Obstetrics

Normal and Problem Pregnancies

SIXTH EDITION

STEVEN G. GABBE, MD
Senior Vice President for Health Sciences
and Chief Executive Officer
Wexner Medical Center at The Ohio State University
Professor of Obstetrics and Gynecology
The Ohio State University College of Medicine
Columbus, Ohio

JENNIFER R. NIEBYL, MD
Professor
Department of Obstetrics and Gynecology
University of Iowa Carver College of Medicine
University of Iowa Hospitals and Clinics
Iowa City, Iowa

JOE LEIGH SIMPSON, MD
Senior Vice President for Research
and Global Programs
March of Dimes Foundation
White Plains, New York;
Professor of Obstetrics and Gynecology
and Human and Molecular Genetics
Formerly Executive Associate Dean
for Academic Affairs
Herbert Wertheim College of Medicine
Florida International University
Miami, Florida

MARK B. LANDON, MD
Richard L. Melling Professor and Chairman
Department of Obstetrics and Gynecology
The Ohio State University College of Medicine;
Clinical Chief of Obstetrics and Gynecology
Wexner Medical Center at The Ohio State University
Columbus, Ohio

HENRY L. GALAN, MD
Professor and Chief of Maternal-Fetal Medicine
Department of Obstetrics and Gynecology
University of Colorado at Denver Health Sciences Center
Aurora, Colorado

ERIC R. M. JAUNIAUX, MD, PHD
Professor in Obstetrics and Fetal Medicine
Institute for Women's Health
University College London
London, United Kingdom

DEBORAH A. DRISCOLL, MD
Luigi Mastroianni, Jr., Professor and Chair
Department of Obstetrics and Gynecology
Perelman School of Medicine
University of Pennsylvania
Hospital of the University of Pennsylvania
Philadelphia, Pennsylvania

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

To Dr. Edward J. Quilligan and Dr. Frederick P. Zuspan, our teachers and mentors, colleagues and friends. "Q" and "Z" trained together as medical students and residents at The Ohio State University and went on to distinguished careers as leaders in obstetrics and gynecology and pioneers in developing the subspecialty of maternal-fetal medicine.*

Professor of Psychiatry, Obstetrics and Gynecology, Reproductive Sciences, Epidemiology, and Women's Studies; Investigator, Magee Women's Research Institute; Women's Behavioral HealthCARE, University of Pittsburgh, Pittsburgh, Pennsylvania
Mental Health and Behavioral Disorders in Pregnancy

Preface

We're pleased to welcome you to the sixth edition of *Obstetrics: Normal and Problem Pregnancies!* Our book, first published in 1986, now enters its fourth decade. Today, medical information is available in so many different formats and from so many different sources. We are honored that you have turned to (or have returned to) *Obstetrics: Normal and Problem Pregnancies* as a companion in your important work. For many readers this textbook has served as a trusted resource through their years of practice. For newer readers who were introduced to our textbook during medical school or residency training, we hope that you too will find it a valuable companion as you develop your knowledge base and apply what you have learned to patient care.

As in our earlier editions, our book begins with chapters devoted to the basic science and physiology of normal and complicated pregnancies, followed by chapters describing how best to manage first normal and then high-risk patients. In each chapter, we have provided the latest information and used evidence-based studies to justify our recommendations. As you will see on the cover of our textbook and in the list of contributors, we no longer list three senior editors and four associate editors. Rather, we now have an integrated team of seven editors, representing not only a broad range of expertise but each region of our country and Europe.

We believe you will find this edition of our textbook to be the best ever! Our planning process for the sixth edition included surveys conducted of our readers in order that we could assess what you liked best, what topics needed to be expanded, and what we needed to change. Accordingly, we have added four new chapters: Developmental Origins of Adult Health and Disease, Nutritional Management During Pregnancy, Trauma and Related Surgery in Pregnancy, and Patient Safety and Quality Measurement in Obstetrical Care. These new chapters reflect important changes in our field and the way we care for our patients. Every chapter now includes bolded statements our authors have highlighted to emphasize what they want you to learn. These bolded statements, as well as the key points that conclude each chapter, should make review easier. We have also focused more on complementary tables and figures to facilitate learning. We have asked our authors to provide for the printed text a list of approximately 100 key references for you at the end of each chapter. By limiting the number of printed references, we have created more pages for new information in the textbook. As in the past, however, our textbook will be fully available online, where you will find a more extensive bibliography that you can turn to for further exploration of each topic. We have also placed the illustrations for Appendix II, Anatomy of the Pelvis, online for easy access. Appendix I, Normal Values in Pregnancy, has been updated and is available both in the printed textbook and online.

The sixth edition could not have been created without the dedication of our authors. This sixth edition again features the work of nine leaders in our specialty who have contributed to *every* edition: Drs. George J. Annas, D. Ware Branch, Sherman Elias, Timothy R. B. Johnson, Mark B. Landon, Adam A. Rosenberg, Philip Samuels, John W. Seeds, and Baha M. Sibai. We thank each of them! Joining this group of dedicated contributors are 26 new authors, and we thank them as well.

We have received outstanding support from our publisher, Elsevier, and the team of dedicated staff including Judy Fletcher, Melissa Dudlick, Lora Sickora, Stefanie Jewell-Thomas, Joy Moore, and Mike Ederer. Each of the editors wishes to recognize those members of our own team who have provided invaluable editorial and secretarial support, including Joan Lorenz, Beth Mastin, and Susan Dupont (Columbus, Ohio); Martha Altman and Jane Berg (Denver, Colorado); Nancy Schaapveld (Iowa City, Iowa); Elaine Singh (London, United Kingdom); Susan Dent and Esther Lopez (Miami, Florida); and Nancy Bernard (Philadelphia, Pennsylvania).

This sixth edition, like the first published in 1986, has been prepared by our editors, authors, and editorial staff to provide an in-depth understanding of obstetrics, of both normal and problem pregnancies, for the interdisciplinary teams caring for our patients and their families. We hope not only that our readers will find our book a valuable introduction to obstetrics as they begin their careers, but also that they will return to our textbook in the years ahead to review a subject or to share information with their own students and colleagues.

CHAPTER 1

Placental Anatomy and Physiology

Graham J. Burton, Colin P. Sibley, and Eric R. M. Jauniaux

Overview of the Delivered Placenta 3
Placental Development 4
The Amnion and Yolk Sac 6
The Maternal-fetal Relationship During the First Trimester 6
Extravillous Trophoblast Invasion and Physiologic Conversion of the Spiral Arteries 7
The Role of the Endometrium During the First Trimester 9
The Topology of the Villous Trees 10
Placental Histology 11
The Integrity of the Villous Membrane 12
Placental Vasculature 12
Physiology of the Secondary Yolk Sac and Exocoelomic Cavity 13
Placental Transport 14
Overview of the Exchange Physiology of the Placenta and Its Development Over Gestation 15
Bulk Flow/Solvent Drag 15
Diffusion 15
Transporter-Protein Mediated Processes 16
Endocytosis/Exocytosis 16
Placental Nutrient Supply and Intrauterine Growth Restriction 17
Placental Endocrinology 17
Progesterone 17
Estrogens 18
Human Chorionic Gonadotropin 18
Placental Lactogen 19
Placental Growth Hormone 19

KEY ABBREVIATIONS

Alpha-fetoprotein	AFP
Adenosine Monophosphate	AMP
Adenosine Triphosphate	ATP
Cytochrome P450scc	P450scc
Dehydroepiandrosterone	DHA
Dehydroepiandrosterone Sulphate	DHAS
Exocoelomic Cavity	ECC
Epidermal Growth Factor	EGF
Glucose Transporter 1	GLUT1
Guanosine Monophosphate	GMP
Human Chorionic Gonadotropin	hCG
Human Immunodeficiency Virus	HIV
Human Placental Lactogen	hPL
Insulin-like Growth Factor	IGF
Immunoglobulin G	IgG
Intervillous Space	IVS
Intrauterine Growth Restriction	IUGR
Kilodaltons	kDA
Killer-cell Immunoglobulin-like Receptor	KIR
Luteinizing Hormone	LH
Major Histocompatibility Complex, Class I, C Antigen	HLA-C
Millivolts	mV
P450 Cytochrome Aromatase	P450arom
Potential Difference	PD
Placental Growth Hormone	PGH
Secondary Yolk Sac	SYS
Type 1 3β-hydroxysteroid Dehydrogenase	3β-HSD

The placenta is a remarkable organ. During a relatively short life span it undergoes rapid growth, differentiation, and maturation. At the same time it performs diverse functions, including the transport of gases and metabolites, immunologic protection, and the production of steroid and protein hormones. As the interface between the mother and her fetus, the placenta plays a key role in ensuring a successful pregnancy. In this chapter, we review the structure of the human placenta and relate this to the contrasting functional demands placed on the organ at different stages of gestation. Because many of the morphologic features are best understood through an understanding of the organ's development, and because many complications of pregnancy arise through aberrations in this process, we approach the subject from this perspective. First, however, for the purposes of orientation and to introduce some basic terminology we provide a brief description of the macroscopic appearance of the delivered organ, with which readers are most likely to be familiar.

OVERVIEW OF THE DELIVERED PLACENTA

At term, the human placenta is usually a discoid organ, 15 to 20 cm in diameter, approximately 3 cm thick at the center, and weighing on average 500 g. These data show considerable individual variation and are also influenced strongly by the mode of delivery.[1] Macroscopically, the organ consists of two surfaces or plates: the chorionic plate to which the umbilical cord is attached, and the basal plate that abuts the maternal endometrium. Between the two plates is a cavity that is filled with maternal blood, delivered from the endometrial spiral arteries through openings

in the basal plate. This cavity is bounded at the margins of the disk by the fusion of the chorionic and basal plates, and the smooth chorion, or chorion laeve, extends from the rim to complete the chorionic sac. The placenta is incompletely divided into between 10 and 40 lobes by the presence of septae created by invaginations of the basal plate. The septae are thought to arise from differential resistance of the maternal tissues to trophoblast invasion, and may help to compartmentalize maternal blood flow through the organ. The fetal component of the placenta comprises a series of elaborately branched villous trees that arise from the inner surface of the chorionic plate and project into the cavity of the placenta. This arrangement is somewhat reminiscent of the fronds of a sea anemone wafting in the seawater of a rock pool. Most commonly, each villous tree originates from a single-stem villus that undergoes several generations of branching until the functional units of the placenta, the terminal villi, are created. These consist of an epithelial covering of trophoblast, and a mesodermal core containing branches of the umbilical arteries and tributaries of the umbilical vein. Because of this repeated branching the tree takes on the topology of an inverted wine glass, often referred to as a lobule, and there may be two to three within a single placental lobe (Figure 1-1). As will be seen later, each lobule represents an individual maternal-fetal exchange unit. Toward term the continual elaboration of the villous trees almost fills the cavity of the placenta, which is reduced to a network of narrow spaces collectively referred to as the intervillous space (IVS). The maternal blood percolates through this network of channels, exchanging gases and nutrients with the fetal blood circulating within the villi, before draining through the basal plate into openings of the uterine veins. **The human placenta is therefore classified in comparative mammalian terms as being of the villous hemochorial type,** although as we shall see this arrangement really only pertains to the second and third trimesters of pregnancy.[2] Before that the maternal-fetal relationship is best described as deciduo-chorial.

PLACENTAL DEVELOPMENT

Development of the placenta is initiated morphologically at the time of implantation, when the embryonic pole of the blastocyst establishes contact with the uterine epithelium. At this stage the wall of the blastocyst comprises an outer layer of unicellular epithelial cells, the trophoblast, and an inner layer of extraembryonic mesodermal cells

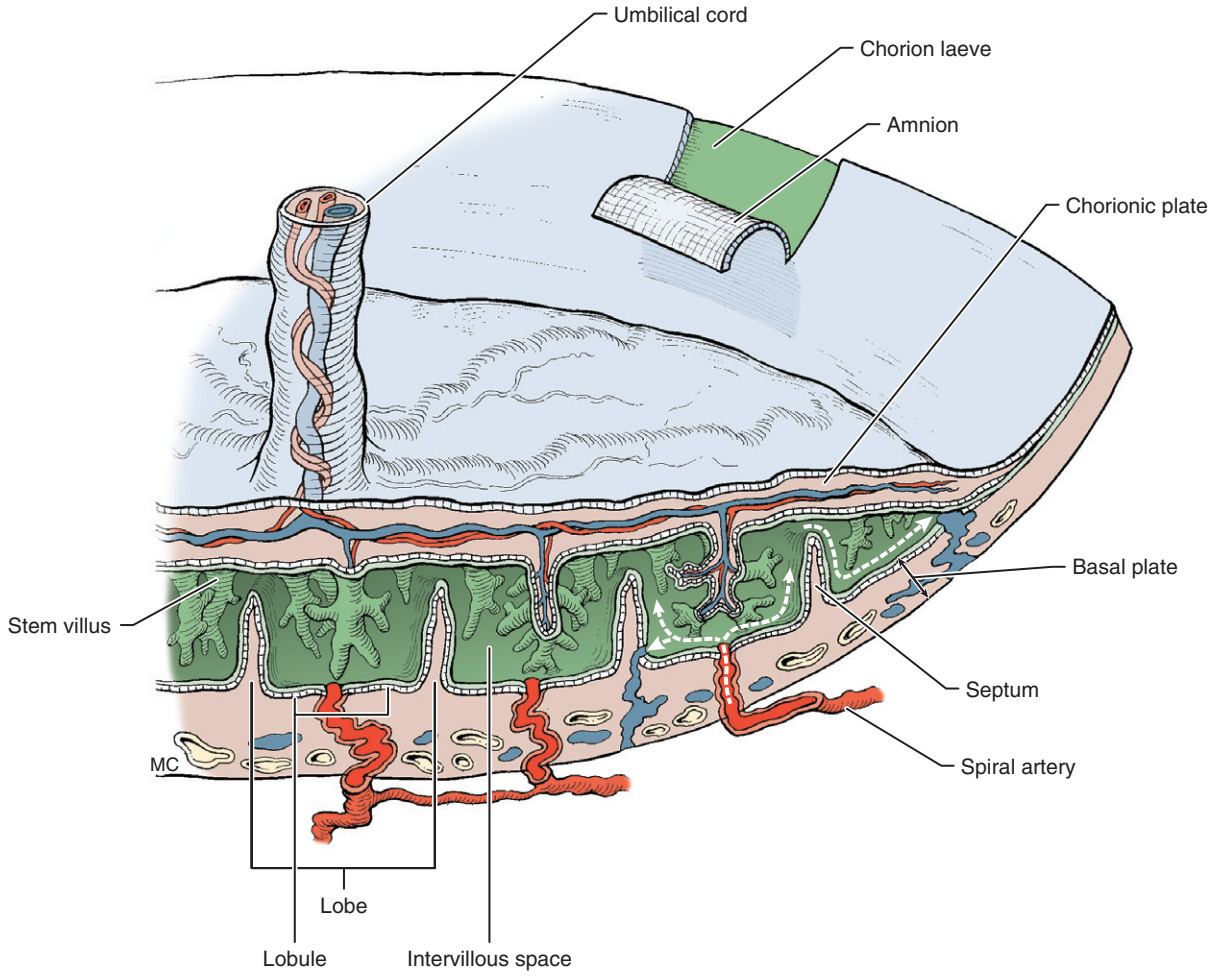

FIGURE 1-1. Diagrammatic cross section through a mature placenta showing the chorionic and basal plates bounding the intervillous space. The villous trees arise from stem villi attached to the chorionic plate, and are arranged as lobules centered over the openings of the maternal spiral arteries.

derived from the inner cell mass.[3] Together, these layers constitute the chorion. The earliest events have never been observed in vivo for obvious ethical reasons, but are thought to be equivalent to those that take place in the rhesus monkey. Attempts have also been made to replicate the situation in vitro by culturing in vitro fertilized human blastocysts on monolayers of endometrial cells. Although such reductionist systems cannot take into account the possibility of paracrine signals emanating from the underlying endometrial stroma, the profound differences in trophoblast invasiveness displayed by various species are maintained. In the case of the human, the trophoblast in contact with the endometrium undergoes a syncytial transformation, and tongues of syncytiotrophoblast begin to penetrate between the endometrial cells. There is no evidence of cell death being induced as part of this process, but gradually the conceptus embeds into the stratum compactum of the endometrium. The earliest ex vivo specimens available for study are estimated to be around 7 days after conception, and in these the conceptus is almost entirely embedded. A plug of fibrin initially seals the defect in the uterine surface, but by days10 to 12 the epithelium is restored.

By the time implantation is complete the conceptus is surrounded entirely by a mantle of syncytiotrophoblast (Figure 1-2). This multinucleated mantle tends to be thicker beneath the conceptus, in association with the embryonic pole, and rests on a layer of uninucleate cytotrophoblast cells derived from the original wall of the blastocyst. Vacuolar spaces begin to appear within the mantle and gradually coalesce to form larger lacunae, the forerunners of the intervillous space. As the lacunae enlarge the intervening syncytiotrophoblast is reduced in thickness, and forms a complex lattice of trabeculae (see Figure 1-2). Soon after, starting around day 12 after fertilization, the cytotrophoblast cells proliferate and penetrate into the

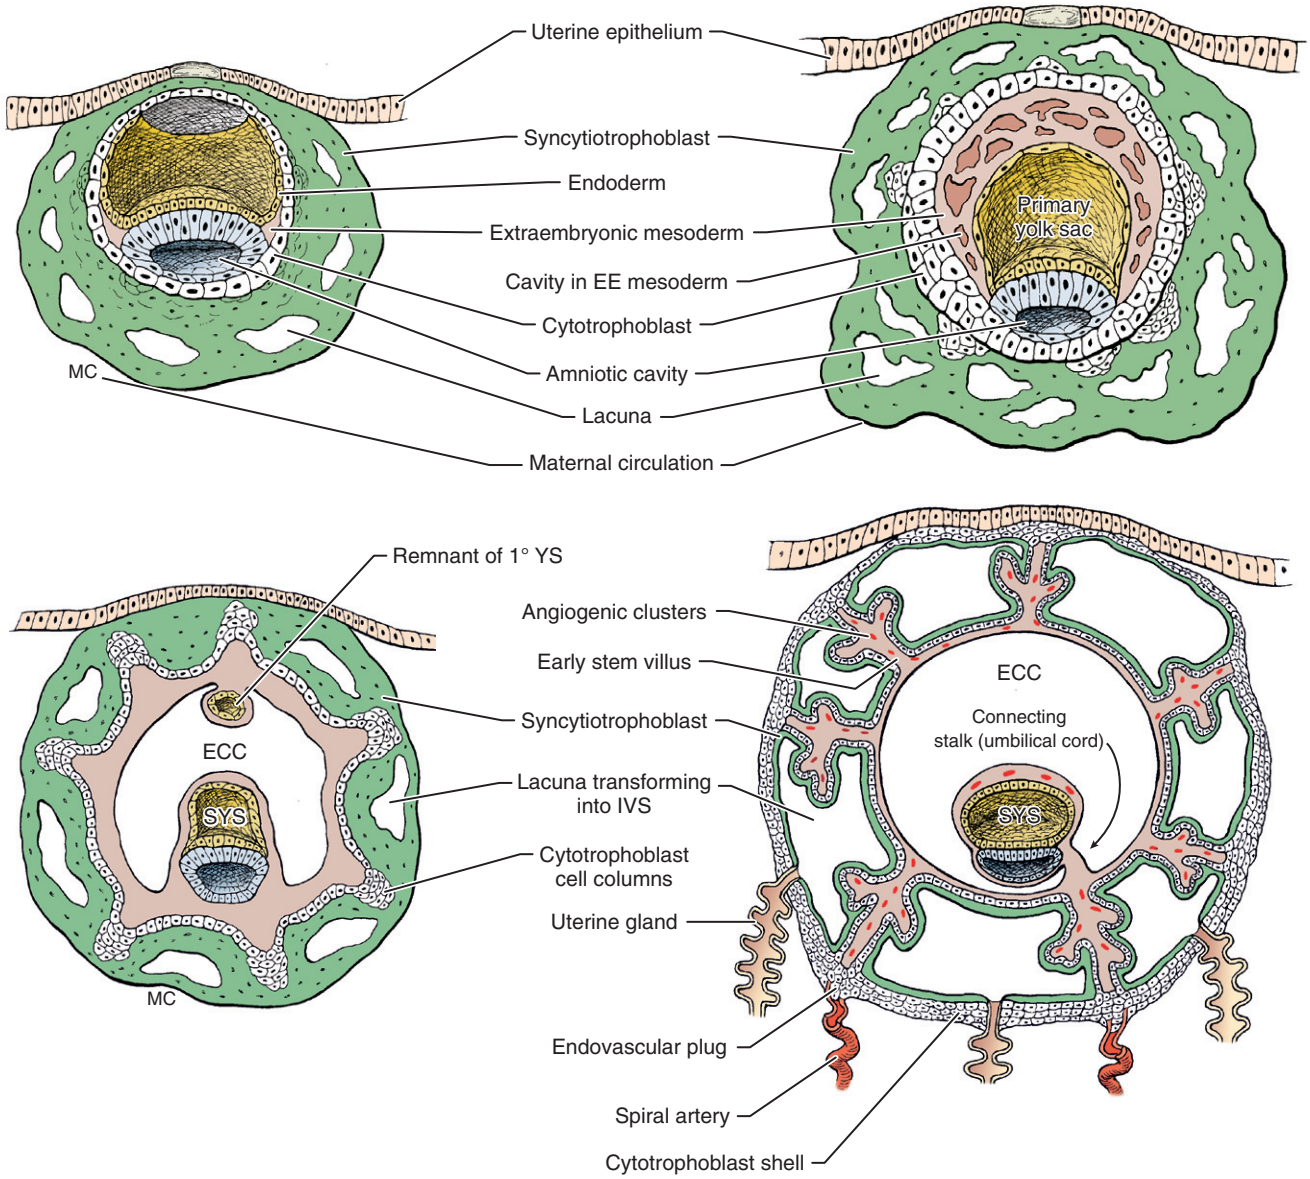

FIGURE 1-2. Schematic representation of early placental development between days 9 and 16.

trabeculae. On reaching their tips, approximately 2 days later, the cells spread laterally, establishing contact with those from other trabeculae to form a new layer interposed between the mantle and the endometrium, the cytotrophoblastic shell (see Figure 1-2). Finally, at the start of the third week of development mesodermal cells derived from the extraembryonic mesoderm invade the trabeculae, bringing with them the hemangioblasts from which the fetal vasculature differentiates. The mesoderm cells do not penetrate right to the tips of the trabeculae, and these remain as an aggregation of cytotrophoblast cells, the cytotrophoblast cell columns, which may or may not have a covering of syncytiotrophoblast (see Figure 1-2). Proliferation of the cells at the proximal ends of the columns, and their subsequent differentiation, contributes to expansion of the cytotrophoblastic shell. Toward the end of the third week the rudiments of the placenta are therefore in place. **The original wall of the blastocyst becomes the chorionic plate, the cytotrophoblastic shell is the precursor of the basal plate, and the lacunae form the intervillous space.** The trabeculae are the forerunners of the villous trees, and repeated lateral branching gradually increases their complexity.

Initially, villi form over the entire chorionic sac, but toward the end of the first trimester they regress from all except the deep pole, where they remain as the definitive discoid placenta. Abnormalities in this process may account for the persistence of villi at abnormal sites on the chorionic sac, and hence the presence of accessory or succenturiate lobes.

THE AMNION AND YOLK SAC

While these early stages of placental development are taking place the inner cell mass also differentiates, giving rise to the amnion, the yolk sac, and the germ disk. The amnion and yolk sac, and the fluid compartment in which they lie, play an important role in the physiology of early pregnancy and so their development will be described at this point. The initial formation of these sacs has been controversial over the years, due mainly to the small number of specimens available for study. However, there now appears to be consensus that at the time of implantation, the amnion extends from the margins of the epiblast layer over the future dorsal surface of the germ disk, whereas the primary yolk sac extends from the hypoblast layer around the inner surface of the trophoblast, separated from it by a loose reticulum thought to be derived from the endoderm.[3] Over the next few days considerable remodeling of the yolk sac occurs, which involves three closely interrelated processes. First, formation of the primitive streak, and the subsequent differentiation of definitive endoderm, lead to displacement of the original hypoblast cells into the more peripheral regions of the primary yolk sac. Second, the sac greatly reduces in size, either because the more peripheral portion is nipped off[3] or because it breaks up into a number of vesicles. Third, the reticulum splits into two layers of mesoderm, except at the future caudal end of the germ disk where it persists as a mass, the connecting stalk, linking the disk to the trophoblast. One layer lines the inner surface of the trophoblast, so contributing to formation of the chorion, and the other covers the outer surfaces of the amnion and yolk sac. In between these layers is a large fluid-filled space, the exocoelomic cavity (ECC). The net result of this remodeling is the formation of a smaller secondary yolk sac (SYS), which is connected to the embryo by the vitelline duct and floats within the exocoelomic cavity (see Figure 1-2).

The exocoelomic cavity is a conspicuous feature ultrasonographically and can be clearly visualized using a transvaginal probe toward the end of the third week after fertilization (fifth week of menstrual age). Between 5 and 9 weeks of pregnancy it represents the largest anatomic space within the chorionic sac. The SYS is the first structure that can be detected ultrasonographically within that space, and its diameter increases slightly between 6 and 10 weeks of gestation, reaching a maximum of 6 to 7 mm, and then decreases slightly. Histologically, the SYS consists of an inner layer of endodermal cells linked by tight junctions at their apical surface and bearing a few short microvilli.[4] Their cytoplasm contains numerous mitochondria, whorls of rough endoplasmic reticulum, Golgi bodies, and secretory droplets, giving them the appearance of being highly active synthetic cells. With further development the epithelium becomes folded to form a series of cystlike structures or tubules, only some of which communicate with the central cavity. The function of these spaces is not known, although it has been proposed that they serve as a primitive circulatory network in the earliest stages of development as they may contain non-nucleated erythrocytes.[5] On its outer surface the yolk sac is lined by a layer of mesothelium derived from the extraembryonic mesoderm. This epithelium bears a dense covering of microvilli, and the presence of numerous coated pits and pinocytotic vesicles gives it the appearance of an absorptive epithelium. Although there is no direct evidence of this function in the human as yet, experiments in the rhesus monkey have revealed that the mesothelial layer readily engulfs horseradish peroxidase. Immediately beneath this epithelium lies a well-developed capillary plexus that drains through the vitelline veins to the developing liver.

By week 9 of pregnancy, however, the SYS begins to exhibit morphologic evidence of a decline in function. This appears to be independent of the expansion of the amnion, which is gradually drawn around the ventral surface of the developing embryo. As it does so it presses the yolk sac remnant against the connecting stalk, forming the umbilical cord. **By the end of the third month the amnion abuts the inner surface of the chorion, and the ECC is obliterated.**

THE MATERNAL-FETAL RELATIONSHIP DURING THE FIRST TRIMESTER

For the placenta to function efficiently as an organ of exchange it requires adequate and dependable access to the maternal circulation. Establishing that access is arguably one of the most critical aspects of placental development, and over recent years has been one of the most controversial. As the syncytiotrophoblastic mantle enlarges it soon comes into close proximity with superficial veins within the endometrium. These undergo dilation, forming sinusoids, which are subsequently tapped into by the

syncytium.[6] As a result, maternal erythrocytes come to lie within the lacunae. Although Hertig and colleagues[6] commented that surprisingly few erythrocytes were visible within the lacunae, their presence has been taken by modern embryologists as indicating the onset of the maternal circulation to the placenta. If this is a circulation, however, it is entirely one of venous ebb and flow, possibly influenced by uterine contractions and other forces. Numerous traditional histologic studies have demonstrated that arterial connections are not established with the lacunae until much later in pregnancy,[7,8] although the exact timing was not known for many years. The advent of high-resolution ultrasound and Doppler imaging appeared to answer this question, for most observers agree that moving echoes indicative of significant fluid flow cannot be detected within the IVS until 10 to 12 weeks in normal pregnancies.

It is now well accepted on the basis of evidence from a variety of techniques that a major change in the maternal circulation to the placenta takes place at the end of the first trimester. First, direct vision into the IVS during the first trimester with a hysteroscope reveals the cavity to be filled with a clear fluid rather than maternal blood.[9] Second, perfusion of pregnant hysterectomy specimens with radiopaque and other media demonstrates that there is little flow into the IVS during the first trimester, except perhaps at the margins of the placental disk.[1,7] Third, the oxygen concentration within the IVS is low (<20 mm Hg) before 10 weeks of pregnancy, and rises threefold between weeks 10 and 12.[10] This rise is matched by increases in the activities of, and concentrations of mRNA encoding, the principal antioxidant enzymes in the placental tissues, confirming a change in oxygenation at the cellular level.[10]

The mechanism underlying this change in placental perfusion relates to the phenomenon of extravillous trophoblast invasion.

EXTRAVILLOUS TROPHOBLAST INVASION AND PHYSIOLOGIC CONVERSION OF THE SPIRAL ARTERIES

During the early weeks of pregnancy, a subpopulation of trophoblast cells migrate from the deep surface of the cytotrophoblastic shell into the endometrium. Because these cells do not take part in the development of the definitive placenta, they are referred to as extravillous trophoblast. **Their activities are, however, fundamental to the successful functioning of the placenta, for their presence in the endometrium is associated with the physiologic conversion of the maternal spiral arteries.** The cell biologic basis of this phenomenon is still not understood, but the net effect is the loss of the smooth muscle cells and elastic fibers from the media of the endometrial segments of the arteries and their replacement by fibrinoid.[11-13] There is some evidence to suggest that this is a two-stage process. Very early in pregnancy the arteries display endothelial basophilia and vacuolation, disorganization of the smooth muscle cells, and dilation. Because these changes are observed equally in both the decidua basalis and parietalis, and also within the uterus in cases of ectopic pregnancies, it seems to be independent of local trophoblast invasion. Instead, it has been proposed that it results from activation of decidual renin-angiotensin signaling. Slightly later, during the first few weeks of pregnancy, the invading extravillous trophoblasts become closely associated with the arteries, and infiltrate their walls. Further dilation ensues, and as a result the arteries are converted from small-caliber vasoreactive vessels into funnel-shaped flaccid conduits.

The extravillous trophoblast population can itself be separated into two subgroups: the endovascular trophoblast, which migrate in a retrograde fashion down the lumens of the spiral arteries replacing the endothelium, and the interstitial trophoblast, which migrate through the endometrial stroma. In early pregnancy, the volume of the migrating endovascular cells is sufficient to occlude, or plug, the terminal portions of the spiral arteries as they approach the basal plate[7,8] (Figure 1-3). **It is the dissipation of these plugs toward the end of the first trimester that establishes the maternal circulation to the placenta.** Trophoblast invasion is not equal across the implantation site, being greatest in the central region, where it has presumably been established the longest.[14] It is to be expected, therefore, that the plugging of the spiral arteries will be most extensive in this region, and this may account for the fact that maternal arterial blood flow is most often first detectable ultrasonographically in the peripheral regions of the placental disk.[15] Associated with this blood flow is a high local level of oxidative stress, which can be considered physiologic as it occurs in all normal pregnancies. It has recently been proposed that this stress induces regression of the villi over the superficial pole of the chorionic sac, so forming the chorion laeve (Figure 1-4).[15]

Under normal conditions, the interstitial trophoblast cells invade as far as the inner third of the myometrium, where they appear to fuse and form multinucleated giant cells.[1] It is essential that the process is correctly regulated, for excessive invasion can result in complete erosion of the endometrium and the condition of placenta accreta, which is associated with a high risk of postpartum hemorrhage. As they migrate, the trophoblast cells must interact with cells of the maternal immune system present within the decidua, in particular macrophages and uterine Natural Killer cells.[16] These interactions may play a physiologic role in regulating the depth of invasion, or in the conversion of the spiral arteries. Extravillous trophoblast cells express the polymorphic antigen HLA-C that binds to KIR on the Natural Killer cells. Recent evidence indicates that certain combinations of HLA-C antigen and receptor subtypes are associated with a high risk of pregnancy complications,[17] emphasizing the importance of immunologic interactions to reproductive success.

Physiologic conversion of the spiral arteries is often attributed with ensuring an adequate maternal blood flow to the placenta, but such comments generally oversimplify the phenomenon. By itself, the process cannot increase the volume of blood flow to the placenta as it only affects the most distal portion of the spiral arteries. **The most proximal part of the arteries, where they arise from the uterine arcuate arteries, always remains unconverted and so will act as the rate-limiting segment.** These segments gradually dilate in conjunction with the rest of the uterine vasculature during early pregnancy, most probably under the effects of estrogen and as a result the resistance of the uterine circulation

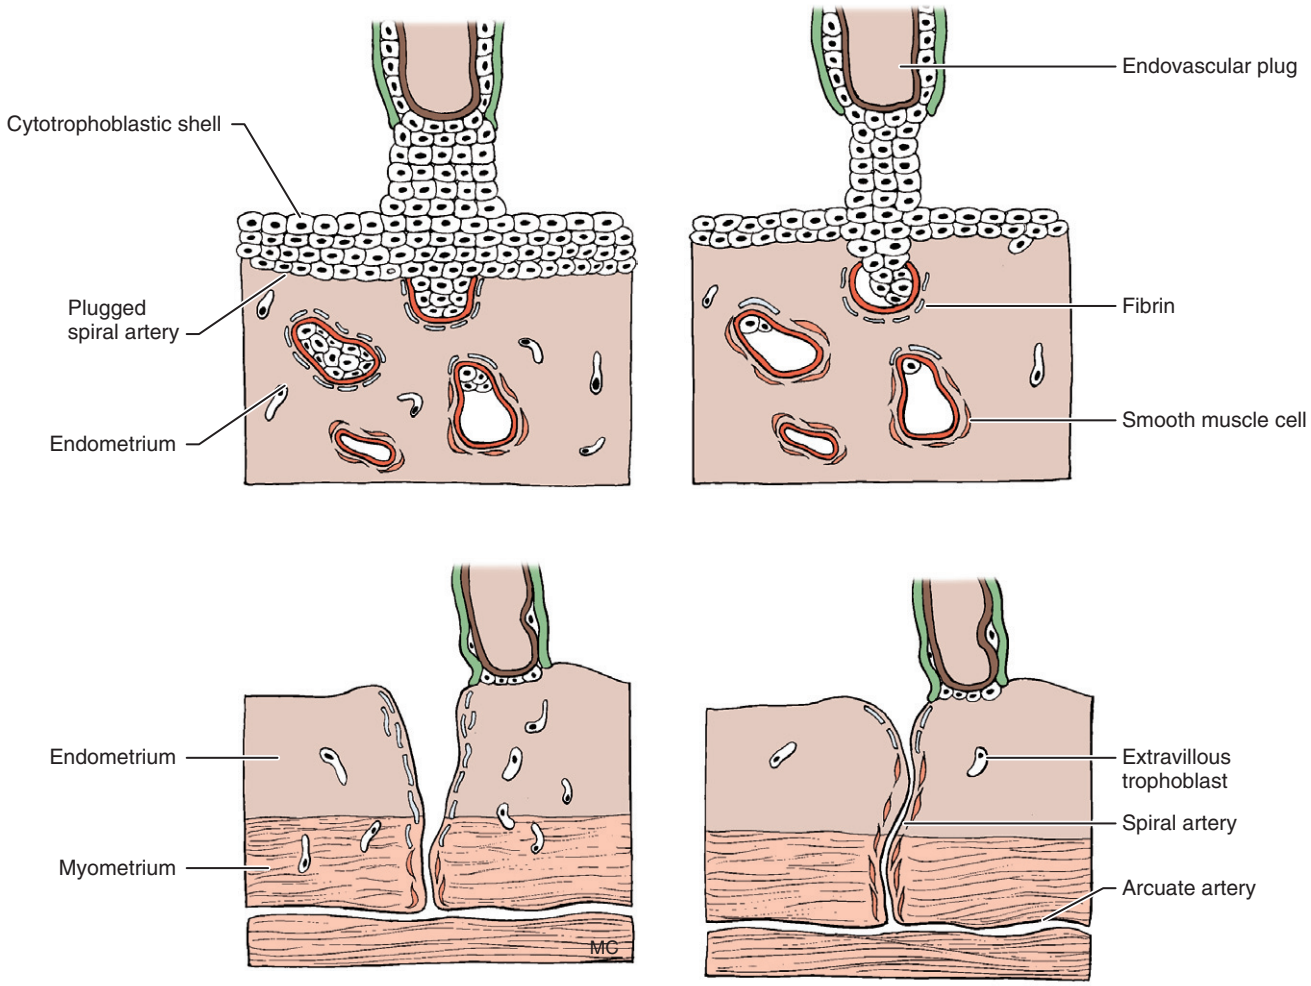

FIGURE 1-3. During early pregnancy the tips of the maternal spiral arteries are occluded by invading endovascular trophoblast cells, impeding flow into the IVS. The combination of endovascular and interstitial trophoblast invasion is associated with physiologic conversion of the spiral arteries. Both processes are deficient in preeclampsia, and the retention of vascular smooth muscle may increase the risk of spontaneous vasoconstriction, and hence an ischemia-reperfusion type injury to the placenta.

falls and uterine blood flow increases from approximately 45 mL/minute during the menstrual cycle to around 750 mL/minute at term. By contrast, the terminal dilation of the arteries will substantially reduce both the rate and pressure with which that maternal blood flows into the IVS.

Mathematic modeling has demonstrated that physiologic conversion is associated with a reduction in velocity from 2 to 3 m/s^{-1} in the nondilated section of a spiral artery to approximately 10 cm/s^{-1} at its mouth.[18] This reduction in the velocity will ensure that the delicate villous trees are not damaged by the momentum of the inflowing blood. Slowing the rate of maternal blood flow across the villous trees will also facilitate diffusional exchange, whereas lowering the pressure in the IVS is important to prevent collapse of the fetal capillary network within the villi.[19] Measurements taken in the rhesus indicate that the pressure at the mouth of a spiral artery is only 15 mm Hg, and within the IVS is on average 10 mm Hg.[20] The pressure within the fetal villous capillaries is estimated to be approximately 20 mm Hg, providing a pressure differential favoring their distention of 10 mm Hg.

Many complications of pregnancy are associated with defects in extravillous trophoblast invasion and failure to establish the maternal circulation correctly. In the most severe cases the cytotrophoblastic shell is thin and fragmented, and this situation is observed in approximately two thirds of spontaneous miscarriages.[21] Reduced invasion may reflect defects inherent in the conceptus, such as chromosomal aberrations, or thrombophilia, endometrial dysfunction, or other problems in the mother. The net result is that onset of the maternal circulation is both precocious and widespread throughout the developing placenta, consequent on absent or incomplete plugging of the maternal arteries.[15] Hemodynamic forces, coupled with excessive oxidative stress within the placental tissues,[22] are likely to be major factors contributing to loss of these pregnancies.

In milder cases the pregnancy may continue, but is complicated by preeclampsia, intrauterine growth restriction, or a combination of the two. The physiologic changes are either restricted in extent to only the superficial endometrial parts of the spiral arteries, or absent all together.[23] In

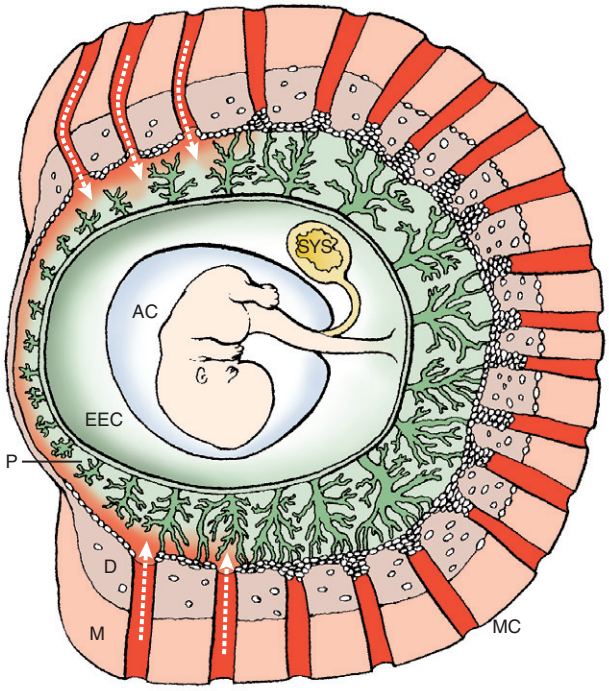

FIGURE 1-4. Onset of the maternal circulation starts in the periphery of the placenta *(arrows),* where trophoblast invasion, and hence plugging of the spiral arteries, is least developed. The high local levels of oxidative stress induced are thought to induce villous regression and formation of the chorion leave. (Redrawn from Jauniaux E, Cindrova-Davies T, Johns J, et al: Distribution and transfer pathways of antioxidant molecules inside the first trimester human gestational sac. J Clin Endocrinol Metab 89:1452, 2004.)

the most severe cases of preeclampsia associated with major fetal growth restriction only 10% of the arteries may be fully converted, compared to 96% in normal pregnancies.[14] There is still debate as to whether this is due to an inability of the interstitial trophoblast to invade the endometrium successfully, or whether having invaded sufficiently deeply the trophoblast cells fail to penetrate the walls of the arteries. These two possibilities are not mutually exclusive and may reflect different etiologies. Whatever the causation, there are several potential consequences to incomplete conversion of the arteries. First, due to absence of the distal dilation maternal blood will enter the IVS with greater velocity than normal, forming jetlike spurts that can be detected ultrasonographically. The villous trees are often disrupted opposite these spurts, leading to the formation of intervillous blood-lakes, and the altered hemodynamics within the IVS result in thrombosis and excessive fibrin deposition.[24] Second, incomplete conversion will allow the spiral arteries to maintain greater vasoreactivity than normal. There is evidence from the rhesus monkey and the human that spiral arteries are not continuously patent, but that they undergo periodic constriction independent of uterine contractions.[15,25] It has recently been proposed that exaggeration of this phenomenon due to the retention of smooth muscle in the arterial walls may lead to a hypoxia-reoxygenation type of injury in the placenta, culminating in the development of oxidative stress. Placental oxidative stress is a key factor in the pathogenesis of preeclampsia, and clinical evidence suggests that hypoxia-reoxygenation is a more physiologic stimulus for its generation than simply reduced uterine perfusion.[26] The third consequence of incomplete conversion is that the distal segments of the arteries are frequently the site of acute atherotic changes.[23] These are likely to be secondary changes, possibly induced by the involvement of these segments in the hypoxia-reoxygenation process, but if the lesions become occlusive they will further impair blood flow within the IVS, contributing to the growth restriction.

THE ROLE OF THE ENDOMETRIUM DURING THE FIRST TRIMESTER

Signals from the uterine epithelium and secretions from the endometrial glands play a major role in regulating receptivity at the time of implantation, but the potential contribution of the glands to fetal development once implantation is complete has largely been ignored. This has been due to the general assumption that once the conceptus is embedded within the uterine wall it no longer has access to the secretions in the uterine lumen. **However, a review of archival placenta-in-situ hysterectomy specimens has revealed that the glands discharge their secretions into the IVS through openings in the basal plate throughout the first trimester[27] (see Figure 1-2).** The secretions are a heterogenous mix of maternal proteins, carbohydrates (including glycogen), and lipid droplets, and are phagocytosed by the syncytiotrophoblast. Recently, it has been demonstrated that the pattern of sialylation of the secretions changes between the late secretory phase of the nonpregnant cycle and early pregnancy.[28] There is a loss of terminal sialylic acid caps, which will render the secretions more easily degradable by the trophoblast following their phagocytic uptake. The fact that glycodelin, formerly referred to as PP14 or α_2-PEG, is derived from the glands and yet accumulates within the amniotic fluid, with concentrations peaking at around 10 weeks, indicates that the placenta must be exposed to glandular secretions extensively throughout the first trimester.

Ultrasonographic measurements suggest that an endometrial thickness of 8 mm or more is necessary for successful implantation, although not all studies have found such an association.[29] Nonetheless these measurements are in line with observations based on placenta-in-situ specimens, in which an endometrial thickness of over 5 mm was reported beneath the conceptus at 6 weeks of pregnancy.[30] Gradually, over the remainder of the first trimester the endometrium regresses, so that by 14 weeks the thickness is reduced to 1 mm. Histologically, there is also a transformation in the glandular epithelial cells over this period. At 6 weeks they closely resemble those of the secretory phase of the menstrual cycle, being tall and columnar in shape, and their cytoplasm containing abundant organelles and large accumulations of glycogen.[27,30] By the end of the first trimester the cells are more cuboidal and secretory organelles are much less prominent, although the lumens of the glands are still filled with secretions.

The overall picture is that the glands are most prolific and active during the early weeks of pregnancy, with their contribution gradually waning during the first trimester.

This would be consistent with a progressive switch from histiotrophic to hemotrophic nutrition as the maternal arterial circulation to the placenta is established. The glands should not be considered solely as a source of nutrients, however, for their secretions are also rich in growth factors such as leukemia inhibitory factor, vascular endothelial growth factor, epidermal growth factor, and transforming growth factor beta.[30] Receptors for these factors are present on the villous tissues, and so the glands may play an important role in modulating placental proliferation and differentiation during early pregnancy, as in other species. The change in sialylation in early pregnancy will ensure that any of the secretions that gain access to the maternal circulation via the uterine veins will be rapidly cleared in her liver. Hence, a proliferative microenvironment can be created within the intervillous space of the early placenta without placing the mother's tissues at risk of excessive stimulation. Attempts to correlate the functional activity of the glands with pregnancy outcome have met with mixed success. Thus, reduced concentrations of mucin 1, glycodelin, and leukemia inhibitory factor have been reported in uterine flushings from women suffering repeated miscarriages.[31] However, one study has shown no significant association between the expression of these markers within the endometrium and outcome.[32] This difference may reflect impairment in the secretory rather than the synthetic machinery of the gland cells, although further work is required to confirm this point.

From the evidence available it would therefore appear that the functional importance of the endometrial glands to a successful pregnancy extends well beyond the time of implantation.

THE TOPOLOGY OF THE VILLOUS TREES

One of the principal functions of the placenta is diffusional exchange, and the physical requirements for this impose the greatest influence on the structure of the organ. The rate of diffusion of an inert molecule is governed by Fick's law, and so is proportional to the surface area for exchange divided by the thickness of the tissue barrier. **A large surface area will therefore facilitate exchange, and this is achieved by repeated branching of the villous trees.**

The villous trees arise from the trabeculae interposed between the lacunae (see Figure 1-2) through a gradual process of remodeling and lateral branching. Initially, the different branches have an almost uniform composition, and the villi can be separated only by their relative size and position in the hierarchic branching pattern. At this stage the mesodermal core is loosely packed, and at the proximal end of the trees it blends with the extraembryonic mesoderm lining the exocoelomic cavity. The stromal cells possess sail-like processes that often link together to form fluid-filled channels that are orientated parallel to the long axis of the villi. Macrophages are often seen within these channels, and so it is possible they function as a primitive circulatory system prior to vasculogenesis. In this way proteins derived from the uterine glands could freely diffuse into the coelomic fluid, and it is notable that the macrophages within the channels are strongly immunoreactive for maternal glycodelin.[27]

Toward the end of the first trimester the villi begin to differentiate into their principal types. The connections to the chorionic plate become remodeled to form stem villi, which represent the supporting framework of each villous tree.[1,33] These progressively develop a compact fibrous stroma and contain branches of the chorionic arteries and accompanying veins. The arteries are centrally located and are surrounded by a cuff of smooth muscle cells. **Although these have the appearance of resistance vessels, physiologic studies indicate that under normal conditions the fetal-placental circulation operates under conditions of full vasodilation.** Stem villi contain only a few small-caliber capillaries and so play little role in placental exchange.

After several generations of branching, stem villi give rise to intermediate villi. These are longer and more slender in form and can be of two types: immature and mature. The former are seen predominantly in early pregnancy, and represent a persistence of the nondifferentiated form, as indicated by the presence of fluid-filled stromal channels. Mature intermediate villi provide a distributing framework, and terminal villi arise at intervals from their surface. Within the core are arterioles and venules, but there is also a significant number of capillaries, suggesting a capacity for exchange.

The main functional units of the villous tree are, however, the terminal villi. There is no strict definition as to where a terminal villus starts, but they are most often short stubby branches, up to 100 μm in length and approximately 80 μm in diameter, arising from the intermediate villi.[33] They are highly vascularized, but by capillaries alone, and are highly adapted for diffusional exchange, as will be seen later.

This differentiation of the villi coincides temporally with the development of the lobular architecture, and the two processes are most likely interlinked. Lobules can be first identified during the early second trimester, following onset of the maternal circulation when it is thought that hemodynamic forces may shape the villous tree. There is convincing radiographic and morphologic evidence that maternal blood is delivered into the center of the lobule, and that it then disperses peripherally, as in the rhesus monkey placenta[34] (see Figure 1-1). Consequently, it is to be expected that an oxygen gradient will exist across the lobule, and differences in the activities and expression of antioxidant enzymes within the villous tissues suggest strongly that this is the case.[35] Other metabolic gradients, for example glucose concentration, may also exist, and together these may exert powerful influences on villous differentiation. Villi in the center of the lobule, where the oxygen concentration will be highest, display morphologic and enzymatic evidence of relative immaturity, and so this is considered to be the germinative zone. By contrast, villi in the periphery of the lobule are better adapted for diffusional exchange.

Elaboration of the villous tree is a progressive event that continues at a steady pace throughout pregnancy, and **by term the villi present a surface area of 10 to 14 m^2.** This may be significantly reduced in cases of intrauterine growth restriction, although this principally reflects an overall reduction in placental volume rather than maldevelopment of the villous tree.[36] In cases of preeclampsia alone the villous surface area is normal and is only compromised if there is associated growth restriction.[36] Attempts have

recently been made to monitor placental growth longitudinally during pregnancy using ultrasound.[37] Although the data show considerable individual variability, they indicate that in cases of growth restriction placental volume is significantly reduced at 12 to 14 weeks, and that thereafter placental development continues at a lower trajectory than normal. These findings suggest that the pathology restricting placental growth has its origins firmly in the first trimester.

PLACENTAL HISTOLOGY

The epithelial covering of the villous trees is formed by the syncytiotrophoblast. As its name indicates this is a true multinucleated syncytium that extends without lateral intercellular clefts over the entire villous surface. **In essence, therefore, the syncytiotrophoblast acts as the endothelium of the IVS, and everything passing across the placenta must pass through this layer, either actively or passively.** This tissue also performs all hormone synthesis in the placenta, and so a number of potentially conflicting demands are placed on it.

The syncytiotrophoblast is highly polarized, and one of its most conspicuous features is the presence of a dense covering of microvilli on the apical surface.[1] In the first trimester the microvilli are relatively long (approximately 0.75 to 1.25 μm in length and 0.12 to 0.17 μm in diameter), but as pregnancy advances they become shorter and more slender, being approximately 0.5 to 0.7 μm in length and 0.08 to 0.14 μm in diameter at term. The microvillous covering is even over the villous surface, and measurements of the amplification factor provided vary from 5.2 to 7.7. Many receptors and transport proteins have been localized to the microvillous surface by molecular biologic and immunohistochemical techniques as will be discussed later. The receptors are thought to reside in lipid rafts, and once bound to their ligand they migrate to the base of the microvilli where clathrin-coated pits are present.[38] Receptor-ligand complexes are concentrated in the pits, which are then internalized. Disassociation of ligands such as cholesterol may occur in the syncytioplasm, whereas other ligands, such as immunoglobulin G, are exocytosed at the basal surface.

Support for the microvillous architecture is provided by a substantial network of actin filaments and microtubules lying just beneath the apical surface. Also present within the syncytioplasm are numerous pinocytotic vesicles, phagosomes, lysosomes, mitochondria, secretory droplets, strands of endoplasmic reticulum, Golgi bodies, and lipid droplets.[38] The overall impression is of a highly active epithelium engaged in absorptive, secretory, and synthetic functions. It is not surprising therefore that the syncytiotrophoblast should have such a high rate of consumption of oxygen.[39,40]

The syncytiotrophoblast is a terminally differentiated tissue, and consequently mitotic figures are never observed within its nuclei. It has been suggested that this condition, which is frequently observed in the fetal cells at the maternal-fetal interface in other species, reduces the risk of malignant transformation in the trophoblast and so protects the mother. Whatever the reason, **the syncytiotrophoblast is generated by the recruitment of progenitor cytotrophoblast cells.** Cytotrophoblast cells are uninucleate, and lie on a well-developed basement membrane immediately beneath the syncytium. A proportion represents stem cells that undergo proliferation, with daughter cells undergoing progressive differentiation.[41] Consequently, a range of morphologic appearances are seen, from cuboidal resting cells with a general paucity of organelles to fully differentiated cells that closely resemble the overlying syncytium.[38,42] Ultimately, membrane fusion takes place between the two, and the nucleus and cytoplasm are incorporated into the syncytiotrophoblast. Early in pregnancy the cytotrophoblast cells form a complete layer beneath the syncytium, but as pregnancy advances the cells become separated and are seen less frequently in histologic sections. In the past this observation was interpreted as indicative of a reduction in the number of cytotrophoblast cells and so a reduction in the proliferative potential of the trophoblast layers. More recent stereologic estimates have revealed a different picture, however, for the total number of these cells increases until term.[43] The apparent decline results from the fact that villous surface area increases at a greater rate, and so cytotrophoblast cell profiles are seen less often in any individual histologic section.

