjected to torsion moments along its span. Hence, as shown in Figure 8, rotation values alternate between negative and positive until reaching the maximum at the loading location at the middle of the span, this agrees with the influence line theory.

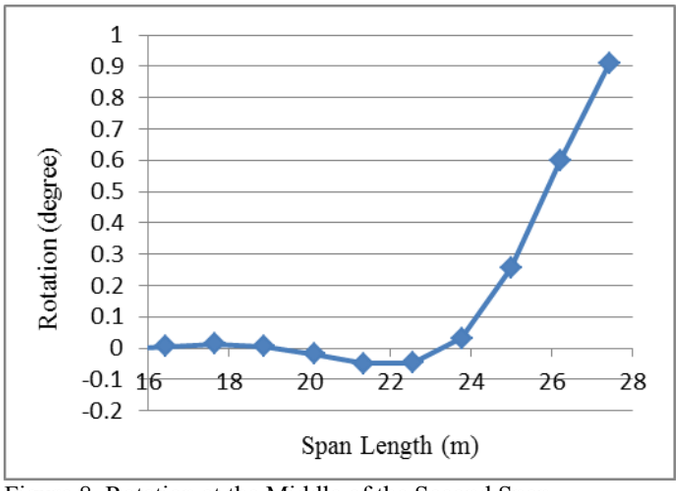

Figure 8. Rotation at the Middle of the Second Span.

Rotation values are also recorded along the second span of the bridge at the same location of the screed machine load with 0.6 m (2 ft) step, as shown in Figure 9. It is clear that the rotation peaks up when the load is located between 2 diaphragms, while it reaches minimum values when the load is close to the lateral support system members, the diaphragms. The results also show that between Pier 1 and the first diaphragm, the maximum rotation recorder is 0.245 degree (0.00427 rad), while between the first and second diaphragm it reaches 0.088 degree (0.01534) rad, and finally at the middle of the span it reaches 0.091 degree (0.01586 rad). This proves that the distance between the diaphragms is the critical factor in exterior girder rotation. When the distance between diaphragms is relatively small, the rotation value is low. The girder segment between Pier 1 and the first diaphragm in the second span of the bridge is 3.35 m (11`- 0``). The maximum rotation recorder at this segment is 70% lower than the maximum in the second segment where the distance between diaphragms is 6 m (19`- 8``). Therefore, it can be conclude that the rotation is very dependent on the location of the screed machine load and the distance between the lateral support system members represented by diaphragms in this study.

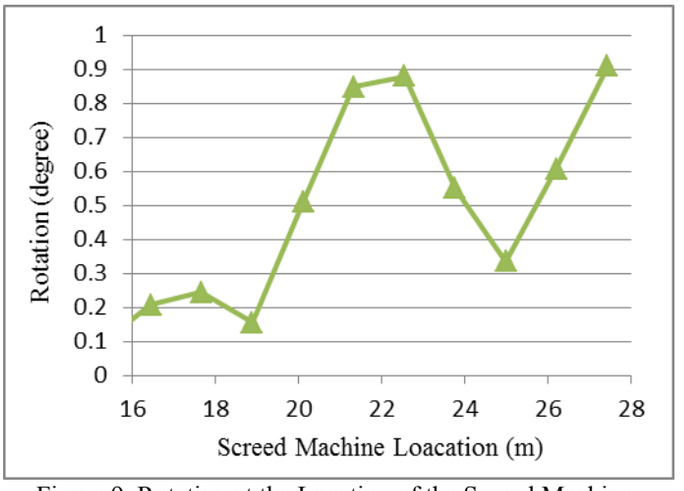

Figure 9. Rotation at the Location of the Screed Machine.

5 SUMMARY AND CONCLUSION

This research focused on understanding the effect of the transverse bracing system spacing, represented by diaphragms, on the rotation of the exterior girders. Finite element models of different bridges have been developed using SAP2000 and the rotations were recorded for each case at the exterior girders and then compared to each other. After analyzing the results the following conclusions can be drawn:

- Diaphragms spacing is a critical parameter in bridge geometry that affects the rotation of exterior girder during construction significantly. Where reducing the spacing between diaphragms by 40% led to more than 60% reduction in rotation.
- The location of the screed machine along the bridge is crucial. The maximum rotation value between two diaphragms is recorded at the load location when the load is at half distance between the diaphragms.
- The rotation of the exterior girder complies with the influence line theory, where the diaphragms act like lateral supports for the continuously braced beam (the exterior girder).

ABSTRACT: In Bingo Bridge which is the suspended bridge in Nara Prefecture, fracture of hanger rod was found in 2015. Furthermore, in this bridge, the surface corrosion of main cable and stiffening girders were also observed. This bridge was closed to traffic until all the hanger rods replaced to the hanger ropes. Therefore, to inspect the corrosion of main cable and the stiffening truss during the road closure, the high sensitivity magnetic nondestructive testing was applied. Additionally, one of the purpose of this research is to investigate the application of high sensitivity magnetic nondestructive testing on site.

1 INTRODUCTION

In Bingo Bridge which is the suspended bridge, fracture of hanger rod and fatigue crack on screw part of hanger rod were observed in 2015. Since these serious damages were found, this bridge was closed to traffic. Furthermore, in this bridge, the surface corrosion of main cable and stiffening truss was also observed.
In this study, inspection of corrosion of cable and stiffening girders was carried out by applying the high sensitivity magnetic nondestructive testing during the road closure. Additionally, one of the purposes of this research is to investigate the application of high sensitivity magnetic nondestructive testing on site.

Figure 1 Bingo Bridge

Figure 2 Fracture of hanger rod

2 BINGO BRIDGE

Figure 1 shows the Bingo Bridge in National Root 425 in Nara Prefecture. This bridge was built in 1963. In this bridge, the maximum vehicle weight for service is limited to 59kN or less. The length and width of road of this bridge are 163m and 4.5m, respectively. As shown in Figure 1, Bingo Bridge is the suspended bridge with stiffening truss.
The fracture of hanger rod and fatigue crack on screw part of hanger rod were found in 2015, as shown in Figures 2 and 3. They were located near the center of the bridge. One of the reasons of fatigue damage is assumed that the cyclic bending moment was introduced in the hanger rods by the

Figure 3 Location of damaged hanger rods

sticking of hinges. Damaged hanger rods were immediately replaced the new hanger rods. However, this bridge was closed until the all hanger rods were replaced to the hanger ropes. Figure 5 shows the replaced hanger rope in Bingo Bridge.

3 HIGH-SENSITIVITY MAGNETIC NONDESTRUCTIVE TESTING

3.1 *ELECT-SAM*

As generally know, the Eddy-current Testing or Electromagnetic Testing (E.T) is widely used as a nondestructive testing for detection of surface flaws. However, the E.T cannot be applied to detection of inner fatigue crack or inner corrosion of steel structures. Extremely Low-Frequency Eddy Current Testing with Spectrum Analysis of Magnetic field (ELECT-SAM) was developed for detection of inner corrosion of steel structures (Tsukada et al. 2016). Figure 5 shows the system of ELECT-SAM. This nondestructive testing system can detect inner corrosion at extremely low frequency by employing a magnetic probe using an anisotropic magnetic resistance (AMR) sensor with the sensitivity of $1\ \mathrm{nT}/\sqrt{\mathrm{Hz}}$. In this system, to estimate the plate thickness, the calibrated equations obtained by magnetic spectrum analysis of each material are prepared.

3.2 *USAC-MFL*

As above mentioned, the conventional E.T is difficult to inspect the inner cracks in steel structures because of its high permeability as well as owing to the variations in it. UnSaturated AC Magnetic Flux Leakage testing (USAC-MFL) was developed for detection of inner crack in thick steel plate and detection of inner defects of steel structures (Tsukada et al. 2017). The measurement system of USAC-MFL is shown in Figure 6.

4 INSPECTION OF INNER CORROSION ON UPPER CHORD IN STIFFENING TRUSS

By using ELECT-SAM, the thickness measurement of the upper chord in stiffening truss was carried out with measuring frequency of 1Hz or 10Hz. Figure 7 shows the situation of thickness measurement by ELECT-SAM. The locations of the thickness measurement are the points A to N in Figure 8 on the upper surface of upper chord. In this bridge, the two materials of JIS-SS400 and JIS-SM490 are used in upper chord. The guaranteed yield stresses of JIS-400 and JIS-SM490 are 245N/mm^2 and 325N/mm^2, respectively.

Figure 4 New hanger rope

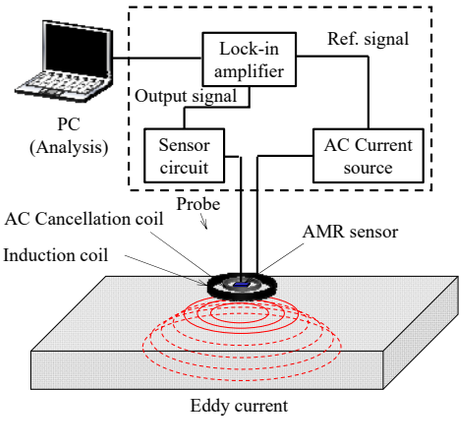

Figure 5 System of ELECT-SAM

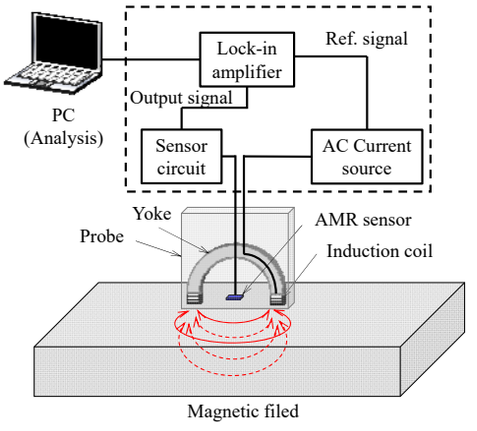

Figure 6 System of USAC-MFL

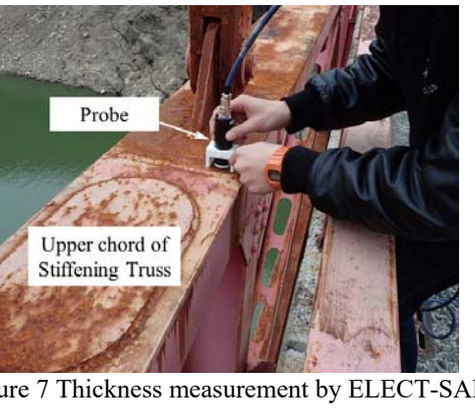

Figure 7 Thickness measurement by ELECT-SAM

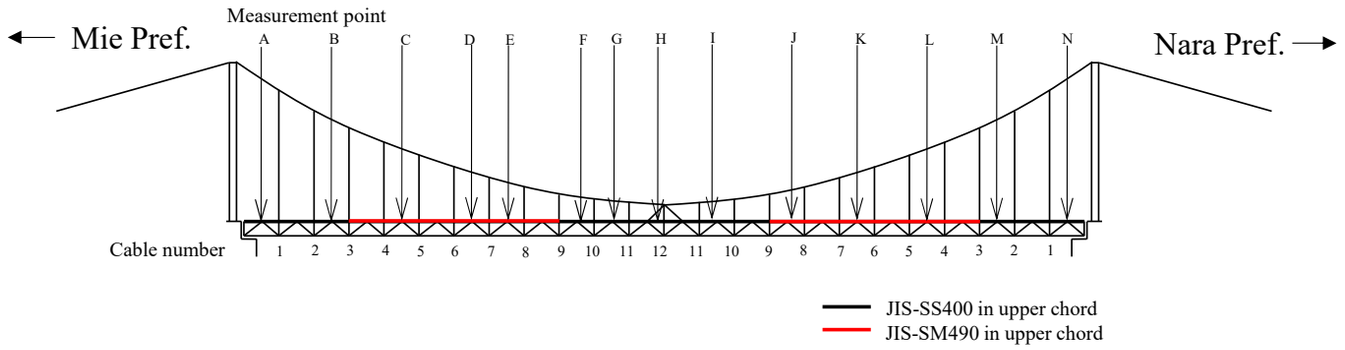

Figure 8 Location of thickness measured in Bing Bridge

Table 1. Measured thickness of top flange in upper chord (mm)

	A	B	C	D	E	F	G	H	I	J	K	L	M	N
Measured thickness	7.83	7.91	7.71	8.71	7.62	8.53	8.72	8.82	7.73	7.47	8.21	7.30	8.31	7.78
Thickness measured by U.T	9.17	9.37	9.80	10.2	10.0	9.28	9.08	9.76	8.73	9.66	9.74	9.21	9.63	9.64

Measured thickness of top flange in upper chord is listed in Table 1. As mentioned in Section 3.1, since the equations for JIS-SM400 and JIS-SM490 given by spectrum analysis are different in ELECT-SAM, each equation was applied to the each material on the upper chord in stiffening truss.

As listed in Table 1, measured thicknesses by ELECT-SAM are 7mm to 9mm. Design thickness of the upper chord in stiffening truss is the 9mm and measured thickness by ultrasonic testing (U.T) is also 9mm to 10mm. Therefore, it is presumed the measured thicknesses by ELECT-SAM are slightly thinner than the actual thickness. It is because the components of materials used in Bingo Bridge might not be completely same as that used in the calibrated new materials. However, the tendency of thickness distribution measured by ELECT-SAM is as same as that measured by U.T. Therefore, ELECT-SAM can be used for the detection and screening of thickness reduction by corrosion attack.

5 INSPECTION OF DETERIORATION IN MAIN CABLE

By using USAC-MFL, the inspection of corrosion in the main cable near the anchorage was carried out. Figure 9 shows the situation of inspection using USAC-MFL. For the line scanning of surface corrosion observed area, the probe for USAC-MFL was moved about 500mm by hand with measuring (measuring frequency of 11Hz). Measured intensity change vs. scanning time diagram was shown in Figure 10. When the corrosion or fracture of the cable are occurred, the intensity change measured by ELECT-SAM changes. As can be seen in Figure 10, difference of the peaks of intensity change is small. Therefore, it was presumed that the any corrosion or fracture inner the main cable was not occurred in the cable near the anchorage.

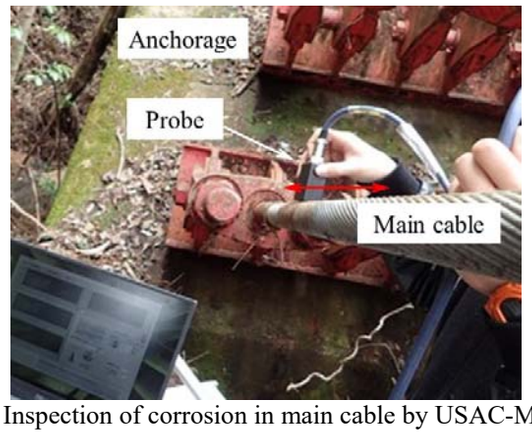

Figure 9 Inspection of corrosion in main cable by USAC-MFL

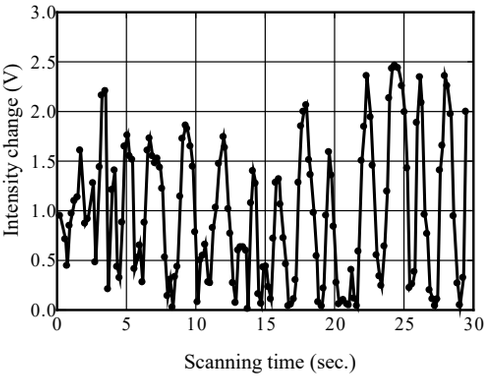

Figure 10 Intensity change vs. scanning time measured in main cable by using USAC-MFL

6 INSPECTION OF DEFECT IN HANGER RODS

The damaged hanger rods has temporarily replaced to the new rod shown in Figure 11 for repair work on Bingo Bridge. After that the all hanger rods have been replaced by the hanger ropes. As shown in Figure 12, the surface flaws were observed in one old hanger rod by magnetic testing (M.T). However, it decided that the surface flaws in Figure 12 is not a fatigue crack, because the crack direction is cor-

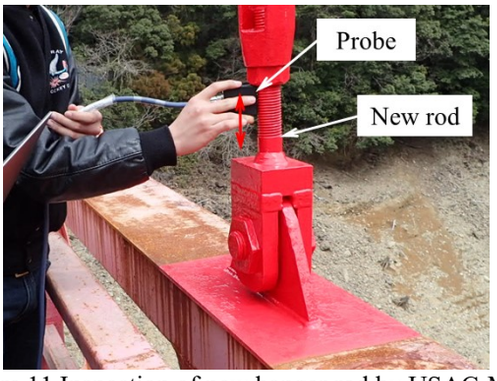

Figure 11 Inspection of new hanger rod by USAC-MFL

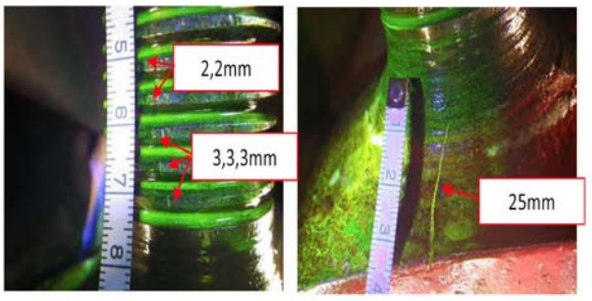

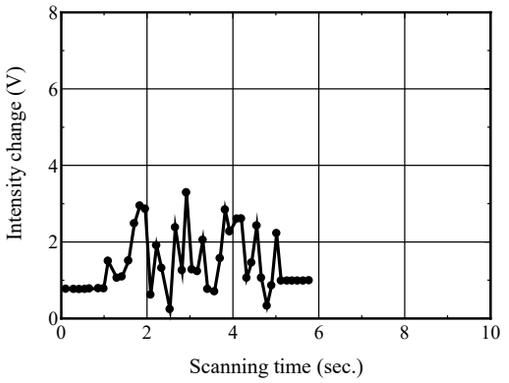

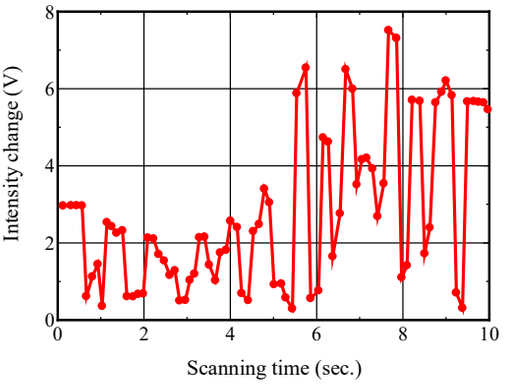

Figure 12 Measured flaws by M.T

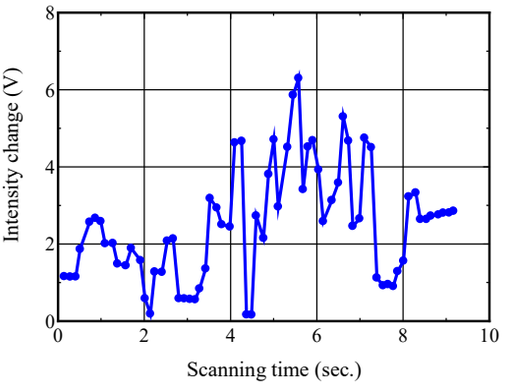

responding to the axial force direction in hanger rod. Therefore, the surface flaws observed rod, intact old rod and temporarily exchanged new rod were measured by using USAC-MFL. For the line scanning, the probe for USAC-MFL was moved between turnbuckle and hinge by hand with measuring (measuring frequency of 92Hz). Measured results are shown in intensity change vs. scanning time diagram in Figure 13. Since the material used in the new rod is different as that in original rods. Furthermore, new rod was fabricated by welding between hinge and rod parts. Therefore, the peak value of intensity change of new hanger rod is different from the old hanger rods. Meanwhile, the intensity change of the surface flaws observed old rod shows the same tendency as that of the intact old rod. Therefore, from the inspection by using USAC-MFL, it was presumed that the surface flaw measured in old rod is not a fatigue crack.

(c) Intact old rod

Figure 13 Intensity change vs. scanning time measured in rod by using USAC-MFL

7 CONCLUSIONS

In this study, the inspection of the main cable, stiffening girder and hanger rods in Bingo Bridge was carried out by applying the high sensitivity magnetic nondestructive testing during the road closure. In the measured parts in this bridge, the serious defects have not detected. Furthermore, it was proved that the ELECT-SAM and USAC-MFL can be applied to the inspection of existing bridge.

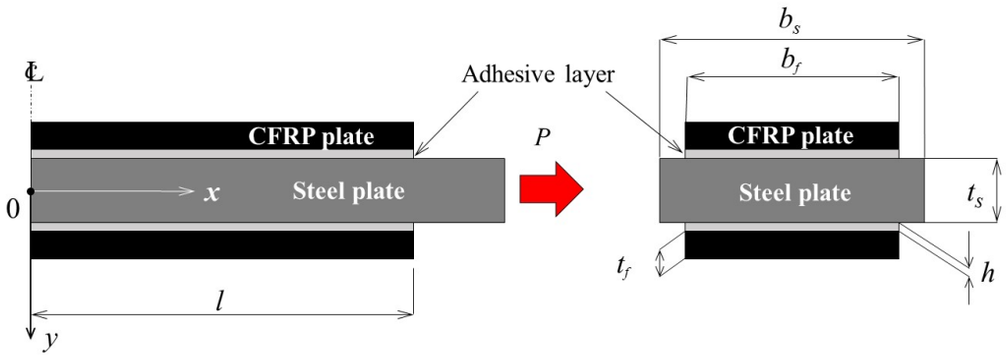
ABSTRACT: Carbon fiber reinforced polymer, CFRP, is starting to be used for the repair and strengthening of steel members. However, debonding of CFRP plate is one of the concerns of this repair method. Therefore, some reduction techniques of stress concentration at the adhesive and were proposed. In this paper, the authors focused on the reduction technique of stress concentration at the adhesive end by using low elasticity adhesive at the plate end. By solving the differential equations regarding the axial force of steel plate and shear force of CFRP plate of CFRP bonded steel plate used low-elasticity adhesive at the plate ends, the characteristics on the shear and normal stresses in the adhesives are clarified. Furthermore, analytical results were verified by the FE analysis of CFRP bonded steel plates.

1 INTRODUCTION

Carbon fiber reinforced polymer, CFRP, is started to be used for the repair method against corrosion damage to steel bridges (Miller et al. 2001, Moy et al. 2007 and Tamai et al. 2005). CFRP plates are expected to be used as repair materials for steel members because the strength of CFRP is higher than that of steel and the weight of CFRP is lighter than that of steel. However, the brittle debonding of the CFRP plate is the most concern for CFRP bonding repair.

So far, for brittle debonding of the CFRP plate, the several methods such as the mechanical fastener at the end of the CFRP plate, the taper at the end of the CFRP plate, the step bonding of the CFRP plates, and the low elasticity adhesive at the end of the CFRP plate have been proposed. Several studies using low elasticity to the CFRP plate ends have been carried out (Coleman 1966, Fitton et al. 2005 and Ishikawa et al. 2008). However, the peel stress in adhesive layer did not investigate for the low-elasticity adhesive at the plate ends of CFRP bonded steel plate under axial loading. In the previous study, it was clarified that the high shear stress as well as high peel stress in the adhesive layer at the ends of CFRP effect for debonding of the CFRP plates. Therefore, some criteria for prevention of debonding the CFRP need both shear and peel stresses at adhesive ends.



Therefore, it is necessary to evaluate the peel stress introduced in the adhesive layer even though the low-elasticity adhesive used at the ends of the CFRP plate.

In this research, by using the differential equations of CFRP bonded steel plate with low-elasticity adhesive at the ends of the CFRP plate, the shear and peel stresses introduced in the adhesive ends of the CFRP plate bonded steel plate under axial loading is derived.

2 THEORETICAL ANALYSIS OF CFRP BONDED STEEL PLATE WITH TWO KINDS OF ADHESIVES

2.1 *General solution of differential equations of CFRP plate bonded steel plates under axial loading*

For the steel plate with the CFRP plates bonded symmetrically to the upper and lower surfaces shown in Figure 1, the sectional forces acting on a differential segment are shown in Figure 2. For the theoretical analysis, the followings were assumed: (1) materials are all linearly elastic, (2) the shear and normal

(a) Side view (b) Cross section

Figure 1. CFRP plates bonded steel plate.

stresses in the adhesive layer are constant through the thickness, (3) the axial force and bending moment in the adhesive layer are negligible because the low Young's modulus of the adhesive.

From the equilibrium of the axial force in the differential segment of steel plate, the second order differential equation on the axial force in the steel plate $N_s(x)$ is given by the following equation (Ishikawa et al. 2013).

$$\frac{d^2N_s(x)}{dx^2} - c^2N_s(x) = -c^2\xi_0 P \tag{1}$$

where,

$$c = \sqrt{\frac{b_f G_e}{h} \cdot \frac{2}{1-\xi_0} \cdot \frac{1}{E_s A_s}} \tag{2}$$

$$\xi_0 = \frac{1}{1 + 2E_f A_f / (E_s A_s)} \tag{3}$$

E_s : Young's modulus of the steel plate,
E_f : Young's modulus of the CFRP plate,
A_s : sectional area of the steel plate,
A_f : sectional area of the CFRP plate,
G_e : shear modulus of the adhesive,
h : thickness of the adhesive,
b_f : width of the CFRP plate,
P : axial loading on the steel plate,
x : distance from the center of the CFRP plate (Figure 1(a)).

The general solution of Eq. (1) is given by the following equation.

$$N_s(x) = A_1 \cosh(cx) + A_2 \sinh(cx) + \xi_0 P \tag{4}$$

where,

A_1 and A_2: undetermined coefficients relevant to the axial force in the steel plate.

The relation between the shear stress in the adhesive $\tau(x)$ and the axial force in the steel plate $N_s(x)$ is given by the following equation.

$$\tau(x) = \frac{1}{2b_f}\frac{dN_s(x)}{dx} \tag{5}$$

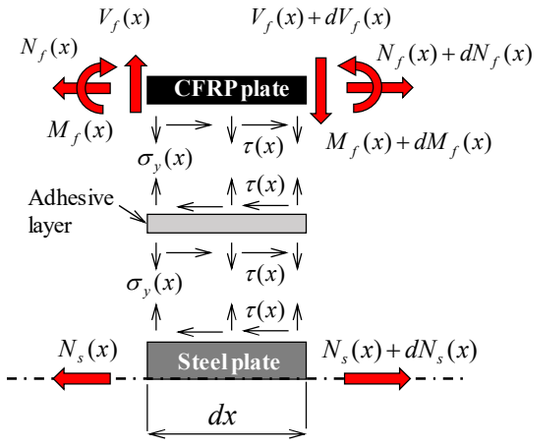


Figure 2. The sectional forces in a differential segment.

On the other hand, the fourth order differential equation for the shear force of the CFRP plate $V_f(x)$ is given by the equilibrium of the sectional forces in the differential segment of the CFRP plate (Ishikawa et al. 2013).

$$\frac{d^4V_f(x)}{dx^4} + 4\omega^4 V_f(x) = \omega^4 t_f \frac{dN_s(x)}{dx} \tag{6}$$

where,

$$\omega = \sqrt[4]{\frac{b_f E_e}{4h} \cdot \frac{1}{E_f I_f}} \tag{7}$$

E_e : Young's modulus of the adhesive,
t_f : thickness of the CFRP plate,
I_f : the moment of inertia of the CFRP plate.

The general solution of the shear force in CFRP plate, $V_f(x)$, is given by the following equation.

$$\begin{aligned} V_f(x) = {} & B_1\mathrm{CH}(\omega x)\mathrm{S}(\omega x) + B_2\mathrm{SH}(\omega x)\mathrm{C}(\omega x) \\ & + B_3\mathrm{CH}(\omega x)C(\omega x) + B_4\mathrm{SH}(\omega x)S(\omega x) \\ & + W\{A_1\mathrm{SH}(cx) + A_2\mathrm{CH}(cx)\} \end{aligned} \tag{8}$$

where,

$$W = \frac{ct_f}{4 + (c/\omega)^4} \tag{9}$$

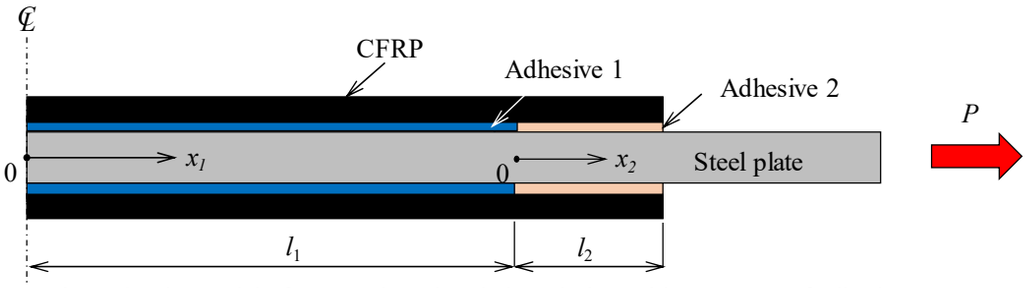

Figure 3. The model of CFRP plates bonded steel plate with two types of adhesives.

B_1, B_2, B_3, B_4 : Undetermined constant relevant to the shear force in the CFRP plate,

C(·) and S(·) : cos(·) and sin(·),

CH(·) and SH(·) : cosh(·) and sinh(·).

The peel stress introduced in the adhesive, $\sigma_y(x)$, is given by the following equation.

$$\sigma_y(x) = -\frac{1}{b_f}\frac{dV_f(x)}{dx} \tag{10}$$

The bending moment introduced in the CFRP plate, $M_f(x)$, is given by the following equation (Ishikawa et al. 2013).

$$M_f(x) = -\frac{1}{4\omega^4}\cdot\frac{dV_f(x)}{dx} \tag{11}$$

2.2 *Theoretical solution of CFRP plates bonded steel plate with two types of adhesives under axial loading*

In this study, differential equation of CFRP plates bonded steel plate with two types of adhesives under axial loading, as shown in Figure 3, is theoretically solved. The general solutions of axial forces in steel plate are given by the following equation. Note that, the boundary conditions at the center of CFRP plates, which are the symmetrical condition, are already applied in the following solutions.

$$N_s(x_1) = A_{11}\cosh(c_1x_1) + \xi_0 P \tag{12}$$

$$N_s(x_2) = A_{21}\cosh(c_2x_2) + A_{22}\sinh(c_2x_2) + \xi_0 P \tag{13}$$

where,

$$c_1 = \sqrt{\frac{b_f G_{e1}}{h}\cdot\frac{2}{1-\xi_0}\cdot\frac{1}{E_sA_s}} \tag{14}$$

$$c_2 = \sqrt{\frac{b_f G_{e2}}{h}\cdot\frac{2}{1-\xi_0}\cdot\frac{1}{E_sA_s}} \tag{15}$$

x_1 and x_2 : The distance from the center of the adhesive 1 and the distance from the boundary between the adhesives 1 and 2,

G_{e1} and G_{e2} : shear modulus of elasticity of adhesives 1 and 2,

A_{11}, A_{21} and A_{22} : Undetermined coefficient.

At the boundary between the adhesives 1 and 2 ($x_1=l_1$, $x_2=0$), the boundary conditions of $N_s(x_1=l_1)=N_s(x_2=0)$ and $\tau(x_1=l_1)h/G_{e1}=\tau(x_2=0)h/G_{e2}$ were applied. Furthermore, by applying the boundary condition of $N_s(x_2=l_2)=P$, undetermined coefficients, A_{11}, A_{21} and A_{22}, are respectively given by the following equations.

$$A_{11} = \frac{(1-\xi_0)P}{n\mathrm{SH}(c_1l_1)\mathrm{SH}(c_2l_2) + \mathrm{CH}(c_1l_1)\mathrm{CH}(c_2l_2)} \tag{16}$$

$$A_{21} = \frac{(1-\xi_0)\mathrm{CH}(c_1l_1)P}{n\mathrm{SH}(c_1l_1)\mathrm{SH}(c_2l_2) + \mathrm{CH}(c_1l_1)\mathrm{CH}(c_2l_2)} \tag{17}$$

$$A_{22} = \frac{n(1-\xi_0)S\mathrm{H}(c_1l_1)P}{n\mathrm{SH}(c_1l_1)\mathrm{SH}(c_2l_2) + \mathrm{CH}(c_1l_1)\mathrm{CH}(c_2l_2)} \tag{18}$$

where,

$$n = c_2/c_1 = \sqrt{G_{e2}/G_{e1}} \tag{19}$$

l_1 and l_2 : the ranges of adhesive 1 and 2, as shown in Figure 3.

On the other hand, the general solutions of the shear force of CFRP plates with two types of adhesives are given by the following equation. Note that, the boundary conditions at the center of CFRP plates, which are the symmetrical condition, are already applied in the following solutions.

$$V_f(x_1) = B_{11}\mathrm{CH}(\omega_1x_1)\mathrm{S}(\omega_1x_1) + B_{12}\mathrm{SH}(\omega_1x_1)\mathrm{C}(\omega_1x_1) + W_1A_{11}\mathrm{SH}(c_1x_1) \tag{20}$$

$$V_f(x_2) = B_{21}\mathrm{CH}(\omega_2x_2)\mathrm{S}(\omega_2x_2) + B_{22}\mathrm{SH}(\omega_2x_2)\mathrm{C}(\omega_2x_2) + B_{23}\mathrm{CH}(\omega_2x_2)C(\omega_2x_2) + B_{24}\mathrm{SH}(\omega_2x_2)S(\omega_2x_2) + W_2\{A_{21}\mathrm{SH}(c_2x_2) + A_{22}\mathrm{CH}(c_2x_2)\} \tag{21}$$

where,

$$W_1 = \frac{c_1t_f}{4+(c_1/\omega_1)^4} \tag{22}$$

$$W_2 = \frac{c_2t_f}{4+(c_2/\omega_2)^4} \tag{23}$$

$$\omega_1 = \sqrt[4]{\frac{b_fE_{e1}}{4h}\cdot\frac{1}{E_fI_f}} \tag{24}$$

$$\omega_2 = \sqrt[4]{\frac{b_f E_{e2}}{4h} \cdot \frac{1}{E_f I_f}} \tag{25}$$

E_{e1} and E_{e2} : Young's modulus of adhesives 1 and 2,

B_{11}, B_{12}, B_{21}, B_{22}, B_{23} and B_{24} : Undetermined coefficients.

Applying the boundary conditions of $V_f(x_1=l_1)= V_f(x_2=0)$, $M_f(x_1=l_1)=M_f(x_2=0)$, $M_f'(x_1=l_1)/E_fI_f = M_f'(x_2=0)/E_fI_f$, $\sigma_y(x_1=l_1)h/E_{e1}= \sigma_y(x_2=0)h/E_{e2}$, $V_f(x_2=l_2)=0$ and $M_f(x_2= l_2)=0$, the undetermined coefficients, B_{11}, B_{12}, B_{21}, B_{22}, B_{23} and B_{24}, are given.

$$\mathbf{B} = C^{-1}\mathbf{k} \tag{26}$$

where,

$$\mathbf{B} = \begin{pmatrix} B_{11} & B_{12} & B_{21} & B_{22} & B_{23} & B_{24} \end{pmatrix}^T \tag{27}$$

$$C = \begin{pmatrix} \mathbf{C_1} & \mathbf{C_2} & \mathbf{C_3} & \mathbf{C_4} & \mathbf{C_5} & \mathbf{C_6} \end{pmatrix} \tag{28}$$

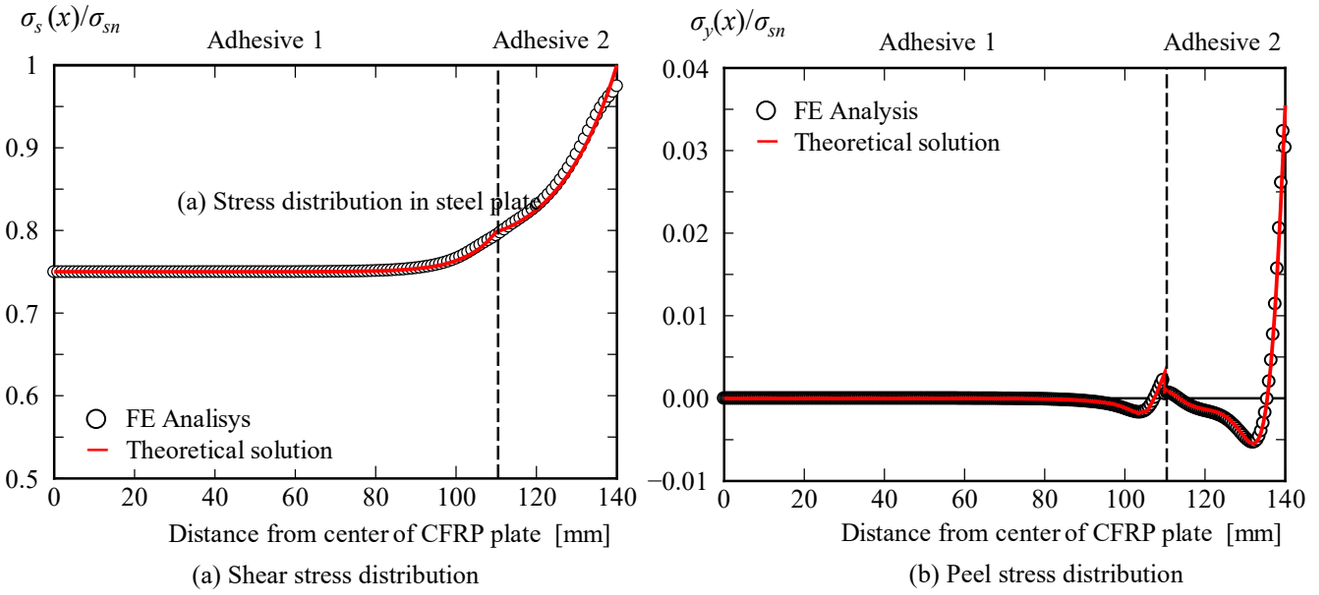
3 COMPARISON OF THE ORETICAL SOLUTION AND FINITE ELEMENT ANALYSIS



To verify the theoretical solution, Finite Element analyses of CFRP plates bonded steel plate with two types of adhesives under axial loading are carried out. Table 1 shows the dimensions and materials of steel plate, CFRP plate and adhesives for FE analyses. For FE analyses, MARC 2012 was used with plane stress condition. The element size of the adhesive was 0.1mm x 0.1mm.

(a) Stress distribution in steel plate

(b) Stress distributions on upper and lower surfaces of the CFRP plate

Figure 4. The stress distributions of CFRP plates bonded steel plate with two types of adhesives under axial loading

(a) Shear stress distribution

(b) Peel stress distribution

Figure 5. Stress distributions in the adhesive layer in CFRP plates bonded steel plate with two types of adhesives under axial loading

Figure 4 shows the stress distributions of the steel plate and the CFRP plate given by the theoretical solutions and FE analyses. In this figure, each stress is normalized by the nominal stress of σ_{sn} ($=P/A_s$). In Figure 4(a), the stress distribution in steel plate at the center of the plate thickness is shown. Since the stress distribution is not constant within the steel plate thickness in the FE analysis, the valued of $\sigma_s(x)/\sigma_{sn}$ given by FE analysis is not corresponding to 1 at x=140mm where the CFRP end. However, the stress distribution calculated by the theoretical solution shows the almost same as that given by the FE analysis.

As shown in Figure 4(b), since a bending moment is generated near the end of the CFRP plate, the stress distributions on upper and lower surfaces of the CFRP plate are different near the end of the CFRP plate. As can be seen from Figure 4(b), the stress distributions on the CFRP plate given by the theoretical solution and the FE analysis show almost the same distribution.

Figure 5 shows the distribution of shear and peel stresses in the adhesive layer given by the theoretical solutions and FE analyses. In this figure, the shear and the peel stresses are also normalized by σ_{sn}. The stress distributions in the center of the adhesion thickness obtained the FE analyses are shown in Figure 5.

As can be seen from Figure 5, the shear and peel stress distributions in adhesive layer given by the theoretical solutions are almost corresponding to the results of the FE analyses. In addition, the gaps of shear and peel stresses at the boundary between adhesive 1 and 2 can be also given by the theoretical solutions.

4 CONCLUSIONS

In this study, as the fundamental study of using low elasticity adhesive at the end of the CFRP plate, the theoretical solution of the stress in the CFRP plates bonded steel plate with two types of adhesives under the axial loading was given. Then, the theoretical solution was verified by using FE analysis result. It was shown that the stress distributions in CFRP plate bonded steel plate with two types of adhesives under axial loading were almost corresponding to the results of FE analysis.

ABSTRACT: Center stay is installed to control a relative displacement between a girder and a cable, to restrict the inclination of short suspenders around the center of a span, and to prevent bending fatigue of the suspender. A center stay was designed so that the rod section breaks with 60% (equivalent of an earthquake whose return period is 25 years) of tension force during an earthquake. However, two rods under force lower than the designed tension broke at a mounting screw section, not at the section with the minimum cross sectional area of the rod, which is the assumed failure point. This paper discusses the detailed survey of a fracture surface observation to confirm damage factors, estimation of the level of fatigue damage by measuring a stress frequency on a real bridge, a method to improve fatigue durability, and the result of a fatigue test of improved rod with which improved fatigue durability is expected.

1. INTRODUCTION

The Honshu-Shikoku Bridges, which connect Honshu and Shikoku with three routes, consist of ten suspension bridges including the Akashi-Kaikyo Bridge, the world's longest suspension bridge, five cable-stayed bridges, one truss bridge, and one arch bridge. Among these long-span bridges, center stays are installed on suspension bridges to control a relative displacement between a girder and a cable.

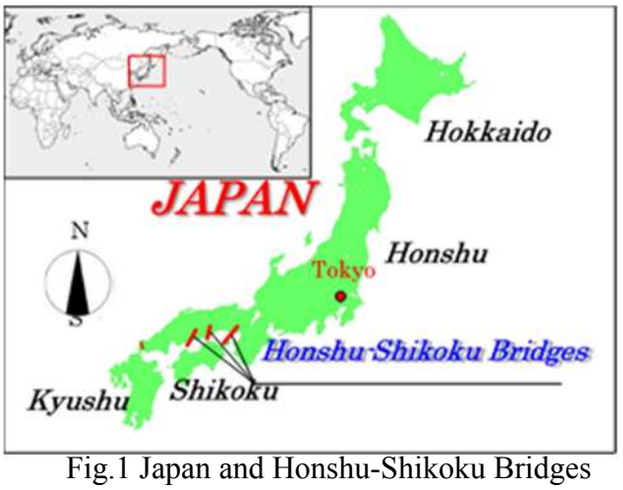

Fig.1 Japan and Honshu-Shikoku Bridges

A damage that differs from the one expected during the design phase occurred to a bridge. This study estimated the causes of the damage, and examined an improvement method. This paper reports the result of this study.

(1) Target bridge

The bridge, which is the subject of this study, is a three span, two hinge suspension bridge with the main span of 600 m. It has an asymmetric geometry with the main towers of varying heights (Fig. 2). Flat hexagonal shaped box girders are used and, as for the form of the bridge in service, the number of lanes changes from the four to two (south side) on the bridge. As a result, the live load is deviated to the south side (Photo1).

(2) Structure of the center stay

The center stay of this bridge is installed to prevent additional stress, such as bending, from occurring on a suspender rope by controlling a relative

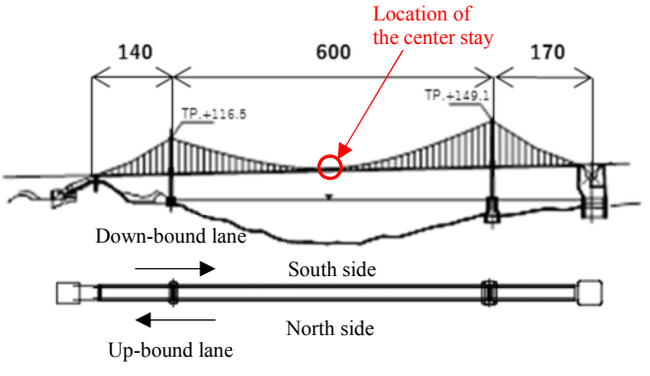

Fig.2 General view of the target bridge

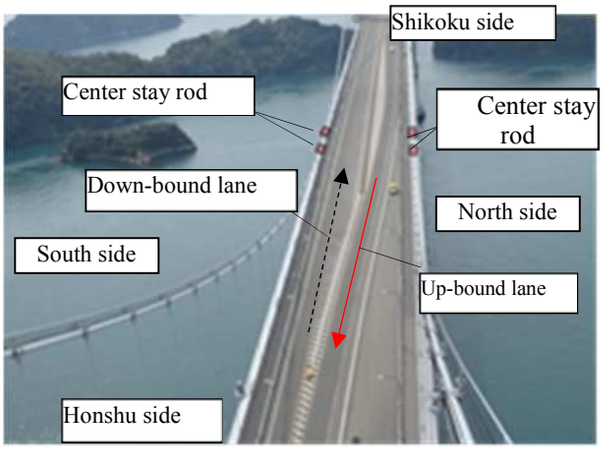

Photo.1 Lanes of the bridge

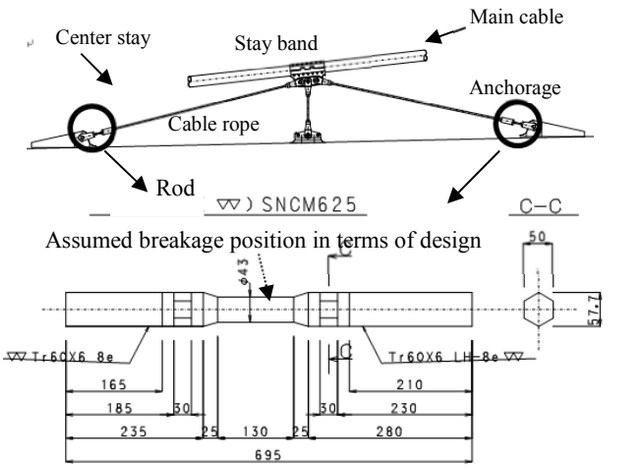

Fig.3 Outline of center stay

displacement between the girder and the main cable in longitudinal direction during a small-scale earthquake.

The center stay is positioned in the center of the main span. It consists of stay band, a stay rod (hereinafter called “rod”), and anchorages as shown in Fig.3 and Photo.2. The total of four center stays are installed on the bridge, two for the up-bound lane side and two for the down-bound lane side. The rod was designed to be broken at the section with the minimum cross sectional area in the center during a large-scale earthquake. These rods was actually broken almost as designed load when the Geiyo earthquake (M 6.7) occurred in March 24, 2001 as shown in Photo3.[1)]

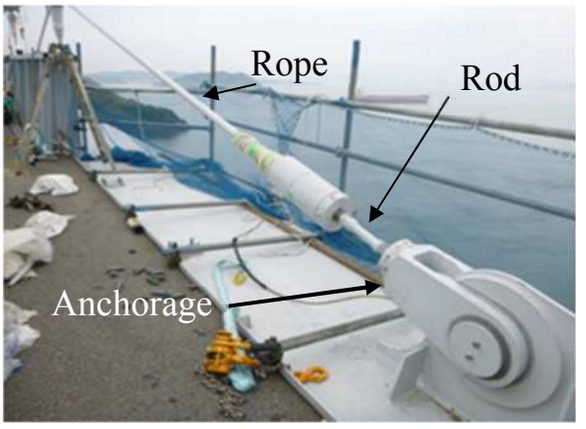

Photo.2 Center stay

Since the rod was designed to break with 60% tension force of the earthquake load, it can be dismounted as it is joined to the socket on the rope side and the anchor pin with screws to facilitate replacing a rod. As for the rod, Tr60 is used for screws, and its length is 695 mm. The material of the rod is SNCM625 (nickel-chrome-molybdenum steel).

During the inspection in 2014, breakage of the rods which were installed to down-bound lane, was found out even no large-scale earthquake occurred.

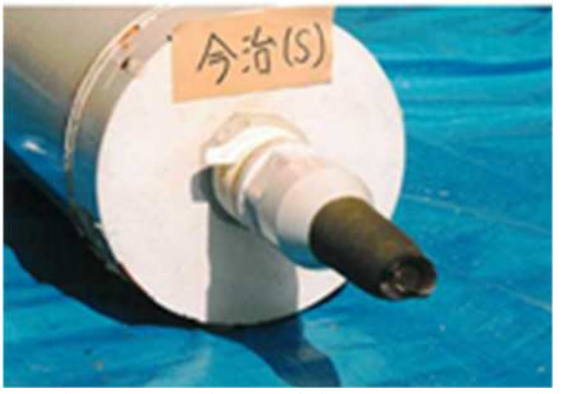

Photo.3 Breakage of the center stay rod caused by the Geiyo earthquake in 2001

2. CONDITIONS OF DAMAGE

The position of the breakage is the thread root at the first screw thread where the rod is engaged with the socket coupler on the rope side. (Photo.4)

The existing rods were replaced because they were broken when the Geiyo earthquake occurred in March 2001. It is relatively new rod as it is about 13 years old. The assumed position of the breakage is the minimum cross sectional area in the center of the rod as shown in Fig. 3, which is a different position of the broken rods this time.

3. INSPECTION OF CAUSE OF DAMAGE

In order to identify the causes of this damage, material characteristics were verified by a chemical composition analysis to conduct a macro-observation of the breakage surface, a micro-observation by SEM (Scanning Electron Microscope), and to investigate the presence of defects of the material. To confirm the condition of the occurrence of live-load stress on the rod, 72 hours continuous stress measurement was conducted on the target bridge. The chemical

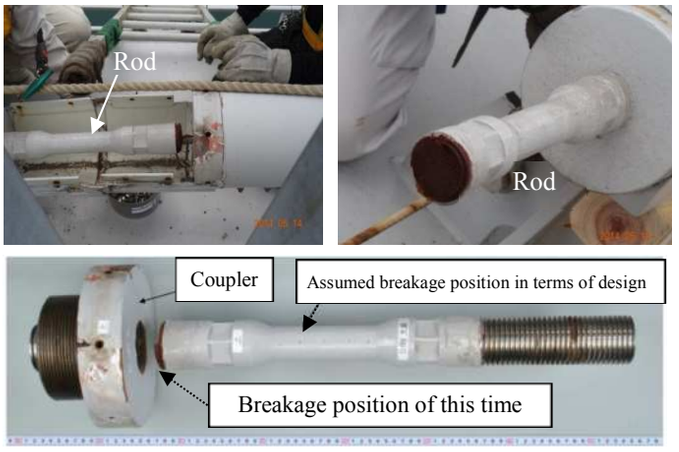

Photo.4 Condition of break in the rod

composition analysis included the rods of the up-bound lane where no damage was found.

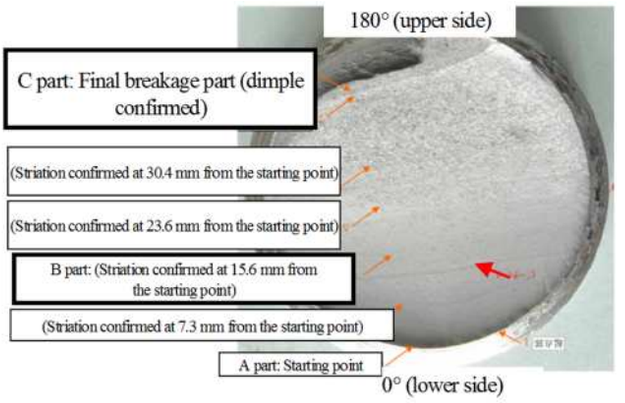
(1) Observation of the breakage surface

a) Result of the macro-observation of the fracture

The result of the macro-observation of the fracture after descaling is shown in Fig.4(a).

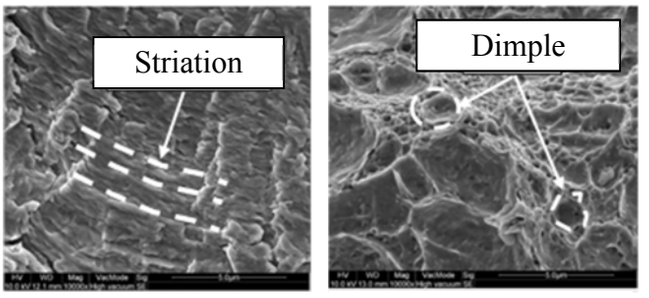
Distinctive beachmark was found on the fatigue fracture of the two broken rods; therefore, it is assumed that fracture developed due to a repetitive stress.

The final breakage part is identified on the top of any section. When the transmission direction was assumed from the pattern of the beachmark, the starting point of the breakage was believed to be on the lower side.



b) The result of micro-observation of fracture by SEM

The trace of occurrence of crack caused by defects and the corrosion was not found from the condition of the fracture in the neighborhood of the starting point. Distinctive striation (a striped pattern) was identified on the fatigue fracture as shown in Fig. 4 (b). And, on the top side that is assumed to be the final breakage part, a significant dimple (a hallow pattern) was identified on the ductile fracture as shown in Fig. 4 (c).



According to the results of the macro-observation and the cross-sectional observation with micro-observation by SEM, no defects including corrosion and fine cracks were identified.

(2) Chemical composition analysis of material

When the result of chemical component analysis was compared with specification values of SNCM625 listed in JIS G 4053 Low-alloyed steels for machine structural use, the all components were satisfied the criteria. In addition, the result matches with the test result during manufacturing, no significant deterioration is found. As a result, it was determined that the material had no problem.

(a) Result of macro-observation

(b) SEM image of B part (c) SEM image of C part

Fig.4 Appearance of breakage surface and the result of SEM observation

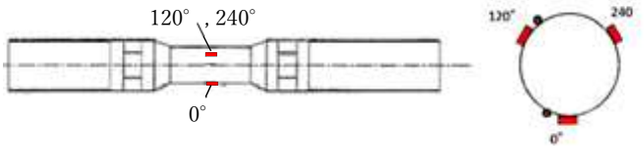


Fig.5 Positions to mount a strain gauge

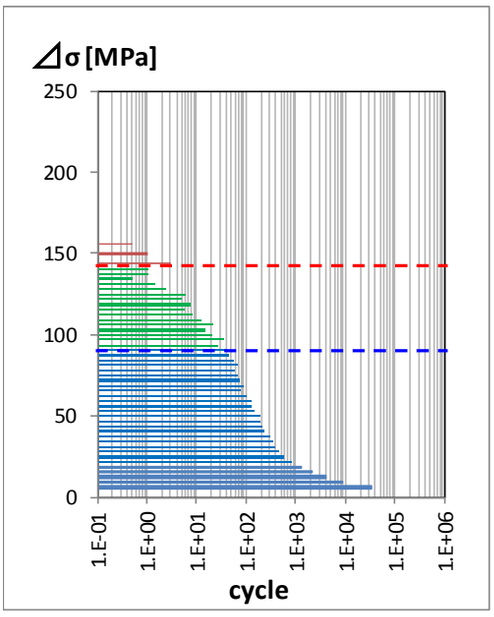
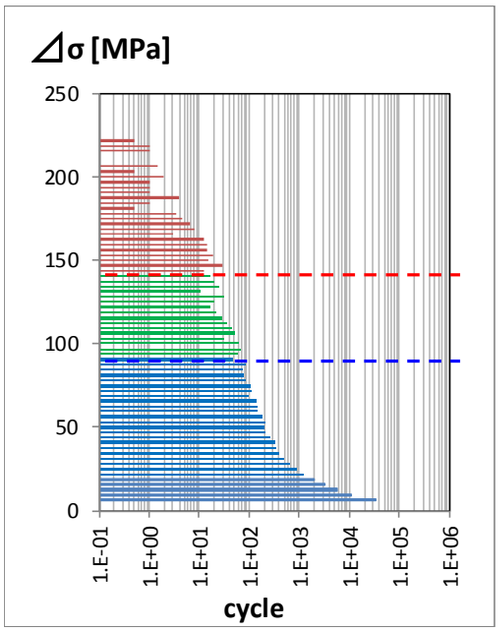
(3) Other investigations



Apart from (1) and (2), although a structure observation, a Vickers hardness test, a liquid penetrant test of the rod screw, and a magnetic-particle test were carried out after etching, neither confirmed abnormality.

From the above mentioned results, it was confirmed that the assumed damage was led to following reason the assumed damage. A crack by repetitive stress gradually developed starting from the thread root so that the decreased cross section cannot bear with a pulling force. As a result, the breakage become large gradually.



(4) Stress frequency measurement

To confirm the condition of the occurrence of live-load stress on the rod, 72 hours continuous stress measurement was conducted on the target bridge.

All four rods on the up-bound and down-bound lanes were measured. Fig.5 shows the positions to put a strain gauge. The gauges were installed at

(a)Up-bound lane
(end point side)
Unbroken rod

(b)Down-bound lane
(end point side)
Broken rod

Fig.6 Result of analysis of frequency

three locations (0° (the lower side), 120°, 240°) of the small diameter part of the center of the rod after recovering since it cannot be directly installed on the thread part on the breakage position.

Fig.6 shows the result of the stress frequency analysis of the measurement result which was converted from strain gauge of 0° to cross section area of thread root by FEM result as described next section. The strength ranges of 0° was larger than 120°, 240°. In addition, the strength ranges of down bound lane was larger than up bound lane.

4. FEM ANALYSIS

(1) Identification of stress concentration

FEM analysis was conducted to identify the stress concentration of the thread root.

a) Modelling

Fig.7 shows a model diagram. The rod and coupler were modelled by using two-dimensionally axisymmetric models to conduct the FEM analysis using ABAQUS, a general-purpose analysis code.

When making the model, the number of remaining screw threads of the coupler was set to three in order to similar the actual structure to reproduce the condition of damaged rod. The thread root R, where crack occurred, was set to 0.3 mm that was measured from a macro photograph of the cross section of the broken rod.

b) Result of the analysis

Fig.8 shows the maximum principal stress contour when tensile load to the axis direction was applied. The stress concentration was identified from the thread root R located in the first raw from the engaged part that is assumed as the starting point of the fatigue crack.

(2) Examination on structure that takes fatigue measures

The structure of rod for the fatigue measures was examined. And, the effect of measures was confirmed by the FEM analysis.

a) Examining measures

The following methods were considered for structural measures to improve the fatigue strength:

[1] A method to reduce stress by increasing the diameter of the thread part.

[2] A method to reduce the stress concentration of the thread root R that was the starting point of the crack.

With the method [1], substantial changes in structure, such as improved socket and anchor pin coupler, were required when increasing the cross sectional area to increase the diameter of the thread part.

On the other hand, with the method [2], change in the thread root R was required. The method [2] is seemed to be comparatively easy to take as it only involves the rod; and substantial structural change is not required. Therefore, the structure of rod for the fatigue was examined with method [2].

b) Modelling

The following two cases were analyzed by FEM analysis. The thread root R of a FEM analysis model

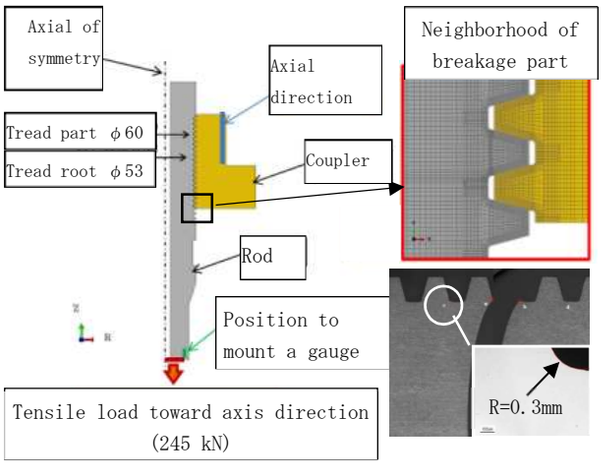


Fig.7 FEM analysis model diagram

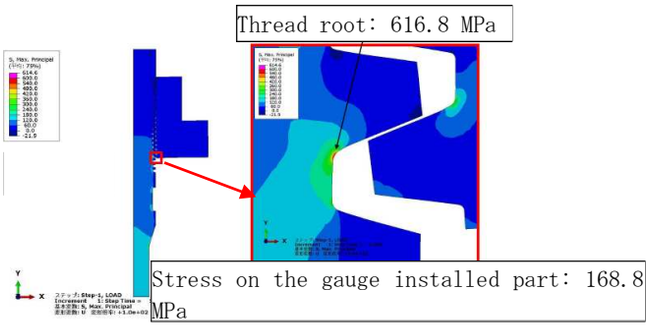

Fig.8 Result of the analysis (figure of the maximum principal stress contour)

Table1 Relation between radius and stress of the thread root R

R(mm)	Stress on the gauge mounted part (MPa)	Stress of the thread root (MPa)
0.3	168.8	616.8
0.5		521.3
0.7		464.7

for calculating stress concentration were set to 0.5 mm and 0.7 mm.

c) Result of analysis

Table 1 shows the relation between radius and stress of the thread root R. In the result of the analysis, reduction of the stress concentration by the increasing the thread root R was confirmed. As a result, the structure of the thread root R of 0.7mm that was decided the structure of rod for the fatigue measures.

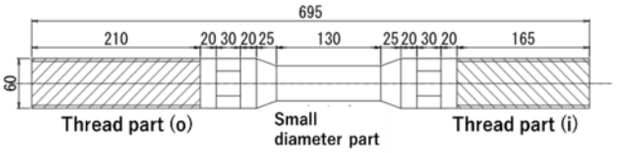
5. FATIGUE TEST

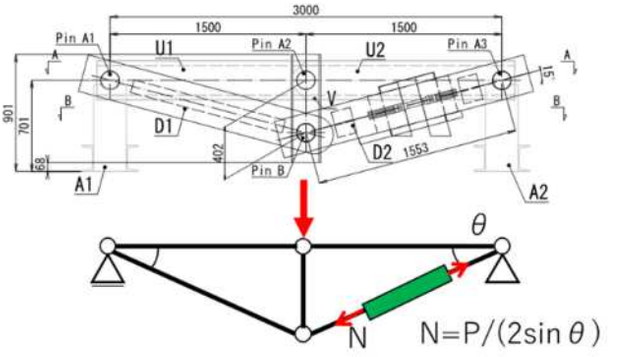
With the results obtained in the previous chapters, improved fatigue durability of a rod can be expected by increasing the thread root R. The fatigue durability of rods was examined by the fatigue test using the manufactured real size test pieces.

(1) Test pieces

Fig.9 and Table 2 show the general drawing, materials, etc., of test pieces that are tested this time. There are three types of test pieces. The existing rod is an actual rod that was not broken at the time of 2014 and had been used for 13 years in the up-bound lane of the actual bridge. The two types of new rods were manufactured, one has the same shape as the existing rod with the thread root R of 0.3mm, and the other has the improved radius of 0.7mm.

The steel of existing rod is SNCM625. But the steel of the new rods are SNCM630. Since the tensile strength of steel used for the new rod is higher than that of the existing rod due to procurement reasons, as for the new rod, the tensile strength of the small diameter part was made the same as that of the existing rod by reducing the diameter of the small diameter part of the rod part.





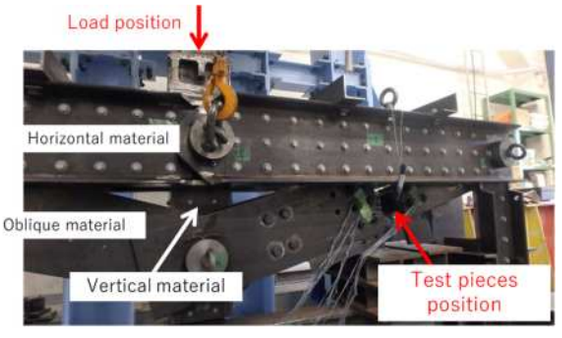


Fig.9 General drawing of test piece

Table.2 List of specifications of test pieces

Test pieces	Steel	Nunber of test pieces	Diameter(mm)	
			Small diameter part	Thread part
Existing rod	SNCM625	1	42.2	Max : 53.0 Min : 60.0
New rod(R0.3)	SNCM630	3	39.9	
New rod(R0.7)	SNCM630	3	39.9	

(a) Loading frame (general drawing)

(b) Loading frame (photo)

Fig.10 Fatigue test loading frame

There are one test piece for the existing rod and three each for the new rods. Fatigue test was conducted using the total of seven test pieces.

(2) Method of fatigue test

Fig.10 shows a loading frame. The loading frame is constructed so that loads can be transmitted to the test piece installed on a diagonal member by applying loads to vertical material. Fig.11 shows the positions to mount a strain gauge. In the small diameter part, single axis gauges with the length of 5 mm are installed at intervals of 90° for measuring nominal stress. In the neighborhood of thread part, single axis gauges with the length of 1 mm are installed at intervals of either 45° or 60° for detecting the occurrence of cracking.

For setting the applying load, the load range ΔP = 130 kN (P = 20-150 kN) is set according to the maximum stress range of the small diameter part obtained from the 72-hour stress frequency measurement at the actual bridge shown in Fig. 12 to allow the maximum stress range of 200 MPa to act at the small diameter part. A repetition frequency is set to 3 Hz.

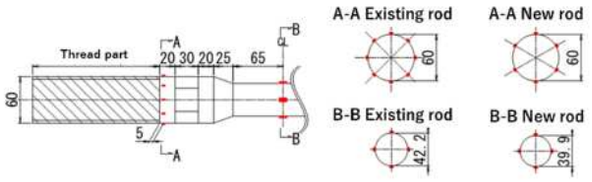

Fig.11 Positions to mount a strain gauge

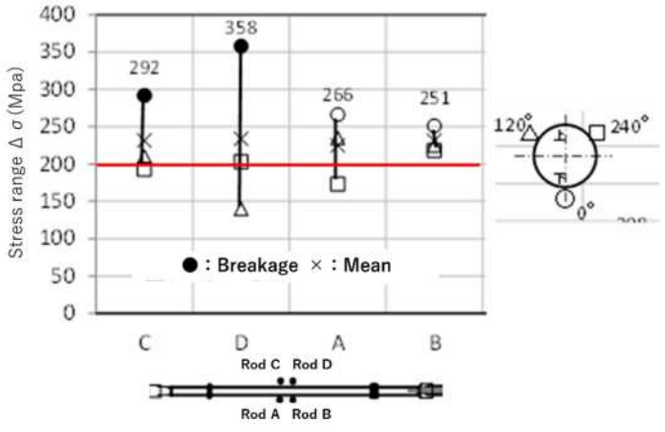

Fig.12 Stress range from 72-hour stress frequency measurement at a actual bridge

(3) Result of fatigue test

Typical results for each test piece are discussed in this section. Photo.5 shows the existing rod after the test. With the existing rod, breakage occurred at the thread part after load was applied 520,000 cycles. The position of breakage is the thread root of the first screw thread engaged with the anchoring body. And, by the breakage surface, to breakage is assumed an arc-like crack occurred in between 0 degree and 90 degrees. Therefore, fatigue breakage occurred at the actual bridge is believed to be reproduced.

Photo.6 shows the new rod (R0.3) after the test. With the new rod (R0.3), breakage occurred at threaded part after load was applied 1,620,000 cycles. The position of breakage is the thread root of the first screw thread engaged with the anchoring body, which is similar to that of the existing rod. And, by the breakage surface, to breakage is assumed an arc-like crack occurred in about 180 degrees.

Photo.7 shows the new rod (R0.7) after the test. With the new rod (R0.7), crack did not occur by the load range ΔP = 130 kN. Therefore, the load range ΔP = 260 kN (P = 20-280 kN) was set. In the result, breakage occurred at threaded part after load was applied 410,000 cycles. The position of breakage is the thread root of the first screw thread engaged with the anchoring body, which is similar to the other rods. And, by the breakage surface, to breakage is assumed an arc-like crack occurred in about 180 degrees.

A fatigue test is conducted on all seven test pieces. Fig.13 shows the result of fatigue test, together with fatigue design curves of cables and high-tensile bolts (K1-K5) that receive direct stress. The vertical axis indicates a stress measured at the small diameter part that is converted into the cross section of the thread root.

From Fig. 13, the existing rod has a shorter fatigue life than the new rod (R0.3). The existing rod is assumed had damage in actual bridge. And, in new rods (R0.3), it is assumed that there is a fatigue limit in 93MPa. In new rods (R0.7), it is assumed that there is a fatigue limit in 144MPa. Therefore, fatigue limit was increased to 1.5times by the changing the fatigue

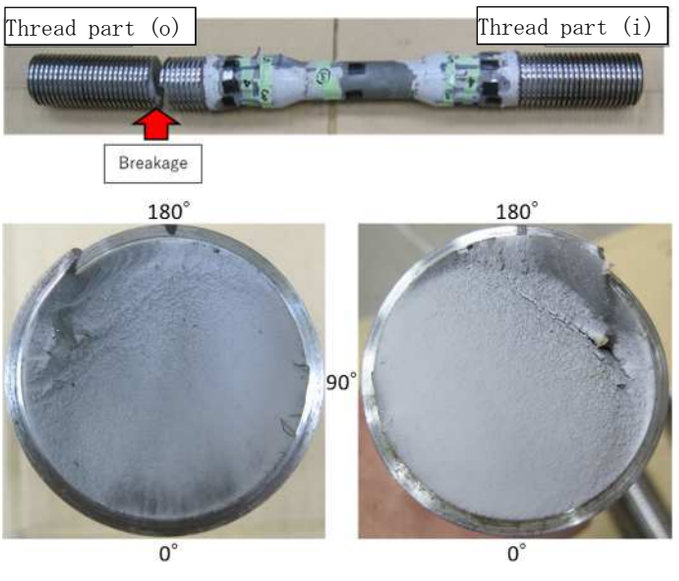

Photo.5 Existing rod after the test

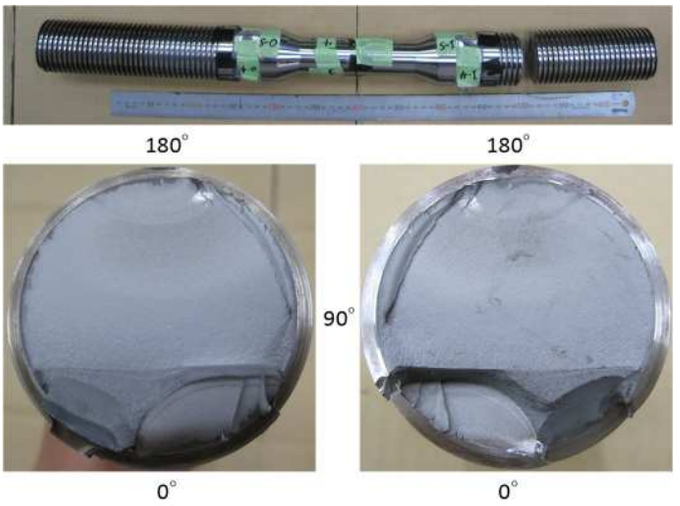

Photo.6 New rod (R0.3) after the test

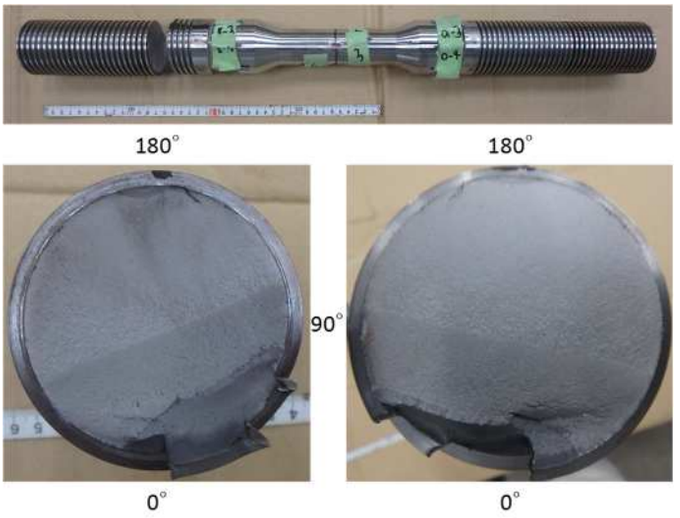

Photo.7 New rod (R0.7) after the test

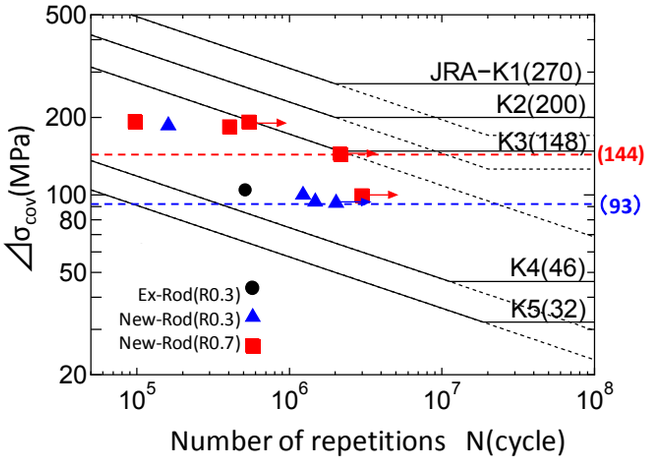

Fig.13 Summary of the result of fatigue tests

limit from 93MPa to 144MPa. Therefore, the fatigue strength is improved by changing the thread root R from 0.3mm to 0.7mm.

Meanwhile, it was confirmed that the fatigue life of one of the new rod (R0.3) and one of the new rod (R0.7) are reversed. According to the hearing investigation of the manufacturer, about ±0.1 mm of error occurs as manufacturing accuracy of the thread root R. In the future, a detailed investigation is required by measuring the thread root R of test pieces.

6. CONCLUSION

In this study, the following knowledge was obtained by conducting an investigation for the causes of breakage on the center stay rod and an actual size fatigue test:

• Inspection of cause of damage

(1)No defects, such as a problem with materials and a crack at the starting point, were found from the broken rod.

(2) In the result of observation of the breakage surface, fatigue crack occurred from lower-side.

(3)The cause of the breakage is a fatigue damage caused on the thread root of the first screw thread on the coupler side of the rod.

(4)The target bridge is in a state where vehicles lean to the down-bound lane. As a result, the stress range of the down-bound lane where the rod was broken becomes large.

(5)Fatigue damage may occur in a short time according to the 72-hour stress frequency measurement.

• Result of fatigue test

(1) Fatigue cracks were initiated at the thread root, and propagated in arc shapes, then finally broke the rod, similarly in the actual structure.

(2)The fatigue limit increased to 1.5times by changing the radius of the thread root from 0.3mm to 0.7mm.

According to the above mentioned result, the improved center stay rod was applied to the actual bridge. However, it is difficult to inspect the rod, since the rod is covered. Therefore, new inspection method that can detect a crack of the thread part without opening cover will be developed.

Repair of corroded steel plate girders with ultra-high performance concrete

K.F. McMullen & A.E. Zaghi
University of Connecticut, Storrs, CT, United States of America
M.P. Culmo
CME Associates, Inc., Mansfield, CT, United States of America

ABSTRACT: As the world's bridge infrastructure ages, there is a growing need to develop new, innovative repair and maintenance methods to rehabilitate these critical structures. Corrosion damage of steel bridges is a prevalent problem especially beneath leaking deck expansion joints. Implementation of conventional repair methods is expensive and disruptive to traffic. The University of Connecticut is developing a novel repair method by encasing corrosion damaged sections with ultra-high performance concrete (UHPC) to restore bearing and shear capacity lost due to severe reduction of the plate thickness. This paper will present preliminary finite element analysis results and the design of a series of large-scale experiments conducted on full-scale corroded plate girders with the UHPC repair. The UHPC repairs have been designed to restore the as-built capacity of the girders. The goal of the study is to demonstrate the versatility and structural effectiveness of the UHPC repair.

1 INTRODUCTION

Throughout the world, corrosion damage of civil structures is a prevalent problem. National Association of Corrosion Engineers (NACE) International released a report estimating that US$2.5 trillion is spent globally on corrosion accounting for 3.4% of the global Gross Domestic Product (Koch et al., 2016). In the United States (US), the Federal Highway Administration (FHWA) estimates that approximately US$273 billion is spent annually on corrosion maintenance and a total of US$8.3 billion is spend solely on the repair and replacement of highway bridges (Koch et al., 2002).

Figure 1. Corrosion damage of steel bridge girders

One of the superstructures types that is susceptible to corrosion damage are steel girder bridges. Over half of the structurally deficient bridges in the US utilize a steel superstructure (FHWA, 2016). In the northern US, highway bridges are exposed to heavy amounts of precipitation, ice, and de-icing chlorides used for snow and ice control on the roads (Shi et al., 2009). The combination of moisture and chlorides expedites the corrosion of steel material (Albrecht and Hall Jr, 2003). The location which experiences the heaviest corrosion is directly beneath leaking bridge deck expansion joints. Girder ends, bearings, abutments, and piers beneath the expansion joints are the structural components that are most commonly effected (Kayser and Nowak, 1989, Usukura et al., 2013, Van de Lindt and Pei, 2006). Figure 1 shows corrosion damage of steel girder ends including web buckling due to section loss.

A recent study cited the lifespan of bridge deck expansion joints to be between 5-20 years (Chang and Lee, 2001). Once the expansion joints begin to fail, runoff and chlorides begin to leak on the girder ends below from the road above. The ends of steel girders transfer large bearing and shear forces from the girder to the bridge bearing. Several research projects have documented the effect of corrosion damage on the load carrying capacity of steel girders including both small-scale and full-scale experimental and analytical testing (Liu et al., 2011, Yamaguchi and Akagi, 2013, Ahn et al., 2013a, Khurram et al., 2014a, 2014b). The results show that when this critical section of the girder experiences section loss due to corrosion, the bearing and shear capacity of the girder are reduced.

The repair method to rehabilitate this type of corrosion at the end of steel girders is standardized for

many US Departments of Transportations (DOTs). The traditional method is to 1) jack up the superstructure to remove load from the girder end, 2) remove the corroded portion of steel, 3) weld or bolt new steel plates to the girder, and 4) lower the beams back on the bearing (FLDOT, 2011, Rossow, 2003 , Wipf et al., 2003, WisDOT, 2015). An example of the conventional repair method is shown in Figure 2. This method is expensive, time consuming, and difficult to construct. A sizable portion of the construction cost is due to jacking of the bridge and abatement and surface treatment of the corroded steel before the repair can be implemented.

Figure 2. Conventional repair for corroded steel bridge girders

Research is being conducted by many institutions to develop a new repair method for steel girder with corrosion damage. Ahn et al. (2013b) and Miyashita et al. (2015) are investigating the potential to apply CFRP sheets over corrosion damage. Ogami et al (2015) has developed a repair which envelopes the corroded area in an epoxy resin. However, these projects have yet to be accepted as a conventional repair method. This leaves a need for the development of a new, more cost-effective repair design.

In collaboration with the Connecticut Department of Transportation and the United States Federal Highway Administration, the University of Connecticut is developing a novel repair method for corroded steel girder ends by encasing the corrosion damage with ultra-high performance concrete (UHPC). UHPC is a flowable concrete material which includes significant quantities of high strength steel fibers. UHPC can achieve very high compressive and tensile strengths resulting in a material that can be facetiously described as "liquid steel." This repair will decrease construction costs, construction time, and traffic interruptions while providing a structurally efficient restoration of the girder capacity.

2 UHPC REPAIR METHODOLOGY

The repair method developed at the University of Connecticut encases the corrosion damage girder end in UHPC. Headed shear connectors, typically used for composite decks, are welded to the intact, uncorroded portions of the web, flanges, and stiffeners of the girder beyond the corrosion zone. UHPC is then cast, encasing the shear connectors and the corrosion damage, creating a structural column or panel at the end of the girder to carry the load demands on the girder. The composite action between the welded shear connectors and the UHPC panel allows the forces to bypass the corroded portion of the web. Bearing and shear forces carried by the girder are transferred from the web through the shear connectors to the UHPC panel.

UHPC was chosen as the desired repair material because of several advantages it has over conventional concrete and structural steel (Russell and Graybeal, 2013). The main advantages which benefit this repair design are the high early strength, high tensile strength, superior fatigue resistance, exceptional durability, and increased flowability. UHPC has the ability to achieve strengths as high as 80 MPa in as little as 12 hrs which would allow for minimal lane closures and traffic delays during construction. UHPC also has a high tensile strength due to the inclusion of steel fibers in the mix which can bridge cracks in the concrete reducing the need for additional reinforcement and performing the performance of the repair under bending moments. UHPC has proven fatigue performance under a large number of loading cycles improving the design life of the repair. The durability of the UHPC will also lead to a longer service life because it is far more impermeable than regular concrete. The flowability of UHPC provides several constructability advantages allowing the concrete to be poured or pumped to encase complex geometries or tight configurations.

The repair may be applied to the bridge while it is in-service and under traffic reducing traffic disruptions and lane closures. Being able to implement the repair in situ will remove the need for jacking of the superstructure by allowing the repair to be installed under load. The simplicity of construction will also reduce construction durations and improve work-zone safety.

3 PREVIOUS RESEARCH STUDIES

The University of Connecticut and the Connecticut Department of Transportation have been conducting extensive research on the constructability and structural performance of the UHPC steel girder end repairs. Phase 1 of the research project focused on design of the repair, extensive finite element modeling, and a proof-of-concept experimental study. This phase of the research study concluded in 2015.

The finite element research explored a broad range of repair configurations and geometries for both rolled girders and plate girders of varying sizes. The results showed that the repair configuration may be

adjusted based on the number of shear connectors, the layout of the connectors, and the geometry of the UHPC panel. Several geometries that were tested included a full-height end panel, a half-height end panel, a full-height bearing column with continued half-height end panel, a full-height bearing column only, and a half-height bearing column only. From the results of the finite modeling, it was apparent that the configuration and geometry were critical in determining the structural behavior and transfer of forces of the composite repair. Extensive results of the finite element studies are described in previous publications (Zmetra, 2015, Esmaili Zaghi et al., 2015, Zmetra et al., 2017a).

A proof-of-concept experimental study was conducted on half-scale, W21x55, 4.25 m long, rolled steel girders to demonstrate the global performance of the repair. Three girders were tested: an undamaged, damaged, and repaired girder. Both the damage and repaired girders had artificial corrosion damage introduced by removing 70% of the web and 40% of the flange. The repaired girder had a partial height UHPC repair applied with shear connectors welded to the undamaged portions of the web and bottom flange of the girder. The girders were tested using a large scale 3-point bend test set up. The results showed that a 70% reduction of the web thickness reduced the bearing capacity of the corroded girder by 76%. After the UHPC repair was applied, the bearing capacity of the repaired girder exceeded that of an undamaged girder shifting the failure mode to flexural yielding. The additional of the UHPC repair reduced the bearing strain demand on the repaired girder by 21 times compared to the undamaged girder. Overall, the results of the experimental study demonstrated the ability of the repair to restore full bearing and shear capacity of a corroded steel girder. Full results of the experimental study have been documented (Zmetra, 2015, Esmaili Zaghi et al., 2015, Zmetra et al., 2017b).

Recently, the Connecticut Department of Transportation and the University of Connecticut have engaged in the design of a field repair for a candidate bridge in Connecticut using the UHPC repair methodology. A design process has been developed to determine demands, design capacities, and necessary design checks for the structural repair design. The results of the design of the UHPC repair for this case study bridge have been documented by McMullen et al. (2017).

4 DESIGN OF EXPERIMENTS

A total of four full-scale plate girder will be experimentally tested to evaluate the structural performance and constructability of the UHPC repair. One of the girders will have corrosion damage with no repair as a baseline, and three of the girders will have three different UHPC repair configurations. The results of the study will be examined for 1) ease of construction including complexities and potential concerns for field application, 2) effect of vibrations during curing to simulate live load traffic during UHPC curing, and 3) structural performance of the different repair types.

4.1 *Test Specimens*

After reviewing several inspection reports, many of the bridges that have experienced heavy corrosion damage of the girder ends are welded plate girders constructed 50-60 yrs ago. To determine accurate sizes and dimensions of the plate girders constructed during this period, design drawings for a number of plate girder bridges in Connecticut were reviewed.

The primary advantage of welded plate girders over rolled girders is the flexibility in the size and dimensions of the members. Therefore, the goal of the design of the experimental plate girder specimens was to accurately represent a large number of diverse designs. After reviewing the drawings, it was found that for a large variety of plate girder designs the ratio of girder depth (D) to web thickness (t_w) and the ratio of stiffener spacing (d_0) to web depth (D) were consistent. Of the bridges reviewed, the average D/t_w ratio was 144 and the average d_0/D ratio was 0.74.

The final design of the plate girder was completed based on the original design of a 54-year-old bridge in East Hartford, CT. The web depth was 1.32 m with a web thickness of 9.5 mm and a stiffener spacing of 1.02 m. These dimensions correspond to a D/t_w ratio of 139 and a d_0/D ratio of 0.77, which was deemed as representative for typical plate girders. For the plate girder specimens, the bottom flange was designed to have a thickness of 25.4 mm and the top flange a larger thickness of 38.1 mm to improve the lateral torsional buckling stability of the specimens due to the lack of a composite deck during testing. The bearing stiffener had a thickness of 12.7 mm and the web stiffener had a thickness of 9.5 mm.

Figure 3. Full-scale plate girder end panel

For experimental testing, the girders will each be tested over a 5.28 m long span. To simplify construction and testing of each of the specimens, a splice connection was incorporated to separate the girder into a baseline section and a test section. The splice connection was placed directly after the end panel of the girder, since the end panel is the critical portion of the girder which is experiencing heavy corrosion damage. The splice connection was designed with a capacity equal to that of the full plastic shear capacity of the end panel of the test specimen. The baseline section of the girder included additional, closer spaced stiffeners as well as two sets of stiffeners directly beneath the point of loading to prevent any damage during testing. Figure 3 shows the plate girder specimen end panel.

The plate girder specimens were fabricated by a professional steel fabricator to ensure that all four specimens were comparable with similar dimensions.

4.2 *Corrosion Damage*

To accurately capture the extent and pattern of typical corrosion damage, inspection reports from over thirty bridges in Connecticut were examined. The bridges chosen had either a plate girder or rolled beam steel superstructure. Each of these bridges varied by span length, traffic volume, overall width, and several other factors. There was a good balance of bridges with extreme damage and structurally deficient ratings and non-deficient bridges with corrosion damage. After an in-depth review of the inspection reports, it was confirmed that there was a common pattern of heavy corrosion damage at the end of girders beneath expansion joints.

Of the bridges reviewed, the length, width, and depth of the corrosion damage varied significantly from surface rust to full perforations of the steel at isolated locations. Although corrosion damage is highly non-uniform and unpredictable, through review of the inspection reports several consistencies were found including the radial shape of the corrosion damage. Heavy corrosion damage is typically limited to the bottom 125 mm of the girder, and corrosion often extends past the end of the bearing towards mid-span.

One of the primary goals of simulating the corrosion damage to the girders was to preserve the non-uniform nature of typical corrosion damage. In previous research studies, corrosion damage has been modeled as a uniform section loss of equal thickness and height and is typically introduced by removing material with a milling machine (Ahn et al., 2013a, 2013b, Khurram et al., 2014a, 2014b). However, this is not representative of the corrosion found on bridges in the field. A non-uniform corrosion pattern was introduced to each of the girders through sandblasting and metal grinding. Another advantage of this method was that it preserved the condition of the end panel. Previous research projects (including the UHPC repair proof of concept project) simulated corrosion by removing a portion of the girder end, milling of the removed portion to simulate corrosion loss, and then welding the portion back into the girder. This introduces an added complexity due to modeling of the experiment because the girder consists of two separate pieces welded together which is not typically the condition found in the field.

Based on the inspection reports that were evaluated, only two limitations were used for introducing the corrosion damage: 1) the corrosion damage did not extend to a height greater than 125 mm, and 2) the corrosion damage extended at least 50 mm past the end of the bearing. To simulate the most extreme case of corrosion damage of steel girders, a target section loss of 70% of the web thickness and 50% of the bearing stiffeners was targeted (however, this was not a limitation). During implementation of the corrosion damage simulation, 100% section loss and full perforations were achieved in isolated locations. Detailed pictures of the corrosion damage of one of the plate girders is shown in Figure 4.

Figure 4. Corrosion damage applied to the plate girders

4.3 *UHPC Repair*

The goal of this research project was to evaluate the performance of repair configurations that would most likely be chosen by engineers for typical corrosion damaged bridges. Based on the Phase 1 and preliminary Phase 2 finite element analysis results, it was determined that repair of the bearing column is critical for rehabilitation of the bearing and shear capacity of the girder. The bearing column consists of the end portion of the web and the bearing stiffeners. This portion of the girder carries bearing and shear forces from the girder directly to the bearing.