The stimuli regulating cytotrophoblast cell proliferation are not fully understood. In early pregnancy (before 6 weeks) epidermal growth factor (EGF) may play an important role, for expression of both the factor and its receptor are localized principally to these cells. EGF is also strongly expressed in the epithelium of the uterine glands,[30] and in the horse a tight spatial and temporal correlation exists between glandular expression and proliferation in the overlying trophoblast. Later during the first trimester, insulin-like growth factor II can be immunolocalized to the cytotrophoblast cells, as can the receptor for hepatocyte growth factor. Hepatocyte growth factor is a powerful mitogen that is expressed by the mesenchymal cells, providing the possibility of paracrine control. Environmental stimuli may also be important, for hypoxia has long been known to stimulate cytotrophoblast proliferation in vitro. A greater number of cell profiles is also observed in placentas from high altitudes where they are exposed to hypobaric hypoxia and conditions associated with poor placental perfusion.[44] Whether this represents increased proliferation or decreased fusion with the syncytiotrophoblast is, however, uncertain.

The factors regulating and mediating fusion are equally uncertain. Growth factors such as EGF, granulocyte macrophage colony-stimulating factor, and vascular endothelial growth factor are able to stimulate fusion in vitro, as are the hormones estradiol and human chorionic gonadotropin (hCG). By contrast, transforming growth factor ß, leukemia inhibitory factor, and endothelin inhibit the process, suggesting that the outcome in vivo depends on a balance between these opposing influences. One of the actions of hCG at the molecular level is to promote the formation of gap junctions between cells, and there is strong experimental evidence that communication via gap junctions is an essential prerequisite in the fusion process.[45] Whether membrane fusion is initiated at the sites of gap junctions is not known at present, but there has been much interest recently in other potential mechanisms of fusion.

One such is the externalization of phosphatidylserine on the outer leaflet of the cell membrane, although whether this represents part of an apoptotic cascade that is only completed in the syncytiotrophoblast[46] or is inherent to cytotrophoblastic differentiation[47] remains controversial. Another is the expression of the human endogenous retroviral envelope protein HERV-W, commonly referred to as syncytin. Expression of syncytin appears to be necessary for syncytial transformation of trophoblast cells in vitro, and ectopic expression in other cell types renders them fusigenic.[48] Syncytin interacts with the amino acid transporter protein ASCT2, and the expression of both is influenced by hypoxia in trophoblast cell lines in vitro. This could provide an explanation for the increased number of cytotrophoblast cells observed in placentas from hypoxic pregnancies.

Although it is clear that the cascade of events controlling cytotrophoblastic proliferation and fusion has yet to be fully elucidated, it appears to be tightly regulated in vivo. Thus, the ratio of cytotrophoblastic to syncytial nuclei remains at approximately 1:9 throughout pregnancy,[43] although it may be perturbed in pathologic cases.

Early reports suggested that there is little or no transcription within the syncytiotrophoblast and that the tissue relies on the continual fusion of cytotrophoblast cells to bring in the required mRNAs. This has been linked to the hypothesis that the syncytial nuclei undergo a progression of apoptotic changes, culminating in their extrusion into the maternal circulation.[49] More recent evidence from immunohistochemistry and the incorporation of fluorouridine suggests that a proportion of the nuclei are transcriptionally active.[50] Furthermore, analysis of the pattern of chromatin condensation displayed by the nuclei does not support the concept of continual syncytial turnover.[51]

THE INTEGRITY OF THE VILLOUS MEMBRANE

One situation that may alter the balance of the two populations of nuclei is damage to the trophoblast layers and the requirement for repair. Isolated areas of syncytial damage, often referred to as sites of focal syncytial necrosis, are a feature of all placentas, although they are more common in those from pathologic pregnancies. Their origin remains obscure, but they could potentially arise from altered hemodynamics within the IVS or physical interactions between villi. One striking example of the latter is the rupture of syncytial bridges that form between adjacent villi, leading to circular defects on the surface 20 to 40 μm in diameter. Disruption of the microvillous surface leads to the activation of platelets and the deposition of a fibrin plaque on the trophoblastic basement membrane. Apoptosis of syncytial nuclei has been reported in the immediate vicinity of such plaques, but whether this reflects cause or effect has yet to be determined. With time, cytotrophoblast cells migrate over the plaque, differentiate, and fuse to form a new syncytiotrophoblastic layer. As a result, the plaque is internalized, and the integrity of the villous surface is restored. In the interim, however, these sites are nonselectively permeable to creatinine.[52]

More widespread apoptosis has been reported in the syncytiotrophoblast layer in pregnancies complicated by preeclampsia, where it may reflect increased turnover of the trophoblast.[53] Placental oxidative stress is considered a key factor in the pathogenesis of preeclampsia,[26] and hypoxia-reoxygenation is a powerful inducer of apoptosis in the syncytiotrophoblast in vitro. The deportation of apoptotic fragments arising from the villous surface has been put forward as one cause of the maternal endothelial activation that characterizes this syndrome.[54]

An even greater degree of trophoblast oxidative stress and damage is seen in cases of missed miscarriage, where complete degeneration and sloughing of the syncytiotrophoblast layer occurs.[15,22] Although there is increased apoptosis and necrosis among the cytotrophoblast cells, the remaining cells differentiate and fuse to form a new and functional syncytial layer. A similar effect is observed when villi from either first trimester or term placentas are maintained under ambient conditions in vitro.

Thus, it is likely that there is considerable turnover of the syncytiotrophoblast over the course of a pregnancy, although in the absence of longitudinal studies it is impossible to determine how extensive this process is. Nonetheless, it is clear that the villous membrane cannot be considered as an intact physical barrier, and that other elements of the villous trees may play an important role in regulating maternal-fetal transfer.

PLACENTAL VASCULATURE

The development of the fetal vasculature begins during the third week after conception (week 5 of pregnancy) with the de novo formation of capillaries within the villous stromal core. Hemangioblastic cell cords differentiate under the influence of growth factors such as basic fibroblast growth factor and vascular endothelial growth factor.[55,56] By the beginning of the fourth week the cords have developed lumens and the endothelial cells become flattened. Surrounding mesenchymal cells become closely apposed to the tubes and differentiate to form pericytes. During the next few days connections form between neighboring tubes to form a plexus, and this ultimately unites with the allantoic vessels developing in the connecting stalk to establish the fetal circulation to the placenta.

Exactly when an effective circulation is established through these vessels is difficult to determine, however. First, the connection between the corporeal and extracorporeal fetal circulations is particularly narrow, suggesting there can be little flow initially. Second, the narrow caliber of the villous capillaries, coupled with the fact that the fetal erythrocytes are nucleated during the first trimester and hence not readily deformable, will ensure that the circulation presents a high resistance to flow. This is reflected in the Doppler waveform obtained during the first trimester, and the resistance gradually falls as the vessels enlarge over the ensuing weeks.

Early in pregnancy the capillary network is labile and undergoes considerable remodeling. Angiogenesis continues until term and results in the formation of capillary sprouts and loops. Both of these processes contribute to the elaboration of terminal villi.[57,58] The caliber of the fetal capillaries is not constant within intermediate and terminal villi, and frequently on the apex of a tight bend the capillaries become greatly dilated, forming sinusoids. These

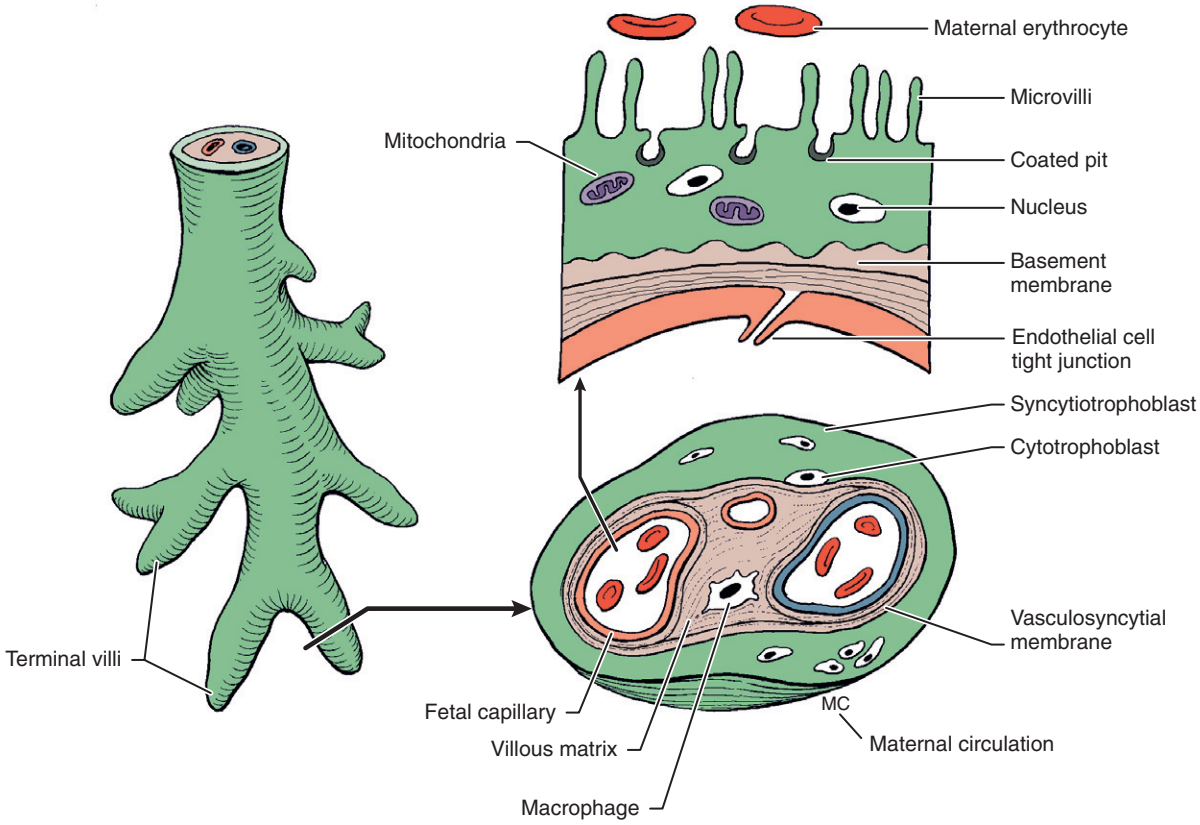

FIGURE 1-5. Diagrammatic representation of an intermediate villus with terminal villi arising from the lateral surface.

regions may help to reduce vascular resistance and so facilitate distribution of fetal blood flow through the villous trees.[57] Equally important is the fact that the dilations bring the outer wall of the capillaries into close juxtaposition with the overlying trophoblast. **The trophoblast is locally thinned, and as a result the diffusion distance between the maternal and fetal circulations is reduced to a minimum (Figure 1-5).** Because of their morphologic configuration these specializations are referred to as vasculosyncytial membranes, and are considered the principal sites of gaseous and other diffusional exchange. The arrangement can be considered analogous to that in the alveoli of the lung where the pulmonary capillaries indent into the alveolar epithelium in order to reduce the thickness of the air-blood diffusion barrier. Thinning of the syncytial layer will not only increase the rate of diffusion into the fetal capillaries, it will also reduce the amount of oxygen extracted by the trophoblast en route. The syncytiotrophoblast is highly active metabolically due to the high rates of protein synthesis and ionic pumping, but by having an uneven distribution of the tissue around the villous surface the oxygen demands of the fetus and the placenta can be separated to a large extent.

It is notable that development of vasculosyncytial membranes is seen to its greatest extent in the peripheral regions of a placental lobule where the oxygen concentration is lowest, and also in placentas from high altitude. In both instances it is associated with enlargement of the capillary sinusoids, and may be viewed as an adaptive response aimed at increasing the diffusing capacity of the placental tissues. Conversely, an increase in the thickness of the villous membrane is often seen in cases of intrauterine growth retardation, and in placentas from cigarette smokers. As mentioned earlier, the hydrostatic pressure differential across the villous membrane is an important determinant of the diameter of the capillary dilatations, and hence of the villous membrane thickness.[19] Raising the pressure in the IVS not only compresses the capillaries, but also increases the resistance within the umbilical circulation. Both effects will impair diffusional exchange, highlighting the importance of full conversion of the spiral arteries.

Vascular changes are observed in many complications of pregnancy,[59] where they may underpin changes in the topology of the villous tree. Thus, increased branching of the vascular network is observed in placentas from high altitude, causing the terminal villi to be shorter and more clustered than normal. At present there are no experimental data indicating that this has any impact on placental exchange, but in theory shortening the arteriovenous pathway may lead to increased efficiency.

PHYSIOLOGY OF THE SECONDARY YOLK SAC AND EXOCOELOMIC CAVITY

Now that development of the placenta and the extraembryonic membranes has been covered we turn to their physiologic roles during pregnancy. Phylogenetically, the oldest membrane is the yolk sac, and the SYS plays a major role in the embryonic development of all mammals. The

function of the yolk sac has been most extensively studied in laboratory rodents, and it has been demonstrated that the extraembryonic yolk sac is one of the initial sites of hematopoiesis.[60]

The endodermal layer of the human SYS is known to synthesize several serum proteins in common with the fetal liver, such as alpha-fetoprotein (AFP), alpha$_1$-antitrypsin, albumin, prealbumin, and transferrin. With rare exceptions, the secretion of most of these proteins is confined to the embryonic compartments, and the contribution of the SYS to the maternal protein pool is limited.[61] This can explain why their concentrations are always higher in the ECC than in maternal serum. AFP is also produced by the embryonic liver from 6 weeks until delivery, has a high molecular weight (±70 kDa), and, conversely to hCG, is found in similar amounts on both sides of the amniotic membrane. Analysis of concanavalin A affinity molecular variants of AFP have demonstrated that both coelomic and amniotic fluids AFP molecules are mainly of yolk sac origin, whereas maternal serum AFP molecules are mainly derived from the fetal liver.[62] These results suggest that the SYS also has an excretory function, and secretes AFP toward the embryonic and extraembryonic compartments. By contrast, AFP molecules of fetal liver origin are probably transferred from the fetal circulation to the maternal circulation, mainly across the placental villous membrane.

The potential absorptive role of the yolk sac membrane has been evaluated by examining the distribution of proteins and enzymes between the ECC and SYS fluids, and by comparing the synthesizing capacity of SYS, fetal liver, and placenta for hCG and AFP.[63] The distribution of the trophoblast-specific protein, hCG, in yolk sac and coelomic fluid, together with the absence of hCG mRNA expression in yolk sac tissues, provided the first biologic evidence of its absorptive function. Similarities in the composition of the SYS and coelomic fluids suggest that there is a free transfer for most molecules between the two corresponding compartments. Conversely, an important concentration gradient exists for most proteins between the ECC and amniotic cavity, indicating that transfer of molecules is limited at the level of the amniotic membrane that separates the corresponding fluids.

These findings suggest that the yolk sac membrane is an important zone of transfer between the extraembryonic and embryonic compartments, and that the main flux of molecules occurs from outside the yolk sac (i.e., from the ECC), in the direction to its lumen and subsequently to the embryonic gut and circulation. The identification of specific transfer proteins on the mesothelial covering[64] lends further support to this concept. When after 10 weeks of gestation the cellular components of the wall of the SYS start to degenerate, this route of transfer is no longer functional, and most exchanges between the ECC and the fetal circulation must then take place at the level of the chorionic plate.

The development and physiologic roles of the ECC are intimately linked with that of the SYS, for which it provides a stable environment. The higher concentrations of hCG, estriol, and progesterone in the coelomic fluid than in maternal serum[61] strongly suggest the presence of a direct pathway between the trophoblast and the ECC. Morphologically, this may be via the villous stromal channels and the loose mesenchymal tissue of the chorionic plate. Protein electrophoresis has also shown that the coelomic fluid results from an ultrafiltrate of maternal serum with the addition of specific placental and SYS bioproducts. For the duration of the first trimester, the coelomic fluid remains straw colored and more viscous than the amniotic fluid, which is always clear. This is mainly due to the higher protein concentration in the coelomic than in the amniotic cavity. The concentration of almost every protein is higher in coelomic than in amniotic fluid, ranging from 2 to 50 times depending on the corresponding molecular weight of the protein investigated.[61] The coelomic fluid has a very slow turnover, and so the ECC may act as a reservoir for nutrients needed by the developing embryo. **These findings suggest that the ECC is a physiologic liquid extension of the early placenta, and an important interface in fetal nutritional pathways.** Molecules such as vitamin B_{12}, prolactin, and glycodelin (placental protein 14, PP14) are known to be mainly produced by the uterine decidua.[61] They are often found in higher concentrations in coelomic fluid than in maternal serum, suggesting that preferential pathways exist between the decidual tissue and the embryonic fluid cavities via the villous trophoblast. This pathway may be pivotal in providing the developing embryo with sufficient nutrients before the intervillous circulation becomes established.[27]

Some analogies can be drawn between the ECC and the antrum within a developing Graafian follicle. It has been suggested that the evolution of the latter was necessary to overcome the problem of oxygen delivery to an increasing large mass of avascular cells. As the contained fluid has no oxygen consumption it will permit diffusion more freely than an equivalent thickness of cells. However, as neither follicular nor coelomic fluids contain an oxygen carrier, the total oxygen content must be low. An oxygen gradient will inevitably exist between the source and the target, whether it be an oocyte or an embryo. Measurements in human patients undergoing in vitro fertilization have demonstrated that the oxygen tension in follicular fluid falls as follicle diameter, assessed by ultrasound, increases. Thus, diffusion across the ECC may be an important route of oxygen supply to the embryo before the development of a functional placental circulation, but it will maintain the early fetus in a low-oxygen environment. This may serve to protect the fetal tissues from damage by O_2 free radicals and prevent disruption of signaling pathways during the crucial stages of embryogenesis and organogenesis. The presence in the ECC of molecules with a well-established antioxidant role as such as taurine, transferrin, vitamins A and E, and selenium supports this hypothesis.

PLACENTAL TRANSPORT

For the bulk of pregnancy, the chorioallantoic placenta is the major site of exchange of nutrients (including oxygen) and of waste products of fetal metabolism (including carbon dioxide) between mother and fetus. As described earlier, histiotrophic nutrition most likely occurs in early pregnancy and the yolk sac placenta probably contributes to this. However, once blood flow to the intervillous space begins at around 10 weeks' gestation, exchange across the

barrier between maternal and fetal circulations within the villi will be predominant, although there may be some limited transfer between maternal blood in the endometrium and the fluid of the amniotic sac. As discussed later in this chapter, many of the transport mechanisms required to effect exchange are present in the placenta by 10 weeks and these may be up- or down-regulated throughout the rest of pregnancy to meet the requirements of fetal growth and homeostasis.

For a molecule to reach the fetal plasma from the maternal plasma, and vice versa, it must cross the syncytiotrophoblast, the matrix of the villous core, and the endothelium of the fetal capillary. The syncytiotrophoblast is the transporting epithelium and is considered to be the major locus of exchange selectivity and regulation. However, both the matrix and endothelium will contribute to the properties of the placenta as an organ of exchange, both because they contribute to the thickness of the barrier and because they may act as a size filter: the finite width of the space between the endothelial cells is likely to restrict the diffusion of larger molecules.

The fact that the syncytiotrophoblast is a true syncytium, with no obvious intercellular or extracellular water-filled spaces, suggests that it forms a "tight" barrier. However, physiologic data, discussed later, suggest that this is not the case. Nevertheless, exchange most likely occurs predominantly across the two opposing plasma membranes, microvillous (maternal facing) and basal (fetal facing) (see Figure 1-5).

OVERVIEW OF THE EXCHANGE PHYSIOLOGY OF THE PLACENTA AND ITS DEVELOPMENT OVER GESTATION

Maternal-fetal exchange across the placenta may occur, broadly, by one of four mechanisms: bulk flow/solvent drag, diffusion, transporter-mediated mechanisms, and endocytosis/exocytosis.

Bulk Flow/Solvent Drag

Differences in hydrostatic and osmotic pressures between the maternal and fetal circulations within the exchange barrier will drive water transfer by bulk flow, dragging with it dissolved solutes. These dissolved solutes will be filtered as they move through the components of the barrier. Water movement may be via paracellular channels (see later discussion) or across the plasma membranes. The latter may be enhanced by the presence of aquaporins, integral membrane proteins forming water "pores" in the plasma membrane.

Hydrostatic pressure gradients will be created by differences in maternal and fetal blood pressure and vascular resistances on the maternal and fetal sides of the placenta. Although the actual pressures are impossible to measure in vivo at this time, evidence suggests that it is lower in the intervillous space than in the fetal capillaries.[19] As this would drive water from fetus to mother, incompatible with fetal growth, there is clearly a deficit here in our knowledge and understanding. The assumptions involved in assessing the hydrostatic pressures could be simply wrong. On the other hand, fetal-maternal water transfer driven by hydrostatic pressures may be opposed and exceeded by maternal-fetal water transfer driven by osmotic pressure gradients created by the active transport of solute to the fetus across the syncytiotrophoblast.[65] These forces may well be altered as gestation proceeds. Altogether, this is an important area in which further research is required.

Diffusion

Diffusion of any molecule occurs in both directions across any barrier. When there is a concentration gradient and/or, for charged species, an electrical gradient, one of these unidirectional fluxes (rates of transfer) is greater in one direction than it is in the other, so that there is a net flux in one direction. Net flux (Jnet) of solute across the placenta for an uncharged molecule may be described by an adaptation of Fick's Law of Diffusion[66]:

$$Jnet = (AD / l)(Cm\text{-}Cf)\ \text{moles/unit time}$$

where A is the surface area of the barrier available for exchange, D is the diffusion coefficient in water of the molecule (smaller molecules will have larger D), l is the thickness of the exchange barrier across which diffusion is occurring, Cm is the mean concentration of the molecule in maternal plasma, and Cf is the mean concentration of solute in the fetal circulation.

Small, relatively hydrophobic molecules such as O_2 and CO_2 will diffuse rapidly across the plasma membranes of the barrier, so that their flux is dependent much more on the concentration gradients than on A or l. As this concentration gradient is affected predominantly by the blood flows in both circulations, the diffusion of such molecules is said to be flow limited. This explains why reductions in uterine and or umbilical flow may result in fetal asphyxia and, consequently, growth restriction.

By contrast, hydrophilic molecules (glucose, amino acids) will not diffuse across plasma membranes easily; their concentration gradients are maintained and flux will be determined predominantly by barrier surface area and thickness. Flux of such membrane-limited molecules will not be affected by blood flow unless this is dramatically reduced but will be altered if abnormal placental development results in reduced A or increased l; there is evidence that this occurs in idiopathic IUGR.[36]

The term (AD/l) in Fick's Law is equivalent to what is described as the permeability of a molecule. Measurements of the passive permeability of the placenta have been made in vivo[67] and in vitro[68] utilizing hydrophilic molecules, which would be unlikely to be affected by blood flow and which are not substrates for transporter proteins. These measurements show that there is an indirect relationship between permeability and the molecular size of the hydrophilic tracer. Such a relationship is explained, most simply, by the presence of extracellular water-filled channels or pores across the exchange barrier through which the molecules can diffuse. The existence of this "paracellular permeability" pathway has been controversial because of the syncytiotrophoblast being syncytial with no obvious paracellular channels. However, there may be transtrophoblastic channels that are not normally visible by electron microscopy. Furthermore, the areas of syncytial denudation that occur in every placenta may themselves provide a route through which molecules may diffuse.[68]

Rates of transfer of hydrophobic molecules by flow-limited diffusion may change over gestation because, as described in previous sections, both uteroplacental and fetoplacental blood flow changes over gestation. Changes in concentration and, for charged molecules, electrical gradients between maternal and fetal plasma will also affect rates of transfer. Gestational changes do occur in the maternal and fetal plasma concentrations of solutes, affecting driving forces. For example, glucose and amino acid concentrations in maternal plasma increase over gestation, at least partly due to the effects of insulin resistance in pregnancy and of hormones such as human placental lactogen. A maternal-fetal electrical potential difference (PD), if expressed across the placental exchange barrier, will have an effect on the exchange of ions. In the human there is a small but significant PD between maternal and fetal circulations (PD_{mf}), being −2.7 ± 0.4 mV fetus negative in midgestation[69] and zero or close to it at term.[70] A PD between the mother and coelomic cavity was measured in first trimester pregnancies.[71] There was no apparent change in the value of this PD (8.7 ± 1 mV fetus negative) between 9 and 13 weeks of gestation, which was somewhat higher than the PD across the syncytiotrophoblast (3 mV) measured using microelectrodes in term placental villi in vitro. The in vitro PD across the microvillous membrane of human syncytiotrophoblast decreases between early (median −32 mV) and late first trimester (median −24 mV), with a small subsequent fall to term (−21 mV). This suggests that the driving force for cation flux into the syncytiotrophoblast decreases and for anions increases as pregnancy progresses.

Transporter-Protein Mediated Processes

Transporter proteins are integral membrane proteins that catalyze transfer of solutes across plasma membranes at faster rates than they would occur by diffusion. Transporter proteins are a large and diverse group of molecules but are generally characterized by showing substrate specificity (i.e., one transporter or class of transporter will predominantly transfer one substrate or class of substrate, e.g., amino acids), by having saturation kinetics (i.e., raising the concentration of a substrate solute will not infinitely increase the rate at which it is transferred on transporters), and by being competitively inhibitable (i.e., two structurally similar molecules will compete for transfer by a particular transporter protein). Transporter proteins are found most abundantly in the placenta in the microvillous and basal plasma membranes of the syncytiotrophoblast. A detailed description of all these is beyond the scope of this chapter but may be found in Atkinson and colleagues.[66] In overview, there are channel proteins that form pores in the plasma membrane allowing diffusion of ions such as K^+ and Ca^{2+}. There are transporters allowing facilitated diffusion down concentration gradients such as the GLUT1 glucose transporter. Exchange transporters, such as the Na^+/H^+ exchanger (involved in pH homeostasis of the syncytiotrophoblast and fetus), and co-transporters such as the system A amino acid transporter (which co-transports small hydrophilic amino acids including alanine, glycine, and serine with Na^+) require the maintenance of an ion gradient through secondary input of energy, often via the Na^+/K^+ATPase. Finally, there are active transporters that transfer against concentration gradients directly utilizing ATP; these include the Na^+/K^+ATPase and the Ca^{2+}ATPase, which pumps Ca^{2+} across the basal plasma membrane from syncytiotrophoblast cytosol toward the fetal circulation.

Gestational changes in the flux of solutes through transporter proteins could result from changes in the number of transporters in each plasma membrane, their turnover (i.e., rate of binding to and release from the transporter), or their affinity for solute, as well as from changes in the driving forces acting on them such as electrochemical gradients and ATP availability. There is a variety of evidence that such developmental changes do occur. Using the technique of isolating and purifying microvillous plasma membrane and radioisotopic tracers to measure transport rates in vesicles formed from these membranes, it has been shown that the V_{max} of the Na^+-dependent system A amino acid transporter increases by about fourfold, per milligram membrane protein, between first trimester and term. The activity of the system y^+ cationic amino acid (e.g., arginine, lysine) transporter increases over gestation, whereas the activity of the system y^+L transporter decreases.[72] This decrease in system y^+L activity is due to a decrease in the affinity of the transporter for substrate and is accompanied by an increased expression of 4F2hc monomer of the dimer protein.[72] The reason for this decline is not known but could well be associated with a specific fetal need. Glucose transporter, GLUT1, expression in microvillous membrane increases between first trimester and term.[73] Na^+/H^+ exchanger activity is lower in first trimester microvillous membrane vesicles as compared to term,[74] a result borne out by studies on the intrasyncytiotrophoblast pH of isolated placental villi from the two stages in gestation.[75] Interestingly, the expression of the NHE1 isoform of this exchanger in the microvillous membrane does not change across gestation, but the expression of both of its NHE2 and NHE3 isoforms increases between weeks 14 to 18 and term.[74] In contrast there is no difference in Cl^-/HCO_3^- exchanger activity or, by Western blotting, expression of its AE1 isoform, between first trimester and term. Understanding of how these gestational changes are regulated is currently sparse; studies in knockout mice suggest that hormones such as IGF-II from the fetus, signaling demand for the nutrients required for growth, are important,[76] but much further work is needed in this area.

Endocytosis/Exocytosis

Endocytosis is the process by which molecules become entrapped in invaginations of the microvillous plasma membrane of the syncytiotrophoblast, which eventually pinch off and form vesicles within the cytosol. Such vesicles may diffuse through the intracellular compartment and, if they avoid fusion with lysosomes, eventually fuse with the basal plasma membrane and undergo exocytosis, releasing their contents into the fetal milieu. **Evidence suggests that immunoglobulin G (IgG) and other large proteins may cross the placenta by this mechanism.**[66,77] Specificity and the ability to avoid lysosomal degradation during the endocytosis phase may be provided by the presence of receptors for IgG in the microvillous membrane invaginations and vesicles. However, this mechanism of transfer and its gestational regulation, if any, is still not well understood.

TABLE 1-1 CHANGES IN ACTIVITY OF TRANSPORTER PROTEINS IN THE MICROVILLOUS (MVM) AND BASAL (BM) PLASMA MEMBRANE OF PLACENTAS FROM IUGR PREGNANCIES AS COMPARED TO NORMAL PREGNANCIES

TRANSPORTER	MVM	BM	REFERENCE
System A	Decreased	No change	93
System L (leucine)	Decreased	Decreased	94
System y^+/y^+L (arginine/lysine)	No change	Decreased	72, 94
System β	Decreased	No change	95
Na^+-independent taurine	No change	Decreased	95, 96
GLUT1	No change	No change	73
Na^+/K^+ATPase	Decreased	No change	97
Ca^{2+}ATPase	Not present	Increased	98
Na^+/H^+ exchanger	Decreased	Activity not present	99
H^+/lactate	No change	Decreased	100

Placental Nutrient Supply and Intrauterine Growth Restriction

The term *placental insufficiency* as a cause of intrauterine growth restriction (IUGR) has been much quoted but little understood until recently. It is often taken as being synonymous with reduced uteroplacental and/or umbilical blood flow. Doppler measurements of such blood flows have been of assistance in diagnosing and assessing the severity of IUGR but are limited in value.[78] It is now clear that other variables determining the capacity of the placenta to supply nutrients may also contribute to IUGR. **For example, the surface area of the exchange barrier is decreased and its thickness increased in IUGR[36];** such changes are likely to markedly decrease the passive permeability of the placenta. Furthermore, there is now considerable evidence that the activity and expression of transporter proteins in the syncytiotrophoblast is altered in IUGR.[78] The reported data are summarized in Table 1-1. As can be seen activity of several transporters decrease, at least one increases, and others show no change at all. This variation in response could reflect whether a change in the placenta is causative in IUGR (e.g., the decrease in system A amino acid transporter activity), or is compensatory (e.g., the increase in Ca^{2+} ATPase activity) as well as differential regulation of the transporters. Understanding these placental phenotypes of IUGR may well give clues to novel means of diagnosing and even treating the condition.[78]

PLACENTAL ENDOCRINOLOGY

The human placenta is an important endocrine organ, signaling the presence of the conceptus to the mother in early pregnancy and optimizing the intrauterine environment and maternal physiology for the benefit of fetal growth. **Two major groups of hormones are produced: the steroid hormones, progesterone and the estrogens, and peptide hormones, such as hCG and human placental lactogen (hPL).** All are predominantly synthesized in the syncytiotrophoblast, and although the synthetic pathways have been generally elucidated, the factors regulating secretion are still largely unknown.

Progesterone

During the first few weeks of pregnancy progesterone is mainly derived from the corpus luteum, but gradually as the placental mass increases this organ's contribution becomes dominant, with the production of around 250 mg per day. The corpus luteum regresses at around 9 weeks, and at that stage it is no longer essential for the maintenance of a pregnancy.

Placental synthesis of progesterone begins with the conversion of cholesterol to pregnenolone, as in other steroid-secreting tissues. Placental tissues are poor at synthesizing cholesterol and so utilize maternal cholesterol derived from low-density lipoproteins taken up in coated pits on the surface of the syncytiotrophoblast. Conversion of the cholesterol to pregnenolone occurs on the inner aspect of the inner mitochondrial membrane, catalyzed by cytochrome P450scc (CYP11A1), and in other steroidogenic tissues the delivery of cholesterol to this site is the principal rate-limiting step in progesterone synthesis. There delivery is facilitated by the steroidogenic acute regulatory (StAR) protein, which binds and transports cholesterol, but this protein is not present in the human placenta.[79] Instead, a homologue, MLN64, may carry out a similar function, as freshly isolated cytotrophoblast cells appear to contain concentrations of cholesterol that are near-saturating for progesterone synthesis, indicating that supply of the precursor is not rate-limiting.[80] Side-chain cleavage requires molecular oxygen, but it is unclear whether the conditions that prevail during the first trimester are rate-limiting. The rate of production of pregnenolone from radiolabeled cholesterol by placental homogenates in vitro increases across the first trimester, and both the concentration and activity of P450scc increase in placental mitochondria from the first trimester to term. These changes, coupled with the expansion of the syncytiotrophoblast, most likely account for the increase in progesterone synthesis observed.

Side-chain cleavage also requires a supply of electrons, and this is provided by NADPH through a short electron transport chain in the mitochondrial matrix involving adrenodoxin reductase and its redox partner adrenodoxin. Preliminary studies in Tuckey's laboratory suggest that the transport of electrons to P450scc is rate-limiting for the enzyme's activity at mid pregnancy,[79] and so further research on the factors regulating expression and activity of adrenodoxin reductase during gestation is clearly needed.

The resultant pregnenolone is then converted to progesterone by the enzyme type 1 3β-hydroxysteroid dehydrogenase (3β-HSD), principally in the mitochondria. The activity of 3β-HSD in placental tissues is significantly higher than that of cytochrome P450scc, and so this step

is unlikely ever to be rate-limiting for the production of progesterone. Once secreted the principal actions of the hormone are to maintain quiescence of the myometrium, although it may have an immunomodulatory role as well. In addition, our new data on the importance of histiotrophic nutrition during the first few weeks of pregnancy suggest that progesterone may be essential to maintain the secretory activity of the endometrial glands.

Estrogens

The human placenta lacks the enzymes required to synthesize estrogens directly from acetate or cholesterol, and so uses the precursor dehydroepiandrosterone sulphate (DHAS) supplied by the maternal and fetal adrenal glands in approximately equal proportions near term. Following uptake by the syncytiotrophoblast DHAS is hydrolyzed by placental sulphatase to dehydroepiandrosterone (DHA), which is further converted to androstenedione by 3β-HSD. Final conversion to estradiol and estrone is achieved by the action of P450 cytochrome aromatase (P450arom) (CYP19), which has been immunolocalized to the endoplasmic reticulum. The syncytiotrophoblast can also utilize 16-OH DHAS produced by the fetal liver, converting this to 16α-OH androstenedione through the action of 3β-HSD, and then to estriol through the action of P450arom. Since approximately 90% of placental estriol production is reliant on fetal synthesis of the precursor 16-OH DHAS, maternal estriol concentrations have in the past been taken clinically as an index of fetal well-being.

Although the synthesis of estrogens can be detected in placental tissues during the early weeks of gestation, secretion significantly increases toward the end of the first trimester. By 7 weeks of gestation more than 50% of maternal circulating estrogens are of placental origin. Analysis of the transcriptional regulation of the P450arom gene has shown it to be oxygen responsive through a novel pathway involving the basic helix-loop-helix transcription factor Mash-2.[81] Production of Mash-2 is increased under physiologically low oxygen conditions, and leads to repression of P450arom gene expression. Hence the change in oxygenation that occurs at the end of the first trimester[10] may stimulate placental production of estrogens.

Human Chorionic Gonadotropin

hCG is secreted by the trophoblast at the blastocyst stage, and can be detected in the maternal blood and urine approximately 8 to 10 days after fertilization. Its principal function is to maintain the corpus luteum until the placenta is sufficiently developed to take over production of progesterone. It is a heterodimeric glycoprotein (approximately 38,000 Da) consisting of α and β subunits that is principally derived from the syncytiotrophoblast. **The α subunit is common to that of thyroid stimulating hormone, luteinizing hormone (LH) and follicle stimulating hormone, and is encoded by a single gene located at chromosome 6q12-21. It is the β subunit that determines the biologic specificity of hCG, and this evolved by a duplication event at the LHβ gene locus.**[82] Mapping has revealed that in the human there are six copies of the hCGβ gene located together with a single copy of the LHβ gene at chromosome 19p13.3. Polymerase chain reaction–based techniques have revealed that at least five, possibly all six, of the genes are transcribed in vivo during normal pregnancy. Most of the steady-state hCGβ mRNAs are transcribed from hCGβ genes 5, 3, and 8, however, with the levels of expression being β5 > β3 = β8 > β7, β1/2.[83] The β subunits of LH and hCG share 85% amino acid sequence homology, and are functionally interchangeable. One of the principal differences between the two is the presence of a 31-amino acid carboxyl-terminal extension in hCGβ compared to a shorter 7-amino acid stretch in LHβ. This extension is hydrophilic, contains four *O*-glycosylated serine residues, and is thought to act as a secretory routing signal targeting release of hCG from the apical membrane of the syncytiotrophoblast.

Assembly of hCG involves a complex process of folding in which a strand of 20 residues of the β subunit is wrapped around the α subunit, and the two are secured by a disulphide bond. Combination of the subunits occurs in the syncytiotrophoblast before the release of intact hCG, and as there is only limited storage in cytoplasmic granules secretion is largely thought to reflect de novo synthesis. Oxidizing conditions promote combination of the subunits in vitro most probably through their effects on the disulphide bond, and so the wave of physiologic oxidative stress observed in placental tissues at the transition from the first to second trimesters[10] may influence the pattern of secretion in vivo.

Concentrations of the hCG dimer in maternal blood rise rapidly during early pregnancy, peak at 9 to 10 weeks, and subsequently decline to a nadir at approximately 20 weeks. The physiologic role of the hCG peak is unknown, for the serum concentration far exceeds that required to stimulate LH receptors in the corpus luteum. In any case the corpus luteum is coming to the end of its extended life, and so the peak may therefore merely reflect other physiologic events. Production of the β subunit follows the same pattern, whereas the maternal serum concentration of the α subunit continues to rise during the first and second trimesters. Synthesis of the β subunit is therefore considered to be the rate-limiting step. Early experiments using primary placental cultures revealed that cyclic AMP plays a key role in the biosynthesis of both subunits, and subsequent work showed it to increase both the transcription and the stability of the α and β mRNAs. The kinetics were different for the two subunits, however, suggesting that the effect occurs through separate pathways or transcription factors. Possible regulatory elements within the α and β genes were extensively reviewed by Jameson and Hollenberg.[84]

Another theory that has been proposed is that intact hCG may modulate its own secretion in an autocrine/paracrine fashion through the LH/hCG receptor.[85] This G protein–coupled receptor has been identified on the syncytiotrophoblast of the mature placenta and contains a large extracellular domain that binds intact hCG with high affinity and specificity. However, during early pregnancy the receptors in the placenta are truncated and probably functionless until 9 weeks.[86] Hence, in the absence of self-regulation maternal serum concentrations of hCG may rise steeply, until the expression of functional LH/hCG receptors on the syncytiotrophoblast toward the end of the first trimester brings it under control. Reduced synthesis of the functional receptor may underlie the raised serum

concentrations of hCG that characterize cases of Down syndrome (trisomy 21).[87]

In addition to changes in the rate of secretion the hormone also exhibits molecular heterogeneity in both its protein and carbohydrate moieties, and the ratio of the different isoforms secreted changes with gestational age. For the first 5 to 6 weeks of gestation hyperglycosylated isoforms of the β subunit predominate, resembling the pattern seen in choriocarcinoma.[88] In normal pregnancies these isoforms then decline and are replaced by those that predominate for the remainder of pregnancy. The rate of decline is greater in pregnancies that go on to spontaneous miscarriage,[88] suggesting there may be some underlying defect in trophoblast differentiation in these cases.

Midtrimester maternal concentrations of hCG were also found to be raised in a retrospective study of early-onset preeclampsia,[89] and a link between the serum concentration and the severity of the maternal oxidative stress has been reported.[90] These data reinforce the putative link between secretion of hCG and the redox status of the trophoblast.

Placental Lactogen

hPL, also known as chorionic sommatotropin, is a single-chain glycoprotein (22,300 Da) that has a high degree of amino acid sequence homology with both human growth hormone (96%) and prolactin (67%). It has been suggested therefore that the genes encoding all three hormones arose from a common ancestral gene through repeated gene duplication. hPL thus has both growth promoting and lactogenic effects, although the former are of rather low activity. The hormone is synthesized exclusively in the syncytiotrophoblast, and is secreted predominantly into the maternal circulation, where it can be detected from the third week of gestation onward. Concentrations rise steadily until they plateau at around 36 weeks of gestation, at which time the daily production rate is approximately 1 g. The magnitude of this effort is reflected by the fact that at term production of hPL accounts for 5% to 10% of total protein synthesis by placental ribosomes, and the encoding mRNA represents 20% of the total placental mRNA.

Little is known regarding the control of hPL secretion in vivo, and maternal concentrations correlate most closely with placental mass. There is evidence that calcium influx into the syncytiotrophoblast or an increase in the external concentration in albumin can cause the release of hPL from placental explants in vitro, and this does not appear to be mediated by activation of the inositol phosphate, cAMP, or cGMP pathways.

The hormone has well-defined actions on maternal metabolism, promoting lipolysis and so increasing circulating free fatty acid levels, and acting as an insulin antagonist and so raising her blood glucose concentrations. It also promotes growth and differentiation of the mammary glandular tissue within the breasts in anticipation of lactation.

Placental Growth Hormone

Placental growth hormone (PGH) is expressed from the same gene cluster as hPL, and differs from pituitary growth hormone by only 13 amino acids.[91] It is secreted predominantly by the syncytiotrophoblast into the maternal circulation in a nonpulsatile manner and cannot be detected in the fetal circulation. Between 10 and 20 weeks of gestation it gradually replaces pituitary growth hormone, which then becomes undetectable until term.[92] In contrast to hPL, PGH has high growth-promoting but low-lactogenic activities.

Secretion on PGH is not modulated by growth-hormone releasing hormone, but appears to be rapidly suppressed by raised glucose concentrations both in vivo and in vitro.[91] Through its actions on maternal metabolism PGH increases nutrient availability for the fetal-placental unit, promoting lipolysis and also gluconeogenesis. It is also one of the key regulators of maternal insulin-like growth factor 1 (IGF1) concentrations, and circulating levels of PGH are reduced in cases of intrauterine growth restriction.[91]

KEY POINTS

- The mature human placenta is a discoid organ consisting of an elaborately branched fetal villous tree that is bathed directly by maternal blood, the villous hemochorial type.
- Continual development throughout pregnancy leads to progressive enlargement of the surface area for exchange (12 to 14 m^2 at term) and reduction in the mean diffusion distance between the maternal and fetal circulations (approximately 5 to 6 μm at term).
- The maternal circulation to the placenta is not fully established until the end of the first trimester; hence organogenesis takes place in a low-oxygen environment of approximately 20 mm Hg that may protect against free radical–mediated teratogenesis.
- During the first trimester the uterine glands discharge their secretions into the placental intervillous space and represent an important supply of nutrients, cytokines, and growth factors before onset of the maternal circulation.
- The exocoelomic cavity acts as an important reservoir of nutrients during early pregnancy, and the secondary yolk sac is important in the uptake of nutrients and their transfer to the fetus.
- Oxygen is a powerful mediator of trophoblast proliferation and invasion, villous remodeling, and placental angiogenesis.
- Ensuring an adequate maternal blood supply to the placenta during the second and third trimesters is an essential aspect of placentation and is dependent on physiologic conversion of the spiral arteries induced by invasion of the endometrium by extravillous trophoblast during early pregnancy. Many complications of pregnancy, such as preeclampsia, appear to be secondary to deficient invasion.
- All transport across the placenta must take place across the syncytial covering of the villous tree, the syncytiotrophoblast, the villous matrix, and the fetal endothelium, each of which may impose its own restriction and selectivity. Exchange will

occur via one of four basic processes: bulk flow/solvent drag, diffusion, transporter-mediated mechanisms, and endocytosis/exocytosis.

- The rate of transplacental exchange depends on many factors, such as the surface area available, the concentration gradient, the rates of maternal and fetal blood flows, and the density of transporter proteins. Changes in villous surface area, diffusion distance, and transporter expression have been linked with intrauterine growth restriction.
- The placenta is an important endocrine gland, producing both steroid and peptide hormones principally from the syncytiotrophoblast. Concentrations of some hormones are altered in pathologic conditions, for example, human chorionic gonadotropin in trisomy 21, but in general little is known regarding control of endocrine activity.

In obstetrical practice, recognition of normal fetal growth, development, and behavior often suggests a nonintervention management plan. However, abnormalities may require clinical strategies for fetal assessment and/or intervention. The basic concepts of placental and fetal physiology provide the building blocks necessary for understanding pathophysiology and thus mechanisms of disease. Throughout this chapter, we have reviewed the essential tenets of placental and fetal physiology, while relating this information to normal and abnormal clinical conditions.

Much of our knowledge of placental and fetal physiology derives from observations made in mammals other than humans. We have attempted to include only those observations reasonably applicable to the human placenta and fetus, and in most instances have not detailed the species from which the data were obtained. Should questions arise regarding the species studied, the reader is referred to the extensive bibliography.

PLACENTAL PHYSIOLOGY

The placenta provides the fetus with essential nutrients, water and oxygen, and a route for clearance of fetal excretory products, and produces a vast array of protein and steroid hormones and factors essential to the maintenance of pregnancy. As a result, it has become increasingly clear that the placenta, far from being a passive conduit, plays a key role in the control of fetal growth.

Placental Metabolism and Growth

Anatomic and histologic aspects of placental growth are detailed in Chapter 1. This section focuses on the physiology of placental metabolism and growth, and its influence on the fetus.

The critical function of the placenta is illustrated by its high metabolic demands. For example, placental oxygen consumption equals that of the fetus, and exceeds the fetal rate when expressed on a weight basis (10 mL/min/kg).[1] Between 22 and 36 weeks of gestation, the number of trophoblast nuclei increases fourfold to fivefold, placing increased metabolic demands on the placenta. Glucose is the principal substrate for oxidative metabolism by placental tissue. Of the total glucose leaving the maternal compartment to nourish the uterus and its contents, placental consumption may represent up to 70%.[2] In addition, a significant fraction of placental glucose uptake derives from the fetal circulation, and reflects placental oxidative metabolism. Although one third of placental glucose may be converted to the three-carbon sugar lactate, placental

metabolism is not anaerobic. Instead, placental lactate is thought to be a fetal energetic substrate. The factors regulating short-term changes in placental oxygen and glucose consumption are at present incompletely understood, although in pregnancies at high altitude, the placenta appears to spare oxygen for fetal use, at the cost of increased placental utilization of glucose.

The regulation of placental growth is incompletely understood, although dramatic advances have been made in the study of genes as they contribute to placental growth and differentiation. Normal term placental weight averages 450 g, representing approximately one seventh (one sixth with cord and membranes) of fetal weight. Large placentas, either ultrasonographically or at delivery, may prompt investigation into possible etiologies. Clinical observations suggest a link between decreased tissue oxygen content and increased placental growth. Thus, increased placental size is associated with maternal anemia, fetal anemia associated with erythrocyte isoimmunization, and hydrops fetalis secondary to fetal α-thalassemia with Bart's hemoglobin. The association of a large placenta with maternal diabetes also has been recognized, possibly a result of insulin-stimulated mitogenic activity or enhanced angiogenesis. Enlarged placentas are also found in cloned animals, presumably because of defects in the expression of specific imprinted genes, as well as in the placentas of animals in whom specific gene products have been deleted. In humans, increased ratio of placental size to fetal weight is associated with increased morbidity, both in the neonatal period and subsequently.[3]

An array of growth-promoting peptide hormones (factors) have been characterized in placental tissue at the protein and/or receptor levels. These include the insulin receptor, insulin-like growth factors I and II (IGF-I, IGF-II), epidermal growth factor (EGF), leptin, placental growth factor, placental growth hormone, placental lactogen, and a variety of cytokines and chemokines, each of which has been shown to play an important role in fetal/placental development. **IGF-I and IGF-II are polypeptides with a high degree of homology to human proinsulin. Both IGF-I and IGF-II circulate bound to carrier proteins, and are 50 times more potent than insulin in stimulating cell growth. Both are produced within the placenta, as well as in the fetus and mother.** EGF increases RNA and DNA synthesis and cell multiplication in a wide variety of cell types. The integrated physiological role of these and other potential placental growth factors in regulating placental growth remains to be fully defined; however, the development of null-mutation mouse models for IGF-1, IGF-II, IGF-1r, and IGF-IIr, as well as for the EGF receptor, have provided evidence in this regard.[4] Specifically, the EGF receptor appears important in placental development, as does IGF-II. Knockout of IGF-II results in diminished placental size, whereas deletion of the IGF-II receptor results in an increase in placental size. IGF-I does not appear to affect placental growth. Chronic exposure to exogenous corticosteroid may also result in diminished placental size.

Placental Transfer

General Considerations

In the hemochorial human placenta, maternal blood and solutes are separated from fetal blood by trophoblastic tissue and fetal endothelial cells. Thus, transit from the maternal intervillous space to the fetal capillary lumen takes place across a number of cellular structures (Figure 2-1). The first step is transport across the microvillus plasma membrane of the syncytiotrophoblast. Because there are no lateral intercellular spaces in the syncytiotrophoblast, all solutes first interact with the placenta at this plasma membrane. The basal (fetal) syncytiotrophoblast membrane represents an additional step in the transport process. The discontinuous nature of the cytotrophoblast cell layer in later gestation suggests that this layer should not limit maternal-to-fetal transfer. The fetal capillary endothelial cell imposes two additional plasma membrane surfaces.

A number of specific mechanisms allow transit of the placental membranes, including passive diffusion, facilitated diffusion, active transport, and endocytosis/exocytosis. Solutes lacking specialized transport mechanisms cross by extracellular or transcellular diffusional transport pathways with permeability determined by size,

lipid solubility, ionic charge, and maternal serum protein binding. **Lipid-insoluble (hydrophilic) substances, which cross the trophoblast via extracellular pores, are restricted by molecular size in relation to the extracellular pore size. Up to a molecular weight (MW) of at least 5000 daltons, placental permeability is proportional to the free diffusion of a molecule in water.**[5] For example, urea (MW = 60) is at least 1000 times more permeable than inulin (MW = 5000).[5] Thus, transfer of small solutes will be governed primarily by the maternal-fetal concentration gradient. Because transfer is relatively slow, and the extracellular pore surface area is limited, transfer of these molecules is referred to as *diffusion limited*. In animal models, food restriction enhances the barrier to diffusion, as does placental IGF-II deficiency.[6] **Conversely, highly lipid-soluble (lipophilic) substances diffuse readily through the trophoblastic membrane. Thus, molecular weight is relatively less important in restricting diffusion.** Ethanol, a molecule similar in size to urea, is 500 times more lipid soluble and 10 times more permeable. Because the entire trophoblast surface is available for diffusion and the permeability is high, transfer rates for lipophilic substances to the fetus are limited primarily by placental intervillous and umbilical blood flows (flow limited). **Both facilitated diffusion and active transport utilize carrier-mediated transport systems, with the latter requiring energy, either directly or indirectly linked with ionic pump mechanisms.** Carrier transport systems are specifically limited to unique classes of molecules (i.e., neutral amino acids). In addition, substances may traverse the placenta via endocytosis (invagination of the cell membrane to form an intracellular vesicle containing extracellular fluids) and exocytosis (release of the vesicle to the extracellular space).

Transfer of Individual Solutes

Respiratory Gases

The exchange or transfer of the primary respiratory gases, oxygen and carbon dioxide, is likely flow limited. Thus, the driving force for placental gas exchange is the partial pressure gradient between the maternal and fetal circulations. **Early in gestation, the human embryo develops in a low oxygen environment. Such an environment appears to be necessary, and is associated with the presence of oxygen sensitive regulatory genes and gene products.** After approximately gestation week 10, the placenta becomes important as a respiratory organ. Indeed, estimates of human placental diffusing capacities would predict that placental efficiency as an organ of respiratory gas exchange will allow equilibrium of oxygen and carbon dioxide tensions at the maternal intervillous space and fetal capillary. However, this prediction varies from the observed 10 mm Hg difference in oxygen tension between the umbilical and uterine veins and between the umbilical vein and intervillous space. In contrast, the P_{CO2} difference from umbilical to uterine vein is small (3 mm Hg). P_{O2} differences could be explained by areas of uneven distribution of maternal to fetal blood flows or shunting, limiting fetal and maternal blood exchange, a process that, as in other respiratory organs (i.e., lungs) may be an active one.[7] The most important contribution, however, is likely the high metabolic rate of the placental tissues themselves. Thus, trophoblast cell O_2 consumption and CO_2 production lower umbilical vein O_2 tension and increase uterine vein CO_2 tension to a greater degree than could be explained by an inert barrier for respiratory gas transfer.