Under severe corrosion damage, the local web buckling of the web plate and the bearing stiffener is the primary failure mode when corrosion is isolated to the girder end. If extreme corrosion extends farther past the bearing into the web end panel, then repair engineers may consider extending the UHPC repair panel into the entire end panel. In extreme cases, where the corrosion damage intercepts the tension field of the web plate, the shear capacity of the end panel may be reduced significantly.

Since heavy corrosion rarely extends far past the bearing towards mid-span, the experimental repair

geometries chosen for this research were predominantly for repair of the bearing column. Two of the girders will utilize a full-height UHPC repair column and one will have a partial-height UHPC repair column. This will provide experimental evidences for the effectiveness of the repair and enables engineers to choose the optimal repair design by minimizing the repaired volume of UHPC. For the design of the UHPC repairs, previous research has found that the number of shear connectors included is the controlling factor for the capacity of the repair (McMullen et al., 2017). Push-out tests were performed on shear connectors welded to a thin web. The individual capacity of a shear connector may be used to determine the capacity of the UHPC repair based on the number of connectors used. The target capacity for the experimental tests was the as-built bearing and shear capacity of the girders.

For this repair, 12.7-mm diameter headed shear connectors were chosen for the large-scale specimens. The results of the push-out tests found the ultimate shear capacity of a single stud to be 59.7 kN. The calculated bearing and shear capacities of the undamaged girder specimen were 1800 kN and 1600 kN, respectively. To restore the shear capacity to the girder a minimum number of 27 shear connectors are needed.

Each of the three repaired girders has 28 connectors welded to both sides of the web. The connectors should be welded to the uncorroded portion of the web. The pattern of the full- and partial-height repairs are shown in Figure 5. A standard Connecticut deck haunch is cast at the end of the girder and a diaphragm channel shape is welded to the bearing stiffener to simulate the typical geometry of the girder end found in real designs. These constraints will influence the constructability of the repair as far as access and forming around complex geometries.

Figure 5. Plate girder specimens before UHPC repairs (connector layout): a) full-height column; b) partial-height column

The UHPC used for the experimental tests will be two different mixes developed by Lafarge Holcim: Ductal JS1000 and Ductal JS1212. Ductal JS1000 is a general, fiber reinforced UHPC mix which can gain a strength of 83 MPa in four days. Ductal JS1212 is a high early strength mix that can achieve a compressive strength of 83 MPa in as little as 12 hours and sets in about two hours.

The first repaired girder will be a full-height column repair with JS1000. The goal of this repaired girder is to investigate the effect of vibrations at early strength of a UHPC repair with a long curing time. This will be done to evaluate if the repair can be implemented with minimal lane closure, and traffic can be restored soon after casting.

The second repaired girder will be a tall column repair with JS1212. This girder will test the ability to cast the repair and allow the UHPC to set and gain strength in a single construction shift allowing for full traffic load to be reestablished with minimal effect on the structural performance of the repair.

The third repaired girder will be a partial height column repair with JS1212. This girder will compare the differences between a taller column with a larger volume of UHPC and a smaller column with connectors welded closer to the corroded section. A partial height repair will also reduce the complexity of having to form around diaphragm connections and the deck haunch.

4.4 *Test Setup*

The previous experimental research on the repair design was conducted on half-scale rolled steel girders. To test full-scale plate girders, the test setup required substantial upgrades. The test setup consists of a large-scale three-point bend test of the plate girders. The load will be applied at $^{3}/_{10}$ the span of the girder closer to the test end panel. The location of the loading was chosen to induce large shear and bearing forces in the test end panel. The load will be applied with a hydraulic load ram. For the previous test, a 2,200 kN hydraulic load ram was used, however to test full-scale plate girders a 4,400 kN load ram was obtained.

The existing load frame had to be modified to support the plate girder specimens. Three additional spread beams were added to the load frame to engage all four columns that are tied in to the strong floor. The load ram will be mounted to the center of the load frame and the load will be applied to the top flange of the girder directly after the splice connection between the test end and the permanent end. The load ram is indicated with a red arrow in Figure 6.

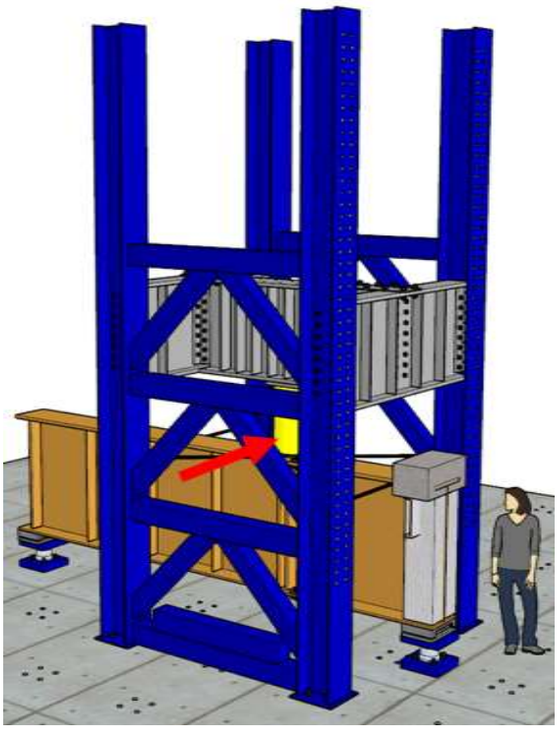

Figure 6. 3D rendition of the experimental test setup

The girder will be supported by two sliding Disktron bridge bearings manufactured by RJ Watson. Lateral support chains will be used to brace the top flange to simulate the lateral stability provided to the girder by a concrete deck.

Over 100 channels of data will be collected during each test. The instrumentation that will be used for the test include two five-degree of freedom load cells beneath each bearing, pressure transducers attached to the hydraulic load ram, strain gauges installed on the web and the flanges, shear studs, and on the UHPC panels, and string and rod displacement transducers. Digital Image Correlation will be used to map the strain distribution at the end panel.

A 3D rendering of the entire experimental test setup is shown in Figure 6.

5 FINITE ELEMENT ANALYSIS

Preliminary finite element models were developed to estimate the expected performance of the specimens. The finite element models were developed in a general-purpose finite element program, LS-Dyna. LS-Dyna was chosen because of its rigorous solving capabilities that enable refined analysis of the models including developing custom material models and capturing geometric nonlinearities.

The goal of developing these models was to evaluate the expected forces and failure modes of each test. This was done to: verify that the test setup was adequately designed to support the full capacity of the girders, ensure that the test specimens were designed correctly and that failure happens at the end panel, and obtain the level of web section reduction needed to introduce a notable reduction in the capacity of the damaged specimens. The models may be used to study different repair configurations and design parameters to finalize the design for each of the experimental plate girder specimens.

The first two models that were created and analyzed were an as-built, uncorroded plate girder and a corroded plate girder with the target section loss assigned to the web and stiffeners. Each of the models included bearings at either end of the girder which allowed for rotation in both the x- and y-direction, a load ram saddle used to apply the loading to the top flange of the girder, and lateral restraints to prevent rotation or lateral torsional buckling of the top flange. Figure 7 shows the full finite element model with all components included.

The steel plate girders including the web, flanges, and stiffeners were modeled using four-node, two-dimensional, shell elements. The bearings and load ram were modeled using eight-node, three-dimensional solid elements. The shell elements were fully integrated and were computationally less expensive compared to solid elements. Yet, they are able to capture the complex stress fields and failure modes, including web buckling, web crippling, and tension field formation. The shell elements also included five integration points through the thickness of the element and warping stiffness control. The lateral restraints were boundary conditions restricting movement of the top flange in the x- and y-directions at eight different points.

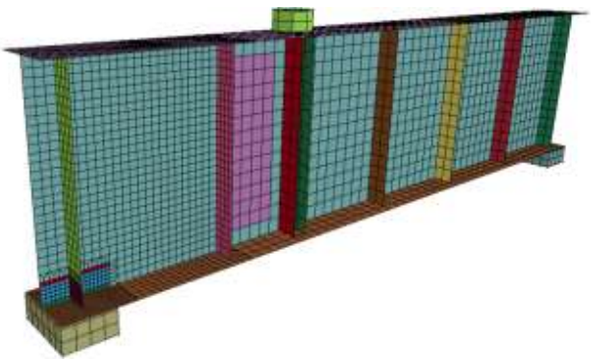

Figure 7. Finite element model of the entire analytical setup

For the preliminary finite element models, the corrosion damage was introduced to the model as a uniform section loss of the web and stiffeners. The corrosion damage applied to the web was 380 mm long and 125 mm tall with 33% (3.175 mm) of the thickness remaining. The corrosion damage applied to the stiffener was the same height as on the web and the full width of the stiffener with 50% (6.35 mm) of the thickness remaining. For the finalized models, 3D scanned geometry of the corrosion damage will be imported into the model to accurately model the non-uniform corrosion of the specimens.

The finite element models of the repaired girders required the addition of two different components: the shear studs and the UHPC panel. The shear connectors were modeled using spotwelds. Spotwelds are a definition in LS-Dyna typically used to model bolted or spot weld connections. Spot welds were used to model the shear connectors because they can capture the observed failure mode of studs embedded in UHPC that was found during the experimental push-out tests. The spot welds may be assigned to any location on the girder and have a contact assignment between the web of the girder and the UHPC panel to provide a secure stud connection. The material model of the spotweld elements was defined to model the load-slip behavior of shear studs captured from the experimental push-out tests. The details about the stud behavior is presented by McMullen et al. (2017) and Zmetra et al. (2017a). The UHPC panel was also modeled as a constant stress solid element. The UHPC material model was adopted from previous research. This model captures the nonlinear behavior of high-strength concrete in tension and compression.

A displacement control loading was applied to the girders. The load ram saddle was used to displace the top flange of the girder using a triangular acceleration profile. The results of each of the models were compared based on the deflection of the bottom flange directly beneath the point of loading and the bearing reaction force at the test end of the girder.

6 RESULTS OF FINITE ELEMENT MODELING

The first finite model that was developed for the intact plate girder. Under initial simulated loading, the girder behaved elastically as a tension field formed in the end panel. The simulated failure mode of the intact plate girder was web buckling of the end panel. This occurred under a load of 2980 kN corresponding to a bearing load of 2060 kN and a vertical deflection of 6.2 mm. The web buckling observed in the end panel was a ductile failure were the intact beam was able to continue to carry approximately 80% of the maximum load applied.

The next model was the damaged plate girder with section loss applied to simulate corrosion damage. Reducing the cross section area of the web and stiffener plates at the bearing induced localized buckling of these plates. The damaged plate girder failed under a load of 1446 kN corresponding to a bearing force of 996 kN and a vertical deflection of 3 mm. Applying a 66% section loss to the web and a 50% section loss to the stiffeners reduced the capacity of the plate girder by approximately 52%.

Next, different repair configurations were simulated to finalize the UHPC geometry, number of connectors, and layout of connectors for the experimental studies. It was concluded that 28 shear studs are needed to restore the bearing and shear capacity of the intact girder. The number of studs required by the finite element models also agrees with the design checks proposed by McMullen et al. (2017). The two UHPC geometries chosen for the repairs were a partial-height column and a full-height column. The partial-height column was 668 mm tall with four independent 152 mm by 152 mm columns as shown in Figure 8. The tall column repair was 1220 mm tall with four independent 152 mm by 152 mm columns as shown in Figure 8. The connectors were placed in a staggered pattern as shown in Figure 5.

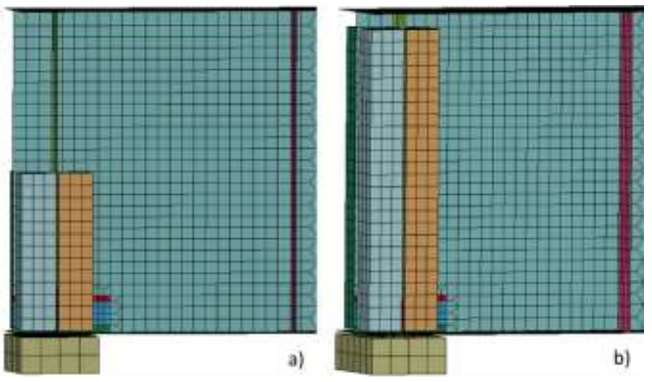

Figure 8. UHPC repair geometries: a) partial height repair; b) tall repair

The finite element simulations show that the partial height UHPC repair fails due to buckling of the end panel web similar to that of the intact plate girder. Failure of the partial height repair occurred under a load of 3220 kN corresponding to a bearing load of 2230 kN and a vertical deflection of 6 mm. The partial height UHPC repair increase the capacity of the plate girder 8% over the capacity of the intact plate girder maintaining the ductile failure mode.

The full-height UHPC repair column also failed due to web buckling of the end panel under a bearing force of 2360 kN and a vertical deflection of 6.76 mm. The tall repair column increased the capacity of the plate girder 15% over the as-built plate girder capacity. The additional capacity provided to the girder by the full-height UHPC repair is because the UHPC repair intercepts the tension field in the end panel providing added buckling support to the web.

The deformed shape and stress distribution of each of the analytical plate girder models is shown in Figure 8. Figure 9 shows the force-displacement relationship for each of the four analytical models.

After the plate girders are scanned and experimentally tested, the finite element models will be updated and refined to capture the conditions of the experimental test. The methodology for the development of the finite element models is described in detail by Zmetra et al. (2017a).

7 CONCLUSION

The experimental and analytical research completed by the University of Connecticut and the Connecticut Department of Transportation has the potential to provide bridge owners with a new, cost-effective repair for corroded steel bridge girders. The novel repair method presented encases corrosion damage of steel bridge girders with UHPC mechanically attached by headed shear studs welded to the web of the girder. The preliminary finite element results demonstrated the adaptability of the repair to allow engineers to use different configurations and geometries to repair girders with complex structures. Both repair geometries presented increased the capacity of the plate girder over that of the as-built, uncorroded plate girder.

The results of the proposed full-scale experiments will validate the repair concept and show that this repair may be implemented in place of the conventional repair methods typically used. Using this repair may be more efficiency than the conventional repair improving constructability, minimizing project costs, preventing excessive traffic disruptions, and improving long-term durability of the repair.

8 ACKNOWLEDGEMENTS

The research presented in this paper was funded by the Connecticut Department of Transportation and the Federal Highway Administration Contract number SPR-2295. The authors would like to thank the ConnDOT for their support and advice through the course of the project especially Rabih Barakat, Timothy Fields, Anne-Marie McDonnell, Mary Baker, Brad Overturf, and Richard Hanley. The Connecticut Transportation Institute is thanked for managing the project and funds. The authors would like to thank our industry sponsors, especially Infra-Metals, United Steel, Lafarge Holcim, and RJ Watson. The support of Dr. Kay Wille, Dr. Kevin Zmetra, Dominic Kruszewski, and Alexandra Hain is also greatly appreciated.

ABSTRACT: Lots of fatigue crackings were reported at the upper end of vertical stiffeners connected to sway bracings and web gap plates under RC slab in steel highway girder bridges. In this study, we investigate fatigue cracking behavior, and propose a retrofitting method against fatigue cracking at the upper end of web gap plates under RC slab. In this method, TRS (Thread Rolling Screw) is used to attach angle steel to upper flange, and HTB (High Tension Bolt) is used to connect angle steels to web gap plate. The effectiveness of the method is investigated through fatigue tests using a beam specimen with the web gap detail of the same size as the actual bridge under alternative loading using two actuators. As a result, the method can reduce the local stress concentration at crack initiation points to about 50~60 %, and can extend fatigue crack initiation life more than 2~6 times and fatigue crack propagation life more than 100 times after grinding away fatigue cracks.

1 INTORODUCTION

Lots of fatigue crackings were reported at the upper end of vertical stiffeners connected to sway bracings and web gap plates under RC slab in steel highway girder bridges (Japan Road Association 1997, Hanshin Expressway Technology Center 2012). Several countermeasures were proposed against those crackings, such as steel plate reinforcement between the upper flange and the vertical stiffener using high tension bolts after breaking RC slab, or re-welding. However, the work of breaking RC slab requires traffic lane closing, and re-welding may cause re-cracking. Whereas, the semicircular cutting method for web gap plate to reduce stress concentration at the weldment were proposed, but cracks may be propagated when short cracks have been already initiated. In this study, we investigate fatigue cracking behavior, and propose a retrofitting method against fatigue cracking at the upper end of web gap plates under RC slab. In this method, TRS is used to attach angle steel to upper flange, and HTB is used to connect angle steels to web gap plate.

The effectiveness of the method is investigated through fatigue tests using a beam specimen with the web gap detail of the same size as the actual bridge under alternative loading using two actuators.

2 EXPERIMENTAL PROCEDURES

2.1 *Specimen*

Figure 1 shows configurations and dimensions of the specimen, and location of strain gages. The depth and space of main girders are smaller than those of the actual bridge (Ichinose 2017), because of capacity of fatigue testing facility. But upper flange and web gap plates are of the same size as the actual bridge. The specimen has three main girders, which reproduce the alternative stress in the top of the middle girder when vehicles run on driving lane and passing lane alternatively. The specimen is made of JIS-SM490YA, SM490YB and SM400 steels, which are of the same grade as the actual bridge. The upper flange and upper end of vertical stiffener are welded with a 2mm gap by CO2 gas shield welding.

The specimen has 4 test parts with or without retrofitting methods as follows, A, B: No retrofitting method; C, D: Angle steel retrofitting method using TRS.

The effectiveness of these two types of retrofitting methods is investigated by comparing fatigue behaviour of these 4 test parts.

(b) Elevation

Figure 3. Angle steel method using TRS

2.2 *Retrofitting method*

Figure 2 shows retrofitting details, and Figure 3 shows appearance of angle steel reinforcement using TRS. This method reduces the local stress concentration at the upper end of vertical stiffener by distributing the load to angle steel.

2.3 *Static loading test procedures*

Figure 4 shows the loading method and Figure 5 shows loading wave form. The static loading test was conducted using two actuators to reproduce the simultaneously and alternatively stress in the middle girder when vehicles pass on the driving lane and passing lane simultaneously and alternatively. Load range was 120kN (Pmax=140kN, Pmin=20kN).

In static loading test and fatigue test, two types of uniaxial strain gages were used. 1mm long strain gages were pasted on the plate side surface 10mm below the weld toe, in order to measure the local stress. Whereas 5mm long strain gages were pasted on the bead surface, in order to monitor initiation and propagation behavior of root cracks.

2.4 *Fatigue test procedures*

The fatigue test was conducted using two actuators under alternative loading to reproduce the alternative stress in the middle girder when vehicles run on the driving lane and passing lane alternatively. Loading frequency was 3-4Hz.

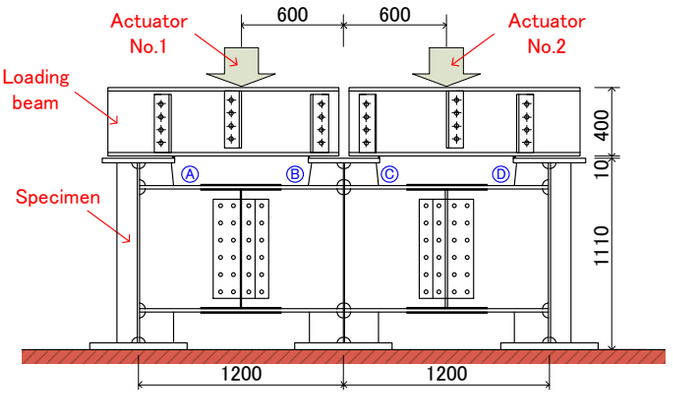

Figure 4. Loading Method

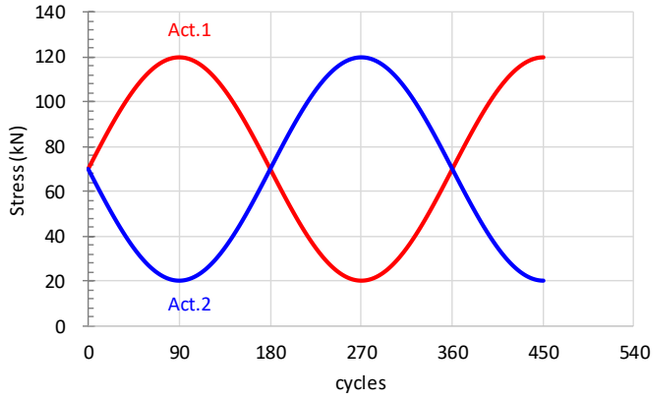

Figure 5. Loading wave form

Table 1. Fatigue test steps

Step	Test part	A	B	C	D
1	Purpose	Preventive measure		Recreating crack	
	Measure	TRS		None	
2	Purpose	Recreating crack		Post cracking measure	
	Measure	None		Grainding crack tips + TRS	

Table 1 gives fatigue test steps.

(1) Step1: In the test part A and B, purpose is to investigate the effectiveness of angle steel reinforcement using TRS. In the test parts C and D, purpose is to recreate cracks without measure.

(2) Step2: In the test part A and B, purpose is recreating cracks without measures. In the test parts C and D, purpose is to investigate the effectiveness of post cracking measure. Angle steel reinforcement using TRS was applied after grinding away crack tips.

Magnetic Particle Testing (MT) was used to detect toe cracks and to measure the crack length. Strain gages pasted on the bead surface were used to monitor initiation and propagation behaviour of root cracks.

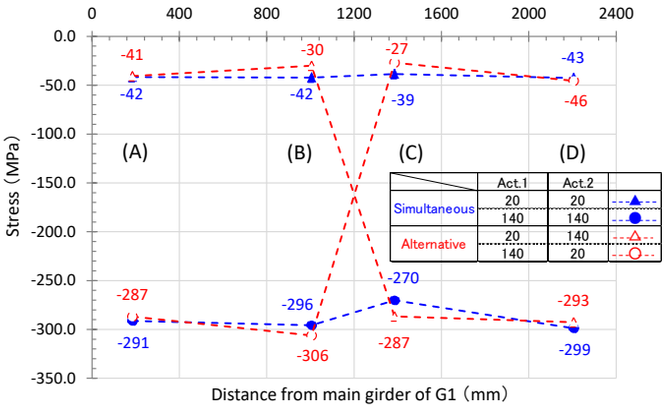

Figure 6. Stress Distributions under Simultaneous Loading and Alternative Loading

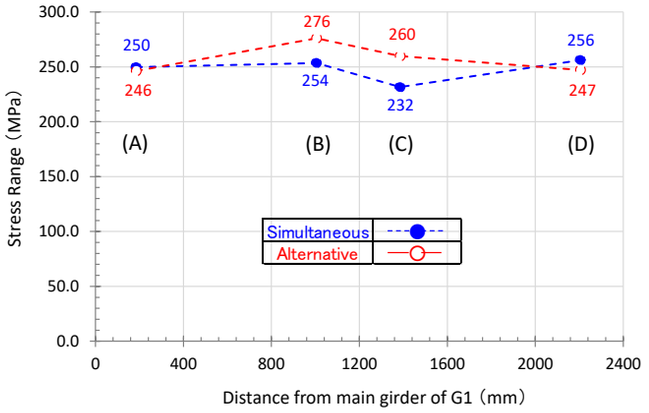

Figure 7. Stress Rage Distributions under Simultaneous Loading and Alternative Loading

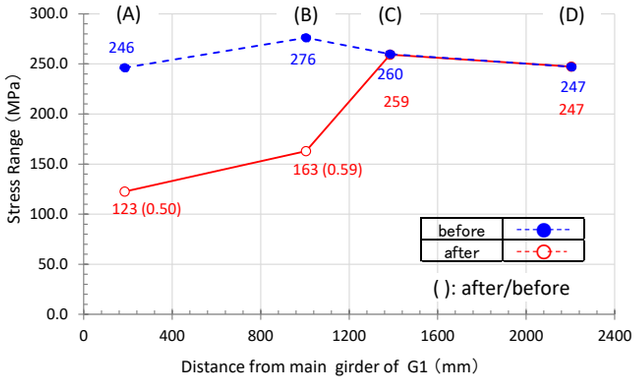

Figure 8. Stress Range Distributions Before and After Retrofitting

3 EXPERIMENTAL RESULTS

3.1 *Static loading test results*

Figures 6 and 7 shows the stress and stress range distributions under simultaneous loading and alternative loading. The stress range in middle girder (B and C) under alternative loading method increases about 10% of that under simultaneous loading. Alternative loading can reproduce the alternative stress at the upper end of web gap plates in the middle girder when vehicles run on the driving lane and passing lane alternatively.

Table 2. Fatigue test results

test part	measure	fatigue life (Mcycles)			crack length (mm)	
		Ns	Nd (R)	Nd (T)	initiate	last
A	preventive	>500	>500	>500	–	–
	none	80	540	110	8 (8)	13 (64)
B	preventive	>500	>500	>500	–	–
	none	>750	–	140	4	8

	post cracking	>750	>750	>750	–	20 (157)
D	none	>500	–	230	7	12
	post cracking	>750	>750	>750	–	2

toe (root)

Figure 8 shows the stress range distributions before and after retrofitting. Angle steel reinforcement using TRS can reduce the local stress concentration to about 50-60% of that before reinforcement.

3.2 *Fatigue test results*

Table 2 gives fatigue test results. Ns is the root crack initiation life defined as the number of loading cycles when the strain changes irreversibly. Nd(R) is the root crack detection life defined as the number of loading cycles when root cracks appears on the bead surface. Nd(T) is the toe crack detection life defined as the number of loading cycles when toe cracks are detected at the weld toe.

Figure 9 shows the relationship between strain and the number of loading cycles and Figure 10 shows the relationship between crack length and the number of loading cycles. Table 3 shows retrofit effectiveness

(1) Step1

a) Recreating crack (Test Part C, D)

In test part C, strain changes irreversibly after N=1.1Mcycles loading without retrofitting method. Therefore Ns can be estimated at 1.1Mcycles. When N=1.9Mcycles, toe cracks detected (Nd(T)=1.9Mcycles), and N=2.9Mcycles, root crack appeared on the bead surface (Nd(R)=2.9Mcycles) as shown in Figure 11. As shown Figure 10, toe crack is hardly propagated, but root crack propagated rapidly after it appeared on the bead surface.

In test part D, When N=2.3Mcycles, toe cracks detected as shown in Figure 12 (Nd(T)=2.3Mcycles).

b) Preventive measure (Test Parts A, B)

In test parts A, B, strain changes very little comparing with test parts C, D, and no fatigue cracks were detected after 5.0Mcycles loading. Angle steel reinforcement using TRS can prevent fatigue cracking and extend fatigue crack initiation life more than 2.2 (5.0Mcycles / 2.3Mcycles) ~ 4.5 (5.0Mcycles / 1.1Mcycles) times as shown Table 3.

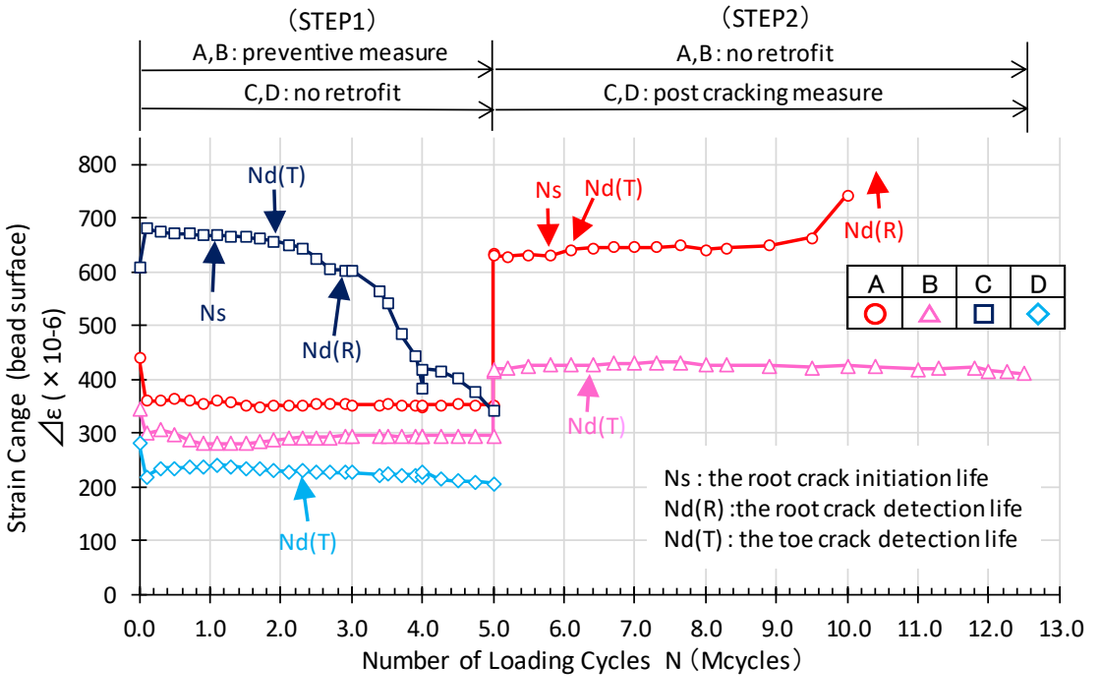

Figure 9. Relationship between strain and the number of loading cycles

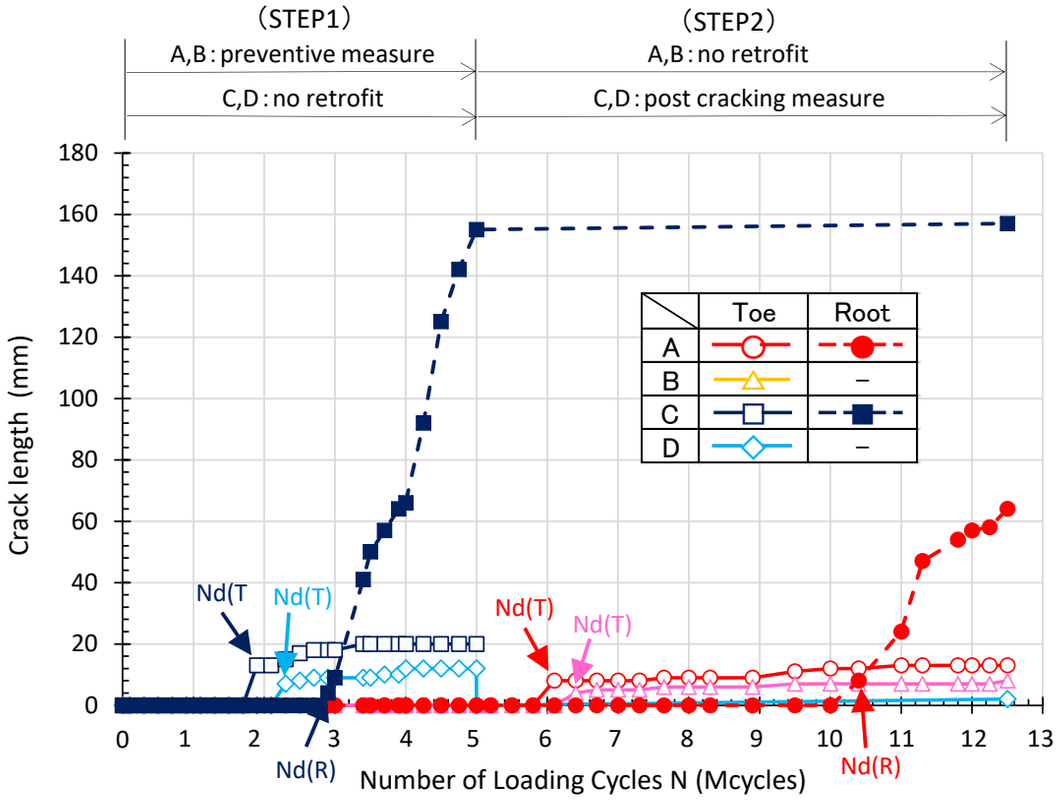

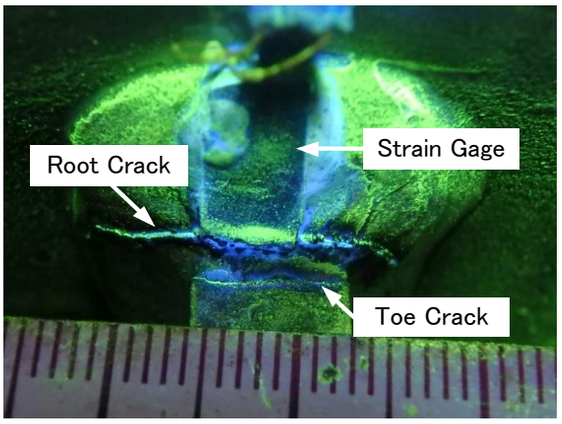

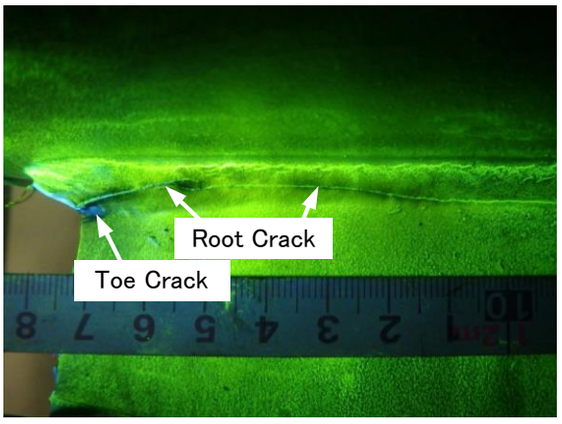

Figure 10. Relationship between crack length and the number of loading cycles

Table 3. Retrofit Effectiveness

test part	fatigue life		fatigue crack initiation life		crack growth rate		crack propagation life
	STEP1	STEP2	AB/C,D(①)	①/②	STEP1	STEP2	①/②
A	>500	80	–	>6.3times	–	–	–
B		140	–	>3.6times	–	–	–
C	110	>750	>4.5times	–	13mm/ 25Mcycles	2mm/ 750Mcycles	200times
D	230		>2.2times	–	7mm/ 20Mcycles	2mm/ 750Mcycles	130times

(a) Side view

(b) Face view

Figure 11. Propagated Toe Crack and Root Crack, Test Part C, N=5.0Mcycles

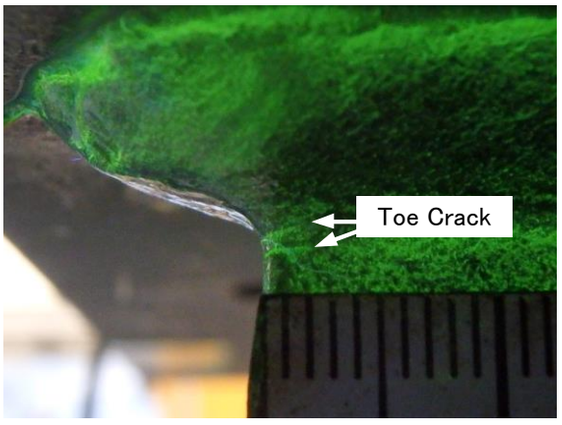

Figure 12. Propagated Toe Crack, Test Part D, N=5.0Mcycles

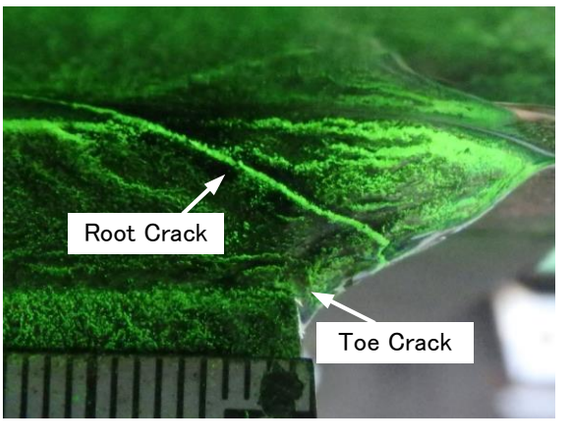

Figure 13. Propagated Toe Crack, Test Part A, N=7.5Mcycles

(2) Step2

a) Recreating crack (Test Parts A, B)

In test part A, strain changes after 0.8Mcycles loading. Therefore Ns can be estimated at 0.8Mcycles. When N=1.1Mcycles, toe cracks detected (Nd(T)=1.1Mcycles) and, when N=5.4Mcycles, root cracks appeared on the bead surface as shown in Figure 13 (Nd(R)=5.4Mcycles).

In test part D, when N=1.4Mcycles, root cracks appeared on the bead surface as shown in Figure 14 (Nd(R)=1.4Mcycles).

Angle steel reinforcement using TRS can prevent fatigue cracking and extend fatigue crack initiation life more than 3.6 (5.0Mcycles / 1.4Mcycles) ~ 6.3 (5.0Mcycles / 0.8Mcycles) times as shown Table 3.

b) Post cracking measure (Test Part C, D)

In test part C, crack tips were ground away by a bar grinder as shown Figure 15. After 7.5Mcycle loading, new root cracks with the length of 2mm was initiated from root tips as shown Figure 16. The retrofitting method can extend fatigue crack propagation life more than 200 (2mm/7.5Mcycles / 13mm/2.5Mcycles) times.

In test part D, crack tips were ground away by a bar grinder as shown Figure 17. After 7.5Mcycle loading, new toe crack with the length of 2mm was initiated as shown in Figure 18. The retrofitting method can extend fatigue crack propagation life more than 130 (2mm/7.5Mcycles / 7mm/20Mcycles) times.

Test Part D, N=7.5Mcycles

4 SUMMARY

The main conclusions obtained through this study are as follows,

(1) Alternative loading can reproduce the alternative stress at the upper end of web gap plate in the middle girder when vehicles run on the driving lane and passing lane alternatively.
(2) Angle steel reinforcement using TRS, can reduce the local stress concentration at the crack initiation point to about 50~60% of that before reinforcement.
(3) Without the retrofitting method, root crack is initiated after 0.8 to 1.1Mcycles loading and toe cracks are detected after 1.1 to 2.3Mcycles loading.
(4) As a preventive measure, the method can prevent fatigue cracking and extend fatigue crack initiation life more than 2.2~6.3 times.
(5) As a post cracking measure, angle steel reinforcement using TRS after grinding away crack tips can extend fatigue crack propagation life more than 100 times of that without the reinforcement.

Adhesive and Bolting Reinforcement for Distortion-induced Fatigue of Steel Bridges

Y.Z. Wang, B. Cui, Q. Wang, L. Duan, C. S. Wang
Engineering Research Center for Large Highway Structure Safety of Ministry of Education, College of Highways, Chang'an University, Xi'an, China

ABSTRACT: Fatigue cracks in web gaps of steel girder bridges have serious effect on the fatigue life of bridges. This study is aimed at evaluating the effectiveness of adhesive and bolting single steel angle reinforcement technique, which means the stiffener is bolted with the steel angle and the flange plate is connected with the steel angle by structural adhesive. Full-scale fatigue tests were carried out to analyze the fatigue performance of weld toe details in the web gap region. Test results show that the stiffness of web gap region increase, and the out-of-plane distortion and the stress of the end of the web-to-stiffener weld toe and the web-to-flange weld toe decrease sharply after reinforcement, and fatigue cracks did not extend. The adhesive and bolting single steel angle reinforcement technique can effectively control distortion-induced fatigue cracking in web gaps of steel girder bridges without disruption to the concrete deck.

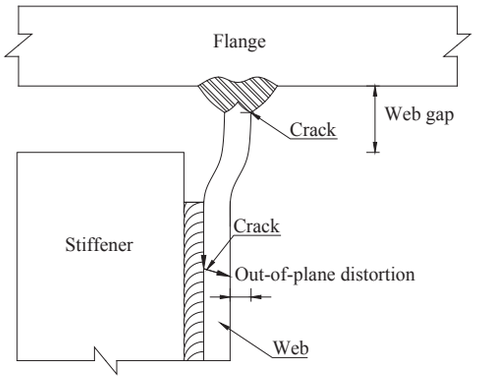
1 INTRODUCTION

In the multi-girder steel bridges, diaphragms or cross-bracing are connected with main girder by vertical stiffeners, which distribute loads transversely. In order to make construction much easier and avoid failures of fatigue details at vertical stiffener and tension flange welds, vertical stiffeners near tension flanges of the girder are cut short usually (Khalil et al. 1998). Therefore, several-centimeter web gaps are left between the vertical stiffener and the tension flange. Under the actions of the vehicle loads, the deflections of adjacent main girders are different, resulting in notable out-of-plane deformation at the web gap region, as shown in Figure 1. Approximately 90% of fatigue cracks in steel bridges were caused by out-of-plane distortion or secondary stresses at fatigue details (Connor and Fisher 2006), and the fatigue damage of the web gap in steel bridges is a typical fatigue problem induced by out-of-plane distortion.

Many studies have been carried out to investigate the reinforcement performance of the out-of-plane distortion-induced fatigue details at web gaps by field tests, finite element analysis, and experimental studies. Increasing the web gap length or connecting vertical stiffener with tensile flange can effectively reduce the stress concentration at web gaps (Fisher et al. 1990). Several alternatives were proved to be effective in reducing distortion-induced strains and stresses in the web gap region, such as connecting a plate between the stiffener and the top flange, and loosening of bolts connecting the cross-bracing to the stiffener (Shifferaw et al. 2013). Andrea proposed increasing the thickness of web gaps by bolting a steel angle to the flange and the web, and this method could increase the stiffness of web gaps and effectively reduced deformation and stress in web gap area (Andrea et al. 2001). Bolting angles with plate and stop-holes reinforcement methods were all effective in preventing the distortion of the web gap region, which drastically reduced the stress demands at the critical points. Slot repair was also used to repair the fatigue details, but results showed that this method had introduced higher magnitude fatigue stress in web gaps, which was believed to be the cause of crack re-initiation and propagation found in many repaired details (Zhao et al. 2007). The method of adhesive-bonded angles was effective to the cracks which did not propagate far away from web gaps and did not propagate perpendicularly to the direction of in-plane stress. In addition, this method was easy to operate on site, and also enhanced the fatigue performance of the detail. However, the risk induced by the adhesive failure due to the effect of the environment should be taken into account (Hu et al. 2006).

This paper carried out full-scale fatigue tests to investigate the effectiveness of the adhesive and bolting steel angle reinforcement, which means the stiffener is bolted with the steel angle and the flange

plate is connected with the steel angle by structural adhesive. Fatigue tests of a full-scale specimen was carried out to analyze the change of the out-of-plane distortion of web gap and the stresses of weld toe details of the end of the web-to-stiffener weld toe and the web-to-flange weld toe with the cyclic loading. The test results show that the stiffness of web gap region increase, and the out-of-plane deformation and the stress of the end of the web-to-stiffener weld toe and the web-to-flange weld toe decrease sharply after reinforcement, and fatigue cracks did not propagate. The adhesive and bolting single steel angle reinforcement technique can effectively control distortion-induced fatigue cracking in web gaps of steel girder bridges without disruption to the concrete deck. Adhesive and bolting reinforcement technique dose not introduce secondary stress into the fatigue sensitive details, and the process of the reinforcement has no negative influence of the fatigue sensitive details of web gaps. Compared with adhesive single steel angle reinforcement technique, the adhesive and bolting reinforcement technique avoid the falling of the steel angle when the structural adhesive failed because of external environment.



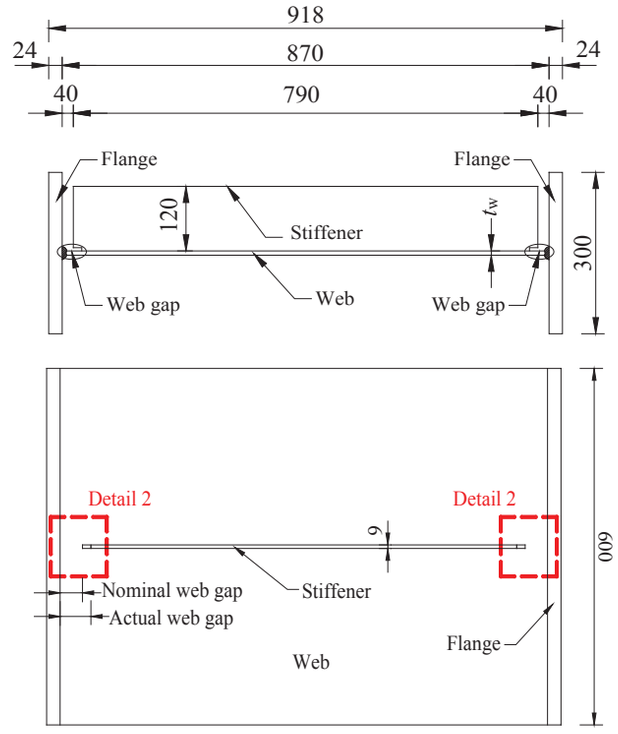


Figure 1. Out-of-plane distortion at web gaps

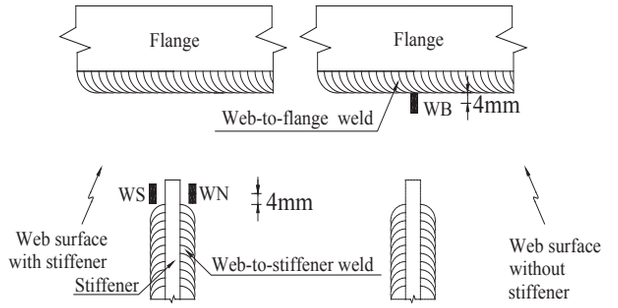
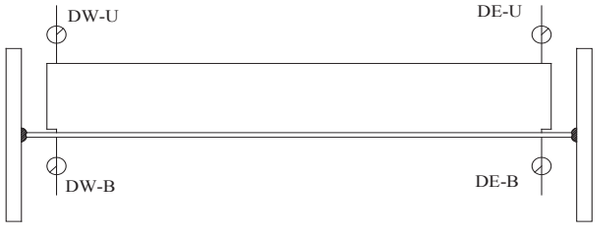


2 FATIGUE TEST PROGRAM

2.1 *Test Program*



The full-scale specimen was I-shaped steel girders, comprised of flange, web and stiffener. The specimen was fabricated by steel grade of Q345qC with normal yield stress of 345MPa, in which q represents steel used in bridges and C means toughness level. The dimensions of the test specimen was determined to reflect the actual fatigue performance of web gaps effectively. Finite element analytical study results indicated that the length of the specimen had negligible effect on out-of-plane distortion and stress state of web gaps (Wang & Cheng 2010). Thus, 600mm long full-scale specimen was adopted, considering fixing and loading condition as well as fatigue test effectiveness. Figure 2 shows the dimensions of the specimen as well as the displacement and strain gauges arrangement. The dimensions of flange, web and vertical stiffener are 600mm × 300mm × 24mm, 870mm × 600mm×8mm, and 790mm × 120mm × 6mm respectively. The nominal web gap is 40mm and the actual web gap is 55mm. Strain gauges were arranged at web gap detail according finite element analysis results.

(a) Specimen dimensions

(b) Locations of strain gages

(c) Locations of dial indicators

Figure 2. Test Specimen (Unit: mm)

A 100kN capacity MTS servo hydraulic actuator is adopted to apply cyclic load (Fig. 3). Eight bolt holes with diameter of 24mm were drilled on two flanges separately, and four bolt holes with diameter

of 24mm were drilled on vertical stiffeners. Cyclic loads were applied by the hydraulic actuator to the stiffener, which simulates the actual acting lateral forces on the stiffener in steel girder bridge (Wang et al. 2014a, b, c). The cyclic load was directly applied on the top flange of the loading beam, and the loading beam was attached to a pair of angles, through which pulling on the vertical stiffener. The flanges were bolted to the fixing device. Consequently, the cyclic loads acted on the connection of vertical stiffener and the steel angles, causing the out-of-plane distortion in web gaps.

The load range of the specimen was determined according to the out-of-plane distortion between 0.2mm and 0.4mm. Then, loading frequency was determined according to the stability of the whole loading setups. Static tests were performed every 100,000 cycles during the process of cyclic loading, in order to record the crack length, out-of-plane distortion, and stress levels. The displacement of out-of-plane distortion and stresses of the test specimen in web gaps were monitored with a dynamic data acquisition system during the fatigue tests. This fatigue loading stopped when the propagation of fatigue cracks affected the stability of test setup.

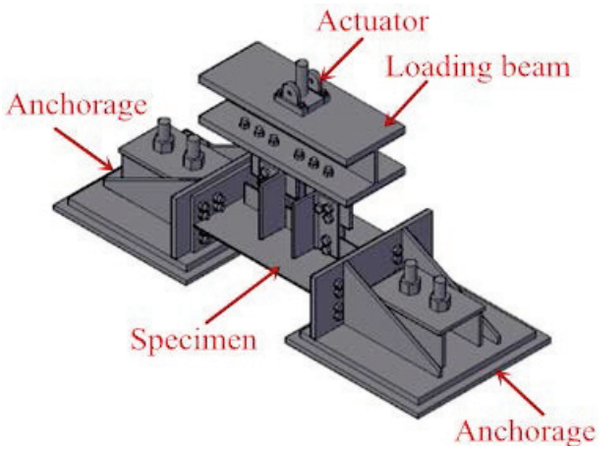


Figure 3. Loading equipment of fatigue test

2.2 *Adhesive and Bolting Steel angle Reinforcement Procedure*

Adhesive and bolting steel angle reinforcement used the mix-linked steel angle that one leg is bolted with the stiffener and the other leg is adhesive with the flange. Compared with the bolting steel angle reinforcement, this method does not need to remove the local part of the concrete deck where out-of-plane distortion induced-fatigue cracks initiate from the top flange at the web gap region. In addition, compared with the adhesive steel angle reinforcement, adhesive and bolting steel angle reinforcement avoids the falling of the steel angle, which is dangerous to the pedestrian and vehicles. Full scale fatigue tests were carried out to verify the feasibility and the practicability of the adhesive and bolting steel angle reinforcement.

(a) Nap the steel angle

(b) Nap steel girder surface

(c) Bolt the steel angle and the stiffener

(d) Finish reinforcement

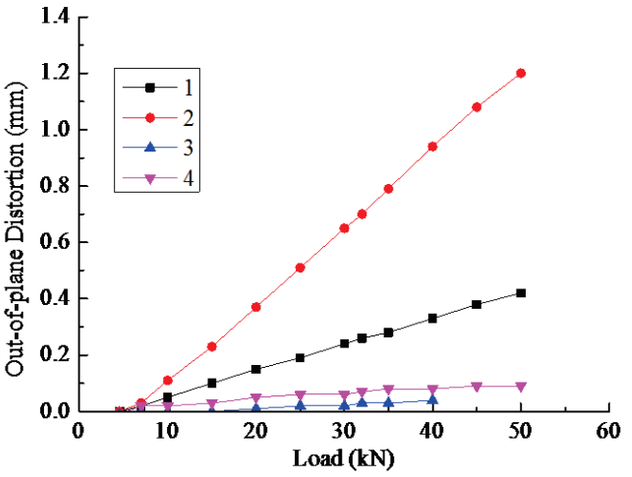
Figure 4. Flowchart of reinforcement

The procedure of adhesive and bolting steel angle reinforcement is a combination of the two reinforcement methods (Fig. 4). The side which uses the adhesive is processed as the adhesive steel angle reinforcement, and the other side is processed as the bolting steel angle reinforcement. The first step is to drill holes at the specimen and the reinforcement steel angle. Then, the position of the bonding steel angle at the specimen and the steel angle were napped to increase the bonding performance of the structure adhesive. After mixing the structure adhesive, the steel angle was bonded with the flange of the specimen. The next step is bolting the steel angle with the stiffener. Finally, the reinforced specimen was installed in the test setups.

3 FATIGUE TEST RESULTS

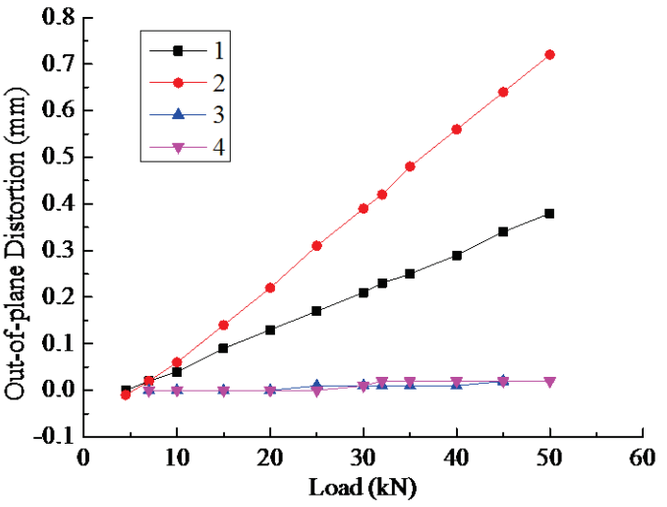
Before the reinforcement, fatigue tests were carried out on the specimen for fatigue pre-cracking. Table 1 shows the number of cycles and the cyclic loading range before and after the reinforcement of the specimen. The finite element analysis of the actual bridges indicated that after the reinforcement of the fatigue details where fatigue cracks initiated in the web gap region, the magnitude of the load that the cross-bracing transmitted to the vertical stiffeners at the web increased due to the improvement of the local stiffness of the web gap. Therefore, the cyclic loading range after the reinforcement is larger than that before the reinforcement.

Table 1. Fatigue test results



Specimen	Number of cycles before reinforcement	Loading range before reinforcement	Total Number of cycles	Loading range after reinforcement
	$\times 10^6$	kN	$\times 10^6$	kN
1	10.62	7-32	12.81	7-37/7-47

The loading cycles of specimen 1 after reinforcement was 2.19 million. In the former 1.6 million cycles, the loading range was 7-37kN. And the loading range was 7-47kN after 1.60 million cycles. After the reinforcement, the existing fatigue cracks at the web gap stopped propagating, and no new crack was observed at the reinforcement steel angle and the web gap region.



4 OUT-OF-PLANE DISTORTION ANALYSIS

4.1 *Out-of-plane Distortion-Load*

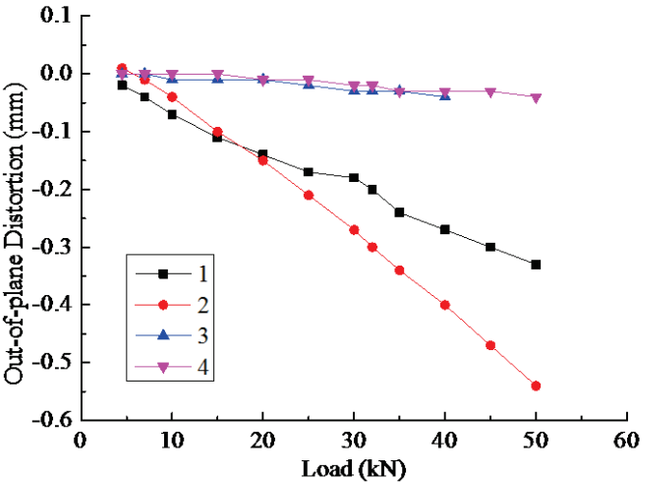


Figure 5 shows the out-of-plane distortion of four dial indicators of the specimen under the action of different load. Curve 1 shows the out-of-plane distortion measured in the static test before cyclic loading, so as to study of the fatigue mechanics of the web gap. And at that time the number of loading cycle is 0. Curve 2 shows the out-of-plane distortion measured in the static test after fatigue pre-cracking process and before the reinforcement. Curve 3 shows the out-of-plane distortion measured in the static test after the reinforcement before the cyclic loading. Curve 4 shows the out-of-plane distortion measured in the static test for the last time at the end of the reinforcement test.

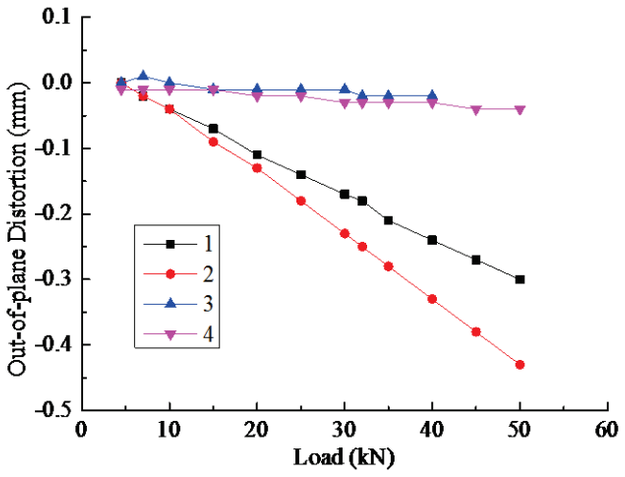

(a) DW-U

(b) DE-U

(c) DW-B

(d) DE-B

Figure 5. Out-of-plane distortion-load

With the number of the cycles increasing, fatigue cracks initiated and propagated at the web gaps, and the out-of-plane distortion of the web gap increased. After the reinforcement, the out-of-plane distortion of the web gap significantly decreased, and the increasing speed of the out-of-plane distortion is close to that of the specimen with no fatigue damage. At the end of the fatigue test, the out-of-plane distortion at web gap was far less than that of the specimen after the fatigue cracks occurred, which indicated that the adhesive and bolting single angle reinforcement was effective to decrease the out-of-plane distortion, thus improving the anti-fatigue property of the fatigue details at the web gaps.

4.2 *Out-of-plane Distortion-Number of Cycles*

During the process of the fatigue tests, the dial indicators DW-B、DE-B、DW-U and DE-U shown in Figure 2 monitored the out-of-plane distortion range at the web gap region. Figure 6 shows the specific out-of-plane distortion curves before and after the reinforcement.

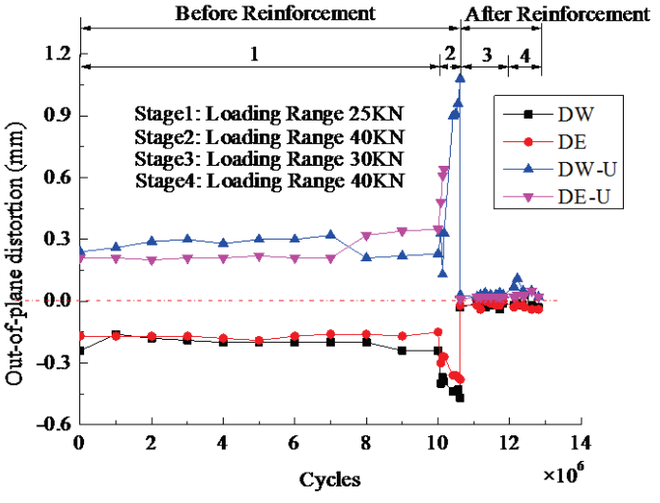

Figure 6. Out-of-plane distortion-number of cycles

Before and after the reinforcement of the specimen, the change of out-of-plane distortion range at the web gaps was recorded in Table 2 in detail. The out-of-plane distortion ①, ②, ③ and ④ in the Table 2 are corresponding to the curve 1, 2, 3 and 4 mentioned above respectively.

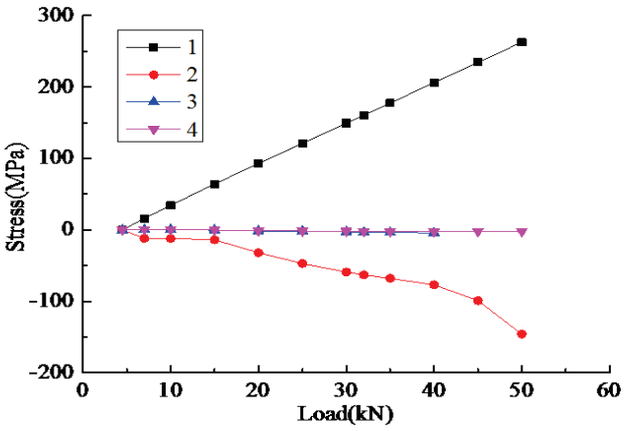
Table 2. Comparing of out-of-plane distortion

Dial indicator	Out-of-plane distortion				
	①	②	③	④	③/②
	mm	mm	mm	mm	
DW-B	-0.18	-0.5	-0.03	-0.03	6.0%
DE-B	-0.18	-0.8	-0.02	-0.04	2.5%
DW-U	0.26	1.13	0.03	0.02	2.7%
DE-U	0.23	0.68	0.01	0.02	1.5%

According to Figure 6 and Table 2, the out-of-plane distortion range of the web gap after the reinforcement decreased to 1.5%～6.0% of that before the reinforcement. The reduction of the out-of-plane distortion range indicated that this reinforcement method effectively improved the stiffness and the fatigue performance of the web gap.

5 STRESS ANALYSIS

The stresses at the web-to-stiffener weld toes and the web-to-flange weld toes at the web gap region were measured during the fatigue tests before and after the reinforcement, and could then be used to evaluate the fatigue strength of such details.



5.1 *Stress-Load Analysis*

5.1.1 *Stress of Web-to-stiffener Weld Toe-Load*

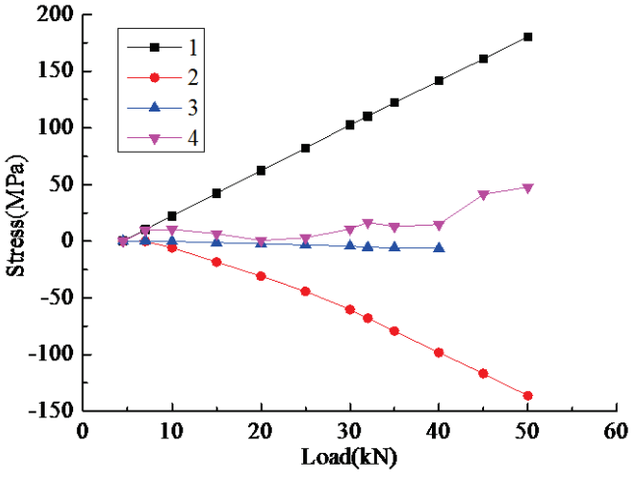


Figure 7 shows the stresses of three measuring points of the web-to-stiffener weld toe of the specimen under the action of different load. Curve 1 shows the stress of the web-to-stiffener weld toe measured in the static test before cyclic loading, so as to study of the fatigue mechanics of the web gap. And at that time the number of loading cycle is 0. Curve 2 shows the stress of the web-to-stiffener weld toe measured in the static test after fatigue precracking process and before the reinforcement. Curve 3 shows the stress of the web-to-stiffener weld toe measured in the static test after the reinforcement before the cyclic loading. Curve 4 shows the stress of the web-to-stiffener weld toe measured in the static test for the last time at the end of the reinforcement test.

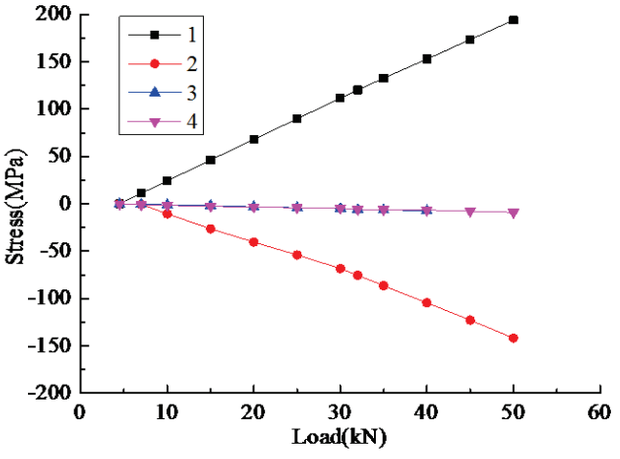
Comparison of the stresses of curve 2 and curve 3 indicated that the adhesive and bolting steel angle reinforcement decreased the stress of the web-to-stiffener weld toe to a large degree. A conclusion can be draw by comparing curve 3 with curve 4 that at the end of the cyclic loading after the reinforce-



ment, the stress of the web-to-stiffener weld toe hardly changed from that at the beginning of the test, which indicated that there was no fatigue damage accumulated at the web gap after the reinforcement, and also indicated the effectiveness of this adhesive and bolting steel angle reinforcement method.

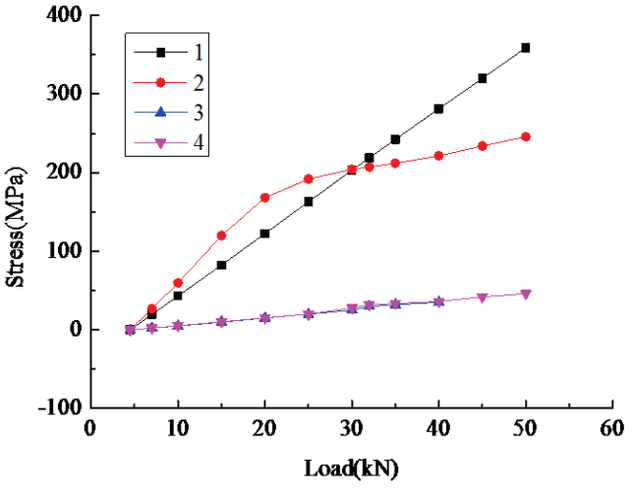

Figure 7. Stress of web-to-stiffener weld toe-load

5.1.2 *Stress of Web-to-flange Weld Toe-Load*

Figure 8 shows the stresses of two measuring points of the web-to-flange weld toe of the specimen under the action of different load. The stages that curve 1, 2, 3, 4 corresponding to are the same with the curves of stress of web-to-stiffener weld toe.

(a) Measuring point WB

(b) Measuring point EB

Figure 8. Stress of Web-to-flange Weld Toe-Load

As shown in the Figure 8, curve 2 indicated that the stress of the cracked details at the web-to-flange weld toe decreased to a lower level. Comparing curve 2 and curve 3, as for the cracking and non-cracking web-to-flange weld toe, the stresses of the web-to-flange weld toe were close to zero after reinforcement. Comparing curve 3 with curve 4, the stresses of the web-to-flange weld toe was also close to zero at the end of cyclic loading after reinforcement, which indicated that there was no fatigue damage accumulated at the retrofit web gap, and also indicated the effectiveness of the adhesive and bolting steel angle reinforcement.

5.2 *Stress-Number of Cycles Analysis*

5.2.1 *Stress of Web-to-stiffener Weld Toe-Number of Cycles*

Figure 9 shows the measurements of the web-to-stiffener weld toes for the specimen. The measured stresses at the end of the web-to-stiffener weld toe

before and after the reinforcement indicated that the adhesive and bolting single angle reinforcement decreased the stress of the web-to-stiffener weld toe to a large degree. After the reinforcement, the stresses of the web-to-stiffener weld toes hardly changed, indicating that there was no fatigue damage accumulated at the web gap after the reinforcement.

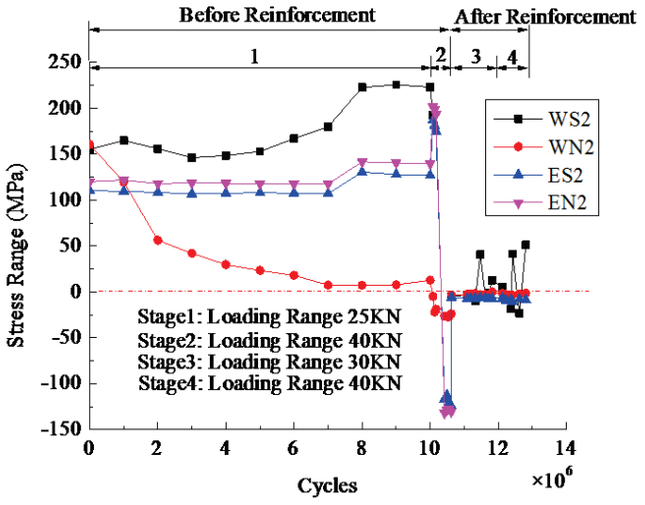

Figure 9. Stresses of web-to-stiffener weld toes

5.2.2 *Stress of Web-to-flange Weld Toe-Number of Cycles*

Figure 10 shows the measurements of the web-to-flange weld toes for the specimen. The stresses of the web-to-flange weld toes decreased to a lower level and close to zero after reinforcement, which indicated that there was no fatigue damage accumulated in the web gap region.

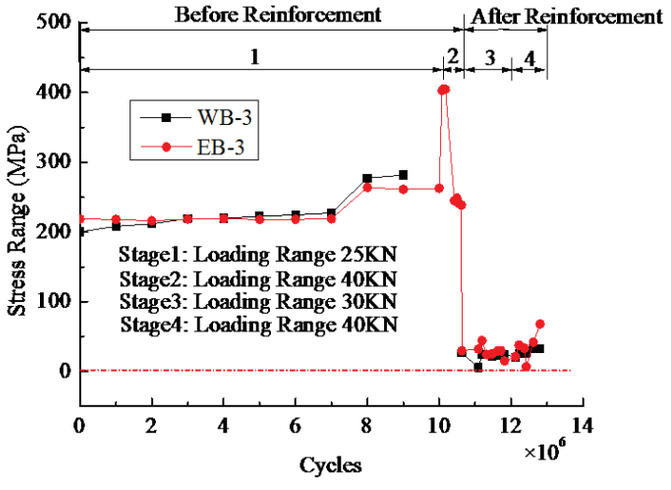

Figure 10. Stresses of web-to-flange weld toes

Before and after the reinforcement of the specimen, the stress ranges of the web-to- stiffener weld toe and the web-to-flange weld toe were recorded in Table 3 in detail. The stress range ①, ②, ③ and ④ in the Table 3 are corresponding to the curve 1, 2, 3 and 4 mentioned above respectively.

According to Table 3, the stress range of the web gap after the reinforcement decreased to 2.7%～14.8% of that before the reinforcement. After the reinforcement, the stresses of the web-to-stiffener weld toes as well as the web-to-flange weld toes reduced below 30MPa after reinforcement. Therefore, the adhesive and bolting steel angle reinforcement significantly improved the stiffness of the web gap region, reduced the stresses of the fatigue details.

Table 3. Comparing of stresses of web-to-stiffener weld toes and web-to-flange weld toes

Measuring point		Stress range ① MPa	② MPa	③ MPa	④ MPa	③/①
Web-to-stiffener weld toe	WS	150	-20	-4	-1	2.7%
	ES	102	-117	-5	51	4.9%
	EN	111	-123	-6	-8	4.8%
Web-to-flange weld toe	WB-3	187	261	27	33	5.4%
	EB-3	203	234	30	68	14.8%

6 CONCLUSIONS

Full-scale fatigue tests were carried out to investigate the availability, feasibility and practicability of the adhesive and bolting steel angle reinforcement. Based on the experimental study results, the following conclusions may be drawn:

(1) Adhesive and bolting steel angle reinforcement does not need to remove the concrete deck plate, and introduce little damage to the original structure.

(2) Adhesive and bolting steel angle reinforcement improves the stiffness of the web gap region. After the reinforcement, the out-of-plane distortion at the web gap region was reduced, and the stresses of the web-to-stiffener weld toe and the web-to-flange weld toe was decreased.

(3) After the web gap region was reinforced by the adhesive and bolting steel angle, the existing fatigue cracks at the web gap stopped propagating and there was no new crack initiating at the steel angle and the web gap.

(4) Compared with the hot reinforcement method, the adhesive and bolting steel angle reinforcement will not introduce the second stress into the fatigue details in the web gap region. The reinforcement process has no negative influence on the fatigue sensitive details in the web gap region.

(5) Adhesive and bolting steel angle reinforcement method has good safety, due to the steel angle will not fall when the structure adhesive fail because of the effect of the environment.

Vibration Study of Train Passing Bridge with Small Radius and Reverse Curve

Y.M. Song
Shanghai University of Engineering Science, Shanghai, China
D.J. Wu & J. Zhang
Tongji University, Shanghai, China

ABSTRACT: In this paper, the vibration study for a newly-built curved railway bridge with small radius and reverse curve was performed. The motion equations of the train passing a bridge were established in moving coordinate systems, where coordinate transformation was used to build the geometric relationship between the train and the bridge. Wheel-rail interaction was simulated based on the modified Kalker linear creep theory. 20 field vibration tests for different operating conditions of the passing train were conducted, followed by the analyses on vibration responses of the test bridge, including characteristics such as natural frequency, acceleration, velocity and displacement. The operating performance for the train passing this small radius reverse curve bridge was evaluated according to the codes, and reasonable suggestions are proposed accordingly. Comparisons are presented between the theoretical analysis and the test results for the key dynamic characteristics, and the reasonable dynamic stiffness for such bridges is discussed.

1 INTRODUCTION

The vibration studies of train passing bridges have attracted much attention for more than one and half centuries. In recent years, due to the application of high-performance materials and the advances in high-speed and heavy-load railways, more slender bridges have been built worldwide, and the vehicle-induced vibration is much more crucial to the performance of such bridges (Au et al., 2001).

The analytical methods for vehicle-induced vibration on bridges are rather meaningful for parameter and mechanism studies (Fryba, 2013), while the finite element (FE) method is more applicable to bridges with complex geometries and components. The numerical models can be optimized and validated by field tests. The natural frequencies, modal damping ratio and mass of the bridge can be used to calibrate the bridge model (Zambrano et al., 2008), while the dynamic tests such as free field vibrations and track responses can be employed to evaluate the reliability of the model (Antolín et al., 2013). In recent years, more focuses were attached on the optimization of calculation efficiency and modelling accuracy. Zambrano et al. (2008) proposed a time-saving method by simplifying both the numerical model and the calculation method. Antolín et al. (2013) considered the nonlinear wheel–rail contact model, and significantly smaller force responses were obtained using this more realistic method due to the incorporation of frictional slip conditions.

In contrast to the extensive studies focusing on the straight bridges, only a few studies were conducted for the dynamic responses of horizontally curved bridges subjected to passing trains. Galdos et al. (1993) analyzed the dynamic responses of a horizontally curved box bridge using the step-by-step direct integration method. A numerical program was developed by Shan (1999) to analyze the dynamic responses of both the curved bridge and the vehicle under various speed. Yang et al. (2001) presented an analytic approach for a horizontal curved beam subjected to both the vertical and the horizontal moving loads. Focusing on the coupled vibration of the train passing the small radius curved bridge. Song et al. (2013) studied the wheel-rail contact force and creep force by considering non-jump and jump cases based on the Hertz's theory of elastic contact and Kalker's creep theory of wheel-rail interaction.

In this paper, the vibration responses of the train passing a bridge with small radius and reverse curve are studied. The transformation matrix between the global coordinate system and the local coordinate system considering curve super-elevation angle was derived, and the differential equations of vehicle-bridge coupled vibration were established by using the mode superposition method. The finite element method was also employed to build the numerical model for the test bridge. Field tests were conducted

on the test bridge and the results were compared to the preliminary theoretical analyses. Given the observed discrepancy, the possible reasons are discussed and the useful suggestions for dynamic stiffness are proposed.

2 COUPLING VIBRATION THEORY FOR THE TRAIN PASSING A CURVED BRIDGE

2.1 *Differential Equations of Motion*

The differential equations of motion for train passing a curved bridge are established as:

$$\begin{aligned}&[M_{\mathrm{v}}]\{\ddot{x}_{\mathrm{v}}\}+[C_{\mathrm{v}}]\{\dot{x}_{\mathrm{v}}\}+[K_{\mathrm{v}}]\{x_{\mathrm{v}}\}\\&=\{F_{\mathrm{vn}}\}+\{F_{\mathrm{vc}}\}+\{F_{\mathrm{ve}}\}+\{F_{\mathrm{va}}\}\end{aligned}\tag{1}$$

where $[M_{\mathrm{v}}]$ is the mass matrix of vehicles, $[C_{\mathrm{v}}]$ is the damping matrix of vehicles, $[K_{\mathrm{v}}]$ is the stiffness matrix of vehicles, $\{x_{\mathrm{v}}\}$ is the vehicle displacement vector, $\{\dot{x}_{\mathrm{v}}\}$ is the vehicle velocity vector, $\{\ddot{x}_{\mathrm{v}}\}$ is the vehicle acceleration vector. $\{F_{\mathrm{vn}}\}$ is the internal force vector including non-proportional damping force and other nonlinear internal force, $\{F_{\mathrm{vc}}\}$ is the wheel rail excitation force vector, $\{F_{\mathrm{ve}}\}$ is the centrifugal force and super high component vector, $\{F_{\mathrm{va}}\}$ is the additional inertia force and inertia moment while train curving bridge.

Modal superposition method is used to solve the equations of motion. The relationship between physical coordinates and modal coordinates for the Nth mode is as follows:

$$\{x_{\mathrm{v}}\}_N=[F_{\mathrm{v}}]_N\{q_{\mathrm{v}}\}_N\tag{2}$$

where $[F_{\mathrm{v}}]_N$ are normalized feature vectors. The train motion equation in modal coordinates is as follows:

$$\{\ddot{q}_{\mathrm{v}}\}+2[x_{\mathrm{v}}][w_{\mathrm{v}}]\{\dot{q}_{\mathrm{v}}\}+[w_{\mathrm{v}}^2]\{q_{\mathrm{v}}\}=[F_{\mathrm{v}}]^T[f_{\mathrm{v}}]\tag{3}$$

where $\{q\}$ is the modal coordinate of vehicle or bridge, $[x]$ is the modal damping matrix, $[w^2]$ is the circular frequency matrix, $[F_{\mathrm{v}}]^T$ is the normalizing modal matrix, $\{f\}$ are the vectors of external forces and pseudo internal forces.

2.2 *Moving Coordinate System and Coordinate Transformation*

The coupling relationship of wheel-rail-bridge can be determined by means of moving coordinate system and coordinate transformation when train passing the curved bridge. Each wheel moving coordinate system was established according to the right-hand rule as shown in Figure 1. Its origin is along the track center line, the coordinate x is along tangent direction of the curve, the coordinate y is in the upward vertical plane of the rail, and the coordinate z is along normal direction of curve.

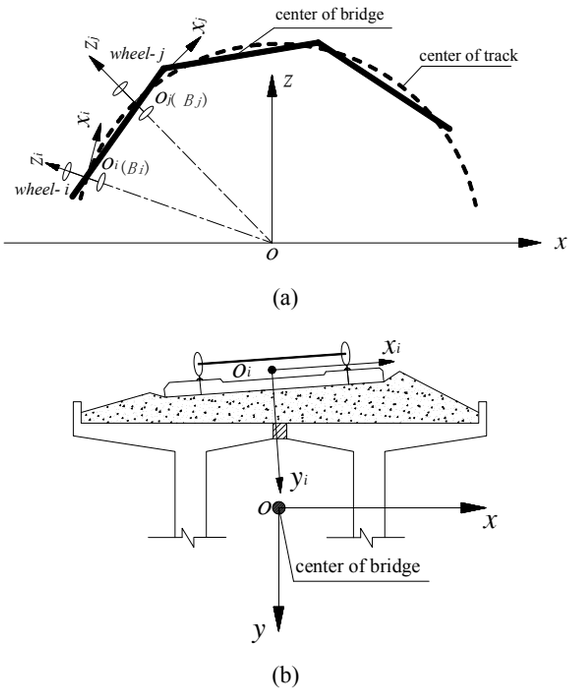

Figure 1. Moving coordinate of vehicle-curved bridge system: (a) horizontal plane, (b) vertical plane.

Assume that train moves forward at constant speed v and the mileage is S_i at time t, the coordinates (x_{Oi}, y_{Oi}, z_{Oi}) in the global coordinate system $oxyz$ can be obtained according to the mileage S_i. In the meantime, the angle α_{i} between tangent of curve and ox axis, the curvature R_{i}, and the angle of super-elevation γ_{i} could all be easily obtained. Therefore, the moving coordinates systems $o_{\mathrm{i}}x_{\mathrm{i}}y_{\mathrm{i}}z_{\mathrm{i}}$ and $o_{\mathrm{j}}x_{\mathrm{j}}y_{\mathrm{j}}z_{\mathrm{j}}$ are determined. In addition, assume that B_i (x_{Bi}, y_{Bi}, z_{Bi}) is a finite element node of bridge's center line, when node B_i coincides with the point of intersection that track center line projects on bridge's center line, the n-order vibration mode displacement vector of node B_i can be transformed into the coordinate system $o_{\mathrm{i}}x_{\mathrm{i}}y_{\mathrm{i}}z_{\mathrm{i}}$, that is:

$$\{\phi\}_{\mathrm{i,B}}=[\lambda]\{\phi\}\tag{4}$$

where $\{\square\}_{\mathrm{i,B}}$ is the vibration mode displacement vector in moving coordinate system, $\{\square\}$ is the vibration mode displacement vector in the global coordinate system, $[\lambda]$ is the coordinate transformation matrix. $[\lambda]$ is as follows by deduction:

$$\begin{cases}[\lambda]=\begin{bmatrix}\lambda_1 & 0\\ 0 & \lambda_1\end{bmatrix}\\ [\lambda_1]=\begin{bmatrix}\cos\alpha_{\mathrm{i}} & 0 & \sin\alpha_{\mathrm{i}}\\ -\sin\alpha_{\mathrm{i}}\sin\gamma_{\mathrm{i}} & \cos\gamma_{\mathrm{i}} & \cos\alpha_{\mathrm{i}}\sin\gamma_{\mathrm{i}}\\ -\sin\alpha_{\mathrm{i}}\cos\gamma_{\mathrm{i}} & -\sin\gamma_{\mathrm{i}} & \cos\alpha_{\mathrm{i}}\cos\gamma_{\mathrm{i}}\end{bmatrix}\end{cases}\tag{5}$$

The connection between the center of the bridge and the center of the track can be assumed to be rigid, so the vibration mode displacement vector in

moving coordinate system (that is $\{f\}_{\mathrm{i,B}}$) needs to be transformed into track center line by means of rigid arm constraint equations as follows:

$$\{\phi\}_{\mathrm{i}}=\begin{bmatrix}1&0&0&0&0&0\\0&1&0&z_{\mathrm{i,B}}&0&0\\0&0&1&-y_{\mathrm{i,B}}&0&0\\0&0&0&1&0&0\\0&0&0&0&1&0\\0&0&0&0&0&1\end{bmatrix}\{\phi\}_{\mathrm{i,B}} \tag{6}$$

where $\{f\}_{\mathrm{i}}$ denotes the vibration mode displacement vector in track center line, ($x_{\mathrm{i,B}}$, $y_{\mathrm{i,B}}$, $z_{\mathrm{i,B}}$) is coordinate value of node B_i in the moving coordinate.

If node B_i doesn't coincide with the point of intersection that track centerline projects on bridge's center line, any node's vibration displacement vector of bridge on the track center line can be determined by means of spline interpolation between two coincidence points.

2.3 *Wheel-Rail Contact Force*

Based on the wheel-rail creep theory of vehicle passing straight lines, the calculation of wheel-rail creep rate while vehicle passing curved bridges can adopt formulas as follows (Zhai, 2007):

$$\begin{cases}\xi_{1\mathrm{j}}'=\xi_{1\mathrm{j}}+(-1)^j\left[-b+\gamma_j\sin(\delta_j)\cos(\psi_{ws})\right]\cdot R_i & \text{(a)}\\ \xi_{2\mathrm{j}}'=\xi_{2\mathrm{j}} & \text{(b)}\\ \xi_{3\mathrm{j}}'=\xi_{3\mathrm{j}}+(-1)^j\cos(\delta_j)\cdot R_i & \text{(c)}\end{cases} \tag{8}$$

where $\xi_{1\mathrm{j}}$, $\xi_{2\mathrm{j}}$ and $\xi_{3\mathrm{j}}$ are respectively the longitudinal creep rate, lateral creep rate and spin creep rate while vehicle passing straight lines, $\xi_{1\mathrm{j}}'$, $\xi_{2\mathrm{j}}'$ and $\xi_{3\mathrm{j}}'$ are respectively the longitudinal creep rate, lateral creep rate and spin creep rate when vehicle passing curved lines, δ_{j} is the contact angle between wheel and rail, R_{i} is the curvature.

Creep coefficient is determined by the geometric relationship between wheel and rail, and is minorly affected by the curve. Hence, we can deal with it according to vehicle passing straight lines only considering the lateral displacement of wheel relative to track centerline.

According to Kalker's linear theory, the wheel rail creep contact force can be expressed as follows (Zhai, 2007):

$$\begin{cases}T_{x\mathrm{j}}=-f_{11}\xi_{1\mathrm{j}}'\\ T_{z\mathrm{j}}=-f_{22}\xi_{2\mathrm{j}}'+f_{23}\xi_{3\mathrm{j}}'\\ M_{\mathrm{j}}=-f_{23}\xi_{2\mathrm{j}}'-f_{33}\xi_{3\mathrm{j}}'\end{cases} \tag{9}$$

Where $\{f_{\mathrm{ij}}\}$ is the creep coefficient, T_{x} and T_{z} are longitudinal and lateral creep forces of wheel and rail, M_{j} is the rotating creep moment.

2.4 *Generalized Force for the Moving Train*

(1) Treatment of the first suspension force and the second suspension force

In theory, the first and the second suspension force should be transformed into the moving coordinate system when motion equations of vehicle are established. In fact, it is unnecessary to be transformed because of the small offset of bogie coordinate system, for example, cos(lr) almost equals to 1.0 even if the smallest radius is 350m.

(2) Centrifugal force and super-elevation component force

Assume that a wheel have the curvature of R_{i} and angle of super-elevation γ_{i} in its position, the centrifugal force and super-elevation component force in moving coordinate system can be obtained as follows (Xia and Zhang, 2005)

$$\begin{cases}C_{\mathrm{wi}}=-m_{\mathrm{wi}}R_{\mathrm{i}}v^2\\ H_{\mathrm{wi}}=m_{\mathrm{wi}}g\sin\gamma_i\\ V_{\mathrm{wi}}=m_{\mathrm{wi}}g(1-\cos\gamma_i)\end{cases} \tag{10}$$

where m_{wi} is the mass of wheel, C_{wi} is the centrifugal force along the direction of $o_{\mathrm{i}}z_{\mathrm{i}}$, H_{wi} is the super-elevation component force along the direction of $o_{\mathrm{i}}z_{\mathrm{i}}$, V_{wi} is the super-elevation component force along the direction of $o_{\mathrm{i}}y_{\mathrm{i}}$.

Take the average of n curvature and angle of super-elevation for each wheel approximately, the centrifugal force and super-elevation component force will be obtained as follows

$$\begin{cases}C_{\mathrm{b,c}}=-m_{\mathrm{b,c}}\left(\dfrac{1}{n}\sum_{i=1}^{n}R_i\right)v^2\\ H_{\mathrm{b,c}}=m_{\mathrm{b,c}}g\sin\left(\dfrac{1}{n}\sum_{i=1}^{n}\gamma_i\right)\\ V_{\mathrm{b,c}}=m_{\mathrm{b,c}}g\left[1-\cos\left(\dfrac{1}{n}\sum_{i=1}^{n}\gamma_i\right)\right]\end{cases} \tag{11}$$

where b denotes bogie, c denotes car body.

2.5 *Numerical analysis and field test*

Numerical analysis was conducted using VBC 2.0, which is a professional program for the analysis of vehicle-bridge coupled vibration developed by Tongji University. The motion equations are solved based on modal coordinate. In this paper, modal analysis was completed by commercial software ANSYS.

Some representative piers are taken as examples to analyze the dynamic response, such as No. 19 on the curved line. The time-history curve of pier top

lateral amplitude is shown in Figure 2 and the dynamic response of vehicle's lateral acceleration is shown in Figure 3 while freight train passing at the speed of 40 km/h.

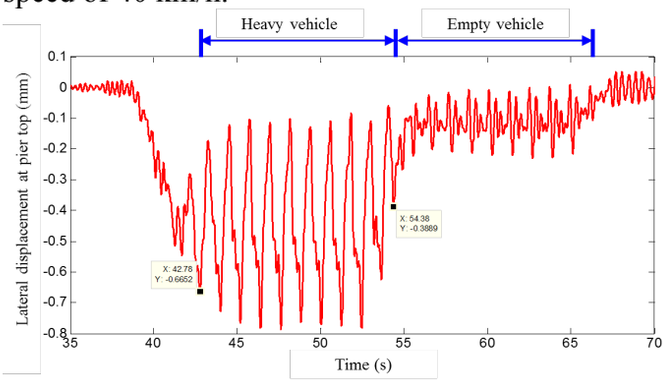

Figure 2. Time-history of lateral displacement at the top of the pier.

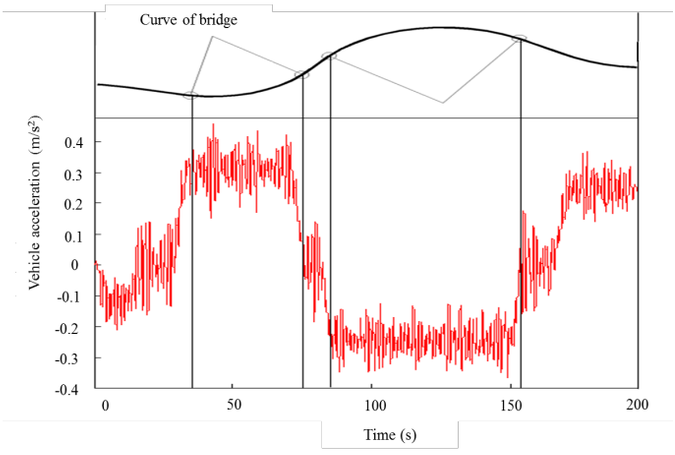

Figure 3. Time-history for the vehicle lateral acceleration.