The arteriovenous difference in the uterine circulation (and venoarterial difference in the umbilical circulation) widens during periods of lowered blood flow. **Proportionate O_2 uptake increases and O_2 consumption remains unchanged over a fairly wide range of blood flows. Thus, both uterine and umbilical blood flows can fall significantly without decreasing fetal O_2 consumption.**[8] Conversely, unilateral umbilical artery occlusion is associated with significant fetal effects.

Carbon dioxide is carried in the fetal blood both as dissolved CO_2 and as bicarbonate. Because of its charged nature, fetal to maternal bicarbonate transfer is limited. However, CO_2 likely diffuses from fetus to mother in its molecular form, and [HCO_3^-] does not contribute significantly to fetal CO_2 elimination.

Glucose

Placental permeability for D-glucose is at least 50 times the value predicted on the basis of size and lipid solubility.[9] **Thus, specialized transport mechanisms must be available on both the microvillous and basal membranes. Membrane proteins facilitating the translocation of molecules across cell membranes are termed *transporters*. The primary human placental glucose transporter is GLUT1,**[10] **a sodium-independent transporter, as compared to the sodium-dependent transporters found in adult kidney and intestine. This transporter, in contrast to that found in human adipocytes (GLUT4), is not insulin sensitive.** The placental D-glucose transporter is saturable at high substrate concentrations; 50% saturation is observed at glucose levels of approximately 5 mM (90 mg/dL). Thus, glucose transfer from mother to fetus is not linear, and transfer rates decrease as maternal glucose concentration increases. This effect is reflected in fetal blood glucose levels following maternal sugar loading. **Modification of transporter expression within the placenta also occurs in response to maternal diabetes.** In this setting, GLUT1 expression is thought to increase on the basolateral membrane, while holding constant on the maternal-facing microvillous membrane.[11] Alterations in transporter expression may also depend on gestational stage (e.g., early in pregnancy, GLUT4 may be present within the placenta), as well as maternal nutrition/placental blood flow. A second transporter, GLUT3, has also been noted in the fetal-facing placental endothelium. Its presence within the syncytiotrophoblast remains controversial.

Amino Acids

Amino acid concentrations are higher in fetal umbilical cord blood than in maternal blood.[12] Like monosaccharides, amino acids enter and exit the syncytiotrophoblast via specific membrane transport proteins. These proteins allow amino acids to be transported against a concentration gradient into the placenta, and subsequently, if not directly, into the fetal circulation.

Multiple transport proteins mediate neutral, anionic, and cationic amino acid transport into the syncytiotrophoblast. These include both sodium-dependent and sodium-independent transporters. Amino acid entry is, in many

cases, coupled to sodium in co-transport systems located at the microvillous membrane facing the maternal intervillous space. As long as an inwardly directed sodium gradient is maintained, trophoblast cell amino acid concentrations will exceed maternal blood levels. **The sodium gradient is maintained by Na^+-K^+ATPase located on the basal or fetal side of the syncytiotrophoblast. In addition, high trophoblast levels of amino acids transported by sodium-dependent transporters can "drive" uptake of other amino acids via transporters that function as "exchangers."** Examples of these include ASCT1 and y^+LAT/4F2HC. Still other transporters function in sodium-independent fashion. Individual amino acids may be transported by single or multiple transport proteins. Transport systems have been defined in human placenta (a general schema may be found in Figure 2-2).

SNAT 1 and 2, responsible for the transport of neutral amino acids with short polar or linear side chains, are sodium-dependent transporters with activity localized on both the microvillous and basolateral membranes of the human placenta. SNAT 4, with similar substrate specificity, is present early in gestation. Other sodium-dependent transport activities localized to the microvillous membrane include that for β-amino acids such as taurine (TauT), as well as perhaps glycine transport via System GLY. Sodium-independent transporters mediating neutral amino acid transfer on the microvillous membrane include System L (LAT-1, 2/4F2HC), which exhibits a high affinity for amino acids with bulky side chains such as leucine, and y^+LAT/4F2HC, capable of transporting both neutral and cationic amino acids such as lysine and arginine. The aforementioned transporters are heterodimeric, requiring the combination of two distinct proteins with the cell membrane for transport to occur. Cationic amino acids may also be transported by the sodium-independent transport protein CAT1, whereas anionic amino acids (glutamate, aspartate) are transported by the sodium-dependent transport proteins EAAT 1-4. Basolateral membrane transport activities are similar; however, a predominance of sodium-independent transport and exchange (e.g., ASCT1) allows flow of amino acids down their concentration gradients into the fetal endothelium/fetal blood space. Although less is known regarding transfer into and out of the fetal endothelium, which, for the most part, abuts the syncytiotrophoblast basolateral membrane, available studies have verified that these cells too have a complement of amino acid transport proteins. Recent reviews of placental nutrient transfer and its impact are available.[13,14]

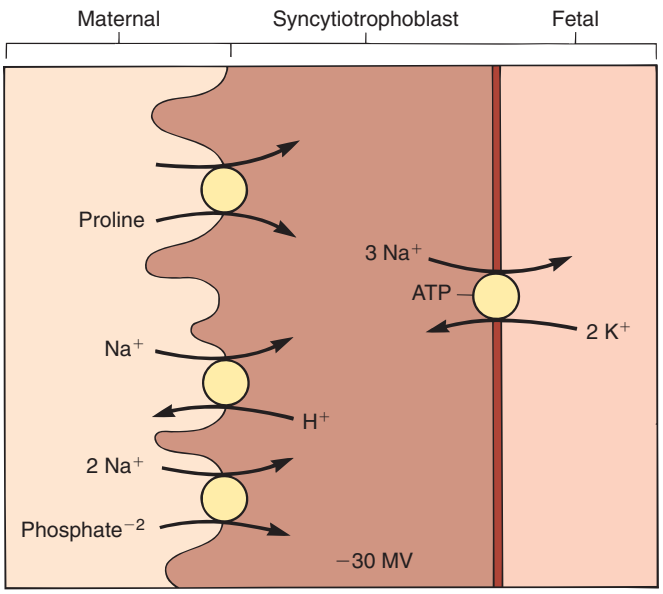

FIGURE 2-2. Pathways for sodium entry into syncytiotrophoblast and exit to the fetal circulation. (Data from online references: Boyd et al., 1981; Whitsett and Wallick, 1980; Lajeunesse and Brunette, 1988; Balkovets et al., 1986; and Bara et al., 1988.)

As implied earlier, more than one protein may mediate each transport activity within a single tissue. Examples include EAAT 1-5, associated with sodium-dependent anionic amino acid transfer; CAT 1, 2, 2a, associated with System y+ activity; and SNAT1, 2, and 4, associated with sodium-dependent transfer of small neutral amino acids. The reasons underlying this duplication within the placenta, more pronounced than in any other organ with the possible exception of the central nervous system, is unclear. Certainly, as is the case for the anionic amino acid transporters EAAT 1-5, differential distribution within different tissue elements plays a role. Differential regulation within single cell types is another likely reason. In isolated trophoblast cells, System A activity (sodium-dependent transfer of small neutral amino acids) is upregulated by the absence of amino acids partially due to an increase in carrier affinity. Conversely, increases in trophoblast amino acid concentrations may suppress uptake (transinhibition). These mechanisms serve to maintain trophoblast cell amino acid levels constant during fluctuations in maternal plasma concentrations. Insulin has also been shown to upregulate this transport activity as has insulin-like growth factor 1. **Placental System A activity is downregulated in intrauterine growth restriction, both in humans and in animal models. It is also downregulated in the placentas of obese mothers.[15] Conversely, System A activity is upregulated in the placentas of diabetic mothers, perhaps contributing to the accelerated growth noted in these fetuses. Mechanisms underlying these changes are as of yet unclear.**

The coordination between placental/fetal metabolism and amino acid transfer is illustrated by the anionic amino acids glutamate and aspartate, which are poorly transported from mother to fetus.[16] **Glutamate, however, is produced by the fetal liver from glutamine and then taken up across the basolateral membrane of the placenta. Within the placenta, the majority of glutamate is metabolized and utilized as an energy source.** As a result, sodium-dependent anionic amino acid transfer activity is of particular importance on the basolateral membrane, as is System ASC (ASCT1) activity, responsible for the uptake of serine, also produced by the fetal liver, into the placenta.

Lipids

Esterified fatty acids (triglycerides) are present in maternal serum as components of chylomicrons and very-low-density lipoproteins (VLDLs). Before transfer across the placenta, lipoprotein lipase interacts with these particles, releasing free fatty acids, which, due to their hydrophobic nature, are relatively insoluble in plasma and circulate

bound to albumin. As a result, fatty acid transfer involves dissociation from maternal protein, subsequent association with placental proteins, first at the plasma membrane (FABPpm), then after transfer into the cell (thought to be via FAT/CD36 and FATP) with intracytoplasmic binding proteins. Transfer out of the syncytiotrophoblast is less well worked out, but is thought to occur via interaction with FAT/CD36 and FATP, which are present at both the microvillous and basolateral placental membrane surfaces. Subsequently, interaction with fetal plasma proteins occurs. Placental fatty acid uptake is in part regulated by PPARγ and RXR. In turn, long-chain polyunsaturated fatty acids taken up by the placenta can be metabolized into PPAR ligands, thus affecting the expression of an array of placental genes, including those influencing fatty acid metabolism and transfer. **Fatty acids may also be oxidized within the placenta, as a source of energy.** Although precise interactions and mechanisms remain uncertain, it is clear that lipid uptake is of profound importance to fetal development. Targeted deletion of FATP4, found within the placenta, results in fetal lethality.[17]

Early studies documented that placental fatty acid transfer increases logarithmically with decreasing chain length (C16 to C8) and then declines somewhat for C6 and C4. More recent work, however, has clarified the fact that essential fatty acids are, in general, transferred more efficiently than are nonessential fatty acids.[18] Of these, docosahexananoic acid seems to be transferred more efficiently than arachidonic acid; oleic acid is transferred least efficiently. As in the case of amino acids discussed earlier, the fetus is significantly enriched in long chain polyunsaturated fatty acids as compared to the mother. Such selectivity may also relate to the composition of triglycerides in maternal serum, as lipoprotein lipase preferentially cleaves fatty acids in the two positions. In general, fatty acids transferred to the fetus reflect maternal serum lipids and diet. Placental fatty transfer has been recently reviewed.[18] **There is also evidence that the placental secretion of leptin, a hormone generally secreted by adipocytes, may promote maternal lipolysis, thus providing both placenta and fetus the means by which to ensure an adequate lipid supply.** Another possible mechanism by which lipids may be excreted from the placenta involves the synthesis and secretion of apolipoprotein (apo) B–containing lipoproteins. The relative importance of this pathway in the human placenta is at present unclear. Placental uptake and excretion of cholesterol is discussed in the section on receptor-mediated endocytosis.

Water and Ions

Although water transfer across the placenta does not limit fetal water uptake during growth, the factors regulating fetal water acquisition are poorly understood. **Water transfer from mother to fetus is determined by a balance of osmotic, hydrostatic, and colloid osmotic forces at the placental interface.** Calculation of osmotic pressure from individual solute concentrations is unreliable because osmotic pressure forces depend on the membrane permeability to each solute. Thus, sodium and chloride, the principal plasma solutes, are relatively permeable across the placenta[19] and would not be expected to contribute important osmotic effects.[20] As a result, although human fetal plasma osmolality is equal to or greater than maternal plasma osmolality, these measured values do not reflect the actual osmotic force on either side of the membranes.[19] Coupled with findings that hydrostatic pressure may be greater in the umbilical vein than the intervillous space, these data do not explain mechanisms for fetal water accumulation. Alternatively, colloid osmotic pressure differences and active solute transport probably represent the main determinants of net water fluxes—approximately 20 mL/day. It is likely, however, given the large (3.6 L/hr) flux of water between mother and fetus, that more active mechanisms, including perhaps controlled changes in end-vessel resistance, play a significant role. In fact, water flux occurs through both transcellular and paracellular pathways. Water channels (aquaporins 1, 3, 8, and 9) have been identified within the placenta, but their roles relative to water flux within the fetal placental unit have not been discerned.[21]

In comparison to other epithelia the specialized placental mechanisms for ion transport are incompletely understood. Multiple mechanisms for sodium transport in syncytiotrophoblast membranes exist. The maternal-facing microvillous membrane contains, at a minimum, multiple amino acid co-transporters, a sodium phosphate co-transporter in which two sodium ions are transported with each phosphate radical, a sodium-hydrogen ion antiport that exchanges one proton for each sodium ion entering the cell, and other nutrient transporters. In addition, both sodium and potassium channels have been described. A membrane potential with the inside negative (–30 MV) would promote sodium entry from the intervillous space. The fetal directed basal side of the cell contains the Na,K-ATPase. The microvillous or maternal facing trophoblast membrane has an anion exchanger (AE1) that mediates chloride transit across this membrane, in association with Cl^- conductance pathways (channels), present in both the microvillous and basolateral membranes.[22] Paracellular pathways also play an important role. The integration and regulation of these various mechanisms for sodium and chloride transport from mother to fetus is not completely understood; there is accumulating evidence that mineralocorticoids may regulate placental sodium transfer. Further, sodium/hydrogen exchange, mediated by multiple members of the NHE family (NHE1-3), is regulated both over gestation and in response to intrauterine growth restriction as is expression of the sodium-potassium ATPase.

Calcium

Calcium is an essential nutrient for the developing fetus. Ionized calcium levels are higher in fetal than in maternal blood. Higher fetal calcium levels are due to a syncytiotrophoblast basal membrane ATP-dependent Ca^{++} transport system exhibiting high affinity (nanomolar range) for calcium. Indeed, analogous to amino acid and sodium/hydrogen exchange proteins, multiple isoforms of the plasma membrane calcium ATPase (PMCA 1 to 4) are expressed within the placenta[23]; the placental expression of PMCA3 has been linked to intrauterine bone accrual. Sodium/calcium exchange proteins (NCX) may also play a role in extrusion of calcium from the trophoblast—again, multiple isoforms are expressed within the placenta. A variety of calcium channels have been identified in both the apical and basal membranes; TRPV6 plays a significant

role in calcium uptake into the syncytiotrophoblast.[23] Intracellular calcium is bound by multiple calcium binding proteins, which have been identified within the placenta; these include CaBP9k, CaBP28k, CaBP57k, oncomodulin, S-100P, S-100alpha, and S-100beta. CaBP9K in particular is thought to have a regulatory and perhaps rate-limiting role. Calcium transport across the placenta is increased by the calcium-dependent regulatory protein calmodulin regulated by 1,25 dihydroxycholecalciferol, calcitonin, parathyroid hormone–related protein, and parathyroid hormone.

Receptor-Mediated Endocytosis/Exocytosis

Endocytosis, via the clatharin-dependent endocytosis pathway, has long been known to occur within the placenta. Placental endocytosis plays a critical role in cell signaling; examples include insulin and EGF receptors, protein recycling (receptors, transporters), substrate transfer (LDL receptor), and transcytosis (immunoglobulin, taken up by endocytosis, and transferred from the maternal to the fetal circulation). The general mechanisms underlying these processes include postligand binding, cell entry, and processing. Following ligand binding, the receptors aggregate on the cell surface and collect in specialized membrane structures termed *clatharin-coated pits* (Figure 2-3). These coated pits invaginate, pinch off, and enter the cell to form vesicles, which fuse to form endosomes. The endosomes move deeper into the cytoplasm where the lower endosome pH facilitates ligand separation from its receptor.

The fate of ligand and receptor differs depending on the specific substrate: Although insulin receptor is probably recycled to the cell surface, maternal insulin does not reach the fetal circulation due to lysosomal degradation. Cholesterol enters the syncytiotrophoblast via the LDL- or HDL-binding scavenger receptors, among others, and may be used for trophoblast pregnenolone/progesterone synthesis and/or transferred across the basal membrane, in part via the ATP-binding cassette transporter.[24] The cholesterol is subsequently transferred across the fetal endothelium into the fetal circulation via ATP-binding cassette transporters ABCA1 and ABCG1. **IgG remains complexed to its receptor (the neonatal Fc receptor [FcRn]) and is transferred to the fetus intact via exocytosis at the basal trophoblast membrane. Immunoglobulin that cannot bind to this receptor is degraded within the placenta.**[25] **Ferrotransferrin carries two ferric ions per molecule and is unique in that it does not separate from the transferrin receptor. Rather, the iron dissociates and binds to ferritin, a cytoplasmic iron-storing protein.** Iron is thought to then escape the trophoblast via ferroportin, to be picked up at the basal side of the cell by fetal apotransferrin, while the maternal apotransferrin/transferrin receptor complex is recycled to the syncytiotrophoblast microvillous membrane.[26,27]

Endocytosis may also occur via caveolin-dependent and lipid-raft associated mechanisms. The mechanisms are not well understood within the placenta; however, the norepinephrine transporter is recycled by the latter mechanism in trophoblast cells.[28]

Placental Blood Flow

The transport characteristics of the placenta allow respiratory gases and many solutes to reach equal concentration between the maternal intervillous space blood (derived from uterine blood flow) and fetal capillary blood (derived from umbilical blood flow). Thus, the rate of blood flow in these two circulations is an important determinant of fetal oxygen and nutrient supply.

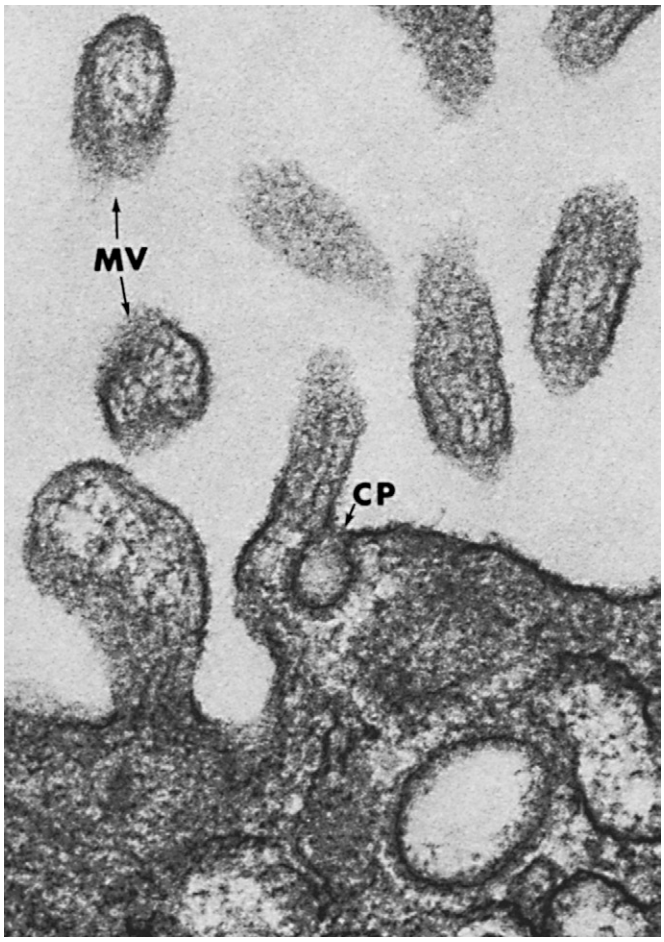

FIGURE 2-3. Electron micrograph of human placental microvillous plasma membrane demonstrating presence of a coated pit *(CP)*. Thornburg, Ph.D., Department of Physiology, Oregon Health Sciences University, Portland, OR.)

Uterine Blood Flow

Uterine blood flow during pregnancy supplies the myometrium, endometrium, and placenta, with the latter receiving nearly 90% of total uterine blood flow near term. Thus, interest has focused primarily on regulation of uteroplacental blood flow. Over the course of a normal singleton ovine gestation, uterine blood flow increases more than 50-fold above nonpregnant values. This long-term increase in uterine blood flow is accompanied by a doubling of maternal cardiac output and a 40% increase in blood volume**. Two primary factors contribute to this dramatic increase in uterine blood flow: placental growth and maternal arterial vasodilation.** Along with fetal and placental growth, placental intervillous space volume almost triples between weeks 22 and 36 of gestation. Thus, the marked growth of the maternal placental vascular bed is consistent with the increase in placental diffusing capacity. **Second, the increase in blood flow is due in part to a direct**

estrogen-induced vasodilation of the uterine vasculature. This effect is mediated through the release of nitric oxide.[29] **These combined effects provide uterine blood flow rates at term of at least 750 mL/min, or 10% to 15% of maternal cardiac output.** The uterine artery behaves as a nearly maximally dilated system; a number of local vasodilatory agents contribute to this effect including prostanoids (PGI_2), nitric oxide, and kinins.[30] Still, uterine blood flow is subject to short-term regulatory influences. Systemically administered vasodilator agents preferentially dilate systemic vessels, reducing uterine blood flow. Thus, concerns regarding administration of antihypertensive agents or regional anesthesia with sympathetic blockade are well founded. **Although pregnant women display a refractoriness to infused pressor agents,**[31] **including angiotensin, pressor agent–induced increases in uterine vascular resistance may exceed increases in systemic vascular resistance, reducing uteroplacental blood flow. Thus, increased maternal plasma catecholamine levels during preeclampsia or pressor agents administered for treatment of maternal hypotension may have adverse effects on uterine blood flow.** Although respiratory gases are important regulators of blood flow in a number of organs, there is no indication that either oxygen or carbon dioxide are responsible for short-term changes in uterine blood flow. During uterine contractions the relationship between uterine arterial and venous pressures and blood flow no longer holds. Since intrauterine pressures are directly transmitted to the intervillous space, increases in intrauterine pressure are reflected by decreases in placental blood flow. Calcitonin gene–related peptide produces uterine artery relaxation and enhances uterine artery blood flow and improved fetal growth. **Phosphodiesterase 5–specific inhibitors, including sildenafil, tadalafil, and vardenafil, enhance nitric oxide's vasodilatory effect by inhibition of cGMP (second messenger in the nitric oxide cascade) breakdown, with resultant relaxation of vascular smooth muscle.**[32] Evidence in animal models suggests that fetal outcomes may be improved by these agents.[33] Conversely, it is not surprising that diminished uterine artery blood flow is associated with diminished fetal growth, presumably because of diminished substrate transfer (nutrient, ions, oxygen, etc.) from mother to fetus.

Umbilical Blood Flow

Fetal blood flow to the umbilical circulation represents approximately 40% of the combined output of both fetal ventricles.[34] Over the last third of gestation, increases in umbilical blood flow are proportional to fetal growth, so that umbilical blood flow remains constant when normalized to fetal weight. Human umbilical venous flow can be estimated through the use of triplex mode ultrasonography. Although increases in villous capillary number represent the primary contributor to gestation-dependent increases in umbilical blood flow, the factors that regulate this change are not known. A number of important angiogenic peptides and factors, including VEGF, have been identified.[35] Short-term changes in umbilical blood flow are primarily regulated by perfusion pressure. The relationship between flow and perfusion pressure is linear in the umbilical circulation. As a result, small (2 to 3 mm Hg) increases in umbilical vein pressure evoke proportional decreases in umbilical blood flow. Because both the umbilical artery and vein are enclosed in the amniotic cavity, pressure changes caused by increases in uterine tone are transmitted equally to these vessels without changes in umbilical blood flow. Relative to the uteroplacental bed, the fetoplacental circulation is resistant to vasoconstrictive effects of infused pressor agents, and umbilical blood flow is preserved unless cardiac output decreases. Thus, despite catecholamine-induced changes in blood flow distribution, and increases in blood pressure during acute hypoxia, umbilical blood flow is maintained over a relatively wide range of oxygen tensions. Endogenous vasoactive autacoids have been identified; nitric oxide may also be important. Endothelin-1, in particular, is associated with diminished fetoplacental blood flow.[36]

Immunologic Properties of the Placenta

The syncytiotrophoblast in contact with maternal blood in the intervillous space and the amniochorion in contact with maternal decidua represent the fetal tissues most prone to immunologic reactions from maternal factors. Maternal tolerance of fetal tissue is an area of active, if as yet incomplete, investigation. A variety of immunoregulatory cells are present within the placental bed; these include uterine natural killer cells, macrophages, dendritic cells, T regulatory cells,T lymphocytes, and natural killer T cells. These cells may vary both numerically and functionally throughout gestation.[37] The manner in which immunoregulatory cells interact with fetal derived tissues to allow tolerance remains an area of intense investigation, but as yet consensus has not been reached. It is likely, however, that they participate in not only the development of fetal tolerance, but also in the establishment of placental vasculature, and in limitation of extravillous trophoblast migration once the vacular bed has been sufficiently established.

Trophoblast cells contain a unique complement of histocompatibility antigens, which are integral to the host's recognition of self and non-self. Neither beta-2-microglobulin (which is tightly associated with HLA antigens) nor the HLA antigens A, B, DR, or DC can be demonstrated on the surface of syncytiotrophoblast. This is thought to be the result of the epigenetic silencing of the Class II transactivator gene within the trophoblast. Invasive human cytotrophoblasts (extravillous trophoblast) express a trophoblast-specific, nonclassical class 1b antigen, HLA-G (reviewed in reference 38), in addition to the more widely disseminated HLA-C and HLA-E, each of which serves as a ligand for uterine natural killer (uNK) cells, the predominant leukocyte type found within the maternal-fetal junction in early gestation.[38] These ligands interact with specific killer-cell immunoglobulin-like receptors (KIRs) on uNK cells. Postulated roles for HLA-G include protection of invasive cytotrophoblast from uNK cells, as well as containment of placental infection. HLA-G is also coexpressed with HLA-E, allowing it to be recognized by KIRs, which then induce inhibition of uNK cells. The interaction of uNK cells and HLA-C appears to be more complex, in that, depending on the combinatorial pattern of KIRs and HLA-C alleles present, uterine invasion by extravillous trophoblast can be either facilitated of inhibited, leading, perhaps, to the development of preeclampsia.[39] Trophoblasts also express HLA-F, but the function and interactions of this antigen remain uncertain.

Other postulated "protective" mechanisms include the presence of proteins that "deactivate" the local complement system, alteration of lymphocytes from a Th1 to a Th2 secretory phenotype, associated with a cytokine profile more conducive to fetal survival, as well as a mechanism by which the fetal membranes may facilitate the apoptosis of specific maternal immunoregulatory cells. Others have shown that indoleamine 2,3-dioxygenase (IDO), which breaks down tryptophan, may be important in the control of maternal lymphocytes; blocking this enzyme activity was associated with a high rate of fetal abortion.[39] In summary, immunologic aspects of the placenta are difficult to separate out from those of the maternal uterus and the mixed deciduas. It is now clear, however, that multiple, elegant, overlapping mechanisms ensure the survival of the placenta, and thus the fetus, in an immunologically hostile environment. For a detailed review of immunology in pregnancy, see Chapter 4.

Amniotic Fluid Volume

Mean amniotic fluid volume increases from 250 to 800 mL between 16 and 32 weeks' gestation. Despite considerable variability, the average volume remains stable up to 39 weeks and then declines to about 500 mL at 42 weeks. The origin of amniotic fluid during the first trimester of pregnancy is uncertain. Possible sources include a transudate of maternal plasma through the chorioamnion or a transudate of fetal plasma through the highly permeable fetal skin, before keratinization. The origin and dynamics of amniotic fluid are better understood beginning in the second trimester, when the fetus becomes the primary determinant. **Amniotic fluid volume is maintained by a balance of fetal fluid production (lung liquid and urine) and fluid resorption (fetal swallowing and flow across the amniotic and/or chorionic membranes to the fetus or maternal uterus).**[40]

The fetal lung secretes fluid at a rate of 300 to 400 mL/day near term. Chloride is actively transferred from alveolar capillaries to the lung lumen, and water follows the chloride gradient. Thus, lung fluid represents a nearly protein-free transudate with an osmolarity similar to that of fetal plasma. Fetal lung fluid does not appear to regulate fetal body fluid homeostasis, as fetal intravenous volume loading does not increase lung fluid secretion. Rather, lung fluid likely serves to maintain lung expansion and facilitate pulmonary growth. **Lung fluid must decrease at parturition to provide for the transition to respiratory ventilation.** Notably, several hormones that increase in fetal plasma during labor (i.e., catecholamines, arginine vasopressin [AVP]) also decrease lung fluid production. With the reduction of fluid secretion, the colloid osmotic gradient between fetal plasma and lung fluid results in lung fluid resorption across the pulmonary epithelium, and clearance via lymphatics. **The absence of this process explains the increased incidence of transient tachypnea of the newborn, or "wet lung," in infants delivered by cesarean section in the absence of labor.**

Fetal urine is the primary source of amniotic fluid, with outputs at term varying from 400 to 1200 mL/day. Between 20 and 40 weeks' gestation, fetal urine production increases about tenfold, in the presence of marked renal maturation. The urine is normally hypotonic and the low osmolarity of fetal urine accounts for the hypotonicity of amniotic fluid in late gestation relative to maternal and fetal plasma. Numerous fetal endocrine factors, including AVP, atrial natriuretic factor (ANF), angiotensin II (AII), aldosterone, and prostaglandins, alter fetal renal blood flow, glomerular filtration rate, or urine flow rates.[41] In response to fetal stress, endocrine-mediated reductions in fetal urine flow may explain the association between fetal hypoxia and oligohydramnios. The regulation of fetal urine production is discussed further under Fetal Kidney later in this chapter.

Fetal swallowing is believed to be a major route of amniotic fluid resorption although swallowed fluid contains a mixture of amniotic and tracheal fluids. Human fetal swallowing has been demonstrated by 18 weeks' gestation,[42] with daily swallowed volumes of 200 to 500 mL near term. Similar to fetal urine flow, daily fetal swallowed volumes (per body weight) are markedly greater than adult values. With the development of fetal neurobehavioral states, fetal swallowing occurs primarily during active sleep states associated with respiratory and eye movements.[43] Moderate increases in fetal plasma osmolality increase the number of swallowing episodes and volume swallowed, indicating the presence of an intact thirst mechanism in the near-term fetus.

Because amniotic fluid is hypotonic with respect to maternal plasma, there is a potential for bulk water removal at the amniotic-chorionic interface with maternal or fetal plasma. Although fluid resorption to the maternal plasma is likely minimal, intramembranous flow from amniotic fluid to fetal placental vessels may contribute importantly to amniotic fluid resorption. Thus, intramembranous flow may balance fetal urine and lung liquid production with fetal swallowing to maintain normal amniotic fluid volumes.

The mechanisms by which water is transferred across the amnion into fetal vessels remains uncertain, but evidence implicates the presence of water channels within the amnion, and, as discussed previously, the placental trophoblast and fetal endothelium. Aquaporins 1, 3, 8, and 9 are found within the placenta and fetal membranes. Mice deficient in aquaporin 1 develop polyhydramnios, suggesting an important role for this protein in intramembranous water transfer.[44] Aquaporins 1 and 3 (important in transplacental water flow) are regulated by AVP and by cAMP, as well as showing changes in expression throughout gestation.[45]

FETAL PHYSIOLOGY

Growth and Metabolism

Substrates

Nutrients are utilized by the fetus for two primary purposes: oxidation for energy and tissue accretion. Under normal conditions, glucose is an important substrate for fetal oxidative metabolism. The glucose utilized by the fetus derives from the placenta rather than from endogenous glucose production. However, based on umbilical vein–to–umbilical artery glucose and oxygen concentration differences, glucose alone cannot account for fetal oxidative metabolism. In fact, glucose oxidation accounts for only two thirds of fetal carbon dioxide production.[46] Thus, fetal oxidative metabolism depends on substrates in addition to glucose. A large portion of the amino acids

taken up by the umbilical circulation are used by the fetus for aerobic metabolism instead of protein synthesis. Fetal uptake for a number of amino acids actually exceeds their accretion into fetal tissues. In addition, other amino acids, notably glutamate, are taken up by the placenta from the fetal circulation and metabolized within the placenta.[47] **In fetal sheep and likely the human fetus as well, lactate also is a substrate for fetal oxygen consumption.[46] Thus, the combined substrates glucose, amino acids, and lactate essentially provide the approximately 87 kcal/kg/day required by the growing fetus.**

Metabolic requirements for new tissue accretion depend on the growth rate and the type of tissue acquired. Although the newborn infant has relatively increased body fat, fetal fat content is low at 26 weeks. Fat acquisition increases gradually up to 32 weeks and rapidly thereafter (about 82 g [dry weight] of fat per week). Because many of the necessary enzymes for carbohydrate to lipid conversion are present in the fetus, fat acquisition reflects glucose utilization in addition to placental fatty acid uptake. In contrast, fetal acquisition of nonfat tissue is linear from 32 to 39 weeks, and may decrease to only 30% of the fat-acquisition rate in late gestation (about 43 g [dry weight] per week).

Hormones

The role of select hormones in the regulation of placental growth was discussed previously under Placental Metabolism and Growth. Fetal hormones influence fetal growth through both metabolic and mitogenic effects. **Although growth hormone and growth hormone receptors are present early in fetal life, and growth hormone is essential to postnatal growth, growth hormone appears to have little role in regulating fetal growth.** Instead, changes in IGF, IGF-binding proteins, or IGF receptors explain the apparent reduced role of growth hormone on fetal growth. Most if not all tissues of the body produce IGF-I and IGF-II and both IGF-I and IGF-II are present in human fetal tissue extracts after 12 weeks' gestation. Fetal plasma IGF-I and IGF-II levels begin to increase by 32 to 34 weeks' gestation. **The increase in IGF-I levels directly correlates with increase in fetal size, and a reduction in IGF-I levels is associated with growth restriction.[48] In contrast, there is no correlation between serum IGF-II levels and fetal growth.** However, there is a correlation between small offspring and genetic manipulations resulting in decreased IGF-II messenger RNA production. IGF-II knockout mice are small, and knockout of the IGF-IIr results in fetal overgrowth.[49] Thus, tissue IGF-II concentrations and localized IGF-II release may be more important than circulating levels in supporting fetal growth.

IGF binding proteins (IGFBPs) modulate IGF-I and II concentrations in serum, with IGFBP1 having an inhibitory and IGFBP3 a comparatively stimulatory effect. As such, diminished fetal concentrations of IGFBP3 and enhanced concentrations of IGFBP1 have been associated with smaller fetal size.[50]

A role for insulin in fetal growth is suggested from the increases in body weight, and heart and liver weights, in infants of diabetic mothers. Insulin levels within the high physiologic range increase fetal body weight, and increases in endogenous fetal insulin significantly increase fetal glucose uptake. In addition, fetal insulin secretion increases in response to elevations in blood glucose, although the normal rapid insulin response phase is absent.[51] Plasma insulin levels sufficient to increase fetal growth also may exert mitogenic effects perhaps through insulin-induced IGF-II receptor binding. Separate receptors for insulin and IGF-II are expressed in fetal liver cells by the end of the first trimester. Hepatic insulin receptor numbers (per gram tissue) triple by 28 weeks, while IGF-II receptor numbers remain constant. Thus, although children conceived of diabetic mothers are at increased risk of cardiac defects, the growth patterns of these infants indicate insulin levels may be most important in late gestation. Though less common, equally dramatically low birth weights are associated with the absence of fetal insulin. Experimentally induced hypoinsulinemia causes a 30% decrease in fetal glucose utilization and decreases fetal growth.

As in the adult, β-adrenergic receptor activation increases fetal insulin secretion, whereas β-adrenergic activation inhibits insulin secretion. Fetal glucagon secretion also is modulated by the β-adrenergic system. However, the fetal glycemic response to glucagon is blunted, probably caused by a relative reduction in hepatic glucagon receptors.

Corticosteroids are essential for fetal growth and maturation. Corticosteroid levels within the fetus rise near partuition, in step with maturation of fetal organs such as the lung, liver, kidneys, and thymus, and slowing of fetal growth. Exogenous maternal steroid administration during pregnancy also has the potential to diminish fetal growth in humans, as well as in a variety of other species, perhaps via suppression of the IGF axis.[50] In addition to the insulin-like growth factors, a number of other factors, including epidermal growth factor, transforming growth factor, fibroblast growth factor, and nerve growth factor, are expressed during embryonic development and appear to exert specific effects during morphogenesis; for example, epidermal growth factor has specific effects on lung growth and growth and differentiation of the secondary palate, and normal sympathetic adrenergic system development is dependent on nerve growth factor. However, a specific role of these factors in regulating fetal growth remains to be defined. **Similarly, the fetal thyroid also is not important for overall fetal growth, but is important for central nervous system development.**

Substantial evidence now exists to support the view that several cell-specific growth factors and their cognate receptors play an essential role in placental growth and function in a number of species. Growth factors identified to date include family members of epidermal growth factor, transforming growth factor beta, nerve growth factor, insulin-like growth factor, hematopoietic growth factors, vascular endothelial growth factor, and fibroblast growth factor. A number of cytokines also play a role in normal placental development. The expression, ontogeny, and regulation of most but not all of these growth factors have been explored. In vitro placental cell culture studies support the concept that growth factors and cytokines exert their functions locally promoting proliferation and differentiation through their autocrine and/or paracrine mode of actions. For example, epidermal growth factor (EGF) promotes cell proliferation, invasion, or differentiation depending on the gestational age. Hepatocyte growth factor and vascular endothelial growth factor stimulate trophoblast DNA

replication whereas transforming growth factor beta suppresses cytoplast invasion and endocrine differentiation. In support of local actions, functional receptors for various growth factors have been demonstrated on trophoblast and other cells. Various intracellular signal proteins and transcription factors that respond to growth factors are also expressed in placenta. A number of elegant studies have identified alterations in growth factors and growth factor receptors in association with placental and fetal growth restriction. Placental defects in growth factor(s) and receptor(s) pathways, explored through the use of transgenic and mutant mice, have provided potential mechanisms for explaining complications of human placental development.[52] **An illustrative example is EGF, a potent mitogen for epidermal and mesodermal cells that is expressed in human placenta. EGF is involved in embryonal implantation, stimulates syncytiotrophoblast differentiation in vitro, and modulates production and secretion of human chorionic gonadotrophin and placental lactogen.** The effects of EGF are mediated by EGF-receptor (EGF-R), a transmembrane glycoprotein with intrinsic tyrosine kinase activity. EGF-R is expressed on the apical microvillus plasma membrane fractions from early, middle, and term whole placentas. Placental EGF-R expression is regulated by locally expressed parathyroid hormone–related protein, itself important in placental differentiation and maternal-fetal calcium flux.[53,54] Decreased EGF-R expression has been demonstrated in association with intrauterine growth restriction. **Targeted disruption of EGF-R has shown to result in fetal death due to placental defects.**[55] **Overexpression of EGF-R activity results in placental enlargement.**[56]

The EGF family now consists of at least 15 members, many of which have been identified in human placenta. Future studies should reveal whether EGF family members play distinct or overlapping functions in mediating placental growth.

Control of fetal growth may occur via the impact of growth factors/hormones on the placenta or may occur as a direct result of action in and on the fetus. It is clear that nutrition may play a role in these processes. However, the number of genes/gene products known to control or affect fetal growth continues to increase**. Imprinted genes (expressed primarily from maternally or paternally acquired allele) play a particularly important role in controlling fetal growth.**[57] **Abnormalities in the expression of these genes often result in fetal overgrowth or undergrowth.** Environmental influences, such as alterations in gene methylation, or in modification of histones associated with genes, may further alter gene expression, and thus fetal growth, making this a rich area for further exploration.

Fetal Cardiovascular System

Development

The heart and the vascular system develop from splanchnic mesoderm during the third week after fertilization. The two primordial heart tubes fuse, forming a simple contractile tube early in the fourth week, and the cardiovascular system becomes the first functional organ system. **During weeks 5 to 8 this single-lumen tube is converted into the definitive four-chambered heart through a process of cardiac looping (folding), remodeling, and partitioning.** However, an opening in the interatrial septum, the foramen ovale, is present and serves as an important right-to-left shunt during fetal life.

During the fourth embryonic week three primary circulations characterize the vascular system. The aortic/cardinal circulation serves the embryo proper and is the basis for much of the fetal circulatory system. Of note the left sixth aortic (pulmonary) arch forms a connection between the left pulmonary artery and the aorta as the ductus arteriosus. **The ductus arteriosus also functions as a right-to-left shunt by redistributing right ventricular output from the lungs to the aorta and fetal and placental circulations.** The vitelline circulation develops in association with the yolk sac, and though it plays a minor role in providing nutrients to the embryo, its rearrangement ultimately provides the circulatory system for the gastrointestinal tract, spleen, pancreas, and liver. The allantoic circulation develops in association with the chorion and the developing chorionic villi, and forms the placental circulation, comprised of two umbilical arteries and two umbilical veins. **In humans, the venous pathways are rearranged during embryonic weeks 4 to 8 and only the left umbilical vein is retained. Subsequent rearrangement of the vascular plexus associated with the developing liver forms the ductus venosus, a venous shunt that allows at least half of the estimated umbilical blood flow (70 to 130 mL/min/kg fetal weight after 30 weeks' gestation) to bypass the liver and enter the inferior vena cava.**[58]

Placental gas exchange provides well-oxygenated blood that leaves the placenta (Figure 2-4) via the umbilical vein. In addition to the ductus venosus, small branches into the left lobe of the liver and a major branch to the right lobe account for the remainder of umbilical venous flow. Left hepatic vein blood combines with the well-oxygenated ductus venosus flow as it enters the inferior vena cava. Because right hepatic vein blood combines with the portal vein (only a small fraction of portal vein blood passes through the ductus venosus), right hepatic vein blood is less oxygenated than its counterpart on the left,[58] and

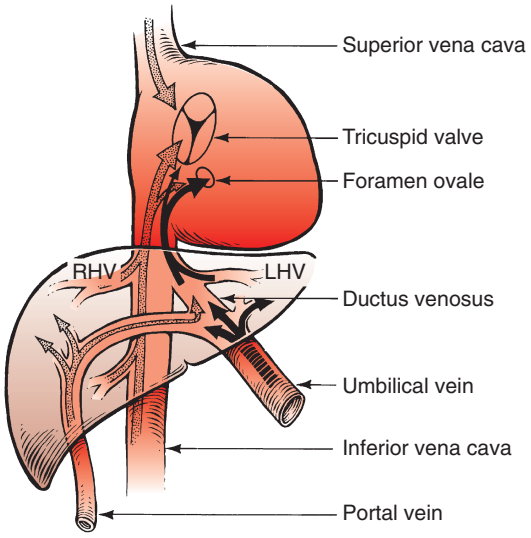

FIGURE 2-4. Anatomy of the umbilical and hepatic circulation. *Dark arrows* represent nutrient-rich and oxygen-rich blood. *LHV,* Left hepatic vein; *RHV,* right hepatic vein. (From Rudolph AM: Hepatic and ductus venosus blood flows during fetal life. Hepatology 3:254, 1983.)

combination of right hepatic/portal drainage with blood returning from the lower trunk and limbs further decreases the oxygen content. Although both ductus venosus blood and hepatic portal/fetal trunk bloods enter the inferior vena cava and the right atrium, little mixing occurs. **This stream of well-oxygenated ductus venosus blood is preferentially directed into the foramen ovale by the valve of the inferior vena cava and the crista dividens on the wall of the right atrium. This shunts a portion of the most highly oxygenated ductus venosus blood through the foramen ovale with little opportunity for mixing with superior vena cava/coronary sinus venous return** (Figures 2-4 and 2-5). **As a result, left atrial filling results primarily from umbilical vein–ductus venosus blood, with a small contribution from pulmonary venous flow. Thus, blood with the highest oxygen content is delivered to the left atrium and left ventricle, and ultimately supplies blood to the upper body and limbs, carotid and vertebral circulations, and the brain.** Inferior vena cava flow is larger than the volume that can cross the foramen ovale. The remainder of the oxygenated inferior vena cava blood is directed through the tricuspid valve (see Figure 2-4) into the right ventricle (see Figure 2-5) and is accompanied by venous return from the superior vena cava and coronary sinus. However, the very high vascular resistance in the pulmonary circulation maintains mean pulmonary artery pressure 2 to 3 mm Hg above aortic pressure and directs most of the right ventricular output through the ductus arteriosus and into the aorta and the fetal and placental circulations.[58]

Fetal Heart

The adult cardiovascular system includes a high-pressure (95 mm Hg) system and a low-pressure pulmonary circuit (15 mm Hg) driven by the left and right ventricles working in series. Although the ejection velocity is greater in the left ventricle than in the right, equal volumes of blood are delivered into the systemic and pulmonary circulations with contraction of each ventricle. The stroke volume is the volume of blood ejected by the left ventricle with each contraction, and cardiac output is a function of the stroke volume and heart rate (70 mL/beat × 72 beats/min = 5040 mL/min). For a 70-kg adult man, cardiac output averages 72 mL/min/kg. In addition to heart rate, cardiac output varies with changes in stroke volume, which in turn is determined by venous return (preload), pulmonary artery and aortic pressures (afterload), and contractility.

In contrast to the adult heart, where the two ventricles pump blood in a series circuit, the unique fetal shunts provide an unequal distribution of venous return to the respective atria, and ventricular output represents a mixture of oxygenated and deoxygenated blood. **Thus, the fetal right and left ventricles function as two pumps operating in parallel rather than in series, and cardiac output is described as the combined ventricular output. Right ventricular output exceeds 60% of biventricular output**[59] **and is primarily directed through the ductus arteriosus to the descending aorta (see Figure 2-5). As a result, placental blood flow, which represents over 50% of the combined ventricular output, primarily reflects right ventricular output. Because of the high pulmonary vascular resistance,**[59] **the pulmonary circulation receives only 5% to 10% of the combined ventricular output.** Instead, left ventricular output is primarily directed through the ductus arteriosus to the upper body and head. Estimates of fetal left ventricular output average 120 mL/min/kg body weight. If left ventricular output is less than 40% of the combined biventricular output,[59] total fetal cardiac output would be above 300 mL/min/kg. The distribution of the cardiac output to fetal organs is summarized in Table 2-1,[34] with fetal hepatic distribution reflecting only the portion supplied by the hepatic artery. In fact, hepatic blood flow derives principally from the umbilical vein and to a lesser extent the portal vein,[60] and represents about 25% of the total venous return to the heart.

The placenta receives approximately 50% of the combined ventricular output, which means the single umbilical vein also conducts 50% of the combined ventricular output. At least half of the umbilical venous blood bypasses the liver via the ductus venosus, and the remainder traverses

TABLE 2-1 GASTROINTESTINAL TRACT PERCENTAGE OF BIVENTRICULAR 40.5 (HEPATIC ARTERY)

ORGAN	PERCENTAGE OF BIVENTRICULAR CARDIAC OUTPUT
Placenta	40
Brain	13
Heart	3.5
Lung	7
Liver	2.5 (hepatic artery)
Gastrointestinal tract	5
Adrenal glands	0.5
Kidney	2.5
Spleen	1
Body	25

Data from Rudolph AM, Heymann MA: Circulatory changes during growth in the fetal lamb. Circ Res 26(3):289, 1970.

the hepatic circulation. The combination of umbilical vein blood, hepatic portal blood, and blood returning from the lower body contributes approximately 69% of the cardiac output that enters the right atrium from the inferior vena cava. Flow across the foramen ovale accounts for approximately one third (27%) of the combined cardiac output.[59] Pulmonary venous return to the left atrium is low and represents approximately 7% of combined ventricular output. Thus, the left atrium accounts for only about 34% (27% + 7%) of the combined ventricular output. Because a volume of inferior vena cava venous return equivalent to 27% of the combined ventricular output is shunted across the foramen ovale, 42% remains in the right atrium and contributes to right ventricular output. With another 21% from the superior vena cava and 3% from the coronary circulation, right ventricular output accounts for 66% of the combined ventricular output. However, only 7% of right ventricular output enters the pulmonary circulation, leaving 59% entering the aorta via the ductus arteriosus. Similarly, 24% of the combined ventricular output derived from the left ventricle is distributed to the upper body and brain, with approximately 10% combining with right ventricular output in the aorta. Thus, 69% of the combined ventricular output reaches the descending aorta and 50% of this accounts for placental flow, with the remainder distributed to the fetal abdominal organs and lower body.

Consistent with the greater contribution of the right ventricle to combined ventricular output, coronary blood flow to the myocardium reflects the greater stroke volume of the right side, and right ventricular free wall and septal blood flows are higher than in the left ventricle.[61] It is not surprising then that fetal ventricular wall thickness is greater on the right side relative to the left. As in the adult, fetal ventricular output depends on heart rate, pulmonary artery and aortic pressures, and contractility. The relationship between mean right atrial pressure (the index often used for ventricular volume at the end of diastole) and stroke volume is depicted in Figure 2-6. The steep ascending limb represents the length–active tension relationship for cardiac muscle in the right ventricle.[62] Under normal conditions, fetal right atrial pressure resides at the break point in this ascending limb and increases in pressure do not increase stroke volume. Thus, the contribution of Starling mechanisms to increasing right heart output in the fetus is limited. In contrast, decreases in venous return and right atrial pressure decrease stroke volume. Compared to the left ventricle, the fetal right ventricle has a greater anteroposterior dimension, increasing both volume and circumferential radius of curvature. This anatomic difference increases the radius/wall thickness ratio for the right ventricle, producing increased wall stress in systole and a decrease in stroke volume when afterload increases.[61] Because the right ventricle is sensitive to afterload, a linear inverse relationship exists between stroke volume and pulmonary artery pressure.[62]

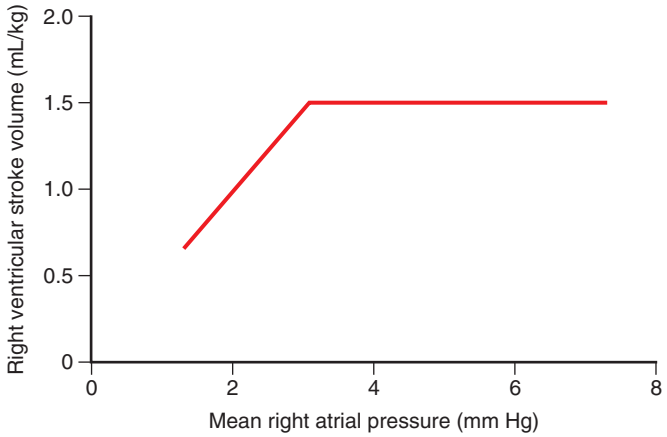

FIGURE 2-6. Stroke volume of the fetal right ventricle as a function of mean right atrial pressure. (From Thornburg KL, Morton MJ: Filling and arterial pressures as determinants of RV stroke volume in the sheep fetus. Am J Physiol 244:H656, 1983.)

The relationship between atrial pressure and stroke volume in the left ventricle is similar to that shown in Figure 2-6 for the right ventricle. Although the break point occurs near the normal value for left atrial pressure, there is a small amount of preload reserve.[61] In distinction to the fetal right ventricle, the left side is not sensitive to aortic pressure increases. Thus, postnatal increases in systemic blood pressure do not decrease left ventricular stroke volume, and left ventricular output increases to meet the needs of the postnatal systemic circulation. Although Starling mechanism–related increases in stroke volume are limited, especially in the right side of the heart, late-gestation fetal heart β-adrenergic receptor numbers are similar to those in the adult, and circulating catecholamine induced increases in contractility may increase stroke volume by 50%.

Although fetal heart rate decreases during the last half of gestation, particularly between 20 and 30 weeks, fetal heart rate averages more than twofold above resting adult heart rates. If analysis is confined to episodes of low heart rate variability, mean heart rate decreases from 30 weeks to term. However, if all heart rate data are analyzed, mean heart rate is stable at 142 beats/min over the last 10 weeks of gestation. Variability in mean heart rate over 24 hours includes a nadir between 2 A.M. and 6 A.M. and a peak between 8 A.M. and 10 A.M. Most fetal heart rate accelerations occur simultaneously with limb movement, primarily reflecting central neuronal brainstem output. Also, movement-related decreases in venous return and a reflex tachycardia may contribute to heart rate accelerations.[63] **Because ventricular stroke volumes decrease with increasing heart rate, fetal cardiac output remains constant over a heart rate range of 120 to 180 beats/min.** The major effect of this inverse relationship between heart rate and stroke volume is an alteration in end-diastolic dimension. If end-diastolic dimension is kept constant, there is no fall in stroke volume and cardiac output increases.

At birth major changes in vascular distribution occur with the first breath. Alveolar expansion and the associated increase in alveolar capillary oxygen tension induces a marked decrease in pulmonary microvascular resistance. This decrease in pulmonary vascular resistance has two effects. First, there is an accompanying decrease in right atrial afterload and right atrial pressure. Second, the increase in pulmonary flow increases venous return into the left atrium and therefore left atrial pressure. The combined effect of these two events is to increase left atrial pressure above right atrial pressure and provides a physiologic closure of the foramen ovale. The return of the

highly oxygenated blood from the lungs to the left atrium, left ventricle, and aorta and the decrease in pulmonary vascular resistance and hence pulmonary trunk pressure allow backflow of the oxygen-rich blood into the ductus arteriosus. **This local increase in ductus arteriosus oxygen tension alters the ductus response to prostaglandins and causes a marked localized vasoconstriction. Concurrent spontaneous constriction (or clamping) of the umbilical cord stops placental blood flow, reducing venous return and perhaps augmenting the decrease in right atrial pressure.**

Autonomic Regulation of Cardiovascular Function

Through reflex stimulation of peripheral baroreceptors, chemoreceptors, and central mechanisms, the sympathetic and parasympathetic systems have important roles in the regulation of fetal heart rate, cardiac contractility, and vascular tone. The fetal sympathetic system develops early, whereas the parasympathetic system develops somewhat later.[64] Nevertheless, in the third trimester, increasing parasympathetic tone accounts for the characteristic decrease in fetal heart rate with periods of reduced fetal heart rate reactivity. As evidence, fetal heart rate increases in the presence of parasympathetic blockade with atropine. Opposing sympathetic and parasympathetic inputs to the fetal heart contribute to R-R interval variability from one heart cycle to the next, and to basal heart rate variability over periods of a few minutes. However, even when sympathetic and parasympathetic inputs are removed, a level of variability remains.

Fetal sympathetic innervation is not essential for blood pressure maintenance when circulating catecholamines are present. Nevertheless, fine control of blood pressure and fetal heart rate requires an intact sympathetic system. In the absence of functional adrenergic innervation, hypoxia-induced increases in peripheral, renal, and splanchnic bed vascular resistances and blood pressure are not seen.[65] However, hypoxia-related changes in pulmonary, myocardial, adrenal, and brain blood flows occur in the absence of sympathetic innervation, indicating that both local and endocrine effects contribute to regulation of blood flow in these organs.

Receptors in the carotid body and arch of the aorta respond to pressor or respiratory gas stimulation with afferent modulation of heart rate and vascular tone. Fetal baroreflex sensitivity, in terms of the magnitude of decreases in heart rate per millimeter of mercury increase in blood pressure, is blunted relative to the adult.[66] However, fetal baroreflex sensitivity more than doubles in late gestation. Although the set-point for fetal heart rate is not believed to depend on intact baroreceptors, fetal heart rate variability increases when functional arterial baroreceptors are absent.[67] The same observation has been made for fetal blood pressure. Thus, fetal arterial baroreceptors buffer variations in fetal blood pressure during body or breathing movements.[67] Changes in baroreceptor tone likely account for the increase in mean fetal blood pressure normally observed in late gestation. In the absence of functional chemoreceptors, mean arterial pressure is maintained[67] while peripheral blood flow increases. Thus, peripheral arterial chemoreceptors may be important to maintenance of resting peripheral vascular tone. Peripheral arterial chemoreceptors also are important components in fetal reflex responses to hypoxia; the initial bradycardia is not seen without functional chemoreceptors.

Hormonal Regulation of Cardiovascular Function

Adrenocorticotropic hormone (ACTH) and catecholamines are discussed under Fetal Adrenal and Thyroid later in this chapter.

Arginine Vasopressin

Significant quantities of AVP are present in the human fetal neurohypophysis by completion of the first trimester. Ovine fetal plasma AVP levels increase appropriately in response to changes in fetal plasma osmolality induced directly in the fetus[68] **or via changes in maternal osmolality.**[69] Because of functional high- and low-pressure baroreceptors and chemoreceptor afferents, decreases in fetal intravascular volume or systemic blood pressure[70,71] also increase fetal AVP secretion. Thus, in the late-gestation fetus as in the adult, AVP secretion is regulated by both osmoreceptor and volume/baroreceptor pathways. Hypoxia-induced AVP secretion has been demonstrated beyond mid-pregnancy of ovine gestation, and reductions in fetal PO_2 of 10 mm Hg (50%) evoke profound increases in fetal plasma AVP levels (about 2 pg/mL to 200 to 400 pg/mL or more). Thus, because fetal AVP responsiveness to hypoxia is augmented relative to the adult (as much as 40-fold), and fetal responsiveness appears to increase during the last half of gestation, hypoxemia is the most potent stimulus known for fetal AVP secretion.

The cardiovascular response pattern to AVP infusion includes dose-dependent increases in fetal mean blood pressure and decreases in heart rate at plasma levels well below those required for similar effects in the adult. Receptors (V1) distinct from those mediating AVP antidiuretic effects in the kidney (V2) account for AVP contributions to fetal circulatory adjustments during hemorrhage, hypotension, and hypoxia.[72] Corticotropin-releasing factor (CRF) effects of AVP may contribute to hypoxia-induced increases in plasma ACTH and cortisol levels. In addition to effects on fetal heart rate, cardiac output, and arterial blood pressure, AVP-induced changes in peripheral, placental, myocardial, and cerebral blood flows directly parallel the cardiovascular changes associated with acute hypoxia. Because many of these responses are attenuated during AVP receptor blockade, AVP effects on cardiac output distribution may serve to facilitate O_2 availability to the fetus during hypoxic challenges. However, other hypoxia-related responses, including decreases in renal and pulmonary blood flows, and increased adrenal blood flow are not seen in response to AVP infusions.

Renin–Angiotensin II

Fetal plasma renin levels are typically elevated during late gestation.[73] A variety of stimuli including changes in tubular sodium concentration, reductions in blood volume, vascular pressure or renal perfusion pressure, and hypoxemia all increase fetal plasma renin activity. The relationship between fetal renal perfusion pressure and log plasma renin activity is similar to that of adults. Consistent with the effects of renal nerve activity on renin release in adults, fetal renin gene expression is directly modulated by renal sympathetic nerve activity.

Although fetal plasma AII levels increase in response to small changes in blood volume and hypoxemia, fetal AII and aldosterone levels do not increase in proportion to changes in plasma renin activity. This apparent uncoupling of the fetal renin-angiotensin-aldosterone system and the increase in newborn AII levels may relate to the significant contribution of the placenta to plasma AII clearance in the fetus relative to the adult. Also, limited angiotensin-converting enzyme (ACE) availability due to reduced pulmonary blood flow and direct inhibition of aldosterone secretion by the normally high circulating ANF levels may contribute. Thus, reductions in AII production and aldosterone responses to AII, augmented AII and aldosterone clearances, and the resulting reductions in AII and aldosterone levels and feedback inhibition of renin may account for the elevated renin and reduced AII and aldosterone levels typically observed during fetal life.

Angiotensin II infusion increases fetal mean arterial blood pressure. In contrast to AVP-induced bradycardia, fetal AII infusion increases heat rate (after an initial reflex bradycardia) through both a direct effect on the heart, and decreased baroreflex responsiveness. Both hormones increase fetal blood pressure similar to the levels seen with hypoxemia. However, AII does not reduce peripheral blood flow, perhaps because circulation to muscle, skin, and bone is always under maximum response to AII, thereby limiting increases in resting tone. Angiotensin II infusions also decrease renal blood flow and increase umbilical vascular resistance, although absolute placental blood flow does not change. Whereas the adult kidney contains both AII receptor subtypes (AT_1 and AT_2), the AT_2 subtype is the only form present in the human fetal kidney. Maturational differences in the AII receptor subtype expressed would be consistent with earlier studies demonstrating differing AII effects on fetal renal and peripheral vascular beds. Thus, the receptors mediating AII responses in the renal and peripheral vascular beds differ during fetal life.

Fetal Hemoglobin

The fetus exists in a state of aerobic metabolism, with arterial blood PO_2 values in the 20 to 35 mm Hg range. However, there is no evidence of metabolic acidosis. Adequate fetal tissue oxygenation is achieved by several mechanisms. Of major importance are the higher fetal cardiac output and organ blood flows. A higher hemoglobin concentration (relative to the adult) and an increase in oxygen-carrying capacity of fetal hemoglobin also contribute. The resulting leftward shift in the fetal oxygen dissociation curve relative to the adult (Figure 2-7) increases fetal blood oxygen saturation for any given oxygen tension. For example, at a partial pressure of 26.5 mm Hg, adult blood oxygen saturation is 50%, whereas fetal oxygen saturation is 70%. Thus, at a normal fetal PO_2 of 20 mm Hg, fetal whole blood oxygen saturation may be 50%.

The basis for increased oxygen affinity of fetal whole blood resides in the interaction of fetal hemoglobin with intracellular organic phosphate 2,3-diphosphoglycerate (2,3-DPG). The fetal hemoglobin (HgbF) tetramer is comprised of two α-chains (identical to adult) and two γ-chains. The latter differ from the γ-chain of adult hemoglobin (HgbA) in 39 of 146 amino acid residues. Among these differences is the substitution of serine in the γ-chain of HgbF for histidine at the β-143 position of HgbA, which is located at the entrance to the central cavity of the hemoglobin tetramer. Due to a positively charged imidazole group, histidine can bind with the negatively charged 2,3-DPG. Binding of 2,3-DPG to deoxyhemoglobin stabilizes the tetramer in the reduced form. Because serine is nonionized and does not interact with 2,3-DPG to the same extent as histidine, the oxygen affinity of HgbF is increased and the dissociation curve is shifted to the left. If HgbA or HgbF is removed from the erythrocyte and stripped of organic phosphates, the oxygen affinity for both hemoglobins is similar. However, addition of equal amounts of 2,3-DPG to the hemoglobins decreases HgbA oxygen affinity (dissociation curve shifts to the right) to a greater extent than for HgbF. Thus, even though overall oxygen affinities are similar, differences in 2,3-DPG interaction result in a higher oxygen affinity for HgbF.

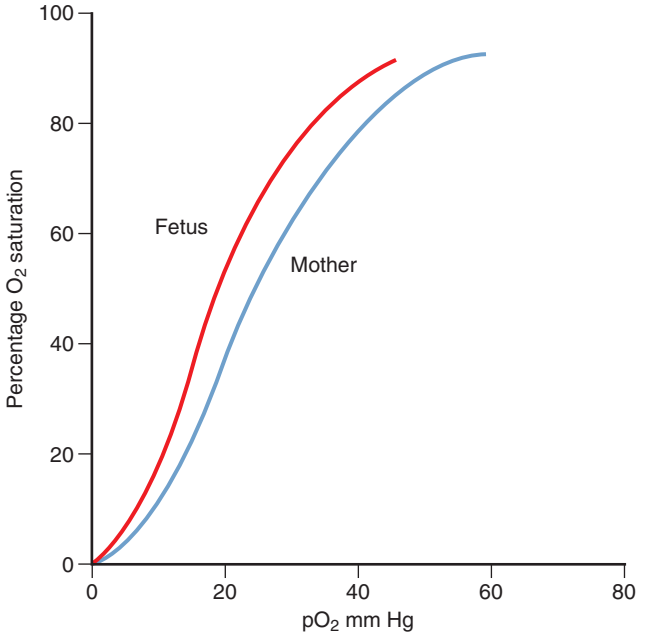

FIGURE 2-7. Oxyhemoglobin dissociation curves of maternal and fetal human blood at pH 7.4 and 37°C. (Modified from Hellegers AE, Schruefer JJP: Normograms and empirical equations relating oxygen tension, percentage saturation, and pH in maternal and fetal blood. Am J Obstet Gynecol 81:377, 1961.)

The proportion of HgbF to HgbA changes between 26 and 40 weeks' gestation. HgbF decreases linearly from 100% to about 70% so that HgbA accounts for 30% of fetal hemoglobin at term. This change in expression from γ- to β-globulin synthesis takes place in erythroid progenitor cells. Although the basis for this switching is not yet known, our understanding of human globin gene regulation has provided important insights into several fetal hemoglobin disorders such as the thalassemias and sickle cell anemia. Duplication of the α-genes on chromosome 16 provides the normal fetus with four gene loci. The genes for the remaining globins are located on chromosome 11 and consist of $^{G}\gamma$, $^{A}\gamma$, δ and β. The two γ-genes differ in the amino acid in position 36; glycine versus alanine. Hemoglobin A synthesis is dictated by the γ- and β-genes, HgbF

by α and γ, and $HgbA_2$ by α and δ. Sequences in the δ region may be responsible for the relative expression of the γ-gene, such that fetal hemoglobin persists when these are absent.

Fetal Kidney

Overall fetal water and electrolyte homeostasis is primarily mediated by fetal–maternal exchange across the placenta. However, urine production by the fetal kidney is essential to maintenance of amniotic fluid volume and composition. Although absolute glomerular filtration rate (GFR) increases during the third trimester, GFR per gram kidney weight does not change because GFR and fetal kidney weight increase in parallel. The genesis of new glomeruli is complete by about 36 weeks. Subsequent increases in GFR reflect increases in glomerular surface area for filtration, effective filtration pressure, and capillary filtration coefficient. Although glomerular filtration is related to hydrostatic pressure, and fetal blood pressure increases in the third trimester, both renal blood flow per gram kidney weight and filtration fraction (GFR/renal plasma flow) remain constant.[74] Newborn increases in filtration fraction parallel increases in arterial pressure, suggesting the lower hydrostatic pressure within the glomerulus contributes to the relatively low filtration fraction and GFR of the intrauterine kidney.[74] A mild glomerulotubular imbalance may describe the early gestation fetus. However, renal tubular sodium and chloride reabsorptions increase in late gestation, such that glomerulotubular balance is maintained in the third-trimester fetus.[74]

Although fetal GFR is low, the daily urine production rate is large (equaling 60% to 80% of the amniotic fluid volume). The large urine output results from the large portion of the filtered water (20%) that is excreted in the form of hypotonic urine. The positive free water clearance characterizing fetal renal function originally led to the hypothesis that the fetal kidney lacked AVP receptors. However, ovine fetal renal collecting duct responses to AVP can be demonstrated in the second trimester, indicating diminished urine-concentrating ability is not caused by AVP receptor absence. Fetal renal V_2 receptors mediate AVP-induced tubular water reabsorption, and functional V_2 receptors are present in the fetal kidney by the beginning of the last third of gestation.[72] In addition, AVP-induced cyclic adenosine monophosphate (cAMP) production is not different from the adult, and AVP-induced apical tubular water channels (aquaporin II) are expressed in the fetal kidney. In fact, the selective AVP V_2 receptor agonist [deamino^1,D-Arg^8]-vasopressin (dDAVP) appropriately increases fetal renal water reabsorption without affecting blood pressure or heart rate.[72] Thus, V_2 receptors mediate AVP effects on fetal urine production and amniotic fluid volume.[72] Instead, the reduced concentrating ability of the fetal kidney primarily reflects reductions in proximal tubular sodium reabsorption, short juxtamedullary nephron loops of Henle, and limited medullary interstitial urea concentrations.

Although fetal plasma renin activity levels are high, effective uncoupling of AII production from plasma renin activity and a high placental clearance rate for AII serve to minimize increases in fetal plasma AII levels. Limiting fluctuations in fetal plasma AII levels may be advantageous for fetal renal function regulation. For example, fetal AII infusion increases fetal mean arterial pressure, and renal and placental vascular resistances. In contrast, fetal treatment with the ACE inhibitor captopril increases plasma renin activity and decreases arterial blood pressure, renal vascular resistance, and filtration fraction, and urine flow effectively ceases. Given the potential for AII to decrease placental blood flow, uncoupling of renin-induced angiotensin I production, limited ACE activity, and augmented placental AII clearance may protect the fetal cardiovascular system from large increases in plasma AII levels. Collectively, plasma AII levels appear to be regulated within a very narrow range, and this regulation may be important to overall fetal homeostasis.

Atrial natriuretic factor (ANF) granules are present in the fetal heart, and fetal plasma ANF levels are elevated relative to the adult. Fetal plasma ANF levels increase in response to volume expansion, and ANF infusion evokes limited increases in ovine fetal renal sodium excretion. Fetal ANF infusion also decreases fetal plasma volume, with minimal effect on blood pressure. These observations suggest that ANF actions in the fetus are primarily directed at volume homeostasis, with minimal cardiovascular effects.

The ability of the fetal kidney to excrete titratable acid and ammonia is limited relative to the adult. In addition, the threshold for fetal renal bicarbonate excretion (defined as the excretion of a determined amount of bicarbonate per unit GFR) is much lower than in the adult. That is, fetal urine tends to be alkaline at relatively low plasma bicarbonate levels, despite the high fetal arterial P_{CO_2}. Because fetal renal tubular mechanisms for glucose reabsorption are qualitatively similar to those in the adult, fetal renal glucose excretion is limited. In fact, the maximum ability of the fetal kidney to reabsorb glucose exceeds that of the adult when expressed as a function of GFR.

Fetal Gastrointestinal System

Gastrointestinal Tract

Amniotic fluid contains measurable glucose, lactate, and amino acid concentrations, raising the possibility that fetal swallowing could serve as a source of nutrient uptake. Fetal swallowing contributes importantly to somatic growth and gastrointestinal development as a result of the large volume of ingested fluid. **About 10% to 15% of fetal nitrogen requirements may result from swallowing of amniotic fluid protein.[75] Amino acids and glucose are absorbed and utilized by the fetus if they are administered into the fetal gastrointestinal tract.[76] Furthermore, intragastric ovine fetal nutrient administration partially ameliorates fetal growth restriction induced by maternal malnutrition.**[77] Further evidence for the role of swallowing in fetal growth results from studies demonstrating that impairment of fetal rabbit swallowing at 24 days' gestation (term = 31 days) induces an 8% weight decrease (compared to controls) by 28 days.[78] The fetal gastrointestinal tract is directly affected, as esophageal ligation of fetal rabbit pups results in marked reductions in gastric and intestinal tissue weight and gastric acidity.[79] Reductions in gastrointestinal and somatic growth were reversed by fetal intragastric infusion of amniotic fluid.[79] Similarly, esophageal ligation of 90-day ovine fetuses (term = 145 to 150 days) induces a 30% decrease of small intestine villus height[80] and a reduction in liver,

pancreas, and intestinal weight.[81] Although ingestion of amniotic fluid nutrients may be necessary for optimal fetal growth, trophic growth factors within the amniotic fluid also importantly contribute. Thus, the reduction in fetal rabbit weight induced by esophageal ligation is reversed by gastric infusion of epidermal growth factor.[82] Studies in human infants support the association of fetal swallowing and gastrointestinal growth as upper gastrointestinal tract obstructions are associated with a significantly greater rate of human fetal growth restriction as compared to fetuses with lower gastrointestinal obstructions.[83]

Blood flow to the fetal intestine does not increase during moderate levels of hypoxemia. The artery–mesenteric vein difference in oxygen content is also unchanged so that at a constant blood flow intestinal oxygen consumption can remain the same during moderate hypoxemia. **However, with more pronounced hypoxemia, fetal intestinal oxygen consumption falls as blood flow decreases and the oxygen content difference across the intestine fails to widen. The result is a metabolic acidosis in the blood draining the mesenteric system**.

Liver

Near term, the placenta is the major route for bilirubin elimination. Less than 10% of an administered bilirubin load is excreted in the fetal biliary tree over a 10-hour period; about 20% remains in plasma. Thus, the fetal metabolic pathways for bilirubin and bile salts remain underdeveloped at term. The cholate pool size (normalized to body surface area) is one third and the synthetic rate one half adult levels. In premature infants, cholate pool size and synthesis rates represent less than half and one third, respectively, of term infant values. In fact, premature infant intraluminal duodenal bile acid concentrations are near or below the level required to form lipid micelles.[84] The unique attributes of the fetal hepatic circulation were detailed during the earlier discussion of fetal circulatory anatomy. Notably, the fetal hepatic blood supply primarily derives from the umbilical vein. The left lobe receives its blood supply almost exclusively from the umbilical vein (there is a small contribution from the hepatic artery), whereas the right lobe receives blood from the portal vein as well. **The fetal liver under normal conditions accounts for about 20% of total fetal oxygen consumption.** Because hepatic glucose uptake and release are balanced, net glucose removal by the liver under normal conditions is minimal. During episodes of hypoxemia, β-adrenergic receptor–mediated increases in hepatic glucose release account for the hyperglycemia characteristic of short-term fetal hypoxemia.[85] **Hypoxia severe enough to decrease fetal oxygen consumption selectively reduces right hepatic lobe oxygen uptake, which exceeds that of the fetus as a whole. In contrast, oxygen uptake by the left lobe of the liver is unchanged.**

Fetal Adrenal and Thyroid

Adrenal

The fetal anterior pituitary secretes ACTH in response to "stress," including hypoxemia. The associated increase in cortisol exerts feedback inhibition of the continued ACTH response.[86] In the fetus and adult, pro-opiomelanocortin posttranslational processing gives rise to ACTH, corticotropin-like intermediate lobe peptide (CLIP), and α-melanocyte–stimulating hormone (α-MSH). The precursor peptide preproenkephalin is a distinct gene product giving rise to the enkephalins. Fetal pro-opiomelanocortin processing differs from the adult. For example, although ACTH is present in appreciable amounts, the fetal pituitary contains large amounts of CLIP and α-MSH. The fetal ratio of CLIP plus α-MSH to ACTH decreases from the end of the first trimester to term. Because pituitary corticotropin-releasing hormone (CRH) expression is relatively low until late gestation, AVP serves as the major CRF in early gestation. With increasing gestational age, fetal cortisol levels progressively increase secondary to hypothalamic-pituitary axis maturation. Cortisol is important to pituitary maturation because it shifts corticotrophs from the fetal to the adult type and to adrenal maturation through regulation of ACTH receptor numbers.[87]

On a body weight basis, the fetal adrenal gland is an order of magnitude larger than in the adult. This increase in size is due to the presence of an adrenal cortical definitive zone and a so-called fetal zone that constitutes 85% of the adrenal at birth. Cortisol and mineralocorticoids are the major products of the fetal definitive zone, and fetal cortisol secretion is regulated by ACTH but not human chorionic gonadotrophin (hCG). Low-density lipoprotein–bound cholesterol (see Receptor Mediated Endocytosis/Exocytosis earlier in this chapter) is the major source of steroid precursor in the fetal adrenal. Because the enzyme 3α-hydroxysteroid dehydrogenase is lacking in the fetal adrenal, dehydroepiandrosterone sulfate (DHEAS) is the major product of the fetal zone. At midgestation, DHEAS secretion is determined by both ACTH and hCG. Both fetal ACTH and cortisol levels are relatively low during most of gestation, and there is not a clear correlation between plasma ACTH levels and cortisol production. This apparent dissociation between fetal ACTH levels and cortisol secretion may be explained by (1) differences in ACTH processing and the presence of the large-molecular-weight pro-opiomelanocortin processing products (CLIP and α-MSH) may suppress ACTH action on the adrenal until late gestation (when ACTH becomes the primary product), (2) fetal adrenal definitive zone ACTH responsiveness may increase, or (3) placental ACTH and/or posttranslational processing intermediates may affect the adrenal response to ACTH.

Resting fetal plasma norepinephrine levels exceed epinephrine levels approximately tenfold. The fetal plasma levels of both catecholamines increase in response to hypoxemia, with norepinephrine levels invariably higher than epinephrine levels. Under basal conditions, norepinephrine is secreted at a higher rate than epinephrine, and this relationship persists during a hypoxemic stimulus. Plasma norepinephrine levels increase in response to acute hypoxemia, but decline to remain above basal levels with persistent (greater than 5 minutes) hypoxemia. In contrast, adrenal epinephrine secretion begins gradually, but persists during 30 minutes of hypoxemia. These observations are consistent with independent sites of synthesis and regulation of the two catecholamines.[88] Although the initial fetal blood pressure elevation during hypoxemia correlates with increases in norepinephrine, afterward the correlation between plasma norepinephrine and hypertension is lost.

Thyroid

The normal placenta is impermeable to thyroid-stimulating hormone (TSH), and triiodothyronine (T_3) transfer is minimal.[89] However, appreciable levels of maternal thyroxine (T_4) are seen in infants with congenital hypothyroidism. **By week 12 of gestation, thyrotropin-releasing hormone (TRH) is present in the fetal hypothalamus, and TRH secretion and/or pituitary sensitivity to TRH increases progressively during gestation. Extrahypothalamic sites including the pancreas also may contribute to the high TRH levels observed in the fetus. Measurable TSH is present in the fetal pituitary and serum, and T_4 is measurable in fetal blood by week 12 of gestation.** Thyroid function is low until about 20 weeks, when T_4 levels increase gradually to term. TSH levels increase markedly between 20 and 24 weeks, then slowly decrease until delivery. **Fetal liver T_4 metabolism is immature, characterized by low T_3 levels until week 30. In contrast, reverse T_3 levels are high until 30 weeks, thereafter declining steadily until term.**

Fetal Central Nervous System

Clinically relevant indicators of fetal central nervous system function are body movements and breathing movements. Fetal activity periods in late gestation are often termed *active* or *reactive* and *quiet* or *nonreactive*. The active cycle is characterized by clustering of gross fetal body movements, a high heart rate variability, heart rate accelerations (often followed by decelerations), and fetal breathing movements. The quiet cycle is noted by absence of fetal body movements and a low variability in the fetal heart period. Fetal heart period variability in this context refers to deviations about the model heart rate period averaged over short (seconds) periods,[90] and is distinct from beat-to-beat variability. **In the last 6 weeks of gestation, the fetus is in an active state 60% to 70% of total time. The average duration of quiet periods ranges from 15 to 23 minutes (see Table IV in Visser and colleagues[90] for a review).**

The fetal electrocorticogram shows two predominant patterns. Low-voltage (high-frequency) electrocortical activity is associated with bursts of rapid eye movements and fetal breathing movements. Similar to rapid eye movement sleep in the adult, inhibition of skeletal muscle movement is most pronounced in muscle groups having a high percentage of spindles. Thus, the diaphragm, which is relatively spindle free, is not affected. Fetal body movements during low-voltage electrocortical activity are reduced relative to the activity seen during high-voltage (low-frequency) electrocortical activity.[91] Polysynaptic reflexes elicited by stimulation of afferents from limb muscles are relatively suppressed when the fetus is in the low-voltage state.[92] Short-term hypoxia[91] or hypoxemia inhibit reflex limb movements, with the inhibitory neural activity arising in the midbrain area.[92] Fetal cardiovascular and behavioral responses to maternal cocaine use previously have been attributed to reductions in uteroplacental blood flow and resulting fetal hypoxia. However, fetal sheep studies indicate acute fetal cocaine exposure evokes catecholamine, cardiovascular, and neurobehavioral effects in the absence of fetal oxygenation changes.[93] It is not yet clear whether cocaine-induced reductions in fetal low-voltage electrocortical activity reflect changes in cerebral blood flow or a direct cocaine effect on norepinephrine stimulation of central regulatory centers. However, these observations are consistent with the significant neurologic consequences of cocaine use during pregnancy.

Fetal breathing patterns are rapid and irregular in nature, and are not associated with significant fluid movement into the lung.[94] The central medullary respiratory chemoreceptors are stimulated by carbon dioxide,[95] and fetal breathing is maintained only if central hydrogen ion concentrations remain in the physiologic range. That is, central (medullary cerebrospinal fluid) acidosis stimulates respiratory incidence and depth and alkalosis results in apnea. Paradoxically, hypoxemia markedly decreases breathing activity, possibly due to inhibitory input from centers above the medulla.[96]

Glucose is the principal substrate for oxidative metabolism in the fetal brain under normal conditions. During low-voltage electrocortical activity, cerebral blood flow and oxygen consumption are increased relative to high-voltage values, with an efflux of lactate. During high voltage the fetal brain shows a net uptake of lactate.[97] The fetal cerebral circulation is sensitive to changes in arterial oxygen content. Despite marked hypoxia-induced increases in cerebral blood flow, cerebral oxygen consumption is maintained without widening of the arterial-venous oxygen content difference across the brain.[98] Increases in carbon dioxide also cause cerebral vasodilation. However, the response to hypercarbia is reduced relative to the adult.

SUMMARY

The fetus and placenta depend on unique physiologic systems to provide an environment supporting fetal growth and development, in preparation for transition to extrauterine life. Because specific functions of the various physiologic systems are often gestation specific, differences between the fetus and adult of one species are often larger than the differences between systems. Thus, the clinician or investigator concerned with fetal life or neonatal transition must fully appreciate these aspects of fetal physiology and their application to their area of study or treatment.

KEY POINTS

- Pregnancy-associated cardiovascular changes include a doubling of maternal cardiac output and a 40% increase in blood volume.
- Uterine blood flow at term averages 750 mL/min, or 10% to 15% of maternal cardiac output.
- Normal term placental weight averages 450 g, representing approximately one seventh (one sixth with cord and membranes) of fetal weight.
- Mean amniotic fluid volume increases from 250 to 800 mL between 16 and 32 weeks, and decreases to 500 mL at term.
- Fetal urine production ranges from 400 to 1200 mL/day and is the primary source of amniotic fluid.

- The fetal umbilical circulation receives approximately 40% of fetal combined ventricular output (300 mL/mg/min).
- Umbilical blood flow is 70 to 130 mL/min after 30 weeks' gestation.
- Fetal cardiac output is constant over a heart rate range of 120 to 180 beats/min.
- The fetus exists in a state of aerobic metabolism, with arterial PO_2 values in the 20 to 25 mm Hg range.
- Approximately 20% of the fetal oxygen consumption of 8 mL/kg/min is required in the acquisition of new tissue.

Major adaptations in maternal anatomy, physiology, and metabolism are required for a successful pregnancy. Hormonal changes, initiated before conception, significantly alter maternal physiology and persist through both pregnancy and the initial postpartum period. Although these adaptations are profound and affect nearly every organ system, women return to the nongravid state with minimal residual changes.[1] A full understanding of physiologic changes is necessary to differentiate between normal alternations and those that are abnormal. This chapter describes maternal adaptations in pregnancy and gives specific examples of how they may affect care. Finally, although women may tire of repetitive reassurance that "it is simply normal and of no concern," a complete understanding of physiologic changes allows each obstetrician to provide a more thorough explanation for various changes and symptoms.

Many of the changes to routine laboratory values caused by pregnancy are described in the following text. For a comprehensive review of normal reference ranges for common laboratory tests by trimester, the reader is encouraged to refer to Appendix A1.

BODY WATER METABOLISM

The increase in total body water of 6.5 to 8.5 L by the end of gestation represents one of the most significant adaptations of pregnancy. The water content of the fetus, placenta, and amniotic fluid at term accounts for about 3.5 L. **Additional water is accounted for by expansion of the**

maternal blood volume by 1500 to 1600 mL, plasma volume by 1200 to 1300 mL, and red blood cells by 300 to 400 mL. The remainder is attributed to extravascular fluid, intracellular fluid in the uterus and breasts, and expanded adipose tissue. As a result, pregnancy is a condition of chronic volume overload with active sodium and water retention secondary to changes in osmoregulation and the renin-angiotensin system. Increase in body water content contributes to maternal weight gain, hemodilution, physiologic anemia of pregnancy, and the elevation in maternal cardiac output (CO). Inadequate plasma volume expansion has been associated with increased risks for preeclampsia and fetal growth restriction.

Osmoregulation

Expansion in plasma volume begins shortly after conception, partially mediated by a change in maternal osmoregulation through altered secretion of arginine vasopressin (AVP) by the posterior pituitary. Water retention exceeds sodium retention; even though an additional 900 mEq of sodium is retained during pregnancy, **serum levels of sodium decrease by 3 to 4 mmol/L.** This is mirrored by decreases in overall plasma osmolality of 8 to 10 mOsm/kg, a change that is in place by 10 weeks' gestation and continues through 1 to 2 weeks postpartum[2] (Figure 3-1). Similarly, the threshold for thirst and vasopressin release changes early in pregnancy; during gestational weeks 5 to 8, an increase in water intake occurs and results in a transient increase in urinary volume but a net increase in total body water. Initial changes in AVP regulation may be due to placental signals involving nitric oxide (NO) and the hormone relaxin.[3] After 8 weeks' gestation, the new steady state for osmolality has been established with little subsequent change in water turnover, resulting in decreased polyuria. **Pregnant women perceive fluid challenges or dehydration normally with changes in thirst and AVP secretion, but at a new, lower "osmostat."**[3]

Plasma levels of AVP remain relatively unchanged despite heightened production, owing to a threefold to fourfold increase in the metabolic clearance. Increased clearance results from a circulating vasopressinase synthesized by the placenta that rapidly inactivates both AVP and oxytocin. This enzyme increases about 300-fold to 1000-fold over the course of gestation proportional to fetal weight, with the highest concentrations occurring in multiple gestations. **Increased AVP clearance can unmask subclinical forms of diabetes insipidus, presumably because of an insufficient pituitary AVP reserve, and causes transient diabetes insipidus with an incidence of 2 to 6 per 1000.** Typically presenting with both polydipsia and polyuria, hyperosmolality is usually mild unless the thirst mechanism is abnormal or access to water is limited.[4]

Salt Metabolism

Sodium metabolism is delicately balanced, facilitating a net accumulation of about 900 mEq of sodium. Sixty percent of the additional sodium is contained within the fetoplacental unit (including amniotic fluid) and is lost at birth. By 2 months postpartum, the serum sodium returns to preconceptional levels. Pregnancy increases the preference for sodium intake, but the primary mechanism

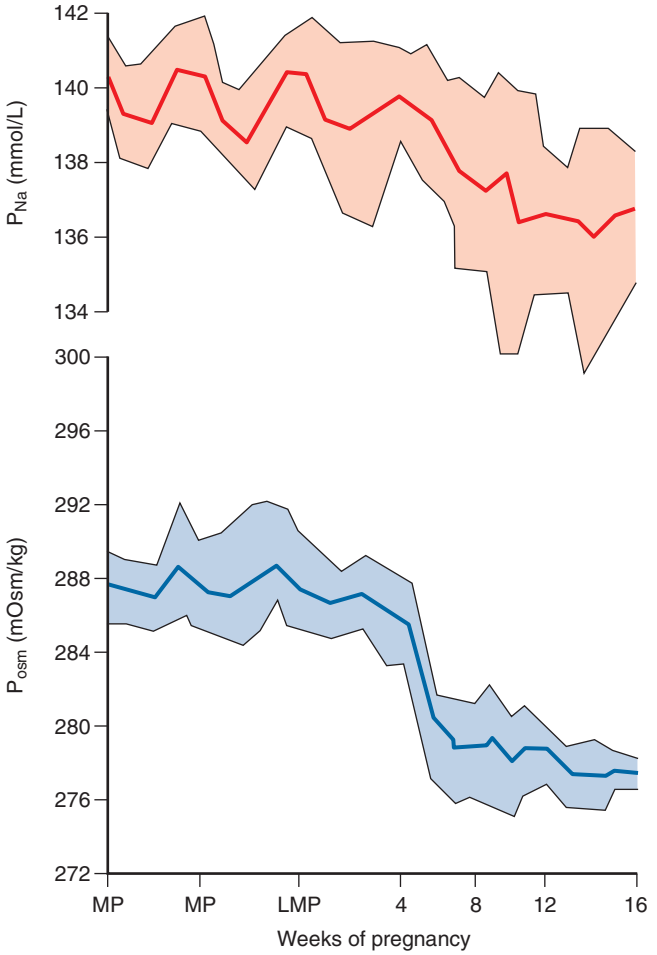

FIGURE 3-1. Plasma osmolality and plasma sodium during human gestation (n = 9: mean values ± SD). *LMP,* Last menstrual period; *MP,* menstrual period. (From Davison JM, Vallotton MB, Lindheimer MD: Plasma osmolality and urinary concentration and dilution during and after pregnancy: Evidence that the lateral recumbency inhibits maximal urinary concentration ability. Br J Obstet Gynecol 88:472, 1981.)

is enhanced tubular sodium reabsorption. Increased glomerular filtration raises the total filtered sodium load from 20,000 to about 30,000 mmol/day; sodium reabsorption must increase to prevent sodium loss. However, the adaptive rise in tubular reabsorption surpasses the increase in filtered load, resulting in an additional 2 to 6 mEq of sodium reabsorption per day. Alterations in sodium handling represent the largest renal adjustment that occurs in gestation.[5] Hormonal control of sodium balance is under the opposing actions of the renin-angiotensin-aldosterone system (RAAS) and the natriuretic peptides, and both are modified during pregnancy.

Renin-Angiotensin-Aldosterone System

Normal pregnancy is characterized by a marked increase in all components of the RAAS system. In early pregnancy, reduced systemic vascular tone (attributed to gestational hormones and increased NO production) results in decreased mean arterial pressure (MAP). In turn, decreased

MAP activates adaptations to preserve intravascular volume through sodium retention.[6] Plasma renin activity, renin substrate (angiotensinogen), and angiotensin levels are all increased a minimum of fourfold to fivefold over nonpregnant levels. Activation of these components of RAAS leads to twofold elevated levels of aldosterone by the third trimester, increasing sodium reabsorption and preventing sodium loss. Despite the elevated aldosterone levels in late pregnancy, normal homeostatic responses still occur to changes in salt balance, fluid loss, and postural stimuli. In addition to aldosterone, other hormones that may contribute to increased tubular sodium retention include deoxycorticosterone and estrogen.

Atrial and Brain Natriuretic Peptide

The myocardium releases neuropeptides that serve to maintain circulatory homeostasis. Atrial natriuretic peptide (ANP) is secreted primarily by the atrial myocytes in response to dilation, and in response to end-diastolic pressure and volume, the ventricles secrete brain natriuretic peptide (BNP). Both peptides have similar physiologic actions, acting as diuretics, natriuretics, vasorelaxants, and overall antagonists to the RAAS. Elevated levels of ANP and BNP are found in both physiologic and pathologic conditions of volume overload and can be used to screen for congestive heart failure outside of pregnancy in symptomatic patients. Because pregnant women frequently present with dyspnea and many of the physiologic effects of conception mimic heart disease, whether pregnancy affects the levels of these hormones is clinically important. Gestational alterations in ANP are controversial because some authors have reported higher plasma levels during different stages of pregnancy, whereas others have reported no change. In a meta-analysis by Castro and colleagues,[7] ANP levels were 40% higher during gestation and 150% higher during the first postpartum week.

The circulating concentration of BNP is 20% less than that of ANP in normal individuals and has been found to be more useful in the diagnosis of congestive heart failure. Levels of BNP are reported to increase largely in the third trimester of pregnancy compared with first-trimester levels (21.5 ± 8 pg/mL versus 15.2 ± 5 pg/mL) and are highest in pregnancies complicated by preeclampsia (37.1 ± 10 pg/mL). The levels throughout pregnancy have been found to be higher than in nonpregnant controls. In pregnancies with preeclampsia, higher levels of BNP are associated with echocardiographic evidence of left ventricular enlargement.[8] **Although the levels of BNP are increased during pregnancy and with preeclampsia, the mean values are still lower than the levels used to screen for cardiac dysfunction (>75 to 100 pg/mL) and, therefore, can be used to screen for congestive heart failure.**[9]

CARDIOVASCULAR SYSTEM

Pregnancy causes profound physiologic changes in the cardiovascular system. A series of adaptive mechanisms are activated as early as 5 weeks' gestation to maximize oxygen delivery to maternal and fetal tissues.[6] In most women, these physiologic demands are well tolerated. However, in certain cardiac diseases, maternal morbidity and even mortality may occur.

Heart

The combination of displacement of the diaphragm and the effect of pregnancy on the shape of the rib cage (described in the respiratory section below) displaces the heart upward and to the left. In addition, the heart rotates on its long axis, moving the apex somewhat laterally, resulting in an increased cardiac silhouette on radiographic studies, without a true change in the cardiothoracic ratio. Associated radiographic findings include an apparent straightening of the border of the left side of the heart and increased prominence of the pulmonary conus. **Therefore, the diagnosis of cardiomegaly by simple radiography should be confirmed by echocardiogram if clinically appropriate.**[10]

Although true cardiomegaly is rare, physiologic myocardial hypertrophy of the heart is consistently observed as a result of expanded blood volume in the first half of the pregnancy and progressively increasing afterload in later gestation. **These structural changes in the heart are similar to those found in response to exercise and result in eccentric hypertrophy as opposed to concentric hypertrophy that is seen with disease states such as hypertension or aortic stenosis.** The eccentric hypertrophy enables the heart to enhance its pumping capacity in response to increased demand, making the pregnant heart mechanically more efficient.[11,12] Most changes begin early in the first trimester and peak by 30 to 34 weeks' gestation. Left ventricular end-diastolic dimension increases 12% over preconceptional values by M-mode echocardiography. Concurrently, left ventricular wall mass increases by 52% (mild myocardial hypertrophy), and atrial diameters increase bilaterally, peaking at 40% above nonpregnant values.[12] Pulmonary capillary wedge pressures (PCWPs) are stable, reflecting a combination of decreased pulmonary vascular resistance and increased blood volume. Twin pregnancies increase myocardial hypertrophy, atrial dilation, and end-diastolic ventricular measurements even further.[13] Unlike the heart of an athlete that regresses rapidly with inactivity, the pregnant heart regresses in size less rapidly and takes up to 6 months to return to normal.[14]

Evaluation of left ventricular function (contractility) is difficult in pregnancy because it is strongly influenced by changes in heart rate (HR), preload, and afterload. Despite the increase in stroke volume (SV) and CO, normal pregnancy is not associated with hyperdynamic left ventricular function during the third trimester, as measured by ejection fraction, left ventricular stroke work index, or fractional shortening of the left ventricle. However, some studies have shown that contractility might be slightly increased in the first two trimesters, whereas other articles report no change throughout the pregnancy, and some report a decline toward term.[12] One recent study showed that in the third trimester the cardiac systolic function declines as evidenced by a decrease in the ejection fraction and the systolic myocardial velocities compared with the first trimester. The results of this study are consistent with impaired contraction and relaxation of the left ventricle at the end of pregnancy and suggest that a decline in cardiac function at term is a feature of normal pregnancy and that an exaggeration of this decline may explain the etiology for peripartum cardiomyopathy.[15]

Within the past decade, clinicians and researchers have focused on abnormalities of diastolic function as important

contributors to cardiac disease and symptom severity, especially in the setting of normal or near-normal systolic function.[16] In a review, diastolic dysfunction was pinpointed as a leading cause of cardiac failure in pregnancy.[17] During the past 5 years, the effects of pregnancy on diastolic function have been thoroughly investigated by using pulsed-wave Doppler echocardiography.[12] In young healthy women, the left ventricle is elastic; therefore, diastolic relaxation is swift, and ventricular filling occurs almost completely by early diastole with minimal contribution from the atrial kick. The E/A ratio compares the peak mitral flow velocity in early diastole (E) to the peak atrial kick velocity (A); although both velocities increase in pregnancy, the overall ratio falls because of a greater rise in the A-wave velocity. **The rise in the A value, which begins in the second trimester and increases throughout the third trimester, indicates the increased importance of the atrial contraction in left ventricular filling during pregnancy.**[12] Veille and associates determined that in healthy women, pregnancy did not adversely affect baseline diastolic function, but that at maximal exercise, diastolic function was impaired. The reason for the impairment was attributed to increased left ventricular wall stiffness. The authors further speculated that this change may be the limiting factor for exercise in pregnancy.[18]

Cardiac Output

One of the most remarkable changes in pregnancy is the tremendous increase in CO. Van Oppen and coworkers reviewed 33 cross-sectional and 19 longitudinal studies and found greatly divergent results on when CO peaked, the magnitude of the rise in CO before labor, and the effect of the third trimester on CO.[19] **However, all of the studies agreed that CO increased significantly beginning in early pregnancy, peaking at an average of 30% to 50% above preconceptional values.** In a longitudinal study by Robson and associates using Doppler echocardiography, CO increased by 50% at 34 weeks from a prepregnancy value of 4.88 L/min to 7.34 L/min[19,20] (Figure 3-2). In twin gestations, CO incrementally increases an additional 20% above that of singleton pregnancies.[13] Robson and associates demonstrated that, by 5 weeks' gestation, CO has already risen by more than 10%. By 12 weeks, the rise in output is 34% to 39% above nongravid levels, accounting for about 75% of the total increase in CO during pregnancy. **Although the literature is not clear regarding the exact gestation when CO peaks, most studies point to a range between 25 and 30 weeks.**[20] The data on whether the CO continues to increase in the third trimester are very divergent, with equal numbers of good longitudinal studies showing a mild decrease, a slight increase, or no change.[19] The differences in these studies cannot be explained by differences in investigative techniques, position of the women during measurements, or study design. This apparent discrepancy appears to be explained by the small number of individuals in each study and the probability that the course of CO during the third trimester is determined by factors specific to the individual.[19] In a recent study, Desai and coworkers reported that CO in the third trimester is significantly correlated with fetal birthweight and maternal height and weight.[21]

Most of the increase in CO is directed to the uterus, placenta, and breasts. In the first trimester, as in the nongravid state, the uterus receives 2% to 3% of CO and the breasts 1%. The percentage of CO going to the kidneys (20%), skin (10%), brain (10%), and coronary arteries (5%) remains at similar nonpregnant percentages, but because of the overall increase in CO, this results in an increase in absolute blood flow of about 50%.[22] By term, the uterus receives 17% (450 to 650 mL/min) and the breasts 2%, mostly at the expense of a reduction of the fraction of the CO going to the splanchnic bed and skeletal muscle. The absolute blood flow to the liver is not changed, but the overall percentage of CO is significantly decreased.

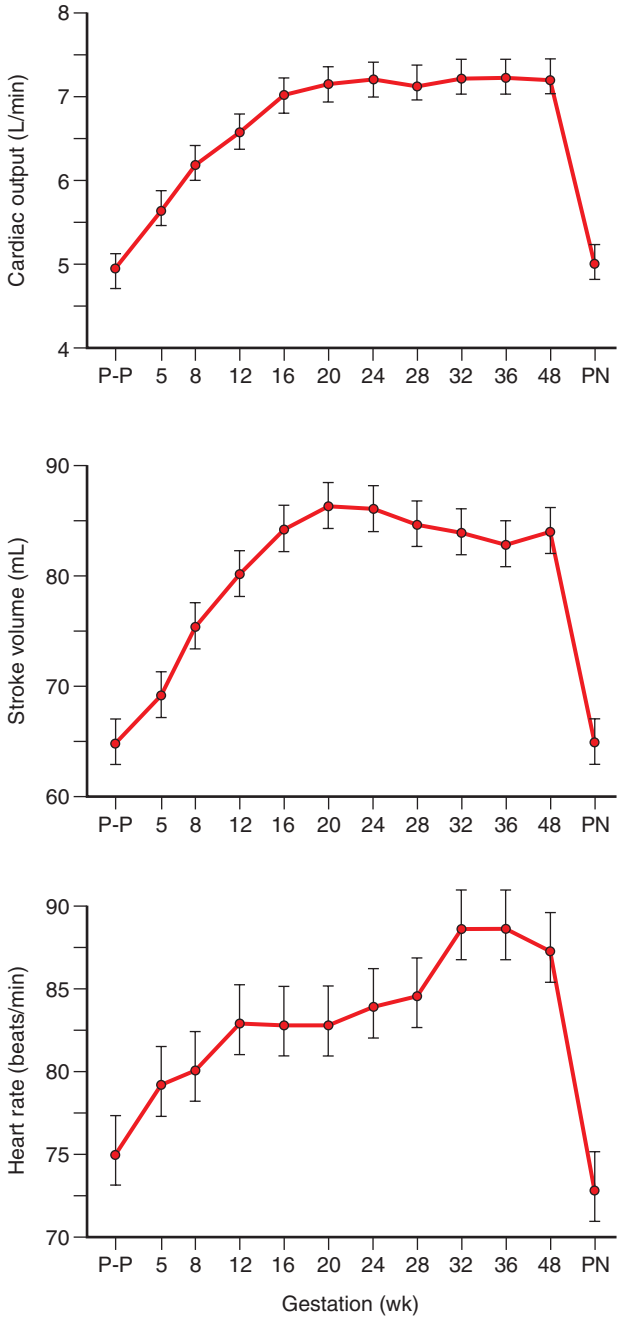

FIGURE 3-2. Increase in cardiac output, stroke volume, and heart rate from the nonpregnant state throughout pregnancy. *PN,* Postnatal; *P-P,* prepregnancy. (From Hunter S, Robson S: Adaptation of the maternal heart in pregnancy. Br Heart J 68:540, 1992.)

CO is the product of SV and HR (CO = SV × HR), both of which increase during pregnancy and contribute to the overall rise in CO. An initial rise in the HR occurs by 5 weeks' gestation and continues until it peaks at 32 weeks' gestation at 15 to 20 beats above the nongravid rate, an increase of 17%. The SV begins to rise by 8 weeks' gestation and reaches its maximum at about 20 weeks, 20% to 30% above nonpregnant values. In the third trimester, it is primarily variations in the SV that determine whether CO increases, decreases, or remains stable, as described earlier.

CO in pregnancy depends on maternal position. In a study in 10 normal gravid women in the third trimester, using pulmonary artery catheterization, CO was noted to be highest in the knee-chest position and lateral recumbent position at 6.6 to 6.9 L/min. CO decreased by 22% to 5.4 L/min in the standing position (Figure 3-3). The decrease in CO in the supine position compared with the lateral recumbent position is 10% to 30%. In both the standing and the supine positions, decreased CO results from a fall in SV secondary to decreased blood return to the heart. In the supine position, the enlarged uterus compresses the inferior vena cava, reducing venous return; before 24 weeks, this effect is not observed. Of note, in late pregnancy, the inferior vena cava is completely occluded in the supine position, with venous return from the lower extremities occurring through the dilated paravertebral collateral circulation.[23]

Despite decreased CO, most supine women are not hypotensive or symptomatic because of the compensated rise in systemic vascular resistance (SVR). **However, 5% to 10% of gravidas manifest supine hypotension with symptoms of dizziness, lightheadedness, nausea, and even syncope.** The women who become symptomatic have a greater decrease in CO and blood pressure (BP) and a greater increase in HR when in the supine position than do asymptomatic women.[24] Some investigators have proposed that the determination of whether women become symptomatic depends on the development of an adequate paravertebral collateral circulation. Interestingly, with engagement of the fetal head, less of an effect on CO is seen.[23] **The ability to maintain a normal BP in the supine position may be lost during epidural or spinal anesthesia because of an inability to increase SVR. Clinically, the effects of maternal position on CO are especially important when the mother is clinically hypotensive or in the setting of a non-reassuring fetal heart rate tracing.** The finding of a decreased CO in the standing position may give a physiologic basis for the finding of decreased birthweight and placental infarctions in working women who stand for prolonged periods.

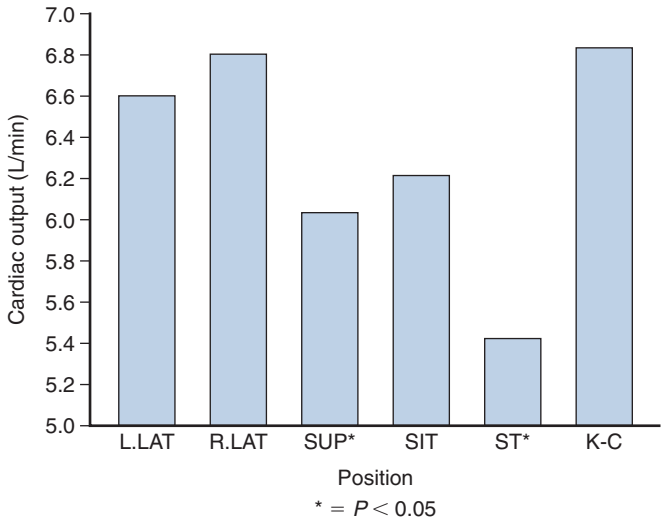

FIGURE 3-3. Effect of position change on cardiac output during pregnancy. *K-C,* Knee-chest; *L.LAT,* left lateral; *R.LAT,* right lateral; *SIT,* sitting; *ST,* standing; *SUP,* supine. (From Clark S, Cotton D, Pivarnik J, et al: Position change and central hemodynamic profile during normal third-trimester pregnancy and postpartum. Am J Obstet Gynecol 164:883, 1991.)

Arterial Blood Pressure and Systemic Vascular Resistance

BP is the product of CO and resistance (BP = CO × SVR). **Despite the large increase in CO, the maternal BP is decreased until later in pregnancy as a result of a decrease in SVR that nadirs midpregnancy and is followed by a gradual rise until term.** Even at full term, SVR remains 21% lower than prepregnancy values in pregnancies not affected by gestational hypertension or preeclampsia. The most obvious cause for the decreased SVR is progesterone-mediated smooth muscle relaxation; however, the exact mechanism for the fall in SVR is poorly understood. Earlier theories that uteroplacental circulation acts as an arteriovenous shunt are unlikely. Increased NO also contributes to decreased vascular resistance by direct actions and by blunting the vascular responsiveness to vasoconstrictors such as angiotensin II and norepinephrine. During conception, the expression and activity of NO synthase is elevated and the plasma level of cyclic guanosine monophosphate, a second messenger of NO and a mediator of vascular smooth muscle relaxation, is also increased.[25] **As a result, despite the overall increase in the RAAS, the normal gravida is refractory to the vasoconstrictive effects of angiotensin II. Gant and colleagues showed that nulliparous women who later become preeclamptic retain their response to angiotensin II before the appearance of clinical signs of preeclampsia.**[26]

Decreases in maternal BP parallel the falling SVR, with initial decreased BP manifesting at 8 weeks' gestation or earlier. Current studies did not include preconception BP or frequent first-trimester BP sampling and, therefore, cannot determine the exact time course of hemodynamic alterations. Because BP fluctuates with menstruation and is decreased in the luteal phase, it seems reasonable that BP drops immediately in early pregnancy. The diastolic BP and the mean arterial pressure [MAP = (2 × diastolic BP + systolic BP)/3] decrease more than the systolic BP, which changes minimally. The overall decrease in diastolic BP and MAP is 5 to 10 mm Hg (Figure 3-4). **The diastolic BP and the MAP nadir at midpregnancy and return to prepregnancy levels by term, and in most studies rarely exceed prepregnancy or postpartum values. However, some investigators have reported that at term, the BP is greater than in matched nonpregnant controls and believe that in the third trimester, the BP is higher than prepregnant values.** Current studies are very limited by the

absence of preconceptional values for comparison within individual patients.