3 TEST OBJECTIVES AND METHODS

3.1 *Overview of the Test Bridge*

The S-shaped curved bridge under test has a total length of 1728.91m. The reverse curve has a radius of 350m, which does not conform to the Section 3.4.5 of the Fundamental Code for Design on Railway Bridge and Culvert (2005). According to the preliminary analytical study and numerical simulation performed in the previous sections, three bridge spans with relatively higher piers between Pier No.45~55 were selected in this dynamic load test. The three spans are detailed as follows:

(1) *Intermediate straight bridge span*, namely 20m simply supported beam bridge span of piers No.45~46 on intermediate straight line (pier height at 11.75m).

(2) *Curved continuous rigid frame bridge span*, namely (20+26+20) m continuous rigid frame bridge span of piers No.50~53 on circular curve with radius R=350 m (pier height at 9.9m~11.3m).

(3) *Circular curve bridge span*, namely 20m simply supported beam bridge span of piers No.54~55 on circular curve with radius R=350 m (pier height at 10.75m). Picture of the testing bridge span is shown in Figure 4.

Figure 4. The curved bridge under test.

3.2 *Objectives and Methods*

According to vibration characteristics of theoretic analysis, the main objectives of the test includes:

(1) Evaluating the operation performance of the train passing the curved bridge with small radius and reverse curve.

(2) Comparing the theoretical analyses with the test results regarding the dynamic characteristics of the bridge under test.

(3) Evaluating the reasonable running speed of freight train passing the test bridge.

20 vibration tests are conducted given different loading and operating information of the passing train. The marshalling of the passing train includes the heavy train, the empty train and the empty heavy train. The test speed was set within the range of 20~40*km*/*h*. The transverse and vertical vibration characteristics of both the piers and the beams were monitored during the test.

3.2.1 *Layout of the Test*

The vibration velocity sensors and transverse displacement gauges were applied in the test with emphasis on the mid-span, where the maximum vibration responses are expected to occur based on preliminary analyses. The transverse vibration sensors were arranged at the top and bottom of Pier No.45. It should be noted that the pier bottom test point was 1.0 m above the top of the pier cap as the bearing platform was covered underground. The layout of the test points on the straight bridge is illustrated in Figure 5.

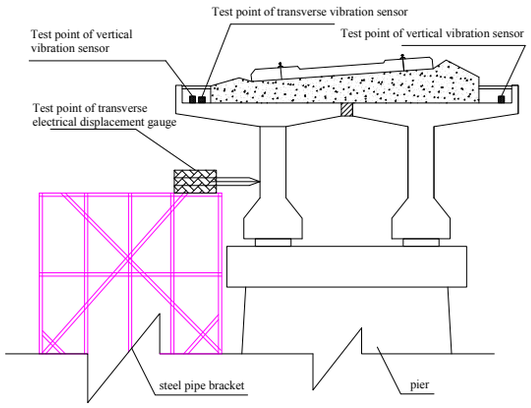

Figure 5. Arrangement of the test points at mid-span.

3.2.2 *Test Data Collecting and Processing*

As the raw data collected could include environmental vibration and instrument noise, further filtering processes are performed.

(1) Velocity Signal Filtering

The frequency spectrum of the velocity signal is analyzed using the Fast Fourier Transformation (FFT). As only the low-frequency responses of the bridge structure are of interest, low frequency signals less than 0.2Hz and high frequency signals greater than 20Hz were removed by filtering to eliminate the possible environmental and instrumental noises as well as the local vibration responses. Given the time history of the velocity signal at any test point, the time history of the displacement and acceleration could be obtained by integrating and differentiating along the time, respectively.

(2) Displacement Signal Filtering

The main difference of vibration characteristics between straight and curved bridges is that the center point of the amplitude shifts to the outside direction of the curve.

Electrical displacement gauges were used to monitor the transverse amplitudes and displacements of the bridge structure. The wavelet de-noising method was used to filter displacement signals. It was found in that the lateral displacement of the beam induced by centrifugal force was also filtered out when the method of velocity signal filtering was adopted. The time history of the displacement and the associated frequency spectra of an example test point is plotted in Figures 6 and 7.

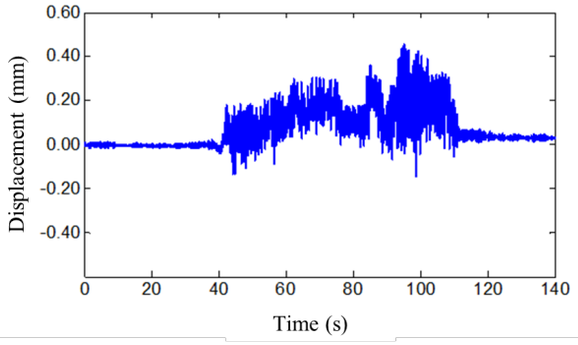

Figure 6. Time history curve for the lateral displacement at the top of Pier 55.

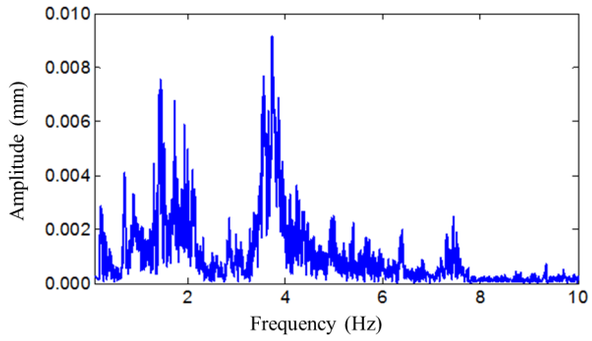

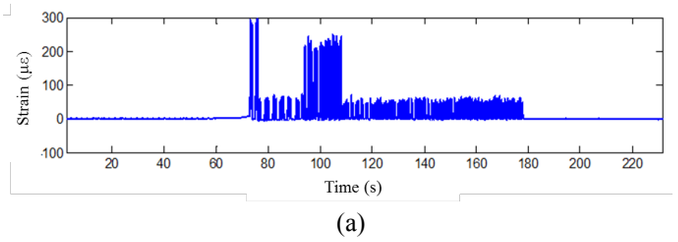

Figure 7. Frequency spectrogram for the lateral displacement at the top of Pier 55.

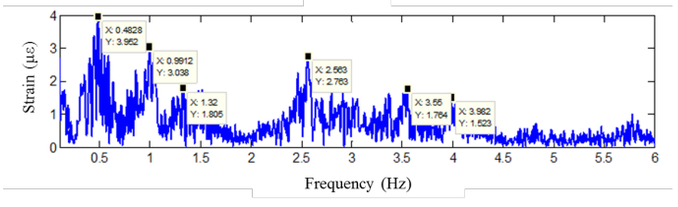
(3) Calculation of Train Speed and Axle Load



Train speed and marshalling information can be obtained by analyzing the strains of the steel rails. The time history of the strains and their associated spectra are shown in Figure 8. L is the length of the train between the two-wheel sets at head and tail, and the time of the two-wheel sets passing each test point is t_1 and t_2. The average speed of train can be computed as follows:

$$v=L/(t_2-t_1) \tag{12}$$

Simultaneously, the actual axle load of each freight train carriage can be calculated using the strain ratio between locomotive and vehicle.

(a)

(b)

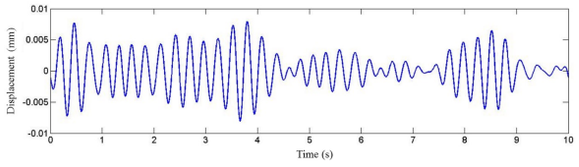


Figure 8. Dynamic responses of rail strains: (a) time history curve, (b) spectrogram.

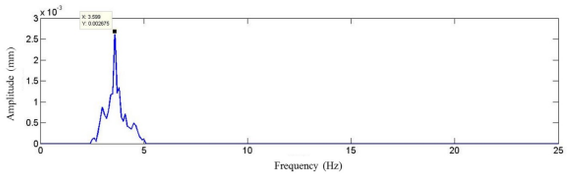
4 BRIDGE VIBRATION CHARACTERISTICS ANALYSIS



4.1 *Transverse Natural Vibration Frequency*

The residual vibration method was adopted in the tests because the train speed was relative slow and the transverse vibration responses of bridge mainly consist of low frequency signals. For example, Figure 9 shows the 10-second residual vibration history obtained by processing the data from the electrical displacement gauges on Pier No.54. It can be seen from the spectra that the 1st transverse vibration frequency of the pier is around 3.6*Hz*.

The average values of three representative groups of measured data are taken as the decision values of the tests, which are then compared against the normal allowance values in the Chinese Code for Rating Existing Railway Bridge (2004), as shown in Table 1. It can be seen that the transverse natural vibration frequencies of the representative bridge spans meet the requirements of the normal limited values of the code (2004). Reasonable stiffness of the pier-beam-system and foundation is also observed.

(a)

(b)

Figure 9. Residual vibration at pier top: (a) time history curve, (b) spectrogram.

Table 1. Frequency of transverse natural vibration of each bridge span.

Type	Intermediate Straight Beam		Curved Rigid Frame Beam		Circular Curved Beam	
	Pier Top	Mid. of Span	Pier Top	Bridge Span	Pier Top	Bridge Span
Average Value	2.87	2.77	3.57	3.50	3.60	3.60
Allowable Value	2.47		2.33		2.66	

4.2 *Vibration Acceleration*

4.2.1 *Transverse Vibration Acceleration*

It is required that the transverse acceleration of the bridge should be less than 1.4m/s^2 when only the modal contribution in the frequency range of 20*Hz* is considered per the Rating code (2004). The maximum transverse acceleration of pier and mid-span are presented in Table 2. The maximum transverse vibration acceleration occurred at mid-span of curved simply supported beam, which is 0.325 m/s^2 and less than the limited value. The transverse acceleration of pier and mid-span on curve was greater than that on straight line. The transverse acceleration of mid-span was greater than that of the top of the pier.

Table 2. The maximum transverse acceleration (m/s^2).

Test Point		Transverse Acceleration	Limit Value
Pier Top	No.45#	0.072	1.4
	No.51#	0.102	
	No.54#	0.130	
Mid Span	Intermediate Straight Beam	0.110	
	Curved Rigid Frame beam	0.325	
	Circular Curved Beam	0.220	

4.2.2 *Vertical Vibration Acceleration*

By reference to EURO-CODE, it is regulated in the Code for Design of High Speed Railway (2015) that the vertical acceleration should be less than 3.5m/s^2. The mid-span maximum vertical vibration accelerations of each test span are shown in Table 3. The maximum vertical vibration acceleration occurs at mid span of curved simply supported beam, and it is 0.463 m/s^2 and less than the limited value. The mid span vertical acceleration of curved simply supported beam is greater than that of the straight simply supported beam. The mid span vertical acceleration of curved continuous rigid frame beam is less than that of simply supported beam.

Table 3. The Maximum Vertical Acceleration (m/s^2).

Test Point		Vertical Acceleration	Limit Value
Mid Span	Intermediate Straight Beam	0.433	3.5
	Curved Rigid Frame Beam	0.419	
	Circular Curved Beam	0.463	

4.3 *Vibration Amplitude and Displacement*

4.3.1 *Transverse Amplitude*

As regulated in the Rating code (2004), when the heavy train speed is less than 80*km/h*, the maximum transverse amplitude of mid-span for the pre-stressed concrete beams should not exceed the following value:

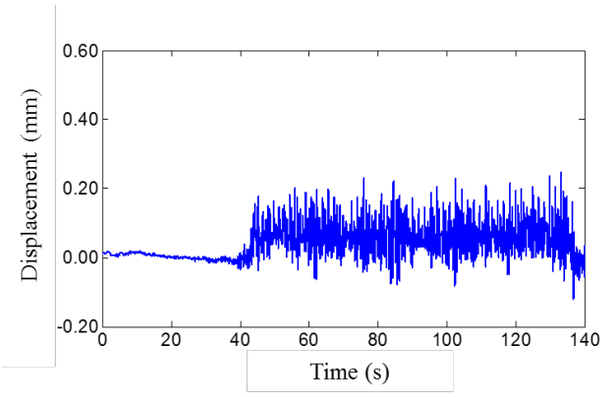
$$A_{\max} \le \frac{L}{7.0B}(mm) \tag{13}$$

where, L is the calculated span of the bridge, and B is the center distance of the beam.

The maximum transverse amplitude at the top of the high pier with the pile foundation should not exceed the following limit:

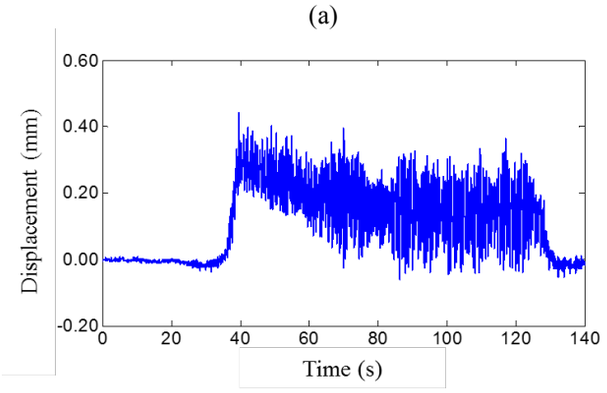
$$A_{\max} \le \frac{(H+\Delta h)^2}{100B} + 0.2(mm) \tag{14}$$

where, B is the average width of the pier in the transverse direction, H is the overall height of the pier (from the top of the pier to the bottom of bearing platform), and Δh is the modified height considering characteristics of foundation soil, which is 1.0 considering the geological condition of this bridge.



The comparisons of the transverse amplitudes between the measured values and the allowable values are shown in Table 4. The peak values of the measured amplitudes of the mid-span in each test span and those at the top of the piers are both less than the allowable values, which meets the safety requirements of train passing.

Table 4. Comparison of Transverse Amplitude Between Measured and Allowable Values (*mm*).



Bridge Span	Mid-span Measured Value	Allowable Value	Pier Top Measured Value	Allowable Value
Intermediate Straight Beam	0.35	0.68	0.17	0.72
Curved Rigid Frame Beam	0.36	0.76	0.22	0.71
Circular Curve Beam	0.22	0.68	0.16	0.65

4.3.2 *Transverse Displacement*

According to the Code for Design of High Speed Railway (2015), the limited safety value of the transverse amplitude at the mid-span is L/9000 for pre-stressed concrete beams. The limited safety value for the test bridge spans are computed as 2.2*mm* for the straight span and 2.9*mm* for the curved span, respectively. The time history of the transverse displacements at the mid-spans are shown in Figure 10 for the straight and the curved simply supported beam, respectively. The maximum transverse displacement of each mid-span is detailed in Table 5.

(a)

(b)

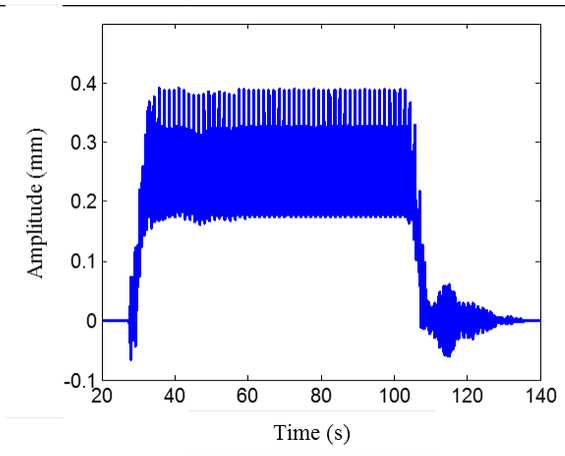
Figure 10. Time history curves of transverse displacement: (a) straight beam, (b) curved beam.

The maximum transverse displacement at each mid-span is far less than the limited value, and the transverse displacement of the curved simply supported beam is greater than that of the intermediate straight one. The reason could be that span have the tendency to shift to the outside of the curve under the action of centrifugal force. The transverse displacement of intermediate straight-line bridge is also shift to the same side irrespective of train driving direction. A possible explanation could be that intermediate straight-line bridge is subject to the smaller centrifugal force and some eccentricity exists between the center line and shear center of the test bridge.

Table 5. Maximum Transverse Displacement (*mm*).

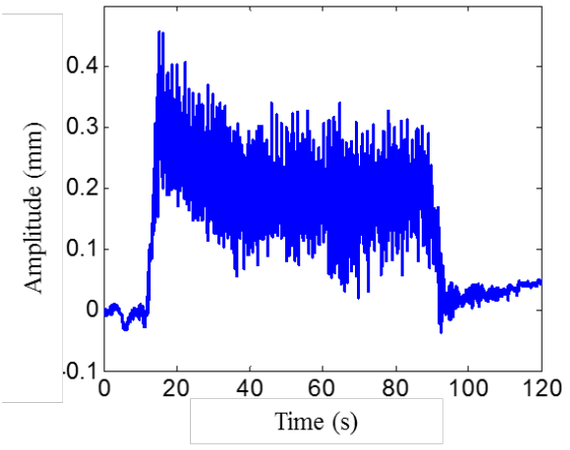
Span	Intermediate Straight beam	Circular Curve beam
Measured Displacement	0.49	0.46
Allowable Value	2.20	2.20

5 REVISING OF CALCULATION MODEL



The finite element model of the test bridge is built in ANSYS. The transverse natural vibration frequency of bridge is calculated. According to the Guidelines for Seismic Design of Highway Bridges (2008), ***m***

method was adopted to calculate the foundation dynamic stiffness in the calculation model, and the dynamic stiffness of the pile was obtained as 3 times of the static stiffness.



The preliminary result shows that the transverse natural vibration frequency obtained from the measured results didn't fit well with that of the numerical calculation results from the model. Therefore, the model was revised to correct the foundation dynamic stiffness according to measured values in Table 1. Assuming the static stiffness is K with ***m*** method, the actual dynamic stiffness can be obtained by inverse calculations performed in Table 6. Then the transverse natural vibration frequency was recalculated according to the revised calculation model. In Figure 11, the time history of the transverse vibration displacement obtained from the revised model and the measured data are compared and much better fit is observed.

Table 6. Comparison of dynamic stiffness and transverse natural vibration frequency.

Beam Type	Pier Bottom stiffness	Transverse Natural Vibration Frequency (*Hz*) Numerical Calculation	Measured Value
Intermediate Straight Beam	K	1.223	2.87
	$3K$	1.591	
	$8K$	2.885	
	Consolidation	4.824	
Circular Curve Beam	K	1.355	3.60
	$3K$	2.593	
	$12K$	3.607	
	Consolidation	5.233

6 CONCLUSIONS

Based on both the theoretical and experimental analyses, it could be concluded that:

(1) The method of moving coordinate systems and coordinate transformation was used to establish the geometric relationship between the train and the bridge, and the wheel-rail contact force was simulated based on modified Kalker's linear creep theory.

(2) The main difference of vibration characteristics between the straight and curved bridge is that the center point of the vibration amplitude shifts to the outside curve.

(3) The main vibration characteristics of the test bridge under the operating train meet the requirements of serviceability and safety specified in the code, including multiple measures such as lateral acceleration, vertical acceleration, transversal amplitude and displacement.

(4) The dynamic stiffness of the foundation is much greater than the static stiffness in this study, indicating that the ***m*** method might not be a good approach, and further study is still needed.

Repairing a sinking bridge over Guadalquivir river

C. Jurado (Ph. D.,m Sc., B. Sc., MBA)
Polytechnic University of Madrid / Ingecal Ingenieros, S. L., Madrid, Spain

ABSTRACT: The bridge over Guadalquivir river, near Alcalá del Rio in Seville (Spain), that has nine spans of 30 m each, with a total length of 270 m, has suffer in the past a sinking of 14 cm and 6 cm on two of the central piers located in the centre of the river. The superstructure is isostatic and the foundation is constituted by two circular pier-piles of 1.50 m of diameter. Among different solutions the best technically and economically selected, was to use Jet Grouting injections

1 INTRODUCTION

The Spanish Administration has carried out in the past the construction of the Road Variant of Alcalá del Rio, which includes a bridge over the Guadalquivir River with nine isostatic spans, whose geometric definition is described later.

The mentioned structure consists of nine spans equal of 30.00m each one, which sums up a total length of 270.00m The deck comprises 10.00m of pavement plus two sidewalks of 1.00m, totaling a width of 12.00m

The bridge was designed with deep foundation in all its supports, due to the existing soft ground in the zone.
The foundation of the bridge is constituted by two circular pier-piles of 1.50 m of diameter for any support of the bridge and 25 m of length in the case of piers. In the piers, the piles has 2 m embedded in gravels and 12 m (8 diameters) in blue marls; the remaining 11 m corresponds to the exempt part of the pier, with the lowest 2 m corresponding to the average water depth of the Guadalquivir River in the above mentioned zone.

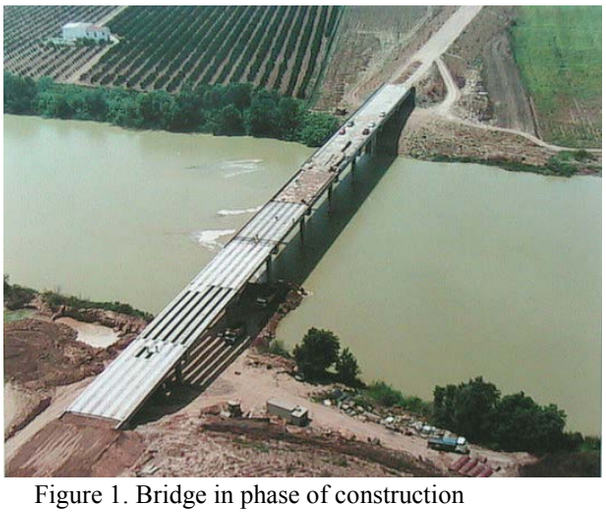

Figure 1. Bridge in phase of construction

Figure 2. Finished bridge

2 DETECTED PATHOLOGY

In the first week of the opening of bridge (in April), it was observed a vertical angle in the metal vehicles barriers and in the handrails of the bridge that was indicating the possibility of a descent of the deck, at the level of the piers P-4 and P-5 in the center of the river (Figure 3).

It was decided to verify the level of the mentioned piers by topography, observing average settlements in piers P-4 and P-5 of 13.9 and 5.4 cm. respectively. Due to this it was decided to carry out a following-up of the settlements by means of topography fixed bases of leveling on both sides of the bridge.

From the day 4th of April until 17th of May, it was observed that both abutments and the rest of the piers did not have suffer any settlement, but the piers P-4 and P-5 continued descending, reaching the average settlements

of 14.6 and 6.0 cm, respectively. The settlement of both pillars of each pier were similar.

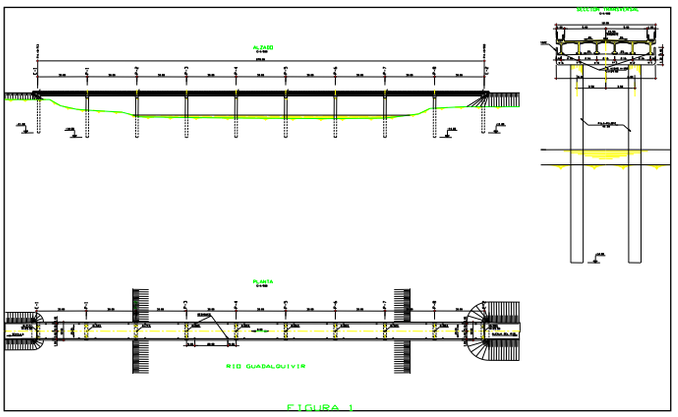

Figure 3. General drawings of the bridge

3 ACTIONS ON THE PIER-PILE

It was decided to review the project of the bridge verifying the validity of this. The actions over the pier-piles were calculated considering mainly the following loads:

- Dead loads.
- Live loads due to a uniform load of 0.40 Ton/m^2 and to a truck load of 60 T on, according to the Spanish Code of Bridges, considering different positions of it.

The maximum characteristic axial load that the piers transmitted to the ground (supposing that both pillars were working equally), without considering the action of the wind and the earthquake, it turned out to be of 503.02 Ton, for each pile. In case of performance of wind and earthquake the maximum and minimal loads were:

$Q_{máx}$: 554.22 Ton.
$Q_{mín}$: 451.82 Ton.

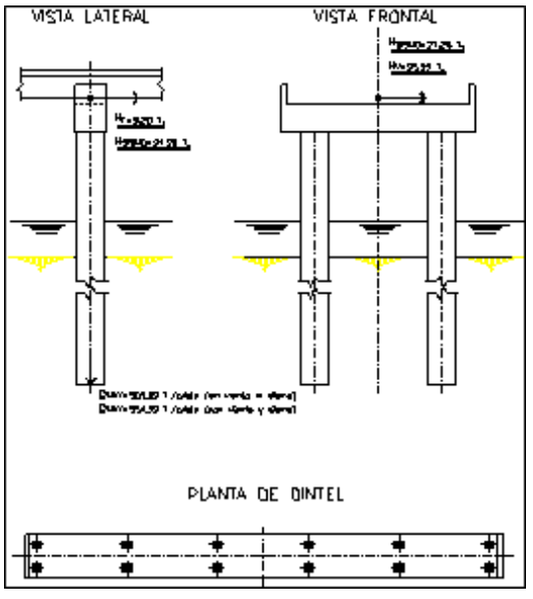

Figure 4. Actions on a pier-pile

Table 1

CP(T)	66.82	79.02	79.02	79.02	79.02	66.82
+	+	+	+	+	+	+
S.C.V.(T)	20.16	25.92	79.27	79.27	25.92	20.16
TOTAL(T	86.98	104.94	158.29	158.29	104.94	86.98

*C.P.DECK= 700.42 T.
*C.P.LINTEL= 72.00 T.
*C.P.PIER–PILES= 233.62 T

TOTAL=1,006.04 T.=503.02 T/pile

During the project of the bridge, a Geotechnical Campaign of soil recognition had been realized, consisting of soil borings, that indicated the existence of one alluvial of several meters of thickness and below it, the Mioceno substrate of marls of unlimited thickness. None of the borings were made under the piers P-4 and P-5. The alluvial was proved to be with a medium compacity and the marl with a compression resistance of q_u = 6.3 kp/cm^2. Inside the soil borings, there were realized S.P.T. tests, turning out to be with an average value of N_{SPT} =62.

With these values the ultimate load capacity for pile was turning out to be:

$$Q_h = Q_p + Q_f = A_p \cdot r_p + A_f \cdot r_f \quad (1)$$

A_p, A_f = Cross section and perimeter of pile
r_p, r_f = unitary ground resistance of tip compression and on lateral friction

$$q_u = 6.3 \text{ k}_p/\text{cm}^2 = 63 \text{Ton/m}^2 \quad (2)$$

In the project it has been adopted:

$$r_p = 5\, q_u = 315 \text{ Ton/m}^2 \qquad r_f = 0.25\, q_u = 15.75 \text{ Ton/m}^2 \quad (3)$$

The ultimate load of pile collapse, despising the collaboration of the resistance of shaft friction of the gravels it turned out to be:

$$Q_h = 1.766 \text{ x} 315 + 56.52 \cdot 15.75 = 1446 \text{ Ton} \quad (4)$$

The safety coefficient for the maximum load of service without magnifying was:

$$F = \frac{Q_h}{N_{\max}} = \frac{1446 Ton}{503 Ton} = 2.88 \quad (5)$$

Which was considered to be acceptable in the project. This coefficient of safety, if it was considered the existence of the earthquake and the transverse wind, was diminishing to F = 2.51 in the most loaded pier, value that also was considered sufficient.

4 RECOGNITIONS REALIZED AND RESULT OBTAINED

In view of the detected pathology it was decided the accomplishment of one additional field campaign of recognition, consisting of two mechanical rotatory soil borings, on the basis of the following hypotheses:

4.1 *Hypothesis*

Due to the similar settlement in the couples of pier-piles of each one of the pillars P-4 and P-5, an hypothesis was made that the marl could not be homogeneous, containing some soft nodules under the tip of the pile or some cavities.

There was discarded the imperfection or bad execution of the pile and especially on the tip, because it seemed to be strange that 4 piles and besides contiguous were badly executed. By the control taken during the construction heterogeneities were discarded also along the pillar.

4.2 *Realized recognition*

The recognition consisted of the execution of two mechanical rotatory soil borings, one between the two pillars of the pier P-4 and other one between those of the pier P-5.

The soil borings were executed on a boat since the piers P-4 and P-5 are located in the center of the river.

In situ standard penetrations test (S.P.T.) were made every 2.00 m of vertical distance in each boring, and recovery of soil-samples for laboratory tests.

4.3 *Result obtained*

The profiles of soil obtained were the following ones:

Table 2

BORING	PIER	MOUTH ELEV.	DEPTH (m)	TIPE OF SOIL
S-1	P-4	-1.98	From 0 to 0.25 m From 0.25 to 2.25m From 2.25 to 28.50m	Lime Gravel Blue Marl
S-2	P-5	-1.93	From 0 to 1.30 From 1.30 to 21.30	Fine Gravel Blue Marl

No hollows or soft zones were detected below the tip of the piles; nevertheless, the recognition put of manifest a consistency of the marl smaller that were awaited.

In effect, the Geotechnical recognition realised in the project indicated that the marl had one N_{SPT} = 62 and one resistance to compression of at least 6.3 kg/cm^2.

The S.P.T. test realized in the last recognition, had registered a N_{SPT} number even the half, along the pile and under the tip.

The average number N_{SPT} it turned out to be of 36 (on S-1) and of 35 (on S-2). All these values lower to N=62 obtained during the project recognition, carried out in the zones of abutments were up to 20 to 23 meters of depth, and there were not obtained number N_{SPT} of 60 or superior.

Applying the relation that proposes the bibliography between the S.P.T. test and the resistance of compression of q_u = N/7.5, it were obtained compression values as low as q_u=21/7.5=2.8 kg/cm^2, very far away from the value of 6.3 kg/cm^2 considered in the initial Geotechnical report during the project.

The tests to simple compression performed on samples gave low values, between 3.40 and 4.91 kg/cm^2, in the first 12 meters, except a value of 10.08 kg/cm^2. Major values of 6 kg/cm^2 were found below 16 m of depth, corresponding to values of N_{SPT} superiors to 50.

As conclusion the following points were indicated:

a) It was not confirmed the existence of large soft zones of soil or caves below the tip of the piles.
b) Nevertheless, it was putting of manifest that in the first 16 recognised meters, the marl had much less consistency than the awaited one in the project.
c) Due to the minor geomechanic resistance of the soil, it was decided to verify the safety coefficients of the piers P-4 and P-5, with new geomechanic parameters.
d) In the new calculations made, it was supposed that the resistance to simple compression along the pile and in the tip was of 5 kg/cm^2, that is equivalent to one number of N_{SPT} = 38 (q_u = 38/7.5 = 5 kg/cm^2). This directed to the conclusion that the piles were working near to the plastic limit of the surrounding soil and it was necessary to reinforce the foundation of the bridge.

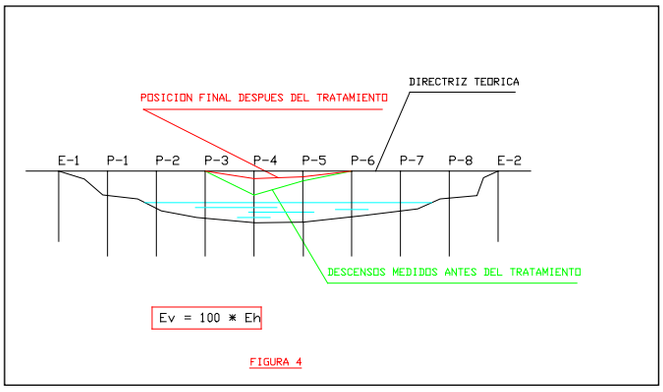

Figure 5. Lifting of piles P-4 and P-5

5 ADOPTED SOLUTION

An economic analysis for three possible solutions was made, obtaining that the best solution was to use Jet Grouting, with the minor cost and the minor problems of accomplishment and at the same time, it could be obtain a reduction in the settlements of piers P-4 and P-5. This solution consisted of the execution of 18 columns of Jet Grouting of injection distributed concentrically with the piles, nine vertical to a distance of the pile of 0,50-1,00 m and the other nine o a distance of the pile of 2,00 m and inclined approximately 6,5 º degrees (figure 6).

The injection would produce a column of soil-cement of approximately 40-50 cm. of diameter, consolidating and refilling the zones of the marls that surround the column.

The columns of Jet Grouting were executed alternatively, so that between 2 adjacent columns executed in the same day, there was at least 1,50 m, or 24 hours of consolidated cement of the adjacent columns, to the injection that was executed in this moment. The object of this gap in space and time was to avoid the possible fluidity of an important area during the injection of the mortar, and that could give place to an unforeseeable increase of the settlements. Also, during the execution of the treatment the traffic was not interrupted, though it was stopped in the lane that was over the pier-pile in treatment in every case and in the other lane the velocity of traffic was reduced.

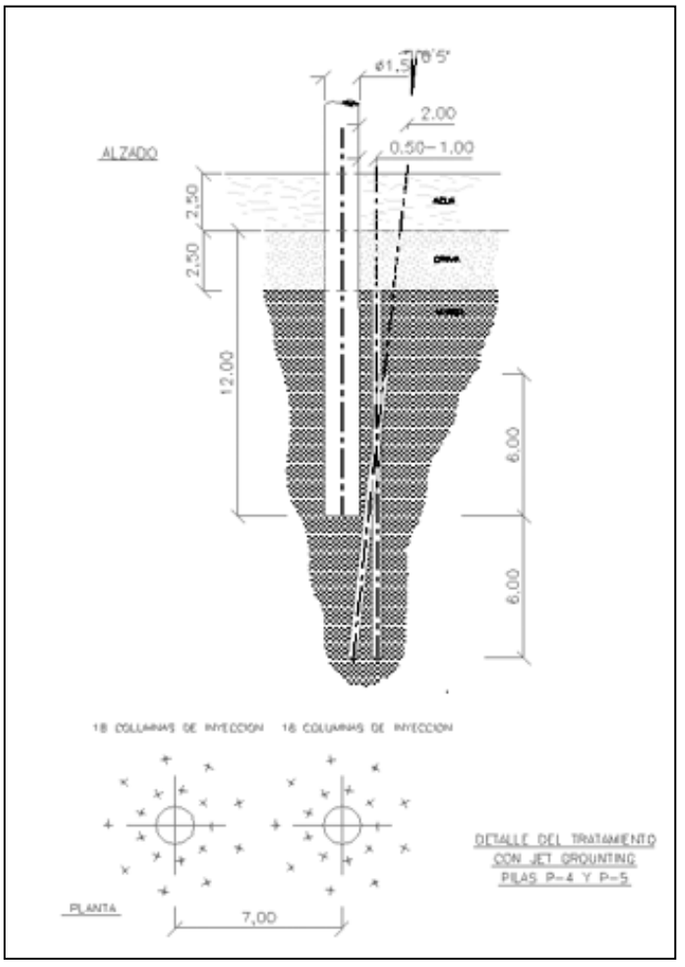

Figure 6. Scheme of jet grouting

The worst moment of the procedure was when one injection was executed. Therefore, it was recommended to make frequent controls of levelling of the affected piers, controlling the raising of the pier and also reducing the speed of the vehicles on t he bridge to avoid important dynamic loads. With the effective treatment, it was corrected the settlement of the piers P-4 and P-5 obtaining a rising of the twin pillars of approximately 10 cm as maximum.

INITIALSEAT	AL SEAT
P-4: 14.6 cm.	4.6 cm.
P-5: 6.0 cm.	3.5 cm.

The work was carried out during the months of June and July of this year.

Traffic load patterning on long span bridges

D. Guo & C. Caprani
Monash University, Melbourne, Australia

ABSTRACT: For highway bridges, current live load models typically replicate the effects of real traffic streams at a certain return period. Most standards stipulate that the worst load effect should be considered, obtained by patterning the live load on the adverse portion of the influence lines only. Certainly, this is a worst-case scenario, but real traffic does not pattern in this manner. This paper examines design standards' approach to load patterning against the behaviour of real traffic. Traffic microsimulation is adopted on a generic 1200 m bridge. We consider the possible road topologies that might give rise to design standard loading patterns. The results show that real traffic cannot achieve the code-inferred traffic pattern. The load effect results are extrapolated to represent assessment and design return periods. A possible road topology is put forward, and it can be the prototype of a new method to assess the load effect.

1 INTRODUCTION

1.1 *Background*

Long span bridges are critical pieces of infrastructure, and it is vital to construct and maintain them as economically as possible. The traffic load model for bridge design and assessment is designed to simulate the extreme load effect (LE) of actual vehicle traffic on the bridge. Normally, the standard requires engineers to pattern the live loads for the most critical case, which means to apply the maximum load on the adverse part of the influence lines (IL), while maintaining the load on the beneficial part at the minimum value (the live load is zero). For instance, the Australian load model SM1600 (Standards Australia 2017) requires that the uniformly distributed load (UDL) component is continuously or discontinuously applied to produce the most adverse effect. Similarly, the Eurocode (2003) load model LM1 requires that the UDL is applied only in the unfavourable parts of the influence surface. AASHTO (2007) also requires patterning the UDL of HL-93 to produce the extreme force effects. The same method and statement have been followed by many other national standards.

The inherent problem of the traditional (or current) load model method is that it is a combination of extremes: it combines extreme load values and extreme load topology. The possibility of this combination of extreme loads and arrangements has not been studied in detail (as will be seen later). As a result, bridge engineering practice follows a worst-case scenario approach that combines extreme (lifetime) load levels in an extreme (lifetime) traffic topology. Because of the formation of the truck platoon and other traffic phenomena, the traffic loading is obviously not perfectly evenly distributed, so it is reasonable to see some load patterning. But a more reasonable basis is needed to estimate the traffic behaviour effect in a long span bridge life cycle.

There can be significant implications when using the current load patterning approach for designing a new bridge. For example, the newly opened (2017) Queensferry Crossing of the Firth of Forth, Scotland. It is a multi-span cable-stayed bridge. The total length is 2700 metres with two main spans of 650 meters (Kite et al., 2011). In the design, the Eurocode load model is used, and the design live load patterning causes a significant moment in the centre tower. As a result, cables are overlapped to reduce the bending moment of the middle tower.

Of course, traffic load patterning does not only affect the new design but also have a great impact on the existing long-span bridge. For example, around 25% of the long-span bridges in North America reach the 75-year design lives and only 63% long-span bridges are in good condition (Maria et al., 2017). It is estimated that the maintenance of bridges in The United States has reached US$123 billion (ASCE, 2017). Obviously, if using a more accurate live load model to assess the status of the existing bridge, a lot of cases may be found to be safe, which can help save a lot of maintenance or repair costs.

1.2 *Traffic Loading on Long Span Bridges*

The traffic load of long-span bridges is governed by high volume traffic, usually congestion. A lot of research work on this topic is based on mixed vehicles and fixed vehicles gaps (Ivy et al., 1954, Buckland, 1981, Ditlevsen and Madsen, 1994, Nowak et al., 2010, Caprani et al., 2012). Such work assumed that cars and trucks were at the smallest bumper distance, and the weight data came from the on-site surveys or weigh-in-motion (WIM). However, WIM data is captured from the free flow traffic as the sensor is inaccurate in the congested traffic. (OBrien et al., 2015). Therefore, these measurements cannot be used directly for long span bridge loading. Another noticeable feature of the traffic is that the vehicle compositions can be quite different across lanes. For example, car drivers tend to change lanes to catch up with slow-moving trucks, which leads the truck ratio on the slower lane exceeding the average. This phenomenon is more serious in traffic congestion, often forming a long truck platoon on a local road. (Carey et al., 2017). Therefore, it can be unrealistic to directly use a survey or WIM data. To overcome this challenge, some researchers used videos of congested traffic (Ricketts and Page, 1997, Nowak et al., 2010, OBrien et al., 2012). Many observations can be obtained from the video, such as typical traffic jam scenario, but it is difficult to obtain accurate quantitative data.

The recent way to overcome the WIM problem is to use traffic micro-simulation to create congested traffic from free-flow traffic measurements. In introducing the intelligent driver model (IDM), Treiber et al. (2000) used the traffic microsimulation to recreate the congested traffic load patterns which have been observed. They introduced the bottleneck strength and discussed the relationship between it and various congestion types (or congestion modes). Caprani and OBrien (2008) first used this microsimulation method to estimate the bridge traffic loads. Later, Caprani et al. (2016) verify the bottleneck strength and congestion types. They use microsimulation to analyse the LE of multi-lane traffic. Contrary to the general view, they found that the full stop traffic was not the worst-case scenario on the bridge. It is the slow-moving traffic which produces the highest lifetime loading. The reason is that there are more opportunities for vehicles arrangements on the road.

There is not too much work done on the patterned traffic loading. Zhou et al. (2015) considered the patterned traffic LEs of multi-span bridge by using the above-mentioned traffic micro-simulation method. In the study, the beneficial part of the IL is ignored. It is found that the LE of the pattern traffic can reach 8 times the normal traffic on the bridge, which shows that the current standard is conservative. In spite of this, most engineers would suggest that the patterned traffic is to replicate the case of traffic accidents, and other cases interrupting the normal traffic.

Recently, Lipari et al. (2017) proposed an integrated approach to determine lifetime levels of traffic loading, considering the probability of occurrence of traffic incidents and incorporating the level of interruption to traffic flow (or 'bottleneck strength'). In doing so, they use traffic microsimulation to determine the traffic topology and estimate the resulting LE. This method shows that traffic micro-simulation is a suitable tool to analyse the hypothesized traffic events and their topologies. Therefore, this method is adopted in this study.

1.3 *Contribution*

This paper assesses the potential of observing patterned traffic topology for theorized traffic activities by using traffic microsimulation, as stipulated by design and assessment codes. The study demonstrates a practical topology that comes as close as conceivable to duplicating the conventional code-referred design. This could be a prototype of the load patterning method and it could have a noteworthy advantage in the plan of new bridges, however most likely in the assessment of existing bridges, where the expenses of extra strength are huge.

2 TRAFFIC MICROSIMULATION

Microsimulation models consist of vehicle-following models and lane-changing models to simulate the vehicle movements on the road. It is powerful and convenient to record the position, direction, speed, axle arrangement, and other features of one single vehicle at any time, making it very useful for bridge loading studies. In recent years, Microsimulation models have been widely used in traffic analysis with different levels of accuracy (Orosz et al., 2010). However, it is quite important to deal with the calibration and validation process, as the data is simulated, to ensure its validity (Treiber et al., 2000). Ten microsimulation models (including IDM) are compared by Brockfeld et al. (2004) and they found it is almost impossible to calibrate results to within 10% variance. The common range of differences is 14 to 16% and the performances of various models are quite similar.

2.1 *IDM & MOBIL Models*

Treiber et al. (2000) developed an Intelligent Driver Model (IDM) which is a car-following model. The model is collision-free with several parameters to control single vehicle driving behaviour in one lane. Many research studies adopted IDM to simulate traffic. The results from IDM simulation can match the

observed actual traffic scenarios quite well and, therefore, it is suitable to use for actual traffic analysis (Treiber et al., 2000, Kesting and Treiber, 2008, Helbing et al., 2009, Chen et al., 2010, Caprani, 2012).

In the IDM, the acceleration of one single vehicle is given by:

$$\frac{dv}{dt} = a\left[1 - \left(\frac{v(t)}{v_0}\right)^4 - \left(\frac{s^*(t)}{s(t)}\right)^2\right] \quad (1)$$

where a is the maximum acceleration; $v(t)$ is the speed of at time t; v_0 is the desired speed; $s(t)$ is the gap between the current vehicle to the front vehicle at time t; and $s^*(t)$ is the minimum desired gap at time t, given by:

$$s^*(t) = s_0 + Tv(t) + \frac{v(t)\Delta v(t)}{2\sqrt{ab}} \quad (2)$$

where s_0 is the minimum gap distance from the current vehicle to the front vehicle; T is the safe time headway; $\Delta v(t)$ is the speed difference between the current vehicle and front vehicle, and b is the comfortable deceleration.

Later on, a lane-changing model called Minimising Overall Braking Induced by Lane changes (MOBIL) was introduced by Kesting et al. (2007). Symmetric (US) or asymmetric (EU) passing rules both can be implemented. In MOBIL, a vehicle will change lane if there is a sufficient acceleration advantage to be gained:

$$\bar{a}_c - a_c > \Delta a_{th} + p\left[\left(a_n - \bar{a}_n\right) + \left(a_o - \bar{a}_o\right)\right] \quad (3)$$

where Δa_{th} is the acceleration threshold and $a(t)$ is the acceleration at time t, which is calculated by Equation 1. The subscript indicates the vehicle: old follower (o), new follower (n) and current vehicle (c) and the bar identifies the situation after a hypothetical lane-changing. The politeness actor, p, controls how much consideration a driver gives to the impact of the lane change on surrounding vehicles' accelerations.

2.2 *SIMBA and Parameters*

Commercial software using traffic microsimulation excludes bridge LE calculation. Consequently, since 2006, Caprani et al. (2012) developed a software program called Simulation for Bridge Assessment (SIMBA). SIMBA uses IDM and MOBIL for vehicle movements, coupled with LE calculation based on ILs at each time step of the simulation. Table 1 shows the model input parameters. They were used in some parts of past works since they have been shown to replicate genuine traffic behaviour quite well (Treiber et al., 2000, Kesting and Treiber, 2008, Caprani et al., 2012, OBrien et al., 2015).

Table 1. IDM and MOBIL parameters.

Parameters	Car	Truck
Safe time headway, T (s)	1.6	1.6
Maximum acceleration, a (m/s^2)	0.73	0.73
Comfortable deceleration, b (m/s^2)	1.67	1.67
Minimum jam distance, s_0 (m)	2	2
Elastic jam distance, s_1 (m)	0	0
Desired velocity, v_0 (km/h)	120±20%	80±20%
Acceleration exponent, Δ	4	4
Lane change politeness factor, p	0.2	0.2
Outside lane bias factor, ΔA_{bias}	0	0
Lane change threshold, ΔA_{th} (m/s^2)	0.4	0.4
Maximum safe deceleration, B_{safe} (m/s^2)	4	4

2.3 *Congestion Types and Bridge Loading*

Interestingly, traffic conditions are not a binary choice between free-flow traffic (FT) and congested flow traffic. Rather, traffic conditions occur over a range, with various forms of congested traffic, such as triggered stop-and-go waves (SGW or TSG), oscillating congested traffic (OCT), and the most severe – homogenous congested traffic (HCT). The difference between demand and capacity, named the bottleneck strength, mostly controls the occurrence of these traffic types. Usually, the higher the bottleneck strength, the lower road capacity at that road section. Treiber et al. (2000) visually illustrated the relationship between the bottleneck strength and different congestion types using a phase diagram. In the paper, the bottleneck strength ΔQ (or the dynamic capacity difference) is the local decrease of the traffic capacity:

$$\Delta Q = Q_{out} - Q'_{out} \quad (4)$$

where Q_{out} is the maximum dynamic road capacity on the (hypothetically) free road and Q'_{out} is the maximum dynamic road capacity with the bottleneck in place.

Bottleneck strength can be presented locally either by specifically decreasing the desired speed v_0 or by increasing the safe time headway T. Both can diminish the road capacity but the latter is more effective (Treiber et al., 2000) and so is used here.

Caprani et al. (2012) and OBrien et al. (2015) studied different types of congestion and their influence on long-span bridge traffic LE. The densest type of traffic, HCT, is that intended to be replicated by bridge live load models. However, since it is a continuous traffic flow, it does not have a natural pattern.

On the contrary, SGW has both dense and free flow regions, and of course, these regions may coincide with adverse and beneficial parts of IL, leading to severe load conditions. Figure 1 illustrates this case. However, no previous studies on this point are known. This paper discussed the LE of SGW and from it develops a traffic load patterning prototype.

Figure 1. An illustrative example of stop-and-go waves. The rectangles represent moving vehicles on the bridge.

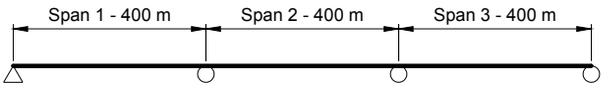

Figure 2. The elevation view of a generic 1200 m bridge.

3 THE TRAFFIC LOAD PATTERNING PHENOMENON

3.1 *Hypothesis*

In this section, we study the phenomenon of traffic load modelling and explain some rules about its real behaviour and code implicit behaviour. To do this, a hypothetical bridge is considered, with an IL that is sensitive to patterned load:

- Study 1: Firstly, we examine whether the natural patterning of traffic has a significant impact on bridge loading. This is done by generating different types of congestion on the bridge and examining the resulting LEs.
- Study 2: Second, by cropping the ILs, we apply code-referred traffic patterns, completely ignore the traffic flows of beneficial parts of ILs, and check the resulting LE.
- Study 3: Finally, we examine whether it is possible to simulate the code-referred traffic patterns through some critical incidents occurring in traffic flows without modifying the ILs. For these hypothetical critical traffic scenarios, we determine the resulting LEs.

A lot of information is gained by a comparison of the LEs from the above studies. However, before examining the results of these studies, the details of the studies are described.

3.2 *Basis of the Studies*

A generic bridge is used for the studies (Figure 2). This geometry can represent some existing bridges, such as The Millau Viaduct (204 + 6 × 342 + 204), Charilaos Trikoupis Bridge (286 + 3 × 560 + 286), and Brooklyn Bridge (283 + 487 + 283). The two traffic directions on the bridge are considered as independent, and so only one direction is considered.

For general bridges, the LE of a hypothetical IL, which is sensitive to load patterning, is considered (Figure 3). Both maximum and minimum values of the LE are studied. The study of the complete IL is used to show the load effect of actual traffic flow (Figure 3a). The code-implied traffic flow considers the worst-case maximum LE by cropping the beneficial region of IL (Figure 3b), and similarly for the worst-case minimum LE (Figure 3c).

The same input traffic data set is used throughout the work to avoid the irrelevant variable affecting the result. Since these studies are only relative comparisons, not to quantify the actual value of loading, this is acceptable. The traffic characteristics simulation data is obtained from A6 highway, near Auxerre in France. These data are important because they form the basis for Eurocode load models (Bruls et al., 1996). The traffic used in this work is randomly generated using Monte Carlo simulation (Jacob and Labry, 2002, Caprani, 2005). In Auxerre data, there is no recording of ordinary cars, but the study manually inserted them (Caprani, 2013, Caprani et al., 2016). The traffic flow is set to 1500 veh/h/lane and the truck percentage as 16% (Lipari, 2013). Additionally, an 80:20% distribution of trucks between lanes is set (Fwa and Li, 1995, Caprani et al., 2016).

For each study, 100-hours of congestion data is generated. Considering 1 hour of congestion per day, 100 hours of congestion is equivalent to 100 days for the bridge. While recording the value of LE, the total amount of load on each span is also recorded. In each simulated hour, the maximum LE is reserved for further analysis, regarded as the largest block (or "block maximum"). Of course, congestion doesn't happen immediately at the beginning of the simulation but takes time to build up on the virtual road. Hence the LEs for the first hour of the simulation are discarded. Following extreme value theory (Castillo, 2012), the generalised extreme value (GEV) distribution is used to fit the block maximum data of LE.

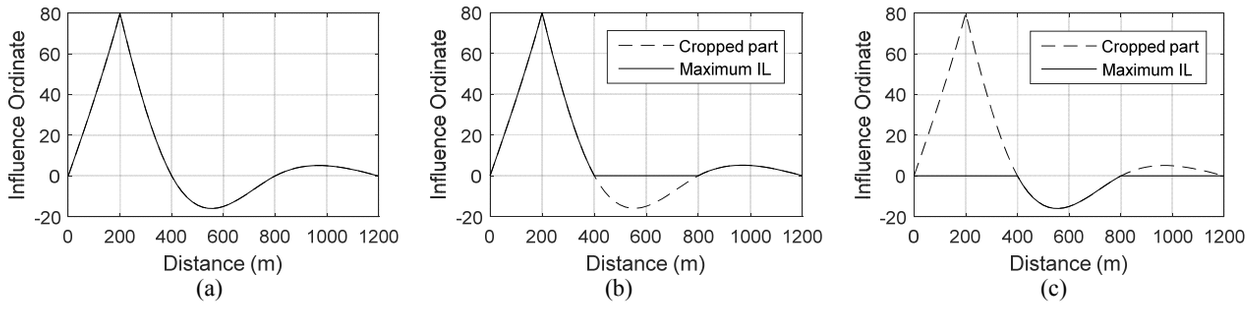

Figure 3. Influence lines of a generic 1200 m bridge for traffic patterning: (a) complete; (b) maximum and (c) minimum

3.3 *Study 1: The relationships between bottleneck and time headway (natural traffic).*

OBrien et al. (2015) and Caprani et al. (2016) respectively consider single and multi-lane LEs caused by different forms of traffic. However, the ILs used in these works are insensitive to load patterning. In fact, little work has been done in the literature to analyse the impact of different forms of traffic congestion on ILs with multiple lobes: those ILs with alternating positive and negative regions that are sensitive to load patterning. To solve this problem, a series of congestion types are generated by the layout settings in Figure 4 with the considered generic bridge and the hypothetical IL. Figure 5 shows the relationship between the locally-modified safe time headway parameter and resulting bottleneck strength which serves as a proxy for the type of congestion, based on the above layout. The results are close to those found in the previous papers (Treiber et al., 2000, Caprani et al., 2012, OBrien et al., 2015, Caprani et al., 2016).

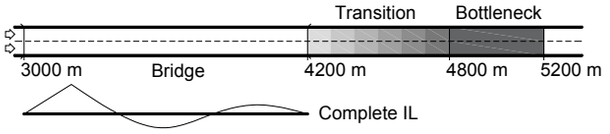

Figure 4. The simulation layout for Study 1.

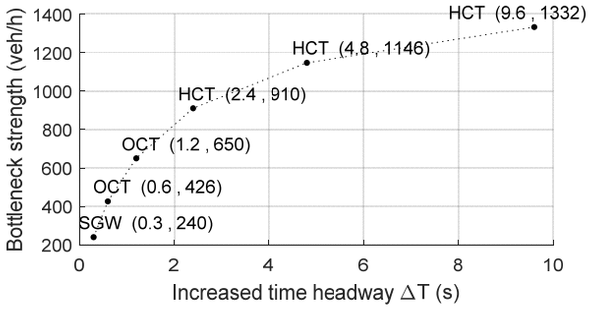

Figure 5. Congestion types and the relationship between time headway ΔT and bottleneck strength ΔQ. The number in the bracket is the coordinate of each dot point.

For each bottleneck strength considered, the maximum and minimum LE are extrapolated using the extreme values described previously. The results are shown in Figure 6. It can be expected that for the maximum LE, the free flow traffic is the least onerous form of traffic, and congestion traffic types give higher LE. However, there is a "saddle" in the graph. The light bottleneck ΔQ = 240 veh/h and strong bottleneck ΔQ = 1332 veh/h both trigger high LEs. These correspond to SGW and HCT congestion respectively. The fact that stop-and-go-wave traffic gives high LEs indicates that the natural 'pressure waves' in traffic do cause onerous LEs for patterning-sensitive ILs. Furthermore, the LE caused by second strongest bottleneck ΔQ = 1146 veh/h is similar to that of the strongest bottleneck ΔQ = 1332 veh/h, but the simulation time is much shorter. Moreover, vehicles in the bottleneck ΔQ = 1332 veh/h are only run at 3 km/h, which is unrealistic. Consequently, the bottleneck of ΔQ = 1146 veh/h is chosen for further study.

Figure 6 shows that for the minimum LE, the SGW bottleneck ΔQ = 240 veh/h produces minimum values. This further proves that the natural variation of traffic is important to pattern sensitive ILs. The critical bottleneck of ΔQ = 240 veh/h is used.

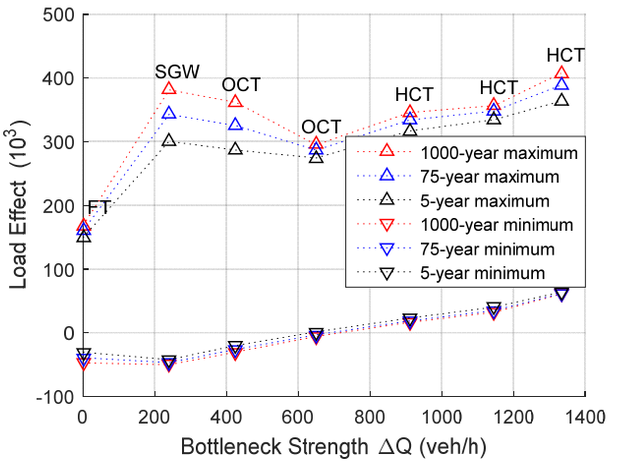

Figure 6. The relationship between middle bottleneck strength ΔQ and extrapolated LE in Study 1.

A useful visual representation of the traffic state is a spatio-temporal space mean speed (ST-SMS) plot (Treiber and Kesting, 2013). For the two critical types of traffic identified above, ΔQ = 240 veh/h and 1146 veh/h, ST-SMS plots are shown in Figure 7.

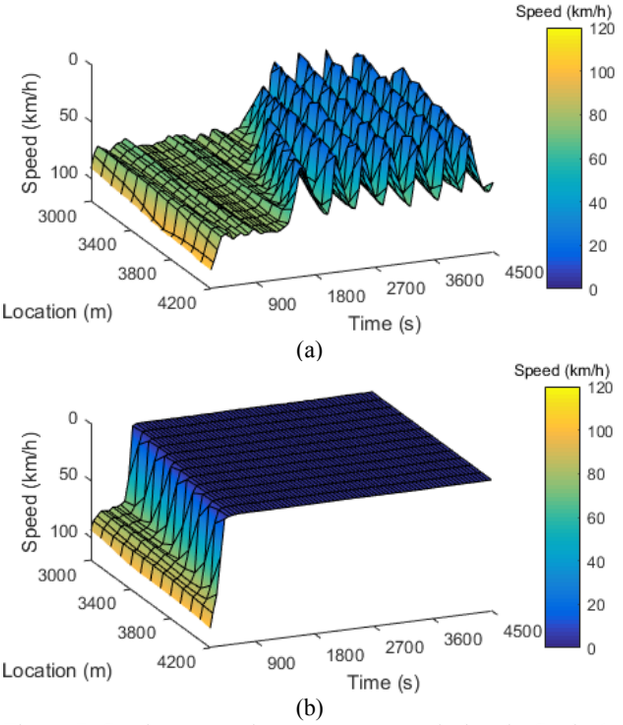

Figure 7. Spatio-temporal space mean speed plots in Study 1. (a) is ΔQ = 240 veh/h and (b) is ΔQ = 1146 veh/h traffic.

The difference in behaviour of the SGW and HCT forms of congestion is clear, and it is also clear that the pressure waves of the SGW are responsible for the high negative (minimum) LE observed. Of course, these findings are intuitively obvious, but the methods employed here allow them to be quantified, and allow further analysis of the less intuitive results.

3.4 *Study 2: Comparison between the real LE and load patterned LE (patterned traffic).*

In this study, the implications of typical code requirements to pattern live load are examined. The layout is shown in Figure 8. For the traffic stream simulated, as described earlier, this is effected by cropping the ILs. From the results of Study 1, the bottleneck strengths ΔQ = 1146 veh/h is used to cause HCT traffic in Study 2, which generates the maximum loading on the adverse or beneficial parts, leading to the maximum and minimum LEs.

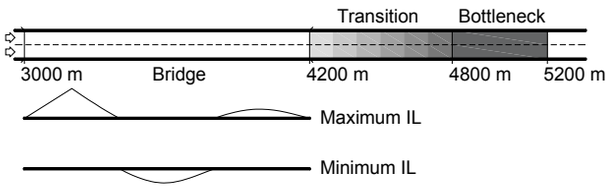

Figure 8. The simulation layout for Study 2.

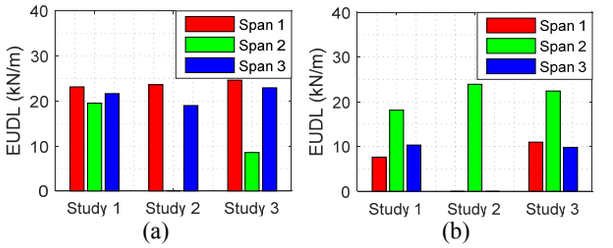

Figure 9. 1000-year extrapolated EUDL arrangement of a generic 1200 m bridge. (a) for maximum load effect and (b) for minimum load effect.

The results are expressed as a ratio to those of Study 1, for the bottleneck considered, and given in Table 2. The coincident total loads on each span are also extrapolated and converted to an equivalent uniformly distributed load (EUDL), and these are shown in Figure 9. For the maximum LE of 1000 years, the patterned traffic is 24.2% higher than that of the actual flow. The reason for this is evident from the EUDLs in Figure 9: Because the congestion traffic states of the characteristic LEs are the same (A small amount of variation is caused by extrapolation), the difference of 24.2% arises from the beneficial effect brought by the load in span 2. For the minimum LE of 1000 years, the difference becomes quite considerable at 124.4% of the LE for real traffic. Two aspects are different for this case: the critical traffic is stop-and-go waves (ΔQ = 240 veh/h), and the ratio of the beneficial and adverse areas of the IL is different.

In general, the conservatism in load modelling is significant, at least for this bridge and for IL.

Table 2. Load effects of a generic 1200 m bridge, expressed as a ratio of the 1000-year actual traffic results in Study 1.

Load effect	T_R*	Study 1	Study 2	Study 3
Maximum	5	93.8%	114.3%	107.2%
	75	97.6%	120.1%	113.0%
	1000	100.0%	124.2%	117.2%
Minimum	5	84.1%	205.6%	130.7%
	75	93.5%	216.7%	141.3%
	1000	100.0%	224.4%	148.0%

*T_R is the return period (years).

3.5 *Study 3: Cause of the critical case load patterning (manually controlled traffic)*

In this study, we examine the possibility that the traffic is actually modelled in a code-implied manner. To do this, we assume that two traffic accidents occur simultaneously at the critical positions of the IL, leading to the worst case maximum and minimum LE values. Figure 10 shows the hypothesized road layout for the worst-case scenario in maximum and minimum. The road topology is rather unrealistic, but in this study, we are only concerned about whether the patterned traffic is at all possible.

The additional bottleneck (No. 2) on the bridge is found to interact with the first bottleneck, limiting the throughput of vehicles in total. Therefore, several trial bottleneck strengths for the additional region are conducted. Again, the purpose is to have the minimum traffic density in the beneficial part of IL, while making the unfavourable part of the maximum density. But if the bottleneck is too small, there will be too many vehicles in the middle span (the two bottlenecks merge into one bottleneck). If it's too large, full congestion on the Span 3 will take longer to occur. In short, there is a trade-off between the vehicle density and congestion formation time. The results indicate that an empirical bottleneck strength of ΔQ = 1073 veh/h at the second incident location is suitable.

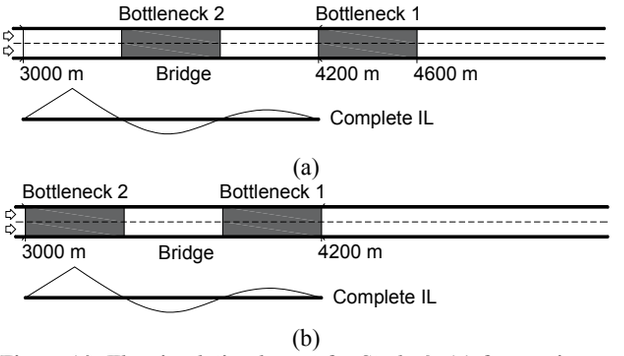

Figure 10. The simulation layout for Study 3. (a) for maximum load effect, and; (b) for minimum load effect.

In general, spatio-temporal density (ST-Density) plots show the vehicle numbers on the road sections. Figuratively speaking, the code-implied ST-Density plot would have a maximum density on the adverse regions and zero traffic density on the beneficial regions (Figure 11). This is considered as the target load patterned traffic densities. Corresponding to the target ST-Density plot, Figure 12 shows the actual ST-Density obtained in the simulation when road layout is simulated in Figure 10a. It can be seen that the road layout produces quite a similar result to the target, with a large number of the vehicles occupying the unfavourable parts. However, there are two points to note: (a) Because the vehicles can travel at high speed, the lowest density in the beneficial region occurs as traffic builds up at the second incident; (b) once the second incident has caused a high-density backlog of vehicles, a non-zero density of vehicles exists in the beneficial portion of the IL. Interestingly, for this optimised bottleneck setup (ΔQ_1 = 1073 veh/h and ΔQ_2 = 1146 veh/h), the beneficial region has a mean speed around 80 veh/km, which is near that of free-flow traffic. The result for the minimum follows the same logic and is listed in Table 2.

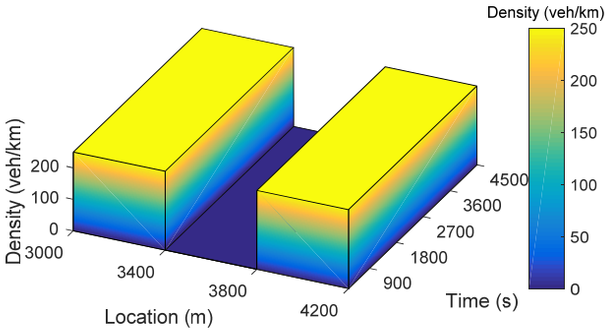

Figure 11. Spatio-temporal density plot for the target load pattern.

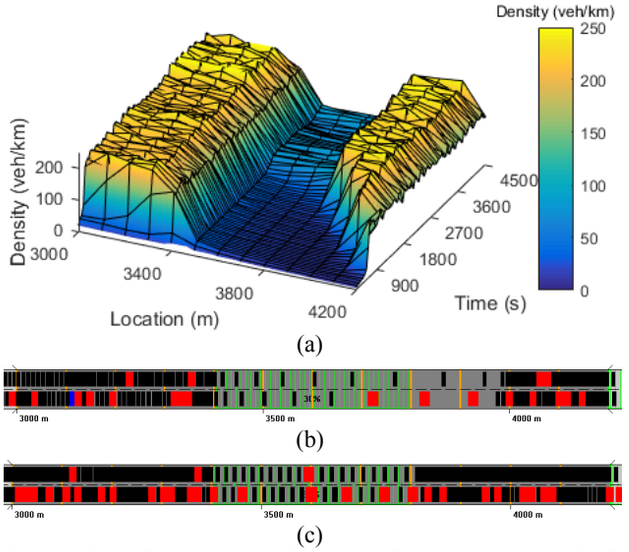

Figure 12. (a) Spatio-temporal density plot with maximum load effect. (b) is the traffic flow at time 1000 s in (a). (c) is the traffic flow at time 3000 s in (a). Note that the black boxes are cars and red boxes are trucks in SIMBA program.

This study suggests that it is possible to approach code-implied traffic patterning. However, multiple aspects must converge to make this possible: incidents must occur at the right place, and at a very specific set of inter-related bottleneck strengths. For normal traffic situations, the joint probability of these events is negligible. Finally, and importantly, in spite of the worst-case scenario approach, the results also show that it is impossible to have no traffic load on the beneficial parts of the IL. Obviously, a more rational approach to load patterning is needed.

4 RECOMMENDATION & CONCLUSION

Current codes and standards use a conservative load patterning approach to determine the design or assessment live load arrangement on the bridge. It only considers the worst-case scenario theoretically but ignores the probabilities of occurrence. The previously considered worst-case scenario is fully congested traffic (or HCT), however, SGW sometimes can be critical.

In this paper, a generic bridge is analysed with traffic microsimulation. It also considers a critical road topology with LE estimation. Three studies have shown that the traditional method is conservative: the LE is up to 1.24 times higher than that of any possible real traffic. It is also shown that it is impossible for traffic streams to pattern as per codes. A new load patterning method is needed for improved design and assessment of long-span bridges.

Traffic and wind simulation for extreme loads on long-span bridges

A.A. Hayrapetova & A.J. O'Connor

ABSTRACT: Long span bridges are repeatedly subjected to the simultaneous presence of multiple vehicles and predominantly vulnerable to wind induced effects. This paper presents an advanced traffic-wind modelling approach that extends and improves the load prediction capabilities within both the above mentioned load categories dependent on the given site-specific traffic and wind conditions. The traffic load on a bridge is modelled using a random mixing process for trucks and cars in each lane, where each vehicle is modelled individually with driver behavior parameters assigned randomly. The wind load on a bridge is divided into erratic components the modelling of which is based on the spectral tensor method. A general framework for analyzing for the combined effect of extreme traffic and associated wind loading in ultimate limit state analysis is developed and studied for a cable-stayed bridge.

1 INTRODUCTION

The design of long span structures such as cable-stayed and suspension bridges are subjected to many uncertainties due to stochastic wind actions and traffic mix/growth factors, detailed consideration of which are outside the scope of the current codes of practice. The European code for bridge design (Eurocode 1, EN 1991) provides a set of comprehensive methods for traffic and wind load representation on bridges having length and height not exceeding 200m. Based on the calculation of the most severe characteristic load effects, the Eurocode simplified load models may lead to conservative results for the longer structures. However, more accurate assessment loading can result in the retention of existing bridges for longer lives and opens up the prospect of designing longer spans.

The method proposed in this paper aims to contribute to the development of the lifetime performance evaluation of long span bridges through the application of accurate load modelling, such as traffic micro-simulation considered with instantaneous simulation of wind components. In the micro-simulation approach, traffic on a bridge is presented as a multi-vehicle system where each vehicle has its own set of geometrical characteristics and driver-behavioural preferences. The wind modelling is based on the spectral tensor representation method (Mann 1998) which leads to a more natural and more direct representation of the three-dimensional wind turbulent velocity field. Combined simulation stochastically and dynamically models discrete vehicle movements and wind fluctuations as a function of time and space within a system of a road-bridge network.

In the interaction mechanism between traffic and wind actions, there are local changes in aerodynamic forces due to the traffic presence on the bridge, which changes the shape of the structure exposed to wind. This effect increases when the dimension ratios between the traffic and bridge increase, e.g., when the traffic is congested.

The present study addresses extreme loading arising only from the governing traffic conditions and associated wind.

2 SIMULATION OF TRAFFIC LOADS AND THEIR EFFECTS

The "micro-simulation on parallel computers" software package Paramics (www.sias.ie) was selected as a traffic simulator in this study. It includes an advanced microscopic car-following model and inclusion of intelligent traffic system, which governs the movement of individual vehicles on the road network. Each vehicle is moved through the network according to its physical characteristics (i.e. vehicle size), the fundamental rules of motion (i.e.

time/velocity/distance) and rules of driver behavior (i.e. car-following rules and lane-changing). The driver behavior is controlled by a set of parameters combining driver constrains (e.g. driver's desired speed, awareness and aggressiveness, road speed limit, incident) and limitations based on vehicle type and kinematics (maximum speed and acceleration/deceleration capability). The mathematical model of the movement of driver-vehicle units in the system is based on the psycho-physical theory (Weidemann 1974, Fritzche 1994).

2.1 *Traffic analytical representation*

2.1.1 *Description of traffic regimes*

The simulations were performed for three distinct traffic regimes incorporating the vehicle velocity and density (Kerner, 2004):

1) $\rho_t^1 > 60$ *vehicle/km/lane,* $v_t^2 \leq 10$*km/hr*: Congested traffic flow where the average speed and the flow rate are nearly synchronised in different road lanes and remain 'stationary' during a relatively long time interval;
2) $20 < \rho_t \leq 60$ *vehicle/km/lane,* $10\text{km/hr} < v_t \leq 50\text{km/hr}$: Transition traffic flow of medium density where there is a difference in vehicle speeds across different lanes on a multi-lane road;
3) $0 < \rho_t \leq 20$ *vehicle/km/lane,* $v_t > 50$*km/hr*: Free-flowing where due to low traffic density lane changes are uninhibited and vehicles are fully free to change lane and to pass.

2.1.2 *Simulation of macro-components of traffic*

In the simulation, time is divided into a sequence of ½ second steps. For every iteration or time-step, three fundamental processes are carried out: (1) release vehicle, (2) set speed and (3) move forward. The vehicle release algorithm uses a number generated from a negative binomial distribution given by $P(n) = q(1\text{-}q)^{n-1}$ where $P(n)$ is the probability of $T_R = n$ and q is the probability of a vehicle being released in any one second. The general principle used within the speed-setting algorithm is that a number of constrains such as the target speed of the driver-vehicle unit, the speed of the vehicle in front, the car following model etc. are defined and an acceleration value is calculated for each constraint. The lowest of all the acceleration values, which may be negative, i.e., a deceleration, is then applied to the current speed to determine the speed of the vehicle in the next time-step. At each time step (Δt) in the simulation, each driver-vehicle unit is moved forward along its road a distance $d_t = v_t \Delta t$, where v_t is the current speed of the vehicle.

2.1.3 *Simulation of micro-components of traffic*

Driver behavior. A driver-vehicle (referred as to a Driver-Vehicle Unit (*DVU*)) response to its environment is described in the model by two parameters, driver's target headway (*h)* and reaction time *(r)*. The target headway is the bumper-to-bumper time gap that drivers try to achieve when following other vehicles in traffic. The reaction time is the lag in time between a change of speed of the preceding vehicle and the following vehicle's reaction to that change. In order to maintain safe operation, the drivers' headway needs to be at least as great as their reaction time.

Driver behaviour in the model is performed to reproduce micro- features of traffic under aggressive, rational and conservative patterns of driver behaviour. High aggressiveness would cause drivers to adopt lesser headways when following each other in the same lane or changing to a target lane. To determine the behaviour type the driver belongs to, a probabilistic model that is based on target headway *(h)* and reaction time *(r)* is used. The distribution, mean value and the coefficient of variation (COV) of the input values for the variables (*h)* and (*r)* are assumed according to inter-vehicle gap and reaction time in seconds, which are typical for drivers' behaviour in the real world and were determined using empirical observation data from earlier studies (Paramics 2002). Thus, for an "aggressive" pattern of behaviour, the mean values of h = 0.6sec and r = 0.4sec, which lead to dangerous driver behaviour in jams, are used. h = 1sec and r = 1sec in moderately dense traffic are dominant and assumed as "rational" behaviour. Finally, h = 2sec and r = 2sec are identified with safety conscious drivers, i.e., "conservative" pattern of behaviour. Heterogeneity across drivers is captured through the (*h)* and (*r)* variables sampled from the Normal statistical distribution that is not skewed to a particular direction of more aggressive or more conservative driver behaviour. Demonstrative scenarios are defined in Table 1 to cover the distinctive load combinations of the stochastic traffic.

Lane changing and overtaking. Variables *(h)* and *(r)* drawn from a statistical distribution and randomly allocated to the vehicles affect propensity to change lane. Lane changing in the model is done using gap-acceptance and gap availability policy. Considering traffic in both the current and the target lane (Figure 1): for a DVU_0 moving at a constant speed, a gap must exist both in front (lead) and behind (lag) the position it would occupy that is at least as large

[1] ρ_t – traffic flow density
[2] v_t – traffic flow average speed

as the target headway for that DVU_0. If there is a speed difference between the two lanes, this expression is extended to take into account the time it would take for the DVU_0 to attain the speed of the DVU_1 it would follow in the target lane. A vehicle will adjust its acceleration to find an acceptable gap. At all times the target range of lanes is adjusted subject to the behaviour parameters associated with the *DVU*: more aggressive drivers accept a smaller gap to force their way in. If no such gap is found, a vehicle will remain in its lane. Vehicles in the target lane DVU_2 may reduce to allow a 'courtesy let in'.

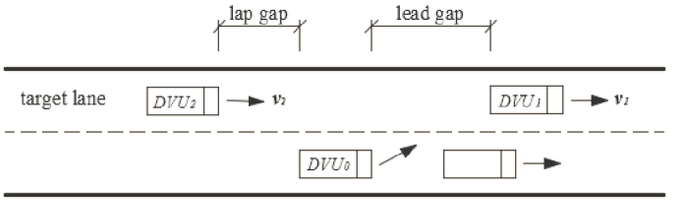

Figure 1. Gap acceptance model.

Table 1. Statistic of random driver behaviour variables.

Traffic regime	Driver behaviour	Statistical distribution	Target headway, *h (sec)*		Reaction Time, *r (sec)*	
			Mean	COV	Mean	COV
congested	aggressive	Normal	0.6	0.2 – 0.3	0.4	0.1 – 0.2
transition	rational	Normal	1.0	0.5 - 1.0	1.0	0.5 - 1.0
free-flowing	conservative	Normal	2.0	1.0 - 2.0	2.0	1.0 - 2.0

2.2 *Traffic load modelling*

The methodology used to derive traffic load models for long span bridges combines traffic microsimulation with bridge finite element analysis. Vehicle weights measured, e.g. from a Weigh-in-Motion station, are used to add statistically representative weights. For each vehicle type the measured histogram of gross vehicle weight is fitted to a bimodal Gaussian statistical distribution (O'Connor et al. 2001). Monte Carlo simulation is then used to generate weight data appropriate to the histogram.

The dynamic effect is modeled by multiplying each simulated static load from the vehicle by a normally generated random factor ϕ_{dyn} determined as (DRD 2004, O'Connor & Enevoldsen 2009):

$$\phi_{dyn} = [1 + N(41.5/W_{veh}\,; 41.5/W_{veh}\,)] \quad (1)$$

where W_{veh} (kN) = total vehicle weight.

In conditional passage of traffic at speeds v_t below 10km/h the dynamic supplement is negligible. Therefore, the following rules were adopted:

$$if\ v_t \le 10,\ \phi_{dyn} = 1$$
$$if\ v_t > 10, 1 < \phi_{dyn} \le 2 \quad (2)$$

2.3 *Model uncertainties*

The factors involved in the assessment of the traffic loads contain uncertainties. The distribution, mean and COV of the model uncertainties for vehicle loads can be introduced into the simulation as suggested in Table 2 (DRD, 2004).

Table 2. Statistical characterization of model uncertainty related to the traffic loads.

Traffic Regime	Distribution	Mean	COV
congested	Normal	1.0	0.2
transition	Normal	1.0	0.15
free-flowing	Normal	1.0	0.1

3 SIMULATION OF WIND LOADS AND THEIR EFFECTS

The wind field model for atmospheric surface layer turbulence developed by Mann was selected as a wind simulator in this study (Mann 1998). The basis of Mann's model is an application of rapid distortion theory implying a linearization of the Navier-Stokes equation, combined with the modelling of eddy lifetimes. The method is based on a model of the spectral tensor for atmospheric surface-layer turbulence at high wind speeds and can simulate three-dimensional fields of wind velocity fluctuations.

The tensor model has been successfully checked and calibrated with data from different atmospheric experiments which have been carried out with the purpose of estimating wind loads on large suspension bridges and wind turbines (Mann 1994).

3.1 *Wind analytical representation*

In the analysis of the wind characteristics, the wind field velocities over horizontal terrain is decomposed into the components of random processes consisting of (1) a constant mean wind speed V_m in the mean wind direction and (2) zero-mean turbulent $u_{x,y,z}(t)$ – along-wind, $v_{x,y,z}(t)$ – across-wind horizontal and $w_{x,y,z}(t)$ – across-wind vertical components fluctuating in space and time. Hence, the wind speed in the mean direction can be assumed as (ESDU 2001):

$$V_{x,y,z}(t) = [V_m + u_{x,y,z}(t), v_{x,y,z}(t), w_{x,y,z}(t)] \quad (3)$$

where V_m depends on the height variation of the wind and can be estimated over a selected time duration T of ten minutes or one hour averages of the basic wind speed irrespective of wind direction and time of year.

3.1.1 *Modelling of mean wind speed*

The long-term mean wind speed can be determined from a database of values recorded at or near the bridge site. The probability distribution function which normally fits the wind data satisfactorily is given by a Weibull PDF (e.g. Tuller & Brett 1984, Edwards & Hurst 2001) expressed as:

$$P(V_m) = 1 - exp[-{}^1\!/_2\,(V_m/\alpha)^k] \quad (5)$$

where k and α are shape and scale parameters, respectively.

The extreme mean wind speed to be used when the wind load effect is dominant is often assumed to follow a Gumbel distribution for the maxima (e.g. Gross et al. 1994, Carta et al. 2009). In an ultimate limit state analysis the extreme loading to be assessed may result from actions including extreme mean wind speeds with a recurrence period of 50 years and extreme wind speed gusts (EN 1991-1-4:2004).

The variation of the mean wind velocity with height over terrain of homogeneous roughness is assumed to be described by the logarithmic profile law (EN 1991-1-4:2004):

$$V_m(z) = k_r(z/z0)v_b, \quad z_{min} \le z \le z_{max} \quad (6)$$

where $k_r = 0.19(z_0/z_{0II})^{0.07}$ = terrain roughness factor depending on the roughness length z_0; z_{0II} = 0.05m for terrain category II; z_{min} = minimum height defined in Table 4.1 of EN 1991-2:2003; z_{max} = 200m; v_b = basic wind velocity.

3.1.2 *Modelling of wind velocity turbulence*

The stochastic field of wind velocity turbulence can be represented in terms of a discrete Fourier series (Mann 1998):

$$u_i(\boldsymbol{x}) = \sum_{\boldsymbol{\kappa}} e^{-i\boldsymbol{\kappa x}}\, C_{ij}(\boldsymbol{\kappa}) n_j(\boldsymbol{\kappa}) \quad (7)$$

where $u_i = i_{th}$ component of the turbulent velocity; $\boldsymbol{x} = (x, y, z)$ vector of spatial coordinates; $\sum_{\boldsymbol{\kappa}}$ = sum over all $\boldsymbol{\kappa}$ = three-dimensional wave vector with components $\kappa_i = m2\pi/L_i$, integer $m = -N_i/2, \ldots, N_i/2$ and L_i = length of the simulated wind field in the i direction; $n_j(\boldsymbol{\kappa})$ = independent Gaussian stochastic complex variables with unit variance; and $C_{ij}(\boldsymbol{\kappa})$ = coefficient matrix (Equation 8).

$$C_{ij}(\boldsymbol{\kappa}) = \frac{(2\pi)^{3/2}}{V(B)^{1/2}} A_{ij}(\boldsymbol{\kappa}) = (\Delta\kappa_1 \Delta\kappa_2 \Delta\kappa_3)^{1/2} A_{ij}(\boldsymbol{\kappa}) \quad (8)$$

where $\Delta\kappa_i = 2\pi/L_i$; $A_{ij} = \sqrt{\Phi_{ij}}$ with Φ_{ij} = spectral velocity tensor (Equation 9).

$$\Phi_{ij}(\boldsymbol{\kappa}) = \frac{\langle dZ_i^*(\boldsymbol{\kappa}) dZ_j(\boldsymbol{\kappa})\rangle}{d\kappa_1 d\kappa_2 d\kappa_3} \quad (9)$$

The corresponding cross-spectra and coherence functions are defined as:

$$\chi_{ij}(\kappa_1, \Delta y, \Delta z) = \iint_{-\infty}^{\infty} \Phi_{ij}(\kappa) e^{-i(\kappa_2 \Delta y + \kappa_3 \Delta y)} d\kappa_2 d\kappa_3 \quad (10)$$

$$coh_{ij}(\kappa_1, \Delta y, \Delta x) = \frac{|\chi_{ij}(\kappa_1, \Delta y, \Delta z)|^2}{F_i(\kappa_1) F_j(\kappa_1)} \quad (11)$$

The implementation of the Mann's model includes the following three steps:

(1) evaluation of the coefficient $C_{ij}(\kappa)$ by Equation 8;
(2) simulation of the Gaussian variable $n_j(\kappa)$;
(3) calculation of $u_i(x)$ from Equation 7 by Fast Fourier transform.

3.2 *Wind load modelling*

To apply the simulated wind velocities to the bridge model, they first have to be transformed into force components. The general expression of wind forces per unit length can be given by the following formulas (EN 1991-1-4:2004):

$$\begin{aligned} F_x(t) &= {}^1\!/_2\, \rho\, V_x(t)^2\, C_x\, (c_s c_d)_x\, d_{tot}\, L\, J_w \\ F_z(t) &= {}^1\!/_2\, \rho\, V_z(t)^2\, C_z\, (c_s c_d)_z\, b\, L\, J_w \\ M_y(t) &= {}^1\!/_2\, \rho\, V_y(t)^2\, C_y\, (c_s c_d)_y\, b^2\, L\, J_w \end{aligned} \quad (12)$$

where ρ = air mass density; $V(t)$ = wind instantaneous velocity, Equation 3; C = wind load factor; $c_s c_d$ = structural factor; L = length; d_{tot} = reference depth; b = width, J_w = factor taking into account the model uncertainties (see Section 3.3).

For a bridge structure the parameter which varies during the service life with and without traffic, is the reference depth d_{tot} (Figure 2) of exposure on wind action transversely to the deck (EN 1991-1-4:2004):

$$\begin{aligned} d_{tot} &= d + d_1 \quad && without\ traffic \\ d_{tot} &= d + d^* && with\ traffic \end{aligned} \quad (13)$$

where d = bridge depth; d_1 = parapet/barrier depth; d^* = 2m and 4m from the level of the carriageway, independently of the location of the vertical traffic loads on road and railway bridges, respectively.

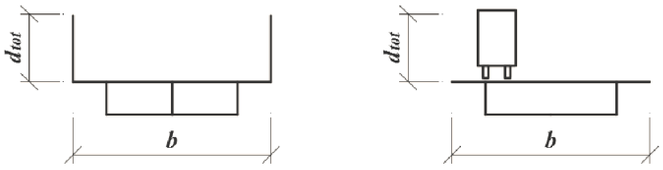

Figure 2. Reference depth.

The methodology used in this study to derive the wind pressure effects of passing vehicles is combined with the traffic micro-simulation model described in Section 2. For this reason, the traffic streams from the 'snapshot' files generated during the micro-simulation are used to calculate d_{tot} for each specified time step interval.

3.3 *Model uncertainties*

The wind model uncertainty J_w (Equation 12) includes the uncertainty of the parameters describing the model scale disagreement (model-size/full-size) and the wind climate. The distribution, mean and COV of the wind forces can be expressed as suggested in Table 3 (SAKO 1999).

Table 3. Statistic of random variables involved in the assessment of the wind loading.

Variable	Distribution	Mean	COV
model scale uncertainty	Lognormal	1.0	0.1
wind climate uncertainty	Lognormal	1.0	0.1

4 ANALYSIS FLOWCHART

The methodology developed in this paper combines three computer-aided techniques: traffic micro-simulation, Mann's model of wind simulation and bridge finite element (FE) analysis. In the first two steps, micro-simulation is used to predict multi-lane traffic and multi-component wind actions on the bridge. In the third step, FE structural analysis is used to compute the response of the bridge structure under the traffic and wind loads predicted in the first two steps. A communication interface program (CIP) is developed to link the three techniques with supplementary features and to compile the input and output data. The application of the theory outlined above is illustrated in the following sections.

5 NUMERICAL EXAMPLE

5.1 *Definition of long span cable-stayed bridge*

The bridge considered in this study is a cable-stayed concrete box girder with spans arrangement of 69.3m-130m-204m-204m-130-70m (Figure 3). It supports the cables by means of three concrete U-shape towers. There are 9 pairs of stay cables on either side of the tower with angle varying from 95 to 115 degrees. The deck of the bridge is 15.9m wide, with a single cell prestressed concrete box at constant depth of 3.5m. The bridge model considered for the analysis of the structure uses 3D frame FE with linear material and geometrical properties.

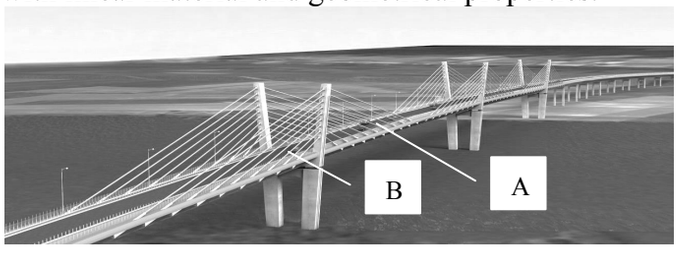

Figure 3. Bridge computer model visualization in isometric view: A – section at mid-span, B – section at support.

5.2 *Traffic load time-series simulation*

The road network has been modelled as a linear corridor adjacent to the bridge of length L = 809m with the approaching roadway at each end of the bridge equal to 5km. It was constructed with details of lanes, types and mix of vehicles and their characteristics.