The position when the BP is taken and what Korotkoff sound is used to determine the diastolic BP are important. BP is lowest in the lateral recumbent position, and the BP of the superior arm in this position is 10 to 12 mm Hg lower than the inferior arm. In the clinic, BP should be measured in the sitting position and the Korotkoff 5 sound should be used. This is the diastolic BP when the sound disappears as opposed to the Korotkoff 4, when there is a muffling of the sound. In a study of 250 gravidas, the Korotkoff 4 sound could only be identified in 48% of patients, whereas the Korotkoff 5 sound could always be determined. The Korotkoff 4 should only be used when the Korotkoff 5 occurs at 0 mm Hg.[27] Automated BP monitors have been compared with mercury sphygmomanometry during pregnancy, and although they tended to overestimate the diastolic BP, the overall results were similar in normotensive women. Of note in patients with suspected preeclampsia, automated monitors appear increasingly inaccurate at higher BPs.

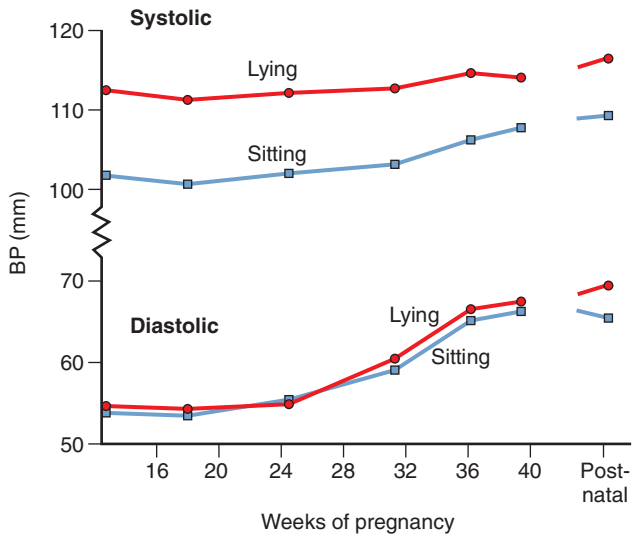

FIGURE 3-4. Blood pressure trends (sitting and lying) during pregnancy. Postnatal measures performed 6 weeks postpartum. (From MacGillivray I, Rose G, Rowe B: Blood pressure survey in pregnancy. Clin Sci 37:395, 1969.)

Venous Pressure

Venous pressure in the upper extremities remains unchanged in pregnancy but rises progressively in the lower extremities. Femoral venous pressure increases from values near 10 cm H_2O at 10 weeks' gestation to 25 cm H_2O near term.[28] From a clinical standpoint, this increase in pressure, in addition to the obstruction of the inferior vena cava by the expanding uterus, leads to the development of edema, varicose veins, and hemorrhoids, and an increased risk for deep venous thrombosis.

Central Hemodynamic Assessment

Clark and colleagues studied 10 carefully selected normal women at 36 to 38 weeks' gestation and again at 11 to 13 weeks postpartum with arterial lines and Swan-Ganz catheterization to characterize the central hemodynamics of term pregnancy (Table 3-1). As described earlier, CO, HR, SVR, and pulmonary vascular resistance change significantly with pregnancy. **In addition, clinically significant decreases were noted in colloidal oncotic pressure (COP) and the COP-PCWP difference, explaining why gravid women have a greater propensity for developing pulmonary edema with changes in capillary permeability or elevations in cardiac preload. The COP can fall even further after delivery to 17 mm Hg and, if the pregnancy is complicated by preeclampsia, can reach levels as low as 14 mm Hg.[29] When the PCWP is more than 4 mm Hg above the COP, the risk for pulmonary edema increases; therefore, pregnant women can experience pulmonary edema at PCWPs of 18 to 20 mm Hg, which is significantly lower than the typical nonpregnant threshold of 24 mm Hg.**

Normal Changes That Mimic Heart Disease

The physiologic adaptations of pregnancy lead to a number of changes in maternal signs and symptoms that can mimic cardiac disease and make it difficult to determine whether true disease is present. Dyspnea is common to both cardiac disease and pregnancy, but certain distinguishing features should be considered. First, the onset of pregnancy-related

TABLE 3-1 CENTRAL HEMODYNAMIC CHANGES

	11-12 WEEKS POSTPARTUM	36-38 WEEKS' GESTATION	CHANGE FROM NONPREGNANT STATE

NS, Not significant. Although data are not presented, the pulmonary artery pressures were not significantly different.

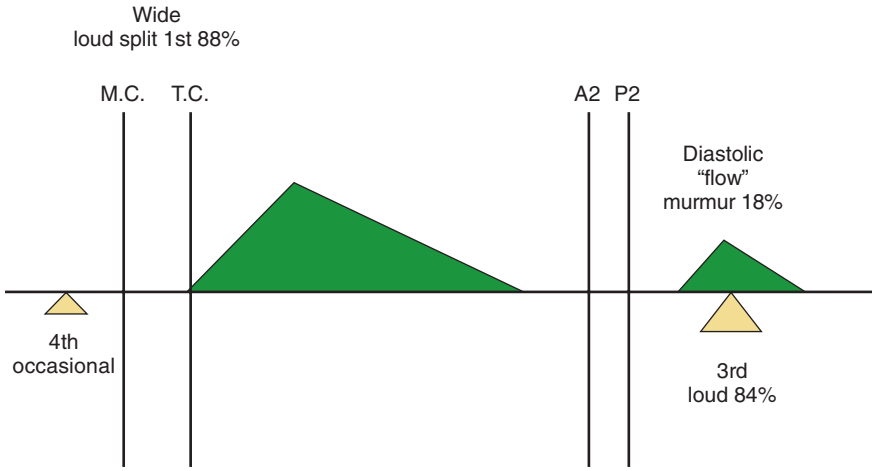

FIGURE 3-5. Summarization of the findings on auscultation of the heart in pregnancy. *M.C.,* Mitral closure; *T.C.,* tricuspid closure; *A2* and *P2,* aortic and pulmonary elements of the second sound. (From Cutforth R, MacDonald C: Heart sounds and murmurs in pregnancy. Am Heart J 71:741, 1966.)

dyspnea usually occurs before 20 weeks, and 75% of women experience it by the third trimester. **Unlike cardiac dyspnea, pregnancy-related dyspnea does not worsen significantly with advancing gestation. Second, physiologic dyspnea is usually mild, does not stop women from performing normal daily activities, and does not occur at rest.**[30] Other normal symptoms that can mimic cardiac disease include decreased exercise tolerance, fatigue, occasional orthopnea, syncope, and chest discomfort. The reason for this increase in cardiac symptoms is not an increase in catecholamine levels, because these levels are either unchanged or decreased in pregnancy. **Symptoms that should not be attributed to pregnancy and need a more thorough investigation include hemoptysis, syncope or chest pain with exertion, progressive orthopnea, or paroxysmal nocturnal dyspnea.** Normal physical findings that could be mistaken as evidence of cardiac disease include peripheral edema, mild tachycardia, jugular venous distention after midpregnancy, and lateral displacement of the left ventricular apex.

Pregnancy also alters normal heart sounds. At the end of the first trimester, both components of the first heart sound become louder, and there is exaggerated splitting. The second heart sound usually remains normal with only minimal changes. Up to 80% to 90% of gravidas demonstrate a third heart sound (S_3) after midpregnancy because of rapid diastolic filling. Rarely, a fourth heart sound may be auscultated, but typically phonocardiography is needed to detect this. Systolic ejection murmurs along the left sternal border develop in 96% of pregnancies, and increased blood flow across the pulmonic and aortic valves is thought to be the cause. Most commonly, these are midsystolic and less than grade 3. Diastolic murmurs have been found in up to 18% of gravidas, but their presence is uncommon enough to warrant further evaluation. A continuous murmur in the second to fourth intercostal space may be heard in the second or third trimester owing to the so-called mammary souffle caused by increased blood flow in the breast (Figure 3-5).

Troponin 1 and creatinine kinase-MB levels are tests used to assess for acute myocardial infarction. **Uterine contractions can lead to significant increases in the creatinine kinase-MB level, but troponin levels are not affected by pregnancy or labor.**[31]

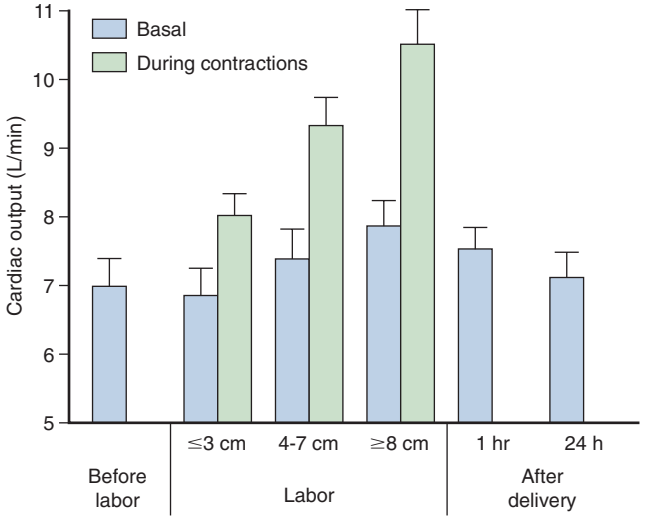

FIGURE 3-6. Changes in cardiac output during normal labor. (From Hunter S, Robson S: Adaptation of the maternal heart in pregnancy. Br Heart J 68:540, 1992.)

Effect of Labor and the Immediate Puerperium

The profound anatomic and functional changes on cardiac function reach a crescendo during the labor process. In addition to the dramatic rise in CO with normal pregnancy, even greater increases in CO occur with labor and in the immediate puerperium. In a Doppler echocardiography study by Robson and associates of 15 uncomplicated women without epidural anesthesia, the CO between contractions increased 12% during the first stage of labor[20] (Figure 3-6). This increase in CO is caused primarily by an increased SV, but HR may also increase. By the end of the first stage of labor, the CO during contractions is 51% above baseline term pregnancy values (6.99 to 10.57 L/min).

Increased CO is in part secondary to increased venous return from the 300- to 500-mL autotransfusion that occurs at the onset of each contraction as blood is expressed from the uterus.[32,33] Paralleling increases in CO, the MAP also rises in the first stage of labor, from 82 to 91 mm Hg in early labor to 102 mm Hg by the beginning of the second stage. MAP also increases with uterine contractions.

Much of the increase in CO and MAP is due to pain and anxiety. With epidural anesthesia, the baseline increase in CO is reduced, but the rise observed with contractions persists.[34] Maternal posture also influences hemodynamics during labor. **Changing position from supine to lateral recumbent increases CO. This change is greater than the increase seen before labor and suggests that during labor, CO may be more dependent on preload. Therefore, it is important to avoid the supine position in laboring women and to give a sufficient fluid bolus before an epidural to maintain an adequate preload.**

In the immediate postpartum period (10 to 30 minutes after delivery), CO reaches its maximum, with a further rise of 10% to 20%. This increase is accompanied by a fall in the maternal HR that is likely secondary to increased SV. Traditionally, this rise was thought to be the result of uterine autotransfusion as described earlier with contractions, but the validity of this concept is uncertain. **In both vaginal and elective cesarean deliveries, the maximal increase in the CO occurs 10 to 30 minutes after delivery and returns to prelabor baseline 1 hour after delivery.** The increase was 37% with epidural anesthesia and 28% with general anesthesia. Over the next 2 to 4 postpartum weeks, the cardiac hemodynamic parameters return to near-preconceptional levels.[35]

The effect of pregnancy on cardiac rhythm is limited to an increase in HR and a significant increase in isolated atrial and ventricular contractions. In a Holter monitor study by Shotan and coworkers, 110 pregnant women referred for evaluation of symptoms of palpitations, dizziness, or syncope were compared with 52 healthy pregnant women.[36] Symptomatic women had similar rates of isolated sinus tachycardia (9%), isolated premature atrial complexes (56%), and premature ventricular contractions (PVCs) (49%), but increased rates of frequent PVCs greater than 10/hour (20% versus 2%, $P = 0.03$). A subset of patients with frequent premature atrial complexes or PVCs had comparative Holter studies performed postpartum that revealed an 85% decrease in arrhythmia frequency ($P < .05$). This dramatic decline, with patients acting as their own controls, supports the arrhythmogenic effect of pregnancy. In a study of 30 healthy women placed on Holter monitors during labor, a similarly high incidence of benign arrhythmias was found (93%). Reassuringly, the prevalence of concerning arrhythmias was no higher than expected. An unexpected finding was a 35% rate of asymptomatic bradycardia, defined as a HR of less than 60 beats/minute, in the immediate postpartum period.[37] In addition, other studies have shown that women with preexisting tachyarrhythmias have an increased incidence of these rate abnormalities during pregnancy.[38] Whether labor increases the rate of arrhythmias in women with cardiac disease has not been thoroughly studied, but multiple case reports suggest labor may increase arrhythmias in these women.

FIGURE 3-7. RESPIRATORY SYSTEM

Upper Respiratory Tract

During pregnancy, the mucosa of the nasopharynx becomes hyperemic and edematous with hypersecretion of mucus due to increased estrogen. These changes often lead to marked nasal stuffiness; epistaxis is also common. Placement of nasogastric tubes may cause excessive bleeding if adequate lubrication is not used.[30] Polyposis of the nose and nasal sinuses develops in some individuals but regresses postpartum. **Because of these changes, many gravid women complain of chronic cold symptoms. However, the temptation to use nasal decongestants should be avoided because of risk for hypertension and rebound congestion.**

Mechanical Changes

The configuration of the thoracic cage changes early in pregnancy, much earlier than can be accounted for by mechanical pressure from the enlarging uterus. Relaxation of the ligamentous attachments between the ribs and sternum may be responsible. The subcostal angle increases from 68 to 103 degrees, the transverse diameter of the chest expands by 2 cm, and the chest circumference expands by 5 to 7 cm. As gestation progresses, the level of the diaphragm rises 4 cm; however, diaphragmatic excursion is not impeded and actually increases 1 to 2 cm. Respiratory muscle function is not affected by pregnancy, and maximal inspiratory and expiratory pressures are unchanged.[39]

Lung Volume and Pulmonary Function

The described alterations in chest wall configuration and the diaphragm lead to changes in static lung volumes. In a review of studies with at least 15 subjects compared with nonpregnant controls, Crapo found significant changes (Figure 3-7 and Table 3-2).[30] The elevation of the

TABLE 3-2 LUNG VOLUMES AND CAPACITIES IN PREGNANCY

MEASUREMENT	DEFINITION	CHANGE IN PREGNANCY
Respiratory rate (RR)	Number of breaths per minute	Unchanged
Vital capacity (VC)	Maximal amount of air that can be forcibly expired after maximal inspiration (IC + ERV)	Unchanged
Inspiratory capacity (IC)	Maximal amount of air that can be inspired from resting expiratory level (TV + IRV)	Increased 5% to 10%
Tidal volume (TV)	Amount of air inspired and expired with a normal breath	Increased 30% to 40%
Inspiratory reserve volume (IRV)	Maximal amount of air that can be inspired at end of normal inspiration	Unchanged
Functional residual capacity (FRC)	Amount of air in lungs at resting expiratory level (ERV + RV)	Decreased 20%
Expiratory reserve volume (ERV)	Maximal amount of air that can be expired from resting expiratory level	Decreased 15% to 20%
Residual volume (RV)	Amount of air in lungs after maximal expiration	Decreased 20% to 25%
Total lung capacity (TLC)	Total amount of air in lungs at maximal inspiration (VC + RV)	Decreased 5%

From Cruickshank DP, Wigton TR, Hays PM: Maternal physiology in pregnancy. *In* Gabbe SG, Niebyl JR, Simpson JL (eds): Obstetrics: Normal and Problem Pregnancies, 3rd ed. New York, Churchill Livingstone, 1996, p 95.

diaphragm decreases the volume of the lungs in the resting state, thereby reducing total lung capacity and the functional residual capacity (FRC). The FRC can be subdivided into expiratory reserve volume and residual volume, and both decrease.

Spirometric measurements assessing bronchial flow are unaltered in pregnancy. The forced expiratory volume in 1 second (FEV_1) and the ratio of FEV_1 to forced vital capacity are both unchanged, suggesting that airway function remains stable. In addition, peak expiratory flow rates measured using a peak flow meter seem to be unaltered in pregnancy at rates of 450 ± 16 L/min.[40] Harirah and associates performed a longitudinal study of the peak flow in 38 women from the first trimester until 6 weeks postpartum.[41] They reported that the peak flows had a statistically significant decrease as the gestation progressed, but the amount of the decrease was minimal enough to be of questionable clinical significance. Likewise a small decrease in the peak flow was found in the supine position versus the standing or sitting position. **Therefore, during gestation, both spirometry and peak flow meters can be used in diagnosing and managing respiratory illnesses, but the clinician should ensure that measurements are performed in the same maternal position.**[41]

Gas Exchange

Increasing progesterone levels drive a state of chronic hyperventilation, as reflected by a 30% to 50% increase in tidal volume by 8 weeks' gestation. In turn, increased tidal volume results in an overall parallel rise in minute ventilation, despite a stable respiratory rate (minute ventilation = tidal volume × respiratory rate). The rise in minute ventilation, combined with a decrease in FRC, leads to a larger than expected increase in alveolar ventilation (50% to 70%). **Chronic mild hyperventilation results in increased alveolar oxygen (PAO_2) and decreased arterial carbon dioxide ($PaCO_2$) from normal levels** (Table 3-3). The drop in the $PaCO_2$ is especially critical because it drives a more favorable carbon dioxide (CO_2) gradient between the fetus and mother, facilitating CO_2 transfer. **The low maternal $PaCO_2$ results in a chronic respiratory alkalosis.** Partial renal compensation occurs through increased excretion of bicarbonate, which helps maintain the pH between 7.4 and 7.45 and lowers the serum bicarbonate levels. Early in pregnancy, the arterial oxygen (PaO_2) increases (106 to 108 mm Hg) as the $PaCO_2$ decreases, but by the third trimester, a slight decrease in the PaO_2 (101 to 104 mm Hg) occurs as a result of the enlarging uterus. This decrease in the PaO_2 late in pregnancy is even more pronounced in the supine position, with a further drop of 5 to 10 mm Hg and an increase in the alveolar-to-arterial gradient to 26 mm Hg, and up to 25% of women exhibit a PaO_2 of less than 90 mm Hg.[30,42]

TABLE 3-3 BLOOD GAS VALUES IN THIRD TRIMESTER OF PREGNANCY

	PREGNANT	NONPREGNANT
PaO_2 (mm Hg)*	101.8 ± 1	93.4 ± 2.04

*Data from Templeton A, Kelman G: Maternal blood-gases, (PAO_2-PaO_2), physiological shunt and *VD*/*VT* in normal pregnancy. Br J Anaesth 48:1001, 1976. Data presented as mean ± SEM.

†Data from McAuliffe F, Kametas N, Krampl E: Blood gases in prepregnancy at sea level and at high altitude. Br J Obstet Gynaecol 108:980, 2001. Data presented as mean ± SD.

As the minute ventilation increases, a simultaneous but smaller increase in oxygen uptake and consumption occurs. Most investigators have found maternal oxygen consumption to be 20% to 40% above nonpregnant levels. This increase occurs as a result of the oxygen requirements of the fetus, the placenta, and the increased oxygen requirement of maternal organs. With exercise or during labor, an even greater rise in both minute ventilation and oxygen consumption takes place.[30] During a contraction, oxygen consumption can triple. **As a result of the increased oxygen consumption and because the functional residual capacity is decreased, there is a lowering of the maternal oxygen reserve. Therefore, the pregnant patient is more susceptible to the effects of apnea, such as during intubation when a more rapid onset of hypoxia, hypercapnia, and respiratory acidosis is seen.**

TABLE 3-4 CHARACTERISTICS OF SLEEP IN PREGNANCY

STAGE OF PREGNANCY	SUBJECTIVE SYMPTOMS	OBJECTIVE (POLYSOMNOGRAPHY)*
First trimester	Increased total sleep time: ↑ naps Increased daytime sleepiness Increased nocturnal insomnia	Increased total sleep time Decreased stages 3 and 4 non-REM sleep
Second trimester	Normalization of total sleep time Increased awakenings	Normal total sleep time Decreased stages 3 and 4 non-REM sleep Decreased REM sleep
Third trimester	Decreased total sleep time Increased insomnia Increased nocturnal awakenings Increased daytime sleepiness	Decreased total sleep time Increased awakenings after sleep onset Increased stage 1 non-REM sleep Decreased stages 3 and 4 non-REM sleep Decreased REM sleep

Modified from Santiago J, Nolledo M, Kinzler W: Sleep and sleep disorders in pregnancy. Ann Intern Med 134:396, 2001.

*Rapid eye movement (REM) sleep is important for cognitive sleep, 20% to 25% of sleep. Stages 1 and 2 non-REM sleep: light sleep, 55% of sleep. Stages 3 and 4 non-REM sleep: deep sleep, important for rest, 20% of sleep.

Sleep

Pregnancy causes both an increase in sleep disorders and significant changes in sleep profile and pattern that persist into the postpartum period.[43] Pregnancy causes such significant changes that the American Sleep Disorder Association has proposed the existence of a new term: *pregnancy-associated sleep disorder*. Emerging evidence indicates that sleep disturbances are associated with poor health outcomes in the general population and that sleep disturbances in pregnancy may contribute to certain complications of pregnancy. It is well known that hormones and physical discomforts affect sleep (Table 3-4). With the dramatic change in hormone levels and the significant mechanical effects that make women more uncomfortable, it is not difficult to understand why sleep is profoundly affected. Multiple authors have investigated the changes in sleep during pregnancy using questionnaires, sleep logs, and polysomnographic studies. From these studies, investigators have shown that most women (66% to 94%) report alterations in sleep that lead to the subjective perception of poor sleep quality. The disturbances in sleep begin as early as the first trimester and worsen as the pregnancy progresses.[44] During the third trimester, multiple discomforts occur that can impair sleep: urinary frequency, backache, general abdominal discomfort and contractions, leg cramps, restless leg syndrome, heartburn, and fetal movement. Interestingly, no changes are seen in melatonin levels, which modulate the body's circadian pacemaker.

In general, pregnancy is associated with a decrease in rapid eye movement (REM) sleep and a decrease in stages 3 and 4 non-REM sleep. REM sleep is important for cognitive thinking, and stages 3 and 4 non-REM sleep is the so-called deep sleep and is important for rest. In addition, with advancing gestational age, there is a decrease in sleeping efficiency and sleep continuity and an increase in awake time and daytime somnolence. By 3 months postpartum, the amount of non-REM and REM sleep recovers, but a persistent decrease in sleeping efficiency and nocturnal awakenings occur, presumably because of the newborn.[43] Although pregnancy causes changes in sleep, it is important for the clinician to consider other primary sleep disorders unrelated to pregnancy such as sleep apnea. The physiologic changes of pregnancy also increase the incidence of sleep-disordered breathing, which includes snoring (in up to 16% of women), upper airway obstruction, and potentially obstructive sleep apnea. The prevalence of sleep apnea in pregnancy is unknown, but it appears to increase the risk for intrauterine growth restriction and gestational hypertension if it is associated with hypoxemia. **Women with excessive daytime sleepiness, loud excessive snoring, and witnessed apneas should be evaluated for obstructive sleep apnea with overnight polysomnography.**[45] **In addition, individuals with known sleep apnea may need repeat sleep studies to determine whether changes in treatment are necessary to prevent intermittent hypoxia.**

Although the majority of gravidas have sleep problems, most do not complain to their providers or ask for treatment. Treatment options include improving sleep habits by avoiding fluids after dinner, establishing regular sleep hours, avoiding naps and caffeine, minimizing bedroom noises, and using pillow support. Other options include relaxation techniques, managing back pain, and use of sleep medications such as diphenhydramine (Benadryl) and zolpidem (Ambien).

Another potential cause of sleep disturbances in pregnancy is the development of restless leg syndrome and periodic leg movements during sleep. Restless leg syndrome is a neurosensory disorder that typically begins in the evening and can prevent women from falling asleep. Pregnancy can be a cause of this syndrome, and in one study up to 23% of gravidas developed some component of this syndrome in the third trimester, although the true prevalence of this disorder during pregnancy is unknown. Although typically this syndrome is not severe enough to warrant treatment, occasionally it is a source of great discomfort to the gravid woman. Treatment options include improving sleep habits, use of an electric vibrator to the calves, and use of a benzodiazepine such as clonazepam or a dopaminergic agent such as L-dopa or carbidopa.

HEMATOLOGIC CHANGES

Plasma Volume and Red Blood Cell Mass

Maternal blood volume begins to increase at about 6 weeks' gestation. Thereafter, it increases progressively until 30 to 34 weeks and then plateaus until delivery. The average expansion of blood volume is 40% to 50%, although individual increases range from 20% to 100%. Women with multiple pregnancies have a larger increase in blood

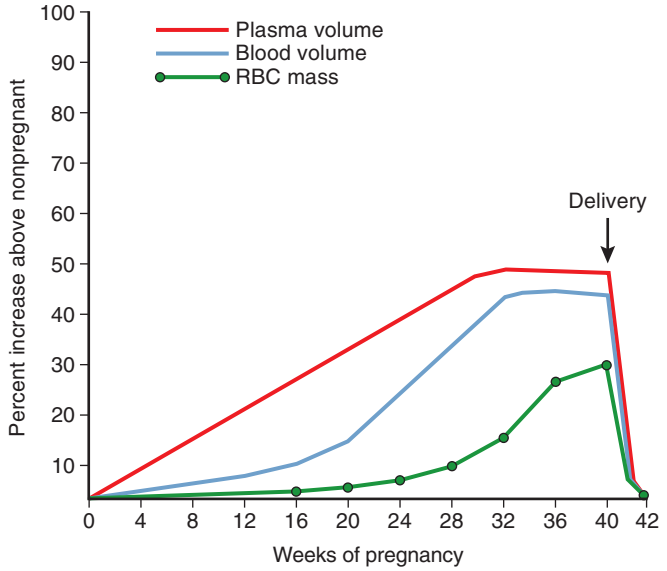

FIGURE 3-8. Blood volume changes during pregnancy. *RBC,* Red blood cell. (From Scott D: Anemia during pregnancy. Obstet Gynecol Ann 1:219, 1972.)

volume than those with singletons.[46] Likewise, volume expansion correlates with infant birthweight, but it is not clear whether this is a cause or an effect. The increase in blood volume results from a combined expansion of both plasma volume and red blood cell (RBC) mass. **The plasma volume begins to increase by 6 weeks and expands at a steady pace until it plateaus at 30 weeks' gestation; the overall increase is about 50% (1200 to 1300 mL).** The exact etiology of the expansion of the blood volume is unknown, but the hormonal changes of gestation and the increase in NO play important roles.

Erythrocyte mass also begins to increase at about 10 weeks' gestation. Although the initial slope of this increase is slower than that of the plasma volume, erythrocyte mass continues to increase progressively until term without plateauing. Without iron supplementation, RBC mass increases about 18% by term, from a mean nonpregnant level of 1400 mL up to 1650 mL. **Supplemental iron increases RBC mass accumulation to 400 to 450 mL, or 30%.[46] Because plasma volume increases more than the RBC mass, maternal hematocrit falls. This so-called physiologic anemia of pregnancy reaches a nadir at 30 to 34 weeks. Because the RBC mass continues to increase after 30 weeks when the plasma volume expansion has plateaued, the hematocrit may rise somewhat after 30 weeks** (Figure 3-8). The mean and fifth percentile hemoglobin concentrations for normal iron-supplemented pregnant women are outlined (Table 3-5). In pregnancy, erythropoietin levels increase twofold to threefold, starting at 16 weeks, and may be responsible for the moderate erythroid hyperplasia found in the bone marrow and mild elevations in the reticulocyte count. The increased blood volume is protective given the possibility of hemorrhage during pregnancy or at delivery. The larger blood volume also helps fill the expanded vascular system created by vasodilation and the large low-resistance vascular pool within the uteroplacental unit preventing hypotension.[30]

TABLE 3-5 HEMOGLOBIN VALUES IN PREGNANCY

WEEKS' GESTATION	MEAN HEMOGLOBIN (g/dL)	FIFTH PERCENTILE HEMOGLOBIN (g/dL)
12	12.2	11.0
16	11.8	10.6
20	11.6	10.5
24	11.6	10.5
28	11.8	10.7
32	12.1	11.0
36	12.5	11.4
40	12.9	11.9

From U.S. Department of Health and Human Services: Recommendations to prevent and control iron deficiency in the United States. MMWR Morb Mortal Wkly Rep 47:1, 1998.

Vaginal delivery of a singleton infant at term is associated with a mean blood loss of 500 mL; an uncomplicated cesarean birth, about 1000 mL; and a cesarean hysterectomy, 1500 mL.[46,47] In a normal delivery, almost all of the blood loss occurs in the first hour. Pritchard and colleagues found that over the subsequent 72 hours, only 80 mL of blood is lost.[47] In the nonpregnant state, blood loss results in an immediate fall in blood volume with a slow re-expansion through volume redistribution; by 24 hours, the blood volume approaches the prehemorrhage level. Isovolemia is maintained with a drop in hematocrit proportional to the blood loss. Gravid women respond to blood loss in a different fashion. **In pregnancy, the blood volume drops after postpartum bleeding, but there is no re-expansion to the prelabor level, and there is less of a change in the hematocrit. Indeed, instead of volume redistribution, an overall diuresis of the expanded water volume occurs postpartum.** After delivery with average blood loss, the hematocrit drops moderately for 3 to 4 days, followed by an increase. By days 5 to 7, the postpartum hematocrit is similar to the prelabor hematocrit. **If the postpartum hematocrit is lower than the prelabor hematocrit, either that the blood loss was larger than appreciated, or the hypervolemia of pregnancy was less than normal, as in preeclampsia.**[47]

Iron Metabolism in Pregnancy

Iron absorption from the duodenum is limited to its ferrous (divalent) state, the form found in iron supplements. Ferric (trivalent) iron from vegetable food sources must first be converted to the divalent state by the enzyme ferric reductase. If body iron stores are normal, only about 10% of ingested iron is absorbed, most of which remains in the mucosal cells or enterocytes until sloughing leads to excretion in the feces (1 mg/day). Under conditions of increased iron needs, the fraction of iron absorbed increases. After absorption, iron is released from the enterocytes into the circulation, where it is carried bound to transferrin to the liver, spleen, muscle, and bone marrow. In those sites, iron is freed from transferrin and incorporated into hemoglobin (75% of iron) and myoglobin or stored as ferritin and hemosiderin. Menstruating women have about half the iron stores of men, with total body iron of 2 to 2.5 g and iron stores of only 300 mg. Before pregnancy, 8% to 10% of women in Western nations have iron deficiency.

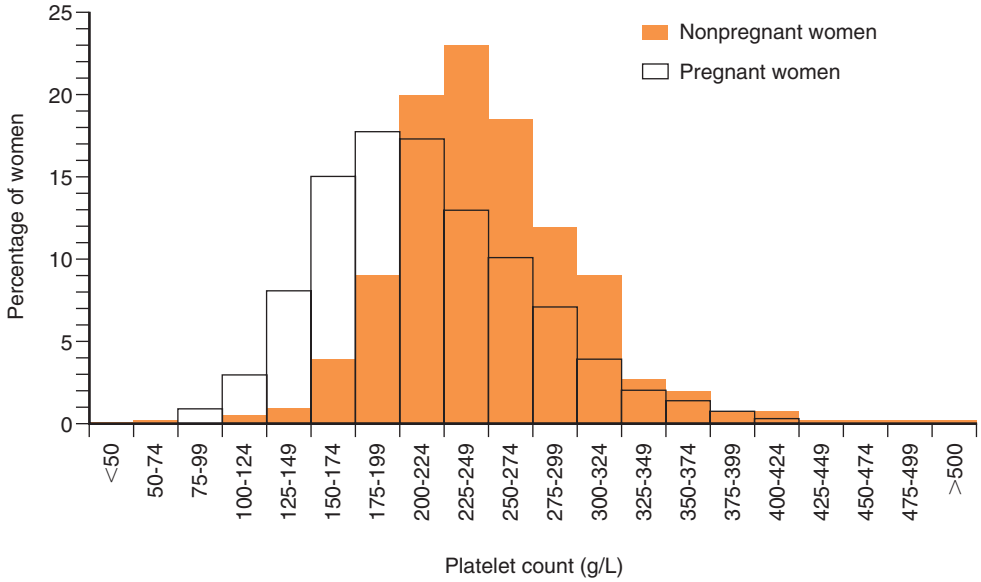

FIGURE 3-9. Histogram of platelet count of pregnant women in the third trimester (n = 6770) compared with nonpregnant women (n = 287). (From Boehlen F, Hohlfield P, Extermann P: Platelet count at term pregnancy: a reappraisal of the threshold. Obstet Gynecol 95:29, 2000.)

The iron requirements of gestation are about 1000 mg. This includes 500 mg used to increase the maternal RBC mass (1 mL of erythrocytes contains 1.1 mg iron), 300 mg transported to the fetus, and 200 mg to compensate for the normal daily iron losses by the mother.[48] Thus, the normal expectant woman needs to absorb an average of 3.5 mg/day of iron. In actuality, the iron requirements are not constant but increase remarkably during the pregnancy from 0.8 mg/day in the first trimester to 6 to 7 mg/day in the third trimester. The fetus receives its iron through active transport, primarily during the last trimester. Adequate iron transport to the fetus is maintained despite severe maternal iron deficiency. Thus, there is no correlation between maternal and fetal hemoglobin concentrations. For a review on use of supplemental iron in pregnancy, see Chapter 42.

Platelets

Before the introduction of automated analyzers, studies of platelet counts during pregnancy reported conflicting results, with some showing a decrease, an increase, or no change with gestation. Unfortunately, even with the availability of automated cell counters, the data on the change in platelet count during pregnancy are still somewhat unclear. Two studies have used true longitudinal methods with serial measurements in the same women. Pitkin and colleagues measured platelet counts in 23 women every 4 weeks and found that the counts dropped from 322 ± 75 × 10^3/mm^3 in the first trimester to 278 ± 75 × 10^3/mm^3 in the third trimester.[49] Similarly, O'Brien, in a study of 30 women, found a progressive decline in platelet counts.[50] Therefore, most recent studies show a decline in the platelet count during gestation possibly caused by increased destruction or hemodilution. **In addition to the mild decrease in the mean platelet count, Burrows and Kelton have demonstrated that in the third trimester, about 8% of gravidas develop gestational thrombocytopenia, with platelet counts between 70,000 and 150,000/mm^3.**[51] **Gestational thrombocytopenia is not associated with an increase in pregnancy complications, and platelet counts return to normal by 1 to 2 weeks postpartum.** Gestational thrombocytopenia is thought to be due to accelerated platelet consumption similar to that seen in normal pregnancy, but more marked in this subset of women.[51] Consistent with these findings, Boehlen and associates compared platelet counts during the third trimester of pregnancy with those in nonpregnant controls. They showed a shift to a lower mean platelet count and an overall shift to the left of the "platelet curve" in the pregnant women (Figure 3-9). This study found that only 2.5% of nonpregnant women have platelet counts less than 150,000/mm^3 (the traditional value used outside of pregnancy as the cut-off for normal) versus 11.5% of gravid women. **A platelet count of less than 116,000/mm^3 occurred in 2.5% of gravid women; therefore, these investigators recommended using this value as the lower limit for normal in the third trimester.** In addition, they suggested that workups for the etiology of decreased platelet count were unneeded at values above this level.

Leukocytes

The peripheral white blood cell (WBC) count rises progressively during pregnancy. During the first trimester, the mean WBC count is 8000/mm^3, with a normal range of 5110 to 9900/mm^3. During the second and third trimesters, the mean is 8500/mm^3, with a range of 5600 to 12,200/mm^3.[49] In labor, the count may rise to 20,000 to 30,000/mm^3, and counts are highly correlated with labor progression as determined by cervical dilation.[52] Because of the normal increase of WBCs in labor, the WBC count should not be used clinically in determining the presence of infection. The increase in the WBC count is largely due to increases in circulating segmented neutrophils and granulocytes whose absolute number is nearly doubled at term. The reason for the increased leukocytosis is unclear, but

it may be caused by the elevated estrogen and cortisol levels. Leukocyte levels return to normal within 1 to 2 weeks of delivery.

Coagulation System

Pregnancy places women at a fivefold to sixfold increased risk for thromboembolic disease (see Chapter 43). This greater risk is caused by increased venous stasis, vessel wall injury, and changes in the coagulation cascade that lead to hypercoagulability. The increase in venous status in the lower extremities is due to compression of the inferior vena cava and the pelvic veins by the enlarging uterus. **The hypercoagulability is caused by an increase in several procoagulants, a decrease in the natural inhibitors of coagulation, and a reduction in fibrinolytic activity. These physiologic changes provide defense against peripartum hemorrhage.**

Most of the procoagulant factors from the coagulation cascade are markedly increased, including factors I, VII, VIII, IX, and X. Factors II, V, and XII are unchanged or mildly increased, and levels of factors XI and XIII decline.[1,53] Plasma fibrinogen (factor I) levels begin to increase in the first trimester and peak in the third trimester at levels 50% higher than before pregnancy. The rise in fibrinogen is associated with an increase in the erythrocyte sedimentation rate. In addition, pregnancy causes a decrease in the fibrinolytic system with reduced levels of available circulating plasminogen activator, a twofold to threefold increase in plasminogen activator inhibitor-1 (PAI-1), and a 25-fold increase in PAI-2.[1] The placenta produces PAI-1 and is the primary source of PAI-2.

Pregnancy has been shown to cause a progressive and significant decrease in the levels of total and free protein S from early in pregnancy but to have no effect on the levels of protein C and antithrombin III.[54,55] The activated protein C (APC)-to-sensitivity (S) ratio, the ratio of the clotting time in the presence and the absence of APC, declines during pregnancy. The APC/S ratio is considered abnormal if less than 2.6. In a study of 239 women,[54] the APC/S ratio decreased from a mean of 3.12 in the first trimester to 2.63 by the third trimester. By the third trimester, 38% of women were found to have an acquired APC resistance, with APC/S ratio values below 2.6.[54] Whether the changes in the protein S level and the APC/S ratio are responsible for some of the hypercoagulability of pregnancy is unknown. **If a workup for thrombophilias is performed during gestation, the clinician should use caution when attempting to interpret these levels if they are abnormal. Ideally the clinician should order DNA testing for the Leiden mutation instead of testing for APC. For protein S screening during pregnancy, the free protein S antigen level should be tested with normal levels in the second and third trimesters being identified as greater than 30% and 24%.**[56]

Most coagulation testing is unaffected by pregnancy. The prothrombin time, activated partial thromboplastin time, and thrombin time all fall slightly but remain within the limits of normal nonpregnant values, whereas the bleeding time and whole blood clotting times are unchanged. Testing for von Willebrand disease is affected in pregnancy because levels of factor VIII, von Willebrand factor activity and antigen, and ristocetin cofactor all increase. Levels of coagulation factors normalize 2 weeks postpartum.

Researchers have found evidence to support the theory that, during pregnancy, a state of low-level intravascular coagulation occurs. Low concentrations of fibrin degradation products (markers of fibrinolysis), elevated levels of fibrinopeptide A (a marker for increased clotting), and increased levels of platelet factor-4 and β-thromboglobulin (markers of increased platelet activity) have been found in maternal blood.[57] The most likely cause for these findings involves localized physiologic changes needed for maintenance of the uterine-placental interface.

URINARY SYSTEM

Anatomic Changes

The kidneys enlarge during pregnancy, with the length as measured by intravenous pyelography increasing about 1 cm. This growth in size and weight is due to increased renal vasculature, interstitial volume, and urinary dead space. **The increase in urinary dead space is attributed to dilation of the renal pelvis, calyces, and ureters. Pelvicaliceal dilation by term averages 15 mm (range, 5 to 25 mm) on the right and 5 mm (range, 3 to 8 mm) on the left.**[58]

The well-known dilation of the ureters and renal pelves begins by the second month of pregnancy and is maximal by the middle of the second trimester, when ureteric diameter may be as much as 2 cm. The right ureter is almost invariably dilated more than the left, and the dilation usually cannot be demonstrated below the pelvic brim. These findings have led some investigators to argue that the dilation is caused entirely by mechanical compression of the ureters by the enlarging uterus and ovarian venous plexus. However, the early onset of ureteral dilation suggests that smooth muscle relaxation caused by progesterone plays an additional role. Also supporting the role of progesterone is the finding of ureteral dilation in women with renal transplant and pelvic kidney.[59] By 6 weeks postpartum, ureteral dilation resolves.[58] A clinical consequence of ureterocalyceal dilation is an increased incidence of pyelonephritis among gravidas with asymptomatic bacteriuria. **In addition, the ureterocalyceal dilation makes interpretation of urinary radiographs more difficult when evaluating possible urinary tract obstruction or nephrolithiasis.**

Anatomic changes are also observed in the bladder. From midpregnancy on, an elevation in the bladder trigone occurs, with increased vascular tortuosity throughout the bladder. This can cause an increased incidence of microhematuria. Three percent of gravidas have idiopathic hematuria, defined as greater than 1+ on a urine dipstick, and up to 16% have microscopic hematuria. Because of the increasing size of the pregnancy, a decrease in bladder capacity develops with an increase in urinary frequency, urgency, and incontinence.

Renal Hemodynamics

Renal plasma flow (RPF) increases markedly from early in gestation and may actually initially begin to increase during the luteal phase before implantation.[60] Dunlop showed convincingly that the effective RPF rises 75% over nonpregnant levels by 16 weeks' gestation (Table 3-6). The increase is maintained until 34 weeks' gestation, when a

TABLE 3-6 SERIAL CHANGES IN RENAL HEMODYNAMICS

		SEATED POSITION (n = 25)*			LEFT LATERAL RECUMBENT POSITION (n = 17)†	
	Nonpregnant	16 wk	26 wk	36 wk	29 wk	37 wk
Effective renal plasma flow (mL/min)	480 ± 72	840 ± 145	891 ± 279	771 ± 175	748 ± 85	677 ± 82
Glomerular filtration rate (mL/min)	99 ± 18	149 ± 17	152 ± 18	150 ± 32	145 ± 19	138 ± 22
Filtration fraction	0.21	0.18	0.18	0.20	0.19	0.21

*Data from Dunlop W: Serial changes in renal haemodynamics during normal pregnancy. Br J Obstet Gynaecol 88:1, 1981.
†Data from Ezimokhai M, Davison J, Philips P, et al: Nonpostural serial changes in renal function during the third trimester of normal human pregnancy. Br J Obstet Gynaecol 88:465, 1981.

decline in RPF of about 25% occurs. The fall in RPF has been demonstrated in subjects studied serially in the sitting and the left lateral recumbent positions. Like RPF, glomerular filtration rate (GFR), as measured by inulin clearance, increases by 5 to 7 weeks. **By the end of the first trimester, GFR is 50% higher than in the nonpregnant state, and this is maintained until the end of pregnancy.** Three months postpartum, GFR values have declined to normal levels.[61] This renal hyperfiltration seen in pregnancy is a result of the increase in the RPF. Because the RPF increases more than the GFR early in pregnancy, the filtration fraction falls from nonpregnant levels until the late third trimester. At this time, because of the decline in RPF, the filtration fraction returns to preconceptional values.

Clinically, GFR is not determined by measuring the clearance of infused inulin (inulin is filtered by the glomerulus and is unaffected by the tubules), but rather by measuring endogenous creatinine clearance. This test gives a less precise measure of GFR because creatinine is secreted by the tubules to a variable extent. Therefore, endogenous creatinine clearance is usually higher than the actual GFR. **The creatinine clearance in pregnancy is greatly increased to values of 150 to 200 mL/min (normal, 120 mL/min).** As with GFR, the increase in creatinine clearance occurs by 5 to 7 weeks' gestation and normally is maintained until the third trimester. GFR is best estimated in pregnancy using a 24-hour urine collection for creatinine clearance. **Formulas that are used in patients with renal disease that estimate the GFR using serum collections and clinical parameters (which avoid a 24-hour urine collection) are inaccurate in pregnancy and underestimate the GFR.**

The increase in the RPF and GFR precede the increase in blood volume and may be induced by a reduction in the preglomerular and postglomerular arteriolar resistance. Importantly, the increase in hyperfiltration occurs without an increase in glomerular pressure, which if it occurred, could have the potential for injury to a women's kidney with long-term consequences.[60] Recently, the mechanisms underlying the marked increase in RPF and GFR has been carefully studied. Although numerous factors are involved in this process, NO has been demonstrated to play a critical role in the decrease in renal resistance and the subsequent renal hyperemia. During pregnancy, the activation and expression of the NO synthase is enhanced in the kidneys, and inhibition of NO synthase isoforms has been shown to attenuate the hemodynamic changes within the gravid kidney.[25] Finally, the hormone relaxin appears to be important by initiating or activating some of the effects of NO on the kidney. Failure of this crucial adaptation to occur is associated with adverse outcomes such as preeclampsia and fetal growth restriction.[7]

The clinical consequences of glomerular hyperfiltration are a reduction in maternal plasma levels of creatinine, blood urea nitrogen (BUN), and uric acid. Serum creatinine decreases from a nonpregnant level of 0.8 mg/dL to 0.5 mg/dL by term. Likewise, BUN falls from nonpregnant levels of 13 to 9 mg/dL by term.[5] Serum uric acid declines in early pregnancy because of the rise in GFR, reaching a nadir by 24 weeks with levels of 2 to 3 mg/dL.[62] After 24 weeks, the uric acid level begins to rise, and by the end of pregnancy, the levels in most women are essentially the same as before conception. The rise in uric acid levels is caused by increased renal tubular absorption of urate and increased fetal uric acid production. **Patients with preeclampsia have elevated uric acid level concentrations; however, because uric acid levels normally rise during the third trimester, over-reliance on this test should be avoided in the diagnosis and management of preeclampsia.**[62]

During pregnancy, urine volume is increased, and nocturia is more common. In the standing position, sodium and water are retained, and therefore, during the daytime, gravidas tend to retain an increased amount of water. At night while in the lateral recumbent position, this added water is excreted, resulting in nocturia. Later in gestation, the renal function is affected by position, and the GFR and renal hemodynamics are decreased with changes from lateral recumbency to supine or standing.[63]

Renal Tubular Function/Excretion of Nutrients

Despite high levels of aldosterone, which would be expected to result in enhanced urinary excretion of potassium, gravid women retain about 350 mmol of potassium. Most of the excess potassium is stored in the fetus and placenta. The mean potassium concentrations in maternal blood are just slightly below nonpregnant levels. The kidney's ability to conserve potassium has been attributed to increased progesterone levels.[64] For information on the changes of sodium, see the section on body water metabolism earlier in this chapter.

Glucose excretion increases in almost all pregnant women, and glycosuria is common. Nonpregnant urinary excretion of glucose is less than 100 mg/day, but 90% of gravidas with normal blood glucose levels excrete 1 to 10 g

TABLE 3-7 COMPARISON OF 24-HOUR URINARY VOLUME PROTEIN AND ALBUMIN EXCRETION

	20 WEEKS (n = 95)	20 WEEKS (n = 175)	SIGNIFICANCE
Protein (mg/24 hr)	98.1 ± 62.3	121.8 ± 71	P = .007
Albumin (mg/24 hr)	9.7 ± 6.2	12.2 ± 8.5	P = .012

From Higby K, Suiter C, Phelps J, et al: Normal values of urinary albumin and total protein excretion during pregnancy. Am J Obstet Gynecol 171:984, 1994.
Values are expressed as mean ± SD.

of glucose per day.[65] This glycosuria is intermittent and not necessarily related to blood glucose levels or the stage of gestation. Glucose is freely filtered by the glomerulus, and with the 50% increase in GFR, a greater load of glucose is presented to the proximal tubules. There may be a change in the reabsorptive capability of the proximal tubules themselves, but the old concept of pregnancy leading to an overwhelming of the maximal tubular reabsorptive capacity for glucose is misleading and oversimplified.[65] The exact mechanisms underlying the altered handling of glucose by the proximal tubules remains obscure. **Even though glycosuria is common, gravidas with repetitive glycosuria should be screened for diabetes mellitus if not already tested.**

Urinary protein and albumin excretion increases during pregnancy, with an upper limit of 300 mg of proteinuria and 30 mg of albuminuria in a 24-hour period.[63] The amount of proteinuria and albuminuria increases both when compared with nonpregnant levels and as the pregnancy advances. Higby and associates collected 24-hour urine samples from 270 women over the course of pregnancy and determined the amount of proteinuria and albuminuria. These investigators found that the amount of protein and albumin excreted in urine did not increase significantly by trimester but did increase significantly when compared between the first and second half of pregnancy (Table 3-7). **They observed that in women without preeclampsia, underlying renal disease, or urinary tract infections, the mean 24-hour urine protein across pregnancy is 116.9 mg, with a 95% upper confidence limit of 260 mg. They also noted that patients do not normally have microalbuminuria, defined as urinary albumin excretion greater than 30 mg/dL. In women with preexisting proteinuria, the amount of proteinuria increases in both the second and third trimesters, and potentially in the first trimester.** In a study of women with diabetic nephropathy, the amount of proteinuria increased from a mean of 1.74 ± 1.33 g per 24 hours in the first trimester to a mean of 4.82 ± 4.7 g per 24 hours in the third trimester, even in the absence of preeclampsia.[66] The increase in the renal excretion of proteins is due to a physiologic impairment of the proximal tubular function within the kidney and the increase in the GFR.[63]

Other changes in tubular function include an increase in the excretion of amino acids in the urine and an increase in calcium excretion (see Chapter 40). Also, the kidney responds to the respiratory alkalosis of pregnancy by enhanced excretion of bicarbonate; however, renal handling of acid excretion is unchanged.

ALIMENTARY TRACT

Appetite

Most women experience an increase in appetite throughout pregnancy. In the absence of nausea or "morning sickness," women eating according to appetite will increase food intake by about 200 kcal/day by the end of the first trimester. The recommended dietary allowance calls for an additional 300 kcal/day, although in reality most women make up for this with decreased activity. Energy requirements vary depending on the population studied, and a greater increase may be necessary for pregnant teenagers and women with high levels of physical activity. Extensive folklore exists about dietary cravings and aversions during gestation. Many of these are undoubtedly due to an individual's perception of which foods aggravate or ameliorate such symptoms as nausea and heartburn. The sense of taste may be blunted in some women, leading to an increased desire for highly seasoned food. Pica, a bizarre craving for strange foods, is relatively common among gravidas, and a history of pica should be sought in those with poor weight gain or refractory anemia. Examples of pica include the consumption of clay, starch, toothpaste, and ice.

Mouth

The pH and the production of saliva are probably unchanged during pregnancy. Ptyalism, an unusual complication of pregnancy, most often occurs in women suffering from nausea and may be associated with the loss of 1 to 2 L of saliva per day. Most authorities believe ptyalism actually represents inability of the nauseated woman to swallow normal amounts of saliva rather than a true increase in the production of saliva. A decrease in the ingestion of starchy foods may help decrease the amount of saliva. No evidence exists that pregnancy causes or accelerates the course of dental caries. However, the gums swell and may bleed after tooth brushing, giving rise to the so-called gingivitis of pregnancy. At times, a tumorous gingivitis may occur, presenting as a violaceous pedunculated lesion at the gum line that may bleed profusely. Called epulis gravidarum or pyogenic granulomas, these lesions consist of granulation tissue and an inflammatory infiltrate (see Chapter 48).

Stomach

The tone and motility of the stomach are decreased, probably because of the smooth muscle–relaxing effects of progesterone and estrogen. Nevertheless, scientific evidence regarding delayed gastric emptying is inconclusive.[67] Macfie and colleagues, using acetaminophen absorption as an indirect measure of gastric emptying, failed to demonstrate a delay in gastric emptying when comparing 15 nonpregnant controls with 15 women in each trimester.[67] In addition, a recent study showed no delay in gastric emptying in parturients at term who ingested 300 mL of water following an overnight fast.[68] However, an increased delay is seen in labor, with the etiology ascribed to the pain and stress of labor.

Pregnancy causes a decreased risk for peptic ulcer disease but, at the same time, causes an increase in gastroesophageal reflux disease and dyspepsia in 30% to 50% of

individuals.[69] This apparent paradox can be partially explained by physiologic changes of the stomach and lower esophagus. The increase in gastroesophageal reflux disease is multifactorial and is attributed to esophageal dysmotility caused by gestational hormones, gastric compression from the enlarged uterus, and a decrease in the pressure of the gastroesophageal sphincter. The decrease in the tone of the gastroesophageal sphincter is caused by progesterone, and estrogen may lead to increased reflux of stomach acids into the esophagus and may be the predominant cause of reflux symptoms. Theories proposed to explain the decreased incidence of peptic ulcer disease include increased placental histaminase synthesis with lower maternal histamine levels; increased gastric mucin production leading to protection of the gastric mucosa; reduced gastric acid secretion; and enhanced immunologic tolerance of *Helicobacter pylori*, the infectious agent that causes peptic ulcer disease[69] (see Chapter 45).

Intestines

Perturbations in the motility of the small intestines and colon are common in pregnancy, resulting in an increased incidence of constipation in some and diarrhea in others. Up to 34% of women in one study noted an increased frequency of bowel movements, perhaps related to increased prostaglandin synthesis.[70] The prevalence of constipation appears to be higher in early pregnancy, with 35% to 39% of women having constipation in the first and second trimester and only 21% in the last trimester.[71] The motility of the small intestines is reduced in pregnancy, with increased oral-cecal transit times. No studies on the colonic transit time have been performed, but limited information suggests reduced colonic motility.[70] Although progesterone has been thought to be the primary cause of the decrease in gastrointestinal motility, newer studies show the actual etiology may be due to estrogen. Estrogen causes an increased release of NO from nerves that innervate the gastrointestinal tract that then results in relaxation of the gastrointestinal tract musculature. Absorption of nutrients from the small bowel (with the exception of increased iron and calcium absorption) is unchanged, but the increased transit time allows for more efficient absorption. Parry and colleagues demonstrated an increase in both water and sodium absorption in the colon.[72]

The enlarging uterus displaces the intestines and, most importantly, moves the position of the appendix. Thus, the presentation, physical signs, and type of surgical incision are affected in the management of appendicitis. Portal venous pressure is increased, leading to dilation wherever there is portosystemic venous anastomosis. This includes the gastroesophageal junction and the hemorrhoidal veins, which results in the common complaint of hemorrhoids.

Gallbladder

The function of the gallbladder is markedly altered because of the effects of progesterone. After the first trimester, the fasting and residual volumes are twice as great, and the rate at which the gallbladder empties is much slower. In addition, the biliary cholesterol saturation is increased, and the chenodeoxycholic acid level is decreased.[73] This change in the composition of the bile fluid favors the formation of cholesterol crystals, and with incomplete emptying of the gallbladder, the crystals are retained, and gallstone formation is enhanced. **During pregnancy, biliary sludge develops in about one third of women, and by the time of delivery 10% to 12% of women have gallstones on ultrasonographic examination. Postpartum, biliary sludge disappears in virtually all women, but only about one third of small stones disappear.**

Liver

The size and histology of the liver are unchanged in pregnancy. However, many clinical and laboratory signs usually associated with liver disease are present. Spider angiomas and palmar erythema, caused by elevated estrogen levels, are normal and disappear soon after delivery. **The serum albumin and total protein levels fall progressively during gestation. By term, albumin levels are 25% lower than nonpregnant levels.** Despite an overall increase in total body protein, decreases in total protein and albumin concentrations occur as a result of hemodilution. **In addition, serum alkaline phosphatase activity rises during the third trimester to levels two to four times those of nongravid women.** Most of this increase is caused by placental production of the heat-stable isoenzyme and not from the liver.[1] The serum concentrations of many proteins produced by the liver increase. These include elevations in fibrinogen, ceruloplasmin, transferrin, and the binding proteins for corticosteroids, sex steroids, and thyroid hormones.[1]

With the exception of alkaline phosphatase, the other "liver function tests" are unaffected by pregnancy, including serum levels of bilirubin, aspartate aminotransferase (AST), alanine aminotransferase (ALT), γ-glutamyltransferase, 5′-nucleotidase, creatinine phosphokinase, and lactate dehydrogenase. In some studies, the mean levels of ALT and AST are mildly elevated but still within normal values.[74] Levels of creatinine phosphokinase and lactate dehydrogenase can increase with labor. Finally, pregnancy may cause some changes in bile acid production and secretion. Pregnancy may be associated with mild subclinical cholestasis resulting from the high concentrations of estrogen. Reports on serum bile acid concentrations are conflicting, with some studies showing an increase and others no change. **The fasting levels are unchanged, and the measurement of a fasting level appears to be the best test for diagnosing cholestasis of pregnancy.**[74] Cholestasis results from elevated levels of bile acids and is associated with significant pruritus, usually mild increases of ALT/AST, and an increased risk for poor fetal outcomes (see Chapter 45).

Nausea and Vomiting of Pregnancy

Nausea and vomiting, or "morning sickness," complicate up to 70% of pregnancies. Typical onset is between 4 and 8 weeks' gestation, with improvement before 16 weeks; however, 10% to 25% of women still experience symptoms at 20 to 22 weeks' gestation, and some women experience symptoms throughout the gestation.[75] Although the symptoms are often distressing, simple morning sickness seldom leads to significant weight loss, ketonemia, or electrolyte disturbances. The cause is not well understood, although relaxation of the smooth muscle of the stomach probably plays a role. Elevated levels of human chorionic gonadotropin (hCG) may be involved, although a good correlation between maternal hCG concentrations and the degree of

nausea and vomiting has not been observed. Similarly, minimal data exist to show the etiology is associated with higher levels of estrogen or progesterone. Interestingly, pregnancies complicated by nausea and vomiting generally have a more favorable outcome than do those without such symptoms.[75] Treatment is largely supportive, consisting of reassurance, avoidance of foods found to trigger nausea, and frequent small meals. Eating dry toast or crackers before getting out of bed may be beneficial. **Recently, the American College of Obstetricians and Gynecologists (ACOG) stated that the use of either vitamin B_6 alone or in combination with doxylamine (Unisom) is safe and effective and should be considered a first line of medical treatment.** A recent review of alternative therapies to antiemetic drugs found that acupressure, wristbands, or treatment with ginger root may be helpful.

Hyperemesis gravidarum is a more pernicious form of nausea and vomiting associated with weight loss, ketonemia, electrolyte imbalance, and dehydration. It occurs in 1% to 3% of women, with persistence often throughout pregnancy, and rarely can result in significant complications, including Wernicke encephalopathy, rhabdomyolysis, acute renal failure, and esophageal rupture. For these patients, the clinician must rule out other diseases such as pancreatitis, cholecystitis, hepatitis, and psychiatric disease. **Hospitalization with intravenous replacement of fluids and electrolytes is often needed. Options of antiemetics include the phenothiazines: promethazine (Phenergan), chlorpromazine (Thorazine), and prochlorperazine (Compazine) or metoclopramide (Reglan), or ondansetron (Zofran).[76] On admission to the hospital, the patient should be given intravenous hydration and tried on one of the above-mentioned medications (intravenously or intramuscularly initially).** Care must be taken not to combine the phenothiazines with metoclopramide because of the additive risks for causing extrapyramidal reactions. Chlorpromazine given rectally (25 to 50 mg every 8 hours) may be highly effective in the more refractory cases. **Recently, use of oral methylprednisolone, 16 mg three times daily for 3 days and then tapered over 2 weeks, has been shown to be more effective than promethazine, but multiple subsequent studies failed to demonstrate benefit from the use of steroids.[76]** Unfortunately, no single therapy works in all women, and occasionally, multiple different medications must be tried before finding the one that is effective. **Because of potential risks, parenteral caloric replacement should only be used after failure of multiple antiemetic treatments and attempts at enteral tube feedings.**

SKELETON

Calcium Metabolism

Pregnancy was initially thought to be a state of "physiologic hyperparathyroidism" with maternal skeletal calcium loss needed to supply the fetus with calcium. It was thought that this could result in long-term maternal bone loss. **It is now evident that most fetal calcium needs are met through a series of physiologic changes in calcium metabolism without long-term consequences to the maternal skeleton.[77]** This allows the fetus to accumulate 21 g (range, 13 to 33 g) of calcium, 80% of this amount during the third trimester, when fetal skeletal mineralization is at its peak. Calcium is actively transported across the placenta. Surprisingly, calcium is excreted in greater amounts by the maternal kidneys so that, by term, calciuria is doubled.

Maternal total calcium levels decline throughout pregnancy. The fall in total calcium is caused by the reduced serum albumin levels that result in a decrease in the albumin-bound fraction of calcium. However, the physiologically important fraction, serum ionized calcium, is unchanged and constant[77] (Figure 3-10). **Therefore, the actual maternal serum calcium levels are maintained and the fetal calcium needs are met mainly through increased intestinal calcium absorption.** Calcium is absorbed through the small intestines, and its absorption is doubled by 12 weeks' gestation, with maximal absorption in the third trimester.[77,78] The early increase in absorption may allow the maternal skeleton to store calcium in advance of the

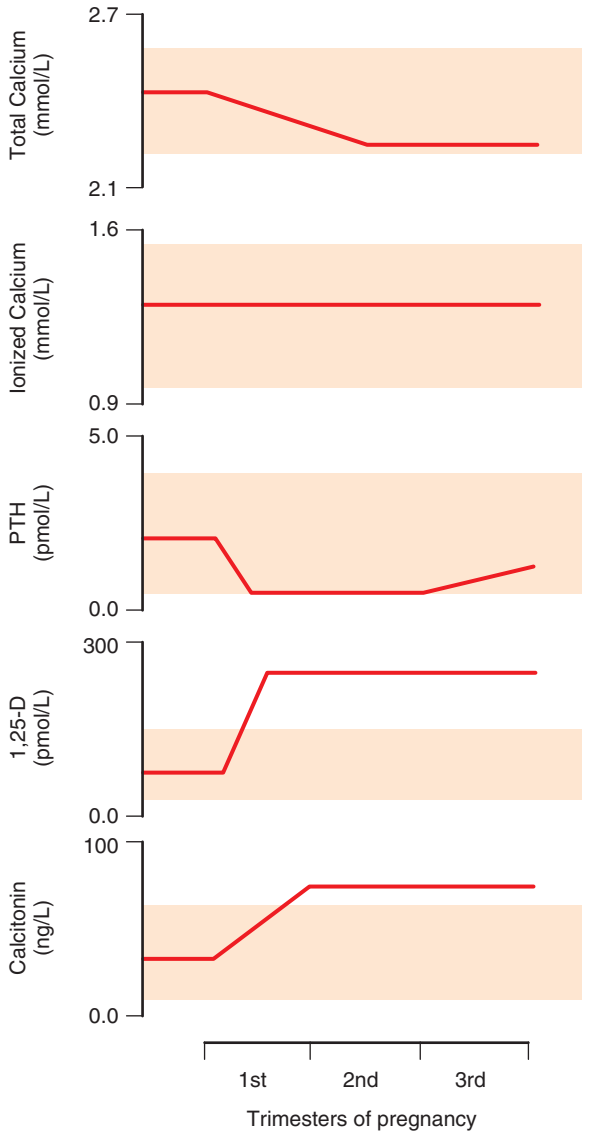

FIGURE 3-10. The longitudinal changes in calcium and calcitropic hormone levels that occur during human pregnancy. Normal adult ranges are indicated by the *shaded areas*. *1,25-D,* 1,25-dihydroxyvitamin D; *PTH,* parathyroid hormone. (From Kovacs C, Kronenberg H: Maternal-fetal calcium and bone metabolism during pregnancy, puerperium, and lactation. Endocr Rev 18:832, 1997.)

peak third-trimester fetal demands. Although most fetal calcium needs are met by increased absorption of calcium, accumulating data confirm that at least some calcium resorption from maternal bone occurs to help meet the increased fetal demands in the third trimester. These data are compatible with the hypothesis that physiologic mechanisms exist to ensure an adequate supply of calcium for fetal growth and milk production without sole reliance on the maternal diet.[78] Maternal serum phosphate levels are similarly unchanged.[77]

Older studies showed an increase in maternal parathyroid hormone (PTH) levels. These studies used less sensitive PTH assays that measured multiple different fragments of PTH, most of which are biologically inactive. In five recent prospective studies, all using newer assays, maternal levels of PTH were not elevated and actually remained in the low-normal range throughout gestation.[77] Therefore, pregnancy is not associated with relative hyperparathyroidism (see Chapter 40).

Vitamin D is a prohormone that is derived from cholesterol and occurs in two main nutritional forms: D_3 (cholecalciferol), which is generated in the skin, and D_2 (ergocalciferol), which is derived from plants and absorbed in the gut. **Serum levels of 25-hydroxyvitamin D (25[OH]D) increase in proportion to vitamin D synthesis and intake. Levels of 25[OH]D represent the best indicator of vitamin D status.**[79] 25[OH]D is furthered metabolized to 1,25-dihydroxyvitamin D or active vitamin D. Levels of 1,25-dihydroxyvitamin D increase overall in pregnancy, with prepregnancy levels doubling in the first trimester and peaking in the third trimester. Levels of 25[OH]D do not change in pregnancy unless vitamin D intake or synthesis is changed. The increase in 1,25-dihydroxyvitamin D is secondary to increased production by the maternal kidneys and potentially the fetoplacental unit and is independent of PTH control. The increase in 1,25-dihydroxyvitamin D is directly responsible for most of the increase in intestinal calcium absorption.[77] **Recently, a great deal of interest in vitamin D deficiency in pregnancy has occurred, with estimated prevalence of 5% to 50% in the United States. Controversy exists over the recommendations to institute universal screening during pregnancy by measuring serum levels of 25[OH]D. Levels less than 32 ng/mL indicate vitamin D deficiency, with recommendations to increase vitamin D supplementation if such a deficiency is diagnosed.**[79] Calcitonin levels also rise by 20% and may help protect the maternal skeleton from excess bone loss.[77]

Skeletal and Postural Changes

The effect of pregnancy on bone metabolism is complex, and evidence of maternal bone loss during pregnancy has been inconsistent, with various studies reporting bone loss, no change, and even gain. Whether pregnancy causes bone loss is not the important question; instead, the critical question is whether pregnancy and lactation have a long-term risk for causing osteoporosis later in life.[80] **In a recent review of 23 studies, Ensom and colleagues[80] concluded that pregnancy is a period of high bone turnover and remodeling. Both pregnancy and lactation cause reversible bone loss, and this loss is increased in women who breastfeed for longer intervals. Studies do not support an association between parity and osteoporosis later in life.** Additionally, in a comparison of female twins discordant for parity, pregnancy and lactation were found to have no detrimental effect on long-term bone loss.

Bone turnover appears to be low in the first half of gestation and then increases in the third trimester, corresponding to the peak rate of fetal calcium needs, and may represent turnover of previously stored skeletal calcium.[77] Markers of both bone resorption (hydroxyproline and tartrate-resistant acid phosphatase) and bone formation (alkaline phosphatase and procollagen peptides) are increased during gestation.[78] In the only study of bone biopsies performed in pregnancy, Shahtaheri and associates observed a change in the microarchitectural pattern of bone, but no change in overall bone mass was found. This change in the microarchitectural pattern seems to result in a framework more resistant to the bending forces and biomechanical stresses needed to carry a growing fetus.[81] In support of this study, multiple recent studies have shown that bone loss occurs only in the trabecular bone and not cortical bone. Promislow and coworkers measured bone mineral density twice during pregnancies using dual-energy x-ray absorptiometry and showed the mean loss of trabecular bone was 1.9% per 20 weeks' gestation.[82] However, women placed on bedrest had significantly greater bone loss. In comparison, the mean bone loss in postmenopausal women rarely exceeds 2% per year. Older studies indicate that the cortical bone thickness of long bones may even increase with pregnancy.

Although bone loss occurs in pregnancy, the occurrence of osteoporosis during or soon after pregnancy is rare. Whether additional calcium intake during pregnancy and lactation prevents bone loss is controversial. Most current studies indicate that calcium supplementation does not decrease the amount of bone loss, but Promislow and coworkers[82] found that maternal intake of 2 g per day or greater was modestly protective. This is greater than the recommended dietary allowance of 1000 to 1300 mg/day during pregnancy and lactation.[78]

Pregnancy results in a progressively increasing anterior convexity of the lumbar spine (lordosis). This compensatory mechanism keeps the woman's center of gravity over her legs and prevents the enlarging uterus from shifting the center of gravity anteriorly. The unfortunate side effect of this necessary alteration is low back pain in two thirds of women, with the pain described as severe in one third. The ligaments of the pubic symphysis and sacroiliac joints loosen, probably from the effects of the hormone relaxin, the levels of which increase 10-fold in pregnancy. Marked widening of the pubic symphysis occurs by 28 to 32 weeks' gestation, with the width increasing from 3 to 4 mm to 7.7 to 7.9 mm. This commonly results in pain near the symphysis that is referred down the inner thigh with standing and may result in a maternal sensation of snapping or movement of the bones with walking.

ENDOCRINE CHANGES

Thyroid

Thyroid diseases are common in women of childbearing age (see Chapter 40). However, normal pregnancy symptoms mirror those of thyroid disease, making it difficult to know when screening for thyroid disease is appropriate. In

addition, the physiologic effects of pregnancy frequently make the interpretation of thyroid tests difficult. Therefore, it is important for the obstetrician to be familiar with the normal changes in thyroid function that occur. Recent data have shown that the correct and timely diagnosis and treatment of thyroid disease is important to prevent both maternal and fetal complications.

Despite alterations in thyroid morphology, histology, and laboratory indices, pregnant women remain euthyroid. The thyroid gland increases in size, but not as much as was commonly believed. **If adequate iodine intake is maintained, the size of the thyroid gland remains unchanged or undergoes a small increase in size that can be detected only by ultrasound.**[83] The World Health Organization recommends that iodine intake be increased in pregnancy from 100 mg/day to 150 to 200 mg/day. In an iodine-deficient state, the thyroid gland is up to 25% larger, and goiters occur in 10% of women.[84] Histologically, during pregnancy an increase in thyroid vascularity occurs with evidence of follicular hyperplasia. **The development of a clinically apparent goiter during pregnancy is abnormal and should be evaluated.**

During pregnancy, serum iodide levels fall because of increased renal loss. In addition, in the latter half of pregnancy, iodine is also transferred to the fetus, further decreasing maternal levels.[84] However, at least one investigator has reported that in iodine-sufficient regions, the concentration of iodide does not decrease.[85] These alterations cause the thyroid to synthesize and secrete thyroid hormone actively.[84] Although there is increased uptake of iodine by the thyroid, pregnant women remain euthyroid by laboratory evaluation.

Total thyroxine (TT_4) and total triiodothyronine (TT_3) levels begin to increase in the first trimester and peak at midgestation as a result of increased production of thyroid-binding globulin (TBG). The increase in TBG is seen in the first trimester and plateaus at 12 to 14 weeks. The concentration of TT_4 increases in parallel with the TBG from a normal range of 5 to 12 mg/dL in nonpregnant women to 9 to 16 mg/dL during pregnancy (increases by a factor of about 1.5). **Only a small amount of TT_4 and TT_3 is unbound, but these free fractions (normally about 0.04% for T_4 and 0.5% for T_3) are the major determinants of whether an individual is euthyroid.** The extent of change in free T_4 and T_3 levels during pregnancy has been controversial, and the discrepancies in past studies have been attributed to the techniques used to measure the free hormone levels. **The current best evidence is that the free T_4 levels rise slightly in the first trimester and then decrease so that by delivery, the free T_4 levels are 10% to 15% lower than in nonpregnant women. However, these changes are small, and in most gravidas, free T_4 concentrations remain within the normal nonpregnant range**[84] (Figure 3-11). In clinical practice, the free T_4 level can be measured using either the free thyroxine index (FTI) or estimates of free T_4. These tests use immunoassays that do not measure the free T_4 directly and may be less accurate in pregnancy because they are TBG dependent. **Lee and colleagues showed that the FTI is a more accurate method for measuring free T_4 and that the currently used estimates for free T_4 may incorrectly diagnose women as hypothyroid in the second and third trimesters; however, other authors have shown that these free T_4 estimates are accurate.**[86,87] Free T_3 levels follow a similar pattern as free T_4 levels.

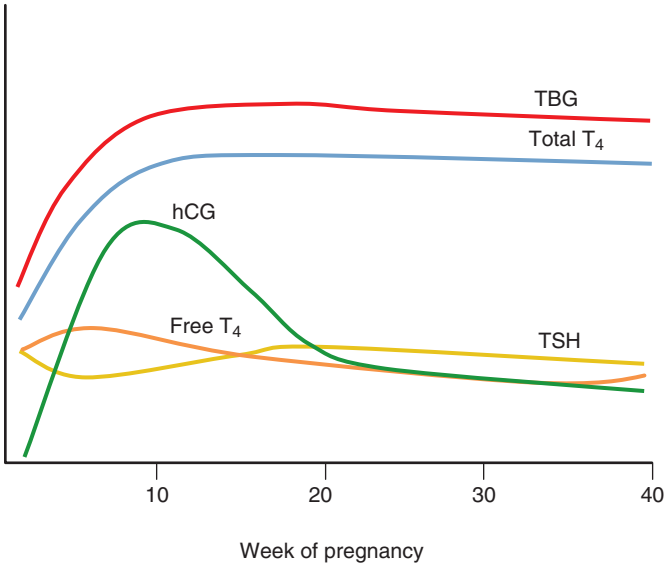

FIGURE 3-11. Relative changes in maternal thyroid function during pregnancy. *hCG,* Human chorionic gonadotropin; *T_4,* thyroxine; *TBG,* thyroxine-binding globulin; *TSH,* thyroid-stimulating hormone. (From Burrow G, Fisher D, Larsen P: Maternal and fetal thyroid function. N Engl J Med 331:1072, 1994.)

Thyroid-stimulating hormone (TSH) concentrations decrease transiently in the first trimester and then rise to prepregnant levels by the end of this trimester. TSH levels then remain stable throughout the remainder of gestation.[84] **The transient decrease in TSH coincides with the first-trimester increase in free T_4 levels, and both appear to be caused by the thyrotropic effects of hCG.** Women with higher peak hCG levels have more TSH suppression. TSH and hCG are structurally very similar, and they share a common α-subunit and have a similar β-unit. **Glinoer and colleagues estimated that a 10,000-IU/L increment in circulating hCG corresponds to a mean free T_4 increment of 0.6 pmol/L (0.1 ng/dL) and, in turn, lowers TSH by 0.1 mIU/L.**[84,88] **These investigators measured TSH levels during successive trimesters of pregnancy in a large group of women and found that TSH was suppressed below normal in 18% in the first trimester, 5% during the second trimester, and 2% in the third trimester.** In the first two trimesters, the mean hCG level was higher in women with suppressed TSH levels.[88] It appears that hCG has some thyrotropic activity, but conflicting data on the exact role of hCG in maternal thyroid function remain.[84] **In some women, the thyrotropic effects of hCG can cause a transient form of hyperthyroidism called gestational transient thyrotoxicosis.**

The influence of maternal thyroid physiology on the fetus appears much more complex than was previously thought. Whereas the maternal thyroid does not directly control fetal thyroid function, the systems interact by means of the placenta, which regulates the transfer of iodine and a small but important amount of thyroxine to the fetus. It was previously thought that little if any transplacental passage of T_4 and T_3 occurred. **It is now**

recognized that T_4 crosses the placenta and that, in fact, in early pregnancy, the fetus is critically dependent on the maternal T_4 supply for normal neurologic development.[89] However, as a result of the deiodinase activity of the placenta, a large percentage of T_4 is broken down before transfer to the fetus. **The human fetus cannot synthesize thyroid hormones until after 12 weeks' gestation, and any fetal requirement before this time is totally dependent on maternal transfer.** Even after the fetal thyroid is functional, the fetus continues to rely to some extent on a maternal supply of thyroxine.

Neonates with thyroid agenesis or a total defect in thyroid hormone synthesis have umbilical cord thyroxine levels between 20% and 50% of those in normal infants, demonstrating that the placenta is not impermeable to T_4. Further evidence that the fetus is dependent on the maternal thyroid for normal development has been published. In women living in iodine-deficient areas, maternal hypothyroidism is associated with neonatal hypothyroidism and defects in long-term neurologic function and mental retardation termed *endemic cretinism*. These abnormalities can be prevented if maternal iodine intake is initiated at the beginning of the second trimester.[90] **Haddow and coworkers[91] have found that maternal hypothyroidism during pregnancy results in slightly lower IQ scores in children tested at ages 7 to 9 years. These findings have resulted in controversy over whether all pregnant women should be screened for subclinical hypothyroidism, which has an incidence of 2% to 5%. Position statements from various organizations are currently contradictory. The Endocrine Society recommends universal screening. ACOG opposes routine screening in pregnancy (Committee Opinion No. 381).** Like T_4, thyrotropin-releasing hormone crosses the placenta; TSH does not.

Because iodine is actively transported across the placenta and the concentration of iodide in the fetal blood is 75% that of the maternal blood, the fetus is susceptible to iodine-induced goiters when the mother is given pharmacologic amounts of iodine. **Similarly, radioactive iodine crosses the placenta and, if given after 12 weeks' gestation when the fetal thyroid is able to concentrate iodine, profound adverse effects can occur.** These include fetal hypothyroidism, mental retardation, attention deficit disorder, and a 1% to 2% increase in the lifetime cancer risk.

Adrenal Glands

Increased steroid production is essential in pregnancy to meet the need for an increase in maternal production of estrogen and cortisol and the fetal need for reproductive and somatic growth development. **Pregnancy is associated with marked changes in adrenocortical function, with increased serum levels of aldosterone, deoxycorticosterone, corticosteroid-binding globulin (CBG), adrenocorticotropic hormone (ACTH), cortisol, and free cortisol and causes a state of "physiologic" hypercorticolism**[92,93] (see Chapter 41 and Appendix A1). Although the combined weight of the adrenal glands does not increase significantly, expansion of the zona fasciculata, which primarily produces glucocorticoids, is observed. The plasma concentration of CBG doubles (because of hepatic stimulation by estrogen) by the end of the sixth month of gestation compared with nonpregnant values, resulting in elevated levels of total plasma cortisol. **The levels of total cortisol rise after the first trimester and by the end of pregnancy are nearly three times higher than nonpregnant values and reach values that are in the range seen in Cushing syndrome.** The diurnal variations in cortisol levels may be partly blunted but are maintained, with the highest values in the morning.

Only free cortisol, the fraction of cortisol not bound to CBG, is metabolically active, but direct measurements are difficult to perform. However, urinary free cortisol concentrations, the free cortisol index, and salivary cortisol concentrations, all of which reflect active free cortisol levels, are elevated after the first trimester.[93,94] In a study of 21 uncomplicated pregnancies, Goland and associates found that the urinary free cortisol concentration doubled from the first to the third trimester.[93] Although the increase in total cortisol concentrations can be explained by the increase in CBG, this does not explain the higher free cortisol levels. The elevation in free cortisol levels seems to be caused in part by a marked increase in corticotropin-releasing hormone (CRH) during pregnancy, which, in turn, stimulates the production of ACTH in the pituitary and from the placenta. Outside of pregnancy, CRH is mainly secreted from the hypothalamus. During pregnancy, CRH is also produced by the placenta and fetal membranes and is secreted into the maternal circulation. First-trimester values of CRH are similar to prepregnant levels, followed by an exponential rise in CRH during the third trimester predominantly as a result of the placental production.[93] Goland and associates have shown that CRH and ACTH concentrations continue to rise in the third trimester despite the increased levels of total and free cortisol levels, supporting the theory that an increase in CRH drives the increased levels of cortisol seen in pregnancy. Furthermore, significant correlation is observed between the rise in CRH levels and maternal ACTH and urinary free cortisol concentrations.[93] Other possible causes for the hypercortisolism include delayed plasma clearance of cortisol as a result of changes in renal clearance, pituitary desensitization to cortisol feedback, or enhanced pituitary responses to corticotropin-releasing factors such as vasopressin and CRH.[92,95]

Although the levels of cortisol are increased to concentrations observed in Cushing's syndrome, little clinical evidence is present for hypercortisolism during pregnancy with the exception of weight gain, striae, hyperglycemia, and tiredness. **However, the diagnosis of Cushing syndrome during pregnancy is difficult because of these changes. The hypothalamic-pituitary axis response to exogenous glucocorticoids is blunted during normal pregnancy and makes interpretations of dexamethasone suppression tests for adrenal excess problematic.[95] In addition, pregnancy causes an enhanced adrenal responsiveness to higher-dose ACTH stimulation tests using 250 mcg of cosyntropin, making the diagnosis of adrenal insufficiency also difficult.**

Deoxycorticosterone (DOC), like aldosterone, is a potent mineralocorticoid. Marked elevations in the maternal concentrations of DOC are present by midgestation, reaching peak levels in the third trimester. In contrast to the nonpregnant state, plasma DOC levels in the third

trimester do not respond to ACTH stimulation, dexamethasone suppression, or salt intake.[92] These findings suggest that an autonomous source of DOC, specifically the fetoplacental unit, may be responsible for the increased levels. Dehydroepiandrosterone sulfate levels are decreased in gestation because of a marked rise in the metabolic clearance of this adrenal androgenic steroid. Maternal concentrations of testosterone and androstenedione are slightly higher; testosterone is increased because of an elevation in sex hormone-binding protein, and androstenedione is increased because of an increase in its synthesis.

Pituitary Gland

The pituitary gland enlarges in pregnancy, principally because of proliferation of prolactin-producing cells in the anterior pituitary (see Chapter 41). Gonzalez and colleagues demonstrated that the mean pituitary volume increased by 36% at term.[96] **The enlargement of the pituitary gland makes it more susceptible to alterations in blood supply and increases the risk for postpartum infarction (Sheehan syndrome) should a large maternal blood loss occur.** Anterior pituitary hormone levels are significantly affected by pregnancy. Serum prolactin levels begin to rise at 5 to 8 weeks' gestation and by term are 10 times higher. Consistent with this, the number of lactotroph (prolactin-producing) cells increases dramatically within the anterior lobe of the pituitary from 20% of the cells in nongravid women to 60% in the third trimester. In the second and third trimesters, the decidua is a source of much of the increased prolactin production. Despite the increase, prolactin levels remain suppressible by bromocriptine therapy.[97] The principal function of prolactin in pregnancy is to prepare the breast for lactation. In nonlactating women, the prolactin levels return to normal by 3 months postpartum. In lactating women, the return to baseline levels takes several months, with intermittent episodes of hyperprolactinemia in conjunction with nursing. **Maternal follicle-stimulating hormone and luteinizing hormone are decreased to undetectable levels as a result of feedback inhibition from the elevated levels of estrogen, progesterone, and inhibin.**[97] Maternal pituitary growth hormone production is also suppressed because of the action of placental growth hormone variant on the hypothalamus and pituitary; however, the serum levels of growth hormone increase as a result of the production of growth hormone from the placenta.[97]

The hormones produced by the posterior pituitary are also changed. The changes in AVP were discussed earlier in this chapter. Oxytocin levels increase from 10 pg/mL in the first trimester to 30 pg/mL in the third trimester. At term, an increase is noted to about 75 pg/mL, and during labor, these levels dramatically rise and peak in the second stage of labor.[98]

PANCREAS AND FUEL METABOLISM

Glucose

Pregnancy is associated with significant physiologic changes in carbohydrate metabolism. This allows for the continuous transport of energy, in the form of glucose, from the gravid woman to the developing fetus and placenta. Pregnancy taxes maternal insulin and carbohydrate physiology, and in all pregnancies, some deterioration in glucose tolerance occurs. In most women, only mild changes take place. In others, pregnancy is sufficiently diabetogenic **to result in gestational diabetes mellitus. Overall, pregnancy results in fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia.**[99] To accommodate the increased demand for insulin, hypertrophy and hyperplasia of the β cells (insulin producing) occur within the islets of Langerhans in the maternal pancreas. For a complete review of the physiologic changes in glucose metabolism, refer to Chapter 39.

Proteins and Fats/Lipids

Amino acids are actively transported across the placenta for the fetus to use for protein synthesis and as an energy source. In late pregnancy, the fetoplacental unit contains about 500 mg of protein. During pregnancy, fat stores are preferentially used as a substrate for fuel metabolism, and thus, protein catabolism is decreased.

Plasma lipids and lipoproteins increase in pregnancy. A gradual twofold to threefold rise in triglyceride levels occurs by term, and levels of 200 to 300 mg/dL are normal. Total cholesterol and low-density lipoprotein levels are also higher so that, by term, a 50% to 60% increase is observed. High-density lipoprotein levels initially rise in the first half of pregnancy and then fall in the second half. By term, high-density lipoprotein concentrations are 15% higher than nonpregnant levels. Triglyceride concentrations return to normal by 8 weeks postpartum even with lactation, but cholesterol and low-density lipoprotein levels remain elevated (Figure 3-12). The mechanisms for the pregnancy-induced changes in lipids are not completely understood but appear to be partly caused by the elevated levels of estrogen, progesterone, and human placenta lactogen. The rise in low-density lipoproteins appears to be necessary for placental steroidogenesis. Despite the increase in cholesterol and lipids, no increase in the long-term risk for atherosclerosis has been found. However, women with preexisting hyperlipidemia can have a transient worsening of their lipid profiles that is accentuated by the necessity for discontinuing medications such as HMG-CoA reductase inhibitors (statins).

EYE

Two consistent and significant ocular changes occur during pregnancy: increased thickness of the cornea and decreased intraocular pressure. Corneal thickening is apparent by 10 weeks' gestation and may cause problems with contact lenses. **Corneal changes persist for several weeks postpartum, and patients should be advised to wait before obtaining a new eyeglass or contact prescription.** Pizzarello found that 14% of women complained of vision changes. All had changes in their visual acuity and refractive error as well as a myopic shift (became more far-sighted) from pregravid levels, with return to baseline vision postpartum.[100] Because of these transient alterations in the eye, pregnancy is considered by most to be a contraindication to photorefractive keratectomy, and it has been recommended that pregnancy be avoided for 1 year after such surgery.

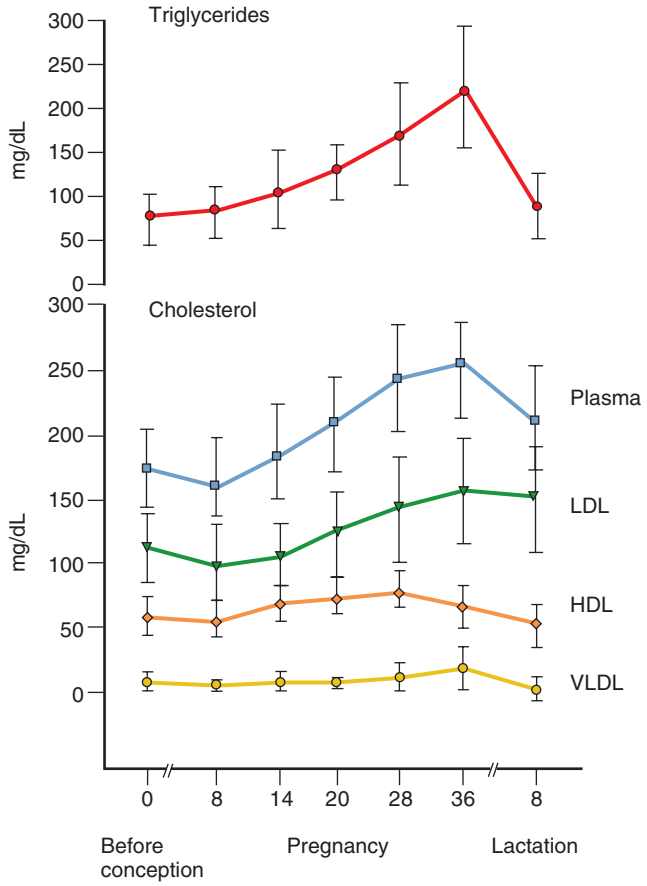

FIGURE 3-12. Triglycerides *(upper panel)* and cholesterol *(lower panel)* in plasma and in lipoprotein fractions before, during, and after pregnancy. *HDL,* High-density lipoprotein; *LDL,* low-density lipoprotein; *VLDL,* very-low-density lipoprotein. (From Salameh W, Mastrogiannis D: Maternal hyperlipidemia in pregnancy. Clin Obstet Gynecol 37:66, 1994.)

Intraocular pressure falls by about 10%, and individuals with preexisting glaucoma typically improve. Pregnancy either does not change or minimally decreases visual fields. Any complaints of visual field changes are atypical and need evaluation.

KEY POINTS

- Plasma osmolality decreases during pregnancy as a result of a reduction in the serum concentration of sodium and associated anions. The osmolality set point for AVP release and thirst is also decreased.
- CO increases 30% to 50% during pregnancy. Supine positioning and standing are both associated with a fall in CO. CO is maximum during labor and the immediate postpartum period.
- As a result of the marked fall in systemic vascular resistance and pulmonary vascular resistance, PCWP does not rise, despite an increase in blood volume.
- Maternal BP decreases early in pregnancy. The diastolic BP and the mean arterial pressure reach a nadir at midpregnancy (16 to 20 weeks) and return to prepregnancy levels by term.
- Pa_{O_2} and Pa_{CO_2} fall during pregnancy because of increased minute ventilation. This facilitates transfer of CO_2 from the fetus to the mother and results in a mild respiratory alkalosis.
- Maternal plasma volume increases 50% during pregnancy. RBC volume increases about 18% to 30%, and the hematocrit normally decreases during gestation, but not below 30%.
- Pregnancy is a hypercoagulable state, with increases in the levels of most of the procoagulant factors and decreases in the fibrinolytic system and in some of the natural inhibitors of coagulation.
- BUN and creatinine normally decrease during pregnancy as a result of the increased glomerular filtration rate.
- Despite alterations in thyroid morphology, histology, and laboratory indices, the normal pregnant woman is euthyroid, with levels of free T_4 within nonpregnant norms.
- Pregnancy is associated with a peripheral resistance to insulin, primarily mediated by human placental lactogen. Insulin resistance increases as pregnancy advances; this results in hyperglycemia, hyperinsulinemia, and hyperlipidemia in response to feeding, especially in the third trimester

KEY ABBREVIATIONS

Alpha-fetoprotein	AFP
B-cell Receptor	BCR
CC Receptor	CCR
Class II Transactivator	CIITA
CXC Receptor	CXCR
Fas Ligand	FasL
Graft-versus-host Disease	GVHD
Helper T Cell Type 1	Th1
Helper T Cell Type 2	Th2
Human Immunodeficiency Virus	HIV
Human Leukocyte Antigen	HLA
Indoleamine 2,3 Dioxygenase	IDO
Immunoglobulin	Ig
Interferon-γ	IFN-γ
Interleukin-1	IL-1
Kilodalton	kDa
Killer Cell Immunoglobulin-like Receptor	KIR
Lipopolysaccharide	LPS
LPS Binding Protein	LBP
Major Histocompatibility Complex	MHC
Membrane Attack Complex	MAC
Natural Killer	NK
Pattern-recognition Receptors	PRR
T-cell Receptor	TCR
TNF-related Apoptosis-inducing Ligand/Apo-2L	TRAIL
Toll-like Receptor	TLR
Transforming Growth Factor-β	TGF-β
Tumor Necrosis Factor-α	TNF-α
Uterine NK Cells	u-NK

The study of maternal-fetal immunology was initially driven by a desire to understand how a genetically foreign fetus could develop within the mother without immune rejection. Sir Peter Medawar described the immunologic paradox posed by pregnancy by asking, "How does the pregnant mother contrive to nourish within itself, for many weeks or months, a fetus that is an antigenically foreign body?"[1] He suggested several possibilities for fetal tolerance, including anatomic separation of the fetus and mother, antigenic immaturity of the fetus, and immunologic inertness of the mother. Although it was later discovered that fetal and maternal cells come into direct contact, these ideas became the basis for many early studies of maternal-fetal immunology. In fact, discovery of complex immunologic mechanisms at the maternal-fetal interface suggest that placental immune functions and active maternal-fetal interactions are critical for fetal development and maternal health. The finding of immunologic proteins in blood, amniotic fluid, and vaginal fluid of women with preterm labor and intra-amniotic infection has further led to the rapid investigation of maternal-fetal immune responses.[2-4] Discoveries arising from the study of immune responses in the mother and fetus have improved our understanding of maternal tolerance of the fetus, infection-associated preterm birth, preeclampsia, and pregnancy loss. Understanding concepts in maternal-fetal immunology will allow the clinician to gain a deeper appreciation for pregnancy and many perinatal complications.

IMMUNE SYSTEM OVERVIEW: INNATE AND ADAPTIVE IMMUNITY

The immune system is classically divided into two arms, the innate (Figure 4-1) and adaptive immune systems

INNATE IMMUNITY

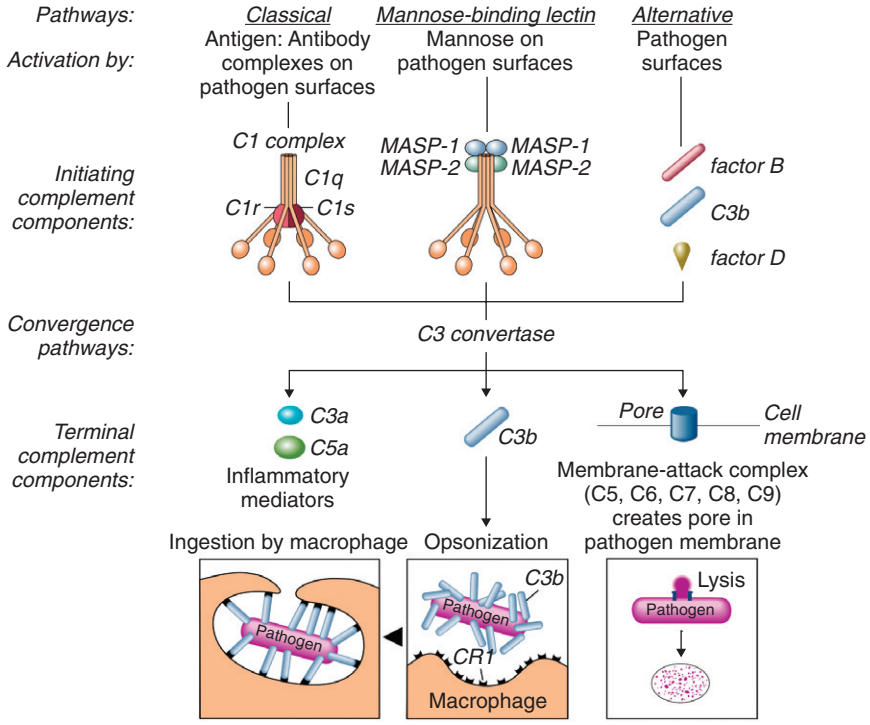
- First line of host defense to infection
- Rapid response
- Nonspecific recognition of broad classes of pathogens
- Preexisting effector cell population *(no amplification required)*
- Inability to discriminate self vs. non-self; only recognizes pathogens

A. Cells

B. Pattern Recognition Receptors: Recognize common microbial patterns and structures

		Example ligand	*Origin of ligand*
• Toll-like receptors (TLR)	— TLR1	Triacyl lipopeptides	Bacteria & mycobacteria
	— TLR2	Lipoprotein/lipopeptides	Various pathogens
		Peptidoglycan & lipotechoic acid	Gram-positive bacteria
• Macrophage mannose receptor	— TLR3	Double-stranded DNA	Viruses
• Mannan-binding lectin	— TLR4	Lipopolysaccharide	Gram-negative bacteria
	— TLR5	Flagellin	Bacteria
	— TLR6	Diacyl lipopeptides	*Mycoplasma*
	— TLR7 & 8	Single-stranded DNA	Viruses
	— TLR9	CpG-containing DNA	Bacteria and viruses
	— TLR10	Unknown	

C. Complement System: Plasma proteins that cooperate to facilitate destruction of pathogens



D. Induced Innate Immune Responses

Cytokines

TNF-α
IL-1
IL-6

Chemokines

IL-8
MIP-1α
MCP-1

Stimulate
- — Fever
- — Acute phase protein production
- — Neutrophil mobilization
- — Adaptive immune response

- — Facilitate leukocyte recruitment
- — Direct leukocyte migration

FIGURE 4-1. The innate immune system. The innate immune system acts as the first line of host defense and consists of immune cells **(A),** the pattern-recognition receptors that target common pathogen structures **(B),** the complement system **(C),** and induced innate immune responses **(D).** The toll-like receptors and their common ligands are listed because they act as the principal immune sensors of pathogens **(B).** Complement activation may occur through three different initiating pathways, which converge with production of the C3 convertase and generation of the terminal complement proteins **(C).** As a result of activation of these components of the innate immune system, neutrophils may be recruited to the site of infection and cytokines/chemokines may be produced **(D).**

(Figure 4-2). Each arm of the immune system fights infection by a slightly different and complementary method. In both systems, there are several important mechanisms to prevent maternal immunity from targeting and killing the fetus. Yet, the immune system must remain competent to overcome an infection to preserve the mother's life. Achieving a balance between controlling normal immune responses and maintaining immune function is one major challenge of pregnancy.

The innate immune system employs fast, nonspecific methods of pathogen detection to prevent and control an initial infection. Innate immunity consists of immune cells such as macrophages, dendritic cells, natural killer (NK) cells, eosinophils, and basophils. In pregnancy, these cells have been implicated in preterm labor, preeclampsia, maternal-fetal tolerance, and intrauterine growth restriction. Many of these cells identify pathogens through pattern-recognition receptors (PRRs), which recognize common pathogen structures such as lipoteichoic acid and lipopolysaccharide (LPS), constituents of the cells walls of gram-positive and gram-negative bacteria. PRRs include the macrophage mannose receptor and toll-like receptors (TLRs), a large family of PRRs that are likely responsible for the earliest immune responses to a pathogen.[5] TLR activation initiates a signaling cascade that leads to release of cytokines, which are small immunologic proteins that are implicated in many obstetrical complications, including preterm labor and preeclampsia. Another component of innate immunity is complement, which is a system of plasma proteins that coat pathogen surfaces with protein fragments, targeting them for destruction.

In many cases, innate immune defenses are effective in combating pathogens. Sometimes pathogens may evolve more rapidly than the hosts they infect or evade innate immune responses, like seasonal influenza viruses. The adaptive immune system must then act to control infection. **Adaptive immunity results in the clonal expansion of lymphocytes (T cells and B cells) and antibodies against a specific antigen. Although slower to respond, adaptive immunity targets specific components of a pathogen and is capable of eradicating an infection that has overwhelmed the innate immune system.** Adaptive immunity also requires presentation of antigen by specialized antigen-presenting cells, production and secretion of stimulatory cytokines, and ultimately, amplification of antigen-specific lymphocyte clones (T cells and B cells). These memory T and B cells provide lifelong immunity to the specific antigen.

INNATE IMMUNITY: FIRST LINE OF HOST DEFENSE

Epithelial surfaces of the body are the first defenses against infection. Mechanical epithelial barriers to infection include ciliary movement of mucus and epithelial cell tight junctions that prevent microorganisms from easily penetrating intercellular spaces. Chemical mechanisms of defense include enzymes (e.g., lysozyme in saliva, pepsin), low pH in the stomach, and antibacterial peptides (e.g., defensins in the vagina) that degrade bacteria.

After a pathogen enters the tissues, it is often recognized and killed by phagocytes, which is a process mediated by macrophages and neutrophils. The presence of TLRs, a family of PRRs, on the surface of macrophages and other innate immune cells, represents the primary mechanism of pathogen detection. TLR activation results in secretion of cytokines, which initiate inflammatory responses. Neutrophils are then recruited to sites of inflammation by small immunologic proteins, called chemokines (i.e., interleukin-8 [IL-8]) released by macrophages. Chemokines and cytokines are small immunologic proteins (e.g., IL-8, IL-6, tumor necrosis factor-α [TNF-α]) that coordinate many immune functions as well as cell activation, replication, and differentiation. Proinflammatory cytokines have been described in the mother, fetus, and amniotic fluid in women with preterm labor and intra-amniotic infection.[2,3]

Antimicrobial Peptides

Antimicrobial peptides are secreted by neutrophils and epithelial cells and kill bacteria by damaging pathogen membranes. Defensins are a major family of antimicrobial peptides that protect against bacterial, fungal, and viral pathogens. Neutrophils secrete α-defensins and epithelial cells in the gut and lung secrete β-defensins. Both α- and β-defensins are temporally expressed by endometrial epithelial cells during the menstrual cycle.[6] Susceptibility to upper genital tract infection may be related in part to the decreased expression of antimicrobial peptides in response to hormonal changes during the menstrual cycle. Many other tissues of the female reproductive tract and placenta secrete defensins, including the vagina, cervix, fallopian tubes, decidua, and chorion. Elevated concentrations of vaginal and amniotic fluid defensins have been associated with intra-amniotic infection and preterm birth.

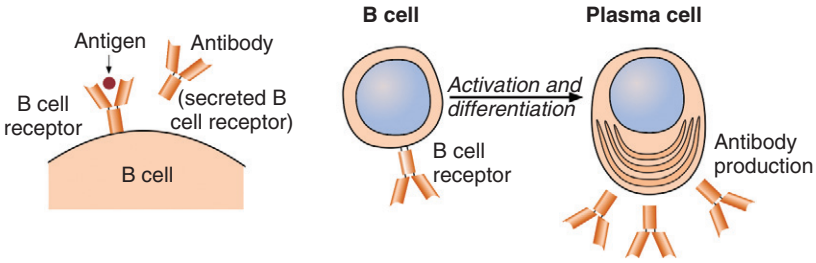
Macrophages

Macrophages mature from circulating monocytes that leave the circulation to migrate into tissues throughout the body. **Macrophages have critical scavenger functions that likely help to prevent bacteria from establishing an intrauterine infection during pregnancy. Macrophages are one of the most abundant immune cell types in the placenta and can directly recognize, ingest, and destroy pathogens.** Pathogen recognition may occur through PRRs, such as TLRs, scavenger receptors, and mannose receptors. Macrophages also internalize pathogens or pathogen particles through phagocytosis, macropinocytosis, and receptor-mediated endocytosis. Multiple receptors on the macrophage can induce phagocytosis, including the mannose receptor, scavenger receptor, CD14, and complement receptors. Macrophages also release many bactericidal agents after ingesting a pathogen, such as oxygen radicals, nitric oxide, antimicrobial peptides, and lysozyme.

Uterine macrophages represent up to one third of total leukocytes in pregnancy-associated tissue during the later parts of pregnancy. Macrophages are a major source of inducible nitric oxide synthetase, a rate-limiting enzyme for nitric oxide production. During pregnancy, nitric oxide is thought to relax uterine smooth muscle, and uterine nitric oxide synthetase activity and expression decreases before parturition. Uterine macrophages are also a major source of prostaglandins, inflammatory cytokines, and matrix metalloproteinases that are prominent during term

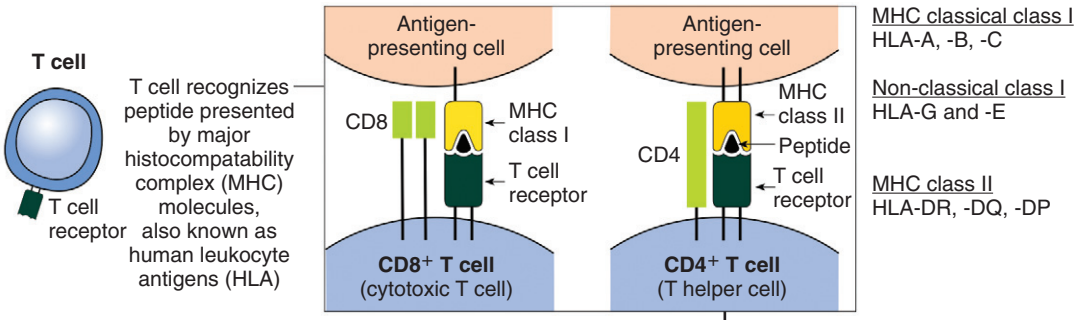
ADAPTIVE IMMUNITY
- Activated when innate immune defenses overwhelmed
- Delayed response
- Specific recognition of small protein peptides
- Requires amplification of lymphocyte clones
- Ability to discriminate self from non-self

A. B Cells Receptors and Antibodies

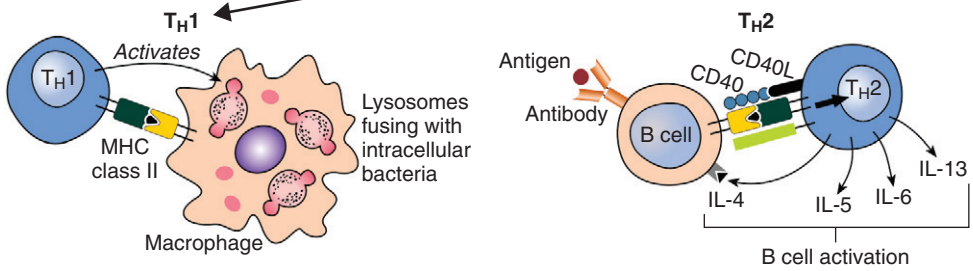


Antibody types
- IgA high in:
  - — Breast milk
  - — Vaginal fluid
  - — Gut
- IgD
  - — Surface Ig on naive B cells
- IgE
  - — Involved in allergic responses
- IgG
  - — Most abundant Ig
  - — Crosses placenta
  - — Involved in immunologic memory
- IgM
  - — Involved in primary B cell responses

B. T Cells and T Cell Receptors



C. T Helper Type 1 (T_H1) and Type 2 (T_H2) Responses



- T helper type 1 response activates macrophages
- Associated cytokines:
  - — IFN-γ
  - — TNF-α
  - — IL-12
  - — IL-18
- Induced by *Listeria monocytogenes* and may contribute to intrauterine fetal death

- T helper type 2 response activates B cells
- Associated cytokines:
  - — IL-4
  - — IL-5
  - — IL-6
  - — IL-13
- Cytokines with anti-inflammatory properties
  - — IL-10
  - — TGF-β
- Thought to dominate over Th1 responses in pregnancy

FIGURE 4-2. The adaptive immune system. The adaptive immune system acts to control infection that has overwhelmed the innate immune system and is also important in transplant rejection and tumor killing. B cells secrete antibodies to protect the extracellular spaces of the body from infection and assist in the activation of helper T ($CD4^+$) cells **(A).** Different classes of antibodies reflect structural variations that allow antibodies to be targeted to different bodily compartments and serve slightly different functions. The first step in T-cell activation occurs when the T-cell receptor recognizes a complex of peptide presented by an MHC molecule **(B).** A $CD4^+$ T cell recognizes peptide presented by MHC class II and a $CD8^+$ T cell interacts with peptides presented by MHC class I. Peptides may be presented by many different types of the listed MHC class I or class II molecules. After activation, the $CD4^+$ T cell (or helper T cell) may either activate macrophages through a helper T-cell type 1 response or activate B cells through the helper T-cell type 2 response **(C).**

and preterm parturition. Throughout pregnancy, macrophages are also in close proximity to invading trophoblasts that establish placentation. Placental growth involves trophoblast remodeling and programmed cell death (apoptosis). Macrophages in the placenta phagocytose apoptotic trophoblast, which also programs the macrophage to release anti-inflammatory cytokines (e.g., IL-10) promoting fetal tolerance.