Three regimes of traffic with assigned driver preferences defined in Section 2, Table 1, were artificially generated from the Auxerre traffic data (A6 motorway, France) on three lanes assuming 10% trucks for each lane. This condition is based on the philosophy of the Eurocode load model development and is by 1-step more severe than the condition measured in Auxerre (O'Connor et al. 2001, Sedlacek 2008).

The input traffic data assigned to scenarios are summarized in Tables 4 and 5. Clearly, the 'behaviour' of traffic at any particular instant is determined by the various conditions prevailing at that instant and these conditions are constantly changing. It is desirable therefore to relate traffic response to the periodic traffic flow without major changes in flow rate within the period. For that reason, the daily traffic volume was subdivided into 12 time periods of 2 hours duration.

Periodic simulation runs of the representative traffic of 1-year duration were executed for the selected bridge. Traffic load streams were obtained from the 'snapshot' files at 1-second intervals. Simulated patterns with the assigned vehicle weights, Table 5, were applied to the bridge model and its responses calculated, Figure 4. The bridge model itself is represented through the IS for longitudinal moments at mid-span (A) and support (B) of the main girder, Figure 3.

Table 4. Input data for traffic scenarios simulation

Variable	Symbol / Unit	Value
Bridge length	L_b *(m)*	809
Road length	L_r *(m)*	5000+L_b+5000
Road speed limit	v_{max} *(km/h)*	100
Number of lanes	N_l	3
Lane width	W_l *(m)*	3
Vehicle configuration	-	Table 5
Weight of vehicles	W_{veh} *(kN)*	Table 5
Percentage of trucks	-	10%
Target headway	*h (s)*	Table 1
Target reaction time	*r (s)*	Table 1
Vehicle desired speed	v_d* *(km/h)*	v_{d_car}=100, v_{d_truc}=75
Max acceleration rate	*a* (m/sec^2)	a_{car}=2.50, a_{truck}=1.40
Max deceleration rate	*d* (m/sec^2)	a_{car}=4.50, a_{truck}=3.70

*v_d – desired speed the driver wants to maintain after considering the road speed limit and the effect of surrounding traffic.

Table 5. Vehicle characteristics

Vehicle Type		Number of axles	Length (m)	Width (m)	Height (m)	Relative frequency (%)	Vehicle weight (kN) unloaded mean	unloaded SD	loaded mean	loaded SD
-	car	-	5.25	1.8	1.4	-	-	-	-	-
Type 1		2	7.5	2.5	4.0	10.6	70	35	190	30
Type 2		3	7.5	2.5	4.0	61.8	115	45	255	40
Type 3		5	14.5	2.5	4.0	25.2	225	60	435	75
Type 4		6	9.5	2.5	4.0	2.4	245	70	450	65

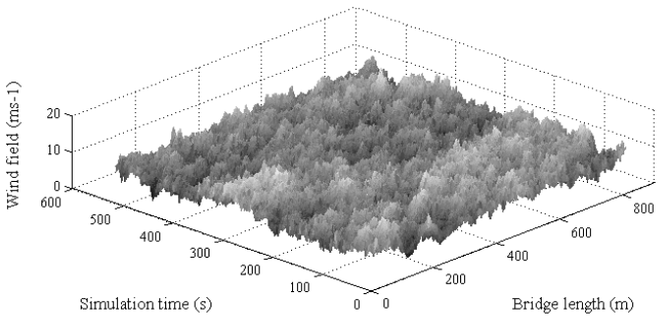

Figure 5. 10-min simulation of wind field on the main girder of the bridge in transverse direction.

5.3 *Wind load time-series simulation*

The wind climate at a given bridge site was characterised by the Weibull PDF of 10-minute wind speed averages V_m. For each value of V_m the Mann's simulator generated an estimate of the correlated along-wind *u(t)* and across-wind components *v(t)* and *w(t)* using spectral tensor function of Equation 7. Figure 5 demonstrates a 10-min simulation of along-wind field in x-direction parallel to the deck width and perpendicular to the span at positions horizontally aligned with 1m-separation.

Simulations of the random wind of 1-year duration were executed for the selected bridge. The input data assigned to the wind model are summarized in Table 6. The wind forces from the mixture of wind components, were calculated according to Equation 12 and applied to the bridge model and its responses calculated (as described in Section 4), Figure 6.

For the transverse wind pressure effects of the passing vehicles, the values of the depth d_{tot} (Equation 13) were obtained from the traffic snapshots at each time step of simulation. Figure 7 shows the distributions of d_{tot} averages for two regimes of simulated traffic compared to the corresponding Eurocode values.

Table 6. Input data assumed for wind simulation.

Parameter	Symbol / Unit / Description	Value
Mean wind speed	Weibull distribution:	
	shape factor	2
	scale factor *(m/s)*	10
Height of structure	*z (m)*	15
Terrain roughness	z_0*(m)*	0.05

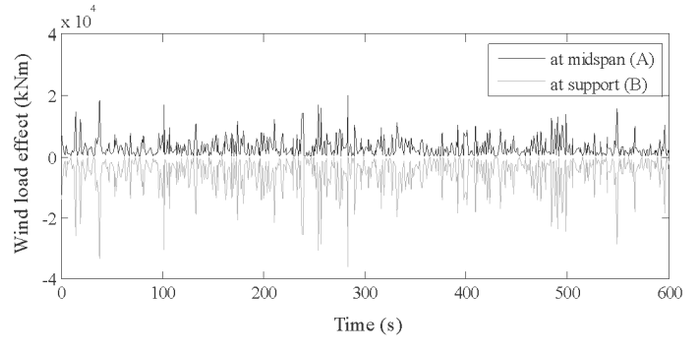

Figure 6. Transverse bending moment histories calculated from along-wind speed components in x-direction under passing congested traffic.

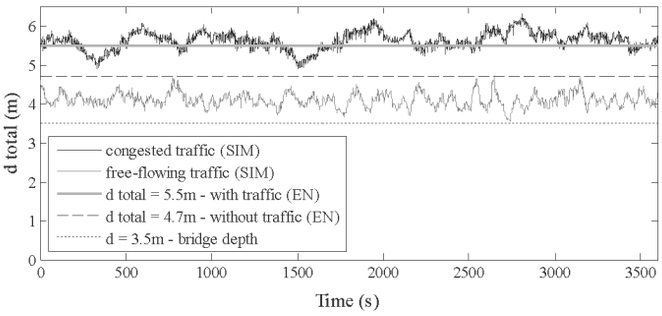

Figure 7. The distribution of the depth d_{tot} averages obtained from different regimes of traffic micro-simulations (SIM – simulated, EN – Eurocode value).

5.4 *Extreme traffic load and accompanying wind load for extreme analysis*

The statistical analysis of data in this study is based on the samples of maximum traffic load effects combined with associated wind in the vertical direction. The largest traffic and associated wind bending moments at critical locations A and B of the bridge deck were selected per hour from the parent popula-

tion of empirical traffic and wind load effects simulated for a 1-year period. Which PDF fits the data best depends on different conditions and the statistical parameters (e.g., size of random sample) are of importance. Since in the current work, the bending moment is obtained from the sum of effects generated from a large number of independent loads from the random vehicle weights, it is to be expected from the central limit theorem that the instantaneous bending moment is normally distributed. Assuming the hourly maximum of the bending moments to be Normal distribution, the extreme value *CDF* and *PDF* can be approximated as:

$$F_x(x) = F^n(x) = \Phi^n[(x-\mu)/\sigma] \quad (14)$$

$$f_x(x) = nF^{n-1}(x)f(x) \quad (15)$$

for some equivalent number n of independent Gaussian random variables in the sample, where Φ is the standardized normal distribution function and μ, σ are the mean and standard deviation, respectively, of the Gaussian random variables. With Δt time step in seconds, each of these bending moment maxima is the maximum of a sample of $3600/\Delta t$ mutually dependent Gaussian random variables. If the traffic speed is v_t, all vehicles within the length of the bridge L_b = 809m are replaced with $L_b/(v_t\Delta t)$ simulation steps. Therefore, there are at least $\frac{\lceil 3600/\Delta t \rceil}{\lceil L_b/(v_t\Delta t)\rceil} = 4v_t$ independent Gaussian variables in each set of moment maxima, which can be assumed to be distributed according to the *CDF* and *PDF,* defined by Equation 14, 15.

Figure 8 illustrates the estimated extreme value distributions (EVDs) fitted well to the data that line up approximately along a straight line. The EVDs have been used to calculate the characteristic moment due to traffic and wind, i.e. the expected value of maximum moment. This is repeated for return periods of 10 to 1000 years.

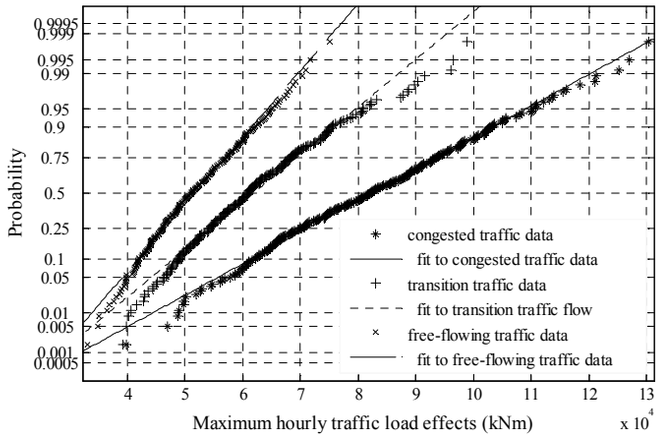

Figure 8. Mid-span moment distribution on probability plot

The extrapolated results are summarised in Table 7 where extreme traffic is combined with associated wind. The results show the peaks of longitudinal bending moments for congestion when the traffic is stationary, $v_t \leq$ 10km/h, and dynamic effect from traffic is ignored, ϕ_{dyn} = 1. The latter corresponds to platoons of trucks and cars travelling bumper-to-bumper. Clearly the lower moments for free-flowing and transition traffic result from the relatively bigger distances between the vehicles and thus simultaneously reduces the presence of loads on the bridge.

Table 7. Combined traffic and wind load effects simulated at mid-span (A) and support (B) of the bridge deck.

Traffic flow regime with associated wind	(a) Longitudinal moments (kNm)		(b) Transverse moments (kNm)	
	mid-span	support	mid-span	support
Free-flowing traffic	168527	177461	6285	-9175
Traffic in transition	200794	211630	8519	-10486
Congested traffic	230410	243993	8896	-11796
Without traffic	-	-	5983	-8738

5.5 *Comparison of results with Eurocode load models*

The simulated characteristic values are compared with the corresponding values for bending moments calculated in accordance with Eurocode 1. EN1991-2:2003 live load model 1 (LM1), consisting of concentrated and uniformly distributed loads, was used to represent the traffic load effect for general verification. The carriageway on the bridge deck was divided into notional lanes according to the formula for $w \geq 6$: $N = int(w/3)$, where w = 9m is the carriageway width. Taking three notional lanes, moments of *257640*kNm and *-296231*kNm were calculated for mid-span and support, respectively.

A simplified formula proposed in EN1991-1:2004 was used for the evaluation of the wind force:

$$F_W = {}^1/_2\ \rho\ v_b^2\ C\ A_{ref}\ C_s C_d \quad (16)$$

where ρ = density of air, v_b = basic wind speed, C = wind load factor, $CsCd$ = structural factor, $A_{ref} = bL$ and $d_{tot}L$ = vertical and transverse reference area.

In this case, the wind forces are the exact values: F_{Wvert} = *9077kN,* F_{Wtrans} = *5366kN* (without traffic), F_{Wtrans} = *6280kN* (with traffic).

The combination rules for variable actions utilised by EN1990 Annex A2 is:

$$E_d = \gamma_{QT} Q_T + \psi_{0W}\gamma_W Q_W \quad (17)$$

where Q_T and Q_W = characteristic values of the leading traffic action and accompanying wind action, respectively, γ_{QT} and γ_W = partial factors for traffic and wind accounting for model uncertainties and dimensional variations, and ψ_{0W} = wind combination

value. The methodology given in EN1990 has been further used to estimate the combined wind and traffic actions. Using the extreme value Normal distribution for time-dependent traffic and wind gives ψ_{0W} = 0.45. Although this value is lower than the value of 0.6 used in EN1990 Annex A1, it was decided to use 0.6 to achieve consistency with the EN1990.

Table 8 summarises the moments at mid-span (A) and support (B) calculated using Equation 17. Irrespective of the conservative assumptions made for the case study the difference is ≈ 25% between the Eurocode LM1 characteristic values and the corresponding simulated values. While the results will vary according to the assumptions made for site-specific situations, the outcome reflects the current code's conservatism for excessive loaded lengths.

Table 8. Comparison of characteristic values for longitudinal bending moment.

Load combination	(a) Simulated value (kNm)		(b) Eurocode value (kNm)	
	mid-span	support	mid-span	support
Traffic only	213617	-226211	257640	-296231
Traffic + wind	230410	-243993	277792	-332505

6 CONCLUSION

This paper proposes the use of advanced micro-simulation procedures in determining characteristic effects of stochastic traffic and wind loads on long-span bridges. The procedures are introduced as a tool for an extensive modelling of bridge-traffic-wind loading conditions derived from the real data when long-run simulation processes are required. The general aspects of the technique are outlined and demonstrated with reference to a specific case. Wind events in 3D turbulent fields are implemented in Mann's turbulence generator including the correlated response of all wind velocity components. Traffic events are generated using a micro-simulation approach as a multi-vehicle system where each vehicle has its own set of geometrical characteristics and driver-behavioral preferences. In the interaction mechanism between traffic and wind actions, the transverse wind pressure on the passing vehicles is obtained through the measurements of the reference depths d_{tot} of exposure from the snapshots of traffic at each time step of micro-simulation.

Developing a new bridge live load model for South Africa

P.F. van der Spuy & R. Lenner
Stellenbosch University, South Africa

ABSTRACT: South Africa's bridge design code, TMH7, was first introduced in 1981. The code was found to be unconservative for narrow and short span bridges and revisions were issued in 1988. In 1991 it was proposed to increase the axle load by 25 % to 180 kN, but the code was not amended. In 1996 the legal limits for GVW and axle loads in South Africa were increased, but TMH7 loading was not updated. One year of WIM data was used to calculate hogging and sagging moments as well as shear forces for span lengths up to 50 m. The forces and axle weights were extrapolated normally to a return period of 975.3 years. The extrapolation resulted in a characteristic axle weight of 170 kN which was applied as a double axle. The extrapolated load effects and the tandem axle were used to calculate a characteristic distributed load of 15 kPa.

1 INTRODUCTION

South Africa's bridge design code, TMH7, was first introduced in 1981 and is based on the CEB-FIP Model Code of 1978 as well as BS5400 and the National Building Code of Canada. With time it was found that the code has various deficiencies, especially for narrow and short span bridges.

Revisions to the code were issued in 1988, but Oosthuizen et al. (1991) showed that the code still underestimated bending moments for spans between 4 m and 9 m as well as shear forces on span lengths below 23 m. A proposal was made to increase the axle load in lane 1 from 144 kN to 180 kN, but this amendment was never made. In 1996 the South African Department of Transport increased the legal gross vehicle weight and axle loads on South African roads, but no study was performed to determine the impact of this on the bridge loading code. The current load model is widely regarded as cumbersome to apply and various different applications thereof exist in industry.

When deriving the code in 1978, Liebenberg noted that a probabilistic study of extreme truck events was not viable due to a lack of statistical information at the time (Anderson 2006). Since then a substantial amount of WIM data has become available in South Africa.

WIM data was used to derive an improved live load model for bridge design in South Africa. This model is both up to date and simple to apply.

2 TMH7 LOAD MODELS

2.1 *NA loading*

NA loading is considered as normal traffic loading and consists of a distributed component (Figure 1) and an axle load in each lane. A dynamic allowance is included according to the Swiss formula (CSRA 1981).

The distributed component of NA loading, Q_{dist}, is 36 kN/m for the first 36 m loaded length and then reduces according to Equation 1.

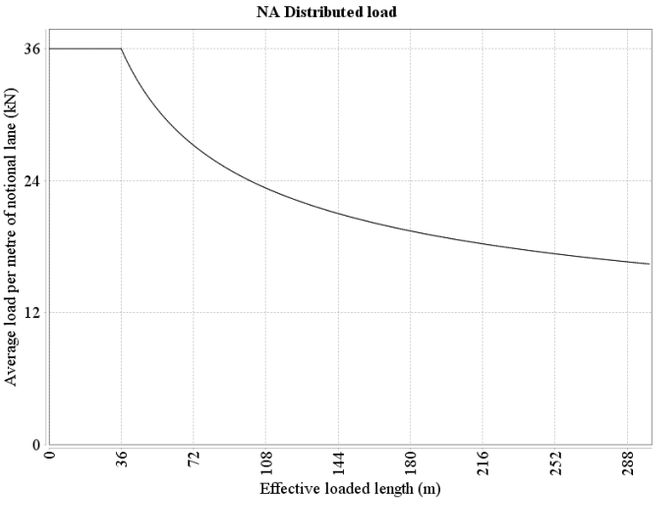

Figure 1. NA distributed load.

$$Q_{dist} = \frac{180}{\sqrt{L}} + 6 \quad (1)$$

where L = total aggregate loaded length.

The axle load component of NA loading, Q_{axle}, is given by Equation 2 in kN.

$$Q_{axle} = 144/\sqrt{n} \quad (2)$$

where n = the number of the notional lane in which the axle load occurs. The axle load therefore decreases as the number of loaded notional lanes increases.

2.2 *NB loading*

Nominal NB loading is a unit loading representing a single abnormally heavy vehicle. Thirty six units of NB loading are typically applied and referred to as NB36. This corresponds to a wheel load of 90 kN, an axle weight of 360 kN and a total weight of 1440 kN. The NB load configuration is shown in Figure 2.

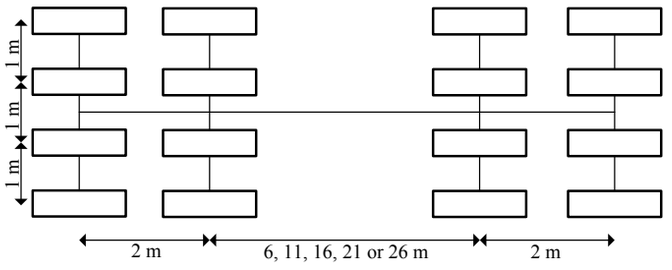

Figure 2. NB load configuration.

Only one NB vehicle is allowed on a bridge at a time without any other traffic loading acting in conjunction. No allowance is made for impact.

2.3 *NC loading*

Nominal NC loading is a loading representing multi-wheeled trailer combinations with controlled hydraulic suspension and steering intended to transport very heavy indivisible payloads. The applied loading is 30 kPa with a configuration as shown in Figure 3.

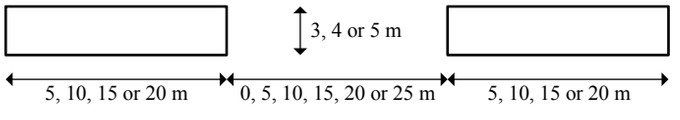

Figure 3. NC load configuration.

NC vehicles shall move along the centre line of a bridge only with an allowance of 1 m either side for moving offline. No allowance is made for impact.

3 REFERENCE TO EUROCODE

South African building and bridge design codes have historically been based on the British codes which have since been superseded by the Eurocodes (Van der Spuy 2014). Many of the building design codes in South Africa incorporate parts of the Eurocode or have adopted the Eurocode entirely. In this study the configuration of Load Model 1 of EN1991-2 (CEN 2003) was adopted as a preliminary measure, but different values were calculated for the axle and distributed loads.

4 WIM DATA

4.1 *Data source*

National Route 3 between Johannesburg and Durban is considered to be the heaviest freight route in South Africa (Lenner et al. 2017) and for this reason a station along this route was used for this study. The Roosboom WIM station has been measuring since November 2000 and the data from this station is considered to be of good quality (de Wet 2010a). One year (2016) of data was used as recommended by Sivakumar et al. (2008). This station measures traffic in the slow lanes in both directions.

4.2 *Traffic composition*

The number of vehicles in the year of data was 859 896. Figure 4 shows the distribution of vehicle types indicating that six and seven axle vehicles dominate the GVW tail.

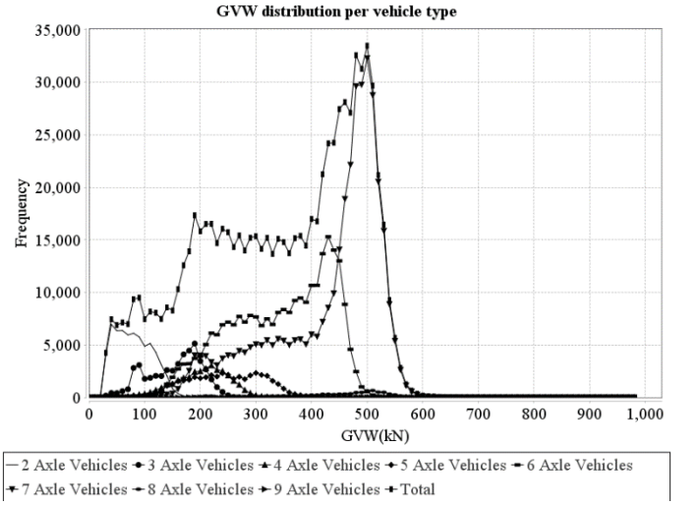

Figure 4. Vehicle type distribution.

Lenner et al. (2017) showed that, when compared to data from Auxerre measured in 1986, the South African axle loads are lower than those in Europe, but the GVW is higher. This serves as motivation not to adopt the Eurocode directly, but to calculate country specific axle and distributed loads for Load Model 1. The data from Auxerre, France, is the data that was

used to derive the Eurocode load models (Enright & OBrien 2012, Sedlacek et al. 2008, Zhou 2013, Zhou et al. 2012).

4.3 *Cleaning*

Slavik developed a technique called Golem (unpublished) to specifically address sources of WIM error for South African data. Golem rejects any vehicle that meets the following criteria:

- Travelling at less than 5 km/h or more than 150 km/h
- Truck length less than 4 m or longer than 26 m
- Fewer than two axles
- GVW less than 3.5 t
- Individual axle weight exceeding 16 t
- Axle spacing shorter than 0.53 m or longer than 10 m

Number of vehicle records removed by this screening is 33 855.

4.4 *Calibration*

De Wet (2010a,b) developed the Truck Tractor (TT) method which is a post-calibration procedure to correct the magnitude of recorded axle loads retrospectively. The application of this method results in a k-factor which is multiplied by all axle weights to suppress the systematic WIM error. The method has been accepted by the South African National Roads Agency Limited (SANRAL) and was applied in this study as a way to calibrate the data.

5 METHODOLOGY

5.1 *Span lengths investigated*

Short to medium span lengths between 5 m and 50 m were investigated based on the assumption that free flowing traffic governs for these span lengths (Caprani & OBrien 2010). Span lengths within this range cover the majority of bridges in South Africa.

5.2 *Creation of vehicle convoy*

Daily convoys of axles were created from the WIM file using axle distances as well as time stamps and speeds to determine inter-vehicle gaps. The time stamp resolution from the Roosboom station is 0.01 s which is preferable (Enright 2010).

5.3 *Calculation of load effects*

The load effects that were investigated are sagging moments and shear forces in single span structures and hogging moments in two span structures (Caprani 2005, Enright & OBrien 2012, Lenner 2014, Lenner et al. 2014). The daily convoys were passed over varying span lengths for the different load effects while recording the daily maximum values for each. The increment distance for the convoys was implemented as 0.444 m which corresponds to a time step of 0.02 s at 80 km/h.

5.4 *Return period*

A 5 % probability of exceedance in 50 years was used in this study, similar to the Eurocode (CEN 2003). This relates to a return period of 975.3 years (Enright 2010).

5.5 *Extrapolation*

With WIM data not being available for the full return period extrapolation techniques were applied. Only the upper tail of a parent distribution contributes significantly to the extrapolated value at the return period (Bailey 1996, Zhou 2013, Zhou et al. 2012) and therefore only the upper $2\sqrt{n}$ of daily maximum values were of interest for this study. To extrapolate to the return period a straight line was fitted to the upper $2\sqrt{n}$ of data points on Gaussian probability paper (Kozikowski 2009, Nowak 1993 1994, Nowak & Hong 1991). In South Africa heavy vehicles are allowed to travel on weekends and holidays and therefore for a return period of 975.3 years and 365 days per year the corresponding value on the vertical axis is 4.540. The Gaussian assumption was made in this study as it is the method that was used in the derivation of the AASHTO code (Nowak 1993) and the Eurocode (Sedlacek et al. 2008).

6 RESULTS

6.1 *Extrapolated load effects*

Daily maximum load effects were plotted on Gaussian probability paper and extrapolated to the return period. Hogging moments are shown in Figure 5, sagging moments in Figure 6 and shear forces in Figure 7. Table 1 gives a summary of the load effect values.

Table 1. Summary of extrapolated load effects.

Span length	Hogging	Sagging	Shear
m	kNm	kNm	kN
5	264	378	340
10	820	1258	528
15	1664	2234	626
20	2318	3535	740
25	2474	4865	826
30	2973	6127	888
35	3523	7451	937
40	4140	8877	975
45	5547	10331	1002
50	6864	11759	1018

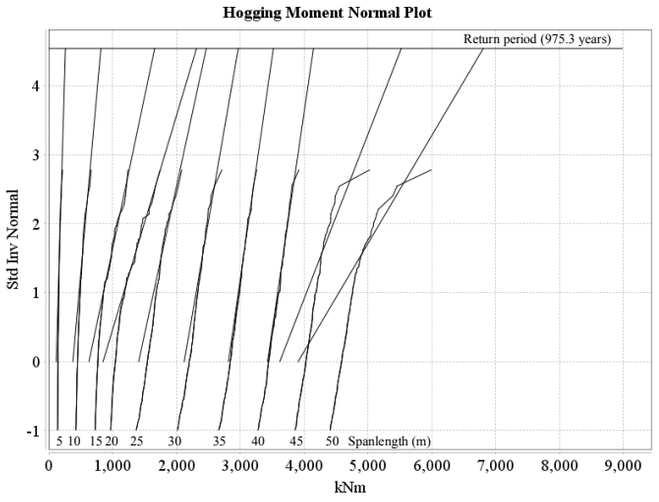

Figure 5. Extrapolated hogging moments.

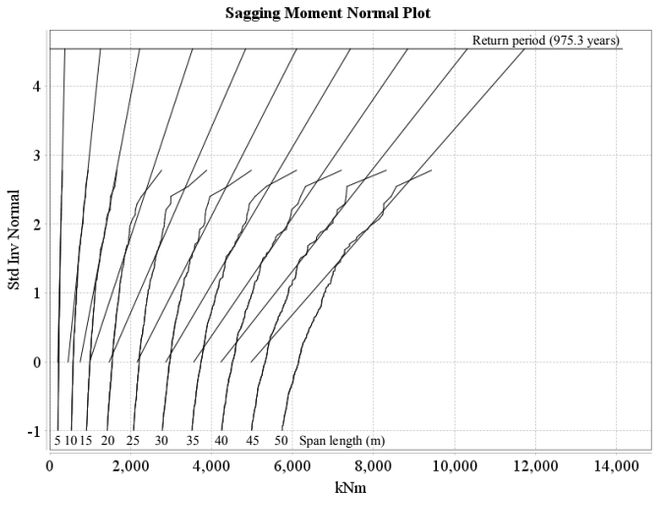

Figure 6. Extrapolated sagging moments.

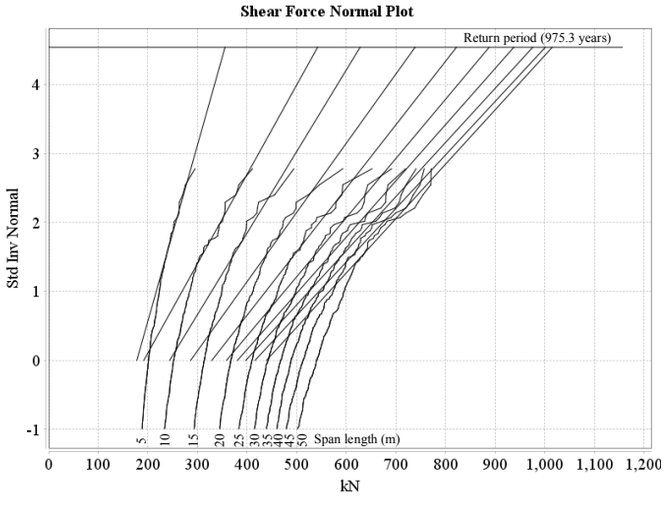

Figure 7. Extrapolated shear forces.

It is clear that for medium to longer span lengths the tails of the load effects do not strictly plot as straight lines on Gaussian probability paper. This is an indication that the Gaussian approximation to the distribution of the load effect tails should be revisited in subsequent research.

6.2 *Extrapolated axle weight*

Daily maximum axle weights were extrapolated as per Sedlacek et al. (2008) who used a half-normal distribution. Once again the upper $2\sqrt{n}$ of daily maximum values were fitted with a straight line on Gaussian probability paper. This resulted in a characteristic axle weight of 170 kN. The extrapolation of the axle weights is shown in Figure 8. From Figure 8 it can be seen that the tail of the axle weights plots as a straight line on Gaussian probability paper, indicating that axle weights closely resemble Gaussian behavior.

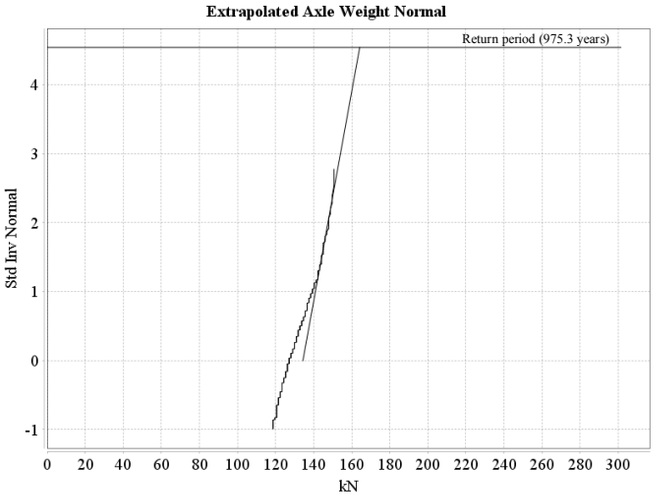

Figure 8. Extrapolated axle weights.

6.3 *Calculation of distributed loads*

The extrapolated axle weight of 170 kN was applied to the different span lengths as a double axle at 1.2 m spacing, similar to the Eurocode (CEN 2003). To reproduce the extrapolated load effects from Table 1, a distributed load was calculated which acts in conjunction with the double axle. The distributed load is shown in Figure 9 for different load effects and span lengths.

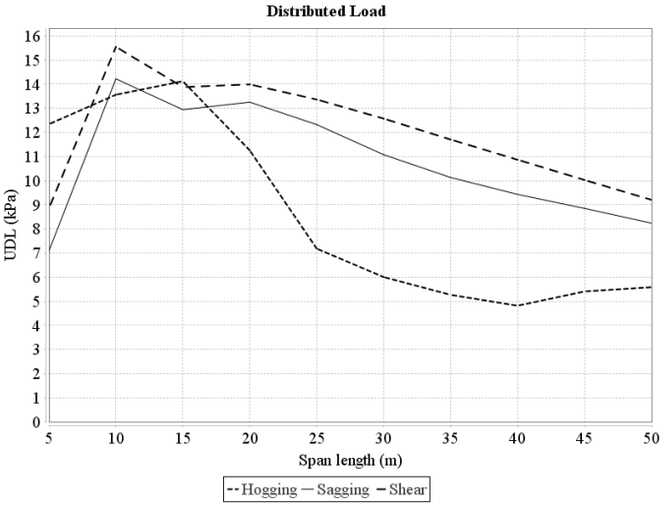

Figure 9. Distributed loads.

It can be seen that the hogging moment load effect for a 10 m span length produces the largest distributed load of approximately 15 kPa. The distributed load decreases with an increase in span length, creating the possibility of distributed load reduction with increasing span length. The proposed load model configuration is shown in Figure 10.

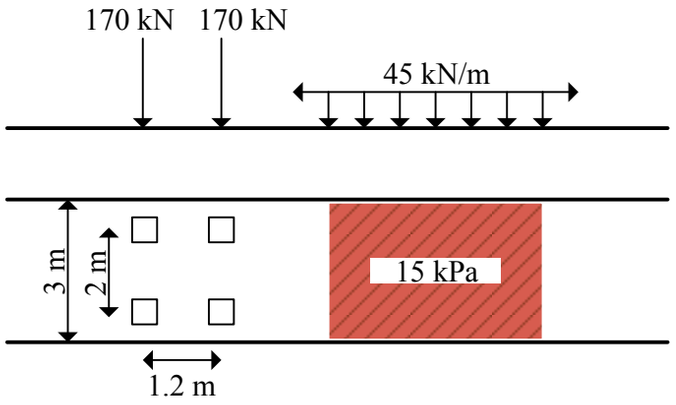

Figure 10. Proposed load model.

7 CONCLUSIONS

A preliminary traffic load model for single lane traffic has been derived for bridge design in South Africa. One year of data from the Roosboom WIM station was used to calculate daily maximum hogging moments, sagging moments and shear forces for span lengths up to 50 m. These forces were extrapolated on Gaussian probability paper to a return period of 975.3 years.

The resulting load model is a double axle of 170 kN each, spaced at 1.2 m apart with a distributed load of 15 kPa, shown in Figure 10. When compared to the Eurocode the load model has a lower axle load (300 kN for Eurocode), but a larger distributed load (9 kPa in the Eurocode) (CEN 2003).

This load model is limited to characteristic values and does not incorporate multiple lane presence or dynamic amplification as these will be addressed in future research.

When comparing this new load model to TMH7 NA loading, with dynamic effects removed, the deficiencies are clear. Figure 11 shows that TMH7 NA loading is under conservative for span lengths up to 22.5 m in hogging. Figure 12 shows deficiencies in sagging moments for span lengths up to 40 m. Figure 13 shows deficiencies in TMH7 for all span lengths in shear.

These deficiencies confirm the work performed in 1991 by Oosthuizen et al. and shows that it is vital to adopt a new live load model for bridge design in South Africa.

ABSTRACT: This paper presents the idea of correlating vehicle lengths extracted from images with weights from Weigh-in-motion (WIM) data. The purpose of this is the estimation of traffic loading on long-span bridges. WIM data from a motorway in Poland containing four months of records, is used to develop the length-weight correlation. As WIM data may contain some errors, a cleaning algorithm is applied to create a reliable database. Monte Carlo simulation is used to show the correlation. A sample of random traffic is simulated and a bootstrapping method is used to verify the correlation approach.

1 INTRODUCTION

The safety of a bridge can be precisely evaluated if the loading and resistance to loading are known. While the resistance has been well investigated in the literature (Attard and Stewart, 1998), (Darmawan and Stewart, 2007), (Pines and Aktan, 2002), (Stewart, 2001), (Stewart and Val, 1999), loading has not received the same attention, particularly in the case of long span bridges. Traffic loading is difficult to predict since it is highly variable and site specific. Clearly the values of load effects (bending moments, shear forces etc.) need to be lower than the values of resistance to ensure that the bridge is safe.

The governing case for long span bridges is known to be congested traffic conditions (Getachew, 2003), (Hwang et al., 2012), (Lutomirska, 2009), (Nowak et al., 2010), (Sedlacek et al., 2008). In this case, traffic loading represents a particular challenge due to lack of information about the inter-vehicle gaps and the car-truck mix. Weigh-in-motion (WIM) technology is the established method for obtaining the vehicle weights (Moses, 1979), (Carey et al., 2017). However, WIM technologies work well only for free-flowing traffic (OBrien et al., 2012). Thus, gathering the weight information of congested traffic is infeasible. Furthermore, WIM methods often only record trucks and provide little or no data about the cars and gaps between cars and trucks.

There have been many studies about traffic loading (Buckland et al., 1978), (Buckland, 1991), (Hayrapetova et al., 2012), (OBrien et al., 2012), but inter-vehicles gaps in congested situations, have not been well investigated. Several researchers use microsimulation to model congested situations (Caprani and OBrien, 2008), (Caprani, 2010), (Caprani, 2012), (Enright et al., 2013), (Treiber et al., 2000). A constant value for the gaps has been considered in other works (Getachew, 2003), (Hwang et al., 2012), (Lutomirska, 2009), (Paeglitis and Freimanis, 2016). Micu et al. (Micu et al., 2016) propose image analysis technique for surveying congested traffic. They show that this approach can provide valuable information about the congested traffic such as vehicle class, length, and inter-vehicle gaps. These parameters can be used in assessing the traffic loading on long span bridges, but the weights of the vehicles cannot be estimated directly from the images.

This paper proposes the correlation of lengths extracted from the images with weights from available WIM data. This means that the lengths extracted from the images are used to infer the vehicle weights. The correlation is constructed using Monte Carlo. This method effectively fits a function to the histogram of the data. For instance, for each extracted length, the authors generate a 'typical' weight using Monte Carlo simulation. The proposed method is used to simulate the vehicle weights from the vehicle lengths available at a Polish WIM site. The simulated weights are compared to the measured weights to assess the reliability of the proposed method. The method is also verified by simulating new traffic using a bootstrapping method. The results show that the vehicle weights can be inferred from the lengths with acceptable accuracy for the purposes of estimating extreme bridge traffic loading.

2 LENGTH-WEIGHT CORRELATION

2.1 *WIM Data*

2.1.1 *Raw data*

WIM data used in this paper is obtained from a WIM system installed on the A4 (E40) motorway with two lanes in one direction at Wroclaw, Poland. This WIM system uses piezo-quartz sensors embedded in the pavement to measure the properties of the passing vehicles. The data measured includes each vehicle's detailed information such as timestamp, wheelbase, total length, speed, vehicle type (car or truck), total weight (GVW), the number of axles, axle spacing, single axle weights, etc. Measurements represent 1,048,546 vehicles on both lanes (fast and slow lane) with 24 % of trucks registered from the period between 1st January and 27th April, 2008. Two sub-datasets are extracted from the database. The first sub-dataset is called WIM1 and the second one is WIM2 in this paper. Each sub-dataset contains 100,000 vehicles recorded on both lanes.

2.1.2 *Filtering rules*

The accuracy of the raw WIM data can be checked using different criteria (Enright, 2010). Some of them are used here to filter the raw data by removing the vehicle records that may contain errors. The vehicles are also classified as cars and trucks to properly discard the errors. First, the vehicles which have no information recorded are removed from the data. After this simple filter, 99,827 vehicles are left in WIM1. The general and specific rules that are then applied to the WIM1 data, are detailed in Table 1. The filtering rules are not applied to WIM2.

Table 1. Filtering criteria to identify records with likely errors.

General criteria	
No. of axles	< 2
Individual axle spacing	> 20 m
Individual axle weight	> 20 t
Wheelbase	> 30 m
GVW	> 100 t
Speed	< 60 km/h or > 120 km/h
Total length	< Wheelbase
Criteria specific to cars	
GVW	< 800 kg
Total length	< 2 m or > 8 m
Criteria specific to trucks	
GVW	< 1000 kg
Total length	< 2 m
Specific criteria	
Total length	= 23 m
GVW	= 920 kg

Many vehicles are recorded having the same length of 23 m but with very different values of weights ranging from the lowest to the highest value. As this might be due to a measurement error, they are removed from the database. Less than 0.1 % of the vehicles are removed at this stage.

Many vehicles are also recorded with the exact same weight of 920 kg but with values of length ranging from 0 m to 20 m. Unlike the 23 m long vehicles, the 920 kg vehicles constitute about 15 % of the whole data. As these vehicles create a very high local density around 920 kg which may cause some issues in the proposed correlation method, they are also discarded from the database. Finally, 82,883 vehicles are left in WIM1 after the filtering process.

Table 2. Evaluation of the loss after filtering.

Vehicle type	Percentage before filtering (99,827)	Percentage after filtering (82,883)	Waste among this graph	Waste among all vehicles
Cars in the slow lane	36.2%	32.7%	25.0%	9.0%
Cars in the fast lane	39.9%	38.5%	19.6%	7.8%
Trucks in the slow lane	22.3%	26.9%	0.4%	0.1%
Trucks in the fast lane	1.6%	1.9%	2.2%	< 0.1%
All the vehicles	100%	100%	17.0%	17.0%

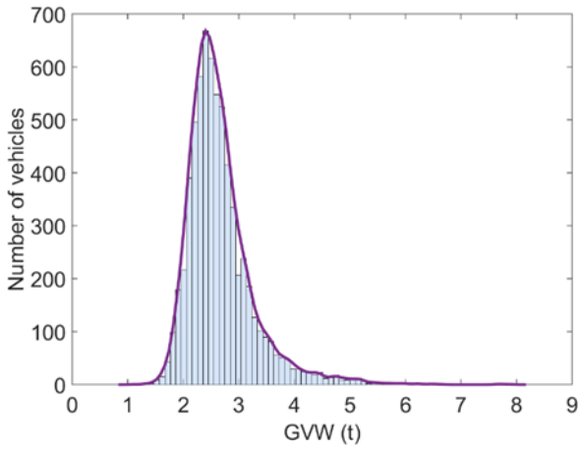

Table 2 gives details of the percentages of vehicles filtered from the database. It shows that the discarding process mostly removes cars rather than trucks. This may because WIM systems are designed to weigh trucks and little priority is given to the weighing of cars.

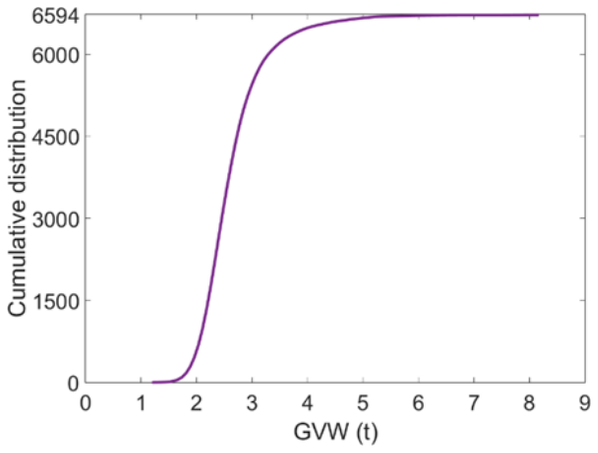
2.2 *Kernel density estimation*

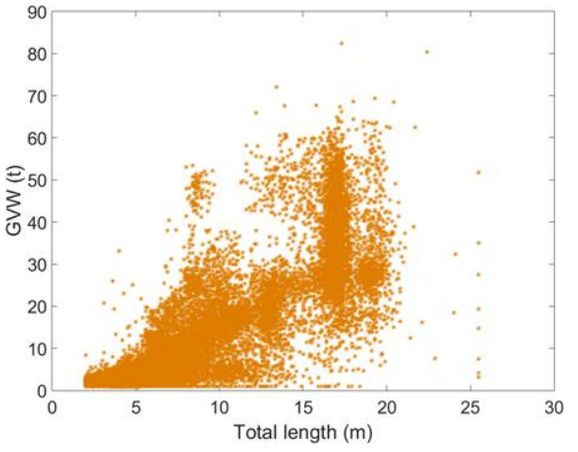


Due to the different distribution of vehicles in the two lanes, the WIM2 data is divided into slow and fast lane data. Using the total length of the vehicles, the WIM2 data is split into 100 slices with the same width for each lane. The lengths of vehicles in each slice are in a specified range. The number of vehicles is different from a slice to another and some slices may be empty.

The numbers of vehicles with given (weight interval, length) combinations are plotted as a histogram. A Normal Kernel density distribution (Jones and Kappenman, 1992) is fitted to the histogram for each slice. Figure 1(a) presents the histogram of the weights in slice 10 for the WIM2 data recorded in the slow lane. It contains vehicles with length ranging between 4.10 m and 4.30 m. It can be seen that most of these relatively short vehicles weigh 2 to 4 tonnes but these are exceptions. A Kernel density distribution fitted to the histogram is also shown. This process is repeated for all slices which results

in a Kernel density distribution for each slice in WIM2. A cumulative distribution function (CDF) is then defined for each Kernel density distribution to represent the probability of different vehicle weights in each slice. Figure 1(b) shows the cumulative distribution function of the data shown in Figure 1(a).

(a)



(b)

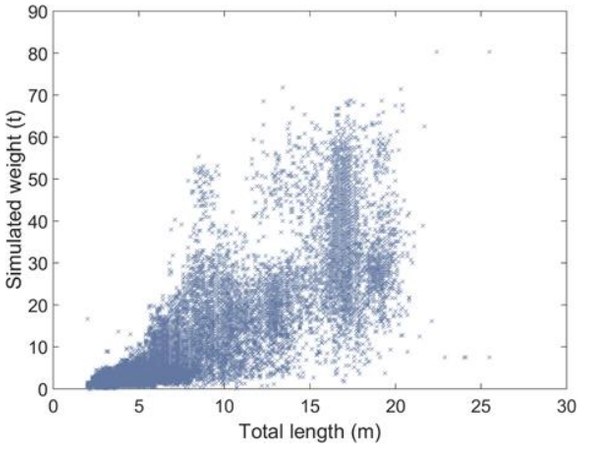


Figure 1. Distribution of the data in slice 10 of WIM2; (a) histogram of the vehicle weights and the kernel density fitted distribution; (b) the Kernel fit cumulative distribution of the vehicle weights.

2.3 *Weight simulation*

It is assumed that only lengths of the vehicles in WIM1 are available. This would be the case if the lengths were found from an analysis of vehicle images. In this section, the weights of the vehicles in WIM1 are generated using a Monte Carlo simulation using the length/weight relationship obtained from WIM2. Regarding the length of each vehicle in WIM1, it belongs to a slice in WIM2 data. Using standard bootstrapping (Taylor, 1989), a number between 0 and the maximum value of the cumulative distribution of that slice, is randomly generated. That number corresponds to a weight in the CDF plot of the slice. This weight is the assumed weight of the vehicle in WIM1. A similar procedure is repeated for all the vehicles in WIM1 to infer their weights from their lengths. The length-weight correlation of the WIM1 data is shown in Figure 2 - the recorded and simulated data are shown in Figures 2(a) and 2(b), respectively. It can be seen that the simulated data is a reasonable match with the recorded data.

(a)

(b)

Figure 2. Length-weight correlation: a) Recorded WIM1; b) Simulated weights for lengths in WIM1.

Figure 3 presents the density of vehicles versus weights for the simulated weights and recorded WIM1 data in slice 10 for both lanes. Both distributions display the same number of vehicles. As can be observed, the simulated weight data matches the recorded WIM1 data very well.

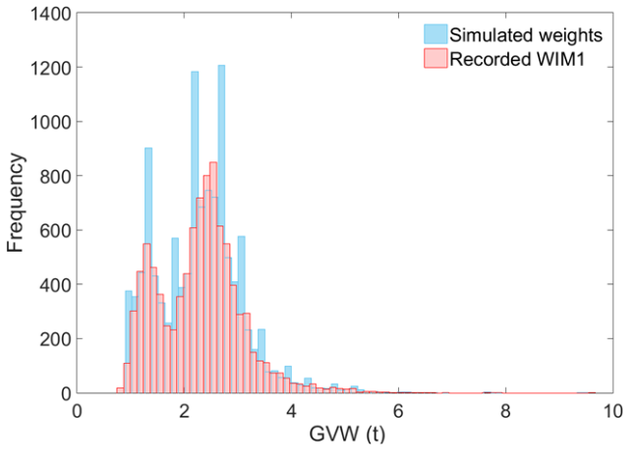

Figure 3. Histogram of recorded WIM1 and of simulated weight data.

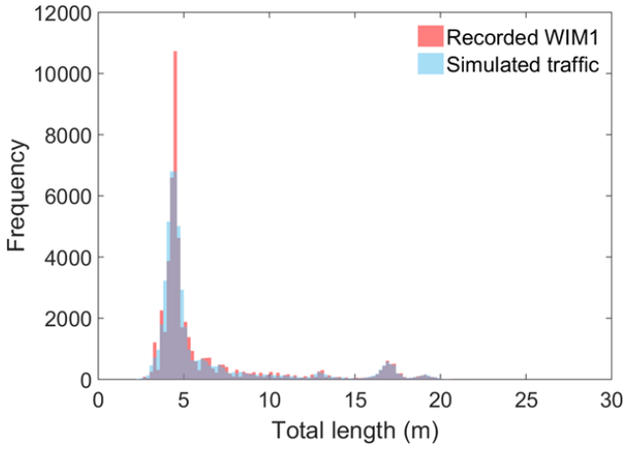
2.4 *Comparison of simulations*

Bootstrapping is used in this section, to resample the data for the verification of the correlation approach. A new traffic is generated using bootstrapping only from the WIM1. This traffic includes the lengths of 82,883 vehicles for the fast and slow lane. Then, the correlation method proposed in Section 2.3, is used to simulate the weights of those vehicles. As a result, a new traffic including 82,883 vehicle lengths is generated using the bootstrapping method which is called "simulated traffic". The histogram of the simulated traffic in the slow lane, is compared to the recorded data in Figure 4. Both samples contain 51,455 vehicles. It is shown that the simulated traffic has a very similar histogram to the recorded data.



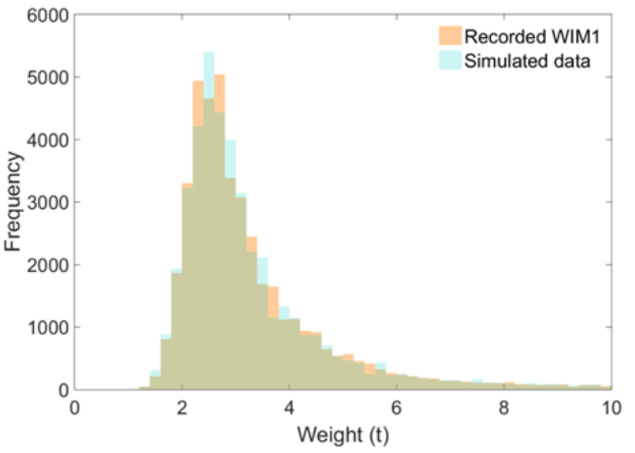


Figure 4. Histogram of recorded WIM1 data and of simulated traffic.

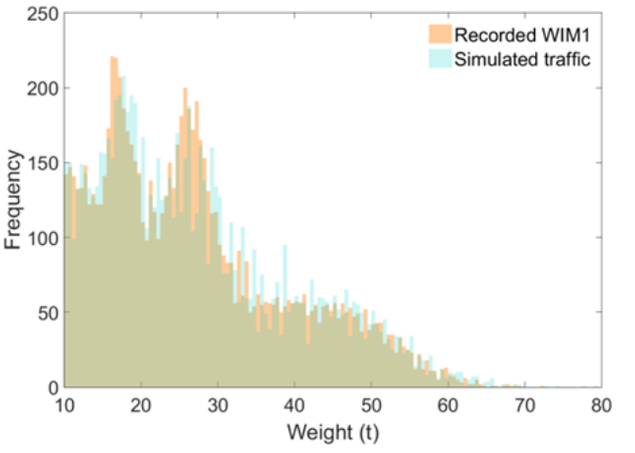
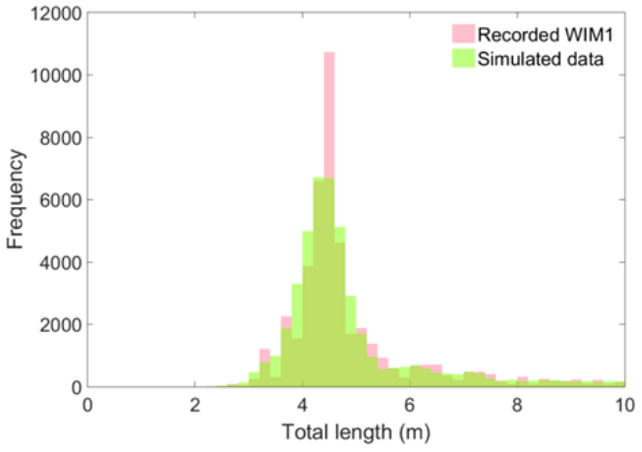


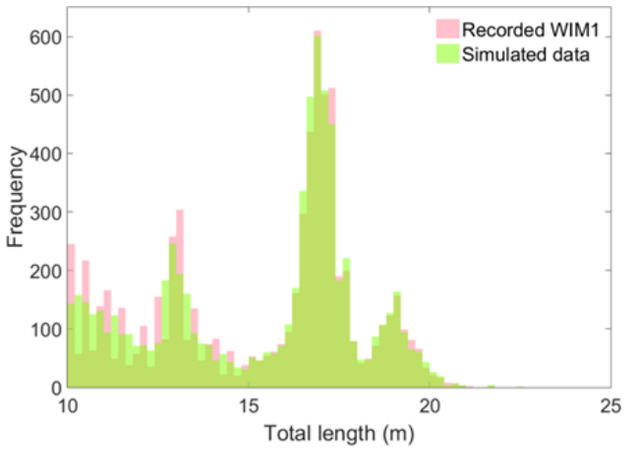
The weights of the vehicles in the new traffic data are simulated using the correlation method explained in Section 2.3.

2.5 *Results and discussion*

Figures 5 show the histogram of the frequency versus weights for the recorded WIM1 data and simulated traffic data at different scales. Figures 5(a) and (b) show the results for the weights from 0 to 10 tonnes which are evaluated every 200 kg and 10 to 80 tonnes which are evaluated every 50 kg, respectively. Figure 5 (b) is enlarged for better illustration due to the relatively low frequency of heavy vehicles.



(a)



(b)

Figure 5: Bootstrapping results - weights: (a) weights from 0 to 10 t evaluated every 200 kg; (b) weights from 10 to 80 t evaluated every 50 kg.

The distribution of the lengths is illustrated in Figure 6. In this case, the lengths are evaluated every 20 cm. Figures 6(a) and (b) show the results from 0 to 10 metres and 10 to 25 metres, respectively. It can be seen in Figures 5 and 6 that the simulated traffic matches the recorded WIM1 data well. Most significantly, the trend of simulated traffic follows closely the trend of the recorded data.

(a)

(b)

Figure 6: Bootstrapping results - lengths evaluated every 20 cm: (a) Lengths from 0 to 10 m; (b) Lengths from 0 to 25 m.

The correlation between lengths and weights for the recorded slow lane WIM1 data and for the simulated traffic is illustrated in Figure 7. It can be observed that the simulated data is well correlated with the recorded data.

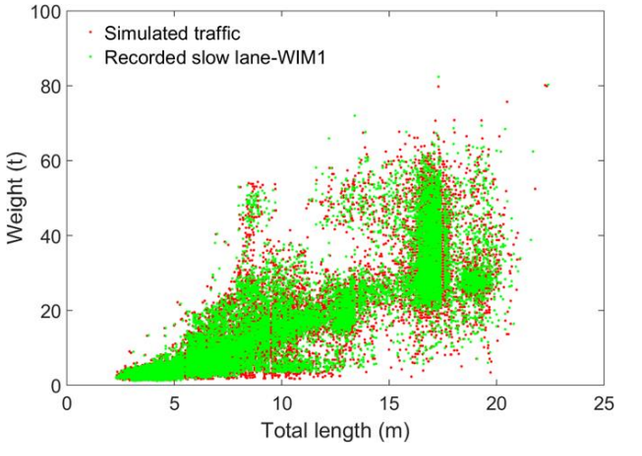


Figure 7: Bootstrapping results - correlation between length and weight.

3 CONCLUSION

This paper examines the possibility of correlating lengths extracted from images with weights from WIM data. Two datasets, WIM1 and WIM2 are used to test the correlation. A set of filtering criteria is used to reduce the possible errors of WIM measurements. The weights of the vehicles from WIM1 are simulated using their lengths. The simulated data are compared to the recorded data and show an acceptable accuracy. Random traffic is generated by bootstrapping. Bootstrapping is also used here to demonstrate the consistency of the Monte Carlo simulation. Appropriately, simulated vehicles have a higher probability of being generated in slices with a greater number of vehicles and will not be generated in slices with no vehicles. The results confirm that the proposed correlation method has good potential to be used for the estimation of the traffic loading on long-span bridges.

ACKNOWLEDGEMENT

The authors would like to thank Science Foundation Ireland for their support of this research under the US/Ireland programme. The authors also gratefully acknowledge the FP7 Samaris Project for providing Weigh-in-Motion data used in this research.

Long span bridges – current age & design life – a global survey

J. De Maria
Undergraduate, Civil Engineering, Monash University, Australia
C. Caprani
Supervisor, Department of Civil Engineering, Monash University, Australia
D. Guo
Co-supervisor, Postgrad, Civil Engineering, Monash University, Australia

ABSTRACT: To identify the in common problems, future needs, and reveal the relationship between the age, design life, and status of long span bridges on an international scale, a global long span bridge survey was conducted and database constructed. From which, the details of location, construction and status per bridge were broken down and analysed to identify any potential relationships, or correlations, between the numerous categories of information recorded for each long span bridge. Analysis concluded that age and bridge type selection of most long span bridges within the North American region has resulted in rare achievement of design life objectives. The global long span bridge database is searchable, organisable, available in several formats, and is a strong foundation for further expansion and detail.

1 INTRODUCTION

1.1 *Background*

Bridges have been constructed to establish direct means of communication and transportation between populations for thousands of years. As construction and engineering technology has progressed, so has the size and number of bridges across the globe. Within the last century there has been unprecedented infrastructure growth, resulting in the construction of bridges that push the limits of their materials and engineering design.

Long span bridges account for only a small percentile of the total number of bridges in use around the globe. However, it is undeniable that these bridges, on a scale of their own, provide vital connections, across; mountains, valleys, bays, rivers, oceans and lakes, that are essential to the daily operation of cities and countries across the globe.

1.2 *Project objective*

Long span bridges, though vital to many communities, lack representation within a searchable, manipulatable and analysable construct. Due to the internet, information regarding long spans bridges is freely available, to an extent, however, this information is yet to be collected and presented in a meaningful and useful format.

Therefore, this project aimed to conduct a comprehensive survey of long span bridges from across the globe, and with the data collected construct a global long span bridge database. The database was then used to help identify in common problems experienced by long span bridges, and help identify the future needs for long span bridge design and construction.

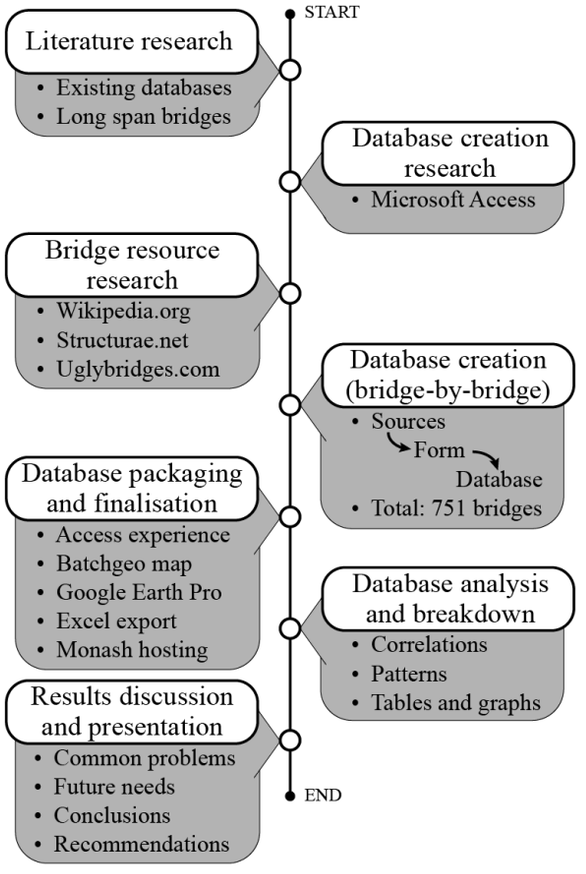

Figure 1. Methodology used to complete the global long span bridge database, database analysis and results discussion

2 DEFINITIONS AND ASSUMPTIONS

2.1 *Global survey*

The survey of long span bridges was as globally extensive as available resources and time allowed. The survey included bridges from a total of 81 countries, which were assigned to one of seven global regions, either; Africa, Asia, Europe, Latin America/Caribbean, Middle East, North America, or Oceania. However, the information freely and easily available for each region or country varied greatly. At a minimum, details regarding location and construction were obtained. North America proved to be the most accessible region, largely due to the National Bridge Inventory being freely available online.

2.2 *Span*

'Span' is a term that may be interpreted to relate to different dimensions of a bridge structure. For this project, and in most interpretations, 'span' is defined as the distance between to ground supports (pylons) of a bridge structure. For this survey, the maximum (longest) span of each bridge structure is its qualification for being a 'long span' bridge, and should not be confused with the overall length of the bridge. See Figure 1 for diagrams clearly defining the 'span' dimension for each bridge type included in the survey and database.

2.3 *Long span*

The term 'Long Span' also needed to be defined in relation to the survey and database. For this project the term 'Long Span' was considered a flexible and relative term, meaning; that there was no set length to be greater than, and that it was relative to the bridge type.

However, it was also determined that, there is a point where the mechanics and effort required to span a given distance becomes so common place that it is no longer irregular, or special. Box girder bridges, usually associated with 'short span', or more common span lengths, can span up to approximately 150 metres. Therefore, to eliminate technology associated with smaller spans, a target was set to obtain details on all bridges across the globe with a main span greater than approximately 150 metres. (Hewson, 2003)

2.4 *Design life*

The concept and definition of 'Design Life', across the various international standards varies slightly from standard to standard, and is closely related with the concept of 'Service Life'. What follows are the definitions of Design Life, and Service Life, from three major international bridge and construction standards. The American Association of State Highway and Transportation Officials Load Resistance Factor Design (AASHTO LRFD), the Eurocode (EN 1990.2002), and the Australian Standard for Bridge Design (AS5100.1-2004).

2.4.1 *AASHTO LRFD Design Life*

Design Life – *"period of time on which the statistical derivation of transient loads is based"*

Service Life – *"the period of time that the bridge is expected to be in operation"*

2.4.2 *EN 1990.2002 Design Life*

Design Working Life – *"assumed period for which a structure or part of it is to be used for its intended purpose with anticipated maintenance but without major repair being necessary"*

Reference Period – *"chosen period of time that is used as a basis for assessing statistically variable actions, and possibly for accidental actions"*

2.4.3 *AS5100.1-2004 Design Life*

Design Life – *"the period assumed in design for which a structure or structural element is required to perform its intended purpose without replacement or major structural repairs"*

Service Life – *"a period over which a structure element is expected to perform its function without major maintenance or structural repair"*

2.4.4 *Database Design Life*

The definition for Design Life accepted and utilised for the survey, database and this report, matches the definitions of; Service Life from the AASHTO LRFD, Design Working Life from EN 1990.2002, and Design Life from AS5100.0-2004.

To be clear, for the survey, database and this report, the definition of Design Life used was - *the period of time assumed in design for which a structure is expected to be in operation with anticipated maintenance but without major repair or unanticipated structural rehabilitation.*

3 *THE GLOBAL LONG SPAN BRIDGE DATABASE*

This section is intended to thoroughly explain the method used, and the components of the global long span bridge database created, to aid readers in understanding the database, or to assist in extending this database, or creating their own database.

3.1 *Program utilised*

To log the details procured per bridge from surveying various internet sources, the computer program Microsoft Access® was utilised. Access is classified as a database management system (DBMS) and was suited to the task at hand due to the programs extensive data input, organisation, exportation, and interfacing features.

3.1.1 *Long span bridge form*

Critical to the completion of the global long span bridge database was the ability to design a 'form'

Figure 3. Global positions of all long span bridges included within the database.
(Locations traced from Batchgeo map, using database coordinates, then composited onto a simplified global map)

within Access to assist in logging the details per bridge. The form is pictured below as Figure 4.

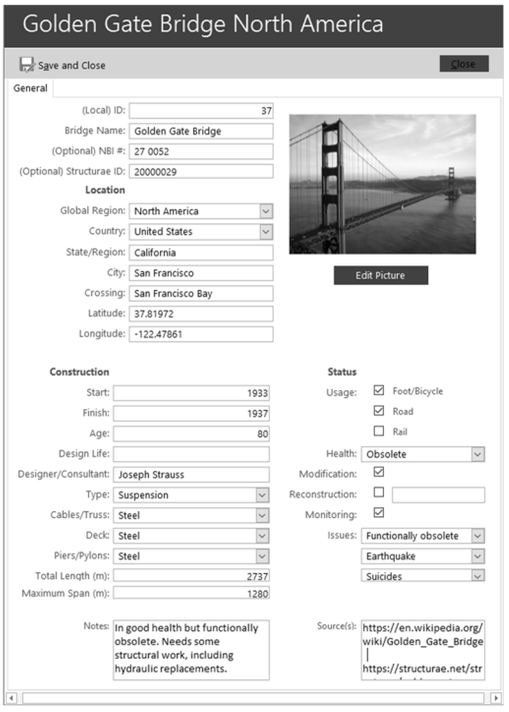

Figure 4. Access form created to log and edit bridge details per bridge surveyed for the database.

3.2 *Database entries*

Data entries per bridge were summarised under three sub categories; Location, Construction and Status. Other entries were present on the form to assist with administration and organisation of the database. The components within each category were as follows. Most entry fields are self-explanatory; however, several require some clarification.

Location
- Global Region
- Country
- State/Region
- City
- Crossing
- Latitude & Longitude

Construction
- Construction Start and Finish (year)
- Age
- Design Life
- Designer/Consultant
- Type
- Material, by;
    - Cable/Truss
    - Deck
    - Pier/Pylon
- Dimensions:
    - Total Length (m)
    - Maximum Span (m)

Status
- Usage;
    - Foot/Bicycle,
    - Road, or
    - Rail
- Health;
    - Good
    - Obsolete
    - Deficient
- Modification
- Reconstruction (with year)
- Monitoring
- Issues (abbreviated. Max 3 issues)

Other
- Database ID (internal)
- Bridge Name
- NBI Number (USA only)
- Structurae ID
- Image
- Notes
- Sources

3.2.1 *Construction type*

Bridge type was restricted to one of five bridge type classifications; Arch, Cable Stayed, Cantilever, Suspension, or Truss. Nearly all bridges surveyed were clearly identifiable with at least one of the classifications. If the structure was a combination of more than one type of bridge then the most dominant classification or the classification of the main span was used, and the other classification(s) were included in the Notes entry field.

3.2.2 *Construction material*

Bridge material was separated into three entry fields; Cable/Truss, Deck, and Pier/Pylon, to allow for improved detail of which structural elements are what material in multi material bridges.

3.2.3 *Bridge health status*

Bridge health was restricted to three possible responses; Good, Obsolete, and Deficient, and was adopted from the National Bridge Inventory (USA). Good defines a bridge structure that does not require any immediate rehabilitation, outside of the regular maintenance schedule, and is functionally suitable for its objective. Obsolete defines a bridge that is structurally sound, and in no need of unanticipated rehabilitation, but is no longer suitable or adequate for its objective. And, Deficient defines a bridge structure that is in need of urgent structural rehabilitation, and should, either; have vehicle load restrictions, or be closed from traffic entirely, depending upon the severity of the structural issues. A bridge within the inventory both obsolete and deficient is classified as deficient only. (Federal Highway Administration, 2016)

3.3 *Database sources*

The required details of each long span bridge surveyed were gathered from several online resources, including;

- Wikipedia.org
- Structurae.net
- Highestbridges.com
- Bridgehunter.com
- Uglybridges.com
    - USA only, uses the NBI
- Designer fact sheets/documents

Due to the National Bridge Inventory being freely available, bridges within the United States contain the most detailed and accurate entries.

All sources used, except for Uglybridges.com, were community, or crowd, collaborative efforts, and therefore the quality and accuracy of details varied greatly. To ensure bridges entered into the database were detailed as accurately as possible, the location, span, materials and usage were confirmed, when available, with satellite imagery (Google Maps), street view imagery (Google Street View), and with photographs available online.

3.4 *Database availability*

At the time of writing the Global Long Span Bridge Database exists in several forms. The database remains in its original form as an Access Database file, complete with imagery, a searchable list and organisable tables. From the Access database, it has been exported to Microsoft Excel, where the entries have been broken down and analysed. From Excel, the database, has also, been exported to a private Batchgeo.com map, where all bridges within the database are presented on a global map, with all database detailing (except imagery), which is filterable, and searchable. From Batchgeo.com the database was exported to a Google Earth (.kml) file, again, with all database detailing.

As will be stated, and explained further, in the conclusion of this report, the Global Long Span Bridge Database at present time of writing is considered to be a solid foundation for further refinement, expansion, detail and scope.

It is expected that the latest version of the database will be made available for research, or continuation, via the Monash University Civil Engineering faculty.

4 DATABASE ANALYSIS AND DISCUSSION

4.1 *Database composition*

Before diving deep into analysis and discussion about the age, status, design life, in common problems, and future needs of the long span bridges, it is important to have an understanding of the distribution of both the location and bridge structure type of the long span bridges included within the database. Table 1 below displays the contribution of long span bridges from each defined global region, as well as the number of individual countries that contributed and the country within with the leading contribution. It is of no surprise that the United States makes the largest contribution of long span bridges. Surprisingly, Norway, was the largest contributor from the European theatre, and whilst not unexpected, it is still very impressive, the contribution China has made, mostly within the last two decades.

Table 1. Number of bridges and countries per region.

Global region	Number of bridges	Number of countries	Major contributing country
North America	266	2	United States (245)
Asia	206	18	China (98)
Europe	199	29	Norway (51)
Latin America.	31	12	Brazil (11)
Oceania	18	2	Australia (16)
Middle East	16	7	Turkey (7)
Africa	15	11	None
Total	751	81	United States (245)

Table 2 below displays the database composition of the different bridge types, defined within the database, per region and in total. Of particular interest, the only region to make significant use of the truss and, closely related, cantilever, bridge structures for long spans is North America (United States). Also of note is the heavy use of cable stayed bridges within the Asia region. These two points of interest, are of importance, and will be recalled later in an analysis and discussion around the health and status of the long span bridges of different types.

Table 2. Number of bridges per bridge type, by region.

Global region	Bridge structure type				
	Arch	Cable stayed	Cantilever	Suspension	Truss
North America	47	29	67	51	72
Asia	39	87	9	64	7
Europe	30	70	42	48	9
Latin America.	3	15	6	7	
Oceania	3	5	8	2	
Middle East	5	5		6	
Africa	5	4	1	5	
Type total	132	215	133	183	88

Figure 5 below shows the distribution of long span bridge construction per global region over the last two centuries. There are several time spans of interest to note from the figure. Firstly, a dramatic increase during the 1930s within North America to combat the Great Depression as part of the Public Works Administration act (Public Works Administration, 1939), which is immediately followed by a reduction of construction during WWII and then the subsequent increase in North America and Europe immediately after. Second period of interest is the infrastructure construction boom within the Asian theatre, in line with, and most likely due to their recent economic boom. In contrast the North American region rate of construction has been declining since peaking in the 1960s.

4.2 *Age and design life*

The concept of 'Design Life' was defined in relation to this project and database in Section 2.4.4 of this report, and was determined, from various international construction standards, to be one of three time periods. From the AASHTO LRFD 2012 for the United States and North American region, the minimum design life for a permanent bridge structure was 75 years. From the Australian Standards AS5100.1 the design life is specified as 100 years, which is also the minimum design life specified in the base Eurocode, EN 1990, and the Chinese Standards. The British Standards BS EN 1990, and many other country specific adaptations of the Eurocode, specify a design life for bridge structures of 120 years.

Using the details logged per bridge regarding age, the number of long span bridges that exist beyond each of the three design lives was determined, and has been summarised in Table 3 below.

Table 3. Number and percentage of bridges beyond design life

Global region	Number and percentage of bridge beyond:					
	>75 years		>100 years		>120 years	
North America	65	24.4%	10	3.8%	3	1.1%
Asia	1	0.5%	0	0.0%	0	0.0%
Europe	20	10.1%	11	5.5%	9	4.5%
Latin America.	4	12.9%	3	9.7%	1	3.2%
Oceania	4	22.2%	0	0.0%	0	0.0%
Middle East	0	0.0%	0	0.0%	0	0.0%
Africa	4	26.7%	2	13.3%	0	0.0%
Global (total)	98	13.0%	26	3.5%	13	1.7%

However, it should be acknowledged that, the obtained design life values are from current editions of bridge design standards, and should only be applied to bridges constructed after the standards date of issue. Design life values from previous editions may have been greater, or lower, than current values, or the concept may not have been in consideration at all. At the time of writing this report, copies of superseded specifications have not been obtained, nor information regarding their inclusion or specification on design life.

Therefore, for the purposes of this analysis and discussion, current design life specifications have been applied and considered for all bridges.

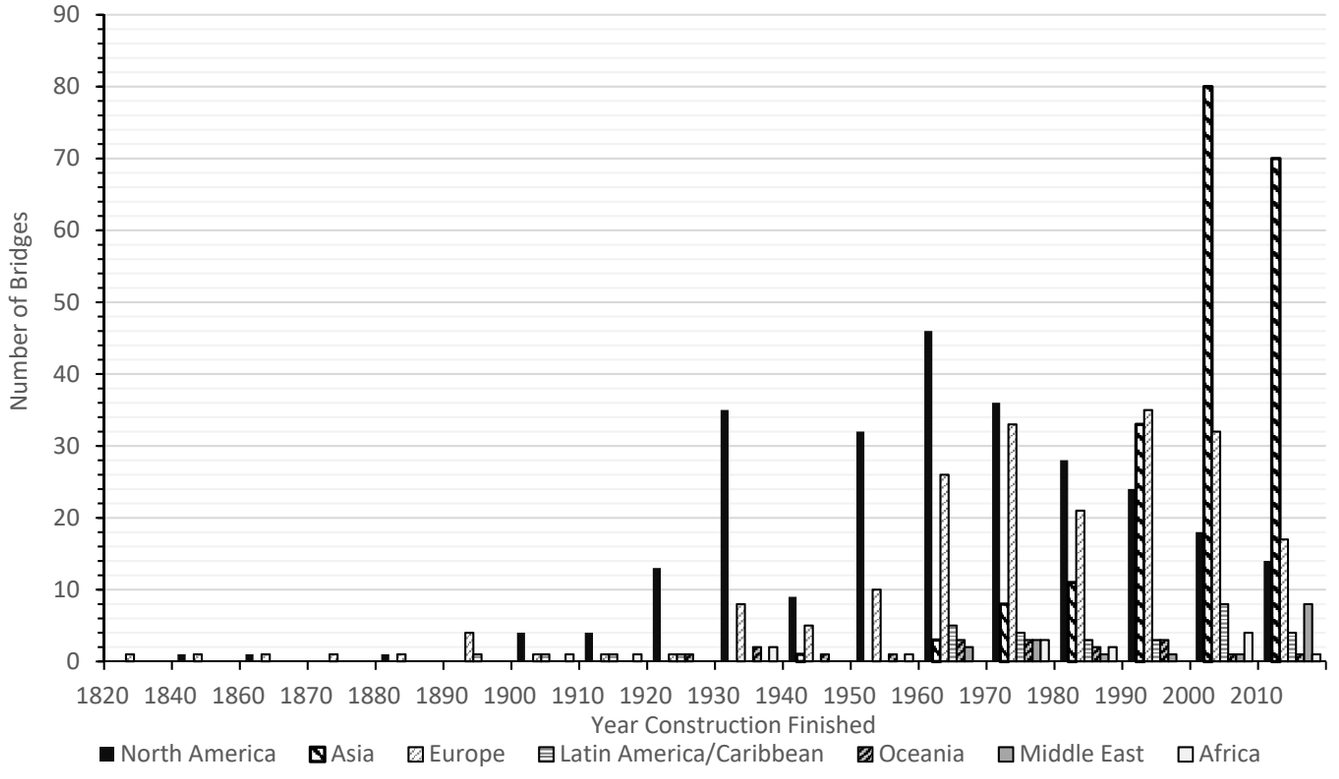

Figure 5. Number of bridges constructed per decade categorised by global region.

Figure 6 below displays the distribution of bridge age within the database entries using 5-year brackets and the three major global regions (for graph clarity). The bridges built during the dramatic construction rate increase during the 1950s and 1960s, in North America and Europe, are approaching the 75-year design life, whilst long span bridges built prior to WWII have passed the 75-year life, and will be approaching 100-years within the next two decades.

4.2.1 *Design Life and Rehabilitation*

Using recorded information of whether bridges underwent major repair, or unanticipated structural rehabilitation, an indication of how many bridges that have achieved target design life can be obtained.

This has been calculated as the number, and percentage, of bridges exceeding design life, that were rehabilitated prior to design life targets, and is summarised above right as Table 4. It is clearly apparent that for the majority of bridges that have exceeded target design life periods, structural rehabilitation has already been performed, and thus target design life, in accordance with the current definition, was not achieved. Only 8% of North American bridges, 5% of bridges in Europe, and collectively 12% of the global total, beyond the AASHTO LRFD specified design life of 75-years, were not structurally rehabilitated prior to reaching the 75 years of age.

Table 4. Number and percentage of bridges exceeding design life, that were rehabilitated prior to design life target

Global region	Bridges rehabilitated prior to design life: (% of bridges exceeding design life)					
	<75 years		<100 years		<120 years	
North America	60	92%	10	100%	3	100%
Asia	1	100%	0		0	
Europe	19	95%	10	91%	9	100%
Latin America.	0		2	67%	1	100%
Oceania	4	100%	0		0	
Middle East	0		0		0	
Africa	2	50%	1	50%	0	
Global (total)	86	88%	23	88%	13	100%

* bridges without rehabilitation dates were assumed rehabilitated prior to design life target

4.3 *Status and common problems*

Using information regarding; global region, bridge type, bridge health status, and bridge rehabilitation data, correlations can be drawn and conclusions made upon the status of the long span bridges around the globe, and the common problems that affect them.

Table 5, on the following page, summarises the health classification per global region as the percentage of bridges within each region. It is important to note that the National Bridge Inventory provided extensive information regarding the health and status of long span bridges located within the United States, which has likely affected results. However, given the fact that the United States contains the oldest collection of long span bridges, the

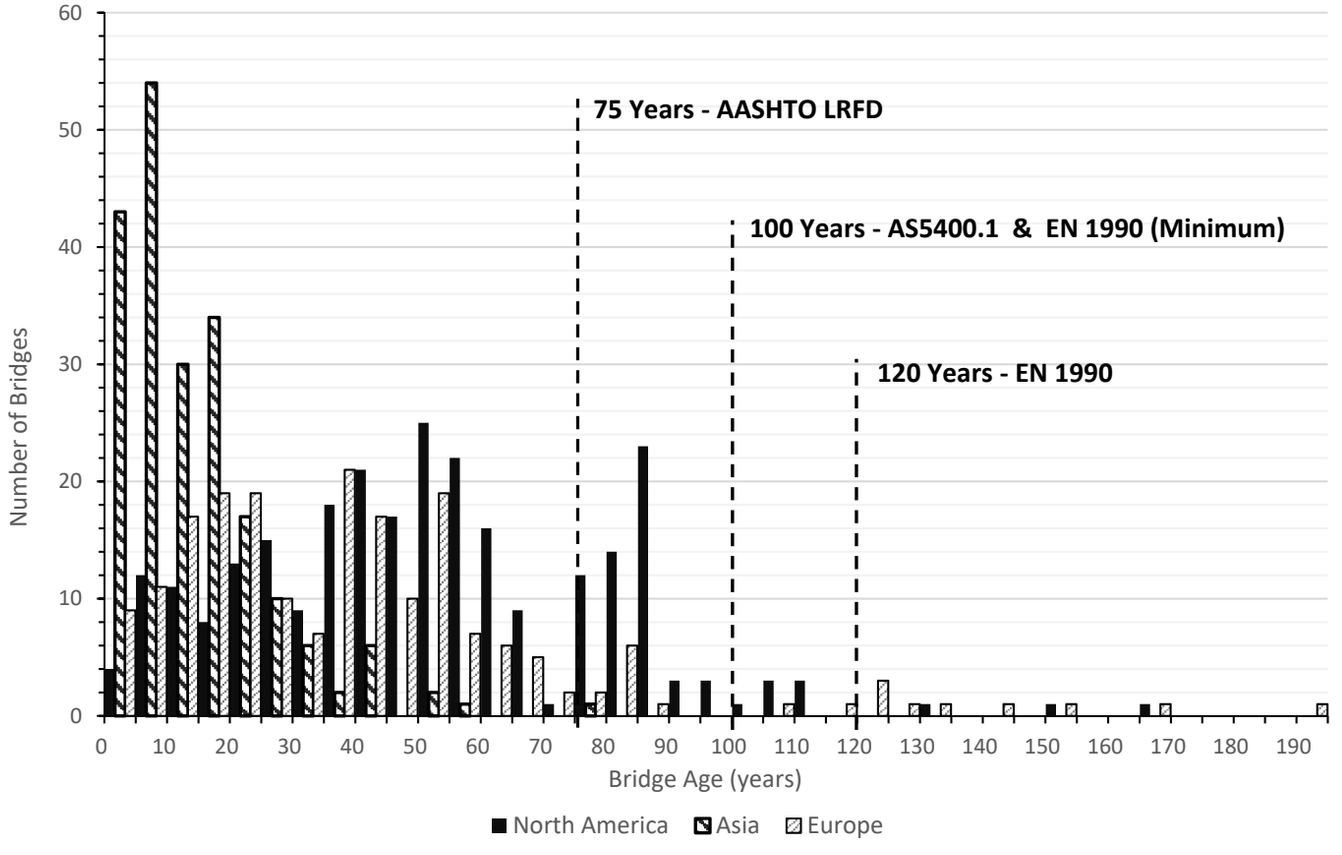

Figure 6. Number of bridges constructed per 5-year age bracket compared to design life.

indication from Table 5 that the North American region contains the highest percentage of structurally deficient bridges is not surprising.

Table 5. Bridge health classification per global region.

Global region	Percentage of global region total:		
	Good	Deficient	Obsolete
North America	63.2%	9.4%	27.4%
Asia	99.0%	0.5%	0.5%
Europe	95.0%	1.5%	3.5%
Latin America.	90.3%	3.2%	6.5%
Oceania	100.0%	0.0%	0.0%
Middle East	100.0%	0.0%	0.0%
Africa	100.0%	0.0%	0.0%
Global (total)	85.0%	4.0%	11.1%

The American Society of Civil Engineers has been publishing yearly Infrastructure Report Cards for the United States for several years now, and recorded that 9.4% of all bridges within the United States were classified as structurally deficient, which closely matches the determined percentage of structural deficient long span bridges within the North American region of this database. However, the latest Infrastructure Report Card reported that only 13.6% of United States bridges were classified functionally obsolete, while 27.4% of North American long span bridges within the database were classified as functionally obsolete. (ASCE, 2017)

A possible reason for the high rate of obsolete classifications amongst long span bridges within the United States is that long span bridges have a higher tendency to be placed along critical transportation routes, and the United States over reliance upon road vehicles for transportation does not assist the traffic capacity requirements of the long span bridge.

Figure 7 below, and Table 6 above right, display information regarding the structural rehabilitation and global region location of long span bridges. Figure 7 displays bridges per decade of construction that have been rehabilitated, which if viewed alongside Figure 5, in Section 4.2 of this report, and Table 6 below gives clear justification as to why the region rehabilitation percentage, of 62.4%, for North America is so high. Majority of bridges rehabilitated originate from the same time period in which North America's long span bridge construction peaks.

Table 6. Percentage bridges rehabilitated per global region.

Global region	Percentage of global region total	
	Only regular maintenance	Rehabilitated (reconstruction)
North America	37.6%	62.4%
Asia	92.7%	7.3%
Europe	58.3%	41.7%
Latin America.	67.7%	32.3%
Oceania	61.1%	38.9%
Middle East	87.5%	12.5%
Africa	46.7%	53.3%
Global (total)	61.3%	38.8%

If bridge type is now taken into consideration with both Table 7, bridge health classification per bridge type totals, and Table 8, bridge rehabilitation percentage per bridge type totals (both tables on the following page), further justification as to why the North American region has the highest percentage of structurally deficient long span bridges becomes apparent. Table 7 displays that the truss bridge type is the bridge type with the highest percentage of structurally deficient bridges, and cantilever being the second highest. Likewise, Table 8 displays that the truss and cantilever bridge types are the bridge types with the highest percentage of structural rehabilitation.

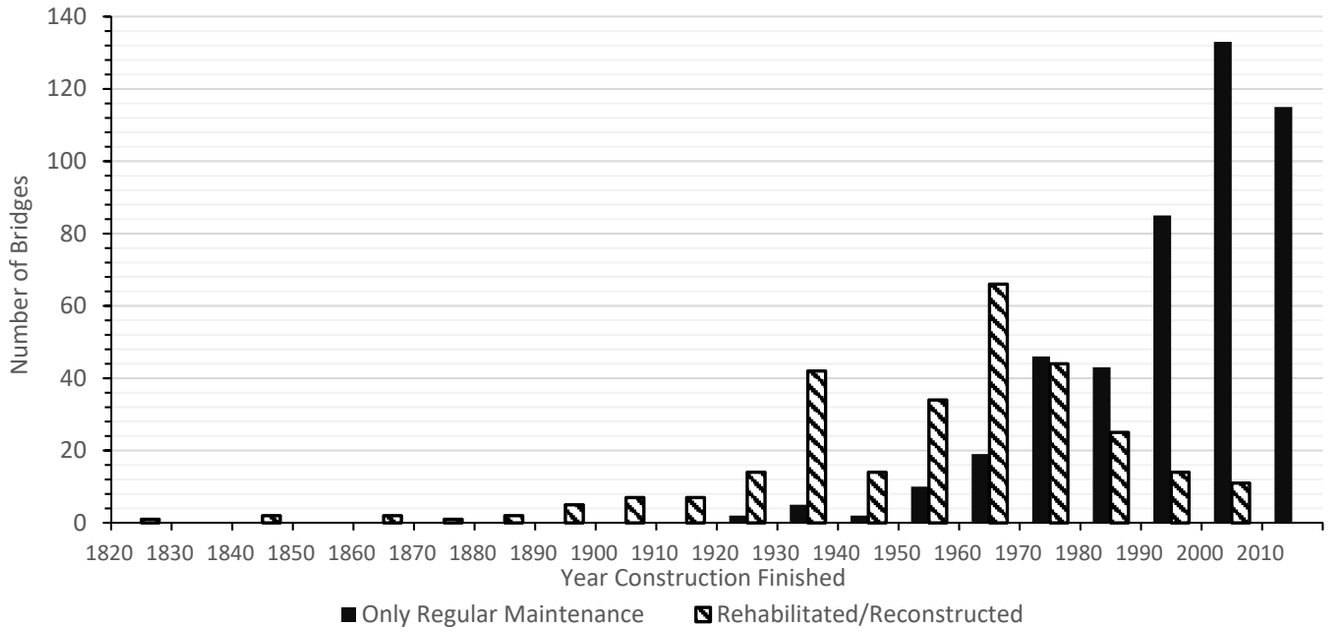

Figure 7. Number of bridges constructed per decade that have been rehabilitated.

Table 7. Bridge health classification per bridge type.

Global region	Percentage of bridge type total		
	Good	Deficient	Obsolete
Arch	87.9%	3.0%	9.1%
Cable Stayed	99.5%	0.0%	0.5%
Cantilever	81.2%	6.0%	12.8%
Suspensions	77.6%	4.4%	18.0%
Truss	65.9%	11.4%	22.7%

Table 8. Bridge rehabilitation per bridge type.

Global region	Percentage of bridge type total	
	Only regular maintenance	Rehabilitated (reconstruction)
Arch	58.3%	41.7%
Cable Stayed	81.9%	18.1%
Cantilever	52.6%	47.4%
Suspensions	57.4%	42.6%
Truss	36.4%	63.6%

Therefore, as the North American region is the region with the highest number of cantilever and truss bridge types, it is understandable that the region has the highest percentage of structurally deficient and rehabilitated long span bridges.

And, from Figure 8 below an indication as to why it is that truss and cantilever long span bridges have the highest percentage of deficiency and rehabilitation is given.

From Figure 8, it can be seen that, the percentage of bridge types affected by corrosion, wearing, capacity and overloading are highest for cantilever and truss long span bridges.

These results are in line with findings that were published in a 2011 ASCE journal performance review of all bridge types and bridges within the United States, using the U.S bridge inventory (NBI). It was concluded that truss bridges have the lowest condition performance, and in general it was concluded that the average bridge life till major rehabilitation was 63% of the objective 75-year design life. (Farhey, 2011)

If truss, cantilever and arch types are removed from the health classification and rehabilitation calculations per region, it is expected that the percentage of deficient North American bridges (Table 5) and percentage of rehabilitated North American bridges (Table 6) will decrease. This proves to be true, although, possibly for alternative reasons. If only cable stayed and suspension bridges are considered, percentage deficient and percentage rehabilitated bridges in the North American region fall to 6.3% and 56.3%, respectively, closer to the international results. However, in Table 9 the percentage of each bridge type number total per 10-year age bracket is summarised, and it can be seen that the truss bridge type is, collectively, the oldest bridge type, with an average age of approximately 52 years, with cantilever and suspension close behind.

Table 9. Percentage of bridge type totals per

Age (years)	Bridge structure type				
	Arch	Cable stayed	Cantilever	Suspension	Truss
0-9	21.2%	35.3%	6.8%	18.0%	4.5%
10-19	19.7%	29.3%	10.5%	14.8%	3.4%
20-29	6.1%	19.5%	12.0%	8.7%	10.2%
30-39	7.6%	9.8%	13.5%	5.5%	12.5%
40-49	8.3%	4.2%	21.1%	10.9%	18.2%

5 FUTURE NEEDS, REVIEW AND RECOMMENDATIONS

5.1 *Future needs of long span bridges*

The present conditions within United States can be used to understand the future requirements of long span bridges around the globe. Except for China and Norway, most countries and individual managing bodies, do not have an infrastructure comparable to the United States, however, the treatment and monitoring of ageing bridges is comparable no matter the number of bridges. The ASCE estimated, in their most recent infrastructure report for the United States that the nation's backlog of bridge rehabilitation requires $123 billion (USD) to clear. (ASCE, 2017) Though this amount is for all bridges, regardless of span length, within the United States, it is still a warning as to the cost of neglect to bridge structures.

Closures on any bridge are disruptive and costly to both the managing body and the surrounding population. This cost is amplified for vital connections, which are often provided by long span bridges. Therefore, it is essential that future long span bridges are designed with the expectation of regular and unexpected maintenance, and that they are designed towards ease of accessibility and upgradeability.

For the ageing, long span bridges within North America, an effective replacement method for severely deficient, obsolete or outdated bridges needs to be devised. The ongoing maintenance costs of the high number of truss, cantilever and arch bridges within the United States can surely be mitigated by commencing their replacement with modern and more durable bridge technologies.

The average age of cable stayed structures is very low in comparison to the other bridge types, though so far the health and rehabilitation rate have been promising. Moving forward cables stayed bridges need to be closely monitored and documented, particularly within the Asian theatre.

Also after conducting this survey and database creation, it should be noted that higher standards in archiving of bridge information needs to be achieved, and if possible publicised. The NBI for the United States was an invaluable resource during this project, and so it is encouraged that other regions and countries around the globe share similar bridge inventory information. With more information, a deeper, more accurate, and meaningful analysis can be conducted, especially outside the United Sates.

5.2 *Database review and recommendations*

The database constructed for this investigation into long span bridges from across the globe has established a strong foundation, and it is recommended that the database be expanded in the future. However, expansion in terms of the quantity of bridges within the database should not be priority, instead, the database detail and scope of information per bridge needs to be improved. There is potential for far deeper and meaningful analysis in regards to the performance of long span bridges. It is recommended that details added include; side span lengths, number of spans, construction cost, maintenance costs, construction technique, traffic information, and design loading. Also, demolished long span structures, were omitted from the survey and should be added to the database.

6 CONCLUSION

The survey conducted and the subsequent database constructed were essential to the breakdown and analysis of long span bridges from around the globe. Whilst analysis has been completed, and valid points drawn regarding the age, design life and status of long span bridge structures, there is a need for more outside the United Sates. It can be concluded that the database created and used is a good foundation for further detail and expansion.

The concept of design life creates an interesting discussion about the expectations of how long a bridge should exist and how well it should perform. Till recently bridge construction has been doing the best we can with what is available, however, with recent strides towards sustainability, achieving the definition of design life is looking more promising than the last half century performance of long span bridge structures.

A New Method to Understanding Loading and Traffic characteristics of Traffic flow

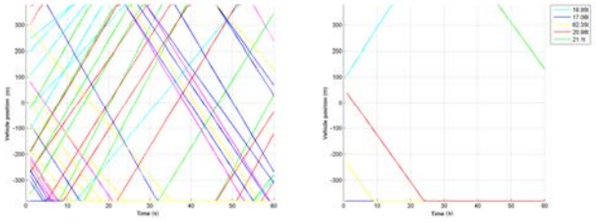
X.J. Wang, & X. Ruan
Department of Bridge Engineering, Tongji University, Shanghai 200092

ABSTRACT: This paper offers a damage identification and structural effect evaluation thought based on health monitoring system for large-scale bridge structures. By analyzing the sensitivity of response to traffic load, the concept and building method of categorized traffic are introduced, which categorizes the traffic into light class and heavy class on statistical periods, and the loading response of heavy class in the evaluation of structural response is prioritized. This concept of categorized traffic can be seen as a new understanding method for traffic flow loading and traffic characteristics. And it provides a new perspective to measure the traffic with different dimensions, which can bring convenience to bridge structure assessment. Then parameter characteristics and relativity of categorized traffic are counted to set the parameters and building forms of response evaluation model of categorized traffic. This paper endeavors to transfer the target of the system evaluation from safety to performance based on the practical application of the system and aims to improve the monitoring sensibility and propose new insight for its development via real-time corresponding between response data and load data over a synchronized period.

1 INTRODUCTION

In order to ensure safety, stability and durability of bridge structure, the health monitoring system is increasingly applied in large-scale bridges. While the introduction of new theories such as neural network algorithm and pattern recognition has made the theoretical system of health monitoring more mature, (S.T. Yang, 2008) there are still many problems to be solved. (X. Ai, 2009) First, the monitoring indicator lacks a reasonable plan, and there is no universal design methods and steps to follow; Second, it's without commonality because different bridges often have different health monitoring programs; Third, the health monitoring system lacks an unified and standardized evaluation criteria for bridge structure performance. (X.T. Jin, 2013) At present, there exists numerous monitoring indicators of the health monitoring system, which are divided into two categories: External load information and bridge response information. Most existing monitoring and early warning systems only study the response information and use their allowable values to judge whether the structure is safe or not. This kind of evaluation system is simple but flawed, mainly reflected in two aspects： First, the load and response data can not be used at the same time and the factors of structural performance can not be considered; Second, the sensitivity to structural changes is poor. By this kind of system, researchers can only measure greater damage but not nip in the bud. Therefore, a monitoring system that monitors the normal state of the structure to replace the monitoring system that monitors the safety state of the structure is in need. In this paper, the concept of 'normal state' for structure safety is presented. The concept is proposed to distinguish the differences between minor damage of structure and greater impairment that affecting structural safety and to raise the level of monitoring from safeguarding structural safety to maintaining normal structural performance. To achieve such monitoring objectives, it is inevitable to make good use of load and response monitoring data in the same period to realize the correspondence between load data and response data at the statistical level. Therefore, it can provide new ideas for structural health monitoring in daily life by using the load information of a certain period to determine whether the corresponding period of response information is reasonable.

In order to study the correspondence between load information and response information, the appropriate load form must be selected first. Among the loads that affect the structural response, the traffic load is the most influential and the most random one. Through the study (see Section 2.1), it



is found that the traffic flow of heavier vehicles has much greater impact on the structural response than that of lighter vehicles. Therefore, by analyzing the sensitivity of response to traffic load, the concept of categorized traffic are introduced, which categorizes the traffic into light class and heavy class on statistical periods. On the one hand, the categorized traffic method facilitates the streamlining of traffic flow data, on the other hand, with focuses on the heavy class of traffic flow in the study of the correlation between load and response, it can greatly increase the efficiency of analysis. Meanwhile, the introduction of this concept lays the foundation for the establishment of the normal state which takes the characteristics of heavy class as the main reference. On the basis of the above, the division standard of categorized traffic is studied, the selection of the representative parameters of categorized traffic and its characteristics is discussed, and the correlation of parameters between heavy class and light class is further explored.

2 A NEW METHOD TO UNDERSTANDING THE TRAFFIC LOAD

For the assessment of bridge structure performance, the vehicle load is the most critical load type mong the load data monitored by the health monitoring system. Among the many characteristics of vehicle loads, weight characteristic has the most influence on the response is the. Therefore, the study of the correlation between load and response should focus on the impact of weight of traffic flow.

2.1 *The concept of categorized traffic*

The influence of weight factor of vehicle load in the structural response is studied by the following data simulation. The vehicle situation of a six-lane freeway within a minute is shown in Figure 1, Figure (a) shows the time chart of all vehicles passing the survey section. The slope of the line represents the speed of the vehicle. The positive slope means that the driving direction of the vehicle is the positive direction of the bridge, and negative slope means the opposite. Similarly, Figure(b) shows the time chart of vehicles over 15 tons. There are five vehicles that meet this condition, they are located on the 1st, 5th and 6th lanes.

(a) *(b)*

Figure 1: Six-lane freeway traffic flow on a bridge within a minute

Fig. 2 to Fig. 3 describe time histories of the traffic flow above for two kinds of response and their corresponding influence lines on a cable-stayed bridge. The time chart and influence line of displacement in the middle of bridge are depicted in the Fig. 2. It can be seen that the load-sensitive section of mid-span displacement effect is within 400m in the middle of the bridge. A large peak of displacement response appears in about 3sseconds, and a small peak appears in about 50 seconds. For the rest of the time the response level is relatively small. Similar observations can be drawn by looking another response. To sum up, there are three vehicles in the sensitive sections of displacement response during the whole measuring period. Two of them are traveling in sensitive sections within the first 10 seconds, they are located in the middle of the bridge at about 3seconds, the total weight of them is 38 tons. Another one enters the sensitive section around 55 seconds, it weights 21 tons. By the comparison of these results, it is not difficult to find that the peak of response is associated with the heavy vehicles above 15t. And the light vehicles have a lesser impact on response.

To sum up, since the contribution of heavy vehicles to the response is much greater than that of light vehicles, analyzing the traffic information of heavy vehicles is the key to studying the correlation between vehicle load and response. Due to the small number of heavy vehicles , the separation of heavy vehicles from traffic can greatly reduce the amount of data and improve the efficiency of monitoring and analysis. Therefore, by studying the vehicle characteristics of different vehicle weight in the traffic flow and comparing the parameter characteristics differents of the lighter vehicle (the light class) and the heavier vehicle (the heavy class) this paper promotes a reasonable category method of categorized traffic.

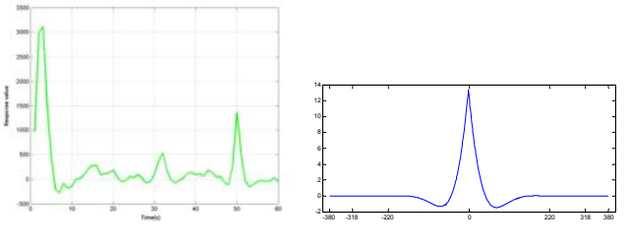

Figure 3: Time chart and Influence Line of Mid - span Moments Response of a Cable - Stayed Bridge

2.2 *Sensitivity Analysis and Determination of Statistical Interval*

In the process of building the categorized traffic, the statistical interval of the traffic flow parameters must be discussed first. Due to the traffic flow and load characteristics should to be considered in the response evaluation, the selection of parameter statistical interval should be based on the two characteristics above; Next, on the basis of determining the statistical interval, the division standard of categorized traffic should to be discussed.

For long-span bridges, due to the large longitudinal load length, the number of vehicles that can be deployed in the area of influence lines is large. The structural response is greatly affected by the overall load of the fleet and is relatively less affected by the axle load of a single vehicle. In the study of vehicle load, the traffic flow characteristics should be calculated during a period of time. The vehicle load characteristics should be analyzed from the traffic flow perspective, not from the perspective of the vehicle, so the appropriate statistical time interval should be chosen.

In the establishment of the traffic statistics model for traffic flow parameters such as flow, density, speed, load concentration and so on, the statistical interval should be firstly determined. The determination of the statistical interval is very important. It directly affects the shape of the traffic flow curve. This effect is more pronounced in the vicinity of the traffic capacity and in the crowded area. (Lloydsbach W. 1998) According to the general experience, when the statistical interval is lengthened, the discreteness of the measured point distribution decreases. At this time, an appropriate interval can be found so that the measured data can form a smooth and continuous curve. When the statistical interval is smaller than the optimal interval, the impact of single vehicle and other random factors can be significant. In previous studies at home and abroad, 15 minutes was usually used as the statistical interval for analyzing traffic flow statistical models, and 15 minutes was also the most commonly used statistical interval for calibrating the traffic flow model. (S. Chen, 2004) In addition, the recommended statistical interval in HCM over the years is also 15 minutes.

At the same time, the statistical interval also has an important influence on the parameters of the traffic flow considering the load characteristics in this paper, and it directly affects the statistical validity of the load concentration. Due to the consideration of vehicle load, traffic flow characteristics have changed significantly, and the statistical interval needs to be re-determined. Similarly, if the statistical interval is too large, the load concentration can hardly reflect the evolution of traffic flow in a short period of time and the stochastic characteristics of the basic parameters are reduced. If the statistical interval is small, the randomness and variability of various traffic parameters are too large, and the noise impact is serious. Therefore, the appropriate statistical interval should be able to eliminate the impact of random noise and to ensure the stability of the characteristics of traffic flow. And at the same time, the real traffic flow characteristics can be reflected to the greatest extent. The research on road capacity shows that the minimum statistical interval of traffic flow is the shortest time to ensure the stability of traffic flow. NRC considers that the statistical interval of 15 minutes can meet the requirements well. If the ratio of the statistical results of other interval to 15min is relatively small, it is considered that the statistical interval also reflects the traffic flow characteristics. Given the above, the statistic interval of 15 minutes is the best choice.

It showed, by example, if the statistical interval of 15 minutes is appropriate for the analysis of the load flow. One-month traffic data of a four-lane expressway of a certain section is selected, with the average traffic volume varying from 20 to 200. The hourly volume of traffic data varies significantly in a day. The traffic flow data is analyzed according to different statistical intervals, and the relationship between the variation of traffic volume and statistical interval is obtained and plotted in Fig. 4.

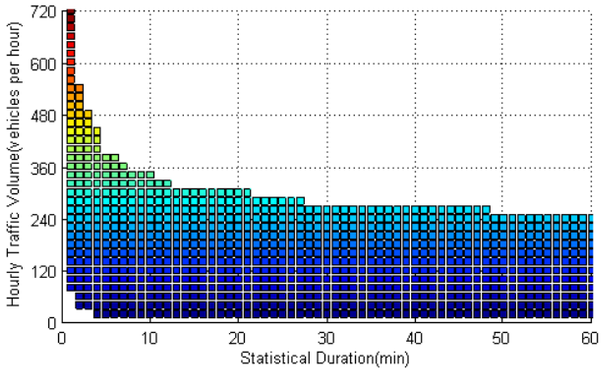

Figure 4: Relationship between statistical interval and traffic volume variability

Figure 4 reflects the relationship between traffic volume variability and statistical interval. Within the statistical interval of 13 minutes, the variability of traffic volume is very large. Some sections of statistical arguments have data, and some sections have no data, which reflects the randomness of traffic statistics and is distorted with the actual situation When the statistical interval exceeds 13min, the variation of traffic volume is basically stable, and the changes of statistical parameters need to be further investigated.

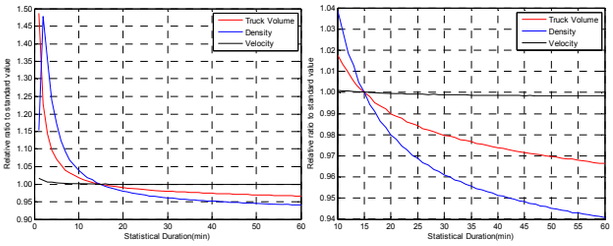

Figure 5: Performance of statistical interval and it's Partial enlargement

Select 15min as the standard statistical interval, and then compare traffic statistics obtained in other statistical intervals. The ratios of traffic statistics of other intervals to that of standard interval are drawn in Figure 5. Obviously, the result of deviation between the standard interval and the statistical interval higher than 15 min is basically within 5%. Therefore, in the subsequent calculation and analysis, the statistical interval of 15m in can meet the statistical requirements. 15min is also the basic statistical interval for data statistics in the traffic area.

Data statistic intervals higher than 60 min are widely regarded as inadequate to describe traffic behavior and characteristics under local traffic peak, so the relevant statistical calculations are also distorted. So the statistical interval of 15 minutes is also suitable for the analysis of traffic flow that incorporated load characteristics.

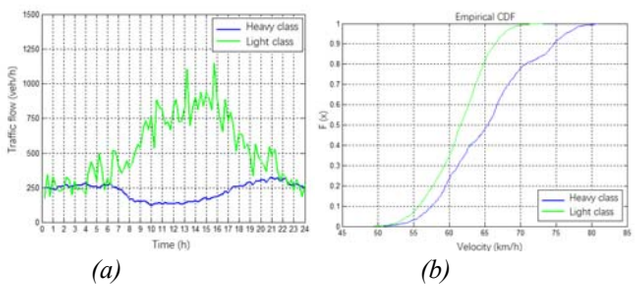
2.3 *Determination of categorized traffic standards*

The study about traffic flow and load characteristics above shows that the load level to a large extent affected the traffic flow characteristics. Considering that the effects of light vehicles below 20t on the response are not significant, the study of response should focus on the characteristics of the heavy class of traffic flow. In the process of forming a categorized traffic, the criteria for dividing the traffic flow should be uniformly selected according to the division standard of heavy truck mixed rate. Within a certain period of time particles (15min), select 20t as the limit of the heavy and light class. [In the 'Implementation on vehicles Overload management throughout the country' published by China's Ministry of Communications, China's Ministry of Public Security and five other ministries at 2004, the limit of overload traffic is prescribed. The standard of two-axle , three-axle, four-axle, five-axle and six-axle vehicles are 20t, 30t, 40t, 50t and 55t respectively. At the same time, according to the related survey results of freeway traffic load, the weight of the third type of vehicles (large buses and two-axle trucks) is about 8 ~ 16 t, and that of the fourth type of vehicles (triaxial large vans) is over 18t. Incorporating the above mentioned two points, within a certain period of time particles (15min), 20t can be selected as the limit of the heavy and light class.] Vehicles larger than 20t are grouped into the heavy class of traffic flow and less than 20t are classified as light class. The analysis of the characteristics of the traffic flow is based on the above conclusion.

In summary, this section presents a traffic classification method based on load characteristics of traffic. In a certain period of time particles, traffic flow is divided into light class and heavy class according to the vehicle load. The criteria of categorized traffic and the size of the time particle (Statistical interval) are determined, which lays the foundation for establishing a vehicle load model for response evaluation.

3 TRAFFIC LOAD AND FLOW PARAMETERS ANALYSIS BASED ON THE NEW METHOD

In the field of traffic the dynamic evolution law of traffic flow can be clarified by of traffic parameters, which is based on traffic engineering. By this method , for a vehicle-loaded bridge, a number of traffic and load parameters can be used to determine the "load flow" acting on the bridge, so as to assess its load response. In which the most crucial point is to analyze the correlation between traffic flow and load parameters by building a dynamic traffic flow model.

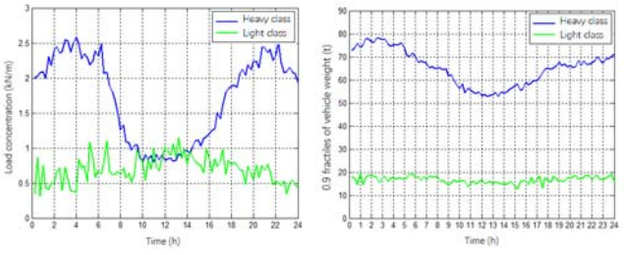


At the traffic level it forms a converged traffic flow by flow-dense statistics and loading. Considering the traffic load, these characteristics of the traffic flow occur essential changes. When considering the traffic flow of the load, the load parameters are combined or related to the relationship of vehicle density, average speed and other parameters. Due to the high randomness of the vehicle load (firstly, the type of vehicle is random , their appearance and axle type are different ; secondly, the load of the same type of vehicle is random , the load is irrelevant). It is difficult to take account of some parameters into the traffic flow. This problem can be solved by the above-mentioned method of categorized traffic. The establishment of categorized traffic greatly weakens the trouble to assimilated traffic caused by the random ness of the vehicle load.

3.1 *Parameter analysis of categorized traffic*

In the traditional traffic engineering , the parameters that characterize the characteristics of the traffic flow include flow, density and speed. In the range of the load flow, the parameters that characterize the traffic flow characteristics include load concentration and vehicle weight of 0.9 times the bifurcation value. The following analysis of categorized traffic is based on the above five parameters.

By analyzing the changes of categorized traffic flow and speed accumulation in one day, we can get Figure 6. As shown in Figure 6 (a), heavy traffic flow is more stable at any time in one day, which is about 250veh / h, during 8 am and 7pm, it appears a slight decline; On the contrary, light class traffic daily flow increased first and then decreased in the above period, the peak flow of which can be up to 1000veh / h, and during the rest time it is stable, which is around 250veh / h. For light class traffic fluctuations we can make a speculation as follows: during 8 am and 7pm, the Traffic flow is larger than that at any other time. During this period, most of the vehicles are small household vehicles and two-axle vans, the weight of the bicycle is lighter relatively. Although the traffic flow is relatively lower during the rest time, the mix-in ratio of trucks approaching the weigh t limit of the light class increases. Therefore, it is speculated that the load concentration levels in the two periods shouldn't differ significantly. The speculation above need to be verified later. If the speculation is consistent with the statistical value, combined with the characteristics that the light class vehicle has less influence on the response, the light class vehicle traffic flow can be simplified into the single parameter of the average load concentration at each moment when building the load model of the evaluation response, As a load model of "base frequency" of traffic flow load, the degree of convergence would be evaluated with the characteristics of heavy class traffic.

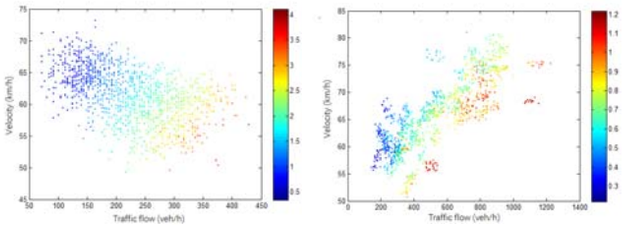


Accoding to Figure 6 (a), the speed distribution range of heavy class traffic is less than that of the light class, consistent with the above analysis results. It is known that the weight of vehicles would affect the speed: the heavier the weight, the slower the speed. So for the light class traffic it can be inferred that: during the daytime, the vehicle speed is faster and the load level is lower; in contrast, at night the speed is slower and the load level is higher. The inference supports the above speculation that the light class traffic has a relatively stable load concentration level at any time, and provides a basis for the assumption that the light class traffic flow takes only a single load concentration as a model parameter.

(a) *(b)*

Figure 6: The flow diversification and the cumulative speed distribution of categorized traffic in one day

For the categorized traffic, by analyzing its load characteristics, load concentration and the 0.9 times the quantile value changes of vehicle weight in a day, we can get Figure 7. As shown in Figure 7(a), the load intensity of heavy class traffic changes in a large range, which reaches the minimum value (about 0.9kn/m) during 8 am and 4 pm and reaches the maximum value (about 2.5kn/m) at night. The less load intensity during the daytime can attribute to less traffic. The load intensity of light class traffic in one day is more evenly distributed (about 0.7kn / m), which confirms the previous inference. Therefore, when building the load model for evaluating response, the light class traffic can be simplified as a single parameter of the average load concentration at each moment to form a load model with light class traffic load concentration as the "fundamental frequency" of the traffic load. According to Figure 7(b), the distribution tendency of 0.9-fold quantile value of heavy class is consistent with that of load concentration distribution, both of which are lower during daytime and larger at night. However, since the upper limit of light class division is 20t and the meaning of 0.9-fold quantile value is to determine the upper limit of traffic load, the 0.9-fold quantile value of light class does not get any time characteristic.

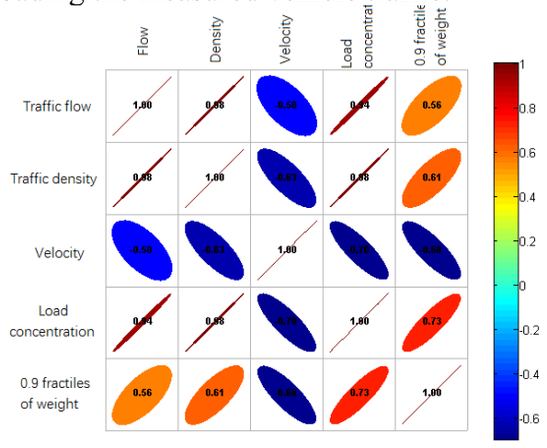


(a) *(b)*

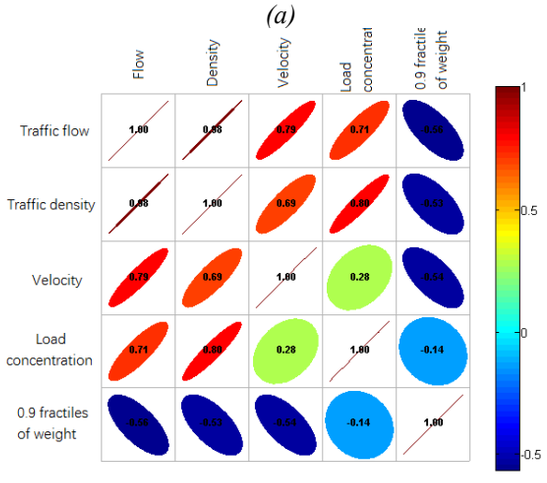
Figure 7: The distribution of load concentration and the 0.9-fold quantile value for categorized traffic weight in one day

3.2 *Parameter correlation of categorized traffic*

Based on a comprehensive analysis of the correlation of the traffic flow, speed and load concentration, we can get Figure 8. According to the fuzzy boundaries of the relevance cloud graph in Figure 8, There is no obvious correlation between the three groups. The heavy class load concentration is evenly distributed with some linear combination between traffic flow and speed. And the correlation is obvious for the heavy class traffic, due to the linear correlation between the three parameters. If the flow rate-velocity matrix interval can be formed, the level of the load concentration between adjacent intervals is uniform and continuous. Therefore, it exits continuity in the response distribution between adjacent sections, which helps to build the load model to evaluate the structural response. Figure 9 shows the correlation between various parameters of



categorized traffic, heavy class shows in Figure (a) and light class in Figure (b).



(a) *(b)*

Figure 8: Relationship between loading concentration, flow and velocity of categorized traffic

In summary, the light class traffic flow can be simplified into a single parameter of average load concentration at each moment when forming the load model of evaluation response. A load model with light class load concentration as the "base frequency" of traffic flow load can be built, and the response of heavy class traffic flow characteristics can be evaluated. Besides, for heavy class traffic, the method of dividing the two parameters into intervals can be applied when building the load model. The change of load concentration in different flow and velocity intervals would be counted, and the range of bridge response would be determined according to the influence line. In addition, the response of loaded bridge would be evaluated and corrected by loading the measured vehicle traffic.

Figure 9: The visual relevance between different parameters

4 CONCLUSION

To sum up, the existing monitoring methods mainly focuses on ensuring the safety performance of the structure, bud it can not find the daily performance changes in the structure. As a result, it can not give the opinion of repair in the structural damage development. In this paper, a kind of bridge health monitoring method based on normal state is proposed. This normal state method can make full use of load information and response information to exert timeliness and diversity of health monitoring system. On this basis, the influence of the load characteristics of traffic flow on the structure response is studied, and the concept of categorized traffic is proposed. The conclusions are as follows:

(1) Since the contribution of heavy vehicles to the response is much greater than that of light vehicles, analyzing the traffic information of heavy vehicles is the key to studying the correlation between vehicle load and response. Due to the small number of heavy vehicles, the separation of heavy vehicles from traffic can greatly reduce the amount of data and improve the efficiency of monitoring and analysis. Considering this, traffic flow is divided into light class and heavy class according to the vehicle load.

(2) 15 minutes is chosen as the statistical interval for analyzing traffic flow, because it is able to eliminate the impact of random noise and to ensure the stability of the characteristics of traffic flow.

(3) In summary, the light class traffic flow can be simplified into a single parameter of average load concentration at each moment when forming the load model of evaluation response. A load model with light class load concentration as the "base frequency" of traffic flow load can be built, and the response of heavy class traffic flow characteristics can be evaluated. Besides, for heavy class traffic, the method of dividing the two parameters into intervals can be applied when building the load model. The change of load concentration in different flow and velocity intervals would be counted, and the range of bridge response would be determined according to the influence line. In addition, the response of loaded bridge would be evaluated and corrected by loading the measured vehicle traffic.

ABSTRACT: Overloaded vehicular traffic on bridges can cause premature damage such as fatigue cracking and accelerated aging and it can consequently reduce the service life. It is also an important part of any assessment of bridge safety at the ultimate limit state. Available Weigh-In-Motion (WIM) data provides an excellent source to study the effect of traffic loads on bridge structures. The objective of this study is to compare various types of traffic load and their effects on bridges in the United States and Europe. The database considered in this study includes WIM measurements from 20 U.S. states with 92 million records and 5 European countries (Poland, Netherlands, Czech Republic, Slovenia and Slovakia) with 2 million vehicles. The raw data is filtered to eliminate systematic errors and other questionable records. The filtering criteria used to process WIM data in the U.S. and Europe are compared.

1 INTRODUCTION

The prescience of traffic loads on bridges and understanding the trends of increasing traffic load is essential to maximize the lives of existing aging infrastructure and to design new bridges. Knowledge of current service level truck traffic helps in existing bridge evaluation and testing as well as bridge maintenance. ASCE's recently released 2017 annual report card grades American infrastructure with a D+ which means it is in poor, at-risk condition. Bridges are a significant part of transport infrastructure, and American bridges were graded C+. This means that they are in mediocre condition and need attention. In the United States (U.S.), the design service life of a bridge is 75 years as specified by AASTHO LRFD (Nowak 1999, AASHTO LRFD 2016). In Europe, the default service life of bridges is 100 years as dictated by the Eurocode although some variation is allowed in the National Annexes.

In this study, vehicular traffic loads and their load effects on bridges are compared across several states in the U.S. and a range of countries in Europe. Load effects, such as moments and shears, are dependent on trucks' axle configurations and distributions of load on each axle rather than just the overall weight of the vehicle (GVW). In this study, Weigh-In-Motion (WIM) data from 45 WIM stations, spatially distributed across 20 states in the U.S. (consisting of 92 million records) and 5 WIM stations in 5 countries across Europe (Poland, Netherlands, Czech Republic, Slovenia and Slovakia) (consisting of 2 million records) are aggregated and studied. The filtering criteria seek to filter rational data without eliminating unlikely axle configurations. Filtering criteria used in the U.S. and Europe are compared. Sorting criteria to sort regular truck traffic are also presented. The results are plotted on probability paper in the form of cumulative distribution functions (CDF's). From each plot, the mean and standard deviation can be easily read. Matlab routines are developed to filter raw data and for analysis purposes.

2 WIM DATABASE

The WIM database considered in this study is one of the most extensive databases available, collected from 45 WIM stations in the United States and 5 WIM stations in Europe. Out of 45 WIM stations, 13 are obtained from Alabama Department of Transportation (ALDOT), 14 from the NCHRP 12-76 (Sivakumar *et al.* 2011) project and 18 from FHWA under special pavement studies (SPSs). Out of 13 locations obtained from ALDOT, data for 2009 to 2014 was obtained first from ALDOT and later data for 2006 to 2008 was gathered from the authors of the ALDOT sponsored project – 'Development of Alabama traffic factors for use in mechanistic-empirical pavement design' (Turochy *et al.* 2015).

Records from the countries in Europe were obtained through the European 6th Framework research project, *ARCHES* and were previously used in other

studies (Enright and OBrien 2011, OBrien and Enright 2013). It is to be noted that the European data obtained were previously filtered, and more detail on the filtering procedures are given in the online report (Enright and OBrien 2011). From the data collected for each location, information about location, date, and time of collection, Gross vehicle weight (GVW), vehicle class, no. of axles, axle spacing, and individual axle loads were obtained for each vehicle recorded. Table 1 and Table 2 show in detail the information about vehicles obtained at each location.

Table 1. Details of WIM stations in Europe.

Country	WIM station	Year	Number of days	Number of records
Poland	Wroclaw	2008	87	176,758
Netherlands	Woerden	2005	77	578,573
Czech Republic	Sedlice	2007-2008	148	540,945
Slovenia	Vransko	2006	39	127,064
Slovakia	Branisko	2005-2006	290	528,198
				1,951,538

3 WIM FILTERING

In the analysis of WIM-based live load, the quality of the data is perhaps more important than the quantity of data. The first step in the analysis of WIM-based live loads is to scrub the data. The error in data recording caused by formatting, inaccurate calibration of sensors, erroneous post-processing, vehicles changing lanes, and other errors are to be filtered out. Also, by doing a general observation of the data, incorrect vehicle records can be seen. The type of sensors at each WIM site and the date last calibrated also contribute to better quality assurance.

Past studies about WIM have shown various reasons for WIM data filtering (Flinner 2004, Traffic Monitoring Guide 2016). NCHRP 12-76 developed some of the filtering criteria based on researcher experience and logical judgment. The SHRP 2 report (Kulicki *et al.* 2015) also used some of these filtering criteria. For the analysis of the data in this paper, filtering is used to reduce error and provide quality data. Sorting criteria are used to sort out regular truck traffic from a pool of WIM collected quality data.

The filtering process is applied to all the WIM data. A GVW threshold limit of 90 kN (20 kips) is used because it was observed that there was a lot of light traffic data that creates less damage on bridges and decreases the processing time. To have uniformity in the filtering, the criteria shown in Table 3 are applied to both data sets, from the two continents. Filtered results are shown in Table 1 and Table 2. The comparison of filtering criteria (Table 3) was made to understand explicitly the criteria's used by most researchers in the United States and Europe.

4 COMPARISION OF FILTERING CRITERIA IN U.S. AND EUROPE

Table 3 summarizes and compares the filtering criterias that are used in retaining the qualitative WIM data and further used for live load analysis. The filtering procedure used in this study is consistent with NCHRP 12-76 and in the study used in European WIM data (Enright and OBrien 2011). However, there is a variation in the threshold limits used; this variation is because of the interpretation of the different researchers and the nature of truck axle configurations in the United States and Europe.

5 DATA ANALYSIS

The quality data of the regular truck traffic after application of the filtering and sorting criteria are plotted on probability paper. GVW and load effects (moment ratio and shear ratio) for all data are combined. The data are plotted on probability paper to show the variability of the loads in each state and country considered in this study.

5.1 *Gross vehicle weight*

The GVW of WIM data for all the stations are plotted on probability paper to compare and see the differences between traffic loads on highways. The cumulative distribution functions (CDF's) of GVW for all locations are shown in Figure 1. It is observed that the mean (0.5 on the Y-axis) varies from 125 kN (28 kips) to 275 kN (62 kips). Variability in the distributions is seen to increase in the top 20% or so of the data (0.8 on the Y-axis), and greater variation in the top 1 % (0.99 on the Y-axis). In general, no single country or state stands out from the others in its traffic distribution. However, compared to all the data in this study, the European countries have heavier traffic loads. The Netherlands has the top 1% of heaviest loads compared to other data. Information on construction and interpretation of the normal probability paper plots can be found in probability textbooks, e.g. Nowak & Collins (2013).

Table 3. Comparison of filtering criteria

Criteria	In this paper	In NCHRP 12-76	In Enright and O'Brien 2011
GVW	< 90 kN	< 54 kN	< 36 kN
axle weight	<9 kN & >312 kN	Same	> 400 kN
total length	< 2.2 m & > 36 m	> 36 m	N/A
steer axle spacing	< 1.5 m	< 1.5 m	N/A
axle spacing	< 1 m	< 1 m	< 0.4 m
speed	< 16 km/h & > 160 km/h	< 16 km/h & > 160 km/h	< 20 km/h & > 120 km/h
GVW	± 10% the sum of axle weights	± 10% the sum of axle weights	± 0.45 kN of sum of axle weights
FHWA class	< 3 & > 14	< 3 & > 14	N/A
sum of axle spacing	> wheel base by 0.3 m	> length of truck	> length of truck
axles	N/A	< 3	N/A
steer axle weight	N/A	< 27 kN & > 112 kN	N/A

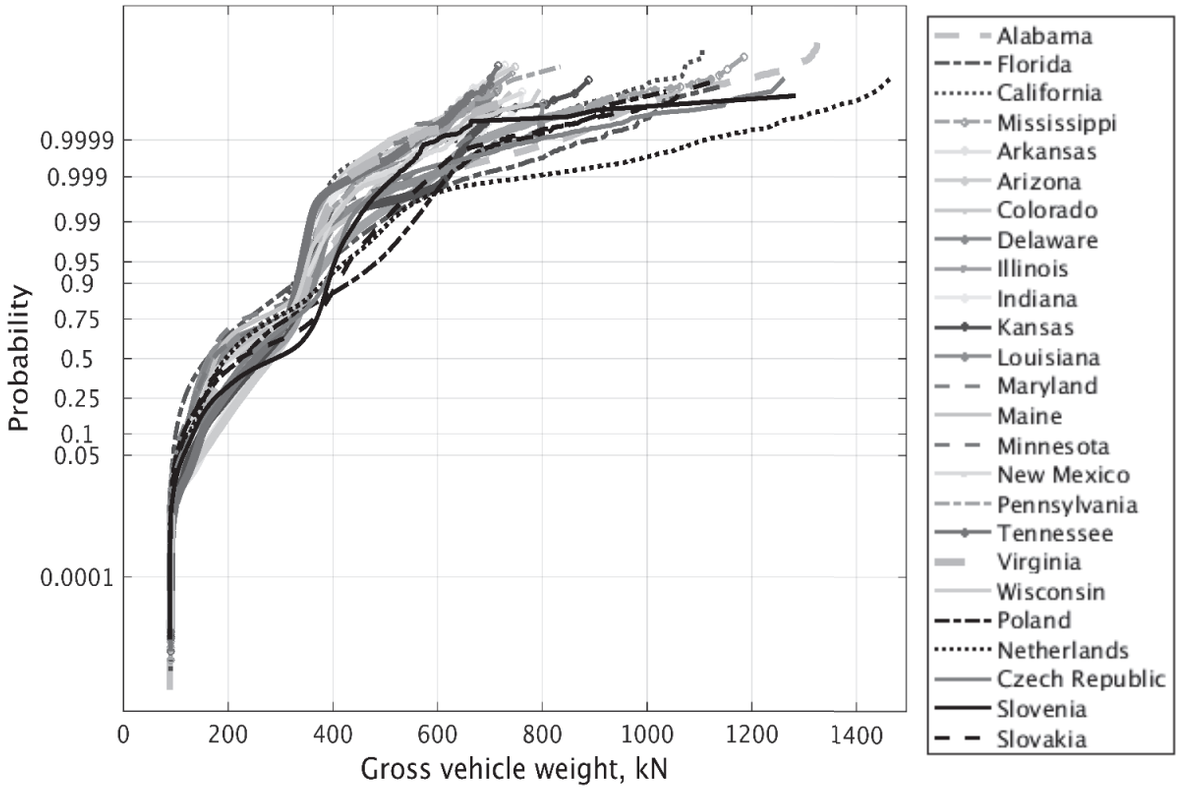

Figure 1. CDF's of GVW for all WIM stations

5.2 *Live load moments and shear forces*

The service life of the bridge is greatly affected by heavy vehicles loads and the resulting stresses on the bridge structure. It is, in fact, the load effects, such as moments and shear forces, that cause damage rather than gross vehicle weights (GVW). However, every state and country has a set of legal load limits to restrict the weights of vehicles and permits are required for those vehicles with loads above the legal limit. By using these regulations moments and shear forces can be controlled by imposing limits on load and axle configurations. To study this effect, the vehicles in the WIM data are run over the influence lines on bridges to obtain the maximum moments and shear forces over simply supported spans ranging from 9 m to 60 m. Each vehicle in this study is run over the influence line, and the resulting load effects were calculated using a MATLAB routine. Spans of 9 m, 18 m, 27 m, 36 m and 60 m are considered. For better interpretation, each calculated traffic load effect was divided by the corresponding effect found using the

current AASHTO design live load model used in the U.S. (HL-93).

In the probability paper plots shown for respective spans ranging from 9 m to 60 m in Figure 2 to Figure 6, the CDF curves for the top 20 % of heaviest vehicles in Poland and Netherlands are similar to the GVW plot. The extreme values of moment ratio are for the 18 m span (Figure 3). The mean values of a moment ratio range from 0.25 to 0.55 in the 9 m span, 0.22 to 0.6 in the 18 m span, 0.25 to 0.6 in the 27 m span, 0.25 to 0.56 in the 36 m span and 0.2 to 0.45 in the 60 m span. They are reasonably similar through the full range of spans.

Shear forces in the form of shear ratios are shown on probability paper plots for respective spans ranging from 9 m to 60 m in Figure 7 to Figure 11. The extreme values of shear ratios are for the 60 m span (Figure 11). Also, the Mississippi, Arkansas, and Florida states in the U.S. have greater shear load effects compared to the European countries. The trend in shear ratios are not similar to that for moment ratios. Shear ratios vary as the span length increases. This is evident in probability paper plots for shear ratios for the 9 m span (Figure 7) to 60 m spans (Figure 11). The mean values of shear ratio range from 0.3 to 0.6 in the 9 m span, 0.33 to 0.68 in the 18 m span, 0.25 to 0.7 in the 27 m span, 0.25 to 0.75 in the 36 m span and 0.2 to 0.8 in the 60 m span. As for moment ratios, they are reasonably similar for the full range of spans.

6 CONCLUSIONS

The extensive database used in this study included 92 million records from the U.S. and 2 million records from Europe. All the vehicular traffic was analyzed, and results are plotted on probability paper. Below are the conclusions from this study:

- Loads and load effects in Europe tend to be higher compared to the U.S.
- There is no single location that stands out for both higher loads and load effects.
- Load effects such as bending moment and shear force are more sensitive to short spans than longer spans.
- The filtering criteria used by the researchers in the two continents are similar. In Europe, additional filtering criteria based on ghost axles and split axles are used as photographic evidence was available. It is hard to present criteria that are definitive as traffic loads and WIM technologies/software are different in some sites and vary between continents.

The filtering criteria for inconsistent data and erroneous data eliminate a reasonable amount of data. Quality control methods should be adopted in each WIM location so that maximum benefits are obtained from the investment. Not only is this economical, but

higher quality data helps in providing a more accurate prediction of vehicular traffic.

Bridge Network Planning for Heavy Vehicles in Queensland

T.M. Pape, P. Shaw, C. Doherty, G. Danicic, A. Robertson
AECOM, Brisbane, Australia

D. Wilson
Queensland Department of Transport and Main Roads, Brisbane, Australia

ABSTRACT: The Queensland Department of Transport and Main Roads (TMR) is responsible for managing approximately 3000 bridges on its road network. Of these, approximately 2200 bridges are on the heavy vehicle network supporting freight movement and the Queensland economy. As the asset manager, TMR is responsible for ensuring that its assets are managed safely and cost-effectively and that heavy vehicle access is permitted where possible to support a vibrant economy. Since 2012, TMR has been assessing the structural capacities and associated risks of TMR's bridges on the defined heavy vehicle road network, which has included developing an understanding and quantification of the current structural capacities of all bridges. Out of this program, TMR, in conjunction with AECOM, has developed a rapid network operation assessment tool suitable for heavy vehicle scenario analyses. Building on this knowledge, TMR are reviewing heavy vehicle network plans for current and future demands to identify network capacity constraints and opportunities for TMR owned or managed bridge structures. This paper discusses the tools and methodology used to investigate heavy vehicle access to the network and presents the findings.

1 INTRODUCTION

Australia's economy is facilitated by freight movements and supports a diverse range of industries and sectors from commodities, import/export services, machinery and other manufacturing goods, agricultural applications, and general consumer and retail requirements (BITRE 2014). To enable this, road infrastructure plays a significant role.

The importance of freight transportation to the economy and wider community is recognized and supported by governments nationwide, and they therefore provide appropriate planning, policy development, funding, construction and management of supporting infrastructure to facilitate ongoing access for the freight community (Austroads, 2014). BITRE (2011) note that the freight task has increased eight-fold over the past five decades, and is predicted to continue growing.

On that basis, there has been renewed focus on enabling High Productivity Freight Vehicles (HPFV) increasing levels of network access. Various sources state direct benefits such as safety, productivity, fuel and environmental savings and indirect benefits such as lowering community freight exposure and slightly lower infrastructure maintenance costs (Austroads, 2014). This has been facilitated by the development of the Performance-Based Standard (PBS) scheme, which was formally adopted by the National Transport Commission (NTC) in 2011 as an alternative heavy vehicle regulatory scheme and is administered by the National Heavy Vehicle Regulator (NHVR). It seeks to match the right vehicles to the right tasks and networks, whilst encouraging innovation in vehicle design to achieve higher productivity, safety and minimize infrastructure impacts (NTC 2007, 2008).

Under the Heavy Vehicle National Law (HVNL), road network access is governed by road managers. Network road access is generally classified into two key types of heavy vehicle classes, namely (Hitchins and Ritzinger, 2016):

- General Access Vehicles: have unrestricted access to the public road network unless otherwise signposted
- Restricted Access Vehicles: can only access certain parts of the network in accordance with Notice or permit requirements

For the PBS scheme, a series of access levels has been established that cater for the various vehicle performance levels (Levels 1-4). Additional sub-levels were developed for PBS levels 2-4 to translate vehicle combination length requirements in gazettals prepared to incorporate PBS vehicles on existing networks (Class "A" and "B") (Hitchins & Ritzinger, 2016). These levels are governed by mass and vehicle length limits respectively, with a maximum gross mass of 50 t presently limiting General Access vehi-

Table 1. Summary of Network Access Requirements under PBS Scheme (NTC, 2008)

PBS Level	Example Vehicle	Network access by vehicle length (L) (m)		Mass Restrictions for Bridge Access (i.e. Bridge Access Formulae) (M = mass, L = length)	
		Class A	Class B	M ≤ 42.5 t	M ≥ 42.5 t
1	Semi-trailer General Access	< 20 (general access, gross mass limit = 50 t)		M ≤ 3L+12.5	M ≤ L+32.5
2	B-double, Truck and Dog	≤ 26	26< L≤ 30	M ≤ 3L+12.5	M ≤ 1.5L +29.5
3	A-double, Double Road Trains	≤ 36.5	36.5< L≤ 42	M ≤ 3L + 12.5	
4	B-triple, A-triple Triple Road Trains	≤ 53.5	53.5< L≤ 60		

cles. Table 1 maps the various PBS levels to network vehicles currently permitted network access.

In order for PBS vehicles to be granted unrestricted general network access, they are required to comply with a number of regulatory and standard requirements in keeping with these PBS levels which broadly take into account vehicle performance, safety, and infrastructure damage control (NTC 2007, 2008). The latter point relates predominantly to pavement and bridge infrastructure.

For bridges, additional access requirements have been implemented, which are outlined in Table 2. As a minimum, a vehicle is deemed to be Tier-1 compliant and be granted access to bridges if the vehicle specification complies with the axle spacing/mass schedule formulae, which are outlined in Table 1. These rules also apply for distances and masses between axle groups. An additional rule for B-doubles for clear spacing between axle groups is required.

Where vehicles do not comply with the Tier 1 conditions, the vehicle is then assessed against Tier 2 conditions, and failing that, Tier 3 conditions which requires a bridge-specific assessment by the asset owner. There is an implied understanding that with increasing tier levels, that increasing access is granted to heavy vehicles (Austroads, 2016).

Table 2. Requirements for bridge access under PBS Scheme (NTC, 2008)

Tier	Description	Requirements
1	*General access or Restricted access*	Access granted if compliant with axle spacing/mass schedule formulae
2	*Special access*	Load effects less than existing network vehicle
3	*Specific link access*	Approval by owner of bridge (detailed, bridge-specific assessment)

There are times where network upgrades are sought to obtain additional productivity gains, namely due to commercial, economic or community drivers. Where this occurs, consideration is required in relation to the impacts on the network as a whole. In particular, the impacts of such upgrades can be significant on bridges located on the network. As bridges are often known to be the cause of network access constraints (Austroads 2016), knowledge of these constraints can inform future planning requirements and inform funding allocation. It is therefore desirable to understand the capability of a bridge network for its current level of access and the capacity of the network to cater for future increases to meet productivity expectations.

The Queensland Department of Transport and Main Roads (TMR) is responsible for managing approximately 3000 bridges on its road network. Of these, approximately 2200 bridges are on the heavy vehicle network supporting freight movement and the Queensland economy. As the asset manager, it is TMR's responsibility to ensure that its assets are managed safely and cost-effectively and that heavy vehicle access is permitted where possible to support a vibrant economy. Since 2012, TMR has been assessing the structural capacities and associated risks of TMR's bridges on the defined heavy vehicle road network, which has included developing an understanding and quantification of the current structural capacities of all bridges. Out of this program, TMR, in conjunction with AECOM, developed a rapid network operation assessment tool suitable for heavy vehicle scenario analyses.

Building on this knowledge, TMR are reviewing heavy vehicle network plans for current and future demands to identify network capacity constraints and opportunities for TMR owned or managed bridge structures. This knowledge can then be used for investment planning for potential bridge renewals or upgrades, as well as confirming what action would be required to support the increased level of access to facilitate freight productivity. TMR were interested in exploring the Tier 1 PBS compliance requirements that defines vehicle access for a bridge network as a baseline.

2 OBJECTIVES

This paper discusses the tools and methodology used to investigate current and future bridge network access (general and unrestricted) for heavy vehicles that comply with current requirements for the TMR network. More specifically, the following objectives were identified.

- To identify and review network-critical bridges for various heavy vehicle configurations for current and proposed network route changes/upgrades.
- To identify and discuss key bridge restrictions and differences between current and proposed network route designations.
- To explore variations in network access for different PBS vehicles that comply with the Tier 1- axle mass and spacing schedule formulae for bridge access (known herein as Tier 1-compliant PBS vehicles).
- To explore any variations between the PBS levels and classes.
- To test the assumptions that underpins the PBS Tier 1 axle mass and spacing schedule formulae.

3 ASSESSMENT PARAMETERS

3.1 *Vehicle Development*

A suite of vehicles was developed to explore the different objectives of the project. Vehicles were divided into different groups according to type and functionality. The key areas for review were:

- Multi-Combination Vehicles (MCV) currently permitted unrestricted network access (compliant with Heavy Vehicle National Law (HVNL) requirements)
- PBS vehicles compliant with the Tier 1 axle spacing and mass schedule formulae (NTC 2007, 2008)
- A-double vehicles, with variations on axle groupings, spacing and configurations which are PBS Level 2B compliant.

Vehicles were defined by axle loads and axle spacings. "Gamed" vehicles were created alongside realistic vehicles aimed to maximise load effects while remaining compliant to the respective guide-line/ notice. For PBS vehicles, the axle loads were limited by the Tier 1formulae as specified Table 1 and GML axle group load levels as defined by HVNL. Figure 1 illustrates the spread of the designed PBS vehicles in each level. In total 35 vehicles were assessed across all PBS levels.

3.2 *Network and Bridge Selection*

Assessments were conducted on all bridges on the TMR freight and general access networks where the bridge information was available. Current and proposed PBS levels were also included. Table 3 gives an overview of the assessed bridge types.

Table 3. Summary of TMR's general access and freight route bridge stock

	Route Type			
	General Access	B-double	Road Train	Total
Simply Supported	581	1330	669	2580
Continuous	86	71	33	190
Timber	197	32	75	304
Excluded	16	4	1	21
Total	880	1437	778	3095

3.3 *Bridge Assessment Tool (NOAD)*

The assessment was carried out using TMR's Network Operational (bridge) Assessment Database (NOAD) and associated application (NOADapp) – which is similar to TMR's permit assessment tool with additional functionality for network application. It includes capacity assessments for all continuous and timber bridges on the TMR's road freight network and a significant proportion of the General Access network. The primary output of NOAD is TMR's accepted load rating factor, Equivalency Ra-

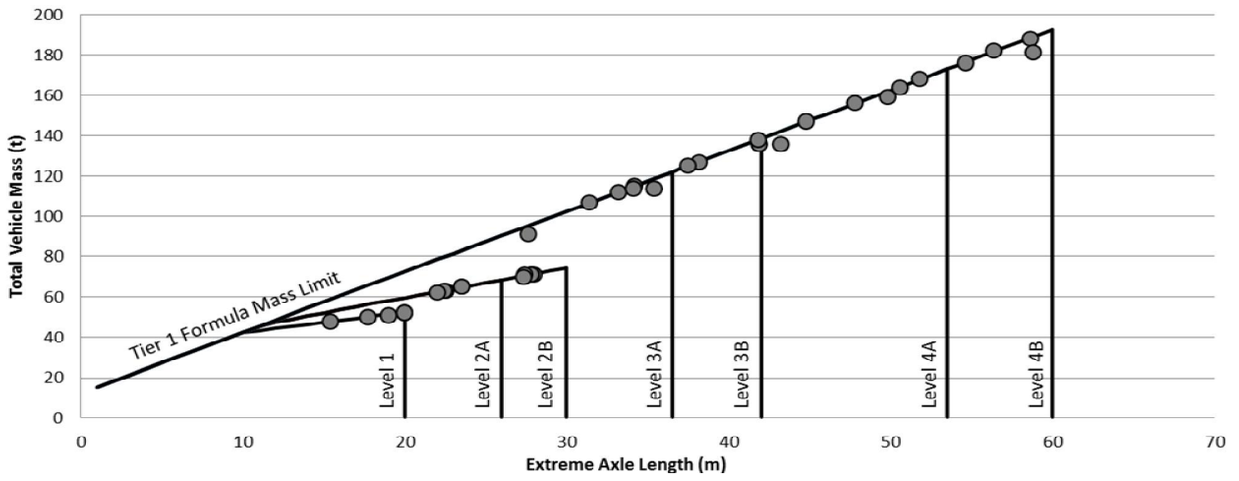

Figure 1. Graphical representation of PBS vehicle mass limits with designed PBS vehicles plotted

tio Traffic (ERT). The 95% confidence intervals ERTlo and ERTup are also computed, the mean of which is referred to as ERTnom. ERT values are calculated for all bridge structural components including superstructure and substructure. The formulation of ERT is given in Equation 1. (Heywood et al., 2014)

$$ERT = \frac{Available\ capacity\ for\ live\ load\ effects}{Live\ load\ applied\ by\ assessed\ vehicles} \quad (1)$$

NOAD produces a number of secondary outputs which allow for deeper investigation of specific bridges and vehicles impacts. These include:

- Critical position of vehicle on bridge
- Critical component of bridge (Superstructure/ Substructure)
- Combined live load factor and dynamic load allowance required for ERT = 1 (Risk Profile)
- Unfactored load effect comparison to the as-of right network vehicle (Useful for benchmarking and Tier 2 assessments)

NOAD is able to assess TMR's entire network for a given vehicle in approximately 1minute. Functionality was added to allow multiple vehicles to be run consecutively and results automatically recorded to a database. The assessment process now runs almost complete autonomously, greatly reducing the time taken for network assessments.

3.4 *Bridge Network Review*

PBS vehicles were assessed at an inventory level with the live loading factors in accordance with AS5100.7. At the completion of all vehicle runs, results were collated and tabulated. The assessment criteria used to review access for each vehicle to the bridge net-work is set out in Table 4.

Table 4. Assessment criteria

Outcome	Description
Accept $ERT_{lo}>1$	Bridge has sufficient capacity for access of the assessed vehicle
Review1 $ERT_{lo}<1$ $ERT_{nom}>1$	Bridge access requires review Permission for access will require certain conditions to be met (e.g. on-board mass monitoring)
Review2 $ERT_{nom}<1$ $ERT_{up}>1$	Bridge access is not permitted unless specific measures justify access. This may include: - Route specific requirements - Isolated bridge restriction in an otherwise accessible route - Intervention/investment Acceptance for access will require: - structure management plans - access controls - acceptance of shortening of asset life and associated risks
Reject ERTup<1	Bridge does not have sufficient capacity for access by the assessed vehicle

Results were collated in terms of their individual assessment criteria, based on either the number of Rejects (least conservative) or the number of non-accepts (Review 1, Review 2 and Rejects), which is the most conservative approach representing a 95% confidence level of access. The latter approach was more in keeping with TMR's high-level future planning objectives, and has been accepted herein. For detailed planning, investment and decision making, TMR may use a position between these two extremes consistent with the decision parameters in Table 4. Note that these assessments do not account for a 'past-performance' check based on current network access (e.g. road train and B-double routes), and are based purely on the capacities of the bridges to support the vehicles assessed.

Results were methodically reviewed, noting any trends and impacts due to vehicle type, bridge-specific issues, and changes in access due to proposed network upgrades. To explore route-specific changes, results were filtered and compared with existing and proposed network access levels. A list of deficient structures was identified for each route giving visibility of the impact different vehicle types have on the network.

4 RESULTS

4.1 *Overview*

Results were collated for all vehicles and bridges in a database allowing for a number of investigations to be conducted. The entire network was assessed for each bridge's designated network vehicle for a specific route (Route MCV) to give a baseline measurement of the network's performance. Comparisons between PBS vehicle at each access level and the TMR Guideline Vehicles were made using the number of Non-Accept bridges A review of the current and proposed PBS routes was presented as well as a comparison of different vehicle types, specifically A-doubles, B-doubles and Truck and Dogs.

4.2 *Current freight network*

One method for assessing network performance is to assess each structure for its Route MCV. Some routes allow Higher Mass Limit (HML) vehicles which are captured in the Route MCV's axle group loads.

Table 5 shows the typical Route MCV vehicle for each route type. Figure 2 illustrates the impact of the Route MCV and TMR assessment vehicles across the whole network and provides a baseline risk profile for assessing other vehicle impacts. It is important to reiterate that a non-accept criteria was used which does not represent a management strate-

gy for the existing network, but rather gives a forward looking planning perspective.

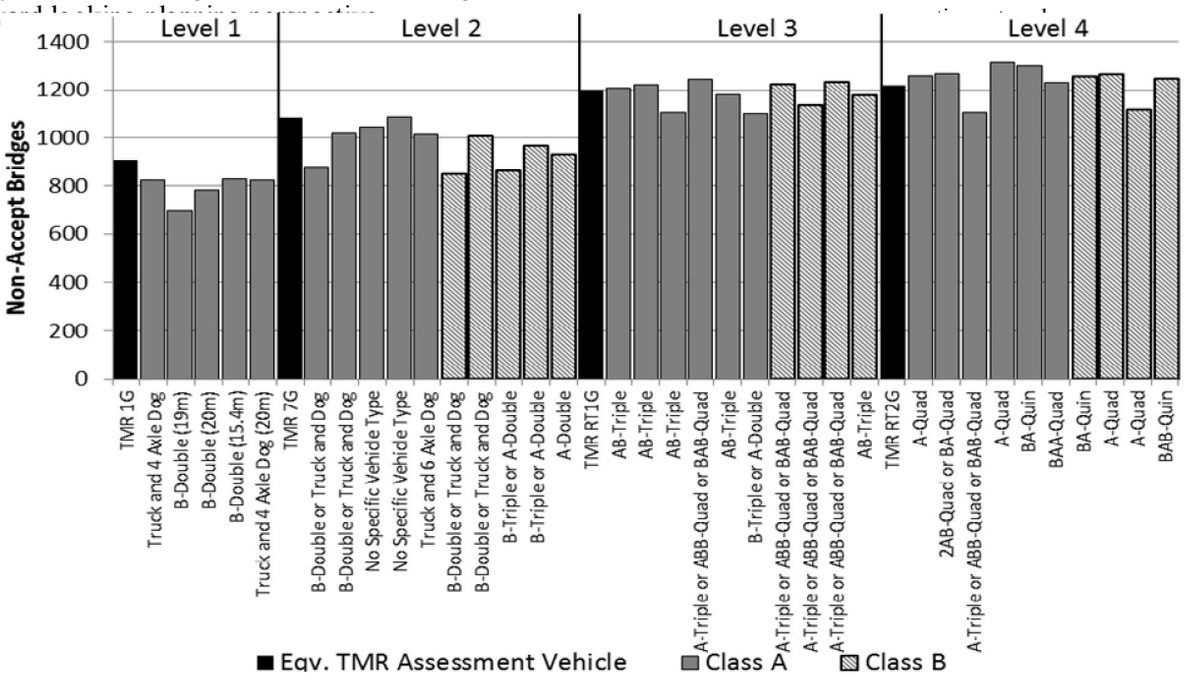

Figure 2. PBS vehicles assessment results across entire network

Table 5. Route MCVs by route type

Route Type	Route MCV
General Access	1G (GML), 1H (HML)
B-double	7G (GML), 7H (HML)
Road Train 1	RT1G(13) (GML), RT1H(13) (HML)
Road Train 2	RT2G(13) (GML), RT2H(13) (HML)

4.3 *PBS Vehicles*

To review the impact of introducing PBS vehicles on the bridge network, the number of non-accept structures was recorded for each PBS vehicle (Figure 3) and compared to the accepted guideline vehicles at GML loading. Generally at higher PBS levels, the impact to the bridge network is higher with some exceptions as discussed later.

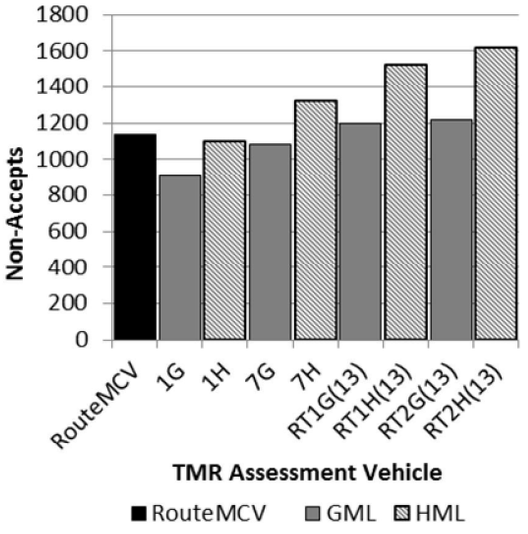

Figure 3. Impact of TMR Assessment Vehicles

Figure 4 provides a count of the critical bridge elements when assessed at each PBS level. It was noted that a structure may have multiple non-accept elements and this is captured. The assessed PBS level includes all sub level vehicle as all levels are compliant to the higher levels (e.g. Assessed PBS level 2B includes vehicles from level 2A and 1).

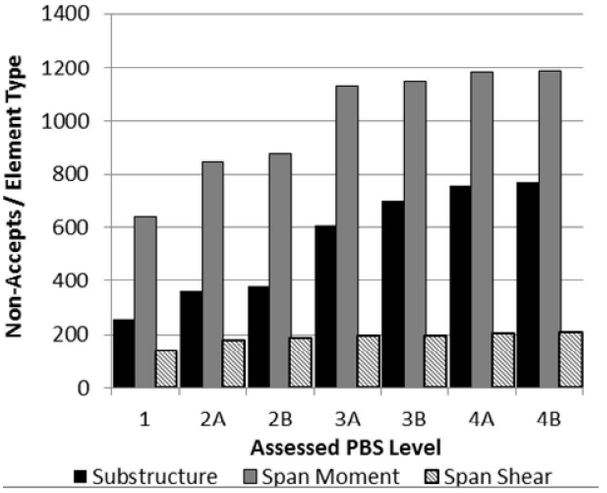

Figure 4. Distribution of non-accepts by critical element

It was found that the Tier 1 formulae may not be appropriate for limiting access consistently across the network. Bridges limited by shear capacity in their superstructure are impacted more by increased load intensity rather than vehicle length. This is in contrast to long span or continuous bridges and bridges limited by pier capacity, where longer vehicles result in

higher load effects with similar load intensities. Short span bridges were not affected by longer vehicles.

PBS Levels 1 and 2 generally produced results less than that of the equivalent TMR assessment vehicles. Levels 3 and 4 PBS vehicles were found to potentially exceed the TMR assessment road trains. B-Class vehicles typically performed better than the equivalent level A-Class vehicles. This was likely due to the design of the B-Class vehicles where it was difficult to add extra axle groups without exceeding the Tier 1 formulae mass limit.

The B-double results highlighted the sensitivity of the network to small changes in vehicle length and axle positions. The shortest B-double assessed was 15.4m and produced the largest number of non-accepts in its group. The 19m B-double, while heavier, produced the least number of rejects in the group. This sensitivity is attributed to the large number of short span bridges on the network, where a larger portion of the shorter vehicle could load bridges. Truck and dog configurations were found to perform slightly worse than the B-doubles.

A-double and A-Triple vehicles typically produced lower number of non-accepts then the equivalent B-double and B-Triple vehicles. This was attributed to the A-double and A-Triple vehicles having lower load intensity then the B Equivalents, possessing an extra axle group and longer overall length. However, the length requirements resulted in the shorter A-double vehicles assessing as PBS Level 2B, whereas B-doubles can run on the Level 2A network.

Timber bridges were found to not always trigger access restraints. Typically they have short spans and were less sensitive to vehicle length, and thus if assessed "Accept" for Level 1 and 2 vehicles, were assessed "Accept" for longer Level 3 and 4 vehicles. Likewise long span and continuous bridges were more commonly assessed as "Non-accept" in the higher Levels 3 and 4.

As part of the study, the sensitivity of the critical vehicle position and critical element due to axle configurations was investigated. It was found that small changes to axle configurations could greatly impact the critical element of the structure. The selection of test vehicles must be varied enough to capture this effect. This remains a risk of this study, that the critical compliant vehicle for each bridge was not found.

TMR currently specifies a number of routes with an existing PBS level and proposed PBS level. Figure 5 shows the impact of the created PBS vehicles on the existing PBS routes and compares it to the Route MCV assessment for that route. Note that no routes currently allow access for 4B PBS vehicles.

It was found that when looking at the existing PBS network only, the PBS vehicles on all levels have similar or less impact than the Route MCV.

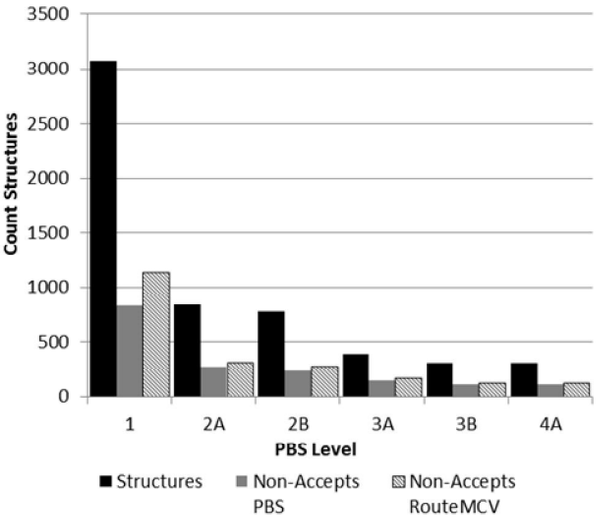

Figure 5. Existing PBS network performance

DISCUSSION

The results have highlighted a number of key observations in relation to TMR's bridge network for the vehicles assessed. These includes

- The variation in access noted across the different vehicles within each PBS level
- The majority of PBS Level 1 and 2 vehicles assess well against the Route MCV with similar access noted. Access results for Level 3 and 4 vehicles were variable and some vehicles exceeded the current network vehicle used to benchmark performance.
- The mass intensity of the vehicle type was found to be more significant than the length of the vehicle (as distinguished by Class "B" vehicles), however identifying an appropriate Class "B" vehicle to assess against the network was found to be difficult.
- The A-double and A-triple variants were found to result in slightly greater bridge access in comparison to B-double and B-triple variants
- The assessed PBS level of a bridge did not always comply with the current or proposed PBS level for a network route.

In addition to these observations, there are also more fundamental questions that have been raised. For Tier 1 compliant vehicles to gain unrestricted access to bridges on a PBS network, the vehicle must comply with the axle spacing/mass schedule formulae, with no further review required from the bridge owner.

As noted in Section 1, TMR have recently been through a process to identify bridges on the freight route that are currently operating at margins less than those recommended by the Australian Standards. These are predominantly structures that were designed for superseded design classes, have higher-

risk failure mechanisms, have condition issues or are insufficient for the loads currently accessing the network. In order to facilitate network access, TMR has maintained access for a number of network specific vehicles (the Route MCV), acknowledging the risks associated with this operation and developing appropriate structure management plans to cater for this. For new vehicles requesting general network access, this is granted where the load effects of this vehicle are less than those of the network vehicle.

From a planning perspective, understanding these risks inform future capital expenditure works (such as strengthening) which may be required to maintain or increase network access for productivity gains.

Risks remain, however, in the use of the Tier 1 bridge access formula. These concerns are not new and have previously been noted in two recent Austroads reports (Austroads 2014, 2016). The origin of the "Bridge Formulae" lies in the publication of the axle spacing/mass schedules to simplify access assessments in a day where computers were not extensively used (Austroads 2014). The schedules were developed from maximum span bending moment using pre-1976 bridge design codes (MS-18 design class). It did not account for shear considerations or substructure components, and made assumptions that access would not be granted to those bridges designed prior to the MS-18 design regime. Austroads also goes on to state that many of the conditions and assumptions on the use of the formulae have been omitted from the current PBS guidelines when assessing bridges. There are also concerns on the rigour of the formulae given the original method was borne out of working stress methodology and is currently being used in a Limit States assessment environment. A more detailed account of these considerations has been discussed previously (Shaw et al. 2017).

Additional considerations in this area include:

- Vehicle access dispensations for HML loading surrounding road friendly suspension
- Planning processes associated with proposed route upgrades for PBS levels
- The permit access regime for single trip and period permits, particularly for load-carrying combination vehicles such as HLPs and low loaders.

To date, very little work has been done to address these concerns which is confirmed by the current work and highlights that additional research is required. Echoing Recommendation 1.01 in the Austroads Report AP-R532-16, the Tier 1 bridge assessment methodology should be reviewed to "eliminate these uncertainties and inconsistencies to provide more robust, consistent and reliable Tier 1 Bridge Assessments". This in turn will lead to greater confidence in network assessments and appropriate risk management strategies when reviewing network operations for current and future access.

5 CONCLUSION

A study has been carried out on TMR's bridge network for PBS vehicles to explore opportunities for improved productivity and identify network-critical bridges that will impact on current and proposed network access. A number of realistic and "gamed" assessment vehicles were developed to comply with the PBS Tier 1 access requirements, which are reliant on axle mass and spacing schedules, for each level (1 – 4) and class (A and B). The bridge network was assessed for access using TMR's Network Operational (bridge) Assessment Database (NOAD), using a set of pre-defined assessment criteria. The assessment included structural capacity outputs for superstructure and substructure components, as well as continuous and timber bridges.

On a network level, results have highlighted the degree of variability within a PBS level that exists between different vehicle types, with axle configuration found to be most influential. Longer and heavier vehicles as defined by PBS Levels 3 and 4 were noted to be more critical for bridges with longer spans or that were continuous. PBS vehicles with A-type couplings were found to produce marginally better assessment results than vehicles with B-type couplings due to the longer draw-bar and additional axle group. A significant proportion of the network was flagged for non-access due to structural deficiencies in substructure or continuous components.

More broadly, the results lead to questions regarding the plausibility of the current PBS Tier 1 vehicle assessment regime which does not account for the assumptions that the original axle spacing mass schedules were based on. It is recommended that bridge access conditions be reviewed for the PBS scheme.

Strength evaluation of prestressed concrete bridges by dynamic load testing

E.S. Hernandez & J.J. Myers
Department of Civil, Architectural and Environmental Engineering, Missouri University of Science and Technology, Rolla, Missouri, USA

ABSTRACT: The load rating of a bridge can be obtained by means of field load testing. The dynamic load allowance or impact factor is one of the parameters used to establish a bridge's flexural capacity during the rating evaluation process. The focus of this study centered on comparing Bridge A7957's dynamic load allowance obtained by experimental and analytical methods proposed in three different design and evaluation codes. To attain this goal, Bridge A7957 was instrumented with accelerometers at different locations. For different dynamic tests, the spans' response was measured with the accelerometers and a laser vibrometer. The dynamic load allowance was obtained experimentally and analytically using current design and evaluation codes. The impact factors obtained analytically resulted in larger values compared to the experimental results. This difference might have repercussions in the strength evaluation results of bridge structures.

1 INTRODUCTION

Field testing has largely confirmed reserves of strength capacity in existing bridges despite their age and existing condition. The sources that explain these differences might be diverse and may be attributed to field parameters that are not considered during the design or strength evaluation process of a bridge structure. The impact factor (IM) or dynamic load allowance (DLA) is a parameter that can be verified by means of a dynamic load test (Cai & Shahawy 2003, AASHTO 2010). Most design codes consider the dynamic load effects, by increasing the magnitude of the static live load applied to a bridge structure in some fraction. An accurate estimation of the DLA yields safe and rational load ratings of existing bridge structures. However, the complex nature of the factors affecting the DLA makes it difficult to estimate its value during the design and strength evaluation of a bridge (Barker & Pucket 2013).

The main objective of this study was to obtain the dynamic load allowance of Bridge A7957 by analytical and experimental methods to compare differences that may arise when both approaches are employed in bridge design and evaluation. To achieve this goal, the dynamic response of Bridge A7957's exterior spans was recorded with accelerometers and a laser vibrometer. The dynamic load allowance (or impact factor) was estimated using the analytical provisions proposed by the Ontario Highway Bridge Design Code (OHBDC) (OMTC 1983), the American Association of State Highway and Transportation Officials (AASHTO) Standard Specifications (AASHTO 1992), and the AASHTO LRFD Bridge Design Specifications (AASHTO 2012). The experimental DLA was estimated by comparing the measured dynamic and static responses of the bridge structure. The following sections detail the instrumentation plan and the static and dynamic tests conducted on Bridge A7957 to estimate its experimental dynamic load allowance before the structure was open in service.

2 ANALYTICAL AND EXPERIMENTAL DYNAMIC LOAD ALLOWANCE

Design codes have traditionally proposed analytical expressions to estimate the dynamic load allowance of a bridge structure as a function of the span length or the fundamental frequency of a bridge. In 1983, the Ontario Highway Bridge Design Code (OHBDC) presented an approach that allows to estimate the DLA in terms of the fundamental frequency of the bridge structure as Figure 1 illustrates. The AASHTO Standard Specifications (AASHTO 1992) recommend an expression to estimate the impact factor in terms of the span length, L, as presented in Equation 1:

$$IM = \frac{15.24}{L + 38} \leq 0.30 \quad (1)$$

In 1994, the AASHTO LRFD Bridge Design Specifications (AASHTO 2012) replaced the term *impact factor* used in the AASHTO Standard Specifications (AASHTO 1992) with the term *dynamic load allowance*. A DLA value independent of the span length was adopted as equal to 0.33 (33% of the static live load) for bridge components other than the deck.

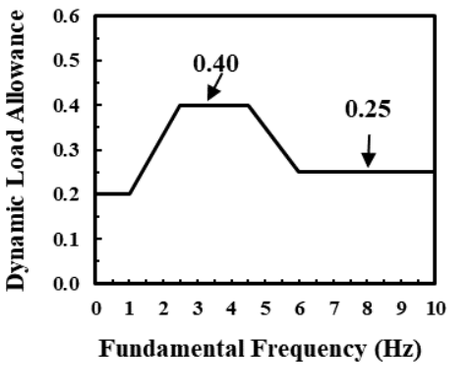

Figure 1. Dynamic load allowance vs. fundamental frequency (OMTC 1983, Paultre et al. 1992).

Several experimental definitions of the DLA have been reported in literature (Bakht & Pinjarkar 1989). As presented by Deng et al. (2015), the DLA is commonly defined as the ratio of the maximum dynamic and static responses regardless of whether the two maximum responses occur simultaneously. Equation 1 allows to calculate the DLA according to this definition.

$$DLA = \frac{R_{dyn} - R_{sta}}{R_{sta}} \quad (1)$$

where DLA = dynamic load allowance; R_{dyn} = maximum dynamic response; and R_{sta} = maximum static response. The estimation of the static response can be obtained by: (1) conducting a quasi-static test where vehicles move across the bridge at a low speed between 5–16 km/h; (2) filtering the measured dynamic response with a low-pass filter to eliminate the dynamic components of the signal; and (3) using finite element models (FEM) to calculate the static response when the vehicle weight and loading position are known (Paultre et al. 1992, Deng et al. 2015). In this study, the first and third options were selected and compared to estimate Bridge A7957's DLA.

3 BRIDGE DESCRIPTION

Bridge A7957, built along Highway 50 in Osage County, Missouri, is a three-span, continuous, precast-prestressed (PC/PS) concrete bridge with a 30-degree skew angle (Figs. 2-3), and excellent road surface condition. Each span has PC/PS concrete Nebraska University 53 (NU53) girders (Hernandez & Myers 2015a, Hernandez & Myers 2016a). The first span's girders are 30.48 m long and fabricated with conventional concrete (CC), defined by the Missouri Department of Transportation (MoDOT) as a Class A mixture, with a compressive strength of 55.2 MPa. The second span's girders are 36.58 m long and cast with high-strength self-consolidating concrete (HS-SCC) of 68.9 MPa. Girders in the third span are 30.48 m long and employed normal-strength self-consolidating concrete (NS-SCC) with a nominal compressive strength of 55.2 MPa. The cast-in-place (CIP) deck was built with a 25% fly ash replacement of a portland cement mixture with design compressive strength of 27.6 MPa. The PC/PS concrete panels, with a target compressive strength of 55.2 MPa, span between the girders' top flange underneath the CIP deck in the transverse direction (Fig. 2b). The superstructure is supported by two abutments and two intermediate bents (Fig. 2a) with target compressive strength of 20.7 MPa. The second intermediate bent and abutments were cast with a concrete mixture that used a 20% fly ash replacement of portland cement and a nominal compressive strength of 20.7 MPa. The third intermediate bent was built using high-volume fly ash concrete (HVFAC) with a 50% fly ash replacement of portland cement and a specified compressive strength of 20.7 MPa.

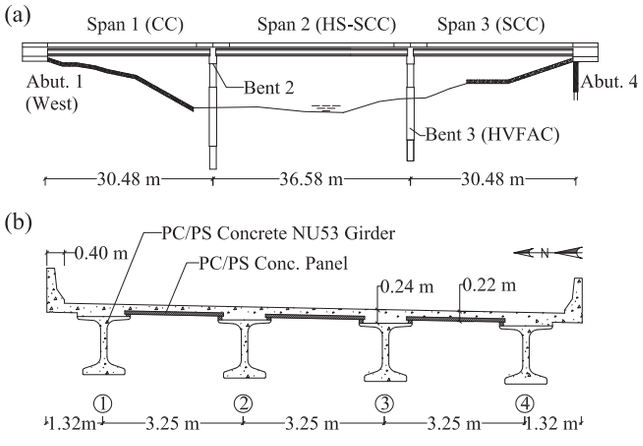

Figure 2. Bridge A7957. (a) elevation; (b) cross-section.

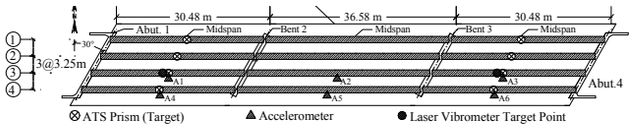

Figure 3. Bridge A7957 plan view and instrumentation layout.

4 FIELD TEST EQUIPMENT

The instrumentation was designed to collect: (1) the static vertical deflection at midspan of girders 1–4

(spans 1 and 3); (2) the dynamic deflection at midspan of girder 3 (spans 1 and 3); and (3) girder 3 and 4's vertical acceleration at midspan locations (Fig. 3). The details about the sensors employed and their installation are described next.

4.1 *Accelerometers*

Six accelerometers were deployed on the bridge superstructure to record the vertical acceleration at midspan sections of PC/PS concrete girders 3 and 4 (Figure 3). Figures 3-4a show details of the measurement instruments mounted to the girders' bottom flange (only at midspan sections).

4.2 *Automated total station (ATS)*

An automated total station (ATS), Leica TCA 2003, was used to estimate the girders' deflection during the static test conducted on the first and third spans. The ATS recorded the coordinates of targets (prisms) placed at the exterior-span girders' bottom flange (at midspan sections), as illustrated in Figures 3-4. The ATS has an accuracy of 1 mm ± 1 ppm (distance measurements) and 0.5 arc-seconds (angular measurements). The accuracy of the ATS has been reported as 0.1 mm in vertical deflection measurements (Merkle & Myers 2004).

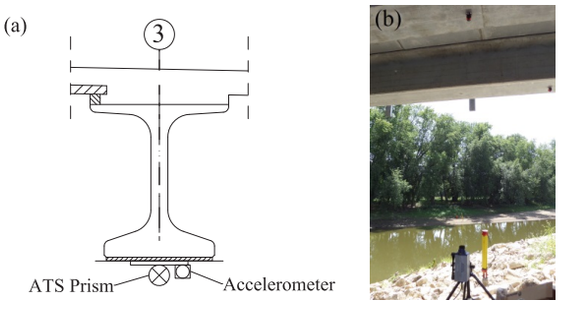

Figure 4. Girder 3's instrumentation. (a) ATS prism and accelerometer. (b) Remote sensing vibrometer (RSV-150).

4.3 *Remote sensing vibrometer*

The remote sensor vibrometer (RSV-150), shown in Figure 4b, was employed to record the dynamic bridge response (vertical deflection) of the exterior spans' girder 3 (at midspan). The RSV-150 has a bandwidth up to 2 MHz for nondestructive test (NDT) measurements and can detect the vibration and displacement of distant structures. The accuracy of the RSV-150 to record the dynamic response of a point is ± 0.025mm.

5 FIELD TEST PROCEDURE

Static and dynamic tests were conducted on Bridge A7957. The following subsections depict the test procedure and load configurations planned to obtain the maximum static and dynamic responses of the bridge superstructure.

5.1 *Static test*

Static load tests were performed on the exterior spans of the bridge. A MoDOT H20 dump truck was utilized to obtain the maximum static response of the bridge superstructure. Quasi-static tests were conducted by passing the truck at a crawl speed of 16 km/h. Figure 5 shows the average truck's dimensions and weight. Figure 6 illustrates the load configuration applied to spans 1 and 3 during the static tests 1and 2.

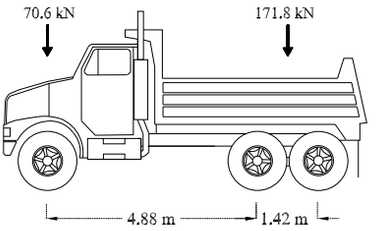

Figure 5. MoDOT H20 dump truck (average dimensions).

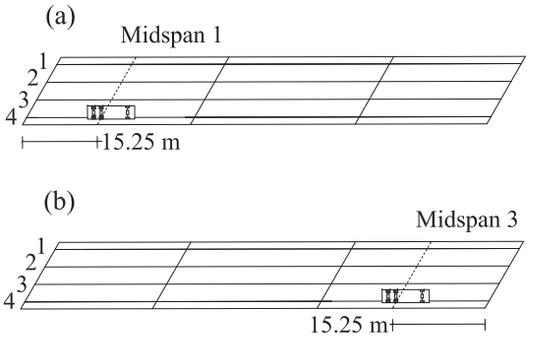

Figure 6. Static test configurations. (a) Static test 1 (span 1). (b) Static test 2 (span 3).

5.2 *Dynamic test*

Speeds varying from 16 km/h to 96.6 km/h were used during the dynamic load tests. For each test, the truck speed was increased at a rate of 16 km/h until the maximum speed of 96 km/h was attained. The maximum dynamic and static responses were compared to estimate the experimental dynamic load allowance. Experimental data was recorded with the RSV-150 at a sampling rate of 120 Hz. The truck was driven over the south side of the bridge (along the west–east and east–west directions), separated 0.60 m from the safety barrier's edge.

6 FINITE ELEMENT MODELING

The commercial finite element software ABAQUS (Simulia 2012) was employed to create 3D, linear,

finite-element simulations of Bridge A7957 for each of the load stops described in Figure 6. The bridge's geometry was created from construction documents and was modeled with solid elements (Fig. 7). The finite element models simulated the bridge's geometry considering the primary members (CIP RC deck and PC/PS concrete girders) and secondary members (RC safety barriers and diaphragms). Each bridge component material was assumed to be linear elastic for the level of load applied during the tests. The modulus of elasticity (MOE) of the different bridge components was obtained by averaging the results of MOE tests conducted on companion specimens the same day of the tests. Table 1 lists the modulus of elasticity of the different bridge component that were used to create the finite element simulations as reported by Hernandez & Myers (2015b) and Hernandez & Myers (2016b). Two different sets of MOE values were used as the FEM input, depending on whether the load stop was conducted in April or August of 2014. Experimental deflection values reported by Hernandez & Myers (2016c) were utilized to calibrate the finite element models and to reproduce a geometry that could predict the bridge's response with a reasonable level of accuracy. The trucks' positions over the slab deck and distances between the trucks' axles were simulated as recorded for each load configuration. Concentrated forces were applied at the location of the trucks' wheels to simulate the axle's weight values reported by MoDOT personnel.

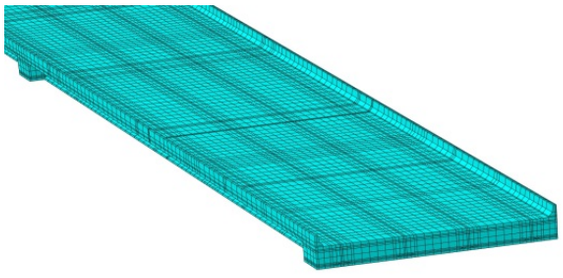

Figure 7. Bridge A7957's finite element model geometry.

Table 1. Bridge Components' MOE.

Bridge Component	April Test (GPa)	August Test (GPa)
Span 1's Girders	38.80	41.20
Span 2's Girders	39.30	42.25
Span 3's Girders	38.70	39.99
Safety Barriers	35.51	33.78
CIP Deck, Diaphragms	31.03	31.03

7 LOAD TEST RESULTS

The vertical static deflection measured at midspan locations of the end spans 1 and 3's girders are shown in Figure 8. Although both exterior spans have the same geometry (Fig. 2) and were subjected to the same truck load, a 5% difference was observed between the deflection responses recorded at midspan 1 and 3. The difference might be attributed to: first, a slight variation on the application of the truck load on each span; second, the accuracy of the ATS might have affected the experimental values due to the low level of load applied during the test. This difference may be corrected in future tests by taking caution regarding the location of truck loads and the level of load used during the test. The level of load applied needs to be relatively high so that the error of ATS measurements is kept low during data recording. In addition, Girder 3's static deflection at midspan (Fig. 8) was compared to the quasi-static (filtered) response recorded with the RSV-150 when the truck passed over the bridge at a crawl speed of 16 km/h and the static deflection value obtained with the FEM simulations. These comparisons were conducted to verify if the quasi-static deflection recorded with the RSV-150 was representative of the bridge's static response and could be used to estimate the dynamic load allowance.

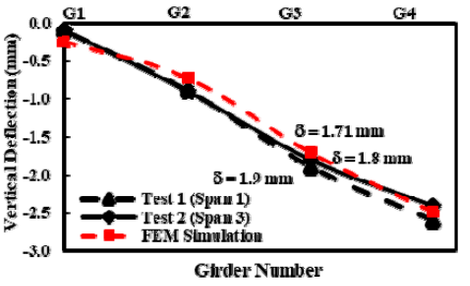

Figure 8. Vertical static deflection (girders' midspan).

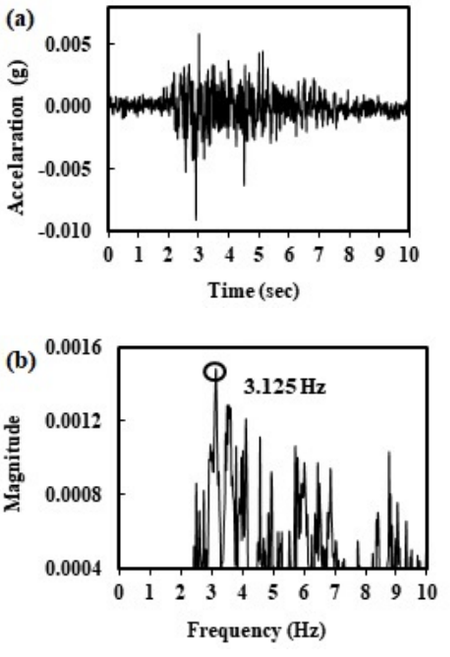

Figure 9. Dynamic response. (a) Measured acceleration. (b) Natural frequency extracted through FFT.