Natural Killer Cells

The NK cell has important functions during pregnancy and becomes the most abundant leukocyte in the pregnant uterus. NK cells differ from T and B cells in that they do not express clonally distributed receptors for foreign antigens and can lyse target cells without prior sensitization. The phenotype of uterine NK (u-NK) cells is different from that of NK cells in peripheral blood, which seems to correlate with different primary functions. Most (90%) NK cells in blood have low CD56 and high CD16 expression ($CD56^{dim}/CD16^{bright}$); in the uterine decidua, u-NK cells have high CD56 expression ($CD56^{bright}$). The level of CD56 expression determines whether an NK cell has a primary cytolytic ($CD56^{dim}$) or cytokine-producing function ($CD56^{bright}$). Analysis of 10,000 genes from peripheral blood NK cells (dim and bright) and u-NK cells revealed more than 250 genes in which expression differed at least threefold. At least two of the upregulated proteins in u-NK cells, galectin-1 and progestagen-associated protein-14, are known to have immunomodulatory and immunosuppressive functions.

u-NK cells are thought to play a major role in remodeling of the spiral arteries to establish normal placentation. Mice with genetically defective u-NK cells fail to undergo spiral artery remodeling and normal decidualization, which are critical to normal placentation. This defect is corrected with administration of interferon-γ (IFN-γ), a prominent NK cell cytokine, suggesting that u-NK cells may play a role in trophoblast invasion.

Toll-like Receptors

TLRs are a recently discovered large family of PRRs on macrophages and many other cell types that play a key role in innate immunity.[5] **TLRs are now recognized as the principal sensors of pathogens and can activate both the innate and adaptive immune system.** At least 11 mammalian toll homologues have been identified, and they recognize a wide range of pathogen ligands (see Figure 4-1, *B*). TLR4 is a TLR that recognizes LPS from gram-negative bacteria, which triggers a signaling cascade leading to cytokine gene expression (Figure 4-3). TLR4 is expressed on macrophages, dendritic cells, endothelium, and numerous epithelial tissues. TLR2 recognizes motifs from gram-positive bacteria, including lipoteichoic acid and peptidoglycan.

Both TLR2 expression and TLR4 expression have been demonstrated in the placenta, and first-trimester trophoblast expresses both TLR2 and TLR4.[7] Activation of TLR2 triggers Fas-mediated apoptosis, whereas TLR4 activation induces proinflammatory cytokine production. The immunologic capability of first-trimester trophoblast to recognize pathogens and induce apoptosis suggests that innate immunity may be an important placental mechanism for triggering spontaneous abortion. TLR4 is also expressed in villous macrophages, villous and extravillous trophoblast, and the amniochorion. Expression of TLR4 and TLR2 increases in the chorioamniotic membranes of women with intraamniotic infection and also in term labor, suggesting an important role in both of these processes.[8]

Although intrauterine injection of LPS induces preterm birth in many murine and nonhuman primate models, administration of LPS to TLR4 mutant mice or LPS blockade with a TLR4 antagonist does not result in preterm delivery.[9,10] This finding suggests TLR4 is required for LPS-induced preterm birth in mice and is an important driver of the inflammatory cascade resulting from intra-amniotic infection. There is also a distinct progression in the responsiveness of fetal murine tissue to

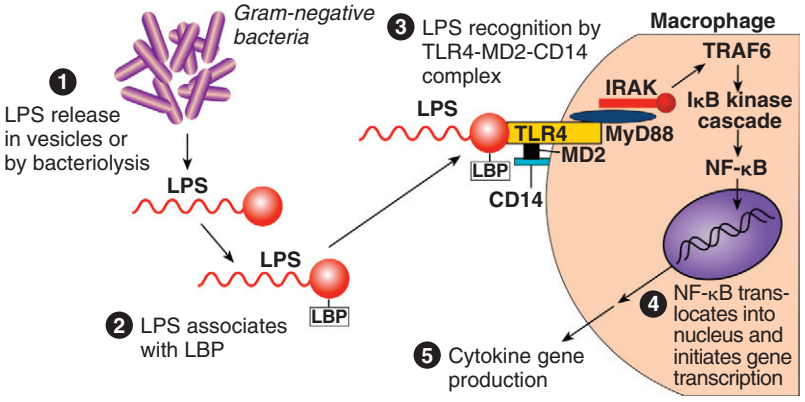


FIGURE 4-3. Toll-like receptor-4 (TLR4) recognition of lipopolysaccharide (LPS). Recognition of LPS by TLR4 occurs through several steps. (1) LPS is released from intact or lysed bacteria. (2) LPS binds to LPS-binding protein (LBP). (3) The LPS-LBP complex is recognized by a cell surface receptor complex TLR4, CD14, and MD-2. Binding of LPS-LBP to the TLR4, CD14, MD-2 receptor recruits the intracellular adaptor molecule, myeloid differentiation factor-88 (MyD88). Binding of MyD88 promotes the association of IL-1 receptor-associated protein kinase-4 (IRAK). Next, tumor necrosis factor receptor–associated kinase-6 (TRAF6) initiates a signaling cascade resulting in degradation of Iκ-B, which releases nuclear factor-κB (NF-κB), a transcription factor, into the cytoplasm. (4) NF-κB translocates into the nucleus and activates cytokine gene expression. Although the figure depicts TLR4 activation in a macrophage, many other immunologic and epithelial cells express TLR4 and induce cytokine production through this mechanism.

LPS as a function of gestational age.[11] When fetal lung is exposed to LPS on fetal day 14 (term is 20 days), both the expression of TLR4 and the acute cytokine response are undetectable. By day 17, TLR4 is expressed and an acute cytokine response occurs in fetal lungs. TLR4 likely controls the magnitude of the LPS-induced cytokine response during the perinatal period, and TLR4 placental expression appears to be dependent on gestational age.

Complement System

An important component of the innate immune system is the complement system, which consists of a large number of plasma proteins that cooperate to destroy and facilitate the removal of pathogens (see Figure 4-1, *C*). Complement proteins are detected in the amniotic fluid during intraamniotic infection, and regulation of complement is necessary to protect placental and fetal tissues from inflammation and destruction. The complement cascade is first activated by the surface antigens of pathogens. The nature of the initial pathogen trigger determines one of three activation pathways: classical, alternate, and lectin-binding pathways. For example, the classical pathway of complement activation is triggered when the complement protein, C1q, binds to antigen-antibody complexes on the surface of pathogens. This binding then results in a series of activation and amplification steps that result in production of the membrane attack complex (MAC), which creates a pore in the pathogen membrane leading to cell lysis. Formation of the MAC is an important mechanism of host defense against *Neisseria* species. Genetic deficiencies in C5-C9 complement proteins have been associated with susceptibility to *Neisseria gonorrhea* and *Neisseria meningitidis*.[12]

Regulatory proteins exist to protect cells from the deleterious effects of complement and are expressed on the placental membranes. Placental tissues at the maternal-fetal interface strongly express several negative regulators of complement activation, including CD59 (MAC antagonist), membrane cofactor protein, and decay accelerating factor (inhibitor of C3 and C5 convertases).[13,14] Whether these regulatory proteins might become overwhelmed during an intra-amniotic infection, leading to weakening of the membranes by complement proteins, is unknown.

Cytokines

The release of cytokines and chemokines by macrophages and other immune cells represents an important induced innate immune response (Table 4-1; see Figure 4-1, *D*) **Activated macrophages secrete cytokines that initiate inflammatory responses to control infections, which include IL-1, IL-6, IL-12, and TNF-α.** These cytokines are often referred to as proinflammatory because they mediate fever, lymphocyte activation, tissue destruction, and shock. Elevations in cytokines may influence the degree of morbidity and mortality associated with maternal influenza infection. Dramatic elevations in IL-6 have been implicated in deaths due to the 1918 influenza virus with an estimated mortality in pregnancy of 27%.[15]

Abnormal cytokine profiles have been associated with both preterm labor and preeclampsia. Proinflammatory cytokines have been identified in the amniotic fluid, maternal and fetal blood, and vaginal fluid of women with intra-amniotic infection.[2-4,16] These cytokines not only serve as a marker of intraamniotic infection but also may induce preterm labor and neonatal complications. The connection between elevated proinflammatory cytokines in fetal blood, preterm labor, and increased adverse fetal outcomes has been described as the "fetal inflammatory response syndrome."[16]

The relative contribution of individual cytokines and chemokines on induction of preterm labor was studied in a unique nonhuman primate model. Preterm labor was induced by intra-amniotic infusions of IL-1β and TNF-α, but not by IL-6 or IL-8. IL-1β stimulated preterm labor in all cases and an intense contraction pattern.[17] TNF-α induced a variable degree of uterine activity among individual animals characterized as either preterm labor or a uterine contraction pattern of moderate intensity. Despite prolonged elevations in amniotic fluid levels, neither IL-6 nor IL-8 induced an increase in uterine contractions until near term. These results suggested a primary role for IL-1β and TNF-α in the induction of infection-associated preterm birth.

Anti-inflammatory cytokines like IL-10 and transforming growth factor-β (TGF-β) act to downregulate inflammatory responses. IL-10 has been tested as a potential therapy for infection-induced preterm labor in a nonhuman primate model.[18] In the model, preterm labor was first induced by intraamniotic administration of IL-1β. IL-10

TABLE 4-1 CYTOKINES AND THEIR PRIMARY ACTION

Regulating Immune/Inflammatory Response

CYTOKINE	PRODUCED BY	PRIMARY ACTION
Interferons	Monocytes and macrophages	Produced in response to viruses, bacteria, parasites, and tumor cells Action includes killing tumor cells and inducing secretion of other inflammatory cytokines One of the first cytokines that appear during an inflammatory response
Interleukin-1	Monocytes and macrophages	Induces fever; co-stimulator of $CD4^+$ helper T cells
Interleukin-2		Primary growth factor and activation factor for T cells, NK cells
Interleukin-4	$CD4^+$ helper T cells	B-cell growth factor for antigen activated B cells
Interleukin-6	Monocytes and macrophages	Regulates growth and differentiation of lymphocytes and growth factor for plasma cells, and induces the synthesis of acute phase reactants by the liver
Interleukin-8	Monocytes	Chemoattractant for neutrophils
Interleukin-10	$CD4^+$ helper T cells	Suppresses production of interferon, suppresses cell-mediated immunity, enhances humoral immunity
Transforming growth factor-β	T cells and monocytes	Inhibits the proliferation of lymphocytes

inhibited IL-1β-induced uterine contractions and elevations in amniotic fluid TNF-α and prostaglandins. However, other proinflammatory cytokines and hormones involved in labor were not suppressed.

Investigation of the individual effect of a single cytokine on pregnancy or complications of pregnancy in humans has proved challenging for several reasons. Many cytokines tend to be functionally redundant, and the absence of one cytokine can be compensated for by another. Second, there are multiple cytokine receptors (i.e., IL-1 receptor antagonist, IL-18 binding protein) that modulate similar cytokine effects. New families of decoy or silent cytokine receptors and suppressors of cytokine signaling have also been discovered in the placenta and amniotic fluid. Finally, molecular variants of cytokines may act as receptor antagonists. Therefore, individual cytokine effects during pregnancy must be interpreted in the context of cytokine receptors, receptor antagonists, silent cytokine receptors, and suppressors of cytokine signaling.

Chemokines

Chemokines are a class of cytokines that act primarily as chemoattractants and direct leukocytes to sites of infection. These chemotactic agents constitute a superfamily of small (8 to 10 kDa) molecules that can be divided into three groups (C, CC, and CXC) based on the position of either one or two cysteine residues located near the amino terminus of the protein. IL-8, macrophage chemoattractant protein-1, and RANTES (CCL5) are a few examples of chemokines. CXC chemokines, like IL-8, bind to CXC receptors (CXCRs) and are important for neutrophil activation and mobilization. IL-8 has been described in the amniotic fluid, maternal blood, and vaginal fluid with infection-associated preterm birth.[19] IL-8 and MCP-1 are also implicated in uterine stretch-induced preterm labor thought to occur in multiple gestation.[20]

Some chemokine receptors are used as a coreceptor for the viral entry of the human immunodeficiency virus (HIV). The two major coreceptors for HIV are CXCR4 and CCR5, both of which are expressed on activated T cells. CCR5 is also expressed on dendritic cells and macrophages, which allows HIV to infect these cell types. Rare resistance to HIV infection was discovered to correlate with homozygosity for a nonfunctional variant of CCR5 caused by a gene deletion in the coding region. The gene frequency for this CCR5 variant is highest in Northern Europeans but has not been detected in many black or Southeast Asian populations, in whom the prevalence of HIV infection is high.[21]

ADAPTIVE IMMUNITY

The function of the adaptive immune system is to eliminate infection as the second line of immune defense and provide increased protection against reinfection through "immunologic memory." Adaptive immunity consists primarily of B cells and T cells (lymphocytes), which differ from innate immune cells in several important respects, including the mechanism for pathogen recognition and lymphocyte activation. Targeting a specific pathogen component in an immune response is a critical feature of the adaptive immune system and necessary, in most cases, for resolution of the infection. However, achieving this specificity requires generation of an incredible diversity of T-cell receptors (TCRs) and B-cell receptors (BCRs). This creates the potential that self-antigens could be mistakenly targeted, resulting in an autoimmune response. Self-reactive T cells and B cells are thought to either undergo apoptosis in the thymus or be regulated in the periphery. A small population of T cells (regulatory T cells) is now known to contribute to peripheral regulatory mechanisms to prevent autoimmune responses and is discussed specifically in reference to mechanisms of fetal tolerance.

Major Histocompatibility Complex

Discriminating cells that are "self" from "nonself" is a critical function of the immune system to determine which cells should be destroyed and which to leave alone. In pregnancy, this process must be carefully regulated to prevent the killing of fetal cells, which express paternal genes that appear foreign to the maternal immune system, in effect expanding the definition of self to include the fetus. The ability of a lymphocyte to recognize self from nonself is based on the expression of unique MHC molecules on a cell's surface, which present small peptides from within the cell. MHC molecules are highly polymorphic proteins produced by a cluster of genes on the short arm of chromosome 6. This gene complex is classically divided into two distinct regions referred to as class I and II. Class I contains classical transplantation human leukocyte antigen (HLA) genes (e.g., HLA-A, -B, and -C) and nonclassical HLA genes that are distinguished by more limited polymorphism (e.g., HLA-G, -E, and -F). Class II contains polymorphic genes that are often matched for transplantation, including HLA-DR, -DQ, and -DP. Reduced HLA matching is associated with graft rejection through activation of T cells. This system is significantly different from the innate immune system, in which recognition of MHC is not necessary for pathogen destruction.

Humoral Immune Response: B Cells and Antibodies

The function of B cells is to protect the extracellular spaces (e.g., plasma, vagina) in the body through which infectious pathogens usually spread (see Figure 4-2, *A*). B cells mainly fight infection by secreting antibodies, also called immunoglobulins. There are many similarities between B and T lymphocytes. B cells also undergo clonal expansion after antigen stimulation and can be identified by a variety of specific cell surface markers (e.g., CD19, CD20, and BCR antigens). Activated B cells may proliferate and differentiate into antibody-secreting plasma cells. Antibodies control infection by several mechanisms, including neutralization, opsonization, and complement activation. Neutralization of a pathogen refers to the process of antibody binding, which prevents the pathogen from binding to a cell surface and internalizing. Alternatively, antibodies coating the pathogen may enhance phagocytosis, also referred to as *opsonization*. Antibodies may also directly activate the classical complement pathway. Activation of the B cell drives the B cell to proliferate and differentiate into an antibody-secreting plasma cell.

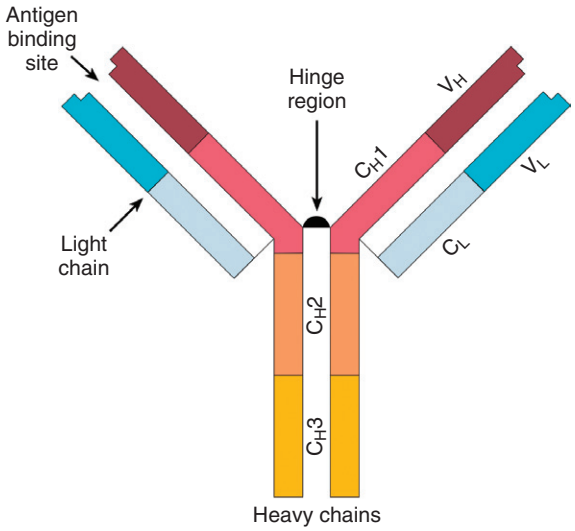

FIGURE 4-4. Structure of immunoglobulin (IgG).

Antibody Isotypes

Antibodies share the same general structure produced by the interaction and binding of four separate polypeptides (Figure 4-4). These include two identical light (L) chains (23 kDa), and two identical heavy (H) chains (55 kDa). The composition of the H chain determines the antibody isotype, function, and distribution in the body. In humans, there are five types of H chains designated mu (M), delta (D), gamma (G), alpha (A), and epsilon (E) that correspond to the five major antibody isotypes (immunoglobulin M [IgM], IgD, IgG, IgA, and IgE). During normal pregnancy, serum concentrations of IgG, IgA, and IgM are unchanged.

To effectively combat extracellular pathogens, antibodies must be specialized to cross epithelia into different bodily compartments. In fact, antibodies are made in several distinct classes or isotypes (i.e., IgM and IgG) that vary in their composition. Naïve B cells express only IgM and IgD. Activated B cells undergo isotype switching, a process that produces different antibody isotypes specialized for different functions and areas of the body.

The first antibody to be produced during an immune response is IgM because IgM is expressed before isotype switching. The serum concentration of IgM is 50 to 400 mg/dL, with a circulation half-life of 5 days. IgM antibodies are low in affinity, but the antibodies form pentamers that compensate by binding at multiple points to the antigen. IgM is highly efficient at activating the complement system, which is critical during the earliest stages of controlling an infection. Other isotypes dominate in the later stages of antibody responses.

IgG represents about 75% of serum immunoglobulin in adults and is further divided into four subclasses (IgG1, IgG2, IgG3, and IgG4). **Two subtypes of IgG, IgG1 and IgG3, are efficiently transported across the placenta and are important in conferring humoral immune protection for the fetus after birth.** The smaller size of IgG and its monomeric structure allows it to easily diffuse into extravascular sites.

IgA is the predominant antibody class in epithelial secretions from the vagina, intestine, and lung. IgA forms dimers and mainly functions as a neutralizing antibody. As a secreted antibody, IgA is not in close contact with either phagocytes or complement and, therefore, is less efficient in opsonization and complement activation. In the vagina, an IgA response mounted against anti–*Gardnerella vaginalis* hemolysin was associated with higher levels of IL-1β.[22] Induction of both innate and adaptive immune responses to lower genital tract infections may be a necessary event in preventing spread to the upper genital tract.

IgA is also the principal antibody in breast milk, which provides the neonate with humoral immunity from the mother. Neonates are particularly susceptible to infectious pathogens through their intestinal mucosa, and IgA is highly effective in neutralizing these bacteria and toxins. Epidemiologic studies indicate that deaths from diarrheal diseases could be reduced between 14-fold and 24-fold by breastfeeding, owing in part to the maternal-infant transmission of IgA.[23]

IgE has the lowest concentration in serum of all the antibodies but is bound efficiently by mast cell receptors. IgE binding of antibody triggers the mast cell to release granules, resulting in an allergic response. Prenatal maternal exposure to allergens may have an effect on IgE in the fetus at birth; concentration of house dust mite allergens has been correlated in a dose-dependent manner, with total IgE measured in heel capillary blood. IgE also plays a prominent role in immune responses to eukaryotic parasites.

T CELLS

When pathogens replicate inside cells (all viruses, some bacteria and parasites), they are inaccessible to antibodies and must be destroyed by T cells. T cells are lymphocytes responsible for the cell-mediated immune responses of adaptive immunity, which require direct interactions between T lymphocytes and cells bearing the antigen that the T cells recognize. Common to all mature T cells is the TCR complex. T cells develop the vast array of antigen specificity through a series of TCR gene rearrangements, and many aspects of TCR rearrangements are similar to those producing antibody specificity. For example, during viral replication inside a host cell, viral antigen is expressed on the surface of the infected cell. These foreign antigens are then recognized by T cells along with HLA. HLA class I molecules present peptides from proteins in the cytosol, which may include degraded host or viral proteins. HLA class II molecules bind peptides derived from proteins in intracellular vesicles, and thus display peptides derived from pathogens in macrophage vesicles, internalized by phagocytic cells, and B cells.

A variety of T cells are recognized based on their expression of different cell surface markers (i.e., CD2, CD3, CD4, CD8). Cytotoxic T cells kill infected cells directly and express a variety of cell surface antigen and specific receptors, including CD8. Helper T cells activate B cells and express CD4. Cytotoxic and helper T cells recognize peptides bound to proteins of two different classes of HLA molecules (see Figure 4-2, *B*). Antigen-presenting cells will present antigen to $CD8^+$ T cells in the context of MHC class I molecules (e.g., HLA-A). In contrast, antigen-presenting cells that present antigens with MHC class II

molecules (e.g. HLA-DR) interact with T cells bearing CD4.

HIV employs multiple strategies to disable T-cell responses. Targeting viral infection to the $CD4^+$ T cells allows the virus to control and ultimately destroy this important T-cell subset. HIV destroys $CD4^+$ T cells through direct viral killing, lowering the apoptosis threshold of infected cells, and through $CD8^+$ T cells that recognize viral peptides on the $CD4^+$ T-cell surface. $CD8^+$ T cells likely contain the infection but are unable to eradicate the virus. Viral mutants produced during one of the earliest steps of viral infection may contribute to escape of virus-infected cells from $CD8^+$ T cell killing. The error-prone reverse-transcriptase copies the RNA viral genome into DNA, making "mistakes" that lead to production of these viral variants. The presentation of peptides from HIV variants by $CD4^+$ T cells may also interfere and downregulate the $CD8^+$ T-cell response to the original (wild-type) virus. Finally, the HIV negative-regulation factor gene *(nef)* downregulates expression of MHC class II and CD4, which decreases the presentation of viral antigens on the cell surface.

Helper T Subsets

$CD4^+$ T cells were originally classified into Th1 and Th2 subsets depending on whether their main function involved cell-mediated responses and selective production of IFN-γ (Th1) or humoral-mediated responses with production of IL-4 (Th2). The number of subsets identified continues to expand and now includes regulatory T cells, Th3, Th17, Th9, Th22, and follicular helper T cells (T_{FH}).[24] Helper T cells are also no longer thought to be committed to this function and may exhibit plasticity between some of these subsets. Description of the Th1 and Th2 subsets follows because there is evidence to suggest that they may play a role in pregnancy tolerance.

The Th1 subset is important in the control of intracellular bacterial infections such as *Mycobacterium tuberculosis* and *Chlamydia trachomatis*. Intracellular bacteria survive because the vesicles they occupy do not fuse with intracellular lysosomes, which contain a variety of enzymes and antimicrobial substances. Th1 cells activate macrophages to induce fusion of their lysosomes with vesicles containing the bacteria. Th1 cells also release cytokines and chemokines that attract macrophages to the site of infection, like IFN-γ, TNF-α, IL-12, and IL-18. Activating a Th1 immune response is a common feature of current vaccines targeting *Chlamydia* species.[25]

Th2 immune responses are mainly responsible for activating B cells by providing a critical "second signal" necessary for B-cell activation. Th2 cells produce cytokines, including IL-4, IL-5, IL-6, IL-10, IL-13, and TGF-β. The signals that trigger differentiation down these two pathways are unknown but are thought to be influenced by cytokines produced in response to the infection.

Th2-type and perhaps Th3-type activity may predominate during pregnancy, a theory based on the adverse effects of Th1 cytokines on murine pregnancy and weakened maternal immunity to intracellular infections requiring Th1 cytokine activity.[26-28] IL-10 may be a critical Th2 cytokine in maintaining pregnancy because it downregulates Th1 cytokine production and prevents fetal resorption in mice genetically predisposed to abortion.[29] In a study of women with a history of recurrent spontaneous abortion, maternal cytokine profiles of stimulated peripheral blood mononuclear cells were compared between women with a successful pregnancy and those with a spontaneous abortion. Increased Th2 cytokines were associated with a successful pregnancy, and elevated Th1 cytokines were associated with a spontaneous abortion.[30] Whether Th1 cytokine production causes spontaneous abortion or occurs after fetal death is unknown. Recent evidence suggests that the Th1/Th2 paradigm may be an oversimplification and that cytokine signaling during pregnancy is likely to be a more complicated process.

FETAL IMMUNE SYSTEM

Descriptions of the development of the fetal immune system are relatively limited, but sufficient information exists to determine that the fetus, even very early in gestation, has innate immune capacity.[31-33] **Acquired immunity, particularly the capacity to produce a humoral response, develops more slowly and is not completely functional until well after birth.** Many of the immune protective mechanisms that are present to protect the fetus from both pathogens and maternal immune recognition occur at the maternal-fetal interface.

Fetal hematologic development initiates in the fetal yolk sac and aortic-genital ridge. The exact contribution of these two sites to hematopoietic development is controversial, with many now favoring the initial site of hematopoietic development for the fetus initiating at the aortic-genital ridge. Hematopoietic stem cells migrate from their site of initial production in the fetal liver, and ultimately reside in the fetal bone marrow, which becomes the major site of hematopoiesis at about 28 weeks of gestation.

Fetal thymic development begins from the third and fourth brachial pouches and cleft. A primordial thymus is present at about 7 weeks' gestation. The thymus is first colonized with cells from the fetal liver at 8.5 to 9.5 weeks' gestation. These cells express primitive (CD34) and early T-cell surface antigen, $CD7^+$. Shortly after this, 20% to 50% percent of cells in the fetal thymus express the common T-cell surface phenotypes (CD7, CD2). Between 12 and 13 weeks, cells within the fetal liver and spleen express the TCR. By 16 weeks' gestation, the fetal thymus has distinct cortical and medullary regions, suggesting functional maturity, and this is confirmed by the brisk response to allogeneic and mitogen stimulation. Functionally, fetal T cells show proliferative capacity very early in gestation. In vitro stimulation by phytohemagglutinin can be demonstrated as early as 10 weeks. Allogeneic responses in mixed lymphocyte culture can be detected in cells obtained from fetal liver as early 9.5 weeks and are consistently seen at 12 weeks of gestation.[34]

The ontogeny of fetal B-cell development in many ways parallels the development of T cells, with early pre-B cells (CD19 and CD20) being identified by cell surface markings in the fetal liver by 7 to 8 weeks' gestation.[35] Ultimately, these cells are produced in the fetal bone marrow as the marrow becomes the primary hematopoietic organ in the second trimester. Surface expression of IgM can be

TABLE 4-2 COMMON IMMUNE DEFECTS

COMMON NAME	DEFECT	CELLS AFFECTED	COMMENTS
X-SCID	Common γ chain of IL-2 receptor	T cells and NK cells	X-linked recessive and most common form of SCID accounting for about 45% to 50% of cases
ADA-SCID	Defect in purine metabolism leading to abnormal accumulation of adenosine	T cells, B cells, and NK cells	Autosomal recessive affecting both male and female infants Accounts for about 20% of SCID cases
Jak-3 deficiency	Mutation on chromosome 19 of Janus kinase-3 that is activated by cytokine binding to the common γ chain of the IL-2 receptor	T cells and NK cells	Autosomal recessive affecting both male and female infants Accounts for about 10% of SCID cases
Hyper-IgM syndrome Autosomal recessive	Defect in CD40 ligand (T cell) and CD40 (B cell) signaling resulting in the inability of immunoglobulin class switching	Elevated IgM	X-linked and autosomal recessive

ADA-SCID, Adenosine deaminase severe combined immunodeficiency; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M; *IL-2*, interleukin-2; *NK*, natural killer; *X-SCID*, X-linked severe combined immunodeficiency.

noted as early as 9 to 10 weeks. Cells in the fetal circulation express the common B-cell antigens (CD20) by 14 to 16 weeks' gestation, and secretion of IgM has been noted as early as 15 weeks. The level of IgM continues to increase and reaches normal postnatal levels by 1 year of age. The appearance of surface IgG and IgA is noted in fetal B cells at 13 weeks with secretion of IgG at 20 weeks' gestation. Postnatal levels of immunoglobulin are not reached until about 5 years of age.

NK cells also play an important role in fetal immunity. Expressed as a percentage of the total lymphocytes, the proportion of NK cells in the fetal circulation is high (30% at 13 weeks). Based on their high number, early presence, and the ability to kill cells directly or through antibody-mediated toxicity, it is likely that NK cells play a significant role in the fetal innate immune system.

Fortunately, abnormalities of normal immune development are relatively rare. However, when they do occur, they can have profound effects on newborn and child health. Some of the more common immunodeficiencies are listed in Table 4-2.[36,37]

Cord Blood Transplantation

Fetal blood contains a high frequency of hematopoietic stem cells as well as naïve T cells and NK cells. All these features make fetal blood an ideal source of cells for bone marrow transplantation. In 1988, the first bone marrow transplantation was carried out in a child with Fanconi anemia using a cord blood sample from an HLA-identical sibling.[38] During the ensuing 20 years, more than 20,000 cord blood transplantations have been performed, and obstetricians are frequently requested to collect umbilical cord blood remaining in the placenta after cord clamping. Cord blood is typically collected into closed-system bags or syringes that contain anticoagulation additives. The average volume per collection is about 75 mL of cord blood, which is processed to deplete red blood cells and then cryopreserved for later use. Cord blood samples are processed at either private or public cord blood banks. Specimens banked at private cord blood banks will be reserved for the donor family, with an estimated need for use between 1 per 1000 and 1 per 200,000.[39] Samples donated to public cord blood banks are processed, HLA typed, and entered into the National Marrow Donor Program, where they are made available to any individual requiring bone marrow transplantation. The major advantage of public banks is that samples are available to ethnic groups, which traditionally have difficulty finding a suitable HLA-matched donor (e.g. Native Americans, Asian/Pacific Islanders, and African Americans).[40] The American Congress of Obstetricians and Gynecologists recommends that if a patient requests information regarding collection and banking of umbilical cord blood, balanced and accurate information regarding the advantages and disadvantages of public versus private banking should be provided. Private umbilical cord blood banking seems to be cost-effective only for children with a very high likelihood of needing a stem cell transplant.[41] Physicians or other professionals who recruit pregnant women and their families for for-profit umbilical cord blood banking should disclose any financial interests or other potential conflicts of interest.

Cord blood specimens were initially used only in children because of the reduced number of $CD34^+$ cells that were present in the donor specimen. As use increased, even in the setting of less than ideal HLA matching, engraftment success was accompanied by a reduction in the frequency of severe (grades 3 and 4) graft-versus-host disease (GVHD). Because of the success noted in children, cord blood specimens are now commonly used in adults. The relative immaturity of the donor cells and total number of stem cells in the donor graft often result in delayed engraftment compared with other sources of donor hematopoietic cells. In some settings, in which the donor CD34 count is considered insufficient or less than ideal, more than one donor cord blood specimen is used. After engraftment, usually only one donor source predominates, and the recipient does not develop multisource mixed chimerism. The National Marrow Donor Program estimates that by 2015, more than 10,000 cord blood transplantations will be carried out annually worldwide, suggesting that cord blood collection for public banking will become commonplace in many obstetrical units. At the present time, the need for autologous cord blood cells is limited. In 2006, the World Marrow Donor Association stated that there were, at present, no established protocols for the use of autologous cord blood. Cord blood has been cited as a potential source of stem cells that could ultimately be used

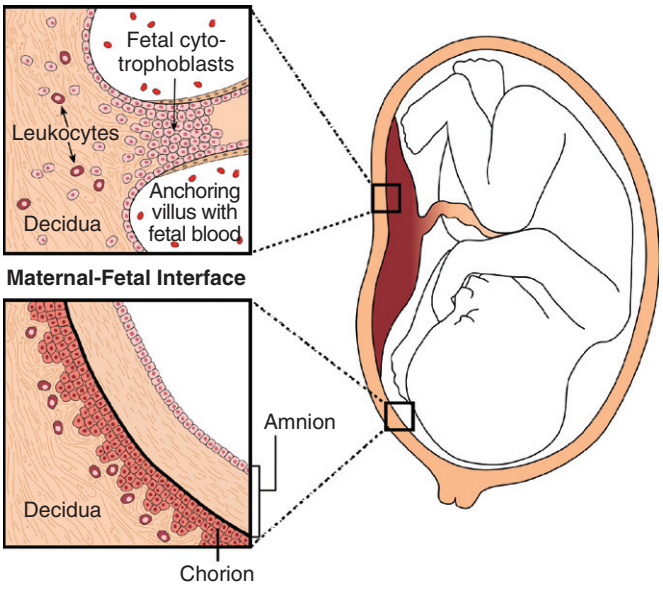

FIGURE 4-5. The maternal-fetal interface and mechanisms of fetal tolerance. Maternal and fetal cells are in close contact in several sites of the placenta, including the decidua and chorion layer of the fetal membranes.

for regenerative medicine and cellular therapy. Currently, the use of cord blood for regenerative cell therapy has not reached a state at which recommendations for autologous cord blood storage can be made.

MATERNAL TOLERANCE OF THE FETUS

Pregnancy is a unique immunologic phenomenon, in which the normal immune rejection of foreign tissues does not occur. The placenta is not a barrier between maternal and fetal cells, and these cells come into direct contact in several locations, which represent the maternal-fetal interface (Figure 4-5). Syncytiotrophoblast, the outermost layer of chorionic villi, is in direct contact with maternal blood in the intervillous space. Extravillous trophoblast in the decidua is in contact with many different maternal cells, including macrophages, u-NK cells, and T cells. Endovascular trophoblast replaces endothelial cells in the maternal spiral arteries and is in direct contact with maternal blood. Fetal and maternal macrophages are also in close contact in the chorion layer of the fetal membranes. A final interface may be considered within the periphery, where shed fetal trophoblast from the placenta and intact fetal cells come into contact with maternal immune cells.[42]

Immunologic mechanisms of fetal tolerance must be acting at the maternal-fetal interface to prevent fetal rejection because the maternal immune system clearly recognizes fetal cells as foreign. About 30% of primiparous and multiparous women develop antibodies against the inherited paternal HLA of the fetus.[43] Persistence of these antibodies does not appear to be harmful to the fetus.[44] Persistent fetal cells in the mother may play a role in the persistence of these antibodies because in some women the antibodies persist, whereas in others they disappear. Formation of IgG antibodies against inherited paternal HLA antigens is associated with the presence of primed cytotoxic T lymphocytes specific for these HLA antigens. Maternal T lymphocytes specific for fetal antigens do exist during pregnancy but appear to be hyporesponsive.[45,46] The normal growth and development of the fetus despite maternal immune recognition requires several maternal and fetal adaptations that, in most women, allow pregnancy to be carried uneventfully to term.

Tolerance Through Human Leukocyte Antigens

Fetal trophoblast and cells in the placental membranes are in direct contact with maternal blood and should be at risk for maternal immunologic rejection. The expression of MHC molecules by these fetal cells may at first appear to be an evolutionary disadvantage that could trigger a graft rejection–type immune response. Of the various forms of placental trophoblast, HLA expression is limited to class I antigens, primarily the class Ib HLA-E, HLA-F, and HLA-G, all of which have limited polymorphisms. The exception to this rule of limited genetic variability is expression of HLA-C, a class Ia molecule that is highly polymorphic and is expressed primarily by extravillous trophoblast. Owing to its unique distribution on fetal trophoblastic tissue, HLA-G is thought to be a significant component of fetal tolerance. Although the exact function of HLA-G is unknown, evidence indicates that HLA-G protects the invasive cytotrophoblast from killing by u-NK cells, as well as containment of placental infection.[47] HLA-G also inhibits macrophage activation through ILT-4, an inhibitory receptor. The presence of a soluble form of HLA-G in high concentration in the amniotic fluid that declines near term suggests a possible role in the initiation of normal labor.[48] **HLA-G, through interactions with u-NK cells, likely contributes to maintaining immune tolerance at the maternal-fetal interface and normal pregnancy.** However, other mechanisms must also contribute to this process because normal pregnancies in women and fetuses lacking a functional HLA-G gene (HLA-G null) have been described.[49]

Tolerance Through Regulation of Maternal T Cells

Maternal T cells acquire a transient state of tolerance for specific paternal alloantigens. This has been elegantly demonstrated in female mice that were sensitized to known paternal antigens before pregnancy.[45,46] The female mice became tolerant to the same paternal antigens expressed by the fetus that were previously recognized and destroyed. Several mechanisms must therefore exist to suppress maternal T-cell responses. This tolerance induction may occur naturally through the generation of paternal-specific regulatory T cells induced after exposure to seminal fluid.[50]

Regulatory T cells suppress antigen-specific immune responses and are elevated in the maternal circulation of women and mice during pregnancy.[51] Outside of pregnancy, regulatory T cells ($CD4^+$, $CD25^+$) act mainly to prevent autoimmune responses from occurring when self-reactive T cells escape from the thymus during normal T-cell development. The mechanism of regulatory T-cell suppression of T-cell responses is unknown but may involve either direct cell contact or production of anti-inflammatory

cytokines, like IL-10 and TGF-β. Estrogen has been shown to increase proliferation of regulatory T cells, and the higher levels of estrogen in pregnancy may drive expansion of this cell population during pregnancy.[52] In addition, spontaneous abortion could be prevented in a unique murine model by the transfer of regulatory T cells from mice with a normal pregnancy into mice destined to abort.[53]

Another strategy for suppressing maternal T-cell responses at the maternal-fetal interface involves tryptophan depletion by indoleamine 2,3-dioxygenase (IDO), an enzyme that catabolizes tryptophan.[54] IDO normally functions as an innate antimicrobial defense mechanism by allowing cells to deplete tryptophan from intracellular pools or local microenvironments. IDO is thought to contribute to T-cell hyporesponsiveness during pregnancy because tryptophan is an essential amino acid for T-cell function. IDO-producing cells can be identified in the decidua of human and murine placenta a few days after implantation. At this interface, IDO creates a local tissue microenvironment that precludes maternal T-cell activation to fetal alloantigens. Inhibition of IDO leads to rapid rejection and abortion of murine fetuses a few days after implantation.[55] By contrast, mice pregnant with a genetically identical fetus did not reject their fetuses after exposure to an IDO inhibitor. Regulatory T cells may also stimulate IDO expression, which may link these two mechanisms for downregulating T-cell responses.[56]

Activated maternal T cells may also be killed through interactions with Fas ligand (FasL) and TNF-related apoptosis-inducing ligand/Apo-2L (TRAIL) expressed on placental trophoblast.[57,58] Both TRAIL and FasL may cooperate to control lymphocyte proliferation after activation and induce apoptotic cell death.

Recently, another mechanism for maternal tolerance of the fetus was proposed that takes into account cell trafficking, which occurs between the mother and fetus.[42,59] Fetal cells escape into maternal blood, and how the mother tolerates these cells is poorly understood. The hypothesis describes how a significant impact on maternal immunity is expected as a result of continuous shedding of apoptotic syncytiotrophoblast debris throughout gestation, a process recently appreciated to result in gram quantities of apoptotic fetal debris entering the maternal circulation daily. Maternal dendritic cells are proposed to present fetal HLA derived from apoptotic syncytiotrophoblast under noninflammatory conditions, leading to tolerogenic signals and tolerance of fetal cells. This novel hypothesis was also suggested to explain the beneficial effects of pregnancy on rheumatoid arthritis, an autoimmune disease that remits or improves in nearly three fourths of women during pregnancy. Amelioration of rheumatoid arthritis may occur during pregnancy as a secondary benefit of changes in the maternal peripheral tolerance to fetal cells.

Tolerance Through Regulation of Complement and Cytokines

In the absence of certain autoimmune disorders, serum complement levels are unchanged or elevated during normal pregnancy.[60,61] However, local inhibition of complement in the placenta may be important in preventing certain immunologically mediated complications of pregnancy. In a murine model of antiphospholipid antibody–induced abortion, antagonism of factor B (alternative complement component) protected against immune-mediated fetal loss.[62] Defects of placental formation were also observed in a murine model associated with activation of the alternative complement pathway and maternal C3.[63] **Finally, several negative regulators of complement are expressed by trophoblast, including CD59 (MAC antagonist), membrane cofactor protein, and decay accelerating factor (inhibitors of C3 and C5 convertases).**[14,64] When a negative regulator of murine complement *Crry* was genetically ablated, embryo survival was compromised and placental inflammation observed.[65] C3 activation plays a major role in fetal rejection in this model because the embryos survived when genetically deficient *Crry* mice were mated to C3-deficient mice. Therefore, complement activation at the maternal-fetal interface may contribute significantly to fetal tolerance.

Although it is speculated that uterine or placental leukocytes regulate trophoblast invasion through cytokine production, many studies in transgenic mouse models have not linked defects in cytokine production with abnormal invasion and pregnancy loss.[66] Among the Th2 cytokines thought to be protective for pregnancy, there is a great deal of functional redundancy. Genetic deficiencies in four of these cytokines (IL-4, IL-5, IL-9, IL-13) did not reduce murine fetal or neonatal survival.[67] Other evidence implicates IFN-γ in normal placental vascular development, which was previously thought to be detrimental for pregnancy.[68] Whether Th2 cytokines play a major role in fetal tolerance and pregnancy maintenance is unknown.[69]

IMMUNITY IN INFECTION-ASSOCIATED PRETERM BIRTH

Preterm birth is a complex process with many different etiologies. **A large body of evidence suggests that intra-amniotic infection and inflammation are important causes of early preterm births, particularly before 28 to 30 weeks of gestation.**[70,71] The immunologic response has been implicated in driving preterm labor in women with intra-amniotic infection. Bacteria recovered from the amniotic fluid usually consist of organisms colonizing the lower genital tract, which then induce production of proinflammatory cytokines like IL-1β, IL-6, IL-8, and TNF-α. Many placental tissues and immune cells in the placenta produce cytokines/chemokines in response to bacteria or bacterial products including amniotic epithelium, macrophages, decidual cells, and trophoblasts.

A role for proinflammatory cytokines and chemokines in the development of preterm labor is based on several observations. Amniotic fluid levels of IL-1, IL-6, IL-8, and TNF-α are elevated in humans and rabbits with intra-amniotic infection and preterm labor. Bacterial products stimulate the production of IL-1β, IL-6, and TNF-α by human placental tissues. These cytokines can then stimulate prostaglandin production in decidual explants and amniotic epithelial cell lines in vitro, as well as fetal membrane apoptosis. Finally, the administration of recombinant IL-1β into the amniotic fluid of pregnant nonhuman primates or systemically in mice induces preterm labor. Other cytokines, like IL-6 and IL-8, are

unlikely to be required for infection-induced preterm birth based on data in a mouse and nonhuman primate model.[17] Interestingly, progesterone reduces apoptosis in fetal membranes induced by TNF-α in vitro, suggesting a possible immune mechanism by which progesterone might inhibit preterm birth.

Gaps in the scientific knowledge of mechanisms leading to preterm labor and those promoting uterine quiescence are significant, particularly when one considers the many different etiologies of preterm birth.[72] Of the many different factors linked to preterm labor, intrauterine infection remains one of the most important and potentially preventable causes. Several immunomodulators have been successful in inhibiting contractions or delaying infection-induced preterm birth in a nonhuman primate model. Initial studies investigated the efficacy of immunomodulators on preterm labor induced by IL-1β. Dexamethasone (corticosteroid), indomethacin (inhibitor of prostaglandin synthesis), and IL-10 (anti-inflammatory cytokine) were studied.[18] All three inhibited IL-1β-induced uterine contractility but differed in their ability to suppress specific amniotic fluid cytokines and prostaglandins. When dexamethasone and indomethacin were used with antibiotics to treat a group B streptococcal infection in the nonhuman primate model, gestation was significantly longer than in controls treated with antibiotics alone.[73] This evidence suggests that blockade of the immune response, in combination with antibiotics, may delay infection-induced preterm birth. Further, blockade of initial immune responses to LPS with a TLR4 antagonist prevented increases in uterine activity, cytokines, and prostaglandins in a nonhuman primate model.[10] Whether immunomodulators ultimately prove to reduce preterm birth or neonatal morbidity in humans remains to be demonstrated.

Fetal systemic inflammation has been hypothesized to directly contribute to the pathogenesis of preterm birth. The fetal inflammatory response syndrome describes a condition with elevated levels of fetal plasma IL-6 and systemic inflammation, which has been documented in fetuses from women with preterm labor and preterm premature rupture of membranes.[74] **This syndrome is a significant predictor not only of preterm labor but also of neonatal morbidity with multiorgan involvement.** How the fetal inflammatory response might trigger preterm birth is unknown, but it has been associated with elevations in fetal hormones linked to parturition. Specifically, fetal inflammation has been associated with elevations in fetal plasma cortisol and an abnormal fetal plasma cortisol–to–dehydroepiandrosterone sulfate ratio, which in turn are associated with a shorter interval to delivery. The fetal inflammatory response syndrome may play a significant role in the timing of preterm birth.

IMMUNITY IN PREECLAMPSIA

Multiple lines of investigation implicate immune dysfunction in the pathogenesis of preeclampsia, including epidemiologic findings and evidence of abnormalities in both innate and adaptive immunity. Epidemiologic studies have found a higher risk for preeclampsia in women with new partners as well as among couples with a shorter duration of cohabitation and who previously used barrier contraception. The risk is also greater in pregnancies using assisted reproductive technologies, particularly when sperm are surgically obtained and in egg donor pregnancies. These relationships support the hypothesis that exposure to paternal antigens, either through intercourse or a prior pregnancy, decreases the risk for preeclampsia and may represent a "tolerizing" phenomenon.[75] Interestingly, in the 1970s, prior blood transfusion was also found to be protective for preeclampsia,[76] further supporting the idea that prior antigenic exposures influence the maternal response to the immune challenge of pregnancy. Animal studies may help to explain these findings; in mice, mucosal exposure to paternal antigens in semen induces paternal-specific regulatory T cells, which modulate the immune response to specific antigens.[50] Some studies have also suggested an association with maternal HLA homozygosity and with maternal-paternal or maternal-fetal HLA sharing, although other studies have not confirmed these associations.

As a framework for understanding abnormal immune responses linked to preeclampsia, it is important to consider maternal-fetal immune interactions within the placenta and also the periphery. Preeclampsia may be considered to develop in two stages: a preclinical stage characterized by abnormal placentation and spiral artery remodeling, followed by clinically evident maternal disease associated with heightened systemic inflammation. Early in gestation, the primary maternal-fetal interface involves interactions of trophoblast with maternal immune cells within the decidua. For example, HLA-G has a crucial function in implantation and placentation; studies have associated decreased placental HLA-G expression with preeclampsia as opposed to normal pregnancy. Later in gestation, there is an additional maternal-fetal interface in the maternal circulation and tissues. Maternal immune cells in the periphery may interact with necrotic debris shed from the syncytiotrophoblast or intact fetal cells predisposing to preeclampsia through aberrant immune interactions.

Successful placentation depends on extravillous trophoblast acquisition of an invasive phenotype, which allows for remodeling of the maternal spiral arteries, lowering blood flow resistance and vasoreactivity. In preeclampsia, extravillous trophoblast does not acquire an invasive phenotype to the same degree as normal pregnancy, limiting spiral arterial remodeling and resulting in persistent hypoxia-reperfusion cycles. Spiral artery remodeling depends on the interactions of extravillous trophoblast with uterine NK cells, primarily through HLA-C and KIR receptors, respectively. Specific maternal-fetal combinations of KIR and HLA-C genotypes are strongly associated with preeclampsia.[77] In addition, trophoblast interactions with maternal T cells likely play a key role in the establishment of a healthy placenta. Early in normal pregnancy, fetus-specific regulatory T cells are recruited from the maternal periphery to the decidua, and the quantity and function of decidual regulatory T cells is increased in the setting of maternal-fetal HLA-C mismatch.[78]

The clinically evident phase of preeclampsia is characterized by widespread inflammation and endothelial dysfunction. Although it is now understood that inflammation underlies pregnancy normally, a broad range of data show that these responses are further heightened in preeclampsia.[79] This generalized response is characterized by

activation of granulocytes and monocytes. Intracellular reactive oxygen species is increased in not only these populations but also lymphocytes. Cytokine abnormalities include higher concentrations of IFN-γ, TNF-α, IL-6, IL-1β, IL-8, and IL-16, and lower concentrations of IL-10 in preeclampsia compared with normal pregnancy. In addition, clotting factor and complement abnormalities are associated with preeclampsia. During this phase, the primary maternal exposure to fetoplacental material occurs through acquisition of syncytiotrophoblast microparticles, but one must also consider the maternal acquisition of intact fetal cells with a more mature HLA expression profile and the ramifications of those interactions within the maternal system.

In addition to the role of T cells in placentation, alterations in T-cell function have also been implicated in clinically evident preeclampsia. Classically, consideration of the adaptive immune response in preeclampsia focused on the paradigm of a Th1/Th2 T-cell dichotomy. Normal pregnancy has been characterized by a shift from Th1 predominance to Th2, and preeclampsia was considered to relate to an insufficient shift. More recently, the complexity of T-cell subpopulations, as well as their interconnectedness and plasticity, has become clear. **Although studies vary by methodology and specific results, most data suggest that regulatory T cells are decreased in number and function in preeclampsia compared with normal pregnancy.** One study has recently shown that the ratio of regulatory T cells ($Foxp3^+$) to IL-17-expressing $CD4^+$ T cells is higher in normal pregnancy than preeclampsia; this suggests that the normal homeostasis in pregnancy between regulatory T cells and IL-17-producing $CD4^+$ T cells compartment was lost in preeclampsia.[80] Whether the proinflammatory Th17 subpopulation is overrepresented in preeclampsia is not yet clear.

Maternal immune dysfunction underlying preeclampsia is an active area of investigation. Additional areas of ongoing study of immune dysfunction include the association of an activating autoantibody against the angiotensin II type I receptor with preeclampsia.[81] The links between the preclinical and clinical stages of disease and between the innate and adaptive immune response also remain a focus, whereby γ/δ T cells have been investigated and found to have increased cytotoxic potential in preeclampsia. IDO, which inhibits proliferation of activated T cells, has been shown to have lower activity in preeclampsia. In addition, the proinflammatory potential of necrotic syncytiotrophoblast microparticles remains a subject of ongoing investigation.

MATERNAL-FETAL HUMAN LEUKOCYTE ANTIGEN COMPATIBILITY AND RECURRENT PREGNANCY LOSS

The hypothesis that maternal-fetal HLA incompatibility is beneficial in mammalian pregnancy was first proposed in the 1960s based on observations of larger placental size with genetically incompatible murine fetuses compared with compatible fetuses.[82] Incompatible murine zygotes were also more likely to implant than compatible zygotes.[83] Several studies began to test the idea that maternal-fetal HLA compatibility in human pregnancy might also result in defective implantation or placentation predisposing to spontaneous abortion. The first studies to evaluate this hypothesis in humans demonstrated significantly more matching at the HLA-A and HLA-B loci among couples with a history of recurrent spontaneous abortion of unknown etiology, compared with fertile control couples.[84,85] **However, more than 30 studies of HLA matching in couples with recurrent miscarriage have yielded conflicting results. There is no clear relationship between HLA matching and fetal loss from these retrospective studies.**[86] Prospective studies in the Hutterites, one of the most inbred human populations, suggest that HLA matching is a significant risk factor for recurrent spontaneous abortion.[87,88] The overall significance of these findings remains unknown. Randomized immunologically based therapeutic trials in couples with HLA compatibility and recurrent pregnancy loss have produced conflicting results likely because they preceded a thorough understanding of this phenomenon and the heterogeneity of the populations tested.[89,90]

MATERNAL-FETAL CELL TRAFFICKING AND MICROCHIMERISM

It was classically thought that the placenta served as an impenetrable barrier between mother and fetus. The application of molecular techniques to the study of human pregnancy has demonstrated that bidirectional cell trafficking occurs routinely between the mother and the fetus. **Thus, in nearly every pregnancy, cells that originate from the fetus can be found in the mother, and conversely, cells that originate from the mother can be found in the fetus. The long-term persistence of fetal cells in the mother and maternal cells in her progeny leads to the coexistence of at least two cell populations in a single person and is referred to as *microchimerism*.**

Fetal microchimerism can be detected in the maternal system as both cell-free fetal DNA and intact fetal cells. Cell-free fetal DNA is detectable throughout gestation, beginning as early as 4 to 5 weeks of gestational age; this material is cleared rapidly from the maternal plasma postpartum.[91] In contrast, cellular fetal microchimerism can also be detected early in gestation but is more commonly detected quite late in pregnancy, and its acquisition may primarily be a peripartum event.[92] The kinetics and prevalence of cell-free fetal DNA in maternal circulation make it an attractive source for performing noninvasive prenatal diagnosis, and active investigation in this area is underway.[93] The amount of cell-free fetal DNA has been found to be greater in pregnancies complicated by obstetrical outcomes such as preeclampsia compared with normal pregnancies. Intact fetal cells, both during pregnancy and in subsequent years, have been shown to occupy many cells types, including $CD34^+$ progenitor cells, and to inhabit many maternal organs, including lymph nodes, liver, thyroid, spleen, heart, and kidneys.[91,94] From an immunologic perspective, the unique characteristics, including HLA expression, of cell-free fetal DNA compared with intact fetal cells raise intriguing questions about mechanisms of maternal tolerance of the fetus and its perturbations.