Figure 9a presents the acceleration response collected with sensor A1 (Fig. 3) deployed at girder 3's midspan. This acceleration data was recorded when the truck was driven from west to east at 96 km/h. Figure 9b presents the fundamental frequency estimated from Fast Fourier Transformation (FFT) applied to the recorded acceleration data shown in Figure 9a. The fundamental frequency of the bridge corresponded to a value of 3.125 Hz. Using the approach proposed by the OMTC (1983), this fundamental frequency yields a dynamic load allowance value of 0.40 according to Figure 1. Figure 10 shows that the quasi-static deflection recorded with RSV-150 was very close to the static deflection collected with the ATS (1.77 mm vs. 1.80 mm) and the value obtained from FEM simulations (1.77 mm vs. 1.71 mm) shown in Figure 8. Consequently, the filtered quasi-static response of the spans was assumed to be the maximum static deflection of girder 3's midspan and was employed to estimate the exterior spans' DLA for the different truck speeds employed during the dynamic test.

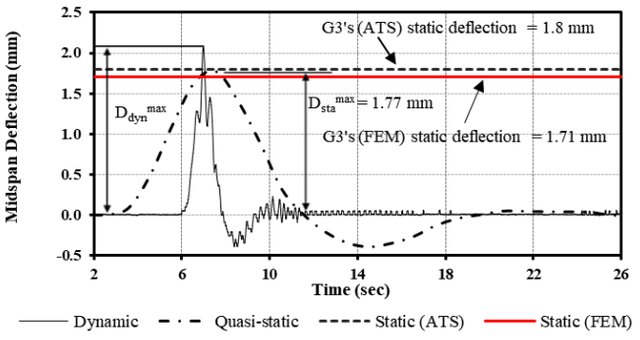

Figure 10. Maximum static and dynamic vertical deflection.

In addition, Figure 10 presents the maximum dynamic deflection (2.08 mm) measured with the RSV-150 when the truck speed was 96 km/h. The experimental DLA was estimated with Equation 3.

$$DLA^{\exp} = \frac{D_{dyn}^{\max} - D_{sta}^{\max}}{D_{sta}^{\max}} \quad (3)$$

where DLA^{exp} = experimental dynamic load allowance; D_{dyn}^{max} = maximum dynamic (measured) vertical deflection (mm); and D_{sta}^{max} = maximum static deflection obtained from passing the test truck at a crawl speed (mm). Table 2 lists shows in row 1 the trucks used to pass the truck over the bridge during the test. The bridge's maximum dynamic and static deflection recorded for the different speeds during the dynamic tests are presented in rows 2 and 3, respectively. In addition, the experimental values of the DLA corresponding to different truck speeds are presented in row 4. The maximum experimental DLA value was 0.175 corresponding to a truck speed of 96 km/h. The values of the experimental dynamic amplification factor, DAF^{exp}, are presented in row 5 and were estimated using Equation 4:

$$DAF^{\exp} = (1 + DLA^{\exp}) \quad (4)$$

Table 2. Experimental and analytical dynamic load allowance.

Speed (km/h)	16	32	48	64	80	96
D_{dyn}^{max} (mm)	1.77	1.79	1.79	1.77	2.03	2.08
D_{sta}^{max} (mm)	1.77	1.77	1.77	1.77	1.77	1.77
DLA^{exp}	0.000	0.010	0.010	0.000	0.150	0.175
DAF^{exp}	1.000	1.010	1.010	1.000	1.150	1.175
DLA*	0.40	0.40	0.40	0.40	0.40	0.40
IM** (spans 1 & 3)	0.222	0.222	0.222	0.222	0.222	0.222
IM** (span 2)	0.204	0.204	0.204	0.204	0.204	0.204
DLA*	0.33	0.33	0.33	0.33	0.33	0.33

Values were estimated according to: * Ontario Highway Bridge Design Specification (OMTC 1983); ** AASHTO Standard Specifications (AASHTO 1992); and *** AASHTO LRFD Bridge Design Specifications (AASHTO 2012).

The DLA estimated as a function of the bridge's fundamental frequency proposed by the OHBDC (OMTC 1983) is presented in row 6. The impact factor obtained with the AASHTO Standard Specifications (AASHTO 1992) and the DLA obtained using the AASHTO LRFD Bridge Design Specifications (AASHTO 2012) are listed in rows 7 through 9. By comparing the maximum experimental DLA to the values obtained using these design specifications (OMTC 1983, AASHTO 1992, AASHTO 2012), it was determined that the analytical methods provided more conservative values compared to the experimental approach. This variation may have different sources and may directly affect the strength evaluation result or load rating of an existing bridge obtained by the analytical methods proposed in current evaluation codes.

8 CONCLUSIONS

The dynamic load allowance of Bridge A7957 was successfully obtained from field measurements and by using three design specifications (OMTC 1983, AASHTO 1992, AASHTO 2012). The DLA obtained with the design specifications resulted in larger values compared to the values obtained experimentally. This disparity might be attributed to the presence of in-situ factors not considered by the theoretical methods proposed in current design and evaluation codes. More importantly, the variation between the experimental and analytical DLA values may have repercussions in the rating factor of exist-

ing bridge structures. Further research is needed to understand the source of these variations.

Limiting exterior girder rotation during construction for non-skewed bridges

L. Hui, F. Hraib, R. Hindi
Department of Civil Engineering
Saint Louis University, St. Louis, MO, United States

ABSTRACT: The construction of bridge deck often introduces torsional moments acting on the exterior girder. To resist these torsional moments and limit the maximum exterior girder rotation, diaphragms are commonly used as transverse bracing system. However, the unbraced lengths of diaphragms are typically not designed for torsional moments introduced by construction loads, which may lead to excessive rotation on bridge exterior girders during bridge deck construction and cause many safety and maintenance issues. In this study, a parametric study was conducted to evaluate the significance of different parameters. Around three thousand finite element models were built to find the relation between the rotation and the ratio of the unbraced length (B) to girder depth (D). Then a simple method, which combines primary curves of B/D ratio in term of rotation and tables of section modification coefficients, was developed for engineers to easily determine the maximum allowable B/D ratio.

1 INTRODUCTION

The bridge decks are generally designed past over the exterior girder to increase the width of decks without increasing the required number of girders. As shown in Figure 1, the construction of deck overhang on steel bridge girders is most often finished with the usage of overhang brackets (Idaho Department of Transportation., 2008). Generally, deck overhang brackets are placed between 0.9 m and 1.2 m along the exterior girder to support the construction loads coming from fresh concrete, screed machine, and other construction live loads. In most cases, these loads on the overhang brackets can result in torsional moments acting on the exterior girders and may lead to exterior girder rotation that is not usually considered in the design of bridges (Yang, 2009).

The maximum rotation of exterior girder can be expected to occur near the midspan section (Ashiquzzaman et al., 2016). In this case, the fresh concrete is placed from the abutment, or the pier of the bridge to the middle of the span, as well as the screed machine is located in the center of the span. As shown in Figure 2, the torsional moments are mainly caused by the loads from fresh concrete and screed machine acting on the overhang bracket. The fresh concrete in the interior bay also affects the total torsional moments, but relatively small due to the fact that the hanger bolts are not able to transfer moment to the girder system.

Figure 1 Overhang bracket used during bridge deck construction

To resist the torsional moments introduced by construction loads, diaphragms are commonly used during bridge design and construction as transverse bracing system. However, the unbraced lengths of the diaphragms are typically designed to resist the lateral loads during service stage, without considering torsional moments introduced by construction loads. This may lead to excessive rotations on the exterior girder of the bridge during bridge deck construction, which can cause bridge failure resulting from global and local instabilities during deck construction (Fasl, 2008). Also, some potential maintenance issues such as thin deck and reduced concrete cover may occur that can lead to long-term corrosion and cracking in the deck.

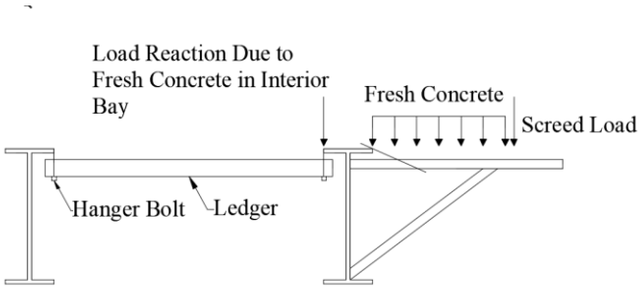

Figure 2 Construction loads during bridge deck placement

A parametric study was conducted in this study to evaluate the effects of girder section, span length, girder spacing, overhang width, number of girders, unbraced length and diaphragm section. The results indicate that the maximum exterior girder rotation is mainly affected by girder section, overhang width, and unbraced length. Based on the results of the parametric study, around three thousand finite element models were created using automatic finite element modeling program developed in this study. By conducting regression analysis, a simple method to determine the maximum allowable ratio of the unbraced length (B) to girder depth (D) was developed. This method uses the combination of primary curves and section modification coefficients to find the maximum B/D ratio based on the required rotation value and specific bridge geometry.

2 PARAMETRIC STUDY

2.1 *Finite Element Modeling*

A parametric study using Finite Element Method was conducted to evaluate the effects of bridge geometry. Seven parameters, including girder section, girder spacing, overhang width, number of girders, unbraced length and diaphragm section, are considered as having most possibilities to affect the exterior girder rotation. Table 1 shows the selected parameters and their ranges of values.

Table 1 Parameters for evaluating effect of span length

Parameters	Range
Girder Section	Wide Flange Section
Span Length (m)	9 to 23
Girder Spacing (m)	1.8 to 3
Overhang Width (m)	0.53 to 1.22
Number of Girders	3 to 6
Unbraced Length (m)	3 to 7.6
Diaphragm Section	W14X53 to W14X90

Finite element models were developed in Sap2000 to conduct the parameter analysis. As shown in Figure 3, thick wall shell elements were used for the bridge girders and diaphragms to include the distortion and warping effects of the girder. The steel overhang brackets were modeled using frame elements to support the loads from fresh concrete and screed machine. In order to simulate the bridge under the maximum rotation, the fresh concrete loads were distributed from the beginning of the span to the middle, while the wheel loads of screed machine were located in the center of the span.

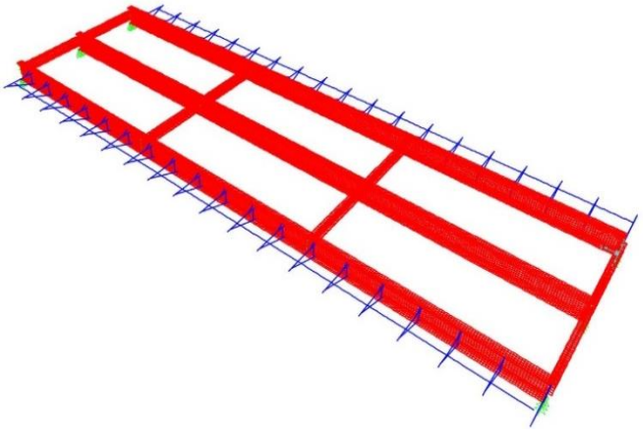

Figure 3 Finite Element Model for Parametric Study

2.2 *Analysis results*

2.2.1 *Effect of girder section*

To evaluate the effect of girder section, six wide flange beam sections, including W27X84, W30X90, W33X118, W36X135, W40X149 and W44X230 from AISC shape database, was chosen to conduct the parametric analysis. As shown in Figure 4, the rotations of exterior girders vary significantly from section to section. When the girder dimensions change, the torsional constant, which affects the abilities of girders to resist torsional moments, also changes correspondingly. In general, the normal weight of the girder can be a convenient indicator to approximately evaluate the ability for the girder to resist the torsional moment.

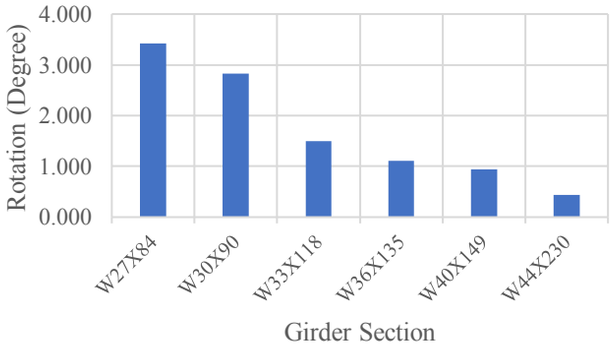

Figure 4 Effect of girder section on exterior girder rotation

2.2.2 *Effect of span length*

The effect of span length was evaluated based on W30X124 wide flange beam section since it is commonly used in bridge design. According to the AASHTO LRFD Bridge Design Specifications, the minimum girder depth is specified as 0.033 of the span length. Therefore, the maximum span length can be taken as 30 times of girder depth, which is around 23 m for W30 section. In order to study the effect of span length on exterior girder rotation, the span lengths were selected from 9 m to 23 m.

Since the diaphragms usually provide strong constraint in between bridge supports to prevent the girder rotation at diaphragm location, the span length has very limited effect on the exterior girder rotation. The finite element results indicate that when the span length changes from 9 m to 23 m, the rotation only changes by about 1% (shown in Figure 5).

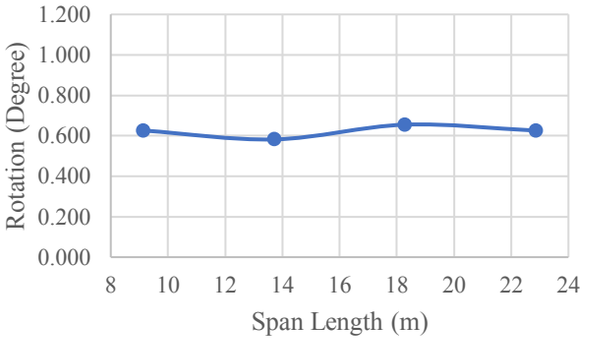

Figure 5 Effect of span length on exterior girder rotation

2.2.3 *Effect of Girder spacing*

During bridge design, a wider girder spacing is generally used when deflection limits do not control the design without considering the effect on girder rotation (Raymond A. Hartle, 2003). In this section, the girder spacing is selected varying from 1.8 m to 3 m, which covers most cases in bridge design.

The results show that the girder spacing does not have much effect on exterior girder rotation during bridge deck construction. As shown in Figure 6, the rotation reduces by only 6% when the girder spacing increases from 1.8 m to 3 m. The reason is that the temporary formwork system for bridge deck placement is typically designed using hanger bolts to connect ledger to the top flange of the girder (Dayton Superior., 2007), which are unable to transfer torsional moments to the girder system.

2.2.4 *Effect of overhang width*

The overhang width is typically designed based on the common rule of thumb that makes the overhang approximately 0.35 to 0.5 times of girder spacing (US Department of Transportation, 2012). Therefore, the overhang widths have been ranged from 0.53 m to 1.22 m to satisfy the design requirements and cover most cases in practice.

A wider overhang often results in an increasing torsional moment which leads to higher chances for the exterior girder rotation to exceed the limit value. Figure 7 shows that when the overhang widths increase from 0.53 m to 1.22 m, the rotations on the exterior girder increase by 175% correspondingly. This suggests that the overhang width has a significant effect on exterior girder rotation since it changes the total torsional moments acting on the exterior girder.

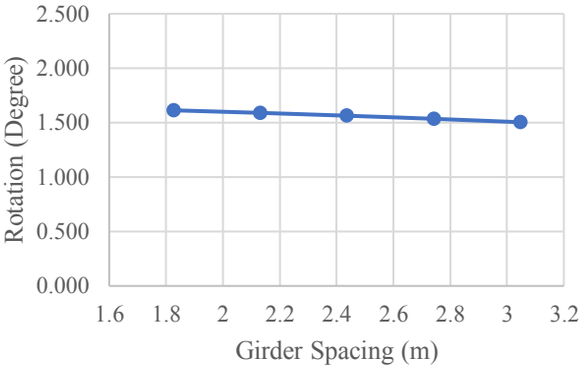

Figure 6 Effect of girder spacing on exterior girder rotation

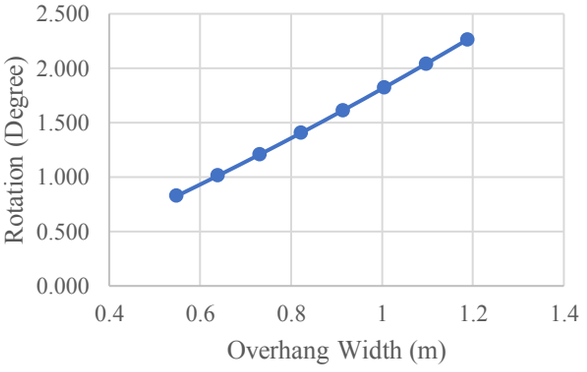

Figure 7 Effect of overhang width

2.2.5 *Effect of number of girders*

The effect of the number of girders has been evaluated using finite element analysis for four bridges with three, four, five and six girders, respectively. The results indicate that the number of girders has not much effect on the exterior girder rotation. As shown in Figure 8, for the bridge with six girders, the rotation only increases by 5% compared with the bridge with three girders.

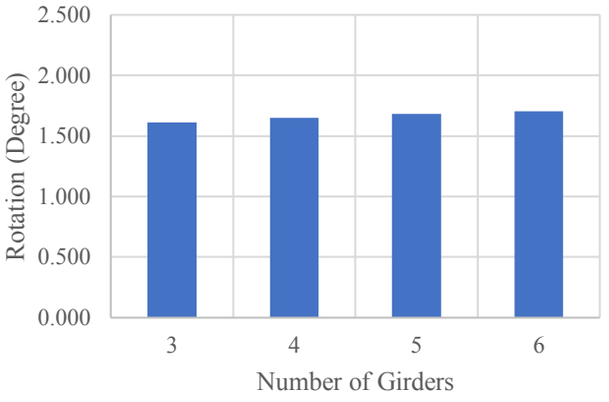

Figure 8 Effect of number of girders

2.2.6 *Effect of Unbraced length*

The unbraced length represents the distance between the braced points along the bridge longitudinal direction to resist the bulking or distortion under considered loads (Haaijer et al., 1982). However, the unbraced length is often designed according to the loads under the service stage, which often result in large unbraced lengths that are not able to limit the exterior girder rotation to the requirements during bridge deck construction. In order to analysis the effect of unbraced length, the maximum unbraced length was taken 7.6 m based on AASHTO specification, while the minimum was 3.0 m.

Figure 9 shows the unbraced length has a significant effect on exterior girder rotation. As the unbraced length increases from 3 m to 7.6 m, the rotation increases by 400%.

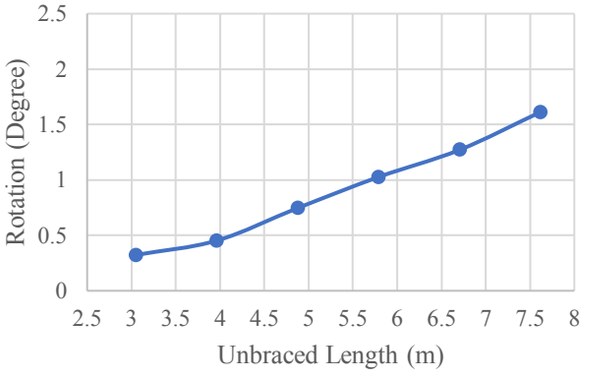

Figure 9 Effect of Unbraced Length

2.2.7 *Effect of diaphragm section*

In order to analyze the effect of diaphragm section, six different diaphragm sections are chosen: W14X53, W14X61, W14X68, W14X74, W14X82, W14X90. The girder section, which is W30X124, is constant during the whole analysis. The results show that the diaphragm section has very limited effect on the exterior girder rotation. As shown in Figure 10, the rotation values keep around 1.6 degree for all diaphragm sections. The maximum difference is only 2%.

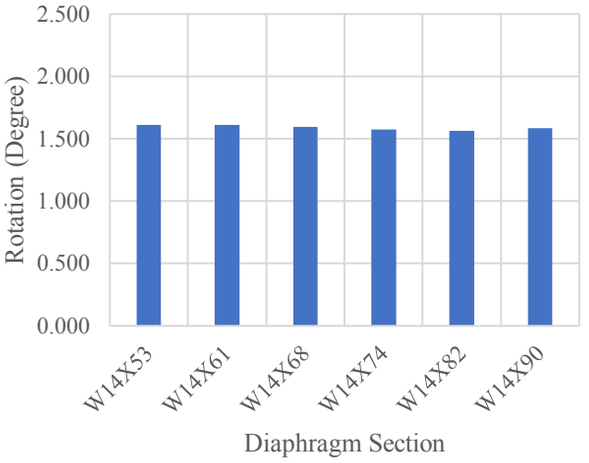

Figure 10 Effect of diaphragm sections

3 ALLOWABLE B/D RATIO

3.1 *Analysis procedures*

According to the parametric study, girder section, overhang length and unbraced length have the most significant effect on exterior girder rotation. The other four parameters including span length, girder spacing number of girder and diaphragm section have limited effects and can be ignored. Also, the previous study indicates that the ratio of the unbraced length (B) to girder depth (D) can be an effective indicator for analyzing the exterior girder rotation (Ashiquzzaman et al., 2016). Therefore, B/D ratios are used as the target values for the evaluation based on the rotation limit of the exterior girder.

To analyze the relations between B/D ratio and other parameters, about three thousand finite element models were built for all the wide flange girder sections from AISC section database. An automatic finite element modeling computer program using MATLAB and SAP2000 was developed to reduce the time consuming for modeling and analysis.

Figure 11 shows the analysis procedures based on this computer program. The pre-processing and post-processing is finished using MATLAB, while the finite element analysis is conducted in SAP2000. The program creates the information for nodes, elements, materials, sections and boundary conditions based on the bridge geometry and then generate the SAP2000 input file. The input file is imported to SAP2000 and finite element analysis is processed using SAP2000 API functions. Then the results are collected by MATLAB for the regression analysis.

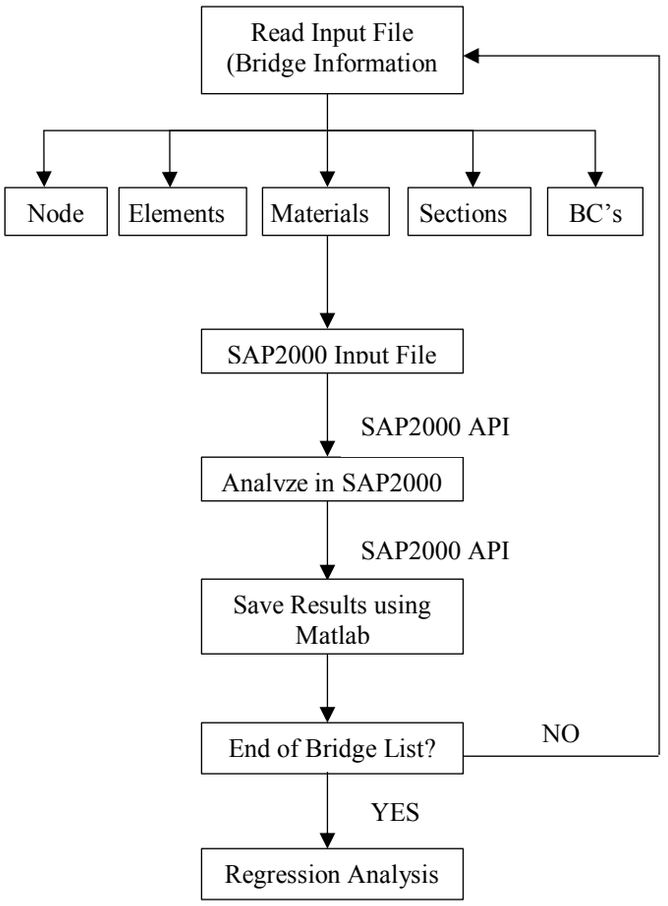

Figure 11 Automatic modeling program using MATLAB and SAP2000

3.2 *Results*

Several primary curves regarding the rotation limit of exterior girder and B/D ratio were developed for wide flange section. For the purpose of including the effect of girder sections and overhang length, section modification coefficients were also developed. Figure 12 shows a primary curve for W30 sections. The B/D ratio increases in corresponding with the increase of rotation limit, which means a larger unbraced length can be used when the bridge has a larger rotation limit. Table 2 shows the section modification coefficients that represent the effects of girder sections and overhang length. The interpolation method can be used to determine the coefficient for the overhang width not listed in Table 2.

Therefore, once the limit of the exterior girder rotation is known, the maximum allowable B/D ratio can be easily determined based on the Equation (1).

$$Ratio = B \times C \quad (1)$$

Where Ratio = Maximum allowable B/D ratio; B = B/D ratio from primary curve; C = Section modification coefficient.

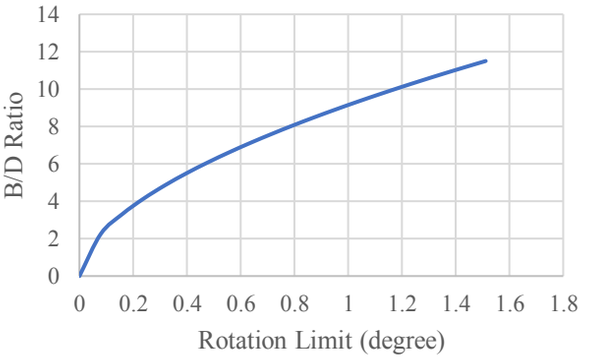

Figure 12 Primary Curve for W30 Section

Table 2 Section Modification Coefficient for W30 Section

Girder Section	Overhang Width (m)						
	0.46	0.61	0.76	0.91	1.07	1.22	1.37
W30X90	1.61	1.14	0.87	0.69	0.56	0.47	0.39
W30X99	1.75	1.25	0.96	0.76	0.62	0.52	0.44
W30X108	1.87	1.34	1.02	0.81	0.66	0.55	0.46
W30X116	2.00	1.41	1.07	0.85	0.69	0.57	0.48
W30X124	2.12	1.49	1.12	0.88	0.71	0.59	0.49
W30X132	2.23	1.57	1.18	0.93	0.75	0.62	0.52
W30X148	2.52	1.74	1.29	1.00	0.80	0.66	0.55
W30X173	3.79	2.41	1.67	1.22	0.92	0.71	0.55
W30X191	4.18	2.66	1.85	1.35	1.02	0.79	0.62
W30X211	4.66	2.97	2.06	1.51	1.15	0.89	0.70
W30X235	5.34	3.33	2.29	1.67	1.26	0.98	0.77
W30X261	6.02	3.76	2.58	1.89	1.44	1.12	0.90
W30X292	7.03	4.29	2.91	2.11	1.61	1.26	1.01
W30X326	8.21	4.90	3.29	2.38	1.81	1.43	1.16
W30X357	9.51	5.52	3.64	2.61	1.98	1.57	1.29

3.3 *Example*

A bridge located in the state of Illinois has basic design information shown in Table 3. The Illinois Department of Transportation recommends 4.8 mm as the maximum overhang deflection in the vertical direction. Thus, the maximum rotation limit can be determined as 0.3 degree for the bridges with an overhang width of 0.91 m.

Table 3 Basic design information for example bridge

Parameter	Value
Span Length (m)	183 + 296 + 183
Girder Section	W30X124
Overhang Width (m)	0.91
Girder Spacing (m)	1.83
Number of Girders	3
Diaphragm Section	W14X53

According to the Figure 12 and Table 2, it is convenient to find that the B/D ratio is 4.6 from the

primary curve, while the section modification coefficient is 0.881 for W30X124 section. Using Equation (1), the maximum allowable B/D can be determined as following:

$$Ratio = B \times C = 4.6 \times 0.881 = 4.05 \quad (2)$$

Therefore, the maximum allowable B/D ratio can be determined as 4.05, which also means the maximum unbraced length is 3.1 m.

4 CONCLUSION

Based on the parametric study and analysis for allowable B/D ratios, the following statements can be concluded:

- The girder section, overhang width and unbraced length have significant effects on exterior girder rotation. The other parameters have very limited effects and can be ignored.
- The allowable B/D ratio increases while the rotation limit increases.
- The allowable B/D ratio can be easily determined without complex calculations based on the method developed in this study.

5 ACKNOWLEDGEMENT

This publication is based on the results of ICT-R27-179, Effectiveness of Exterior Beam Rotation Prevention Systems for Bridge Deck Construction - Phase II. ICT-R27-179 was conducted in cooperation with the Illinois Center for Transportation; the Illinois Department of Transportation, Office of Program Development; and the US Department of Transportation, Federal Highway Administration.

Impacts of Specialized Hauling Vehicles on the Texas Bridge Network

José Weissmann
University of Texas at San Antonio, USA
Angela J. Weissmann
University of Texas at San Antonio, USA

ABSTRACT: The Federal Highway Administration (FHWA), by a memorandum dated November 15, 2013, requires a state to certify that it either does not permit operation of Specialized Hauling Vehicles (SHV) or conducts bridge force effects load rating analyses using the standard American Association of State Highway and Transportation Officials (AASHTO) HS20 or HL93 loads and applicable SHV load configurations. Texas does allow operation of SHVs, although the number and range of actual gross vehicle weights, axle weights, axle configurations, and spacing was previously unknown. AASHTO has adopted one SHV Notional Load Rating (NRL) configuration for screening purposes and four SHV bridge load rating configurations (SU4, SU5, SU6 and SU7) which are now incorporated in the Manual for Bridge Evaluation (MBE). However, due to the specific types of SHVs this project found operating within Texas, it may be necessary to supplement the AASHTO SHV load configurations with SHV configurations unique to Texas to ensure accurate bridge load rating practices. This paper discusses the network level bending moment analysis that screened the approximately 32,000 Texas bridges for impacts of the actual SHV configurations found operating in Texas, determined candidates for posting and calculated an initial posting load for the selected bridges.

1 INTRODUCTION

A single-unit truck is designed such that the engine, driver compartment and the cargo are carried on the same truck chassis. A Specialized Hauling Vehicle (SHV) is a modified single-unit truck with 4 to 7 axles. The SHV is modified by adding from 1 to 4 liftable axles that can be raised once the cargo is delivered or, when loaded, to make steering through an intersection easier (although the potential for overturning might be increased). SHVs may be designed as dump trucks, construction trucks, ready mix trucks, solid waste trucks and other types. Figure 1 depicts and example of a 5 axle SHV dump truck.

The Federal Highway Administration (FHWA) by a memo dated November 15, 2013 (FHWA,2013), requires a state to certify that it either does not permit operation of Specialized Hauling Vehicles (SHV), or conducts bridge force effects load rating analyses using the standard American Association of State Highway and Transportation Officials (AASHTO) HS20 and HL93 loads and applicable SHV loads based on five configurations that are now incorporated in the Manual for Bridge Evaluation (MBE) (AASHTO, 2011). These recommendations and regulations are in anticipation of significant impacts on short span bridges for the five proposed SHV rating configurations documented in the MBE. Bending moment ratios higher than one based on operating rating loads for a particular bridge may lead to bridge capacity limitations and possible posting needs. Depending on the SHV configuration, live load moment ratios, calculated using the operating rating for the bridge as a basis, may be of the order of 1.2 leading to increase of 20% to the live load stresses.

The FHWA memo also establishes a short deadline – December 31, 2017 – for the evaluation of bridges with spans shorter than 200ft. Analysis of a current version of the Texas bridge inspection data base for the on- and off-system roads shows that this encompasses about 21,000 on-system bridges and 11,000 off-system bridges. On-system bridges are managed directly by TxDOT whereas off-system bridges are managed by municipalities and counties. About 25% of on-system bridges have load ratings that make them sensitive to SHVs. About 54% of the off-system bridges have low ratings that make them vulnerable to SHV operations.

This paper summarizes the network level analysis that screened the bridges that are candidates for posting and calculates an initial posting load for these screened bridges.

Extensive road side surveys and visits to different quarries and truck operators using static scale measurements determined axle loads and spacing for 11

standard 4 to 7 axle SHVs operating in Texas. The 4 AASHTO configurations were also analyzed.

Figure 1 illustrates the six axle SHV configuration dump truck identified by the field research. Several four, five, six and seven axle SHVs were also identified and had their load patterns characterized for this study.

Figure 1. Six Axle SHV Dump Truck.

2 METHODOLOGY

When a load rating analysis shows that a bridge does not have sufficient load capacity for the SHVs identified by the surveys or for the ones specified by AASHTO, the bridge must be posted for load. Posting signs must conform to the Manual on Uniform Traffic Control Devices (MUTCD). The MUTCD has only one sign (R12-5) that depicts silhouettes of trucks for load posting; these silhouettes represent the three standard legal vehicles. The MUTCD does not allow any other truck silhouettes to be used on signs, so there will be no new silhouettes depicting the SHVs on a posting sign. This makes sense, considering that there is a safety issue of having truck drivers attempting to count the number of axles depicted on a sign while traveling at highway speeds.

Several states are in the process of developing bridge posting signs for regulating SHV operations. Sign designs developed by Virginia, Oregon, Ohio, Delaware, and Kentucky DOTs that provide weight limits for SHVs have one thing in common: they tie an allowable Gross Vehicle Weight (GVW) to the number of axles in the Single Unit (SU) truck. Oregon DOT has been active on this issue and has several recommendations for SHV posting signs.

The posting sign depicted in Figure 2 is intended to be used without any other posting signs when a bridge has sufficient capacity for routine commercial traffic and permit loads, but does not have sufficient capacity for the different SHV configurations.

The methodology discussed later in this paper takes into consideration these proposed signing approaches and is directed at calculating a GVW limit for the different SHV axle configurations.

Figure 2. Oregon DOT SHV Posting Sign for Bridges Posted for SHVs Only.

The recommended posting analysis for Texas' on and off-system bridges is based on moment ratios calculated for every on and off-system bridge statewide. The denominator of these moment ratios is always the bending moment induced by the operating rating load recorded in PonTex/BRINSAP – this is the National Bridge Inventory (NBI) (FHWA,1995) version of the Texas bridge database. The numerator is the moment induced by each SHV configuration analyzed in this study, and by the SU/SHV configurations proposed by AASHTO. These are described in an FHWA memo dated November 15, 2013, and are also included in the latest AASHTO bridge load rating recommendations summarized in the MBE. The AASHTO SHVs must also receive a comprehensive analysis of impacts and associated posting requirements.

The analyses of the six- and seven-axle configurations together with the six and seven axle configurations defined by AASHTO are used to illustrate the bridge rating analysis methodology.

The first step of the analysis consists in running the MOANSTR (Weissmann et al., 2002). network bridge analysis program to calculate moment ratios for the SHV configurations under consideration. The MOANSTR program's core is a finite differences routine that calculates live load moment envelopes generated by the studied SHV configurations and PonTex/BRINSAP operating rating loads. The MOANSTR routine incorporates previous research by Matlock (Matlock et al., 1968) and others (Ibsen, 1987, Weissmann & Harrison, 1992 and Weismann et al., 2002). MOANSTR calculates moment envelopes and identifies the maximum live load bending moments (positive and negative) induced by the SHV configuration and the operating rating load for all on- and off-system bridges statewide. For the posting analysis, these moment ratios are calculated based on

the operating rating load recorded in PonTex. This assumes that the TxDOT Bridge Division uses the operating rating as a limit when it comes to bridge posting decisions.

3 CALCULATIONS

SAS computer code was written to compare the proposed rating GVW for all these configurations taking into account any existing possible GVW limitations already recorded in PonTex bridge database under the variables "Loading Restriction" and "Load Restriction in Thousands of Pounds." Variable values 3 and 9 for item "Loading Restriction" are of particular interest for the posting analysis, since they represent bridges that are already posted for GVW. Existing postings need to be compared with the SHV calculated postings to check if they may control the GVW posting. There are 492 off-system bridges and 48 on-system bridges with a code of 3 or 9 for item "Loading Restriction" in PonTex (September 2016 version).

A specific off-system bridge (Structure ID=121020AA2241001) is used to illustrate the computerized calculations performed for all on- and off-systems bridges statewide. Figure 3 shows the GIS map of this bridge location. Figure 4 depicts the street view from Google Maps and part of the bridge data block. This bridge is located in Harris County with a structure length of 75 ft and three simply supported spans of 25 ft each. This bridge is already posted for GVW, as may be observed in Figure 4, with a limit of 36 tons. The operating rating recorded in PonTex for this bridge is also 36 tons represented by a HS load configuration.

Figure 3. GIS Snapshot of Off-System Bridge 121020AA2241001.

Table 1 summarizes the computerized calculations to determine the posting load for bridge 121020AA2241001, for the 6- and 7-axle configurations identified by the field work, and for the theoretical AASHTO SHV configurations. This process was repeated thousands of times by the computerized routines developed during this project for every on- and off-system bridge in Texas.

0000_StructureID	7 Fac Carried	41 1 Load Type	41 2 Load 1000 lb	latitude	longitude
121020AA2241001	HOLLAND AVE	9	72	29.7593	-95.2337

Figure 4. C Street View and Basic Information for Off-System Bridge 121020AA2241001.

The calculations summarized in Table 1 resulted in moment ratios exceeding operating rating for the 6 and 7 axle AASHTO SHV configurations and for the 6 axle SHV configuration identified in this project. The 7-axle SHV configuration did not induce moments above operating rating on this bridge, so these calculations were not included in Table 1.

Recommended posting tons for the 6- and 7-axle configurations were then calculated using the following approach: GVW for each configuration should be capped to operating rating moment values. In other words, the GVW limit for a given configuration is calculated by dividing the GVW for the configuration by the operating rating moment ratio so as to reduce the GVW for the SHV configuration to operating rating levels.

For example, the recommended posting GVW for the AASHTO SU6 vehicle for this particular bridge is calculated by dividing the GVW of the AASHTO SU6 vehicle, which is 34.75 tons, by 1.199, the moment ratio. This resulted in the recommended 29 tons GVW posting for the AASHTO SU6 vehicle.

The same process was implemented for the 6-axle SHV. Dividing this truck's 37.29 tons of GVW by the operating rating moment ratio for this load, which is 1.243, results in a recommended posting load of 30 tons. Therefore, the recommended load that should appear on the bridge posting sign for the 6 axle single unit truck should be the lowest value of 29 tons, controlled by the AASHTO SU6 configuration. Note that 29 tons is also lower than the existing posting for this bridge (36 tons GVW is recorded in PonTex).

The same procedure was followed for the only 7-axle configuration exceeding operating rating, the AASHTO SU7. The recommended posting load for the 7 axle single unit truck for this bridge should be 32 tons. This value is the AASHTO SU7 GVW

(38.75 tons) divided by its moment ratio 1.221. This is the controlling load for the 7-axle SHV posting and it is determined by the AASHTO SU7 configuration.

Table 1. Rating Calculations for Off-System Bridge 121020AA2241001

Six Axle SHV	Moment ratio AASHTO SU6	1.199
	Recommended Posting tons AASHTO SU6	29
	Moment ratio X-XXX-OO 6-axle dump truck	1.243
	Recommended posting X-XXX-OO-6-axle dump truck	30
	Item 41.2 Pontex tons	36
	Lowest tons	29
	Governing Rating Load	SU6 AASHTO
Seven Axle SHV	Moment Ratio AASHTO SU7	1.221
	Recommended Posting tons AASHTO SU7	31.7
	Moment Ratio X-XXX-OO-X 7-axle dump truck	N/A
	Recommended Posting tons CTR 7 axle SHV	N/A
	Item 41.2 Pontex tons	36
	Lowest tons	31.7
	Governing Rating Load	SU7 AASHTO

The limits for the 4 and 5 axle SHVs were calculated in an analogous manner. Table 2 shows the full summary of the results for this specific bridge. Table 2 also includes some of the data field values, variable names and definitions. A Microsoft Access data base was developed, summarizing the calculations for all on- and off-system bridges that presented bending moment ratios above one as previously discussed. The on-system data table of recommended SHV postings encompasses 1,956 bridge records whereas the off-system table encompasses 6,081 bridge records. The Access data set contains all the necessary information to identify a specific bridge in the system including its geographic coordinates, thus enabling an easy display of the results using a geo referenced computerized environment such as ArcMap.

Table 2. Recommended Posting Tons for Off-System Bridge 121020AA2241001

SHV Type	Variable Definition	Data Set Variable	Data Set Value
4 Axle	Recommended SHV GVW Posting (tons)	PostedTons4	25.1
4 Axle	Controlling Rating Load	RatingLoad4	Garbage_x_x_oo_4postedtons
4 Axle	Bending Moment Ratio for Rating Load	Garbage_x_x_oo_4ratio	1.274
5 Axle	Recommended SHV Posting	PostedTons5	27.9
5 Axle	Controlling Rating Load	RatingLoad5	AASHTOSU5postedtons
5 Axle	Bending Moment Ratio for Rating Load	AASHTOSU5ratio	1.112
6 Axle	Recommended SHV Posting	PostedTons6	29
6 Axle	Controlling Rating Load	RatingLoad6	AASHTOSU6postedtons
6 Axle	Bending Moment Ratio for Rating Load	AASHTOSU6ratio	1.199
7 Axle	Recommended SHV Posting	PostedTons7	31.7
7 Axle	Controlling Rating Load	RatingLoad7	AASHTOSU7postedtons
7 Axle	Bending Moment Ratio for Rating Load	AASHTOSU7ratio	1.221

The Access data tables containing calculations of recommended posting loads for the four, five, six and seven-axle configurations for both on- and off-system bridges are also available in GIS map format. The data items summarized in Table 2 and those for the bridge posting calculation example are included in the GIS data block for all the on- and off-system bridges statewide.

Figure 5 shows a snapshot of the GIS system developed for this project. It highlights the data block for an off-system bridge in the outskirts of Kerrville, Kerr County – Structure ID 151330G00020001. This particular bridge is located 0.13 miles SW of SH16 and the recommended posted load for the six axle SHV is controlled by the AASHTO SU6 configuration and limited to 31.9 tons, which should be rounded to 32 tons for the posting sign. The bending moment ratios for the AASHTO SU6 and the 6 axle dump truck configurations are respectively 1.09 and 1.13, or 9% and 13% above the operating load recorded as an HS load with 36 tons of GVW. This bridge is not currently posted. The recommended posting load for the four-axle SHV is 28.6 tons, which should be rounded to 29 tons. The 4 axle posting load is controlled by the garbage truck characterized during the field survey. For the 5-axle SHV configurations, the recommended posting load for this specific bridge is 32.4 tons and it is being controlled by the garbage truck characterized during the field survey.

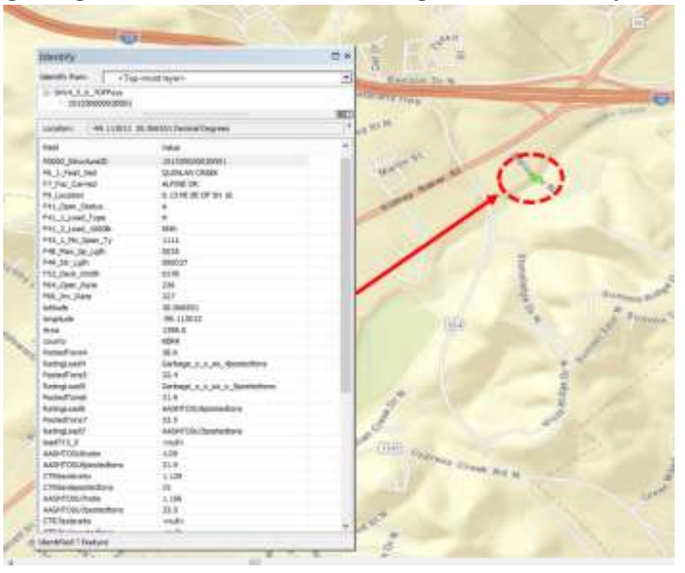

Figure 5. GIS System Summarizing Bridge Recommended Postings Statewide.

4 CONCLUSIONS AND RECOMMENDATIONS

The computerized data sets for on- and off-system bridges discussed in this paper should be used to prioritize bridges for detailed posting analysis on a bridge by bridge basis, and subsequent implementation of adequate SHV posting signs. The computerized tools developed in this project provide an invaluable management tool for the TxDOT Bridge Division. They should be implemented in a timely manner in order to meet the tight deadlines for the review of bridge posting policies for SHVs established by the FHWA memo dated November 15, 2013.

One possible way of streamlining the task of evaluating thousands of bridges for posting could be by grouping these bridges in blocks segmented by the bending moment ratios available in the Access database generated by this project, then evaluating the

posting for the highest moment ratios statewide first. In addition, criteria to prioritize bridges for posting based on risk should be developed. Risk attributes could be identified that measure the strategic importance of a given bridge, such as traffic volume and composition, and availability of detours.

SHVs are primarily short haul vehicles used on local activities that require equipment to haul solid waste (garbage trucks), granular materials (dump trucks) and concrete (concrete drum trucks) and thus are expected to operate in specific urbanized areas of the State of Texas. These specific urbanized areas and associated road networks and bridges should be identified and used as one of prioritization criteria for posting bridges impacted by SHVs.

The potential magnitude of the SHV impacts in Texas is particularly critical for the off-system bridges that are managed by counties and municipalities. While about 2,000 of the approximately 21,000 on-system bridges will experience live load bending moments induced by SHV configurations that supersede the operating rating moments, a significantly higher percentage of the off-system bridges is affected. About 6,000 of the 11,000 off-system bridges will experience live load bending moments induced by SHV configurations that supersede the operating rating moments. This reflects the average age of the off-system bridge system, which is older than the on-system age. Due to their age, many Texas off-system bridges were designed for lower design loads such as H loads and do not have the load capacity to support SHV operations. This lower original load capacity may also have been reduced by deterioration due to the bridge age.

Impact of quantity of weigh-in-motion data on load effects on bridges

A. Žnidarič, M. Kreslin & J. Kalin
Slovenian National Building and Civil Engineering Institute, Ljubljana, Slovenia

G. Turk
University of Ljubljana, Faculty of Civil and Geodetic Engineering, Ljubljana, Slovenia

ABSTRACT: Quantity of weigh-in-motion (WIM) data influences the results of bridge (and pavement) load modelling. However, no clear recommendations existed about how many vehicle records are needed for reliable prediction of load effects. Impact of quantity of WIM data on the results of bridge traffic load modelling was studied using three WIM dataset that contained almost one million heavy vehicle records. The main goals of the study were to investigate (a) variation of the bridge load modelling results as a function of WIM data sample size, and (b) how much data is needed for the results to converge. The datasets were quality-checked, which included visual validation of all heaviest vehicles. Vehicles with more than seven axles were eliminated to minimise the influence of random special transports. Convolution method was used as an efficient traffic load modelling tool to generate a multitude of different outcomes. Paper describes the approach taken and results from three locations with different traffic densities. Results for bending moments and shear forces are presented as a function of bridge span (5, 15, 25, 35 and 45 m) and size of data sample, which varies from 10 000 vehicles to the full dataset. Paper concludes with recommendations about the required number of WIM records for reliable bridge load effect modelling.

1 INTRODUCTION

Modelling of load effects (bending moments and shear forces) caused by heavy traffic is a standard procedure to evaluate the effects of heavy traffic on bridges. The results of modelling greatly depend on quality and quantity of axle load information that is in most cases collected by weigh-in-motion (WIM) systems. Unfortunately, no clear recommendations exist about how much WIM data is needed for reliable prediction of load effects. The only criteria, based on engineering judgment, are given in the European specifications for WIM (COST 323, 2002), where it is suggested that:

- accuracy of WIM data for bridge traffic load modelling shall be of at least class C(15), meaning that errors of roughly 95 % of gross weights shall be within ±15 %, and axle loads within ±20 % of the static values, and that
- as many vehicle records as possible (but at least 100 000) shall be used.

The purpose of work was to investigate influence of number of WIM vehicle records on the results of bridge traffic load effect modelling and to set some recommendations for the future work. In other words, the study investigated:

- variability of the traffic load effects calculated from equally sized WIM subsets, and
- how quickly the calculated load effects converge and how much data is needed to provide stable and reliable results.

2 WIM DATA SOURCES

All data in the study was collected at three different sites using a bridge weigh-in-motion (B-WIM) system.

2.1 *Bridge WIM*

Bridge-WIM or B-WIM refers to a specific method that uses an instrumented bridge or culvert to weigh the heavy vehicles while they cross the structure. B-WIM systems provide equivalent set of vehicle parameters (axle loads, gross weight, axle spacing, velocity, vehicle category…) as the more established pavement WIM systems, but also have some specific advantages (Žnidarič et al., 2016):

- The instrumentation is completely portable and can be moved from a bridge to another. Unlike the pavement WIM systems, portable installations

provide similar quality of results as the permanent ones.
- Accuracy of results is generally high, especially on smooth pavements. Installations are possible on rougher or rutted surfaces, where pavement WIM installations would not even be considered.
- In most installations all sensors are mounted underneath the bridge deck. Consequently, installation and maintenance activities do not interrupt the traffic. This is advantageous for sites where cutting into the pavement is not allowed, when installation of a pavement based system is not feasible due to heavy traffic or if permits for road closures are difficult to obtain.
- Collected strains records can be used to generate bridge related indicators (influence lines, dynamic amplification factors, girder factors), in order to optimise structural assessment (ARCHES, 2009; Žnidarič & Lavrič, 2010).

The obvious weakness of B-WIM is that a suitable bridge is needed to install the system. Furthermore, while instrumenting common slab or beam-and-slab bridges is straightforward, setting-up a less common structure requires substantial knowledge about bridges. A typical installation of an underpass under a four-lane highway is shown in Figure 1. The sensors in the middle row are used for weighing, while the separate pairs of sensors, one per lane, are used to determine vehicle velocities.

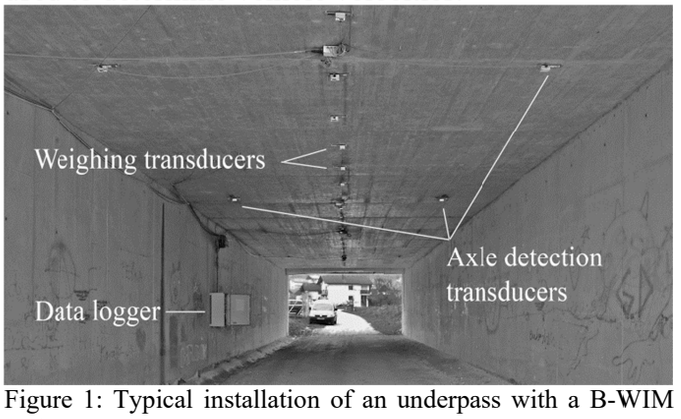

Figure 1: Typical installation of an underpass with a B-WIM system

2.2 *Data sets*

The primary source of data, denoted as Dataset 1, contained 793 799 or almost two years of vehicle-by-vehicle records collected on a low-volume motorway. It was complemented by Datasets 2 and 3 from the busiest motorway in Slovenia, containing 147 525 and 106 872 vehicle records resp. All three datasets were temperature and velocity calibrated (Žnidarič et al., 2016). In the final stage, all vehicles within the top 10^{th} quantile with respect of their gross weight and axle loads were visually checked with dedicated software, to provide the highest possible quality of the data (Žnidarič, 2017), without any abnormally heavy axle loads that might appear in the measured data as a result of misdetected axles. This software visually compares the measured and the calculated strain responses, which, with the help of the photos, allows to either approve the result, or to reweigh the vehicle after adding or deleting the misdetected axles.

3 CONVOLUTION METHOD

The convolution method is an established technique for modelling of bridge traffic load effects. It is computationally less demanding than the full simulations. Moses and Verma (1987) and Žnidarič (2017) have also shown that the convolution can give similar results to Monte Carlo simulation, if the assumption of independent traffic in the two lanes is valid. Good matches between results were obtained with convolution and other more sophisticated traffic load modelling methods in the ARCHES project (2009). In Slovenia, the convolution method, similar to the one proposed by Moses & Verma (1987), has been used for over 20 years (Žnidarič & Moses, 1997; Žnidarič, 2010).

It shall be noted that for bridge traffic load modelling applications, the WIM systems must not only provide information about axle configurations and loads of each vehicle, but also time stamps of individual vehicles at a resolution of at least one hundredth of a second, to allow accurate modelling of inter-vehicle spacings. These are required to properly simulate the extreme loading events (Žnidarič et al., 2015).

3.1 *Calculation of load effects*

As the first step, the quality-approved vehicle records, containing information about their individual axle loads and spacings, are converted into load effects (bending and hogging moments, shear forces) by using the influence lines, either theoretical or experimental. The predicted *static* load effect, Q_S, moment or force, is determined as:

$$Q_S = \sum_{i=1}^{N} AL_i I(x_i) \quad (1)$$

where AL_i is load of axle i, N is number of axles of the vehicle and I_i is the value of the influence line due to axle i at location x. The Q_S values of all vehicles are combined into histograms of static load effects, separately for each traffic lane. In most cases, tail modelling or smoothing is used to extend the results beyond the measured values.

The convolution method assumes that the highest load effect is achieved when two vehicles from independent traffic flows in each traffic lane are placed side by side on a bridge at the place of maxi-

mum effect, which is defined as a loading event. In Europe, such an approach can be justified on well over 90 % of bridges (SAMARIS D19, 2006; Žnidarič et al., 2011) which influence lines are shorter than 30 m. On these bridges, due to the length of common heavy vehicles which does not exceed 15 m, the critical event happens due to *one* vehicle in each of the two traffic lanes.

Assuming that the distributions of the load effects for both lanes are independent, which can be justified for opposing traffic, but taken with reserve for traffic in the same direction, the probability mass function (PMF) for a combined event, with vehicles meeting each other, can be expressed as:

$$\mathrm{f_Z(z)} = \sum_{\mathrm{k=-\infty}}^{\infty} \mathrm{f_X(k)\, f_Y(z-k)} \tag{2}$$

where f_X and f_Y are the probability mass functions of load effects from two adjacent lanes, and f_Z is the new probability mass function of the load effects for multiple-presence events composed of vehicles from both lanes of traffic. X and Y are random variables representing load effects for lanes 1 and 2, respectively, whereas Z is a random variable representing load effect for a multiple-presence event. If f_X and f_Y are divided into m bins, then the length of f_Z will be equal to $2m - 1$ bins (MathWorks, 2013).

The probability function $f_Z(z)$ includes all possible combinations of vehicles from lanes 1 and 2, including the highly unlikely multiple presences of the heaviest vehicles on both lanes.

3.2 *Probability distribution of extremes*

Many engineering applications require predictions of future conditions, typically the highest possible (likely) loading and the lowest bearing capacity. This inevitably requires extrapolation from the available data (Ang & Tang, 2006).

If Z is the initial random variable, in this case the convoluted load effect, with known initial distribution function $F_Z(z)$, then we can divide the sample space Z into N_T observation periods, where each sample will be a subset of observations ($z_1, z_2, \ldots, z_N$). Since every observed value is unpredictable prior to being actually observed, we can describe the maximum value Z_N of the sample of size N_T as:

$$\mathrm{Z_N} = \max_{1 \le i \le N_T} \mathrm{Z_i} \tag{3}$$

The largest value of the sample size N_T taken from population Z is also a random variable whose distribution can be derived from that of the initial variate Z. If Z_N is less than some value z, then all other sample random variables must also be less than w. If we assume that $Z_1, Z_2, \ldots, Z_N$ are independent and identically distributed as the initial variate Z:

$$\mathrm{F_{Z_1}(z) = F_{Z_2}(z) = \cdots = F_{Z_N}(z) = F_Z(z)} \tag{4}$$

then the distribution function for Z_N is

$$\begin{aligned} \mathrm{F_{Z_1}(z)} &= \mathrm{P(Z_N \le z)} \\ &= \mathrm{P(Z_1 \le z, Z_2 \le z, \ldots, Z_N \le z)} \\ &= \mathrm{\left(F_Z(z)\right)^{N_T}} \end{aligned} \tag{5}$$

N_T is defined as:

$$N_T = N_{ADT}\, N_D\, N_P\, \alpha \tag{6}$$

where N_{ADT} is the measured or average daily number of heavy vehicles, N_D is number of days in a year, typically taken as 250 working days, and N_P is the period that the load effects are forecasted to, expressed in years. Parameter α defines the probability of exceedance of load effect. It is either taken as the mean or median value or is calculated to correspond to a specific return period (Žnidarič, 2017). In traffic load modelling words, if we:

- have a measured dataset of load effects from N_T days of traffic and
- assume that the distribution is stationary (if drastic changes happen, measurements shall be repeated),

we can approximate the maximum expected load effect by raising the measured distribution F_Z to the power of N_T.

The adopted procedure is demonstrated with the highest quality, visually cleaned dataset 1. 25-m long generic simply supported influence line was used to generate the bending moments and shear forces for all 793 799 vehicles. Then the load effects were converted into histograms. Fifty bins were used over the entire data range, meaning that the bin sizes were not constant, but were adjusted according to the size of data subsets. Calculations of load effects were performed separately for the slow and for the fast lane. Results were convoluted and raised on the power of N_T. In this case, the 75-year return period was considered, which corresponds to α equal to 0.6346. No traffic increase was accounted for (Leahy et al., 2016), as it has no effect on demonstration of influence of quantity of data on bridge traffic load modelling.

3.3 *Example*

Individual steps of this procedure are shown in Figure 2, from the individual lane PDFs ((a) and (b)), convoluted PDF (c), with tail detail (d), convoluted CDF on powers of N_T , corresponding to 10, 20 and 75-year return periods (e).

For comparison, the Figure 2 (f) compares the maximum daily bending moments on the Gumbel proba-

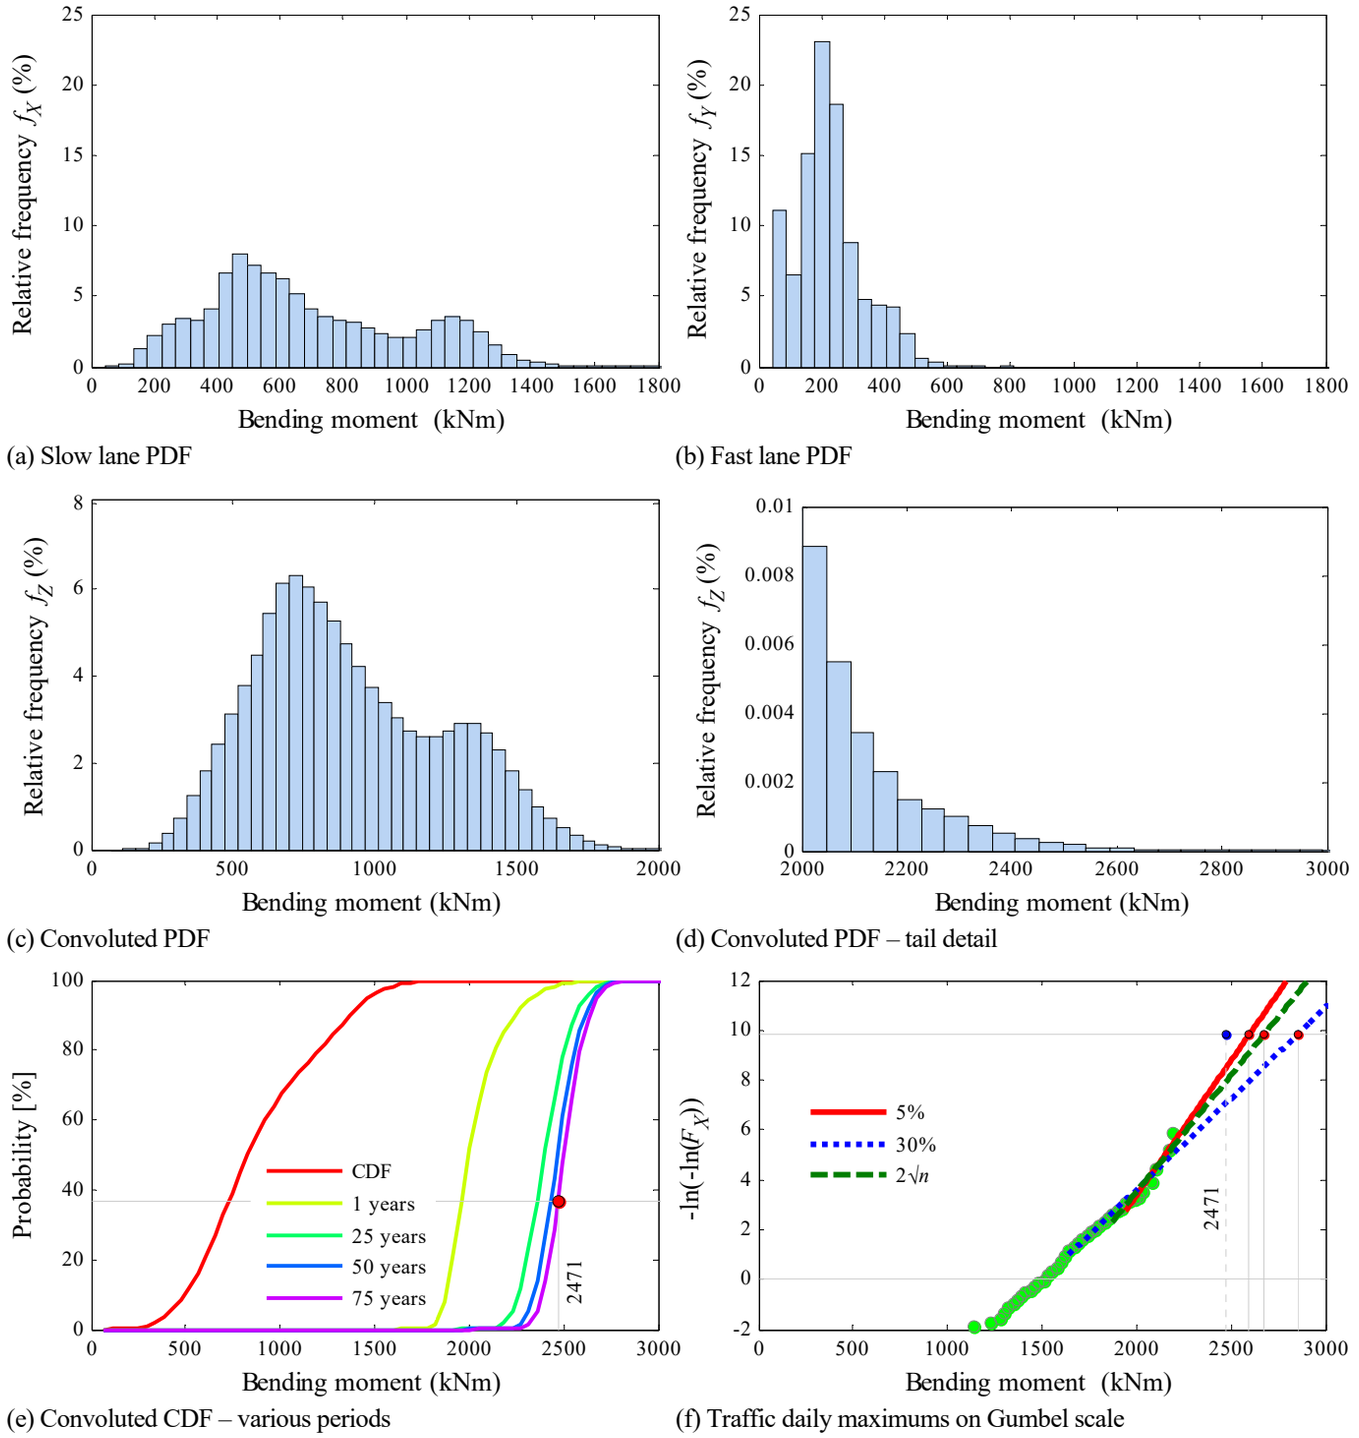

Figure 2: Dataset 1: steps of convolution procedures, all data, 50 bins, 75-year return period

bility plot, using three different number of data from the tail for extrapolation: top 5%, top 30% and top $2\sqrt{n}$ results, where n is the size of data sample (Castillo, 1988). This diagram compares the 75-year return period bending moment, calculated with convolution, with three extrapolated daily maximum values based on different number of points in the tail.

4 INFLUENCE OF QUANTITY OF WIM DATA

In the next step the dataset 1 was divided into subsets of various lengths. The shortest individual ones comprised 15 days of data and 17 250 vehicles each. Figure 3 displays all 46 subsets of 75-year return period results. Only the complete days, with all 24 hours of traffic, were considered. Each subset started at midnight, immediately after the previous subset ended. In all subsequent examples, moderate Gaussian kernel smoothing was applied (Žnidarič, 2017), to soften the tails with sparse data, particularly in the shorter subsets. Figure 3 also displays the mean value and the ±1 standard deviation (sigma) curves. From there the mean value of 2471 kNm and coefficient of variation of 5.5 % are established.

Evident is the wide variability of the results, caused by insufficient number of vehicles and by in-

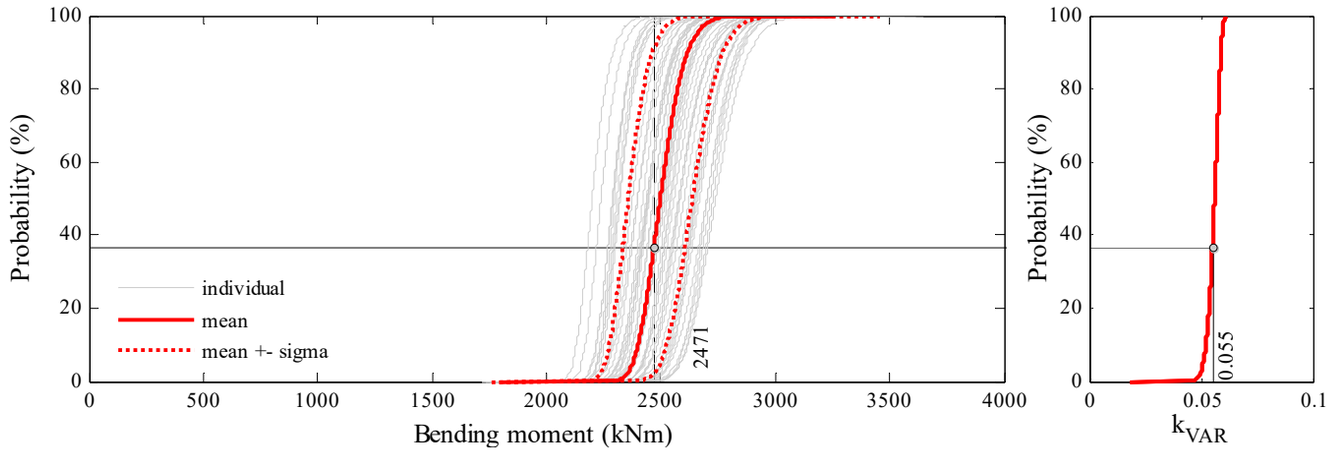

Figure 3: Bending moments for 2-week data slots – mean value and standard deviation

consistent number of exceptionally heavy vehicles in these short individual subsets.

The procedure was repeated for nine different measurements periods: 2 weeks, 1, 2, 3, 4 and 6 months, 1 year, 1 year and a half and for all 696 days. With more data, the mean value of the characteristic load effect starts to increase and at certain point reaches the level of the results of the largest dataset. This is summarised in Figure 4 that displays the mean bending moments and their coefficients of variations as a function of days of data in the subsets. To compare the results with those from Datasets 2 and 3, with different number of heavy vehicles per day, the procedure was rerun with datasets organised not in days but in number of vehicles. Data sets containing 20-, 50-, 75-, 150-, 250-, 400- and all 794-thousands of vehicles were generated. As expected, the graphs in Figure 5 resemble those from the previous figure.

Finally, the procedure was repeated for five different lengths of influence lines. Resulting bending moments and shear forces at bridge entrance, for all five spans and the first two datasets are presented in Figures 6 and 7. All results are normalised to the end

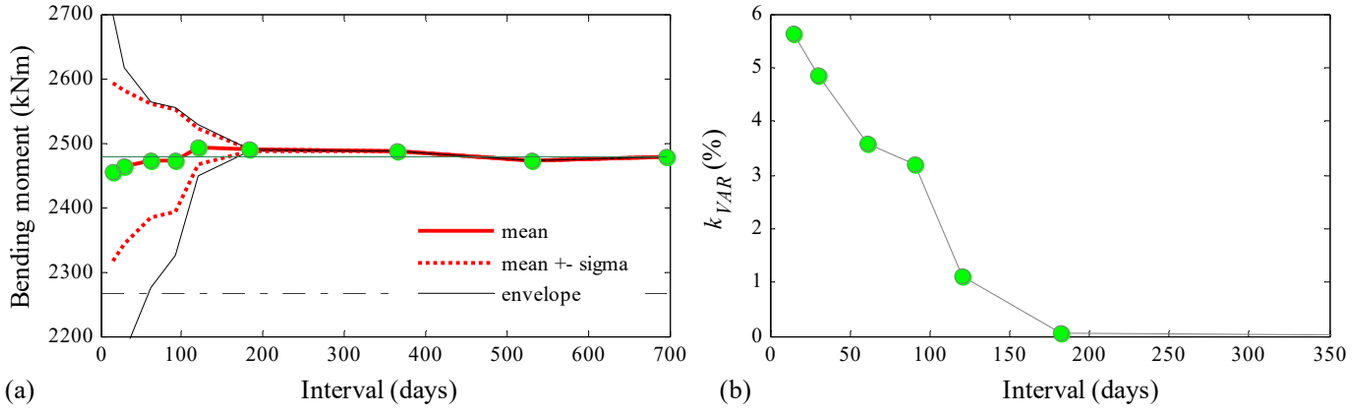

Figure 4: Dataset 1: Influence of the duration of measurements on 75-year return period bending moments, (a) mean values and (b) coefficients of variation

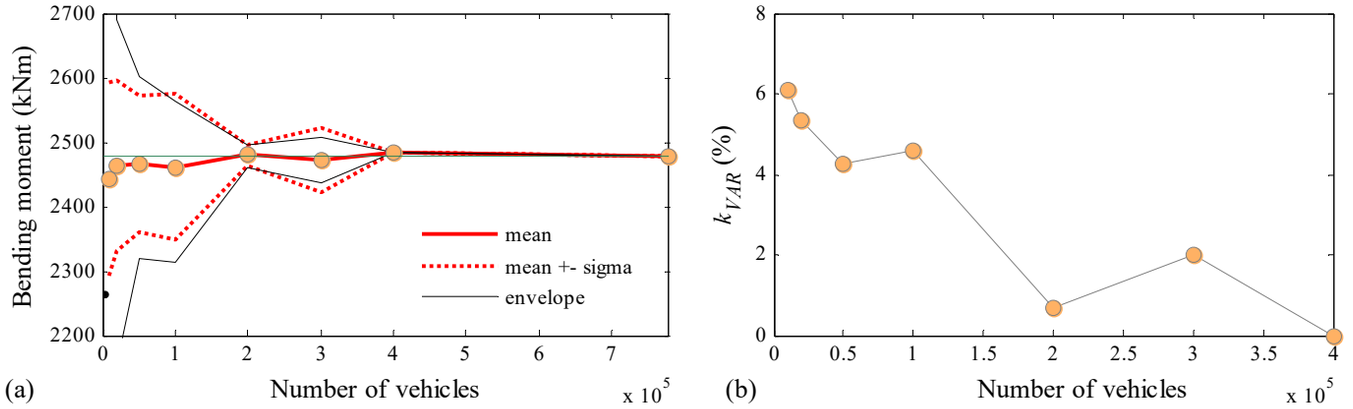

Figure 5: Dataset 1: Influence of number of vehicles on 75-year return period bending moments: (a) mean values and (b) coefficients of variation

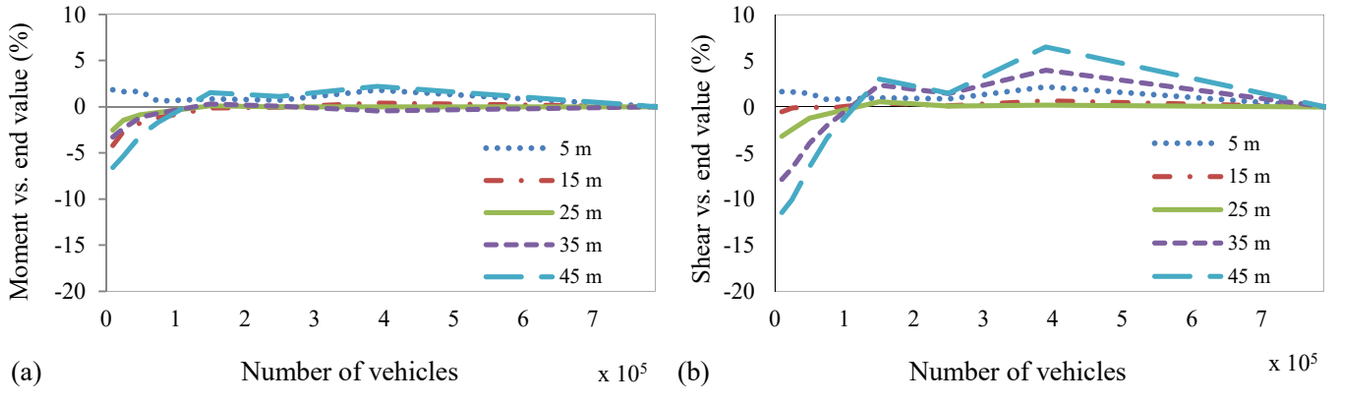

Figure 6: Dataset 1: Influence of number of vehicles on 75-year return period load effect, for various spans: (a) bending moments and (b) shear at bridge entrance

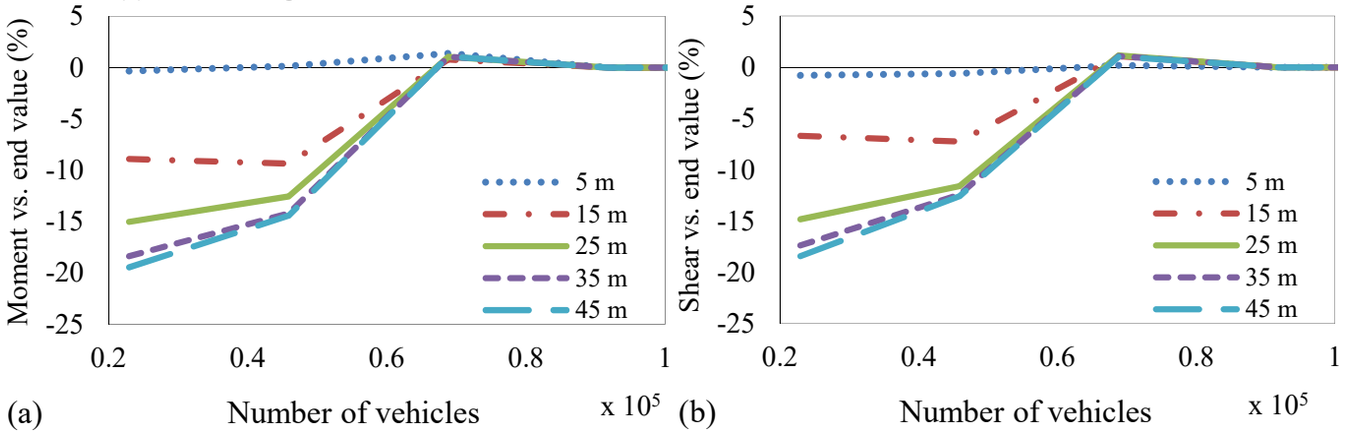

Figure 7: Dataset 2: Influence of number of vehicles on 75-year return period load effect, for various spans: (a) bending moments and (b) shear at bridge entrance

values compiled from the largest datasets that provide the most reliable reference for the specific sites.

4.1 *Results*

Table 1 summarises the attained differences, in %, with respect to the end values, for all three datasets, for five spans and for various sizes of subsets. Figure 8 summarises all differences (errors) for bending moments and shear forces from Table 1.

The clear conclusion for the three sites is that having more than 100,000 vehicles will, regardless of the span length, provide stable results that vary insignificantly with more data. Results may be underestimated for up to 5 % if the datasets contain between 50,000 to 100,000 vehicles. Datasets with less data provide unpredictable, in most cases severely underestimated results. By far the most consistent are results for the 5 m span, which error never exceeds the ±2 % interval, which might suggest, after verification with more datasets, that for very short bridges less data might be sufficient.

4.2 *Discussion*

The following can be concluded in relation to the impact of the quantity of data on modelled characteristic load effects on bridges:

– The three datasets are fundamentally different. The first one was collected on a motorway with low-volume traffic, but contains nearly 800 000 vehicles accumulated over almost two years. The other two datasets contain data from another high-volume motorway. Both measurements were considerably shorter and the datasets contain only 13 % to 18 % of vehicles from the dataset 1. In addition, the dataset 2 was acquired almost 10 years ago, with an older generation of B-WIM software, while the other two datasets are from years 2013 to 2016.
– To eliminate the effect of sparse extremely heavy vehicles, those with more than seven axles were treated as escorted special vehicles and were not considered in data modelling.

- On all three sites the most reliable, visually inspected results were used. The subsets with less than 50 000 vehicles generated lover values of load effects, with higher coefficients of variations. This means that the load effects from smaller subsets, based on shorter measurements, are less reliable and can generate results which can be either greatly underestimated or even overestimated, if some extremely heavy vehicles had been captured in that specific timeslot.
- The above seems not to be valid for the shortest 5 m span, where the bending moments and shear forces at the bridge entrance do not change for more than ±2 %, regardless of the size of the subsets. The most probable reason is that the extreme axle loads on shorter vehicles (4-axle rigid trucks) are common and can be captured regularly, even in smaller subsets of WIM data. The longer vehicles with extreme gross weights (cranes and low-loaders that carry bulky loads), which affect longer spans, are on the other hand less common and are captured only during longer measurements.
- For all other spans, and in all six cases (bending moments and shear forces on three locations), the mean load effects reached the 'accurate' end values at around 50,000 to 100,000 vehicles. At those instants, the coefficients of variation typically dropped below 3 %.
- Based on the three sets of WIM data (more would strengthen the conclusion) it can be recommended that bridge traffic load modelling should be based on at least 100,000 vehicles.
- Datasets with at least 50,000 vehicles may give usable, but less conservative outcomes, with higher uncertainties that need to be evaluated and accounted for in the results.
- A convergence test, using the above approach with varying size of the datasets, is a useful tool to test how the results depend on the number of vehicles in the database.

5 CONCLUSIONS

Parametric studies were performed to give an answer about how much weigh-in-motion data is needed for reliable calculation of load effects on bridges. For this purposes, three sets of WIM data have been prepared. The first one was collected over a period of almost two years on a low-volume motorway. The other two measurements lasted only 31 and 57 days resp., but have been collecting data on the busiest motorway in Slovenia, with three to four times more traffic than in the first case.

On all three sites, the most reliable, visually inspected datasets were used as a reference to test the impact of the quantity of data on the modelled load effects. The procedure was repeated with subsets of data containing different number of vehicles. The goal was to assess how quickly the results, as a function of the subset size, converge to the 'accurate' results, which were calculated from the maximum available size of the sample.

The results of the analysis confirm the existing recommendations, which were based on engineering judgement, that at least 100 000 vehicle records are needed for reliable forecast of load effects on bridges. Datasets between 50 000 and 100 000 vehicles are acceptable, but the results will likely be underestimated for up to 5%, with higher coefficient of variation. The datasets with less than 50,000 vehicles will either considerably underestimate or overestimate thee load effects, depending on the extremely heavy vehicles that have or have not been captured in the specific subset.

The exception was the shortest 5 m span, where the bending moments and shear forces at the bridge entrance did not change for more than ± 2 %, regardless of the size of the subsets. The explanation is that the very heavy axle loads on the shorter rigid vehicles (3- and 4-axle trucks) are captured regularly, even in smaller subsets of WIM data. The extremely heavy longer vehicles that affect longer spans, are on the other hand less common and are captured randomly.

It is evident that using a few more long-lasting datasets would be beneficial. Nevertheless, the results give some clear indications about quantity of weigh-in-motion data needed to reliably model the traffic load effects on bridges.

ABSTRACT: The main scope of the research is to develop an integrated health monitoring system to improve serviceability assessment of bridges in Romania. The system must integrate the actual practice mainly based on visual inspections and combines the response of different reliable sensors, installed on the structure to monitor the damage progress, with enhanced realistic deterioration models. The system was developed to cover the parameters for the most important deterioration mechanisms: reinforcement corrosion, concrete carbonation and the changes in the structures behavior.

The use of permanent monitoring systems has several advantages:
- A more reliable prediction of the damage progress
- Traffic interference is reduced
- An input for defining maintenance and repair strategies
- The costs of access to the structure and resources for inspection and testing are reduced
- Structural elements with difficult access are easily monitored
- An evaluation of the need for further inspection and testing

1 INTRODUCTION

In 2017 in Romania five people died every day due to traffic accidents, finding an increase in their number from year to year. This must stop in no time establishing himself adopting a strategy that will lead primarily to remove the causes that favors road accidents. There are multiple causes: poor technical state of bridges and roads, failure to traffic rules, vehicle built to modern highway traffic regime, but obliged, without alternative, to circulate on infrastructure in its great majority built in the 1980s.

In accordance with the studies and researches realized in the last years, especially regarding the bridges exploited from the network of the national roads it is revealed the fact that the majority of these bridges is at the limit between the satisfactory state and the unsatisfactory one. From the data gathered as a result of the studies undertaken in Romania on a sample of approx. 1000 of bridges, it has been concluded that over 90% from the total number of bridges had major degradations.

The observations made over the technical state of the bridges from the network of national roads in Romania, have pointed to the necessity to applies an modern program of health monitoring system in order to allows the application of a system identification and damage detection, the optimization to planning process of the necessary works with beneficial implications regarding the management, the allocation of the financial resources and thus, an efficient system to administration of the patrimony of bridges.

The current methods of service-life prediction in Romania are based especially on visual inspections having a pronounced subjective character to carry out the condition assessment. These methods present a series of major disadvantages:

1) The low precision in indicating the moment of apparition of the evolution stage and of the achievement of the critical manifestation level of the structural degradation processes

2) The high costs in order to ensure the access of the surveillance staff in those parts of the structure of bridges

3) The long interval of time necessary between inspections and the adoption of the intervention decision in the case of signalization of the manifestation on the structure of major degradations that can severely affect the security and the functionality of the bridge

In order to ensure the viability of the state of bridges, Faculty of Civil Engineering and Building Services of the "Gheorghe Asachi" Technical University from Iasi has developed a research program with the main scope to develop a SHM system for durability assessment (Comisu et al. 2006). The system

must interface and integrate the actual practice mainly based on visual inspections and combine the response of a number of different reliable sensors, installed on the structure to monitor the severity of a structural damage, with enhanced realistic deterioration models. The SHM system is based on a network of sensors developed to cover the most important deterioration mechanisms: corrosion of reinforcement in bridges, carbonation of concrete, freeze-thaw cycles, alkali-silica reaction and mechanical damage, as well as the changes in the structures behavior and safety, static deformation, strains, crack widths and vibrations.

2 OBJECTIVES AND SCOPE

The program of health monitoring system of bridges network in Romania has the following objectives:

1) Improving the durability requests of bridge structures through the application of an integrated permanent and active monitoring system of the transportation substructure from Romania

2) The program of health monitoring system of bridges network must cover the most important deterioration mechanisms: corrosion of reinforcement in bridges, carbonation of concrete, freeze-thaw cycles, alkali-silica reaction and mechanical damage, as well as the changes in the structures behavior and safety: static deformation, strains; crack widths and vibrations (frequencies, amplitudes, accelerations and vibration modes)

3) The identification of the most relevant degradation processes and mechanisms, specific to the structure of the bridges

4) The projection of an active integrated monitoring system of bridges network in Romania. The experimental research program consists of the testing in lab and in situ, in order to calibrate, some specific sensors within the scope of monitoring the degradation mechanisms through corrosion, carbonation, critical displacements and deformations, vibrations (frequencies and amplitudes)

5) The projection of a data acquisition and transmission system to a central monitoring unity. The experimental program deals with the calibration, in lab and in situ, of the data acquisition and transmission system at the Faculty of Civil Engineering and Building Services within the "Gheorghe Asachi" Technical University from Iaşi

6) The projection of a data processing and analysis system. It will be created a soft dedicated to the processing and analysis of the acquired data. The experimental program consists of the calibration in a lab and in situ of the processing and analysis system of the data acquired in situ

7) The integration of the information obtained within the surveillance and revision works by a technical authorized staff (this system is being applied at the moment) with the data acquired from the sensors deposited on the monitored structure (the new proposed monitoring system). The validation of the integrated continuous monitoring system of the transportation substructure, and especially of the bridges structure

8) The possibility to adopt a decision in time. The dynamic testing process, of identification of the dynamic characteristics, of the 3D calculation model calibration, of comparison with the values calculated in the previous phase, and of starting the warning protocol, must develop in a precise and rapid succession. The decision of launching the warning and protection protocol of the bridge must be a precise, clear and detached process from any shade of human subjectivism

9) The optimized administration of the transportation substructure. The access from time to the data base, to a calibrated 3D calculation model, enables the diagnosis in time of the technical condition of the section from the transportation substructure, and especially of the specific bridge. The calculation model enables the identification of the degradation type, the position of the degradation on the structure, the severity of the process, so that it can be established precisely:

- The duration in which the bridge can still be exploited in the established security and comfort of the traffic conditions
- The type of the necessary reparation works (the material consumption, manual labor, machines
- The rational repartition of the financial resources

10) Turning efficient the flux of necessary information in order to adopt in time the decisions to effectuate the reparation and consolidation works, to optimize the maintenance and financial resources allocation strategies necessary in the field of transportation substructure

11) The application of an integrated active monitoring and structural identification system will offer in time a complete and precise picture of the technical condition of the transportation substructure, thus realizing an efficient work instrument in the management process

12) The extrapolation of the results achieved at national and international level (through internet, participation to conferences and profile symposiums, initiation of national and international collaboration programs) by correlating and systemizing the data achieved in the field of the bridges in synthesis works and application instructions for all the engineering constructions (tunnels, railways, roads, industrial and profile constructions)

3 ACTIVE HEALTH MINITORING SYSTEM

The bridges network in Romania will be equipped with a system of sensors which will permanently determine their technical condition, indicating the temperature, the humidity and implicitly the moment of the apparition of the white frost, the PH and also the corrosion state of the metal fitting and of the concrete, the condition of crack, of deformation, displacement and vibrations (frequent and amplitudes). This information will be transmitted through a wireless system to a center zone of monitoring, where they will be centralized, registered, processed, and analyzed with the help of dedicated software to this scope. The information regarding the temperature, the humidity, the apparition of the white frost, the PH, the degree of corrosion, the degree of cracking, the degree of deformation, the displacements and vibrations, will be visualized in a direct and continuous manner, in a real time and on monitors placed in the center zone monitoring, which will be placed at the beginning in a research lab from the Faculty of Civil Engineering and Building Services from Iaşi, the technical assistance will be ensured on the entire duration of the exploitation by the research collectives consisting of teachers, the students, those from the master and the doctoral candidate will be directly involved in this research program. The software used in order to analyze the monitored information will be equipped with a decisional protocol that will break out a warning signal in the moment in which the values of the monitored parameters will surpass a critical level established by the alert (Sousa et. al., 2016).

In order to be able to identify the critical line of alert and to make the warning signal, especially in the case of the bridges, the software has to have stocked in his memory for each parameter monitored the mathematic model of the specific degradation model and also the possibility to identify in a real time the progressive stage in which the degradation process manifests at the structural level. Within this scope, there has to be effectuated separately for each degradation process, theoretical and experimental studies that will be able to identify a correspondent mathematic model, the evolutionary manifestation process on the structure and the critical alert levels, and who's surpassing to displace the active monitoring protocol, of protecting by the application of the maintenance and/or reparations works of the degraded structure.

1) The active monitoring of the temperature parameters and the humidity allow the identification in a real time of the apparition moment of the fog and of the white frost on the road section or on the monitored bridge. The active monitoring of the process enables the fact that immediately after reaching the critical alert level, the protective protocol of the structure is tripped. In case of fog and white frost on the highway sections, the consequences are very severe, with numerous victims and very important material losses, so the protection protocol has to start in time and consists of releasing visual and sound signals in order to reduce the driving speed, to increase the distance between the vehicles, to direct quickly the police and SMURD towards the specific sector, to deviate the circulation towards local deviation variants, to put into function the bridges, a heating system installed in the dale that will remove the white frost from the bridge

2) The active monitoring of the PH enables the identification of the starting moment of the process of carbonating the concrete and also of structural fission followed by the corrosion of the resistance metal fitting. The active monitoring of the process allows that immediately after achieving the critical level of alert, a structure protection protocol starts, that can consist, according to the seriousness of the degradation process, of the preventive application of some current maintenance works, special reparation works that will ensure the structural protection by removing the degradation process from the structure

3) The active monitoring of the displacement condition enables the identification of the moment in which, under the action of the current duties from the traffic, or after the production of a special event (earthquake, floods followed by the erosion of the substructures, the modification of the route or of the bed trellis of the course bed crossed, accidents through hitting the construction materials, too heavy transportations, massive landslips, terrorists attacks, etc.) the arrow of the structure exceeds the admissible value (critical level of alert), and thus there is the danger of surpassing the capacity of the structure and of losing the structural stability, followed by the collapse of the bridge and thus In the case in which it is built on a highway, it will produce very severe consequences with numerous victims and important material losses. The active monitoring of the process of the displacement condition of a bridge built on a highway enables the application of a protection and administration crisis protocol, by directing rapidly the police and SMURD teams towards the affected sector, an imposition protocol of the restrictions regarding the speed and the weight, followed by the deviation of the circulation towards other routes.

The active monitoring processes of the temperature parameters and humidity, of the pH and of the displacement conditions, is permanently developed on the level of transportation substructure, following that on the monitors placed in the center regional of monitoring, the surveillance staff will be enabled to visualize these parameters continuously. The process of monitoring enables the starting, in the moment of surpassing, the critical alert levels, in time the active protection protocol of the monitored section.

Trough comparison with the permanent and continuous monitoring process of the parameters of

temperature, humidity, pH and arrows, the monitoring of the vibration parameters is applied periodically (frequencies, amplitudes and specific forms of vibrations) in an interval of maximum one year, and compulsory, after the production of some special events (earthquakes, floods followed by the erosion of the substructures, modification of the route or of the bed trellis of the crossed course bed, accidents caused by the percussion of the constructive elements, too heavy transportations, massive landslips, terrorists attacks, etc.) and consists of the dynamic testing of the bridge with the help of a series of apparatus of dynamic exercise, acquisition, processing and analysis (fig. 1), installed in a mobile lab which will be displaced periodically in the location of the bridge (Sousa et.al., 2013, Khoo et.al., 2004).

Monitoring the vibration parameters will be applied at the beginning of the bridge's exploitation, being considered as dynamic testing at T_0 time, and deals with the covering of the following 3 standard stages:

1) Exercising the bridge with an electrodynamics vibrator or through impact produced with the help of a special hammer

2) Identification of the dynamic characteristics (values and special vectors, amortization characteristics) with the help of electronic equipment used for data acquisition and of a calculation program dedicated to the modal analysis

3) Calibration of the 3D calculation model is realized in time and consists of a comparison between the dynamic characteristics obtained by testing dynamically the bridge, and the dynamic characteristics of a 3D calculation model of the tested bridge built with the help of a dedicated calculation program based on the finitely element method

The instruction process will be realized in the Bridge Tests Lab, one time only, on the occasion of the first modal testing, at the T_0 time, of the specific bridge. The calibration process deals with the modification in successive stages of the theoretical dynamic characteristic values, of the 3D model, until theses will coincide with those experimentally obtained, in situ, and considering that at the T_0 time the bridge presents a very good technical condition, and having a total index $I_{ST} > 80$ points.

The 3D calculation model thus calibrated at the T_0 time is stocked in the data base of the specific bridge, as a *"dynamic stamp"* of the bridge, at the T_0 time that will enable the *"dynamic identification"* of the specific structure.

Periodically, at an interval of maximum one year, and compulsory after the production of a series of special events (earthquakes, floods followed by the erosion of the substructures, accidents caused by the percussion of the constructive elements, too heavy transportations, massive landslips, terrorists attacks, etc.) the cycle consisting of 3 standard stages will repeat: exercising, identification of the dynamic characteristics and calibration of the model. All the subsequent calibrations of the 3D calculation model socked in the data base, will be made in successive steps, at T_i time and will consist of the modification both of the mechanical characteristics of the materials (because of the rheological processes of contraction and slow flowing of the concrete, relaxation and corrosion of the metal fitting, carbonation of the concrete) and of the modification of the structural geometrical characteristics (as an effect of the propagation of a fissure process, displacement, deformation or vibration of the structure) in relation with the calculation calibrated model from the previous test stage, at the Ti-1 time (Haritos et al., 2004).

The monitoring process continues in successive steps on the entire duration of exploitation of the bridge until, as a result of the modal analysis effectuated at a T_Z time, modifications with significant values of the dynamic characteristics will be identified, situation in which an active monitoring process will start, process which consist of the following stages:

1) The starting of a warning protocol produced by a modification with significant values of the dynamic "stamp" of the bridge and which indicates the presence on the monitored bridge of a structural degradation process

2) The identification of the type of degradation, its position on the structure and the degree of development of the degradation process, the place on the structure where it manifests and its seriousness is realized by calibrating the 3D calculation model stocked in the data base. The process bears the name of "structural identification" of the bridge

3) The starting of the protection protocol which consists of imposing a reduction of the speed and of the weight, of increasing the distance between vehicles, of closing certain circulation lines, of directing the firemen, the police, and of the SMURD teams towards the monitored bridge, and finishing with forbidding the circulation on the bridge and complete and precise indication of the duration of closure, of the possible deviation routes.

4 INTEGRATION OF THE PROCESS OF MONITORING AND IDENTIFICATION SYSTEM

After the calibration and the implementation of the active monitoring system and of the structural identification system in dynamic regime, at the level of the road section and according to the financial resources allocated and of the priority offered in the strategic plan of development at the national level, the integration process follows directed to two strategic axes of action:

At the knowledge extraction and decision-making supported by the SHM data stage, the following steps are covered (Fig. 1):

Step 1. Monitoring of the chemical parameters enables the identification of the appearance moment of the process of carbonating the concrete followed by the corrosion of the steel reinforcing roads (Swartz and al. 2009, Jang and al. 2002)

Step 2. Monitoring of the bridges enables the identification of the moment in which, under the action of the traffic, or after the production of a catastrophic event (earthquake, floods followed by the erosion of the substructures, terrorist's attacks, etc.), the deformation state of the bridge exceeds the admissible value, and achieves a critical level of alert

Step 3. By comparing with the permanent and continuous monitoring process of the physical and chemical parameters and structural deformations of bridge, the monitoring of the dynamic parameters is applied periodically (frequencies, amplitudes and specific forms of vibrations) in an interval of maximum one year and compulsory, after the production of some catastrophic events (earthquakes, floods followed by the erosion of the substructures, accidents caused by the percussion of the constructive elements, heavy transportations, terrorists attacks etc.)

Step 4. Each the dynamic testing of the bridge performed in situ is followed in the laboratory by a process of recalibration of 3D model of each bridge. If monitoring of the dynamic characteristics to the T_i step does not identify significant changes in the dynamic mark of the bridge from the T_{i-1} step, then the technical condition of the bridge is diagnosed as being "adequate"

Step 5. Monitoring process continues in successive steps on the entire duration of exploitation of the bridge until, as a result of the structural monitoring of the bridge, in T_z step, will be identified modifications with significant values of the dynamic characteristics in relation with the dynamic mark of the bridge from the T_{z-1} step (Karbhari and al. 2009)

The use of permanent monitoring systems has several advantages once the system is installed:

- A more reliable prediction of the progress of damage as a function both of the measured parameters and of the application of realistic deterioration models, as well as a better understanding of individual deterioration mechanisms and their interaction
- Traffic interference is reduced
- An input for defining maintenance and repair strategies (time and extent) as a function of the actual and foreseeable levels of deterioration
- The costs of access to the structure and resources for inspection and testing are reduced
- Structural elements with difficult access are easily monitored
- An evaluation of the need for further inspection and testing

5 CASE STUDY

The suspended bridge over an arm of the Danube River, has a length of 360 m, with three openings of 60+240+60 m (fig. 2). The bridge ensures the passage of light vehicles with a weight of up to 3.5 tons, on a single lane, with traffic light. The superstructure of bridge is hybrid, consisting of two sections of 70 m precompressed concrete panel and a 220 m metallic panel on the central opening.

They were executed precision measurements in 38 characteristic points, 19 upstream and 19 downstream, with a Leica Sprinter 150M digital level with a precision of 1.5 mm per 1 km measured. The topographical landmarks were installed on both sides of the bridge, both downstream and upstream. On the bridge abutment, two sections were measured to determine possible rotations. On the marginal openings, measurements were made in the bearing points and in the middle of the opening. On the central opening, were made measurements from the joining of the metal plate to the concrete one and continued from each third cable to the middle of the bridge.

5.1 *Precise level measurement*

Measurements were made of precision levelling in characteristic measuring points.

The points are fitted on both sides of the bridge from both downstream and upstream towards.

Abutments were measured on two sections to determine the possible rotations. The marginal openings were made measurements of end points and mid-span.

Were measured 38 points, 19 sections (19 upstream and 19 downstream).

5.2 *Dynamic characteristics of the suspended bridge*

To measure the dynamic characteristics of the suspended bridge, the Pulse model 3560B with the 7540A frame has been used, with 5 input channels and 1 output channel. The maximum measurement frequency is 25.6 kHz. To identify the values and eigenvectors, 6 piezoelectric accelerometers, model 4507B-002 Delta Tron, were mounted on each opening of the bridge.

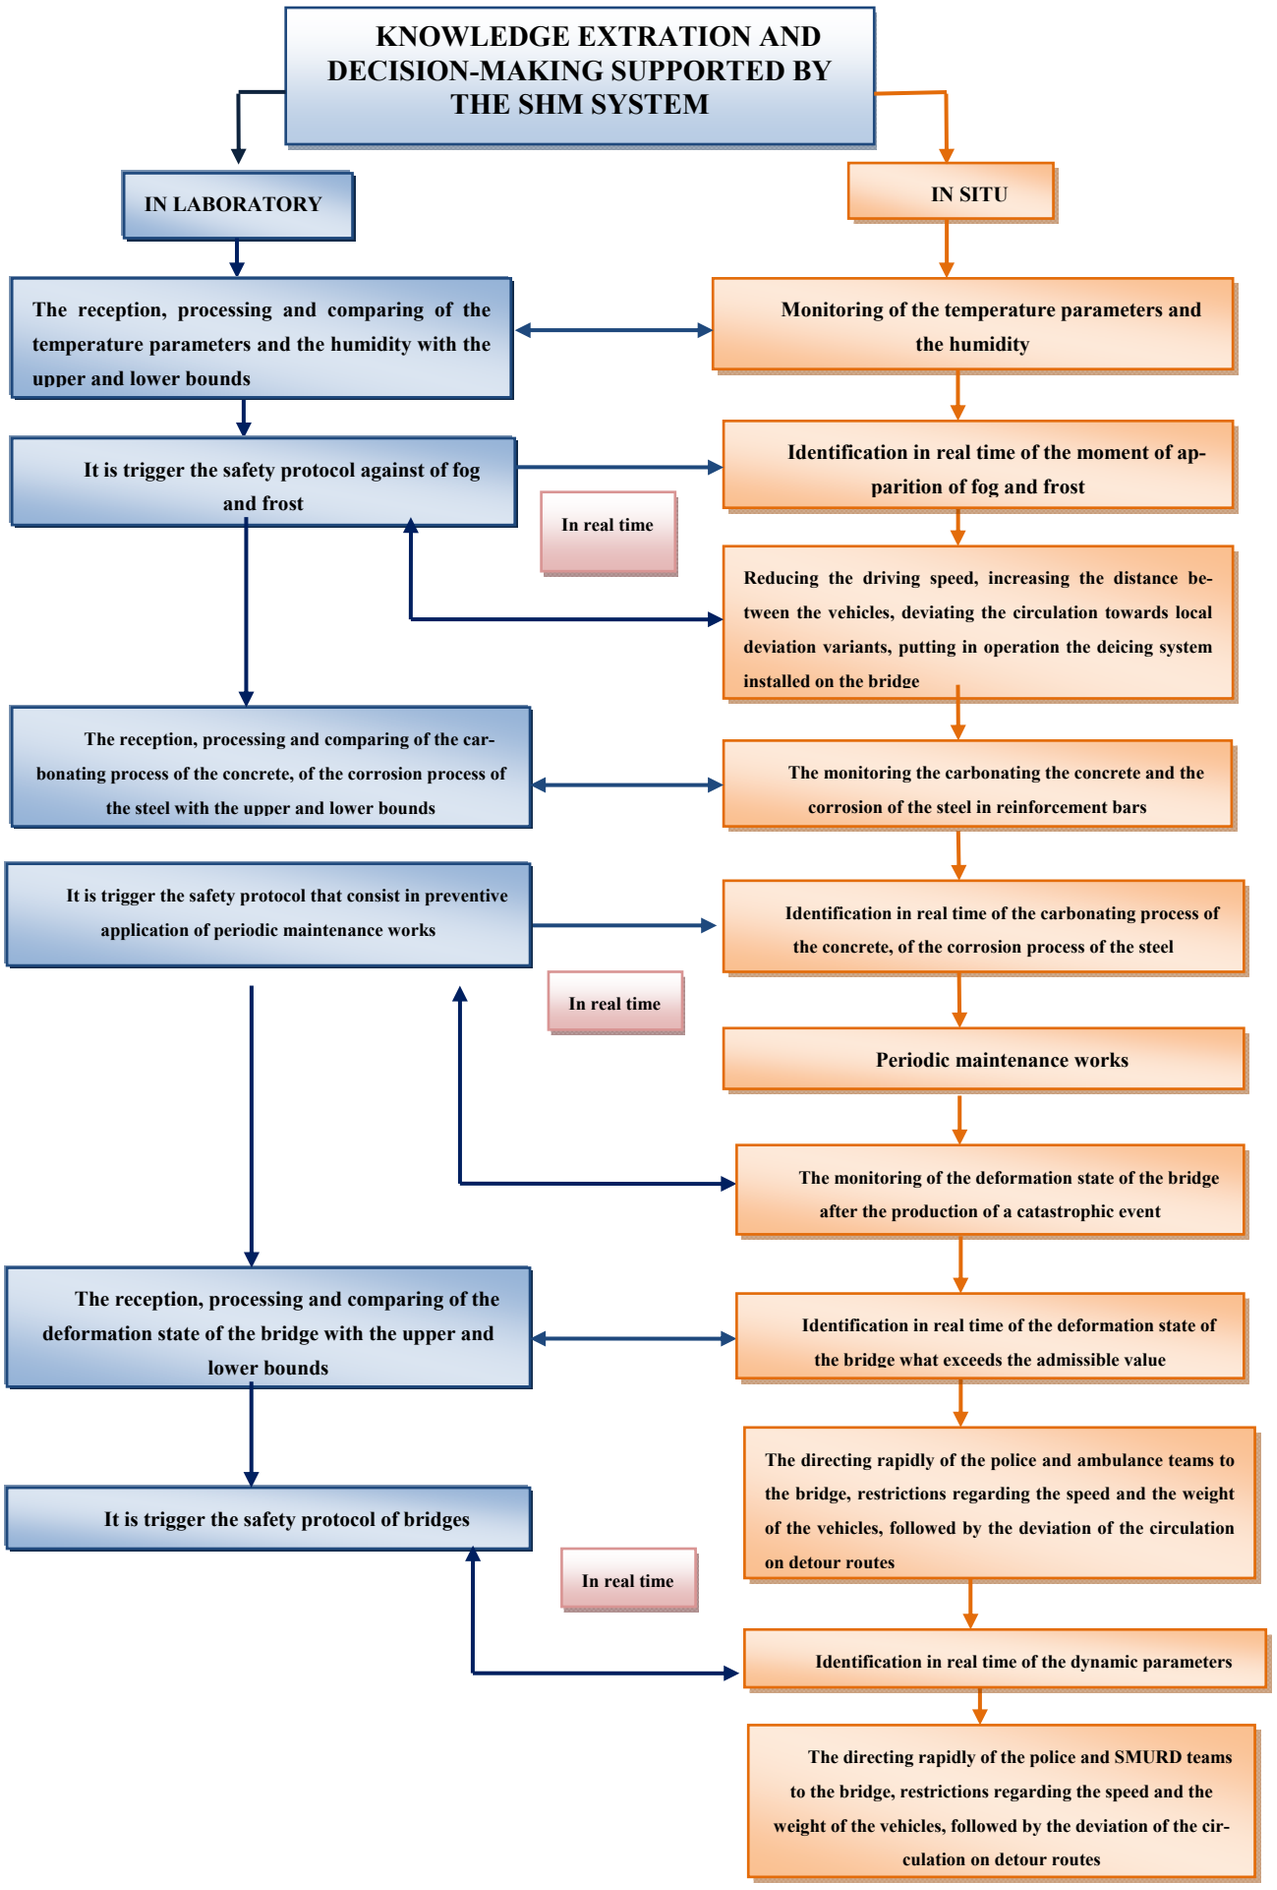

Fig. 1 – Knowledge extraction and decision-making supported by the SHM System

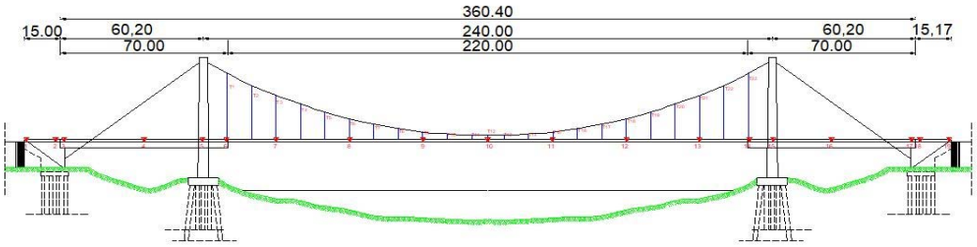

Fig. 2. Longitudinal lengths

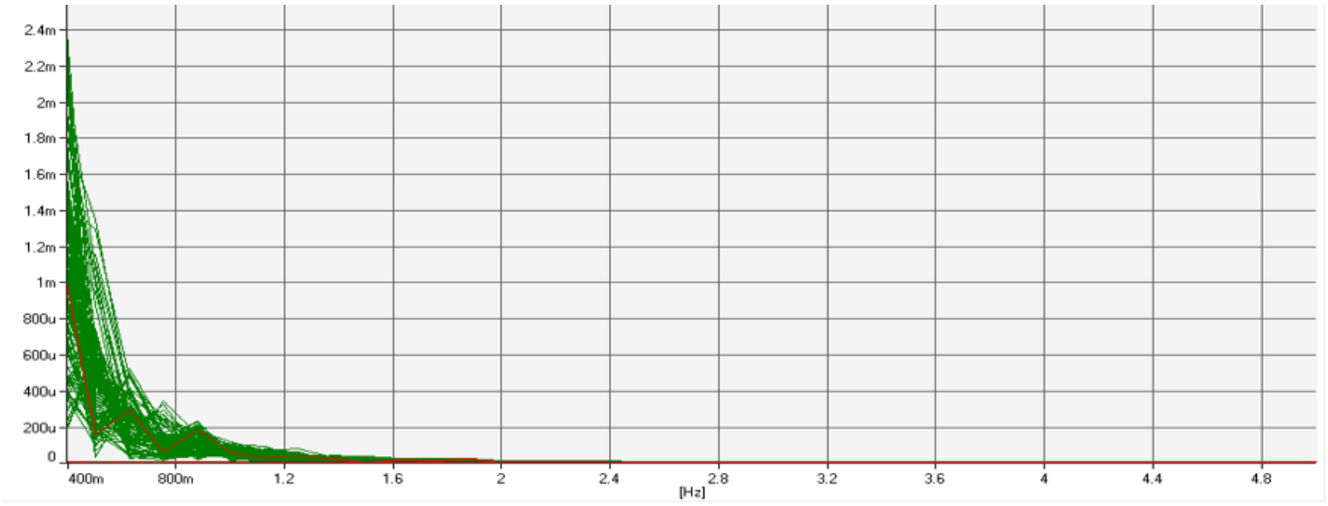

Fig. 4. Autospectrum (Signal 1) Working Measurement 2: Multi-buffer 1: FFT Analyzed

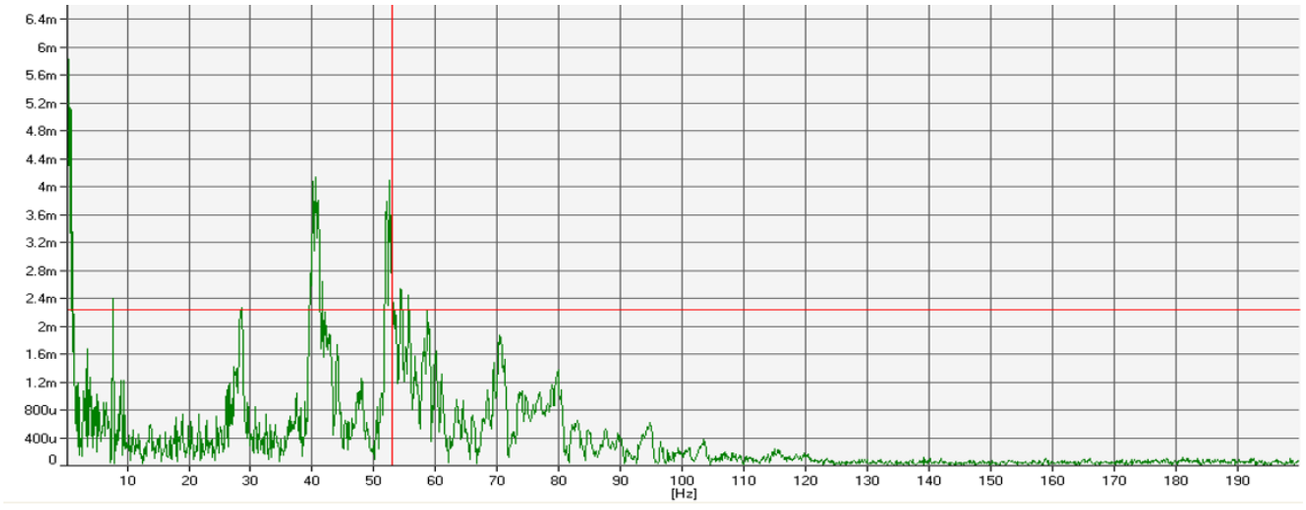

Fig. 5. Autospectrum (Signal 1) Working Measurement 2: Multi-buffer 1: FFT Analyzed

A total of 300 recordings were made at 400 ms.

The dynamic characteristics of the bridge were identified in the frequency domain, covering a range of 52.39 s.

The resolution in the frequency domain is 125 mHz and in the time domain in 1.953 ms.

Under the action of mobile loads of the road traffic on the bridge, the following response spectrum was recorded.

The first 10 frequencies were identified: 1.125 Hz, 1.5 Hz, 3 Hz, 7.625 Hz, 13.63 Hz, 16.13 Hz, 18.75 Hz, 28.38 Hz, 40.37 Hz, and 52.38 Hz (Fig. 5).

The fundamental frequency of the value was identified f_1=1.125 Hz.

By double integration of the previously obtained accelerations, the values of the vertical displacements are obtained.

The maximum dynamic range is 2.4 mm (Fig. 4).

5.3 *Conclusion of level measurements*

From the analysis of measurements performed, shows the following:

1) Improving the durability requests of bridge structure through the application of an integrated permanent and active monitoring system.

2) The identification of the most relevant degradation processes and mechanisms, specific to the structure of this bridge.

3) The projection of a data acquisition and transmission system to a central monitoring unity.

4) The projection of a data processing and analysis system. The experimental program consists of the calibration in a lab and in situ of the processing and analysis system of the data acquired in situ - suspended bridge over an arm of the Danube River.

5) The integration of the information obtained within the surveillance and revision works.

6 CONCLUSIONS

The aim of SHM system is the improved knowledge of the current state and long-term behavior of bridges in Romania. The monitoring system must integrate the actual practice mainly based on visual inspections and combines the response of a number of different reliable sensors, installed on the structure to monitor the progress of damage, with enhanced realistic deterioration models. The system and the sensors were developed to cover the parameters for the most important deterioration mechanisms: corrosion of reinforcement in bridges, carbonation of concrete, freeze-thaw cycles, alkali-silica reaction and mechanical damage, as well as the changes in the structures behavior and safety: static deformation, strains; crack widths and vibrations. In order to be able to identify the warning levels, the monitoring process must be equipped with a data base including mathematic models for each degradation process, and also an evaluative characteristic process of the latter.

In the moment in which the monitoring systems signals the surpassing of an alert level regarding a degradation process, the process of structural identification will begin. This process consists of the application of 3 successive phases: dynamical testing, identification of the dynamical characteristics and calibration of a 3D calculation model built from finite elements. The dynamic testing is realized by exercising the structure with the help of an electrodynamics vibrator or special impact hammer, according to the size and static scheme of the bridge. The testing enables the identification of the dynamic characteristics through modal analysis in the field of frequencies. The calibration of the calculation model enables the comparison of the value between the dynamic characteristics determined at the specific moment and the values determined at a previous time; the significant differences established between the values of the dynamic characteristics identified in different moments, indicate the presence on the monitored structure of a major degradation process. From this moment it begins the application of the structural identification process by calibrating the calculation model in order to enable the exact establishment both of the place in which the process of degradation manifests, and of the consequences over the monitored structure. According to the severity with which the process of degradation manifests over the element of the transportation structure, it starts a protection protocol which can impose speed and weight reductions, increasing the distance between vehicles, closing certain circulation lines, directing the firemen, the police of the SMURD teams, towards the monitored bridge, and finishing with closing the traffic on the bridge and the precise indication of the duration of closure, of the possible deviation routes and of the reparation and/or consolidation necessary works.

Deformation Monitoring of a Simply Supported Railway Bridge under Varying Dynamic Loads

K. Faulkner, F. Huseynov, J. Brownjohn & Y. Xu
Vibration Engineering Section
University of Exeter, Exeter, UK

ABSTRACT: Structural health monitoring is a useful tool for evaluating the condition of bridges, with permanent systems installed on bridges which form vital links on the major transport network. The economic cost of the monitoring systems limits their installation on smaller bridges which make up the wider transport network. A short-term monitoring system can be quickly installed and adjusted to suit the requirements of individual bridges. These systems are ideal for rural regions with a high number of single span bridges on isolated road and rail networks. This report will review a single span bridge on a private heritage railway under loading from passing steam engines, including the Flying Scotsman. Acceleration data are used to determine the rotations and deflections of the bridge deck. To verify the data, deflection measurements at mid-span were recorded using a video-based measurement system. The deflection measurements from the accelerometers correlate with the video imagery measurements.

1 INTRODUCTION

1.1 *Bridge Failures*

Bridge failures pose a significant risk to human life but can also have a major economic impact on the affected regions. The collapse of the I-35 W bridge in Minnesota, US in 2007 killed 13 people and led to a loss of US$17 million in 2007 and US$43 million in 2008, excluding any of the indirect costs (Deng et al. 2015). Across Europe the infrastructure is ageing, with an estimate of 30% of bridges exceeding 100 years of age (Connolly et al. 2016). In the UK, a review of the railway infrastructure during the period of 1846 to 2013 by van Leeuwen & Lamb (2014) attributed 138 bridge and culvert failures to flooding alone. A more recent report identified that 25% of the 603,168 bridges in the United States are rated as deficient by the Federal Highways Agency (FHWA) (Elsaid & Seracino 2012). Elsaid & Seracino (2012) further reported that the American Association of State Highway and Transport Officials (AASHTO) identified in 2009 that 50% of the bridges in the US are over 40 years and without sufficient knowledge of their current condition. A detailed review of the causes and mechanisms of bridge failure was performed by Deng et al. (2015).

Structural health monitoring (SHM) of large multi-span bridges is becoming increasingly commonplace, with systems been retrofitted to older bridges and with complex data acquisition systems installed on new builds. A review of SHM techniques was carried out by Webb et al. (2014) who categorised SHM into five categories; (1) anomaly detection, (2) sensor deployment studies, (3) model validation, (4) threshold check and (5) damage detection. Sohn and Farrar (2001) further categorised damage detection into five categories, building on previous work performed by Rytter (1993): (1) identification of the presence of damage in a structure, (2) localisation of the damage, (3) identification of the type of damage, (4) quantification of the severity of the damage and (5) prediction of the remaining service life of the structure.

There is a recent trend towards damage detection, particularly towards identifying damage through a decrease in the natural stiffness of a structure. Brownjohn et al. (2011) reviewed vibration-based damage detection techniques, but determined that for damage detection, vibration-based methods are not suitable for all but the most severe cases of damage. This study will instead follow the form of a sensor deployment study, with the intention to measure a series of parameters to determine the performance of the bridge under varying loading conditions.

Predominantly SHM systems are installed on long span bridges, which are vital links on major

transport routes, due to the cost of both installing the instrumentation and also the processing cost required to correctly interpret the data. This study will focus on a short span bridge on a heritage railway, as the bridge is representative of a large number of the smaller bridges which make up the wider transport network across the country, particularly in rural areas. The aim is to eventually develop a system that can be easily transported between a number of bridges and can be quickly adapted to fit the testing requirements of each bridge.

2 WEST SOMERSET RAILWAY

The West Somerset Railway (WSR) is the longest heritage railway in England, with almost 23 miles of track servicing 10 stations. The railway, located in South West England, was opened in 1862 and was originally servicing villages between Taunton and Watchet. The service was further expanded in 1874 as far as Minehead.

The route was closed by National Rail in 1971 but re-opened in 1976 to service local routes with predominantly diesel locomotives. By 1986, the railway was operating as a heritage railway using mainly steam-powered locomotives, travelling between Bishops Lydeard and Minehead. The railway predominantly operates through the Spring to Autumn months, with additional special services in place throughout the year.

2.1 *Mineral Line Bridge*

The Mineral Line Bridge, located to the west of Watchet station, was originally designed to carry the route over the West Somerset Mineral Railway, which now operates as a bridleway open to the public. The bridge is a 14.8 m steel girder single span bridge, with two masonry abutments and with a single track running on it. The abutments are orientated with a skew angle of $60°$ to the main beams of the bridge.

The bridge was originally constructed in the 1870s of wrought iron plate girders, carrying a timber deck supporting the ballasted track bed. The abutments were constructed from stone. A comprehensive maintenance and repair programme to the bridge was carried out in 2011.

2.2 *Locomotives*

The service is predominantly serviced by steam-powered locomotives, but a small number of diesel continue to operate on the route. The largest and most powerful locomotive owned by the WSR is the Raveningham Hall, weighing 76.4 tonnes with a single axle load of 17 tonnes.

Table 1: Steam locomotive details

Locomotive	Year Built	Length [m]	Gross Weight [tonnes]
Flying Scotsman	1923	21.3	97.8
Raveningham Hall	1944	19.2	76.4
7F Class 2-8-0 53808	1925	17.9	65.8

Figure 1: Flying Scotsman locomotive passing over the Mineral Line bridge

Every year the National Railway Museum loans the Flying Scotsman locomotive for special tours across the country and in September 2017 the locomotive came to the WSR. The Flying Scotsman has a gross weight of 97.8 tonnes and a varying axle load of 4 to 11 tonnes. Table 1 presents an overview of all the steam locomotives used during the experiment. The weight indicated in Table 1 is the gross weight of the engine when full, but does not include the tender behind. The Flying Scotsman and Ravenington Hall are depicted in Figure 1 and 2, respectively.

The direction of travel for the train determined the position of the locomotive and the tender. In the Watchet to Minehead direction, the engine preceded the tender and on the return route the tender was at the front of the train. The orientation of the engine and the tender is summarised in Table 2. The times for the train are adjusted to the nearest 5 minute mark.

3 METHODOLOGY

There were two aims for this study:

1. to determine the rotation of the bridge deck under varied loading conditions;

2. to determine deflection at mid-span under the loading conditions.

3.1 *Rotation*

Inclinometers are the most common method used to measure the angle of rotation of an object, but can only be used to measure the rotation with respect to

Table 2: Locomotives passing on track

Train	Time	Locomotive	Direction	Locomotive Configuration	Number of Carriages
1	11:15	Raveningham Hall	BL - MN	Engine	8

gravity. Gyroscopes are frequently used in aerospace and navigational industries but have limited use in structural health monitoring to date. Sung et al. (2013) recommend gyroscopes as a method of refining damage detection techniques at hinged supports of bridges using the measured angular velocity.

For this study, accelerometers were used to define the angles of rotation in place of inclinometers. For this study, a single axis of acceleration was used to determine the angle of rotation. The rotation is determined by projecting the gravity vector on the axes of acceleration.

3.2 *Deflection*

The deflection of the bridge was determined using the accelerometers positioned in Figure 4 and confirmed against the deflections measured using Imetrum cameras. The following procedure for calculating deflection is derived from the method presented by Helmi et al. (2015).

Helmi et al. (2015) proposed a method of deflection calculation using accelerometer and strain gauges. The method can be used without strain gauges if a sufficient number of inclination sensors are installed on the bridge. With 5 test measurement points along the length of the 14.8 m bridge span, accelerometer data is sufficient to calculate the deflection for this testing scenario. Their method is reproduced in the following paragraphs.

The rotation along the beam is a measurable parameter and can be explained as a n^{th} order polynomial, expressed as

$$\varphi = a_1 x^n + a_2 x^{n-1} + \cdots + a_i x^{n-i+1} + \cdots + a_n x + a_{n+1} \quad (1)$$

where φ is the angle of rotation, x is the distance along the bridge and a_i is the polynomial coefficient.

Deflection, δ, at any point along the bridge can be determined from the following relationship:

$$\delta = \int \varphi dx \quad (2)$$

Therefore deflection can be calculated by integrating Equation 1:

$$\delta = \frac{a_1}{(n+1)} x^{n+1} + \frac{a_2}{n} x^n + \cdots + \frac{a_i}{n+2-i} x^{n+2-i} + \cdots + \frac{a_n}{2} x^2 + a_{n+1} x + a_{n+2} \quad (3)$$

If we consider one of the abutments as a reference point, with $x = 0$ and $\delta = 0$, then $a_{n+2} = 0$. Using this, we can simplify Equation 3 to

$$\delta = \frac{a_1}{(n+1)} x^{n+1} + \frac{a_2}{n} x^n + \cdots + \frac{a_i}{n+2-i} x^{n+2-i} + \cdots + \frac{a_n}{2} x^2 + a_{n+1} x \quad (4)$$

Using Equation 4, deflection at any point along the bridge can be determined if the polynomial coefficients are known, which is the main advantage of this method. The polynomial coefficients are determined from the following matrices, provided that rotation and deflections are known at $n+1$ or more points:

$$\begin{bmatrix} x_{\varphi 1}^n & x_{\phi 1}^{n-1} & \cdots & x_{\varphi 1} & 1 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ x_{\varphi i}^n & x_{\varphi i}^{n-1} & \cdots & x_{\varphi i} & 1 \\ \frac{x_{\delta 1}^{n+1}}{n+1} & \frac{x_{\delta 1}^n}{n} & \cdots & \frac{x_{\delta 1}^2}{2} & x_{\delta 1} \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ \frac{x_{\delta k}^{n+1}}{n+1} & \frac{x_{\delta k}^n}{n} & \cdots & \frac{x_{\delta k}^2}{2} & x_{\delta k} \end{bmatrix} \begin{bmatrix} a_1 \\ a_2 \\ \vdots \\ a_n \\ a_{n+1} \end{bmatrix} = \begin{bmatrix} \varphi_1 \\ \vdots \\ \varphi_i \\ \delta_1 \\ \vdots \\ \delta_k \end{bmatrix} \quad (5)$$

4 TEST SET UP

In this section we summarise the equipment used during the testing and the sampling programme. Testing was performed on the 5th September 2017; the first day of the Flying Scotsman special tour on the WSR. The locomotive previously travelled the length of the track on the 29 August at reduced speed to confirm the clearances of the platforms and the bridges was sufficient for the locomotive but the passing of the Flying Scotsman on the 5th September was the first time the locomotive passed at full speed agreed for travel along the route.

The purpose of the study was to examine the Mineral Line Bridge under loading from a number of different locomotives, including the Raveningham Hall and the Flying Scotsman. Whilst all bridges and track along the WSR were analysed prior to the arrival of the Flying Scotsman locomotive, to ensure the WSR met the required capacity, this study measured the performance of the structure to confirm the review.

4.1 *Accelerometers*

A total of 11 single axis Honeywell QA750 inertial grade sensors accelerometers were installed on the bridge deck, with three accelerometers installed at quarter-span, mid-span and three quarter-span to measure the x, y and z channels. A single accelerometer was installed in the longitudinal (x) direction at

Figure 4: Layout of the accelerometers on the deck

each of the supports.

The accelerometers were positioned on the northern side of the bridge deck, with Test Point 1 located on the eastern abutment, increasing to Test Point 5 on the western abutment. The test layout is presented in Figure 4.

4.2 *Measurements with Video Imagery*

The Imetrum measuring system was developed by the University of Bristol to use image processing to accurately determine deflection and strain measurements in structures. The cameras are particularly useful for outdoor environments where it can be difficult to install measuring devices on large structures.

A total of three cameras were installed at site, with one camera positioned to measure deflection at mid-span on the bridge and two cameras positioned to measure deflections on the abutment. The measurements on the abutments are not considered as part of this study. The Imetrum camera layout is presented in Figure 5.

4.3 *Processing*

The data was analysed in MATLAB using the procedures outlined in Section 3. A low pass filter was applied to isolate the accelerations caused by the movement of the train. The data was further smoothed by applying a moving average filter.

Figure 5: Layout of the Imetrum cameras

4.4 *Test Procedure*

Rotation data was calculated from the accelerometers positioned in the horizontal axes. The deflection at mid-span was later determined using the rotation data obtained from the accelerometers and confirmed against the results of the Imetrum camera.

Data collection commenced before the train was due, to allow sufficient time to analyse the bridge under ambient loading before each test. As the exact arrival time at the bridge was not available, the data collection time before the train approached the bridge varied for each train. The running order of the trains and the direction of travel is recorded in Table 2.

Table 3: Measured Rotations

Train	Locomotive	Rotation [deg]
1	Raveningham Hall	0.093
2	Diesel	0.044
3	Flying Scotsman	0.098
4	Raveningham Hall	0.095
5	Flying Scotsman	0.099
6	7F Class 2-8-0 53808	0.081
7	Raveningham Hall	0.089
8	Flying Scotsman	0.108

4.5 *Environmental Considerations*

Weather conditions during the testing were varied throughout the day, with periods of heavy rain intermixed with periods of sunshine. As the sensors are not completely waterproof, a number of tests were performed with plastic bags on the sensors to protect the sensors from excessive rainfall. Whilst every effort is made to limit the amount of air in the bag and to reduce the possibility of buffeting, the bags can cause excess background noise during measurements. During the analysis of the results, the noise produced by the plastic bags was found to be negligible.

5 RESULTS

This section presents the measured rotations and deflections recorded during the aforementioned testing. For each steam locomotive, the measured rotation and deflection plots presents a clear peak for the locomotive followed by smaller peaks of equal amplitude representing the trailing carriages. Within the peak of the locomotive, it is also possible to determine the orientation of the tender and the engine, as the engine is responsible for the larger peak. The reduced diesel locomotive weight results in a measured rotations and displacements similar to the carriages behind.

5.1 *Rotation Data*

Rotation of the bridge under loading was calculated using the method proposed in Section 3.1. The maximum rotation of the bridge under loading from each locomotive is presented in Figure 6. The measured maximum rotation for each loading scenario is presented in Table 3.

Rotation was measured in the longitudinal direction. The maximum rotation was always measured at the abutment furthest away from the approaching trains for the steam engines.

The maximum rotation of $0.108°$ was recorded at Test Point 5, the western abutment, under loading from the Flying Scotsman (Train 8), with the other two passings of the train measuring a rotation of $0.098°$ to $0.099°$.

The Raveningham Hall displayed smaller rotations than the Flying Scotsman locomotive, with a maximum measured rotation of $0.095°$. Though the Raveningham Hall has a greater axle load than the Flying Scotsman, the heavier weight of the Flying Scotsman results in larger rotations.

Only a single measurement was recorded for the 7F Class 2-8-0 53808 steam engine. The maximum rotation measurement recorded for engine was $0.081°$, which was expected for the lighter engine. Following this trend, the maximum measured rotation for the diesel locomotive was significantly smaller, with a maximum deck rotation of $0.044°$.

The same carriages are used to form each train, but it can be seen that the rotations caused by the carriages following the Flying Scotsman are the highest. As each of the Flying Scotsman journeys were operating at full capacity, the increased rotations are likely to be a resultant of the increased live load of these carriages.

5.2 *Deflection Data*

Deflection was calculated at the mid-span of the bridge using the method proposed in Section 3.2. The maximum deflection calculated for each locomotive is presented in Figure 7, plotted against the measured deflections from the Imetrum data. The measured deflection at mid-span and quarter-span for each train is presented in Table 4.

The maximum deflection measured was 7.00 mm for Train 3, the Flying Scotsman. The higher deflection for Train 3 can be attributed to the train travelling at a faster speed during this passing of the train. The speed of the train was determined from determining the entry and exit times of the train on the bridge. Similar to the rotation measurements, the Raveningham Hall deflections measurements were marginally smaller, with a maximum measured deflection of 6.58 mm.

The correlation between the deflection measurements recorded for the Flying Scotsman and the Raveningham Hall indicate that the increased weight of the Flying Scotsman has a negligible effect on the bridge.

The deflection measurements for the carriages exhibit a similar trend to the rotation data, with increased deflections measured for the carriages following the Flying Scotsman locomotive.

Prior to the Flying Scotsman arriving to the railway, essential maintenance was carried out by the bridge owner to ensure the bridge was capable of carrying the increased size of the locomotive.

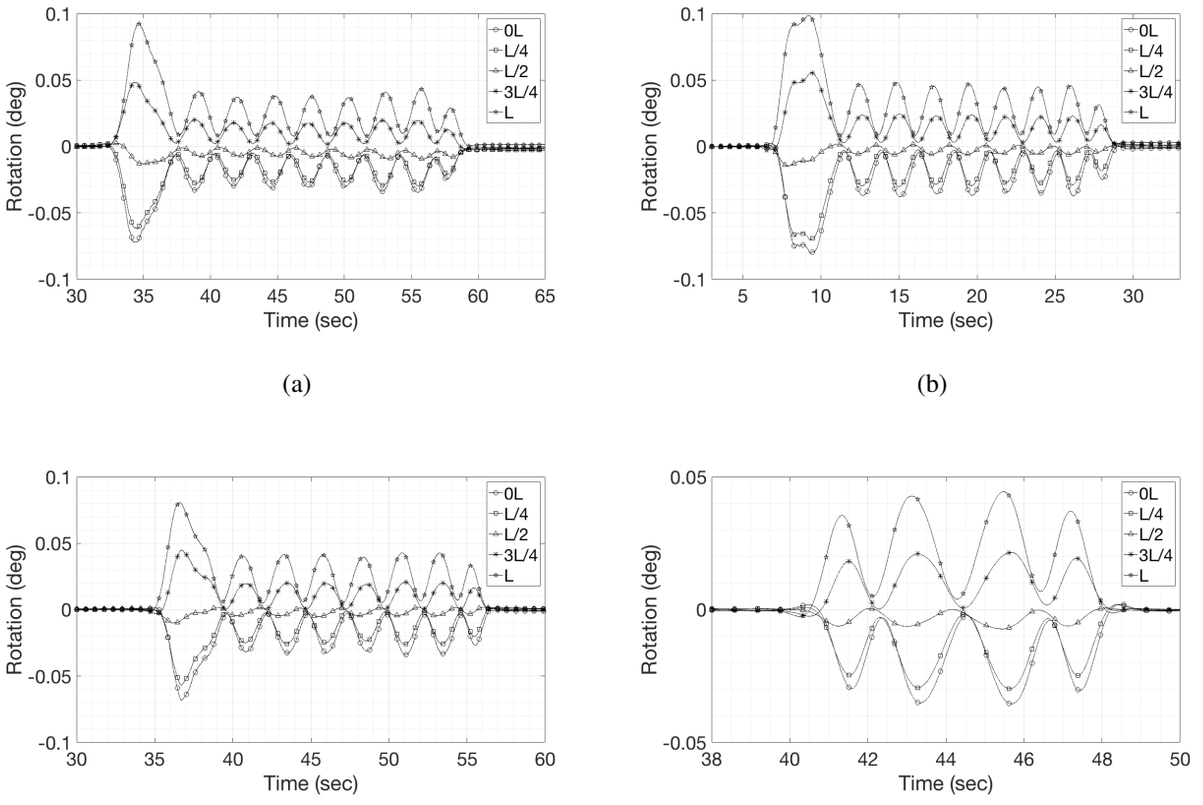

Figure 6: Rotations from accelerometer data under different train loads, (a) Raveningham Hall (Train 1), (b) Flying Scotsman (Train 3), (c) 7F Class 2-8-0 53808 (Train 6) and (d) Diesel (Train 2)

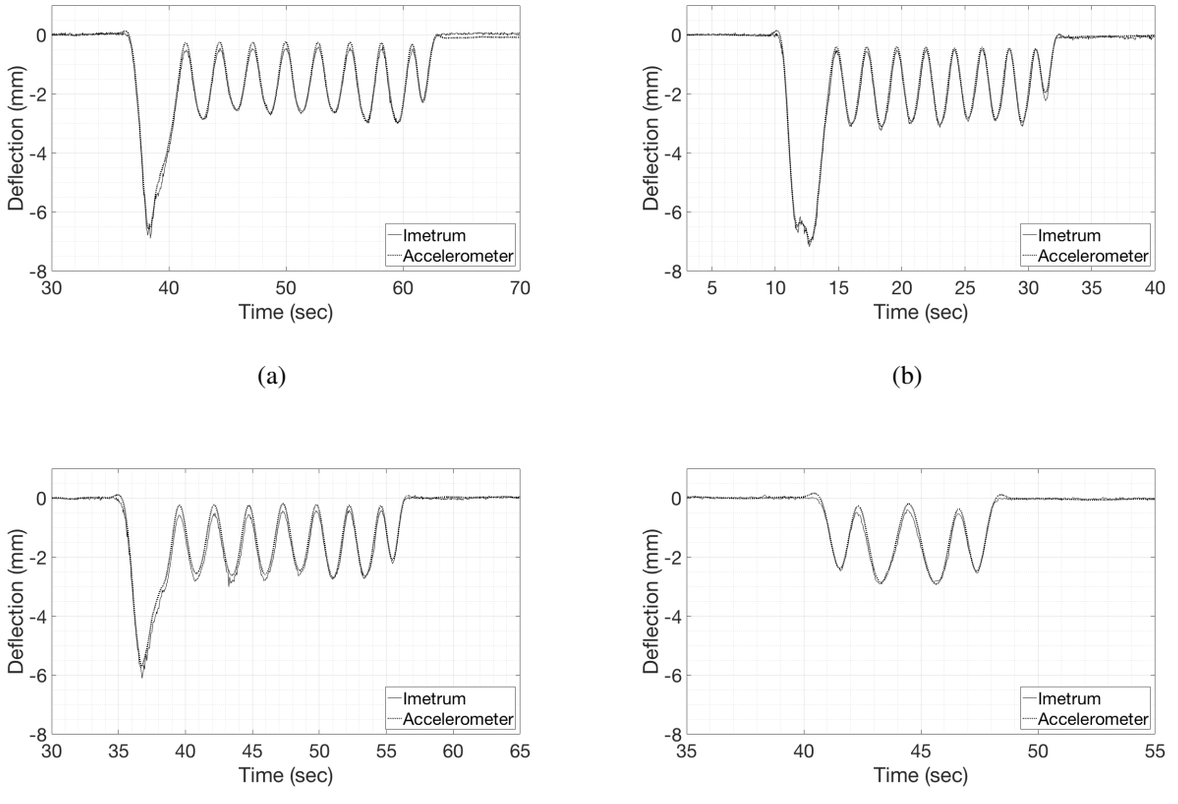

Figure 7: Deflections at mid-span under different train loads , (a) Raveningham Hall (Train 1), (b) Flying Scotsman (Train 3), (c) 7F Class 2-8-0 53808 (Train 6) and (d) Diesel (Train 2)

Table 4: Deflections calculated from measured rotations

Train	Locomotive	Deflection at Mid-Span [mm]
1	Raveningham Hall	6.58
2	Diesel	2.91
3	Flying Scotsman	7.00
4	Raveningham Hall	6.44
5	Flying Scotsman	6.63
6	7F Class 2-8-0 53808	5.70
7	Raveningham Hall	6.16
8	Flying Scotsman	6.80

The results of this study confirm that the bridge has sufficient capacity to carry heavier locomotives than the Raveningham Hall.

6 POTENTIAL FOR FURTHER WORK

The next aim for the study is to construct a stand-alone data monitoring system that is easily adaptable and transportable, to allow for monitoring of the wider transport network.

7 CONCLUSIONS

The purpose of this test was to establish how the Mineral Line bridge performs when subjected to different loading conditions, including the passing of the Flying Scotsman. Accelerometers were situated at five test points along the deck to measure deflections and rotations. The calculated deflection at mid-span was compared against measured deflections from the Imetrum camera positioned at mid-span of the bridge.

The results of the testing showed that the bridge experiences greater magnitude of deflections and rotations under the Flying Scotsman locomotive to those experienced through passage of the other locomotives. The diesel engine, which was the lightest of all the engines, resulted in the lowest measured deflections and rotations.

The correlation between the deflection measured by the Imetrum camera and the deflection calculated using the technique proposed here proves that a small number of accelerometers are sufficient to determine the performance of a bridge under train loading.

8 ACKNOWLDGEMENTS

The team would like to acknowledge the continued support of the West Somerset Railway, particularly David Depoix and Andrew Young.

DIC-monitoring of full-scale concrete bridge using high-resolution wide-angle lens camera

P.S. Halding, J.W. Schmidt & C.O. Christensen
Technical University of Denmark, Kgs. Lyngby, Denmark

ABSTRACT: Monitoring in combination with proof- and high magnitude load testing can evaluate potentially higher load carrying capacities in existing bridges. However, such in-situ testing provides challenges like limited test-time, difficult calibration under in-situ conditions etc. Consequently, in-situ load-testing significantly amplifies the requirements to monitoring. This paper focuses on results from in-situ DIC-monitoring. The method was used to evaluate deformations- and crack initiation on large concrete bridge surfaces during high magnitude load-testing. DIC-measurements are very susceptible to light, surface texture and contrast, etc. Laboratory testing and preliminary site inspections were done to investigate the measurement conditions. Monitoring was executed with conventional- and wide-angle lens DSLR-cameras positioned underneath the bridge, measuring vertically to the surface. The 2D output from the DIC-software was corrected for wide-angle lens distortions and out-of-plane deflections. The method seems desirable for a more generic use, and has potential for the evaluation of stop criteria.

1 INTRODUCTION

An extensive amount of monitoring approaches have been used during the last decades as a mean to evaluate the structural behavior of in-situ bridge structures in service or during load testing. Monitoring during load testing can be divided into at least two different groups depending on the project scope:

1) *Proof loading*, which includes loading of the structure within the elastic structural domain to demonstrate a certain behavior or capacity. The method is used in a way, which prevent significant damages on bridge structures, and thus enables the structure to remain in service after the load testing.
2) *Failure loading*, where high magnitude load is applied to the bridge to evaluate the response until structural damage have occurred. This enables evaluation of the full structural response, and thus evaluation of boundary conditions, failure modes, crack initiation etc.

Load to failure in conjunction with monitoring can be utilized to more precisely determine stop criteria for future proof load tests of similar bridge types mostly supported by related calibration of theoretical- and FE-models and optimization of probabilistic models.

One promising method for monitoring of concrete bridges during load testing is Digital Image Correlation (DIC), where the concrete surface is photographed before and during loading, and the digital images are analyzed in a computer software to determine deformations- and related strains. This paper presents a novel DIC-monitoring method used on a full-scale In-situ concrete bridge as well as bridge sub-components with wide-angle lens during loading into the failure regime.

1.1 *Digital Image Correlation*

DIC can be seen as an extended version of photogrammetry, and the original technological basis is explained by several researcher (e.g. (Sutton *et al.* (1983) and Bruck *et al.* (1989)). Small subsets (of a predetermined pixel size $X \cdot X$) on digital photographs are analyzed by determining a normalized cross-correlation coefficient, S, based on the image grey level from undeformed, I_u, to deformed shape, I_d:

$$S\left(x, y, u_x, u_y, \frac{\partial u_x}{\partial x}, \frac{\partial u_x}{\partial y}, \frac{\partial u_y}{\partial x}, \frac{\partial u_y}{\partial y}\right) = 1 - \frac{\sum I_u(x,y) I_d(x^*, y^*)}{\sqrt{\sum I_u(x,y)^2 \sum I_d(x^*, y^*)^2}} \quad (1)$$

The parameters, x and y, are coordinates to a point in the undeformed subset, and x^* and y^* are the coordinates of the same point in the subset after translation and deformation:

$$x^* = x + u_x + \frac{\partial u_x}{\partial x}\Delta x + \frac{\partial u_x}{\partial y}\Delta y \quad (2)$$

$$y^* = y + u_y + \frac{\partial u_y}{\partial x}\Delta x + \frac{\partial u_y}{\partial y}\Delta y \quad (3)$$

Δx and Δy are directional components from the center of the subset to a point (x,y) in the subset, see Figure 1.

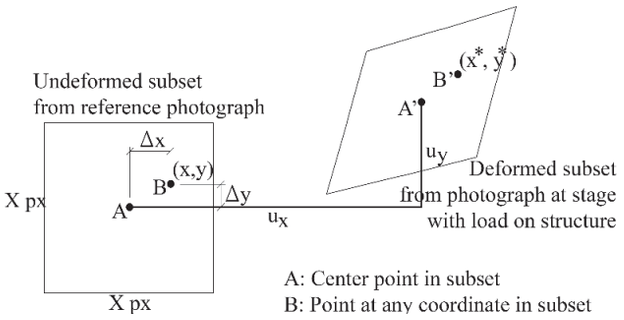

Figure 1: Terminology of undeformed and deformed subsets. Based on figure from Yoneyama & Morimoto (2003).

The displacement from A to A', and B to B' are found by searching for the best displacements and displacement gradients, which minimize the correlation coefficient. This can be done by different approaches such as Newton-Rapson method and Fourier transform (Yoneyama & Morimoto (2003)).

1.1.1 *DIC precision estimates*

Since the grey scale of the photograph is of significant importance for the computation of deflection and strain on surfaces measured by DIC-systems, the surface must have a random pattern of high contrast for DIC software to distinguish the subsets the best way possible. There seem to be no general guidelines or consistent advises available in the literature in regards to pattern types, subset sizes etc. for tests on real structures.

Bornert *et al.* (2009) evaluated DIC errors of digitally deformed computer generated "synthetic" patterns, but they do not apply the results in relation to measurements on real structures, where the type of camera, texture of the surface etc. has a major influence. Fazzini *et al.* (2010) and Wang *et al.* (2011) did similar studies but with actual photographed random patterns manipulated digitally.

Wang et al. showed results for three types of pattern fineness, and there was a relation between pattern fineness, and measurement precision, where a finer pattern showed a better measurement accuracy.

Lecompte *et al.* (2006) reached this conclusion as well with a similar type of experiment. They investigated three sizes of random patterns (mean speckle diameter in pixels: 3, 10 and >10) to conclude that the chosen size of the subsets had to relate to the fineness of the pattern. Best results were detected for small subsets of 13x13 pixels for the fine pattern, and larger subsets of 33x33 pixels for the rough pattern. Furthermore, they realized that the results were only valid for the specific case, and that more systematic research must be conducted for general verification.

Triconnet *et al.* (2009) did experiments with DIC on steel specimens and compared to strain gage data. The focus was on texture influence on the precision and showed a tendency for decreasing uncertainty on strain measurements as the subset size increased.

1.1.2 *DIC in bridge load tests*

For evaluation during actual bridge load testing, DIC-methods have rarely been applied (Yoneyama *et al.* (2007), Tian *et al.* (2013), McCormick, Waterfall & Owens (2014) and Shan *et al.* (2016)).

To the knowledge of the authors, only Yoneyama et al. (2007) and McCormick, Waterfall & Owens (2014) have applied DIC on a larger surface on the side of concrete bridges. McCormick, Waterfall & Owens describe how no random pattern was applied to the surface, and how they still measured both deflections and strains (including crack initiation). Furthermore, they claim that usually, the type of interpolation performed in typical DIC-software gives a precision of between 1/20 and 1/10 pixel.

1.2 *New project with field monitoring*

A new bridge testing project was initiated 2016 in Denmark. The project includes full-scale testing of existing short span (up to 12 m) concrete road bridges (mainly so called "OT-beam bridges") with a novel test rig to apply a high magnitude load in conjunction with conventional- and state-of-the-art monitoring methods. A DIC-system was so far applied to two out of a range of bridges tested in 2016 and 2017. This paper focuses mainly on the method and evaluation of DIC-monitoring during load testing of an in-situ tested bridge in 2017. The project was initiated as a collaboration between the Danish Road Directorate, COWI Denmark, and the Technical University of Denmark.

2 APPLIED DIC-SYSTEM

2.1 *Equipment*

Two DSLR cameras were used: A Canon 6d with a wide-angle lens (Canon EF 16-35mm f/2.8L II USM), to achieve a very large surface for evaluation, and a Canon 550d with a standard lens (Canon EF-S 18-55 IS). Canon 6d had the option of wifi-image transfer. Both cameras were mounted on a tripod pointing perpendicular to the concrete on the bottom surface of the bridge deck. However, this paper only includes results from the wide-angle lens camera in order to elaborate on the novel use- and results gained when using it for DIC-measurements.

The DIC-software used for the photograph analysis was GOM Correlate Professional (2016).

2.2 *Calibration of wide angle lens camera*

It is necessary to correct the direct output from the photographs if strains or in-plane deflections are the purpose of the 2D-analysis. If this is not done, the output deviates from the true deformation values due to non-perpendicular angles from camera to surface, lens distortion of the camera optics, and out-of-plane deflections of the surface (3D-behavior).

2.2.1 *Correction of non-perpendicular angles*

A correction of direct deflection output from DIC-analysis requires information about the camera lens optics. However, it is possible to analytically estimate the level of in-plane deflection correction based on the following method.

Figure 2 shows some of the parameters required for a manual calibration.

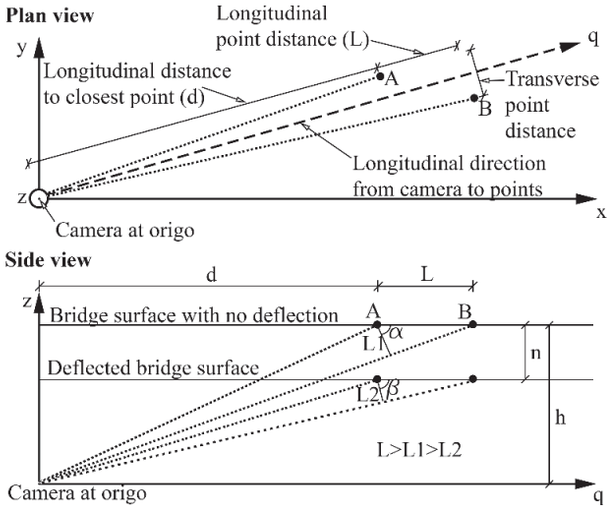

Figure 2: Plan- and side view of points on bridge surface (for strain analysis) and with camera positioned in (0;0;0) pointing in z-direction.

The plan- and side view show two lines from the position of the camera in origo to each of the two points A and B on the underneath surface of the bridge. The in-plane deflection is to be corrected in the direction between the two points. The horizontal distance to the closest point, d, in the longitudinal direction, q, is shown as well as the longitudinal distance between the points, L. L is assumed very small and hence, the triangle with side lengths L and L1, and the corner angle, α, is right-angled. The vertical height (z-direction) from camera to surface is denoted, h, while the downwards deflection of the surface during loading is, n.

2D DIC is typically based on the analysed (small) object being perpendicular to the viewing direction of the camera. When the skew angle on a bigger analysed surface is large in the sides (even more pronounced with wide-angle lens), the deflection output starts deviating from the true value.

When analysing the deflection between points A and B in the figure, the x and y coordinate of the closest point, A, projected to the q-axis is called dx and dy.

$$L1 = L\cos(\alpha) \tag{4}$$

$$\alpha = \operatorname{atan}\left(\frac{\sqrt{dx^2 + dy^2}}{h}\right) \tag{5}$$

$$\text{since } \cos(\operatorname{atan}(x)) = \frac{1}{\sqrt{1 + x^2}} \tag{6}$$

$$L1 = \frac{L}{\sqrt{1 + \left(\frac{\sqrt{dx^2 + dy^2}}{h}\right)^2}} = \frac{L}{\sqrt{1 + \frac{dx^2 + dy^2}{h^2}}} \tag{7}$$

The denominator of L1 (7) is a correction factor to the deflections in the longitudinal direction from camera to the measured points without any out-of-plane deflections occurring (only due to the non-perpendicular angle). The same method applies for L2 (including surface deflection measured by another monitoring instrument during testing) for the triangle L, L2 and angle β, and gives:

$$L2 = \frac{L}{\sqrt{1 + \left(\frac{\sqrt{dx^2 + dy^2}}{h - n}\right)^2}} = \frac{L}{\sqrt{1 + \frac{dx^2 + dy^2}{(h - n)^2}}} \tag{8}$$

The denominator of (8) also takes into account the correction from the extra change in angle due to the out-of-plane surface deflection.

The correction of transverse in-plane deflections between A and B due to a non-perpendicular angle can be estimated as well, but is highly dependent on the camera lens optics. Therefore, a method based on an automatic lens distortion correction is preferable.

Surface strains are not affected by a non-perpendicular angle, since they are determined relative to a length.

2.2.2 *Wide-angle lens distortion*

Applying a wide-angle lens distorts the photographs. This challenge can be overcome by applying an automatic algorithm from Adobe Photoshop (2015), where corrections for a range of different lenses can be applied. The correctness of this method was lab-tested for practical use by capturing photographs of a white surface with a pattern of black squares of 0.1 m.

Figure 3 shows such photograph before and after the lens distortion correction. The unbroken lines are the actual photographed lines of the square pattern, while the dashed lines form an overlay of a geometrically correct pattern. Before the lens correction, the difference between the photographed and the correct patterns is significant, especially near the edges of the image. After the correction, the two patterns are alike. Utilizing this method for correction of lens distortion eliminates the requirement for a manual alteration of deflections due to non-perpendicular angles between camera and surface. The only additional correction of the output now comes down to the out-of-plane deflection of the surface during testing.

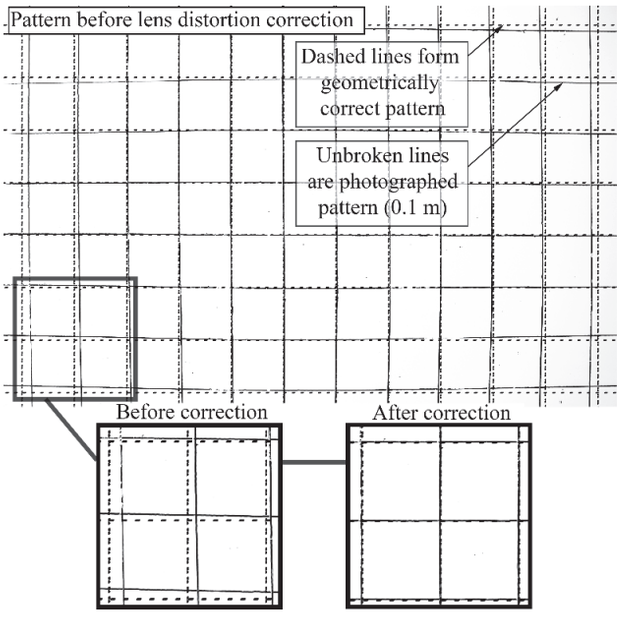

Figure 3: Correction of lens distortion by Photoshop algorithm for the specific wide-angle lens.

2.2.3 *Out-of-plane deflection correction*

When applying DIC in 2D, the assumption is that the distance between camera and surface is constant, which is not the case in the specific bridge tests. The monitored surface deflects out-of-plane, and these deflections must therefore be closely monitored by e.g. lasers or LVDT's for the method to be applicable. Even relatively small deflections can have a large consequence on strain readings, so the correctness of deflection measurements is crucial for the method to work.

The idea behind the out-of-plane deflection correction is depicted in Figure 4.

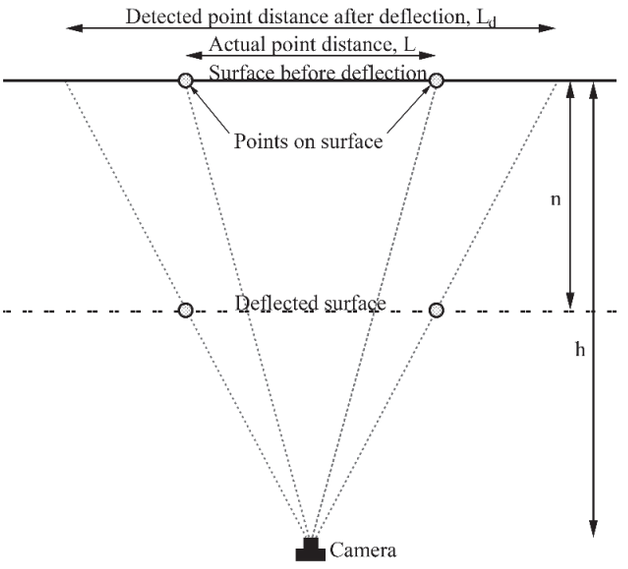

Figure 4: Out-of-plane deflection correction

If the distance from the camera to the surface of the bridge, h, is reduced by the deflection, n, towards the camera, the actual distance between two points on the surface, L, will be detected larger than it is, L_d. By trigonometry the relation between the detected, and actual point distance is:

$$L_d = \frac{L \cdot h}{h - n} \tag{9}$$

The strain alteration from out-of-plane deflection is then determined by:

$$\varepsilon_{oop} = \frac{h}{h - n} - 1 \tag{10}$$

In case of a small deflection compared to the camera to surface distance, the relationship between deflection and altered strain is close to linear. For a deflection of 10 mm for a camera to surface distance of 4 m, the level of strain alteration is 0.25 %.

3 DIC-MONITORED LOAD TESTS

3.1 *Laboratory sub-component testing*

Five double-beams were cut out of an actual bridge (in good condition) for sub-component laboratory testing with DIC. The beam type was similar to that of the in-situ load tested bridge: Overturned T-beams (OT-beams). An additional double-beam was cut out for coupon testing of material properties.

3.1.1 *Test setup*

The load testing was performed as a four-point bending to failure of the components at a rate of 1.7 mm/min. The distance between the loading points for the four-point bending setup was 1.4 m, which is similar to typical axel distances of heavy special vehicles

in the Danish regulations (Danish Road Directorate (2009)). The supports were hinged, and the span was 5.3 m. The setup, as well as the position of the DIC, LVDT's, and strain gages are seen in Figure 5. Three DIC cameras were individually applied to three ranges of the front surface, each at a distance of approximately 1 m. Measuring on the beam side surface meant that no out-of-plane deflections would occur.

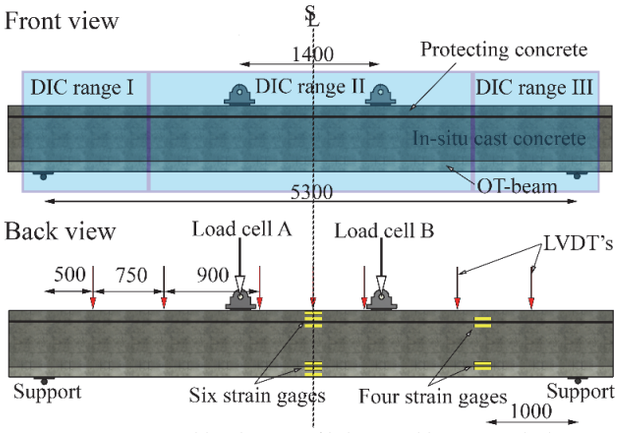

Figure 5: Front and back view of lab-tested beams including position of monitoring equipment. Unit is mm.

Consequently, only lens distortion corrections had to be done. Range II was covered by the wide-angle lens camera, and is the part that is evaluated in this paper. A high-contrast random pattern was applied to the surface of each specimen.

A cross-section of the cut-out beams are shown in Figure 6. The beams consisted of pre-fabricated OT-beams with tested concrete cylinder mean strength of 72 MPa. The in-situ cast concrete above and in-between the beams had a tested mean strength of 41 MPa, which was the same as the protecting concrete layer on top of the beam. A thin membrane of bitumen was applied between the protecting concrete and in-situ cast concrete. The 7 mm in diameter pre-tensioning strands had a 5-percentile strength of 1800 MPa.

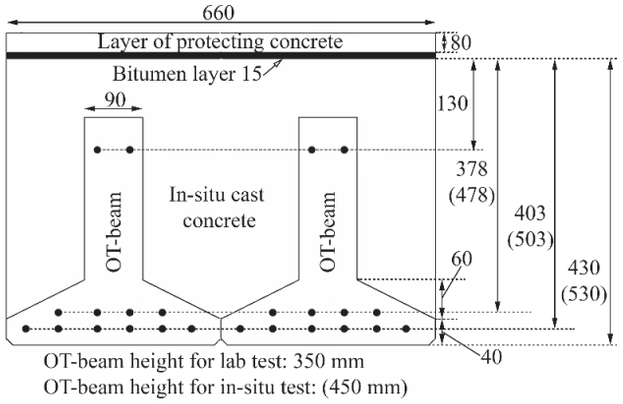

Figure 6: Cross-section of bridge for lab-tests and in-situ tests. Unit is mm.

3.1.2 *Results and evaluation of lab-test*

The lab test showed that the DIC-system could be utilized in detecting cracks on concrete surfaces during load testing with the wide-angle lens camera. Deflection/load-curves from the tested beams are shown with positions of crack detection in Figure 7.

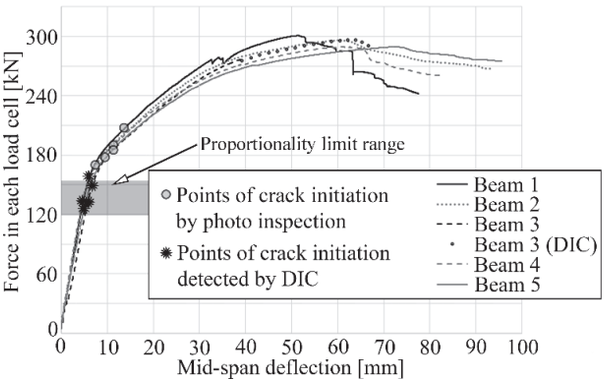

Figure 7: Deflection/load-curves of tested double OT-beams in lab.

Even by thorough inspection of the photographs, the cracks were not detectable until beyond the actual proportionality limit of the load/deflection-curves. When detecting cracks by the DIC-equipment, they were identified in close proximity of the proportionality limit. Furthermore, the applied 50 mm strain gages on the back surface of the specimens (measuring longitudinal strains), verified the DIC-readings of the time of crack initiation. Foil strain gages are not designed for detecting exact crack initiation in tension, and the output was not significantly scattered, but the precision depended on the exact position (in average within 11 % of DIC-measurements).

In Figure 8, an example output from the Beam 5 DIC-evaluation is shown for the point of crack initiation by photograph inspection (183 kN load), and for maximum load (289 kN). The crack initiation load detected by DIC was 128 kN.

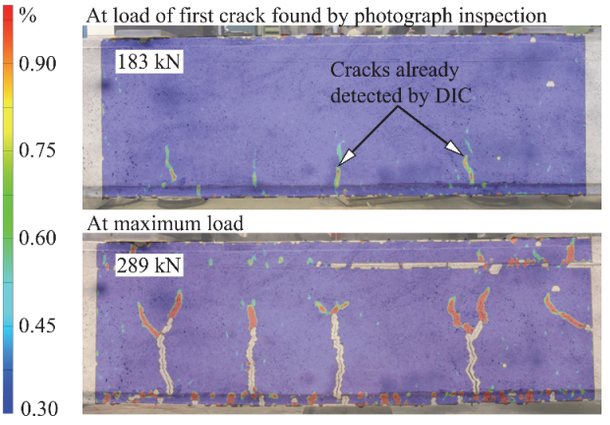

Figure 8: Beam 5 DIC-output at load level 183 kN and 289 kN. Photographed at mid-span by wide-angle lens.

3.2 *In-situ testing*

A full-scale OT-beam bridge was load tested in cold (around freezing point), humid, and windy weather in January 2017. First part of the test was of the full width of the bridge, while the second part was on two strips cut out with a large diamond saw, each with a width of 11 OT-beams.

3.2.1 *Test setup*

A novel loading rig was used to apply the load on the bridge of 9 m span in accordance with the Danish regulations (EN 1991-2 (2003) and Danish Road Directorate (2009, 2010)), see Figure 9. Two cradles

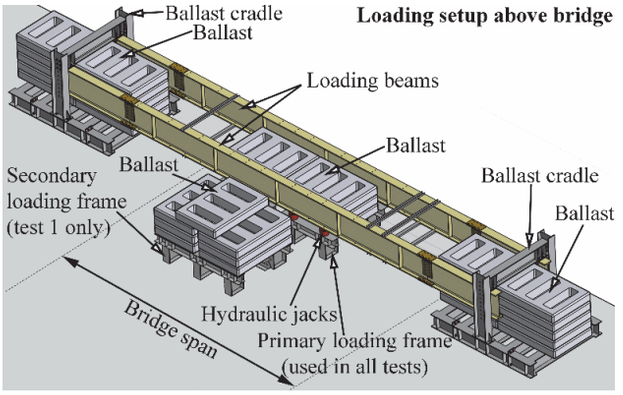

Figure 9: Loading rig with ballast, loading beams, and hydraulic jacks to apply load.

with dead load was positioned above the supports. Between the cradles were two large HE1000B profile steel beams spanning along the bridge span. Specially produced loading frames were placed under the steel beams, in order to apply a precise wheel load. Hydraulic jacks were positioned between the loading frames and the steel beams to apply a controllable static load to the bridge in conjunction with gravity controlled loading from weights. In the test of the full width bridge, an additional load, similar to a second heavy vehicle in the code, was situated next to the loading rig.

Figure 10 shows the position of the DIC-cameras underneath the bridge as well as the position of the load. Strip 1 and 2 had comparable setups, so only strip 1 is shown in the figure. The Canon 6d (wide-angle lens) camera was positioned with a distance to the underneath surface of the bridge of approximately 3.8 m, (whereas the Canon 550d was positioned with a distance of 2.6 m). Deflections were measured by distance lasers, LVDT's and a land surveyor station, and the relevant measuring points are given in Figure 10 as well.

3.2.2 *DIC in-situ results*

The first test concerned DIC measurements performed on the full un-cut bridge structure. The monitoring turned out to be a well-functioning deformation evaluation, but no cracking was detected at the very

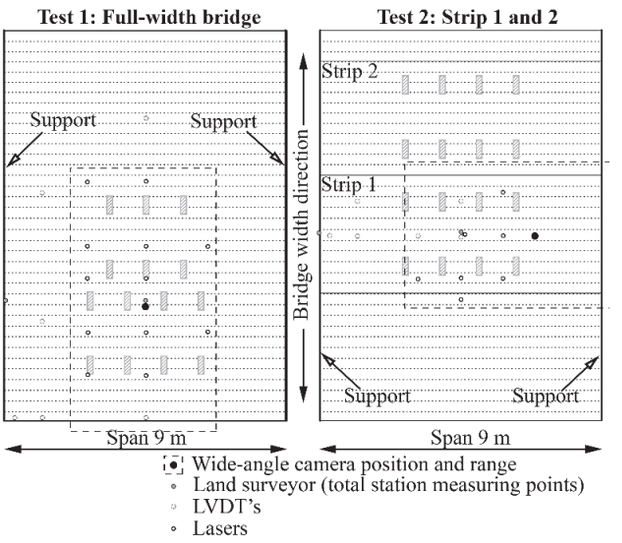

Figure 10: Plan drawings with position of wheel load and deflection- and DIC-measurements.

high magnitude of loading (100 tonne axle load, which was the test rig limit). In the second test, it was decided to cut out longitudinal strips in order to create more simple boundary conditions, to evaluate the effect of asphalt contribution to the capacity, and to verify monitoring accuracy etc.

The strips were successfully loaded to cracking and into the non-linear regime. Strip test 1 was including the asphalt layer, and in strip test 2, the asphalt layer was removed. The precision of each test was evaluated in GOM Correlate Professional at different subset sizes (called facets in GOM), by comparing the first two photographs captured in each test (no load on structure) to see the deviation in longitudinal strain over a defined line on the surface from first to second photograph.

In Figure 11 and 12 a captured photograph from strip test 1 is seen as well as a plot of the precision as function of subset size (both for the wide angle lens camera). The photographs were adjusted in Photoshop to grey scale images with lens distortion cor-

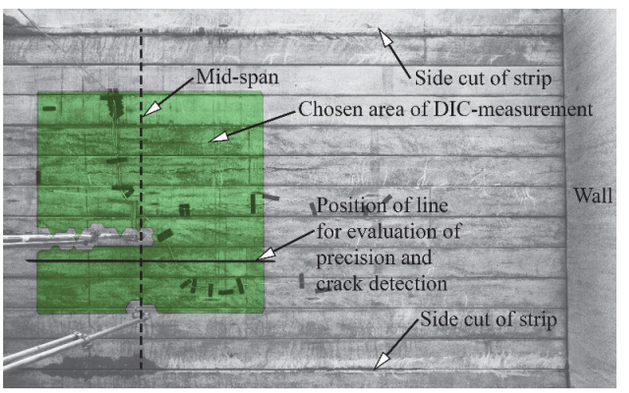

Figure 11: Photograph by wide-angle camera from test 2 strip 1. Location of area for DIC-measurements marked.

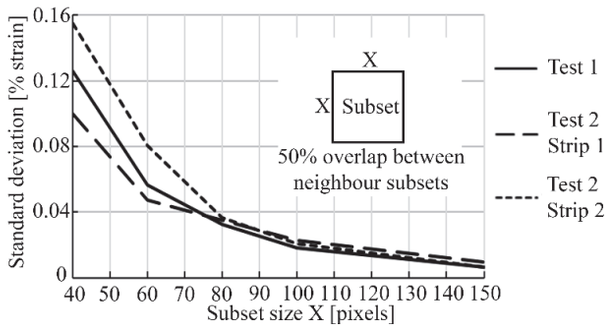

Figure 12: Precision based on deviation between first and second photograph (with no load on bridge).

rection and optimization of the grey level for best possible recognition in GOM Correlate Professional. The Canon 6d with wide-angle lens captured all photographs in all tests by ISO 200 and focal ratio 16.

To directly measure strain values, it is seen that the most reliable data is obtained by using large size subsets in the given example. The directly measured strain value should then subsequently be corrected for out-of-plane deflections.

Cracks were assessed by evaluating contour plots of the longitudinal strains on the surface. Such plots are given in Figure 13 for both strip tests, at the load of first clearly appearing cracking (lines of increased longitudinal tensile strain). The response in the figure has not been corrected for out-of-plane deflection of the OT-beams. The photographic inspection without the DIC-system showed that cracks were not visual until the highest load step was reached.

In Figure 14, a section of 1 m in length (from strip test 1) in direction of the OT-beams is shown. The figure shows data from the longitudinal strain in every point of the section before and after correction

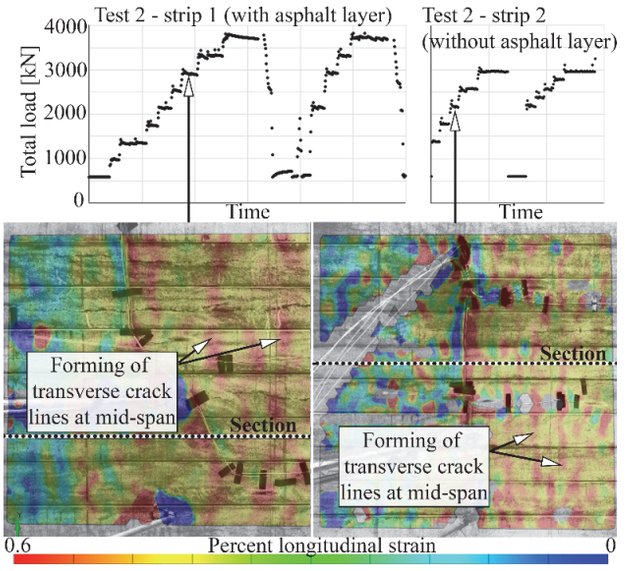

Figure 13: Loading scheme and contour plots of crack initiation without out-of-plane correction.

for out-of-plane deflection of the surface. The measured out-of-plane deflection for the specific load level was 29.5 mm in the left side of the section and 28.0 mm in the right side of the section.

Furthermore, the figure shows the deviation between an analysis based on subset sizes of 80 pixels and 150 pixels. It is seen that using the 80 pixels subset is more precise when determining the position where cracks cross the section. The larger subset size of 150 pixels is too large for fine crack detection in the example.

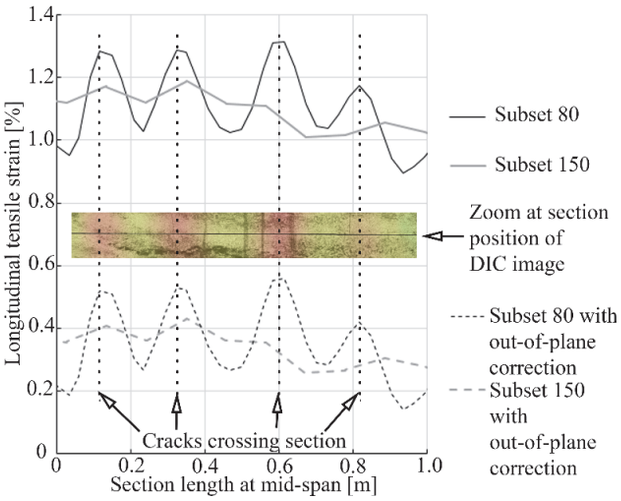

Figure 14: Longitudinal strain of longitudinal section for test 2 strip 1 at first load peak.

4 CONCLUSION

The paper proposes a method for application of a DSLR-camera with wide-angle lens for capturing photographs vertically underneath a concrete bridge during controlled load testing. The method includes correction of lens distortion and out-of-plane deflections of the evaluated surface, which was applied successfully to in-situ tests. Initially, lab-tests were performed of beams during loading (with painted random pattern of high contrast and with no out-of-plane deflection), where crack propagation was followed with the wide-angle lens camera and the lens distortion correction enabled. Later, in-situ tests of a full-scale concrete bridge was performed with the equipment, and both lens distortion correction and out-of-plane deflection corrections were used (and no random pattern was painted on the surface). The results showed that cracks could be found by the wide-angle camera at a distance of approximately 3.8 m with a precision depending on the chosen size of the subsets in the analysis in the DIC-software GOM Correlate. Larger subsets would give a better accuracy, but are too rough for proper crack detection, while a small subset size would give an insufficient accuracy. For the given camera to surface distance a

medium subset size of 80x80 pixels performed well when evaluating deformations- and crack initiations.

5 ONGOING- AND FUTURE WORK

In the project, the DIC wide-angle camera is used together with several other monitoring methods in order to justify the use and consequently optimize it for a more generic purpose.

The method is therefore being evaluated more thoroughly and is compared with the other promising monitoring methods for proof loadings and failure tests of concrete bridges.

The other methods contain e.g. also the regular lens DIC-camera, strain gages, 3D laser scanning, as well as ongoing- and upcoming equipment portfolio which includes tiltmeters, optical fibers and acoustic emission.

AKNOWLEDGEMENTS

The authors would like to thank the project partners at the Danish Road Directorate and COWI for the great cooperation and good ambience in the project. Furthermore, we gratefully acknowledge the contribution from the crane company BMS, and the technical staff at the Technical University of Denmark.

Monitoring crack width and strain during proof load testing

E.O.L. Lantsoght

Concrete Structures, Delft University of Technology, Delft, The Netherlands

ABSTRACT: In a proof load test, the applied load is representative of the factored live load, to demonstrate experimentally that the bridge fulfils the code requirements. Signs of distress must be caught with the instrumentation by defining stop criteria. In the literature, several stop criteria for flexure are available. The German guidelines describe, amongst others, a limiting crack width and strain. However, the background of these limiting values is not clear. Therefore, a theoretical approach based on flexural theory is followed. The theoretically derived values are then compared to experimental results obtained from beam experiments. The result of this research work is a limiting value of crack widths and strains that can be used during proof load testing of concrete bridges. The arbitrary stop criteria that were used in the past can now be replaced by stop criteria that are based on the theory of concrete beams in flexure.

1 INTRODUCTION

The majority of the existing bridges in the Netherlands are reaching the end of their originally intended service life, and are subjected to larger live loads than those loads these bridges were originally designed for. Since the mid-2000s, the Dutch Ministry of Infrastructure and the Environment has taken steps to assess its bridge stock. These first assessments (Walraven, 2010, Vergoossen et al., 2013) showed that upon initial assessment, a large number of reinforced concrete bridges do not fulfil the requirements of the currently governing codes NEN-EN 1991-2:2003 (CEN, 2003) for the loads and NEN-EN 1992-1-1:2005 (CEN, 2005) for the capacity of concrete members. Therefore, increasing Levels of Assessment (Lantsoght et al., 2017c, Schlune et al., 2011) for the evaluation of reinforced concrete bridges were proposed. When analytical methods are not sufficient for the evaluation of an existing bridge, or when the uncertainty on the capacity is large (for example as a result of material degradation), proof load testing can be a viable assessment method.

In a proof load test (Anay et al., 2016, Aguilar et al., 2015, Zwicky and Brühwiler, 2015, Casas and Gómez, 2013, Au et al., 2013, Olaszek et al., 2012), the applied load is representative of the factored live load, to demonstrate experimentally that the bridge can sustain this load level. For this reason, it is important to instrument the tested bridge, so that signs of distress can be caught and irreversible damage can be avoided. The threshold values of these measured quantities are called the stop criteria.

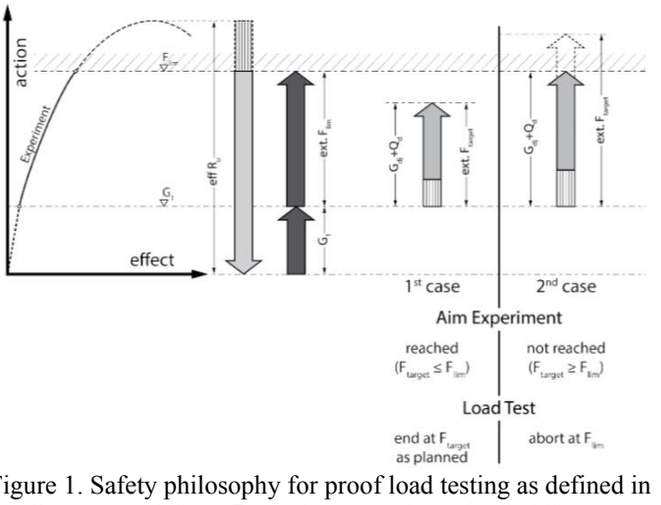

Figure 1. Safety philosophy for proof load testing as defined in the German guideline (Deutscher Ausschuss für Stahlbeton, 2000, Vos, 2016, Lantsoght et al., 2017h).

The safety philosophy for proof load testing is shown in Figure 1. The onset of nonlinear behaviour, which should be captured with the stop criteria, is represented by the load F_{lim}. The load level corresponding to the permanent loads is G_1. The maximum load corresponds to the structural capacity $eff.R_u$. The maximum load that can be applied during a proof load test in order not to have irreversible damage is $F_{lim} - G_1 = ext.F_{lim}$. The load that needs to be applied to the bridge in order to demonstrate that it fulfils the code requirements is $ext.F_{target}$, which corresponds to the factored live loads Q_d and addi-

tional factored superimposed dead loads G_{dj}. If this load is smaller than $ext.F_{lim}$ (1st case in Figure 1), the proof load test is considered successful and it has been shown that the bridge can carry the code-prescribed loads. If, on the other hand, $ext.F_{lim}$ is reached before $ext.F_{target}$, a stop criterion is exceeded before the target load is applied, and further loading than $ext.F_{lim}$ is not permitted. Depending on the largest load level that is reached during the proof load test, it can then be found that the bridge fulfils the requirements for reduced live loads and that a traffic restriction should be imposed.

During the last five years, research at Delft University of Technology has been done to explore the suitability of proof load testing for the evaluation of reinforced concrete slab bridges in shear and flexure. A campaign of pilot proof load tests (Lantsoght et al., 2017f, Lantsoght et al., 2017a, Lantsoght et al., 2017b, Lantsoght et al., 2017d, Lantsoght et al., 2017g), a collapse test (Lantsoght et al., 2017e, Lantsoght et al., 2016a, Lantsoght et al., 2016b, Lantsoght et al., 2016c), additional testing in the laboratory (Lantsoght et al., 2016b, Lantsoght et al., 2017i), and desk research (Lantsoght et al., 2017h) led to the conclusion that proof load testing seems to be a viable option, but that further laboratory testing is necessary to define the stop criteria for shear, and that a theoretical basis for the stop criteria for flexure should be sought. In this paper, the available stop criteria for flexure are improved with a stop criterion that is derived based on flexural theory for reinforced concrete members. As such, the proposed method is suitable for reinforced concrete slab bridges, which often are found not to fulfil the code requirements in the Netherlands.

2 EXISTING STOP CRITERIA FOR FLEXURE

2.1 *German guidelines*

The German guidelines for load testing of concrete structures (Deutscher Ausschuss für Stahlbeton, 2000) are suitable for plain and reinforced concrete buildings subjected to a load test for flexure. The first stop criterion limits the concrete strain ε_c:

$$\varepsilon_c < \varepsilon_{c,lim} - \varepsilon_{c0} \tag{1}$$

with ε_c = the strain measured during proof loading; ε_{c0} = the analytically determined short-term strain in the concrete caused by the permanent loads that are acting on the structure before the application of the proof load and $\varepsilon_{c,lim}$ = 800 $\mu\varepsilon$ for concrete with a compressive strength larger than 25 MPa. The second stop criterion limits the strain in the reinforcement steel ε_{s2}:

$$\varepsilon_{s2} < 0.7\frac{f_{ym}}{E_s} - \varepsilon_{s02} \tag{2}$$

with f_{ym} = the average yield strength of steel on the tension side of the cross-section; E_s = the modulus of elasticity of reinforcing bars; and ε_{s02} = analytically determined strain (assuming cracked conditions) in the reinforcement steel caused by the permanent loads that are acting on the structure before the application of the proof load. For the crack width, w, and the increase in crack width of an existing crack, Δw, the requirements from Table 1 have to be fulfilled. The fourth stop criterion limits the residual deflection in the cracked state to 10% permanent (plastic) deformation after removal of the load.

Table 1. Requirements for crack width for newly developing cracks w and increase in crack width for existing cracks Δw (Deutscher Ausschuss für Stahlbeton, 2000).

	During proof loading	After proof loading
New cracks	$w \leq 0.5$ mm	$\leq 0.3w$
Existing cracks	$\Delta w \leq 0.3$ mm	$\leq 0.2\Delta w$

2.2 *Czech and Slovak codes*

The Czech and Slovak codes (Frýba and Pirner, 2001) describe acceptance criteria that are typically verified after a load test. The first acceptance criterion for a load test is the condition of elastic deformation S_e, with S_{cal} the calculated value:

$$\beta < \frac{S_e}{S_{cal}} \leq \alpha \tag{3}$$

For reinforced concrete bridges, α = 1.10 and β = 0.60. The second acceptance criterion looks at the condition of permanent deformation S_r as a function of the total deformation $S_{tot} = S_r + S_e$:

$$\frac{S_r}{S_{tot}} \leq \alpha_1 \tag{4}$$

with α_1 = 0.25 for reinforced concrete. The third acceptance criterion gives the maximum crack widths as a function of the environmental class, see Table 2.

Table 2: Limitations to crack widths that can occur in a load test for reinforced concrete bridges (Frýba and Pirner, 2001).

Environmental class	Maximum crack width
1 (dry)	0.4 mm
2, 3 (humid)	0.3 mm
4, 5 (aggressive)	0.1 mm

2.3 *Other existing codes and guidelines*

ACI 437.2M-13 (ACI Committee 437, 2013) describes acceptance criteria based on the maximum deflection, residual deflection, deviation from linearity index, and permanency ratio. The deviation from linearity index and permanency ratio can only be used as acceptance criteria when the loading protocol described by ACI 437.2M-13 is used. This loading protocol differs from the protocol recommended for load testing of concrete bridges (Lantsoght et al., 2017i).

The Manual of Bridge Evaluation (AASHTO, 2016) describes the target proof load, but does not quantify stop criteria. This code only mentions that no nonlinear behavior should occur during the test.

Similarly, the Swiss code (SIA, 2011) prescribes that the behavior during the test should be linear, that the residual displacements should be zero, and that the crack width should be "within acceptable limits."

The Polish code (Research Institute of Roads and Bridges, 2008) allows no nonlinear behavior and limits the residual deformations to 20% of the maximum for reinforced concrete bridges.

In Hungary (Hungarian Chamber of Engineers, 2013) a crack width in the concrete of 1 mm is a stop criterion. Under the service loads, the crack width and maximum deflection should not be larger than the limit from NEN-EN 1992-1-1:2005 (CEN, 2005). The residual deformation is limited to 25% of the maximum for reinforced concrete structures.

2.4 *Limitations of existing stop criteria*

As can be seen from the previous sections, in the literature and in existing codes and guidelines, several stop criteria for flexure are available. The German guidelines describe a limiting crack width and strain, as well as other parameters. However, the background of these limiting values is not clear, and the proposed limiting strain seems arbitrary. The proposed limiting crack widths seem to be related to serviceability and durability requirements, which can be exceeded in a short-term proof load test. A theoretical basis, derived from flexural theory, for the stop criteria for flexure is needed.

A limiting strain in the steel reinforcement is not a practical stop criterion, as this criterion requires the removal of the concrete cover in the field, which is often not permitted by the bridge owner.

Many codes describe stop and acceptance criteria based on the largest deflection. However, beam experiments (Lantsoght et al., 2017i, Lantsoght et al., 2016d) indicated that a stop criterion based on a maximum and residual deflection is not reliable. Therefore, stop criteria for the concrete strain and crack width based on flexural theory are derived in this paper.

3 DERIVATION OF THEORETICAL STOP CRITERIA

3.1 *Stop criterion for the limiting flexural strain*

Flexural beam theory is used to derive a stop criterion for flexure, see Figure 2. A beam with an area of reinforcement A_s is studied. The resulting strains are shown in Figure 2b, with ε_c the strain in the concrete under compression, ε_s the strain in the steel and ε_{bot} the strain in the concrete on the bottom. The effective depth is d, the height of the beam h and the height of the compression zone c. Figure 2c shows the stresses, with f_c the stress in the concrete under compression and f_s the stress in the steel. The compressive resultant C and the tensile resultant T are sketched in Figure 2d.

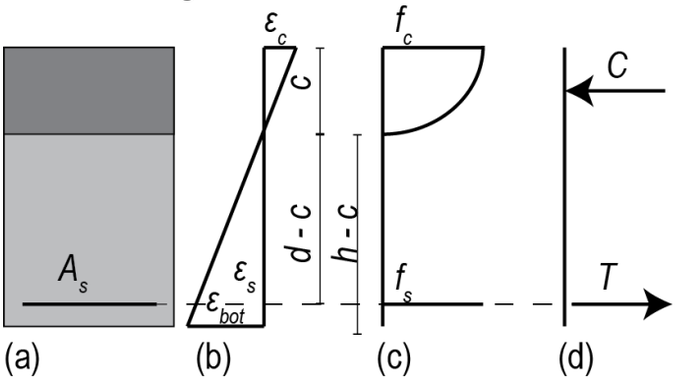

Figure 2. Notations used for derivation of stop criterion based on flexural beam theory: (a) cross-section of beam; (b) strains; (c) stresses; (d) forces.

The strain at the bottom of the cross-section can be calculated as:

$$\varepsilon_{bot} = \frac{h-c}{d-c} f_s \tag{5}$$

To avoid yielding of the steel reinforcement, f_s should be limited to 90% of f_y, the yield strength of the steel, resulting in:

$$\varepsilon_{bot,\max} = \frac{h-c}{d-c} 0.9 \frac{f_y}{E_s} \tag{6}$$

The Young's modulus of steel is E_s. It is then proposed to limit the strain during a field test to 65% of $\varepsilon_{bot,max}$. This maximum strain should be calculated prior to a field test. It is recommended to use Thorenfeldt's stress-strain parabola, see Figure 3. This parabola is described by the following expressions:

$$n_{th} = 0.8 + \frac{f_{cm}}{17.24MPa} \tag{7}$$

$$\varepsilon_0 = \frac{f_{cm}}{E_c}\left(\frac{n_{th}}{n_{th}-1}\right) \tag{8}$$

$$k_{th} = \begin{cases} 1 \text{ if } \dfrac{\varepsilon_c}{\varepsilon_0} \le 1 \\ 0.67 + \dfrac{f_{cm}}{62.07MPa} \text{ if } \dfrac{\varepsilon_c}{\varepsilon_0} > 1 \end{cases} \tag{9}$$

$$f_{c,th} = \frac{0.9 f_{cm} \times n_{th} \times \dfrac{\varepsilon_c}{\varepsilon_0}}{n_{th} - 1 + \left(\dfrac{\varepsilon_c}{\varepsilon_0}\right)^{n_{th} k_{th}}} \tag{10}$$

$$\beta_{th} = \frac{\ln\left(1+\left(\frac{\varepsilon_c}{\varepsilon_0}\right)^2\right)}{\frac{\varepsilon_c}{\varepsilon_0}} \tag{11}$$

$$C = \beta_{th} \times f_{c,th} \times b \times c \tag{12}$$

$$T = A_s \times 0.9 \times f_y \tag{13}$$

The constants n_{th} and ε_0 are material parameters defined by the concrete compressive strength f_{cm} and the Young's modulus of the concrete E_c. The factor k_{th} is a function of the strain ration $\varepsilon_c/\varepsilon_0$. The maximum stress in the parabola is $f_{c,th}$. The average stress is $\beta_{th} \times f_{c,th}$. The resultant of concrete under compression C should equal the resultant of steel under tension T. From this equilibrium, the height of the compression zone c can be found. Once c is known, the value of $\varepsilon_{bot,max}$ can be calculated according to Eq. (6). Then, the maximum strain in the proof load test can be calculated as:

$$\varepsilon_{stop} = 0.65\varepsilon_{bot,\max} - \varepsilon_{c0} \tag{14}$$

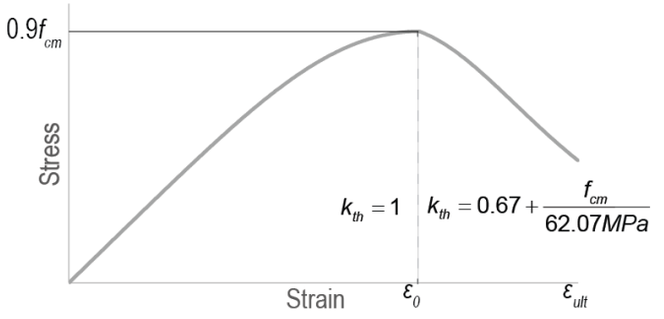

Figure 3. Thorenfeldt's stress-strain parabola.

3.2 *Stop criterion for the limiting crack width*

According to the *fib* Model Code 2010 (fib, 2012), the crack width w can be calculated as:

$$w = 2l_{s,\max}\left(\varepsilon_{sm} - \varepsilon_{cm} - \varepsilon_{cs}\right) \tag{15}$$

$$\varepsilon_{sm} - \varepsilon_{cm} - \varepsilon_{cs} = \frac{\sigma_s - \beta\sigma_{sr}}{E_s} + \eta_r\varepsilon_{sh} \tag{16}$$

With σ_s the stress in the reinforcement steel, σ_{sr} the stress in the steel at cracking, β and η_r terms that depends on the type and duration of loading as given in Table 7.6-2 from the *fib* Model Code 2010 (fib, 2012), and ε_{sh} the shrinkage strain. Since a proof load test is short in duration, it is assumed that no shrinkage occurs during the test and thus $\varepsilon_{sh} = 0$. For short-term loading, the value of $\beta = 0.6$. If the limit of 90% of yielding of the steel is used again for the development of the stop criterion for crack width, then $\sigma_s = 0.9f_y$. The stress at cracking is calculated as:

$$\sigma_{sr} = \frac{f_{ctm}}{\rho_{s,eff}}\left(1 + \alpha_e\rho_{s,eff}\right) \tag{17}$$

The cracking stress can be calculated as (ACI Committee 318, 2014):

$$f_{ctm} = \frac{7.5}{12}\sqrt{f_{cm}} \tag{18}$$

The ratio of the Young's moduli is $\alpha_e = E_s/E_c$. The effective reinforcement ratio $\rho_{s,eff}$ of the fictitious tension tie in the beam depends on the effective height h_{eff}:

$$h_{eff} = 2.5\left(h - d\right) \le \frac{h-c}{3} \tag{19}$$

The effective reinforcement ratio is then:

$$\rho_{s,eff} = \frac{A_s}{b \times h_{eff}} \tag{20}$$

The crack spacing is calculated as:

$$l_{s,\max} = k \times c_{cover} + \frac{1}{4}\frac{f_{ctm}}{\tau_{bms}}\frac{\phi_s}{\rho_{s,eff}} \tag{21}$$

The constant k can be taken as $k = 1$. The concrete cover is c_{cover}. According to Table 7.6-2 from the *fib* Model Code 2010 (fib, 2012), $\tau_{bms} = 1.8f_{ctm}$. The diameter of the reinforcement bars is φ_s. Combining this information, the expression for the maximum crack width can then be determined as:

$$w_{stop} = 2\frac{0.9f_y - 0.6\sigma_{sr}}{E_s}\left(c_{cover} + 0.139\frac{\phi_s}{\rho_{s,eff}}\right) \tag{22}$$

4 BEAM EXPERIMENTS

4.1 *Beams taken from the Ruytenschildt Bridge*

The Ruytenschildt Bridge (Lantsoght et al., 2016b) was tested to collapse in two spans in the summer of 2014. Beams sawn from a span that was not tested were taken to the laboratory for additional testing. Five experiments on three beams were done. Table 3 gives an overview of the geometric properties of the five tested cross-sections. All beams were 6 m long. Beams RSB01 and RSB02 were 500 mm wide and beam RSB03 was 1000 mm wide.

The concrete compressive strength is f_{cm} = 52.2 MPa. The yield strength of the steel is 282 MPa for QR 24 steel, a type of plain reinforcement that was commonly used until the 1960s in the Netherlands.

The beams were tested in three-point bending with a span length of 5 m. For RSB01F and RSB03F, the load was placed at midspan. For RSB02A and RSB02B the distance between the load and support was a = 1.25 m and for RSB03A a = 1.3

m. The load was applied in a cyclic manner. In experiments RSB01F, RSB02A, RSB02B, and RSB03F, a flexural failure was achieved. The load at failure P_{max} is given in Table 4. The results of these experiments can thus be used for the verification of the proposed stop criteria.

Table 3. Properties of cross-sections of the beams taken from the Ruytenschildt Bridge.

RSB	01F	02A	02B	03F	03A
d (mm)	503	515.5	520	521	515
A_c (m^2)	0.290	0.297	0.307	0.596	0.537
Rebar	4Ø22	4Ø22	4Ø22	9Ø22	7Ø22
	4Ø19	4Ø19	5Ø19	8Ø19	8Ø19
ρ_l	0.91%	0.89%	0.96%	0.95%	0.92%

4.2 *Beams cast in the laboratory*

Four experiments on two beams (P804 and P502) reinforced with plain bars and cast in the laboratory were carried out to study stop criteria and the loading protocol for proof load testing (Lantsoght et al., 2017i). Beam P804 had a height of 800 mm, width of 300 mm, and length of 10 m. Beam P502 had a height of 500 mm, width of 300 mm, and length of 8 m. The beams were tested in three point bending, see Figure 4. The span length for beam P502 was 5 m. The load was applied in a cyclic manner to study stop criteria and the required loading protocol in field tests.

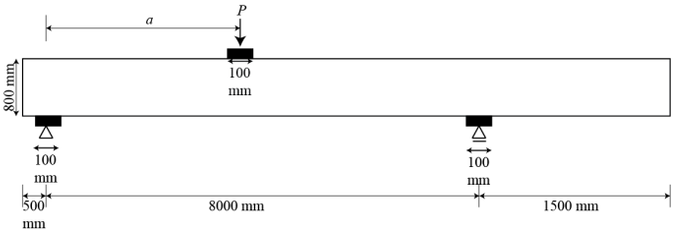

Figure 4. Loading arrangement for beam P804.

The concrete compressive strength of beam P804 is 63.5 MPa and of P502 71.5 MPa. Plain reinforcement bars with a measured yield strength of 297 MPa were used. For beam P804, six reinforcement bars with a diameter of 20 mm were used, and for P502, three bars. The effective depth for P804 was 755 mm and for P502 465 mm. The resulting reinforcement ratio of P804 was 0.83% and of P502 0.68%.

The two experiments in which a flexural failure was achieved are P804A1 and P502A2. The shear span a in P804A1 was 3 m and in P502A2 a = 1 m. The failure load in P804A1 was 207 kN and in P502A2 150 kN.

5 COMPARISON BETWEEN STOP CRITERIA AND EXPERIMENTAL RESULTS

To verify the proposed stop criteria for the concrete strain on the bottom of the cross-section ε_{stop} (Eq. (14)) and for the crack width w_{stop} (Eq. (22)), the results of the experiments in which a flexural failure was achieved are studied.

First, the value of ε_{stop} and w_{stop} are calculated in a spreadsheet. Then, the test results are analyzed to see at which load the stop criteria are exceeded. The results of this analysis are given in Table 4, in which P_{max} is the load at failure in the experiments, P_ε the load for which the strain stop criterion is exceeded, and P_w the load for which the crack width stop criterion is exceeded. "Lim" denotes the percentage of the maximum load at which a stop criterion is exceeded. The lowest load at which a stop criterion is exceeded is marked in grey, as for this load in the field the experiment would be stopped. This value is then also used to calculate Lim.

Table 4. Overview of experimental results and comparison to proposed stop criteria.

Test	P_{max} (kN)	ε_{stop} ($\mu\varepsilon$)	w_{stop} (mm)	P_ε (kN)	P_w (kN)	Lim (%)
RSB01F	276	900	0.177	141	147	51
RSB02A	369	908	0.174	222	224	60
RSB02B	416	903	0.178	235	284	56
RSB03F	607	900	0.170	335	396	56
P804A1	207	910	0.191	120	140	58
P502A2	150	972	0.185	111	92	61

The results of Table 4 show that the resulting strain limit is slightly higher than the limiting strain of $800\mu\varepsilon - \varepsilon_{c0}$ as prescribed by the German guideline (Deutscher Ausschuss für Stahlbeton, 2000). On the other hand, the limiting crack width is slightly smaller than the limits from Table 2 as prescribed by the German guideline (Deutscher Ausschuss für Stahlbeton, 2000).

For the larger beams (RSB beams and P804), the limiting strain criterion is governing. For P502A2, the limiting crack width criterion is governing. The governing stop criterion is exceeded between 51 – 61% of the maximum load. As such, it can be concluded that the proposed stop criteria are conservative and can be used for the preparation of proof load tests for flexure.

6 DISCUSSION

For the stop criteria available in the existing codes and guidelines, the background of the proposed limiting values is not clear. Therefore, a theoretical approach based on flexural beam theory is followed in this paper to derive a stop criterion for the limiting strain and for the limiting crack width. The theoretically derived values were compared to experimental

results obtained testing of beams in the laboratory. The result of this research work is a proposal for the stop criteria for crack widths and strains that can be used during proof load testing of concrete bridges, when the failure mode of flexure is expected. The arbitrary stop criteria that were used in the past can now be replaced by stop criteria that are based on the theory of concrete beams in flexure. The proposed stop criteria are valid for reinforced concrete members. For prestressed concrete members, a similar theoretical derivation could be made.

A possible drawback of the presented stop criteria is that a calculation is required to determine the limiting values, whereas the German guidelines presented a single limiting value. However, linear finite elements and spreadsheets are typically used for the preparation of a proof load test. As such, adding the proposed formulas to the spreadsheets used for the preparation of, for example, the expected load – deflection diagram can be quickly done.

This paper proposes stop criteria for the maximum strain and maximum crack width. For the residual crack width, the limits from the German guideline, see Table 2, could be kept, as also proposed earlier (Lantsoght et al., 2017i).

Note as well that the proposed stop criterion for the limiting crack width is based on expressions for beams reinforced with ribbed bars. This expression is here verified with the results of beams reinforced with plain bars, for which the bond behaviour is different. Further experimental validation of this stop criterion on specimens with ribbed bars is recommended to study if the proposed criterion is generally valid for reinforced concrete.

7 SUMMARY AND CONCLUSIONS

Proof load testing of bridges can be a viable option to demonstrate experimentally that a given bridge fulfils the code requirements. This type of testing requires high loads, and involves higher risks for irreversible damage to the structure or even collapse. Therefore, the structural response of the bridge must be followed closely during a proof load test. When the response exceeds a certain predetermined level, the proof load test needs to be terminated as further loading can result in irreversible damage or collapse. For different types of structural response, these limits are defined as “stop criteria”.

In the currently available codes and guidelines for proof load testing for the failure mode of flexure, stop criteria for flexure are available. These stop criteria are based on a single limiting value, for which a theoretical basis is not directly available.

As earlier analyses indicated that the best results are obtained for stop criteria based on strains and crack widths, this paper aimed at developing a proposal for flexural stop criteria for the strain and crack width based on flexural beam theory. The limiting strain in the concrete is 65% of the strain that corresponds to 90% of the strain at yielding of the steel. The limiting crack width corresponds to the crack width at a stress in the steel of 90% of the yield stress.

To verify the proposed stop criteria, the results from beams taken from the Ruytenschildt Bridge and for beams with plain bars cast in the laboratory, are studied. In total, 6 experiments in which a flexural failure was achieved are used for the analysis in this study.

The comparison between the proposed stop criteria and the experimental results shows that the proposed stop criteria are exceeded prior to failure for all cases (i.e., they work as a stop criterion indeed), and that the stop criteria are exceeded at a load that is 51% - 61% of the failure load. As such, the proposed stop criteria are conservative and can be recommended for the use in proof load tests in which the load is placed at a flexure-critical position.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude and sincere appreciation to the Dutch Ministry of Infrastructure and the Environment (Rijkswaterstaat) for financing this research. The contributions our colleagues Albert Bosman and Yuguang Yang to the experiments described in this paper are gratefully acknowledged. For the desk research on stop criteria, funding was obtained through the program of Chancellor Grants from Universidad San Francisco de Quito. This funding is gratefully acknowledged.

ABSTRACT: In 1997 the Second Stichtse Bridge, a high strength concrete box girder bridge was built in the Netherlands using the balanced cantilever method. At that time, the long-term behaviour of this material (with a cube compressive strength of 75 MPa) was not known. Therefore, it was proposed to monitor the material behaviour and the deflections of the bridge for ten years, and a few properties have been monitored for twenty years. To evaluate the concrete material properties over time, concrete cubes were cast with the segments, and stored inside the bridge at the section locations. These samples have been tested periodically. Also shrinkage measurements were carried out on a concrete sample stored inside the bridge. The deflections of the bridge superstructure have been measured periodically along both edges of the bridge. Based on the available data, it is found that the concrete compressive and splitting tensile strength, as well as the shrinkage deformations, remain constant. The deflections are stabilizing as well.

1 INTRODUCTION

The in-situ balanced cantilever method can be used for the construction of prestressed concrete bridges with a variable height and with a box girder cross-section. Until 1984, these bridges were built in the Netherlands by using lightweight concrete or normal strength normal weight concrete with gravel aggregates. The advantage of using lightweight concrete was the reduction in self-weight, but in practice problems were observed: during construction, the high pressure used to prepare the ducts resulted at some locations also in air and the propagation of cracks in the concrete, which led to spalling of the concrete. As a result, in the 1990s the option of using high strength concrete was explored.

In 1997, the successful construction of the Second Stichtse Bridge, see Figure 1, marked the first application of high strength concrete ($f_{c,cu}$ = 75MPa) in a prestressed concrete balanced cantilever bridge. At that time, the governing codes did not include high strength concrete classes, and there was insufficient knowledge about the long term performance of high strength concrete mixes. For this reason, it was decided to monitor the material properties and overall structural behavior of the Second Stichtse Bridge. The originally planned duration for the monitoring was ten years, but this period was extended to twenty years for a number of parameters.

Figure 1. View of the Second Stichtse Bridge

In particular, the development of the concrete compressive and splitting tensile strength, the effect of creep and shrinkage (including autogenous shrinkage), and the resulting deflections over time were not well-known at the time of design. Estimating the elastic and time-dependent deflections during the construction stages is important to determine the required camber of the main span. Additionally, the creep and shrinkage behavior of the concrete needs to be known to estimate the time-dependent deflections. To analyze these parameters, experiments have been carried out on samples that were cast during construction of the bridge and stored in the bridge, as well as on samples that were cast during construction and then transported, stored, and tested in the Stevin II laboratory of Delft University of Technology. The deflections of the bridge are measured on site.

2 DESCRIPTION OF BRIDGE

The Second Stichtse Bridge was built in the Netherlands in 1997, and was the first prestressed concrete bridge constructed with the balanced cantilever method in high strength concrete. This bridge parallels the First Stichtse Bridge, a prestressed concrete bridge constructed with the balanced cantilever method in lightweight concrete, which opened in 1983. The Second Stichtse Bridge was necessary to double the traffic capacity of the crossing. The goal was to design the Second Stichtse Bridge in such a way that its overall geometry would look similar to that of the First Stichtse Bridge to respect the overall aesthetics. These bridges connect the provinces of Flevoland and Noord Holland and cross a canal that connects the Gooi lake and Eem lake.

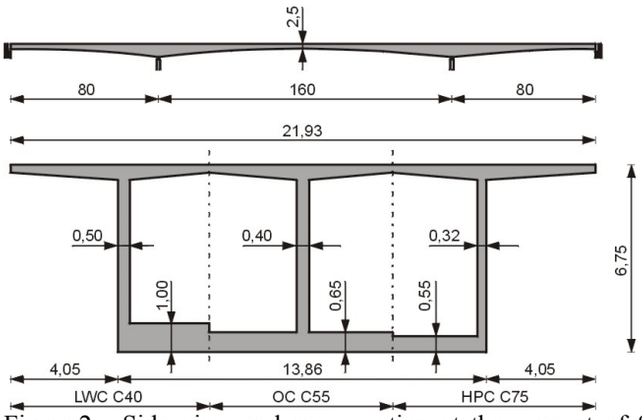

Figure 2. Side view and cross-section at the support of Second Stichtse Bridge. The cross-section compares the necessary dimensions in lightweight concrete, normal concrete, and high strength concrete from left to right (Van der Veen and Kaptijn, 2002).

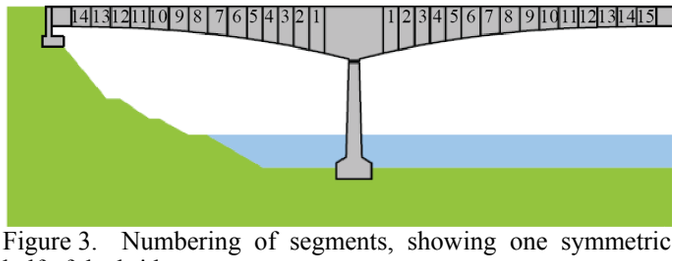

Figure 3. Numbering of segments, showing one symmetric half of the bridge.

The Second Stichtse Bridge has three spans: two end spans of 80 m and a main span of 160 m, see Figure 2. Originally, three designs were developed for comparison (Van der Veen and Kaptijn, 2002): 1) lightweight concrete ($f_{c,cu}$ = 40 MPa, with $f_{c,cu}$ the design concrete cube compressive strength), 2) normal weight normal strength concrete ($f_{c,cu}$ = 55 MPa), and 3) high strength concrete ($f_{c,cu}$ = 75 MPa), as shown Figure 2. The lowest cost was obtained for the design with high strength concrete. Since the dimensions and the weight of the high strength concrete option are smaller than for the normal strength option, larger segments could be developed and the erection time could be shortened by three months. The numbering of the segments is shown in Figure 3. The discussed specimens were cast together with the main span segments.

3 LONG TERM MATERIAL BEHAVIOR

3.1 *Concrete compressive strength*

The concrete compressive strength and the concrete splitting tensile strength have been monitored for twenty years. For this purpose, concrete cubes were cast at the time of construction of the bridge segments, and stored inside the box girder at the position of the respective segments. To determine the material properties, these cubes were retrieved from the bridge, transported to the laboratory, and tested there. This procedure was carried out at 84 days and 124 days after casting, as well as after 1, 2, 5, 10 and 20 years. All results are given in the full measurement report (Lantsoght and van der Veen 2017).

After 10 years of monitoring the results for the compressive strength of high strength concrete, a reduction in the compressive strength of 5% for the cubes stored with segments 8 and 9 was found. It was then concluded that a continued increase in the concrete compressive strength over time cannot be expected for high strength concrete.

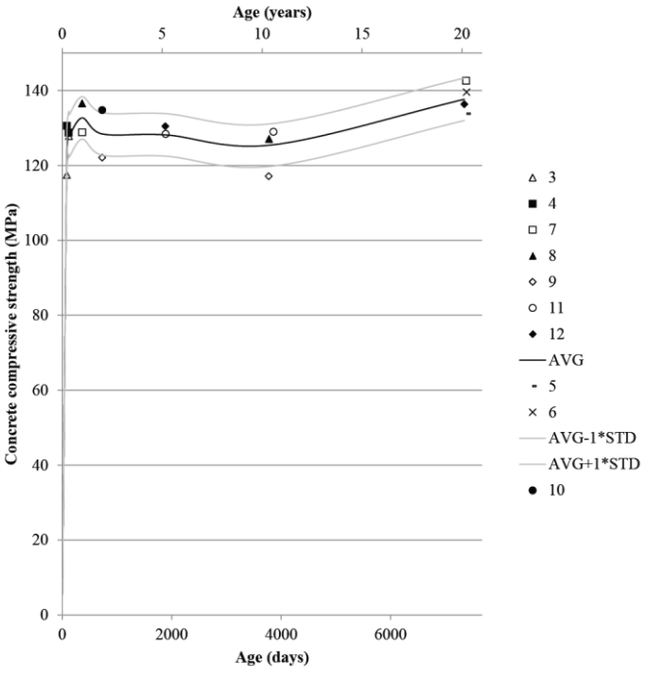

Figure 4. Development of concrete compressive strength over time. The legend shows the number of the segment with which the cubes were cast. Average values of the tested cubes are shown in the figure. The lines of 1 standard deviation above and below the overall average are shown as well.

After 20 years, cubes stored with segments 5, 6, 7 and 12 were tested. The concrete compressive strength as a function of the time is shown in Figure 4, based on the average values of the cubes per segment. These results shown no (further) decrease of the concrete compressive strength, and even indicate

a possible increase over time. It can thus be safely concluded that the compressive strength of high strength concrete does not decrease as a function of time. This conclusion is further reinforced when the variation of the results is taken into account. In Figure 4 the lines of one standard deviation above and below the average value are given. This average value is determined as the average of all cubes tested at a certain age, regardless of the segment. The standard deviation was calculated as 5.67 MPa. Note that this value is slightly larger than the value of 4.88 MPa that is assumed for the cylinder concrete compressive strength in NEN-EN 1992-1-1:2005 (CEN, 2005). From these results, it can be seen that the average value plus one standard deviation after one year (138 MPa) is similar to the average value after twenty years (138 MPa). For finely ground cement, no doubling or tripling of the concrete compressive strength is found over time, which is the case for coarsely ground cement.

3.2 *Concrete splitting tensile strength*

After ten years of monitoring a splitting tensile strength, determined on cubes, of 7 MPa on average was found. Only after two years, temporarily lower values were found (6 MPa). These values are still higher than the average tensile strength of C55/67 concrete, which according to NEN-EN 1992-1-1:2005 should be $f_{ct,m}$ = 4.2 MPa. The general conclusion after ten years of monitoring was that the splitting tensile strength remained constant.

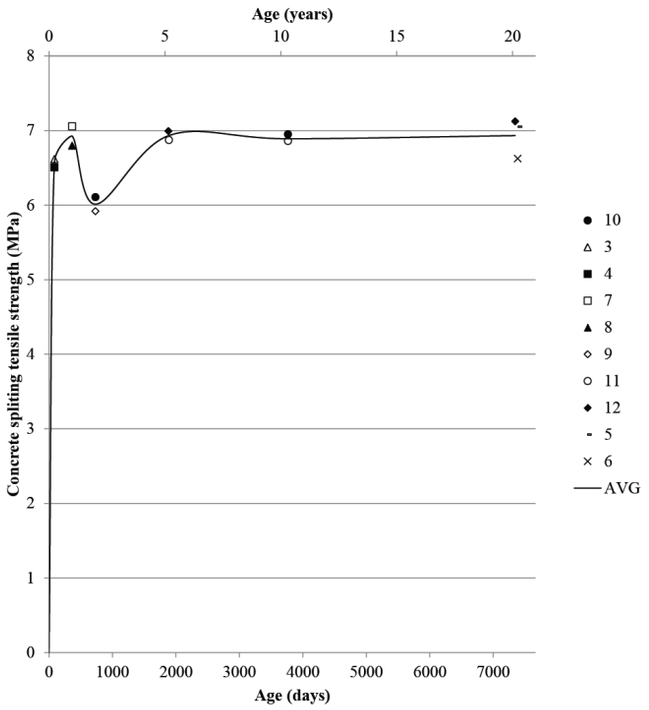

Figure 5. Development of concrete tensile splitting strength over time. The legend shows the number of the segment with which the cubes were cast. Average values of the tested cubes are shown in the figure.

After twenty years, the splitting tensile strength was determined on cubes cast together with segments 5, 6 and 12. These results confirm that the concrete splitting tensile strength determined on cubes remains constant, and about 7 MPa. These results are shown in Figure 5. The line of the average plus and the average minus one standard deviation is not shown in Figure 5, since the relation between the mean and characteristic tensile splitting strength in NEN-EN 1992-1-1:2005 (CEN, 2005) is not determined with a relation that involves the standard deviation.

Another observation that could be made based on the determination of the splitting tensile strength of the concrete over twenty years, is a small increase of the standard deviation on the measured splitting tensile strength. The value increased from about 0.5 MPa during the first years to 0.7 MPa after twenty years.

The general conclusion of monitoring the splitting tensile strength of the high strength concrete mixture for twenty years is that the tensile strength remains constant after five years.

3.3 *Shrinkage*

During the first ten years, shrinkage measurements were taken in the laboratory as well as on concrete blocks stored inside of the bridge box girder. For the specimens stored in the laboratory, the shrinkage strain ε_{sh} is determined for loading high strength concrete of 14 days old and concrete of 1 year old. All specimens were stored at a constant temperature of 20°C and a relative humidity of 50%. For the concrete loaded at 14 days until ten years, a shrinkage strain of $\varepsilon_{sh} = 0.35\times10^{-3}$ was found, and for the concrete load at 365 days old until ten years, a shrinkage strain of $\varepsilon_{sh} = 0.25\times10^{-3}$ was found. The shrinkage effect that was measured in the laboratory was mostly drying shrinkage, since autogenous shrinkage mainly occurs in the first weeks after casting concrete.

Figure 6. Specimen for shrinkage measurements inside box girder.

The specimens that were stored inside the box girder were cast together with segments 13 and 15 and have the same thickness (320 mm) as the web of the box girder. The size of the specimens is 320 mm

× 600 mm × 1000 mm. The deformations are measured at three positions (two on top of the specimen and one on the bottom) over a length of 800 mm. The specimen inside the box girder is shown in Figure 6. The shrinkage deformations are found as the difference between the measured deformations and the deformations caused by temperature variations. The strain caused by the temperature ε_{temp} is determined as:

$$\varepsilon_{temp} = \alpha\left(T_{meas} - T_{ref}\right)l_{meas} \quad (1)$$

with α = 12×10^{-6}/ºC×m, T_{meas} the temperature when the measurement is taken, T_{ref} the reference temperature of 9.7ºC on April 11th 1997 at 11 am when the measurements were started, and l_{meas} the length over which is measured (i.e. 800 mm).

The results of the shrinkage measurements for the specimen cast with segment 13 are shown in Figure 7 and for the specimen cast with segment 15 in Figure 8. As shown in Eq. (1), the effect of the deformations caused by temperature fluctuations needs to be taken into account. No difference between the measurements on the top and bottom of the specimen are observed.

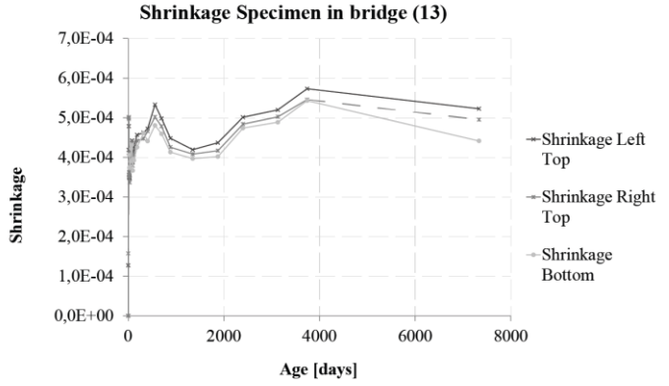

Figure 7. Shrinkage as measured in specimen 13, assuming temperature of 9ºC.

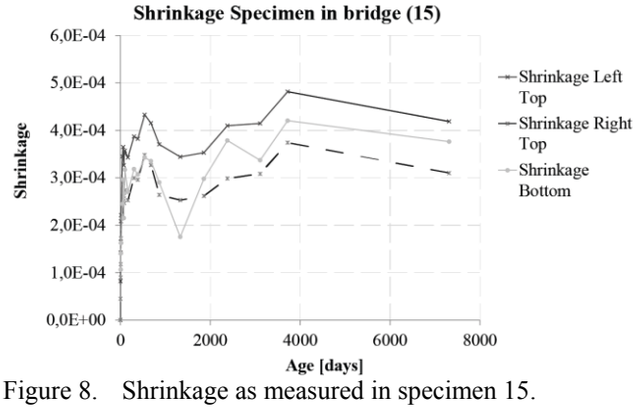

Figure 8. Shrinkage as measured in specimen 15.

During the first ten years of monitoring, the temperature and humidity inside and outside of the box girder were measured. For the measurements after twenty years, the temperature was estimated based on the observations of the Royal Dutch Meteorological Institute (Royal Dutch Meteorological Institute, 2017). The nearest observation stations (Schiphol, Berkhout, De Bilt, Lelystad) reported temperatures on April 26th 2017 at 2 pm ranging between 8.3ºC (De Bilt) and 9.7ºC (Schiphol). An exterior temperature of 9ºC can thus be assumed. This temperature was used to determine the resulting shrinkage strain in Figure 7 and Figure 8.

Since the specimen on which the shrinkage measurements were taken was stored inside of the box girder, the temperature inside may have been larger than the exterior temperature. Based on the measurements of temperature and relative humidity from the first ten years of monitoring, it can be concluded that the difference between the inside and outside temperature is on average 1.5ºC (Van der Veen 2008). The temperature inside of the box girder is more constant than the exterior temperature. The largest temperature differences are observed during winter and summer, and are maximum 9ºC. During the spring months, the largest observed differences between the temperature inside the girder and outside are 5ºC. Therefore, it is assumed that the temperature inside the box girder can have been maximum 14ºC. The results for the shrinkage strain, after a correction for the strain caused by a temperature of 14ºC, are shown in Figure 9.

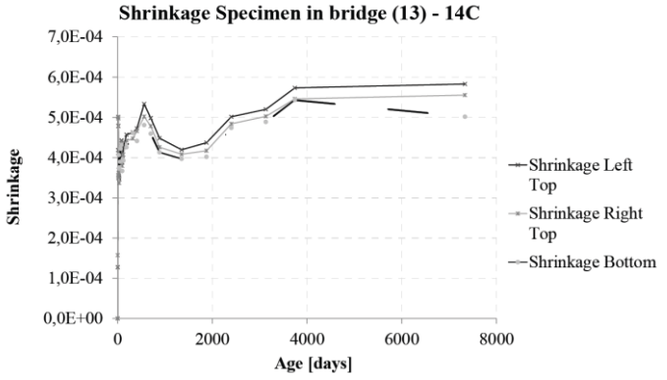

Figure 9. Shrinkage as measured in specimen 13, assuming a temperature of 14ºC.

When a temperature inside the box girder of 9ºC is assumed (Figure 7 and Figure 8), a small amount of swelling of the specimens can be observed after twenty years in comparison with the measurements after ten years. When a temperature inside the box girder of 14ºC is assumed (Figure 9), virtually no difference between the shrinkage strain after ten and twenty years is found. During the first 18 months, a clear increase of the shrinkage strains was observed. Subsequently, a period of swelling of the specimens was observed until three years after casting the concrete. For the time period between three and ten years, a continuous shrinkage is observed in all specimens. this shrinkage process was thus not continued until the concrete reached an age of twenty years. It can thus be concluded that no further increase in shrinkage is observed after twenty years and that the time-dependent deformations have sta-

bilized in the observations between ten and twenty years.

3.4 *10 years of monitoring creep*

The effect of creep is measured in the laboratory as well as on site (De Boer and van der Veen 2012). The creep measurements in the lab are carried out on beams with dimensions of 100 mm × 100 mm × 400 mm, see Figure 10. The length over which the deformations are taken is 200 mm. These measurements are done by using four LVDTs per specimen. The specimens are not sealed, so that the measurements have to be corrected for the effect of shrinkage. The test is carried out in a room with constant temperature of 20°C and RH = 50%.

Three ages of loading the specimens are selected: 14 days, 28 days, and 365 days. For the specimens loaded at 14 and 28 days, a stress of 10 MPa is used, and for the specimen loaded at 365 days 20 MPa. This load level was kept constant for 10 years. The measurements led to the conclusion that a very small creep factor (defined as related to the elastic deformation at 28 days) of between 0.5 and 1.0 is observed for the studied high strength concrete for all ages of loading of the concrete.

Figure 10. Test setup in laboratory for monitoring creep during 10 years.

After ten years, the load was removed from the creep specimens. The occurring deformations during unloading were measured as well. Afterwards, the specimens were loaded to a stress level of 35 MPa (about 30% of the actual measured compressive strength). The behavior during loading was linear elastic and could be used to determine the modulus of elasticity, which was found to increase as the age of the concrete at first loading increased. As such, it is possible to determine the load level that occurred in a sample by loading the sample again. It must be considered that the modulus of elasticity is influenced by the load level and the age of first loading. After unloading, the delayed elastic deformations occurred within 60 minutes after removing the load. These observations are important for the assessment of existing bridges, where the effect of prestressing on the concrete needs to be determined.

To determine the modulus of elasticity, beams of 100 mm × 100 mm × 400 mm are tested under compression. The modulus of elasticity is determined at 1/3rd of the failure load. It is found that for concrete of one year old, the modulus of elasticity is 10% higher than after 28 days.

In addition to the laboratory tests, measurements were taken on the web of the box girder for segments 2, 13, and 15. Measurement points were applied on the box girder. Since a specimen inside the box girder (Figure 6) was monitored for shrinkage, the difference in behaviour between the web and the shrinkage specimen can be attributed to creep. Therefore, the measurements on the web have to be corrected for the effect of shrinkage (determined based on the specimen stored inside the bridge), and the effect of temperature to find the effect of creep. The results for segment 13 for ten years of monitoring are shown in Figure 11. The large increase in the strains at 120 days of age were caused by the casting of the asphalt layer. These results can be used for calculations with for example finite element models.

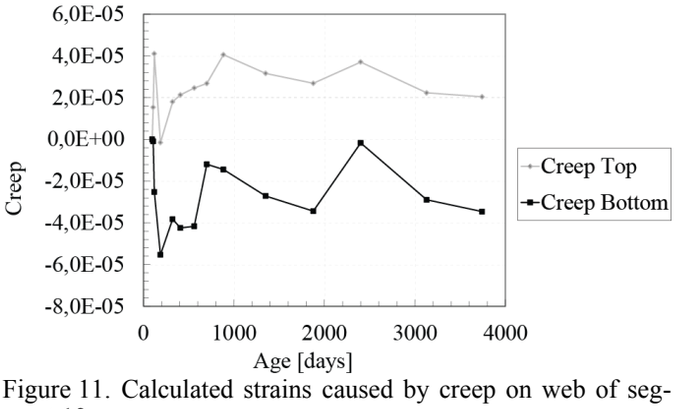

Figure 11. Calculated strains caused by creep on web of segment 13.

4 LONG TERM STRUCTURAL BEHAVIOR

4.1 *Deflection measurements*

At several points in time between 1997 and 2016, the deflections of the bridge have been measured by an external surveyor. Two sets of measurements at 13 positions (on both sides (West and East) of the bridge) are taken, see Figure 12 and Figure 13. The measured deformations are deflections (positive for hogging and negative for sagging) at the second

support (Sup 2), at midspan of the 160 m middle span (Span), and at the third support (Sup 3).

To find the net deflection at midspan, without the effect of the settlements at the support, the effect of all support settlements should be taken into account. A large settlement occurs at support 1; the measured value of this settlement is -22.3 mm in 2016. Such a settlement would result in a hogging at midspan of the main span between supports 2 and 3. To find the hogging or sagging deflection at midspan of the main span, a beam model is used of the box girder modeled as a girder with a variable moment of inertia I.

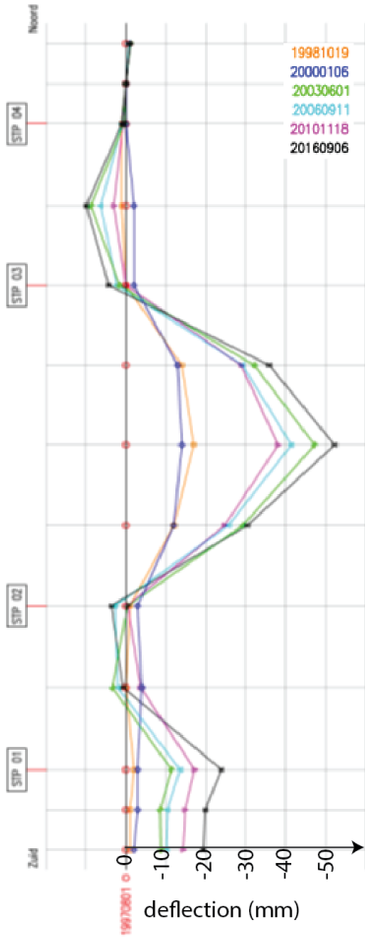

Figure 12. Measured deflection profiles reported in 2016, profile 101-113, with date of measurements in YYYYMMDD format (Sikken, 2016)

The variability in the moment of inertia I results from the changes in the height of the cross-section, as shown in Figure 2. For spans 1 and 3, the height varies parabolically between 2.5 m and 6.75 m. The expression is as follows:

$$h(x) = 6.64\times10^{-4}\frac{1}{m}x^2 + 2.5m \qquad (2)$$

For the central span, the height is also assumed to vary parabolically between the supports and the midspan:

$$g(x) = 6.64\times10^{-4}\frac{1}{m}x^2 - 0.10625\times x + 6.75m \qquad (3)$$

All other properties of the section, required to calculate I, are taken from Figure 2. The top flange is simplified as of constant height, and assumed to be 0.35 m. The value of the Young's modulus of the concrete is taken as E = 46725 MPa, as measured after one year (Van der Veen 2008). In the beam model, elements with a length of 5 m (the largest length of a segment that was used during construction) are used, with a different value of I, calculated based on the different value of the height.

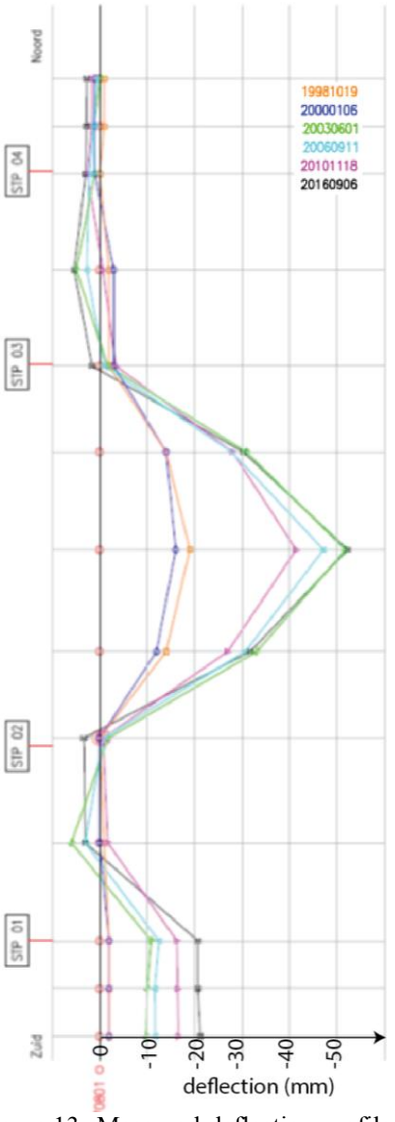

Figure 13. Measured deflection profiles reported in 2016, profile 401-413 (Sikken, 2016).

For the deflection measurements of 2016, the support settlements measured at the four supports resulted in a calculated hogging of 11.35 mm at midspan for the central span. Since a sagging deflection at midspan was measured of -52.25 mm, it can be found that the net deflection equals -63.60 mm.

The effect of the support settlements on the midspan deflection for the central span is calculated for all sets of measurements, see Table 1. These results are then used to calculate the net deflection at midspan of the central span, see Table 2. Additionally, the outside temperature T at the day of the observations as reported by the surveyor is included in Ta-

ble 2. In 2008 (Van der Veen 2008) it was mentioned that the deflections measured in 1999, at a temperature of 8ºC were lower and below the trend of the measurements taken at higher ambient temperatures. Similarly, it can be seen that the deflections measured in 2010, at a temperature of 8-12ºC were lower as well.

The calculated net midspan deflections of the central span can then be shown as a function of the time, see Figure 14. This figure also shows that the increase in deflections between the structure with an age of five years and with an age of twenty years is limited.

Table 1. Average support settlements and midspan deflection

Date DD-MM-YYYY	Sup 1 (mm)	Sup 2 (mm)	Span (mm)	Sup 3 (mm)	Sup 4 (mm)
04-08-1997	0.00	0.00	0.00	0.00	0.00
07-09-1998	-2.00	0.00	-18.00	-1.00	0.50
15-11-1999	-2.50	-1.00	-15.00	-2.50	0.50
17-11-2003	-11.15	-0.60	-49.55	-0.05	0.70
11-09-2006	-13.05	1.45	-44.25	0.65	1.55
18-11-2010	-16.75	-0.40	-39.75	-1.70	1.60
06-09-2016	-22.30	3.95	-52.25	2.95	1.95

Table 2. Calculated effect of support settlements and resulting net deflection at midspan

Date DD-MM-YYYY	Effect (mm)	Net (mm)	*T* (ºC)
04-08-1997	0.00	0.00	21.7
07-09-1998	-0.355	-17.65	17.4
15-11-1999	-2.185	-12.82	8
17-11-2003	2.517	-52.07	23-25
11-09-2006	4.443	-48.69	25
18-11-2010	2.735	-42.49	8-12
06-09-2016	11.35	-63.60	20

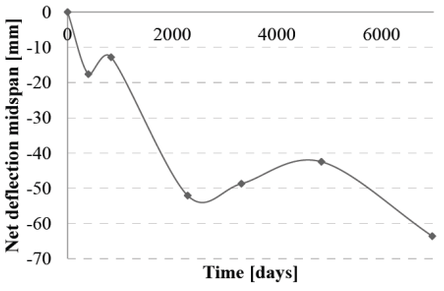

Figure 14. Net deflection at midspan of the central span, corrected for the effect of the support settlements.

For the measured deflections, two conclusions can be drawn. The first conclusion is that the measured deflections are larger when the temperatures are larger, and that this observation should be kept in mind when evaluating the results of the measurements. The second conclusion is that the net deflection at midspan of the central span after twenty years (-63.60 mm) can be considered as small. This deflection is 1/2516 of the span length of 160 m.

4.2 *Comparison to predictions*

During the design stage and after construction of the Second Stichtse Bridge, several predictions have been made of the long-term deflections. The most recent, and most advanced calculations (Louman, 2005), were carried out in TNO Diana Release 8 (TNO DIANA, 2005) using staged execution of the structure and using the modulus of elasticity as a function of the time, the creep as a function of the time and load, related to the actual construction and load scheme of the bridge, and the shrinkage dependent on the time of removing the formwork. The creep and shrinkage models of NEN-EN 1992-1-1:2005 (CEN, 2005), Model Code 1990 (CEB-FIP, 1993) and Han (Han, 1996), a modified model of the Model Code 1990 with the inclusion of parameters for high strength concrete, have been studied. The results for the predictions for 100 years are given in Figure 15a. These are then compared to the measurements in Figure 15b. From this comparison, it can be seen that the predictions using the creep and shrinkage methods of Eurocode 2 and Han give better results than Model Code 1990, which overestimates the long-term deflection.

5 DISCUSSION

The presented results contain unique data with regard to the long-term material and structural behavior of high strength concrete box girder bridges. These results can be used to compare to the strains caused by creep and shrinkage as prescribed by the governing codes, which are determined based on only laboratory test results. Since the presented results are determined based on laboratory specimens as well as on an actual structure, they can be used to improve the assessment practice for existing prestressed high strength concrete bridges. These field data can also be used to optimize the design of high strength concrete balanced cantilever bridges. Future analysis of the bridge can include the material models of the *fib* Model Code 2010 (fib, 2012), and/or using a plane stress model to study shear.

6 SUMMARY AND CONCLUSIONS

In 1997, the Second Stichtse Bridge was the first high strength concrete prestressed box girder bridge constructed using the balanced cantilever method in the Netherlands. At that time, the code provisions did not include high strength concrete classes and the creep function was not considered dependent on the load. Therefore, assumptions with regard to the

long-term concrete behavior had to be made during the design stage.

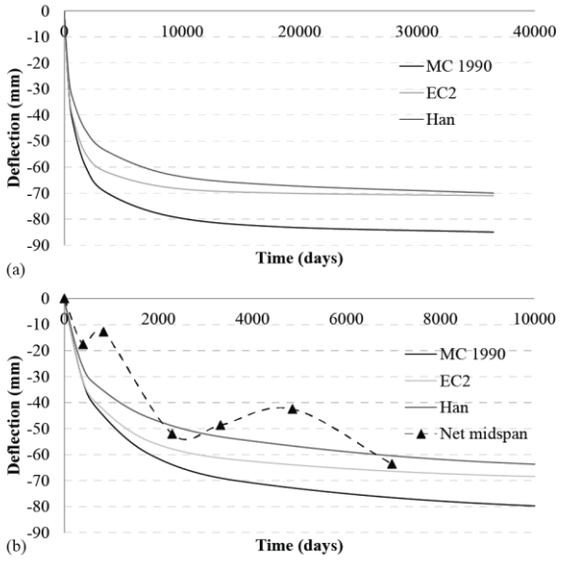

Figure 15. Long-term deflection at midspan of central span: (a) predictions for 100 years (Louman, 2005); (b) comparison between results of twenty years of measurements and predictions

To verify the assumptions with regard to the material behavior, and to learn more about the long-term behavior of high strength concrete in large bridges, a monitoring program was started. The concrete compressive strength and splitting tensile strength were determined based on cubes stored inside the box girder. The effect of shrinkage was determined based on specimens in the laboratory and inside the box girder. The effect of creep was determined from measurements on the web of the box girder. The structural behavior was monitored by measuring the deflections at regular intervals.

After ten years of monitoring, a small decrease of the concrete cube compressive strength was measured. However, the results of testing after twenty years show that the concrete compressive strength remains constant and that there should be no concern with regard to a decrease of the compressive strength.

After twenty years of monitoring the cube splitting tensile strength, it is concluded that this strength has remained constant since the concrete had an age of one year.

After twenty years, the deformations caused by shrinkage have stabilized and are not increasing further. The calculated shrinkage strain does depend on the temperature inside the box girder, which had to be estimated since the temperature and humidity measurements were stopped after ten years of monitoring.

The deflections of the superstructure are determined at regular intervals by surveyors. The analysis in this paper showed that the effect of the support settlement for support 1 resulted in an effect of hogging at the midspan of the central span. When this effect is considered, a net deflection of the central span after twenty years of 63.6 mm is found, which is a small deflection. This value corresponds to the predicted deflections from a finite element model using the long-term material behavior from Eurocode 2 and Han.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude and sincere appreciation to the Dutch Ministry of Infrastructure and the Environment (Rijkswaterstaat) for financing this research work. The help of Fred Schilperoort, Ger Nagtegaal and the late Erik Horeweg during the experiments in the Stevin II laboratory of Delft University of Technology and during the field measurements is also gratefully acknowledged.

Estimating Climate Effects on Bridge Decks Deterioration

Shuang Liu, Hongping Zhu, Lifei Yang & Muhammad Habib
Huazhong University of Science and Technology, Wuhan, China

ABSTRACT: In this paper, a two-step methodology is proposed to enrich the traditional National Bridge Inventory (NBI) database by taking some environmental information into consideration and estimate climate effects on bridge decks deterioration. The NBI database is firstly extended with more detailed National Oceanic and Atmospheric Administration (NOAA) weather station data which includes temperature, daily temperature difference, relative humidity and freeze-thaw cycles, by means of bridge longitude and latitude records. After that, Different climate factors are used to classify climate regions and the numerical analysis of climate effect on bridge decks deterioration is implemented based on the new database. The results indicate that region 3 with higher freeze-thaw cycles shown a more faster trend on deck deterioration than region 1 and 2. While, when the number of freeze-thaw cycles is less than 80 per year, concrete carbonization caused by temperature and humidity will be the predominant environmental factor for bridge deck deterioration. This proposed method makes the traditional National Bridge Inventory (NBI) database more comprehensive and easy to update and expand, it helps to obtain accurate prediction of the future condition of bridge decks in bridge management system.

1 INTRODUCTION

The condition of the nation's aging bridges has been of the highest concern in recent decades. FHWA estimates that $20.5 billion will need to be invested annually in order to eliminate the United States bridge deficient backlog by 2028. As bridge deck deterioration is one of the primary concerns and cost factors for transportation agencies, the accurate prediction of the future condition of bridge decks becomes an important and urgent task. To accomplish this comprehensive work, the factors that affect the deterioration should be studied thoroughly, which is also a prerequisite of developing deterioration models.

With the aid of NBI database, bridge deck deterioration modeling has been performed by numerous researchers over the year. Many recommended deck deterioration models are built by using third-degree polynomial regression, Markov chain and Weibull-based approach (Bolukbasi et al. 2004; Agrawal et al. 2009; Cruz 2013; Zhang et al. 2003; Scherer and Glagola 1994; Dekelbab et al. 2008), these models describe the relationship between condition rating and bridge age. Some other studies on this topic, account for deck deterioration not only due to bridge age but also other NBI explanatory factors, such as, geometric information, applied load (traffic), and wearing surface information (Ben-Akiva and Gopinath 1995; Mauch and Madanat 2001; Morcous and Hatami 2011; Radovic et al. 2016). These manually selected candidate variables may not be effective for all states and locations and may also exclude potentially important factors. For instance, Wells (1994) recognized the potential differences in deterioration rates of bridge elements due to differences in climatic exposure and operating practices. Dadson (2001) proposed that the region affect the service life of the bridge in Virginia. Kim et al. (2009) found that water is a factor that cannot be ignored during the bridge deterioration analysis. TU Saeed et al. (2017) carried out sensitivity and marginal effects analyses to quantify the effect of the influential factors and found that freeze index, freeze-thaw cycles has a significant adverse effect on bridge condition. Particularly bridge deck is the most immediate component of bridge structure exposed to the harsh conditions of climatic changes, that means it is highly vulnerable to external environment. Damage due to temperature and relative humidity, deicing salts, freeze-thaw cycle induced stresses, fatigue and above all corrosion of rebars, have been confirmed through field tests and numerical modeling (Bremner et al., 2001; Berntsson, L et al. 1995; Gong et al., 2014; Oneill et al., 2001; Nawy, 2008).

Above literature review indicates that a rather spare research can convenient incorporate climate effects into consideration during the bridge deck deterioration. The fundamental reason is that the NBI database lacks environment related items. For this

reason, this paper introduces a two-step methodology to make the traditional NBI database more comprehensive and easy to update and expand.

1. Create NBI and climate database with the aid of SQL server software, and then connect every bridge with the nearest weather station using the information of longitude and latitude. Through these analyses, this paper adds some climate items (temperature, relative humidity, No. of days above 32℃, No. of days below 0℃, freeze-thaw cycles, and No. of daily temperature difference more than 20℃) into the traditional NBI database.

2. Using different climate factors to divide climate zones, and three climatic regions were selected and the deck degradation trends were analyzed and compared.

2 DATA COLLECTION AND DATABASE CONSTRUCTION

2.1 *NBI database*

The National Bridge Inventory (NBI) is a database (FHWA), compiled by the Federal Highway Administration, with information on all bridges and tunnels in the United States. It includes identification information, bridge types and specifications, operational conditions, bridge data (geometric data, functional description, and inspection data). Bridges longer than 20 feet (6.1 meters) used for vehicular traffic is included (Chase et al. 1999).The inventory is developed with the purpose of having a database for bridges to ensure the safety of the traveling public as required by the Federal-Aid Highway Act of 1968 (Graybeal et al. 2002). For further normalization of the NBI data, the FHWA published the Recording and Coding Guide for the Structure Inventory and Appraisal of the Nation's Bridges in 1971. This coding guide outlined the specific bridge elements that are required to be inspected, and provided the guidelines on how to conduct an inspection and records formats.

Based on the NBI coding guide (FHWA 1995), "Condition ratings are used to describe the existing, in-place bridge as compared to the as-built condition." Condition codes are representative of the general condition of the entire component (i.e., deck, superstructure, or substructure). In this rating system, bridge elements condition ratings vary from 0 to 9, and their description for decks is shown in Table 1. These condition ratings are subjective assessments assigned by bridge inspection teams where 9 indicates the best and 0 shows the worst condition.

Table 1. Description of condition rating of bridge decks in NBI

Rating	Description
N	NOT APPLICABLE
9	EXCELLENT CONDITION
8	VERY GOOD CONDITION - no problems noted.
7	GOOD CONDITION - some minor problems.
6	SATISFACTORY CONDITION
5	FAIR CONDITION
4	POOR CONDITION
3	SERIOUS CONDITION
2	CRITICAL CONDITION
1	"IMMINENT" FAILURE CONDITION
0	FAILED CONDITION

To facilitate data storage and extraction, this paper introduced the software Microsoft SQL Server 2008 R2 to convert the ASCII format data to table records. Through the deep study on the original data we found some inconsistencies, such as, the same bridge have two built year records during the inspection period, or a bridge may have the Route_Prefix_005B, Base_Hwy_Network_012 records after year 1996, but before this year may not. Thus, appropriate update is necessary to ensure their consistencies.

The process of data adjustment is done by examining the records for each bridge. All records are selected into one table ordered by structure number and inspection date. Inspection records with the same structure number that show a partial missing of the location, geometric, functional description items will be added by the other complete records. For rebuilt bridges, this data supplement work should be divided into two phases before or after the reconstruction. The flowchart describing method is given in Figure 1.

2.2 *Climate database*

The climate database(CDB) obtains daily weather data for stations all around the United States using the Global Surface Summary of the Day (GSOD) dataset (NOAA). This dataset provides daily mean temperature, maximum temperature, minimum temperature, precipitation, air pressure, mean dew point and wind speed observed for weather stations around the world. These basic data could be used to compute key weather metrics, which are much more important in climate effects analysis, including the actual average annual temperature, relative humidity, No. of days above 32, No. of days below 0℃, freeze-thaw cycles, and No. of daily temperature difference more than 20℃.

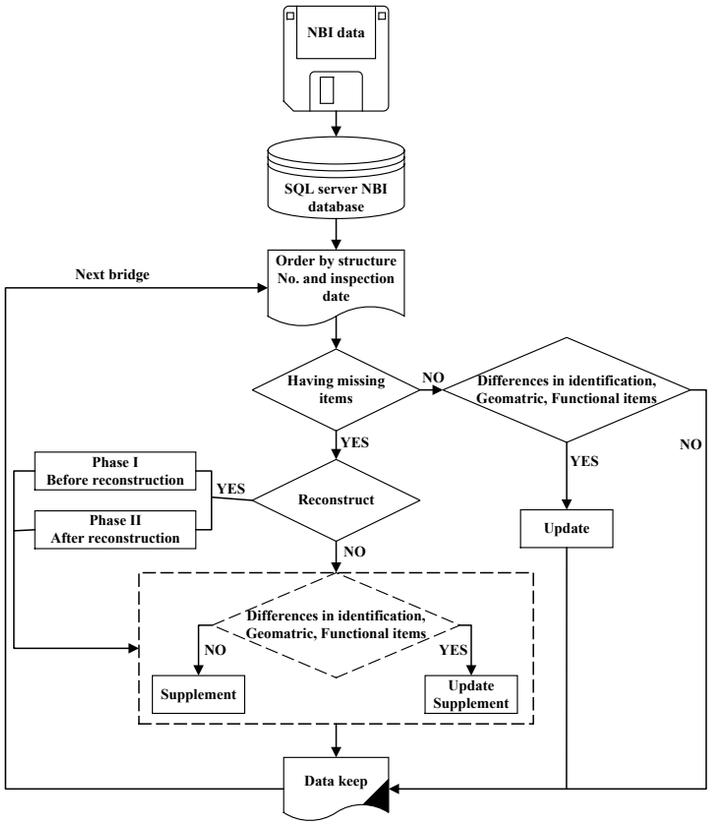

Figure 1. Flowchart for the NBI data adjustment.

Table 2. Derived Climatic Data

Data Element	Monthly		Annual	
	Average	No. of Days	Average	No. of Days
Mean temperature	√	√	√	√
Maximum temperature	√	√	√	√
Minimum temperature	√	√	√	√
No. of days above 32℃		√		√
No. of days below 0℃		√		√
Freeze-thaw cycles		√		√
Relative humidity	√		√	
Daily temperature difference >20℃		√		√

The GSOD set includes thousands of weather stations. In order to determine which stations to use, CDB went through a rigorous process to identify stations with complete data going back to at least the year 1990.

CDB will fill in gaps by averaging the preceding and following days together for occasionally missed data of an individual station for a day or more. This process of averaging values together is consistent with how NCDC fills in gaps for their own datasets and analyses. In the case that an entire month is missing, CDB will use the climate normal value to fill in that month. If a weather station stops reporting data more than five months, then CDB will remove that station from our list.

Based on this integration and processing, there are more than one thousand weather stations used for the United States every year, Figure 2 illustrates the locations of these stations in year 2016 and the number of stations used every year.

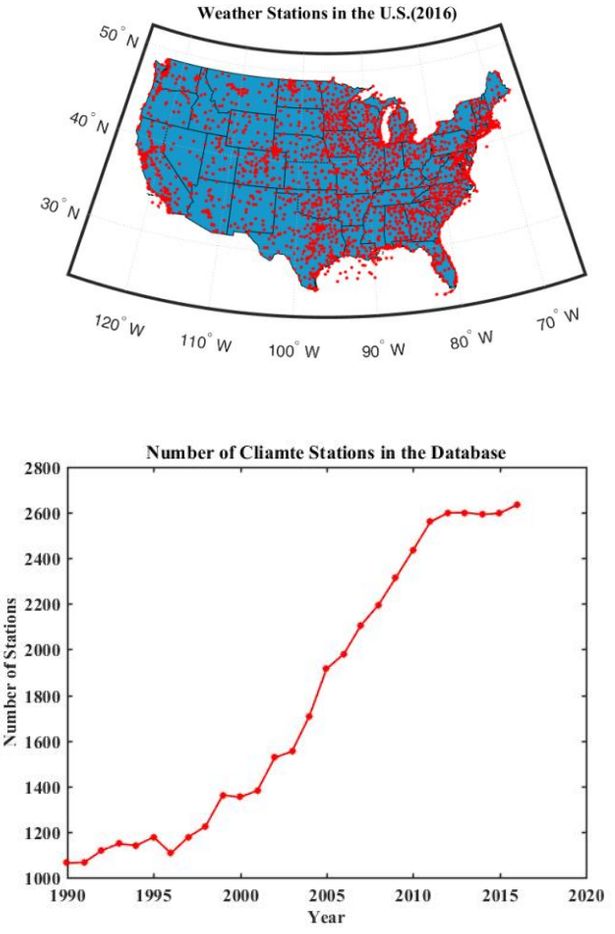

Figure 2. Weather Stations in the USA

2.3 *Database connection*

FHWA's Recording and Coding Guide (FHWA 1995) declared that the structure number(item 8) must be unique for each bridge within the state, and once established should preferably never change for the life of the bridge. At the same time, every NBI bridge has some identification items, such as bridge latitude and longitude information illustrated in item 16, item17 as mentioned in the above chapter. So we can believe that each bridge has a fixed corresponding longitude and latitude. Based on this assumption, the records having no information of longitude and latitude in the early years can be modified and supplemented by the big data analysis from 1992 to 2016. After that, a MATLAB code was written to calculate the nearest weather station for every bridge using its location.

3 CLIMATE EFFECTS ANALYSIS

3.1 *Climatic regionalization*

The freeze-thaw cycle is a main environmental factor which leads to the initiation of cracks and erosion of chloride ion at bridge deck. Figure 3 compares the freeze-thaw cycles recorded from 1992 to 2016 in the database. The figure divides the interstate highway bridges into four parts (less than 40 days; between 40 and 80 days; between 80 and 120 days; more than 120 days) based on the number of freeze-thaw cycles per year. In this division, we use a statistical method that, if the records in a certain interval are more than two-thirds of the total during the bridge inspection period, we determine the bridge into that freeze-thaw interval.

Figure 4 shows the annual mean temperature distribution of the interstate highway bridges. Using the k-means cluster method to divide the bridges into four parts. The cluster centroids are 20.6℃, 16.3℃, 11.4℃ and 7.2℃, respectively. These census data justify the noticeable difference in temperature among the states. This same method was also used to assess the variation of relative humidity in different regions as shown in figure 5, and the centroids are 69.60%, 57.28% and 37.50%, respectively.

According to the climatic regionalization, two representative states per regions (except region 4, In order to control the number of climatic explanatory variables) were selected (Table 3) to do the following analysis.

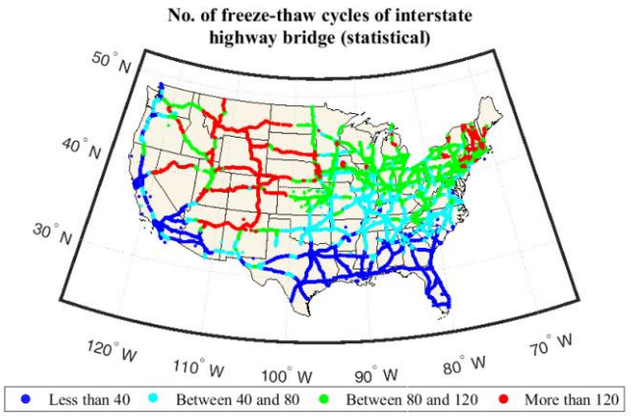

Figure 3. Climatic regionalization based on No. of freeze-thaw cycles per year

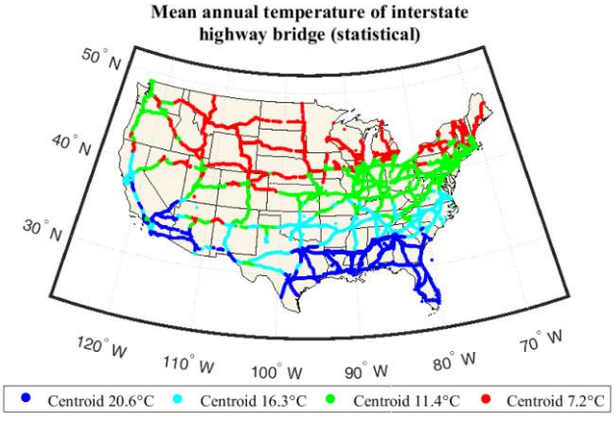

Figure 4. Climatic regionalization based on mean annual temperature

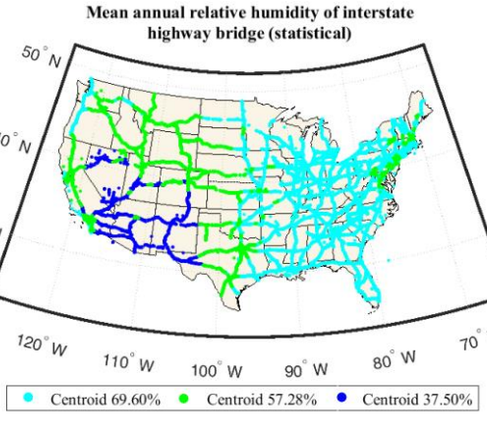

Figure 5. Climatic regionalization based on mean annual relative humidity

Table 3. Bridge data selected

Region	States	No. of freeze-thaw cycles per year	Mean annual temperature (cluster centroid)	Mean annual relative humidity (cluster centroid)
1	Alabama(AL),Georgia(GA)	less than 40	20.6℃	69.60%
2	Tennessee(TN), North Carolina(NC)	between 40 and 80	16.3℃	69.60%
3	Indiana(IN),Ohio(OH)	between 80 and 120	11.4℃	69.60%

3.2 *Data filtering*

In the NBI database, Some bridge elements have undergone major maintenance, rehabilitation, and replacement actions that were not recorded during the service period of the bridge, which may result in erroneous element condition versus age (outliers). For instance, a 50-year-old bridge deck with a condition rating of 9 or 2 or 3 condition rating for a relatively new constructed superstructure (e.g., age 2 years). This kind of phenomenon is much more common in the bridge deck deterioration records, probably because a bridge deck is the most immediate component of bridge structure exposed to the impact of traffic loads and climatic changes. Previous studies(Saito 1988; Markow et al. 1993; Bolukbasi et al. 2004) have shown that decks have a much shorter life than other bridge components. Furthermore, when a bridge is scheduled for reconstruction of its superstructure, the deck will also be replaced along with the other members. In order to eliminate this kind of records, this paper adopts the rules that bridges in the NBI with a date of construction or date of major reconstruction (NBI Item 27) within the past 10 years will not be considered a deficient bridge, will not be eligible for HBRRP funding applies to bridges replaced or reconstructed with any Federal-aid funds. For example, a date of 1976 will be used for the determination until the end of 1985. For the scope of this study, only the highway (excepted county highway) bridges with average daily traffic more than 5000 built during 1981 and 1990 were analyzed.

3.3 *Analysis and results*

Six cases of comparisons between the deterioration rates calculated by average condition rating are considered to demonstrate the climate effects on bridge deck deterioration. These cases show comparison between different regions and highway systems for the following: (1) interstate highway bridge decks without protection in region 1-3; (2) numbered highway bridge decks without protection in region 1-3; (3) state highway bridge decks without protection in region 1-3; (4) interstate highway bridge decks with and without protection in region 3; (5) numbered highway bridge decks with and without protection in region 3; (6) state highway bridge decks with and without protection in region 3.

Figures 7-9 illustrate the variation of average deck condition rating by inspection year. As can be seen from the figures, the deterioration of the bridge decks revealed a trend that region 3 deterioration rate is much faster than the others, while the region 2 is the slowest. The detailed numerical results are presented in table 4. This phenomenon indicates that the deterioration of the deck is relatively rapid when the bridges have experienced more freeze-thaw cycles in the moist environment. Because bridges serviced under this condition have high water content, water held in the pores of cement paste will freeze at low temperatures. As ice occupies a bigger volume than water so expansive forces can be generated, thus can result in surface cracks. More cycles of freezing and thawing result in progressively deeper damage. At

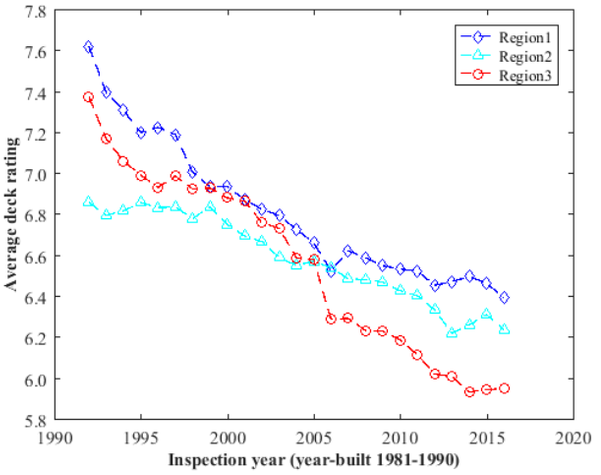

Figure 7. Average condition of the interstate highway bridge decks

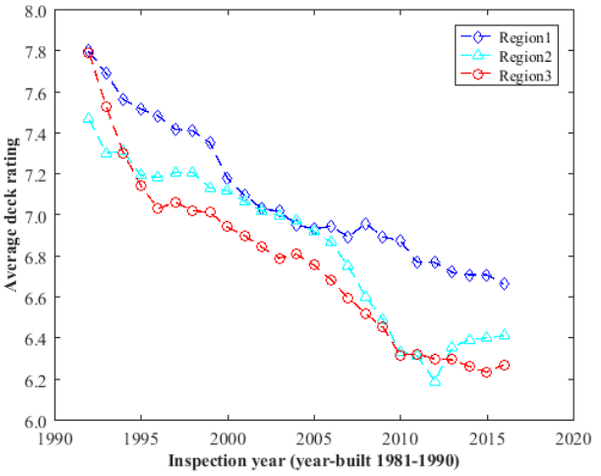

Figure 8. Average condition of the numbered highway bridge decks

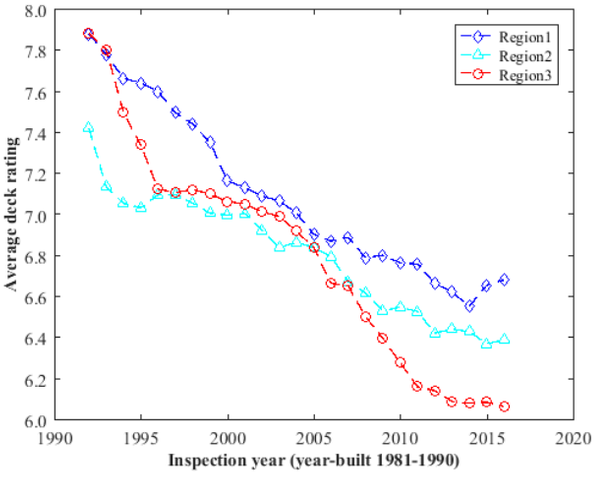

Figure 9. Average condition of the state highway bridge decks

Table 4. Deterioration rates of highway bridge deck condition (without protection)

Region	Interstate highway		Numbered highway		State highway	
	⩾7	Total	⩾7	Total	⩾7	Total
1	-0.084	-0.045	-0.070	-0.052	-0.075	-0.053
2	—	-0.029	-0.035	-0.050	-0.124	-0.038
3	-0.126	-0.060	-0.105	-0.061	-0.083	-0.072

the same time, the more cycles of freezing and thawing mean the greater possibility use of de-icing salts, which can also, accelerates the deterioration process. Comparing region 1 and region 2, the concrete carbonation caused by temperature and humidity will be the predominant environmental factor for the degradation of the bridge deck when the number of days of freeze-thaw cycles are below 80 per year.

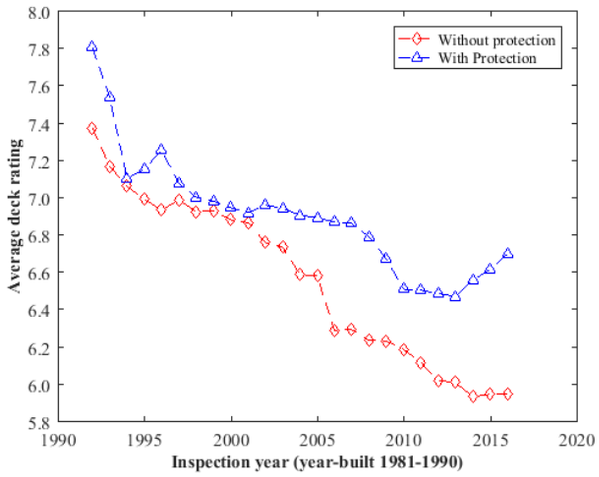

Figure 10. Average condition of the interstate highway bridge decks

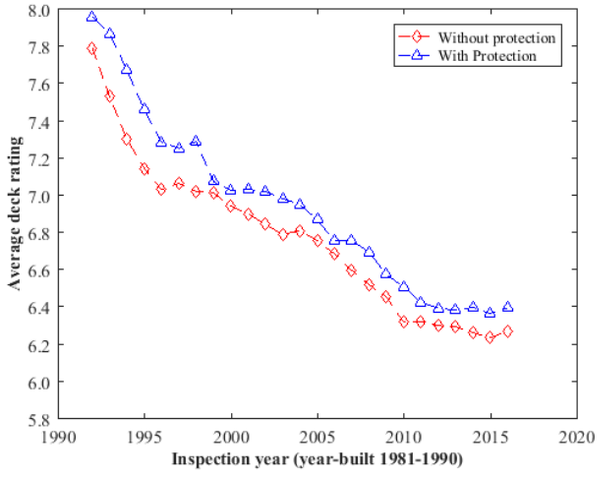

Figure 11. Average condition of the numbered highway bridge decks

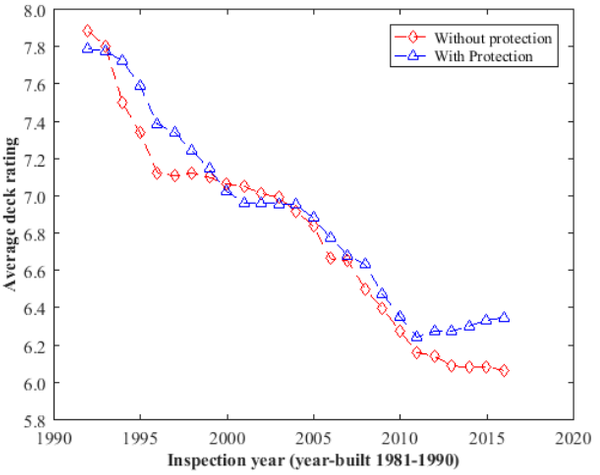

Figure 12. Average condition of the state highway bridge decks

Table 5. Deterioration rates of highway bridge deck condition (with protection)

Region	Interstate highway		Numbered highway		State highway	
	⩾7	Total	⩾7	Total	⩾7	Total
3	-0.351	-0.039	-0.118	-0.062	-0.103	-0.076

In the cold states of region 3, there are bridge decks built with protection measures, such as epoxy-coated reinforcement used in the construction. The deck with protection presents a higher average rating during the inspection period 1992-2016 as shown in figures 10-12. Table 5 presents the deterioration rates of bridge deck with or without protection in three different highway systems. In the interstate highway system, it shows that the decks with protection have a much slower deterioration rate. But in the numbered and state highway systems, the deterioration rates show no significant differences. The reason may be the same as Walker (1998) concluded that epoxy coated reinforcement could be easily damaged in the construction process and that the reduced bond between concrete and epoxy-coated reinforcement increased the widths of flexural cracks。 When the average condition ratings are greater than 7, the deterioration rates exhibit a faster trend than the total, evidenced by the figures 7-12. This can be attributed to two reasons; the duration of a deck in rating 8 and 9 is short (Bolukbasi et al. 2004), and the inspectors tend to record a lower rating to make the element more redundant for the public traffic.

4 SUMMARY AND CONCLUSIONS

This paper has discussed the climate effects on the U.S. highway bridge decks based on the NBI and NOAA database analysis. Data are categorized into four service regions (regions 1-4) in accordance with the number of freeze-thaw cycles per year. Two typical states were selected for regions 1-3 (except region 4, In order to control the number of explanatory variables) to represent the condition ratings of re-

spective regions. Before the factor analysis, this paper proposed a method to connect bridge with NOAA weather stations, this method can be implemented for the real-time NBI climate items updating. The following conclusion are drawn:

Each service region exhibited its own deterioration trend during the inspection year 1992-2016. In area with high freeze-thaw cycles (region 3), the interstate highway bridge deck deterioration rates are much faster (-0.0595) than the region 1 and 2 (-0.0447, -0.0285, respectively).However, in regions 1 and 2 (freeze-thaw cycles less than 80 times per year) it shows that concrete carbonation caused by temperature and humidity will be the predominant environmental factor for the degradation of the bridge deck.These results can be confirmed in the U.S. numbered highway (-0.0517, -0.0493, -0.0610, respectively) and state highway (-0.0533, -0.0384, -0.0719, respectively).

In all highway systems of region 3, the average condition ratings of protected deck (epoxy coated reinforcing) are much higher than the unprotected. but the deterioration rates have no significant change except in interstate highway system, that the protected ones have a slower rates than the unprotected.

The deterioration trends of bridge decks in all service regions indicate that when the average condition is more than seven, the local trends will be faster than the whole.

ABSTRACT: The paper presents a railway bridges monitoring system. The system is focused on monitoring of new and old steel bridges. The system is using inertial sensors: inclinometers and accelerometers. These transducers do not require any referential points. The elaboration of the method which uses inclinometers together with an accelerometer for indirect displacement measurement under the dynamic load is the main achievement of the system. Inclinometers are installed in one line on a span and accelerometer at the point of displacement examination. During the passage of a train all the signals from the inclinometers and accelerometer are registered by a central unit and then sent to a server via Internet. A special software platform was developed to test various algorithms of processing the signals registered by the monitored structures during train passages. The system presented herein was checked on arch bridge with span length of 75 m.

1 INTRODUCTION

The dynamics of railway bridges is one of the most complex areas of theoretical analyses and experimental studies – (Frýba 1996, Yang et al. 2004). And the examination of the dynamics of railway bridges located in high speed railway is particularly interesting. Experimental examinations can be carried out under test or service loads. Such tests can be carried out only as one-time test loads conducted for the purpose of structure's acceptance testing or to assess the load capacity of an "old" structure already in use for some time. They can also be carried out as cyclic tests or continuous tests, such as automated monitoring of a structure.

Excessive bridge deformations can endanger traffic by creating unacceptable changes in vertical and horizontal track geometry, excessive rail stresses and vibrations in bridge structures. Excessive vibrations can lead to ballast instability and unacceptable reduction in wheel rail contact forces. Excessive deformations can also affect the loads imposed on the track/bridge system, and create conditions which cause passenger discomfort (EN 1990:2002). Thus, inspection of bridge deformations should be performed with respect to rail safety and passengers' comfort.

It is extremely important to control displacements and accelerations. It should be emphasized here that the measurements of vertical displacements (and especially the measurements of vertical displacements of spans and supports) are one of the most important activities in the process of assessing the structure's technical condition.

They are also one of the most important elements of the process of controlling the structural behaviour during acceptance tests (test loading) before putting a structure into service, as well as during periodic inspections of a structure (every few years).

While the measurements of the accelerations are relatively simple to carry out, the measurements of displacements in an automatic, unattended mode create considerable difficulties. Major difficulties are encountered especially in case of structures with restricted or impossible access to the area under them (bridges over busy roads, railway lines or rivers). In case of spans of great length, the monitoring systems applied nowadays all over the world usually use robotic total stations with the technology of automatic target recognition (ATR) and piezo-technology-based drives as well as GPS (Global Positioning System). Total stations cannot simultaneously measure many points of an examined structure with high accuracy or high sampling rate. In case of observing one point of a bridge it is possible to only perform limited dynamic analysis up to frequency of a few Hz (Cosser et al. 2003, Psimoulis & Stiros 2007, Psimoulis & Stiros

2013). And, a disadvantage of GPS is its obtainable accuracy (Ko & Ni 2005), which limits its usefulness to monitor bridge structures with consider-able displacements.

One of the most important elements of the developed solution is its innovative system of indirect measurement of displacements based on measurements using inclinometers and accelerometers. Many researchers carry out works connected with using for this purpose detectors which do not require a reference point – which are based on inertia. They present works on using accelerometers to measure both accelerations and displacements of bridges under dynamic loads. A disadvantage of this method is the necessity of double integration of an acceleration signal, which can lead to considerable errors in estimating the displacements. There are various methods suggested to correct those errors (Gindy et al. 2008, Sekiya et al 2016, Park et al. 2013), but generally it is not possible to accurately estimate the displacements on the basis of accelerations without additional measurements, for example such as strain gauge measurements (Park et al. 2016).

Many papers were also published related to the application of inclinometers to automatically monitor bridge structures displacements. Most of those papers are limited to measurements under static load. (Olaszek 2014).