Fetal acquisition of maternal microchimerism during pregnancy has also been shown to occur physiologically.

Maternal cells have been detected at an early gestational age in many fetal tissues, including liver, lung, heart, thymus, spleen, adrenal, kidney, pancreas, brain, gonads, and lymph nodes.[91] Within fetal lymph nodes, maternal cells are found ubiquitously, and they appear to influence the development of fetal regulatory T cells.[95]

Cells exchanged in pregnancy, persisting as durable maternal or fetal microchimerism, continue to inhabit immunologically competent or pluripotent cell populations. As such, they may play a functional role in health and disease. A role in autoimmune disease has been hypothesized to occur, similar to chronic GVHD in transplantation, when an "auto"-immune response to or by the microchimeric cells becomes generalized.[96] Several autoimmune diseases, including systemic sclerosis, autoimmune thyroid disease, and neonatal lupus syndrome, have been linked to microchimerism.[91,97,98] On the other hand, microchimerism may also serve in a protective, immunosurveillance role. This has been supported by the association of lower levels of fetal microchimerism in women with breast cancer compared with healthy controls.[99] Pregnancy history also seems to influence the type of microchimerism harbored by women because increasing parity, reflecting the acquisition of a greater number of fetal sources of microchimerism, is associated with lower levels of maternal microchimerism.[100]

The long-term consequences of naturally acquired microchimerism derived from pregnancy are not yet clear. It is likely that microchimerism can have an adverse, neutral, or beneficial effect on the host, depending on other factors, with HLA genes and the HLA relationship among cells probably of key importance. Elucidating the mechanisms by which naturally acquired microchimerism is permitted without detriment to the host may lead to novel strategies with application to prevention or treatment of autoimmune diseases.

SUMMARY

During pregnancy, the immunologic adaptations, particularly at the maternal-fetal interface, are remarkable. No other condition in medicine allows foreign tissue to be so readily accepted and tolerated. Although we have gained tremendous insight into how the maternal-fetal interface adapts to the challenge of maintaining the pregnancy and protecting the fetus from immunologic attack, mechanisms that control this aspect of pregnancy are only partially understood. As we gain more knowledge of how pregnancy is maintained in the context of an otherwise normally functioning immune system, we hope to also gain insight into the development and treatment of common complications of pregnancy such as preeclampsia and preterm labor.

KEY POINTS

- The innate immune system employs fast, nonspecific methods of pathogen detection to prevent and control an initial infection. Innate immunity consists of immune cells such as macrophages, dendritic cells, natural killer (NK) cells, eosinophils, and basophils.
- The adaptive immune system targets specific components of a pathogen and is capable of eradicating an infection that has overwhelmed the innate immune system by clonal expansion of lymphocytes (T cells and B cells) and antibodies against a specific antigen.
- The fetal immune system, even very early in gestation, has innate immune capacity. Acquired immunity, particularly the capacity to produce antibodies, develops more slowly and is not completely functional until well after birth.
- Fetal blood contains a high frequency of hematopoietic stem cells, making it an ideal source of cells for hematopoietic stem cell transplantation. The estimated need for use of privately banked cord blood is between 1/1000 and 1/200,000, which is cost-effective only for children with a very high likelihood of needing a transplant.
- HLA-G, through interactions with u-NK cells, likely contributes to maintaining immune tolerance at the maternal-fetal interface and normal pregnancy.
- Several mechanisms exist to suppress maternal T cell responses, including the generation of paternal-specific T-regulatory cells, tryptophan depletion by IDO production, and interactions with FasL and TRAIL.
- Serum complement levels are unchanged or elevated during normal pregnancy but are balanced by trophoblast expression of several negative regulators of complement.
- The proinflammatory cytokine response to an intrauterine infection is thought to drive preterm labor in most cases of early preterm births. Fetal systemic inflammation with elevated plasma IL-6 is a significant predictor of preterm labor and neonatal morbidity with multiorgan involvement.
- The clinically evident phase of preeclampsia is characterized by widespread inflammation and endothelial dysfunction. Specific maternal-fetal combinations of KIR and HLA-C genotypes are strongly associated with preeclampsia. Regulatory T cells are decreased in number and function in preeclampsia compared with normal pregnancy.
- There is no clear relationship between HLA matching and fetal loss from more than 30 retrospective studies.
- In nearly every pregnancy, cells that originate from the fetus can be found in the mother, and conversely, cells that originate from the mother can be found in the fetus. The long-term persistence of fetal cells in the mother and maternal cells in her progeny leads to the coexistence of at least two cell populations in a single person and is referred to as microchimerism.
- It is likely that microchimerism can have an adverse, neutral, or beneficial effect on the host, depending on several factors, with HLA genes and the HLA-relationship among cells probably of key importance.

Polycystic Ovary Syndrome	PCOS
Small for Gestational Age	SGA

Perinatal care has progressed remarkably from an original focus on maternal mortality, which approximated 1% per pregnancy in the early 1900s. Following the tremendous strides in reducing maternal morbidity and mortality rates, obstetrical care has made great advances in regard to optimization of fetal and neonatal health, including the diagnosis, prevention, and treatment of congenital malformations, reduction in infectious disease, and improvements in sequelae of prematurity. It is now commonplace to deliver infants who would not have survived childbirth or the neonatal period in previous eras. For example, low-birth-weight (LBW) premature infants routinely survive beyond 400 to 500 g. Conversely, large-for-gestational-age (LGA) infants are often delivered by cesarean section, avoiding potential trauma of labor. As we now examine the long-term consequences associated with this improved survival, as well as effects of treatment aimed at improving outcomes (e.g., maternal glucocorticoids), we have begun to recognize long-term health effects in the adult. An understanding of the developmental origins of adult health and disease provides an appreciation of the critical role of perinatal care and may ultimately guide our treatment paradigms.

The concept of developmental origins of adult disease should not be surprising to obstetricians. Teratogenesis represents perhaps the most acute consequence of developmental effects. In the late 1950s, thalidomide was marketed as both a sedative and a morning sickness prescription for pregnant women. Although the drug was not actively marketed in the United States (due to lack of Food and Drug Administration [FDA] approval), more than 2.5 million tablets were distributed to private physicians in the United States. Thalidomide was widely used in Europe, and was included in some 50 over-the-counter products for a diversity of indications. Thalidomide-induced limb malformations are now well recognized. Notably, similar to mechanisms of developmental programming discussed later in this chapter, thalidomide may induce its teratogenic effects through epigenetic mechanisms. As described by Stephens and colleagues,[1] thalidomide likely binds to promotor sites of insulin-like growth factor and fibroblast growth factor, as well as downstream signaling genes that regulate angiogenesis. The resulting inhibition of angiogenesis truncates limb development. A diversity of mechanisms may "program" the offspring phenotype via aberrations in cellular signaling or epigenetic function.

Whereas the short-term consequences of thalidomide were rapidly recognized, longer-term programming effects of diethylstilbestrol (DES) were slow to be recognized. Before FDA approval in 1947, DES was used off-label to prevent adverse pregnancy outcomes in women with a history of miscarriage. Despite a double-blind trial in the early 1950s demonstrating no benefit of taking DES during pregnancy,[2] DES continued to be given to pregnant women throughout the 1960s. It was not until 1971, in response to a report demonstrating the link between DES and vaginal clear cell adenocarcinoma in girls and young women, that the FDA advised against the use of DES in pregnant women. Similar to thalidomide, it is now recognized that the oncogenic and teratogenic effects of in utero DES exposure may be mediated via epigenetic mechanisms. As reported by Bromer and colleagues,[3] in utero

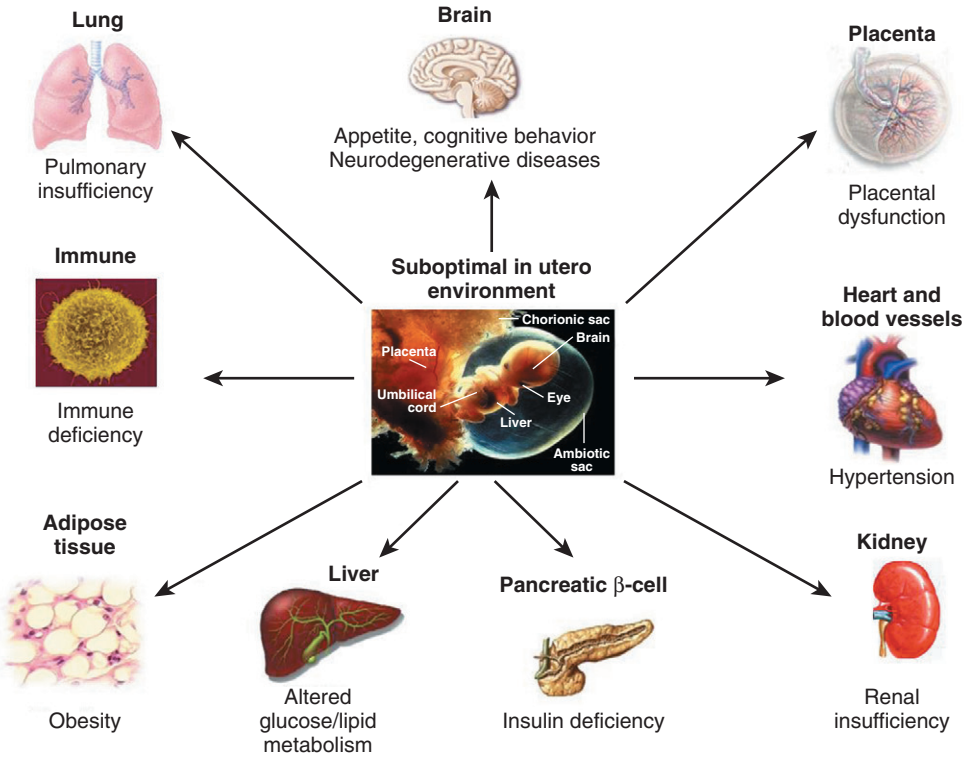

Figure 5-1. Impact of gestational programming on organ systems.

DES exposure results in hypermethylation of the HOXA10 gene, which regulates uterine organogenesis. Thus, both the short-term anatomic defects associated with thalidomide and the delayed oncogenic effects associated with DES are examples of developmental origins of adult disease mediated via epigenetic effects.

EPIGENETICS AND PROGRAMMING

The essential concept of "gestational programming" signifies that the nutritional, hormonal, and metabolic environment provided by the mother permanently alters organ structure, cellular responses, and gene expression that ultimately affect metabolism and physiology of her offspring (Figure 5-1). Further, these effects vary depending on the developmental period, and as such, rapidly growing fetuses and neonates are more vulnerable. The programming events may have immediate effects, for example, impairment of organ growth at a critical stage, whereas other programming effects are deferred until expressed by altered organ function at a later age. In this instance, the question is how the memory of early events is stored and later expressed, despite continuous cellular replication and replacement. This may be mediated through epigenetic control of gene expression, which involves modification of the genome without altering the deoxyribonucleic acid (DNA) sequence itself.

Epigenetic phenomena are a fundamental feature of mammalian development that cause heritable and persistent changes in gene expression without altering DNA sequence. Epigenetic regulation includes changes in the DNA methylation pattern and/or modifications of chromatin packaging via posttranslational histone changes.

DNA methylation represents a primary epigenetic mechanism. The DNA of the early embryo is hypomethylated, and with progressive increases in DNA methylation in response to environmental signals, organogenesis and tissue differentiation occur. DNA methylation typically occurs on cytosine bases that are followed by a guanine, termed *CpG dinucleotides*. The methylation by a DNA methyl-transferase leads to recruitment of methyl-CpG binding proteins, which induce transcriptional silencing both by blocking transcription factor binding and by recruiting transcriptional corepressors or histone-modifying complexes. Anomalous DNA methylation in normally hypomethylated CpG-rich regions of gene promoters is associated with inappropriate gene silencing (e.g., cancer). It is during embryogenesis and early postnatal life that DNA methylation patterns are fundamentally established, and are imperative for silencing of specific gene regions, such as imprinted genes and repetitive nucleic acid sequences. The epigenome is reestablished at specific stages of development and is largely maintained throughout life, making it a prime candidate as the basis for fetal programming. As such, changes in epigenetic marks are associated with multiple human diseases, including many cancers, neurologic disorders, and even inflammation. As methylation involves the supply and enzymatic transfer of methyl groups, it is plausible that in utero nutritional, hormonal, or other metabolic cues alter the timing and direction of methylation patterns during fetal development (Figure 5-2).

Another essential mechanism of gene expression and silencing is the packaging of chromatin into open (euchromatic) or closed (heterochromatic) states, respectively. Chromatin consists of DNA packaged around histones into

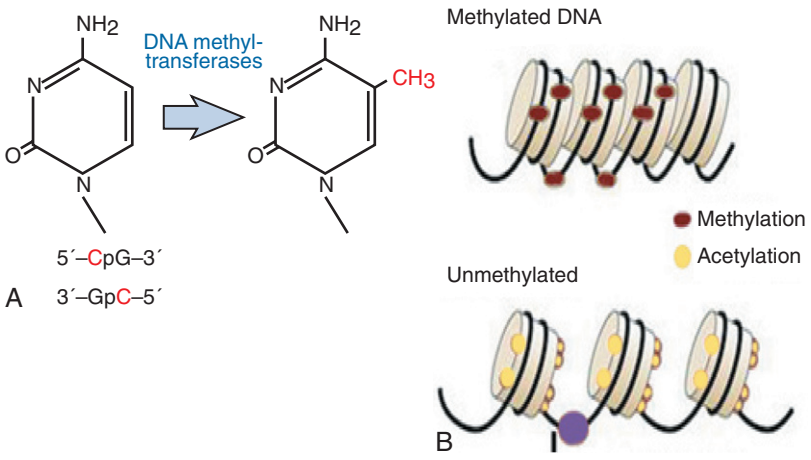

Figure 5-2. DNA methylation. **A,** Methylation by DNA methyltransferases at CpG islands. **B,** DNA demethylation relaxes chromatin structure allowing histone acetylation and the binding of transcriptional complexes.

a nucleo-protein complex. Posttranslational modification of histone tails through acetylation, methylation, phosphorylation, ubiquitination, and sumoylation can alter histone interaction with DNA and recruit proteins (e.g., transcriptional factors) that alter chromatin conformation. Histone tail acetylation by histone acetyl-transferases promotes active gene expression, whereas histone tail deacetylation by histone deacetylases (HDACs) is associated with gene silencing (Figure 5-3). Histone modifications and DNA methylation patterns are not exclusively independent, and thus can reciprocally regulate one another's state.

Finally, microRNAs are emerging as a potential third epigenetic mediator. Although these noncoding RNAs are usually associated with regulation of gene expression at the translational level, recent work suggests they may be involved in DNA methylation as well, thereby further regulating transcription of their targets.

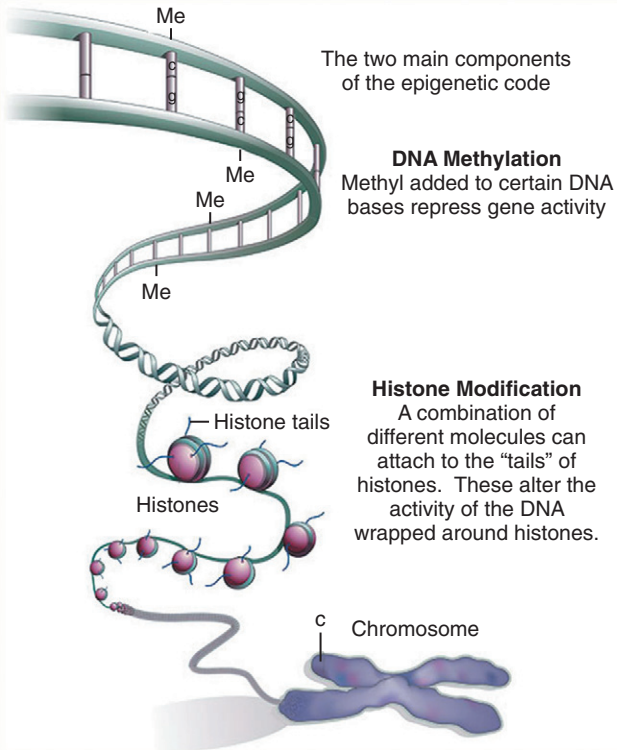

Figure 5-3. DNA methylation and histone modification.

FETAL NUTRITION AND GROWTH

Unquestionably, nutrition is one of the cornerstones of health. More important, there is good evidence that appropriate nutritional supplementation before conception and during pregnancy may reduce the risk of some birth defects. **Perhaps the most convincing argument that can be made for the need to consider maternal nutrition as a critical modulator of embryonic development is the observation that maternal iodine supplementation has eradicated the occurrence of iodine-deficiency-induced cretinism (iodine-deficiency-associated developmental defects).** In addition, adverse maternal nutrition that has an immediate and visible impact on the outcome of pregnancy is seen in the case of folate deficiency and spina bifida. The functional mechanism for folate likely involves epigenetic effects because it generates the principal methyl donor (s-adenosyl methionine) that participates in methylation of DNA and histones.

Animal studies too have irrevocably shown the importance of a mother's diet in shaping the epigenome of her offspring. A classic example is that of permanent hypomethylation of certain regions of the genome as a result of deficient folate or choline (methyl donors) during late fetal or early postnatal life. Specifically, in mice, when the agouti gene is completely unmethylated, the mouse has a yellow coat color, is obese, and is prone to diabetes and cancer. When the agouti gene is methylated (as it is in normal mice), the coat color is brown and the mouse has a low disease risk. Although both the fat yellow and skinny brown mice are genetically identical, the former exhibits an epigenetic "mutation."[4]

Although teratogenesis, structural malformations, and even oncogenic risks can be linked to developmental insults, it is only recently that the epidemic of metabolic syndrome has been attributed, in part, to consequences of fetal and newborn development. **Obesity now represents**

a major public health problem and health epidemic. As recently reported, the adverse consequences of obesity are projected to overwhelm the beneficial effects of reduced smoking in the United States,[5] and have resulted in an actual decline in life expectancy. In the United States, 66% of adults are overweight (body mass index [BMI] 25 to less than 30 kg/m^2) and 33% are obese (BMI ≥30 kg/m^2). Of concern to obstetricians, there is a marked and continuing increase in the prevalence of obesity among pregnant women, a factor associated with both high-birth-weight newborns and a known risk factor for childhood obesity. Whereas the epidemic of obesity in the United States was originally attributed to changes in the work environment, a surplus of high calories, inexpensive food, and a lack of childhood exercise, it is now recognized that the risks of obesity in metabolic syndrome can be markedly influenced by early life events, particularly prenatal and neonatal growth and environmental exposures. Barker and Hales in the early 1990s brought attention to this field with epidemiologic studies demonstrating that nutritional insufficiency during embryonic and fetal development resulted in latent disease in adulthood. A series of studies have demonstrated a marked increase in deaths from coronary heart disease and adult hypertension in association with small-for-gestational-age (SGA) newborns. In addition to coronary heart disease, investigators observed impaired glucose tolerance or diabetes in association with LBW.

Whereas the incidence of growth restriction continues to rise in the United States, there has been an approximately 25% increase in the incidence of high-birth-weight babies during the past decade. **Epidemiologic studies have confirmed that the relationship between birth weight and adult obesity, cardiovascular disease, and/or insulin resistance is in fact a U-shaped curve, with increasing risks at both the low and high ends of birth weight.** Importantly, the sequelae of programming do not occur as a threshold response associated with either very low or very high birth weight, but represents a continuum of risk for adult disease in relation to variance from "an idealized newborn birth weight."

As will be described, these studies have spawned a burst of epidemiologic and mechanistic studies of the developmental origins of adult diseases; the original focus on cardiovascular disease and metabolic syndrome has been extended to a diversity of adult diseases including those affecting kidneys, lung, immunity, learning ability, mental health, aging, cancer, and others. **Thus, the field of developmental origins of adult disease has progressed from short-term toxic or teratogenic effects to long-term adult sequelae of LBW or high birth weight.** In addition to these influences, additional factors, including maternal stress, preterm delivery, and maternal glucocorticoid therapy, among others, may significantly affect adult health and disease. This chapter reviews the consequences and mechanisms of these prenatal/neonatal influences on developmental programming. We will primarily focus on the associations demonstrated in human studies, using evidence from case reports, epidemiologic studies, and meta-analyses. We selectively discuss evidence from animal models that confirms the phenotype or suggest pathogenic pathways and potential mechanisms.

ENERGY BALANCE PROGRAMMING

As noted, epidemiologic studies demonstrate that metabolic syndrome, a cluster of conditions including obesity, hypertension, dyslipidemia, and impaired glucose tolerance, may be a result in part of the effects of LBW. **Ultimately, obesity results from an imbalance in energy intake and expenditure, as regulated by appetite, metabolism, adipogenic propensity, and energy utilization. Hales and Barker proposed the "thrifty phenotype hypothesis"[6] in 1992.** These authors suggested that in response to an impaired nutrient supply in utero, the growing fetus adapts in utero to maximize metabolic efficiency, which will increase survival likelihood in the postnatal environment. This adaptation would be beneficial in response to environmental cycles of famine/drought in which reduced maternal and fetal nutrient supply would likely be replicated in the subsequent extrauterine environment. Numerous studies have demonstrated the increased risk of obesity associated with LBW. In addition to obesity, LBW appears to predispose to excess central adiposity, a phenotype specifically associated with the risk for cardiovascular disease.

Although the long-term effects of LBW are linked to adult obesity, several studies have demonstrated important effects of newborn or childhood catch-up growth among the LBW infants. Those infants that are born small, and yet remain small (in comparison to peers), exhibit a lower risk of obesity and metabolic syndrome than those born small who catch up and exceed normal weights through infancy or early adolescence. These findings, replicated in animal models, have great significance for neonatal and childhood care. For example, a major goal of treatment for premature, LBW infants is the achievement of a weight satisfactory for discharge. Contrary to current practice, it may be advisable to limit the rapid weight gain in the neonatal period. **Importantly, breastfeeding results in a lower obesity risk compared to formula feeding.**[7] Breastfeeding may have advantages to formula feeding both in nutrient and hormone composition and the natural limitation that avoids excessive feeding.

As discussed, programming effects of birth weight simulate a U-shaped curve, as LGA infants also are at an increased risk of adult cardiovascular disease and diabetes.[8] Understandably, LGA infants are often born to obese women, who frequently express glucose intolerance/insulin resistance and who often consume high-fat Western diets before and throughout pregnancy. Studies demonstrate that each of these risks (obesity, glucose intolerance, high-fat diet) and outcomes (LGA) may individually contribute to programming of adult obesity. When combined with variations in maternal feeding and childhood diets, it is understandable that epidemiologic studies have not yet determined which of these factors is paramount in programming mechanisms. Animal models demonstrate programming effects independently associated with each of these risks.

Animal models of LBW, using a variety of methods, such as maternal nutrient restriction (global or specific), placental uterine ligation, or glucocorticoid exposure, among others, have effectively demonstrated increased adult adiposity. Similar to human studies, the propensity to obesity is particularly evident in LBW newborns exhibiting

postnatal catch-up growth.[9] Studies primarily on rodents and sheep have provided important insights into the underlying mechanisms of programmed obesity, which include lasting changes in proportions of fat and lean body mass, central nervous system appetite control, adiposity structure and function, adipokine secretion and regulation, and energy expenditure.

The hypothalamic regulation of **appetite** and satiety function develops in utero in precocial species in order to prepare for newborn life. In the rat and humans, although neurons that regulate appetite and satiety become detectable in the fetal hypothalamus early in gestation, the functional neuronal pathways form during the second week of postnatal life in the rat and likely during the third trimester in humans. Notably, the obesity (ob) gene product **leptin,** which is synthesized primarily by adipose tissue and placenta, is a critical neurotrophic factor during development. In the fetus/newborn, leptin promotes the development of satiety pathways. In contrast, in the adult, leptin acts as a satiety factor. In leptin-deficient (ob/ob) mice, satiety pathways are permanently disrupted, demonstrating axonal densities one-third to one-fourth those of controls.[10] Treatment of *adult* ob/ob mice with leptin does not restore satiety projections, but leptin treatment of *newborn* ob/ob mice does rescue the neuronal development,[10] indicating the critical role of leptin during the perinatal period.

Early life leptin exposure is likely a putative programming mechanism in SGA and LGA human newborns. In LBW human offspring, leptin levels are low at delivery as cord blood levels reflect neonatal fat mass. In contrast to the low serum levels of leptin in SGA newborns, LGA infants have elevated leptin levels. Obese pregnant mothers further have elevated leptin levels related to maternal adiposity, and breast milk leptin levels also reflect maternal fat mass.

Leptin binding to its receptor activates pro-opiomelanocortin neurons and anorexigenic downstream pathways. Obesity is often associated with leptin resistance, resulting in an inability to balance food intake with actual energy needs. The leptin pathway is counterregulated by the orexigenic neuropeptide-Y (NPY) (Figure 5-4). Impaired leptin signaling could result in increased expression of NPY, which would promote increased nutrient intake while decreasing overall physical activity. In LBW newborns, appetite dysregulation has been demonstrated as a key predisposing factor for the obese phenotype.[11] Studies on LBW offspring specifically indicate dysfunction at several aspects of the satiety pathway, as evidenced by reduced satiety and cellular signaling responses to leptin.[12] **Recent studies have demonstrated an up-regulation of the hypothalamic nutrient sensor (SIRT1), a factor that epigenetically regulates gene transcription of factors critical to neural development.** Importantly, neuronal stem cells from rodent SGA fetuses/newborns demonstrate reduced growth and impaired differentiation to neurons and glial cells.[13] **Thus, impaired neuronal development (and ultimately reduced satiety pathways) may be a consequence of a reduction in neural stem cell growth potential and reduced leptin-mediated neurotrophic stimulation during periods of axonal development.**

In addition to appetite/satiety dysfunction, mechanisms regulating adipose tissue development and function

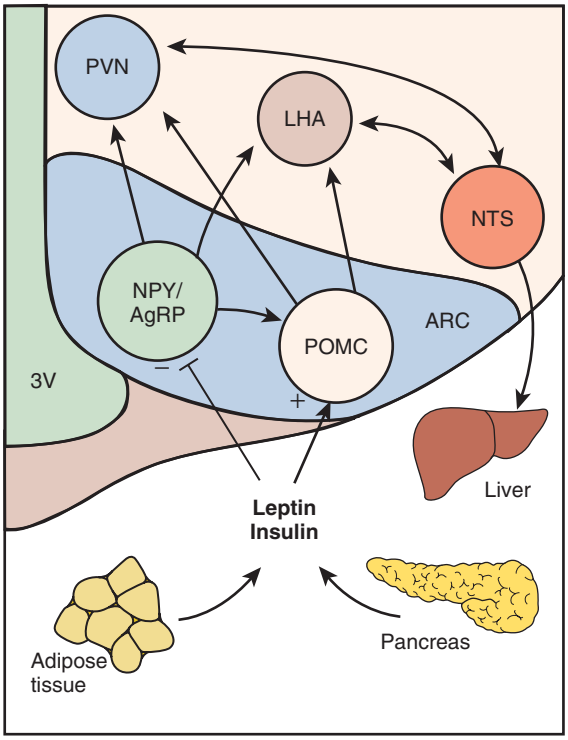

Figure 5-4. Leptin secreted by adipose tissue and insulin by pancreas suppress NPY and increase POMC. *3V,* Third ventricle; *ARC,* arcuate nucleus; *PVN,* paraventricular nucleus; *LHA,* lateral hypothalamic area; nucleus of the solitary tract; orexigenic peptides—*NPY,* neuropeptide Y; *AgRP,* agouti gene-related protein; anorexigenic peptide—*POMC,* pro-opiomelanocortin.

(lipogenesis) may be a key factor in the development of programmed obesity. Increase in adipose tissue mass or adipogenesis occurs primarily during the prenatal and postnatal development, though some adipogenesis continues throughout adulthood. The process of adipogenesis requires highly organized and precisely controlled expression of a cascade of transcription factors within the preadipocyte (Figure 5-5). **Of note, LBW offspring show a paradoxical increased expression of principal adipogenic transcription factor (peroxisome-proliferator-activated receptor, [PPARγ]) as a result of upregulated PPARγ co-activators.** As the signaling pathways of adipogenesis and lipogenesis are up-regulated before the development of obesity, they may be among the crucial contributory factors that predispose to programmed obesity. Furthermore, cellular studies indicate that LBW adipocytes at birth have fundamental traits that are identical to those seen with thiazolidine (PPAR agonist) treatment; that is, they are more insulin sensitive and demonstrate increased glucose uptake and thereby facilitate increased lipid storage within the adipocytes. Thus, early activation of PPAR or its downstream targets could promote the storage of lipids, thereby increasing the risk of developing obesity. This concept reverberates with study on maternal exposure to PPAR agonists, which induce fetal mesenchymal stem cells along the adipocyte lineage, and a reduction in the osteogenic potential in these cells, resulting in greater fat mass in adult offspring.[14] The role of stem cell precursor programming in metabolic disease pathways in response to

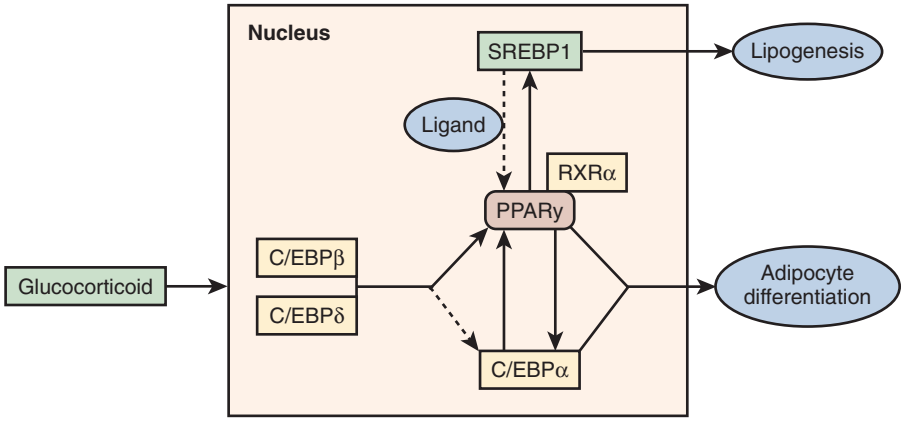

Figure 5-5. Transcriptional regulation of adipogenesis. *C/EBP,* CCAAT/enhancer binding protein; *SREBP,* sterol regulatory element binding proteins; *RXR,* retinoic X receptor; *PPAR,* peroxisome proliferator-activated receptor.

maternal nutrient supply is an intriguing area for understanding developmental plasticity and potential preventive therapeutic strategies.

Akin to LBW, offspring born to obese rat dams fed a high-fat diet also demonstrate increased food intake, adiposity, and circulating leptin levels.[15] The underlying phenotype appears to be similar to that of LBW with altered appetite regulation, enhanced adipogenesis, and reduced energy expenditure. Nonetheless, there are salient mechanistic differences such as increased proliferation of orexigenic neurons in the fetus, inability of elevated leptin to down-regulate NPY, and decreased PPARγ corepressors.

HEPATIC PROGRAMMING

In conjunction with the increased incidence of childhood and adolescent obesity, children and adolescents now have an increased risk of developing nonalcoholic fatty liver disease (NAFLD) and type 2 diabetes. Type 2 diabetes has increased tenfold in regions of the United States during the past decade and the prevalence is particularly high in adolescent North American Indians, approaching rates of 6%. NAFLD (as determined by elevated serum aminotransferase) may occur in up to 10% of obese adolescents in the United States, though studies using ultrasonographic measures of fatty liver have estimated rates of up to 25% to 50% of obese adolescents.[16] As a reflection of the severity of metabolic syndrome, cases of cirrhosis associated with nonalcoholic steatohepatitis in obese children have been described recently. Further evidence suggests that obesity can potentiate additional insults to the liver such as alcohol and hepatitis C infection.

Men and women with reduced abdominal circumference at birth, potentially reflecting reduced hepatic growth during fetal life, have elevated serum cholesterol and plasma fibrinogen. Similarly, poor weight gain in infancy is associated with altered adult liver function, reflected by elevated serum total and low-density lipoprotein cholesterol and increased plasma fibrinogen concentrations.[17] Although human studies have focused on the diagnosis and consequences of NAFLD in obese children and adolescents, animal studies indicate the early expression of fatty liver in fetuses exposed to maternal high-fat diet, though not expressing LGA. Consequently, there may be a heretofore undiagnosed increase in liver adiposity among normal-weight offspring of mothers exposed to Western, high-fat diets.

Animal models of maternal nutrient restriction and excess demonstrate presence of NAFLD, alteration in liver structure, and changes in key metabolic transcription factors and enzymes involved in glucose/lipid homeostasis in the offspring. Specifically, maternal protein restriction during rat pregnancy shifts the enzyme setting of the liver in favor of glucose production rather than utilization, as evident by increased phosphoenolpyruvate carboxykinase and decreased glucokinase enzyme activities in the offspring. Furthermore, these key hepatic enzymes of glucose homeostasis retained the ability to respond to the challenge of a high-fat, high-calorie diet, though with an altered "set point" of regulation. Moreover, as these enzymes are predominantly located in different metabolic zones of the liver (glucokinase in perivenous and phosphoenolpyruvate carboxykinase in periportal zone), the altered activities have been attributed to clonal expansion of periportal and contraction of perivenous cell population.[18]

Five potential mechanisms lead to abnormal hepatic lipid metabolism and NAFLD (Figure 5-6). On a molecular level, PPAR transcription factors are implicated in regulating lipid metabolism. PPARα in particular is predominantly expressed in the liver and regulates genes involved in fatty acid oxidation. Although PPARγ is expressed at very low levels in the liver, PPARγ agonists can ameliorate NAFLD in a rat model.[19] **In addition, PPARα and PPARγ modulate the inflammatory response. PPAR activators have been shown to exert anti-inflammatory activities in various cell types by inhibiting the expression of acute-phase proteins, such as C-reactive protein (CRP).**[20,21] CRP is produced by hepatocytes in response to tissue injury, infection, and inflammation and is moderately elevated in obesity, metabolic syndrome, diabetes, and NAFLD. Rat studies have demonstrated NAFLD and elevated hepatic CRP levels in LBW adult offspring, and this is associated with reduced expression of hepatic PPARγ and PPARα.[22]

PANCREAS PROGRAMMING

Although programmed adult obesity or diet-induced obesity may be attributed to the etiology of insulin resistance, studies in humans and animals indicate that in utero nutrition and environmental exposures directly affect the

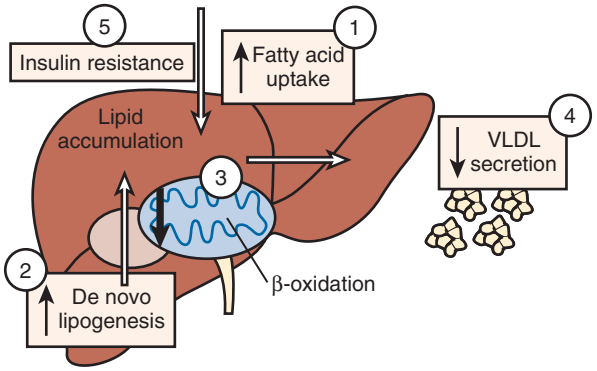

Figure 5-6. Mechanisms for nonalcoholic hepatic steatosis (NAFLD): (1) increased fatty acid uptake by the liver and increased triglyceride synthesis; (2) increased de novo lipogenesis; (3) decreased fatty acid oxidation; (4) decreased VLDL secretion, preventing release of fatty acid from the liver; (5) hepatic insulin resistance (promotes lipogenesis and gluconeogenesis and inhibits lipolysis).

pancreas. **Alterations of pancreatic β-cell mass by maternal malnutrition was demonstrated in the mid-1960s. Whereas LGA human neonates have pancreatic β-cell hyperplasia and increased vascularization, SGA infants have reduced plasma insulin concentrations and pancreatic β-cell numbers.**[23] Consistent with adverse effects of rapid catch-up growth, the greatest insulin resistance is observed in individuals who are LBW but develop adult obesity.[24] In humans, growth in utero is directly associated with fetal insulin levels. **Importantly, beyond the regulation of glucose uptake, insulin has important developmental functions, including skeletal and connective tissues and neural development**.

The extremes of weight are critical, as the risk of insulin resistance in adult life is twofold greater among men who weighed less than 8.2 kg at 1 year of age and those who weighed 12.3 kg or more.[25] There is further a link between reduced early growth and pro-insulin concentrations, suggesting that pancreatic tissue or function may be impaired, and other studies have suggested that fetal programming may alter the structure or function of insulin-sensitive target tissues.

Notably, depending on the prevalence of obesity, approximately 25% of individuals with normal glucose tolerance have similar insulin resistance as those with type 2 diabetes, but compensate for this with enhanced insulin secretion.[26] These individuals are at increased risk of development of overt diabetes. Studies of fetal programming have focused on the finding that birth weight and newborn plasma glucose levels are directly correlated in normal as well as diabetic pregnancies. Far less focus has been paid to levels of amino acids in maternal or fetal blood, although amino acids are major determinants of fetal growth.

In addition to low and high birth weight, studies suggest that antenatal exposure to betamethasone itself may result in insulin resistance in adult offspring. A 30-year follow-up of a double-blind placebo-controlled randomized trial of antenatal betamethasone for the prevention of neonatal respiratory distress syndrome demonstrated no differences among those exposed to betamethasone or placebo in body size, blood lipids, blood pressure, or cardiovascular disease. However, offspring exposed to betamethasone demonstrated higher plasma insulin concentrations at 30 minutes of a 75 g oral glucose tolerance test and lower glucose concentrations at 120 minutes.[27] The authors suggest that antenatal exposure to betamethasone may result in insulin resistance in adult offspring. A study of 20-year-old offspring demonstrated significantly reduced blood pressure in betamethasone-exposed offspring.[28] In view of these findings, the authors recommend that obstetricians use a single course, rather than multiple courses, of antenatal glucocorticoids.

Various animals models of maternal diabetes, nutritional manipulation (undernutrition and overnutrition), and uterine ligation all have reported altered β-cell growth, disturbances in insulin secretion, and long-term effects on insulin sensitivity. Reduced β-cell growth and insulin secretion have been observed in LBW offspring,[29] whereas accelerated β-cell mass and excess insulin secretion were observed in offspring of obese pregnancy.[30] Despite differing nutrition and growth, both lead to β-cell failure, tissue-specific insulin resistance, and development of diabetes in the adult offspring. This phenomenon has been attributed to developmental epigenetic regulation. **The β-cell transcription factor pancreatic duodenal homeobox-1 (Pdx-1) is critical for β-cell development, and progressive silencing of Pdx-1 expression has been observed in β-cells isolated from LBW offspring.** Importantly, this silencing corresponds with persistent altered epigenetic regulation of the Pdx-1 gene. Additionally, increased circulating lipids can induce β-cell apoptosis via endoplasmic reticulum stress pathways. Interestingly, Pdx-1 is protective against pancreatic endoplasmic reticulum stress in response to high-fat feeding in rodents. Although obese pregnancy can increase pancreatic fat deposition in rodent models, whether this in turn leads to permanent changes in gene expression as observed with growth-restricted pregnancies remains unknown.

In a rat model of maternal diabetes, there is evidence of transgeneration diabetogenic effect: female offspring of diabetic mothers develop gestational diabetes and induce the effect in their fetuses and thereby in the next generation. Notably, male offspring have impaired glucose tolerance, but do not transmit the effect to their offspring.[31]

CARDIAC PROGRAMMING

In addition to the aforementioned glucocorticoid effects on insulin resistance, there is evidence that maternal betamethasone treatment of preterm infants is associated with long-term adverse cardiac outcomes, including hypertrophic cardiomyopathy.[32] Animal models confirm the association of fetal cortisol exposure with increased left ventricular cardiomyocyte size. A reduction in cardiomyocyte number through either reduced cellular proliferation or increased apoptosis appears to be a central feature. As cardiomyocytes are highly differentiated and rarely replicate after birth, an inappropriate prenatal reduction of cardiomyocytes is likely to result in a permanent loss of myocardium functioning units and thereby increasing susceptibility to cardiac hypertrophy and ischemic heart disease. Confounding the direct association, left ventricular hypertrophy also has been reported in growth-restricted infants.

Similar to programming of metabolic syndrome, extensive epidemiologic data have demonstrated the association of birth weight with adult coronary heart disease. Slow growth during fetal life and infancy followed by accelerated weight gain in childhood predisposes to adult coronary heart disease in both men and women.[33] The association between LBW and coronary heart disease has been replicated among men and women throughout North America, the Indian subcontinent, and Europe.

As a result of similar pathophysiologic mechanisms, there is a strong interaction of these risk factors with stroke. However, the impact of programming is again evident in the marked differences in adult phenotype depending on the fetal and childhood environment. In a study of over 2000 people within the Helsinki birth cohort, two different paths of early growth preceded the development of hypertension in adult life.[34] Small body size at birth and low weight gain during infancy followed by a rapid gain in BMI during childhood was associated with an increase in coronary heart disease as adults. In contrast, LBW in utero and throughout infancy followed by a persistent small body size at adolescence resulted in an increased risk of a stroke and an atherogenic lipid profile.[35] These two different paths of growth may lead to hypertension via altered biologic processes. Although restriction of rodent weight gain following LBW prevents an obese phenotype, there are significant atherogenic and pancreatic abnormalities. Notably, these offspring exhibit markedly elevated cholesterol levels and insulin deficiency.[36]

In addition to the effect of fetal nutrient exposure on cardiac development, there are significant vasculogenesis mechanisms underlying the programming of hypertension. These may include modifications in arterial stiffness, arterial elastin, and the size of the arterial and capillary bed.[37] Although there is no direct evidence that elastin synthesis is impaired in the developing of large arteries of human fetuses whose growth is restricted, children with a single umbilical artery demonstrate striking asymmetry in the compliance of iliac arteries at 5 to 9 years of age.[38]

Although this chapter does not seek to review all toxic teratogenic exposures, prenatal cocaine exposure has been demonstrated to have significant effects on neonatal and offspring cardiac function. Cocaine exposure results in an increased rate of neonatal arrhythmia and transient ST elevation. Though a blinded cross-sectional study did not demonstrate any significant differences in human left ventricular cardiac function,[39] prenatal cocaine exposure did result in changes in diastolic filling in neonates with the degree of change correlated to the degree of cocaine exposure. Some changes persisted to age 26 months, particularly in those infants exposed to high levels of in utero cocaine.[40] The mechanisms of cocaine effects may relate to the inhibition of dopamine, serotonin, and norepinephrine reuptake. In addition to direct effects, cocaine programming of cardiac function may be mediated via effects on the autonomic nervous system. Some, though not all, studies have demonstrated an alteration in resting heart rate and heart rate variability.[41] A well-performed study further demonstrated a dose-dependent effect of fetal cocaine on neonatal heart rate at 4 to 8 weeks of age, though the duration of this effect is unknown.[42] Further effects on static stress, renal sympathetic activity, and heart rate variability further confirm offspring effects of cardioregulatory systems by cocaine. Taken in sum, these studies suggest that fetal cocaine has at least a short-term cardiac impact and potentially a longer-term cardiac impact in humans.

Although there is no clear epidemiologic evidence to link prenatal hypoxia and adult cardiovascular disease, animal models suggest an effect of hypoxia on adult cardiac function. Chronic hypoxia during the course of pregnancy also results in LBW newborns with altered myocardial structure and heart development. Among other effects, prolonged hypoxia in utero suppresses fetal cardiac function, alters cardiac gene expression, increases myocyte apoptosis, and results in a premature exit of the cell cycle of cardiomyocytes and myocyte hypertrophy.[43]

OSTEOPOROSIS PROGRAMMING

Recent evidence indicates that the fetal and neonatal life may be a critical factor in the development of osteoporosis, a disease typically associated with aging. In considering the major determinants of bone mass in later life, the most critical issues are (1) peak bone mass achieved during the third decade of life and (2) the rate of bone loss following this period. Thus, bone mass in the elderly is largely determined by peak bone mass occurring much earlier in life. Several epidemiologic studies have demonstrated that LBW and weight at 1 year are directly correlated with reduced bone marrow content, as well as bone mineral density.[44] Consistent with these findings, poor childhood growth is associated with an increased risk of hip fracture in elderly adults.[45]

The mechanisms by which the fetal and neonatal period can influence peak bone mineral content include the interaction of vitamin D and calcium, as well as additional factors including fetal and neonatal growth hormone, cortisol, and insulin-like growth factor 1. An undernourished fetus, deprived of calcium, may up-regulate vitamin D activity in an attempt to increase calcium availability.[46] Although more than 60% of peak bone mass is gained during puberty, there is a growing body of evidence suggesting that a substantial proportion of peak bone mass is determined by growth earlier in life. Additional maternal factors may influence neonatal bone mineral content. Low maternal fat stores, maternal smoking or increased physical exercise in late pregnancy, and low maternal birth weight all predict lower whole body bone marrow content in the neonate.[45] In rats, maternal diet modulation or uterine ligation affects offspring bone structure.[47] The adult offspring has lower serum 25-OH vitamin D levels, bone mineral content, and bone area, which is also associated with changes in the growth plates. This is consistent with the nutritional programming of skeletal growth trajectory and complements the epidemiologic evidence for programming of osteoporosis in humans.

BRAIN PROGRAMMING

As complex as is cerebral function and development during the critical fetal/neonatal window, it is understandable that a number of stressors during early life may affect a diversity of cerebral functions, including cognition, behavior, anxiety, and even addictive potential. In utero exposure to cocaine,

and perhaps methamphetamine, demonstrates a diversity of cerebral effects.[48] Among children exposed to prenatal cocaine, there are significant effects on behavior (aggression), attention-deficit/hyperactivity disorder (ADHD), offspring substance abuse (e.g., cigarettes), and impaired language (reviewed in reference 48). Additional studies have suggested potential impairment of intelligence quotient (IQ), cognition, motor function, and school performance. Understandably, windows of exposure and dose-dependent responses are difficult to quantify. Nevertheless, a number of studies have suggested that heavy cocaine use is related to worse outcome in regard to behavior, language, and IQ.[48] Studies of neuroimaging have demonstrated significant alterations in brain-region-specific volumes among cocaine-exposed children, when assessed as children, adolescents, or adults.[49] Studies of diffusion tensor imaging and functional magnetic resonance imaging (MRI) demonstrate increased creatine in the frontal white matter, potentially a sign of abnormal energy metabolism.[50] Cocaine-exposed children demonstrate greater activation in the white inferior frontal cortex and the caudate nucleus during response inhibition, suggesting that prenatal cocaine may affect the development of brain systems involved in the regulation of attention and response inhibition.[48]

Considering other substances of abuse, among children exposed to methamphetamine, magnetic resonance spectroscopy demonstrated increases in total creatine in the basal ganglia, again indicative of possible alterations in cellular energy metabolism.[51] Neuroimaging of children exposed to opiates in utero further demonstrate smaller intracranial and brain volumes, including smaller cerebral cortex, amygdala, brain stem, and cerebellum white matter, among other areas.[52] **This is consistent with animal studies that indicate prenatal nicotine or cocaine exposure targets specific neurotransmitter receptors in the fetal brain, eliciting abnormalities in cell proliferation and differentiation, and thus leading to reduced neurogenesis and altered synaptic activity.**[53] The underlying mechanism may involve increased apoptosis of neuronal cells.

Maternal Stress and Anxiety

Although the effects of maternal substance abuse may be a direct effect of the specific drug-receptor interaction, the commonality of offspring behavioral effects suggests that disruption in the fetal neuroendocrine environment, potentially associated with increased fetal ACTH/cortisol, may affect fetal/neonatal brain development. In view of these findings there has been extensive epidemiologic investigation of maternal stress and anxiety. **During the second trimester, increased maternal anxiety has been associated with lower neonatal dopamine and serotonin levels, greater right frontal electroencephalograph (EEG) activation, and lower vagal tone.**[54] In late pregnancy, maternal anxiety has been associated with salivary cortisol levels among 10-year-old children, suggesting that maternal anxiety during pregnancy programs offspring stress responsiveness.[55] In a recent study, neonates of high-anxiety mothers demonstrated altered auditory evoked responses, suggesting differences in attention allocation.[56] In addition to chronic maternal anxiety, acute stress responses during pregnancy may include death of close relatives, natural disasters, and maternal neuropsychiatric conditions. Many of these stress exposures have a significant impact on offspring neurodevelopmental consequences. Children of mothers with posttraumatic stress disorder during pregnancy display altered cortisol levels that are accompanied by signs of behavioral distress during the first 9 months of life.[57]

The role of the maternal hypothalamic-pituitary-adrenal axis (HPA) is recognized as contributing to maternal stress-mediated effects on fetal development. Although the developing fetus is normally protected from high levels of circulating maternal cortisol by the placental enzyme 11-β-hydroxysteroid dehydrogenase type 2 (11β-HSD2), which metabolizes cortisol to inactive cortisone, downregulation of placental 11β-HSD2 may occur in response to drug exposure, maternal diet, and obstetrical conditions, including preeclampsia, preterm birth, and intrauterine growth restriction.[58] A reduction in placental 11β-HSD2 may thus increase fetal exposure to maternal cortisol levels and secondary effects on brain maturation and development. Among pregnant women undergoing amniocentesis, there is a strong correlation between maternal plasma and amniotic fluid cortisol levels (indicative of fetal levels). The correlation with maternal anxiety suggests that measures of amniotic fluid cortisol may serve as an index for fetal hormone exposure.

Offspring psychiatric disorders associated with maternal pregnancy stress may be a consequence of cortisol binding to select brain regions during development. Notably, most fetal tissues express glucocorticoid receptors from midgestation onward. It is well established that steroid hormones in the fetus are involved in organ development and maturation (brain, heart, lungs, gastrointestinal tract, kidneys). Of note, the hippocampus, which is critical for learning and memory, has extensive glucocorticoid receptors. Although not studied in humans, glucocorticoid exposure in rat dams results in a reduction in the volume and number of cells in the nucleus accumbens, a central limbic nucleus critical to reward circuitry.[59] These findings may provide a mechanism by which maternal stress and/or substance abuse contributes to offspring addictive behavior, itself representing a dysfunction of the limbic system.

The effects of maternal stress may extend beyond fetal/neonatal neurologic/behavioral issues. Maternal prenatal anxiety/stress predicts a significant adverse effect on infant illness and antibiotic use,[60] whereas a wide range of prenatal stressors are associated with child morbidity. **Specifically, prenatal anxiety has been associated with childhood asthma, whereas stress-related maternal factors have been associated with increased eczema during early childhood.**[61,62]

A generational effect of fetal programming and the HPA axis is suggested by findings that LBW babies have raised cortisol concentrations in umbilical cord blood and raised urinary cortisol secretion in childhood.[63] Nilsson and colleagues demonstrated that there was a continuous relationship between size at birth and stress susceptibility,[64] whereas other studies have demonstrated that cortisol responses to stress were significantly and inversely related to birth weight.[65] Similarly, in regard to physiologic responses, LBW is associated with increased blood pressure and heart rate responses to psychological stressors in women, though not men.[66]

In corroboration of the human data, findings from experiments with rodent models show that prenatal stress (such as restraint) and administration of exogenous glucocorticoids not only impair cognition, increase anxiety, and increase reactivity to stress but also alter brain development.[67] Furthermore, prenatal stress increases sensitivity to nicotine and other addictive drugs. **Maternal nurturing affects offspring epigenome and behavior.** In rats, maternal nurturing behavior altered the offspring epigenome at a glucocorticoid receptor gene promoter in the hippocampus. As a result, highly nurtured rat pups demonstrated less anxiety than those that received minimal nurturing.[68]

More recent studies on nonhuman primates implicate chronic consumption of a high-fat diet during pregnancy for increased anxiety-like behavior in offspring, thought to be caused by perturbations in the fetal brain serotonergic/melanocortin pathways.[69]

Glucocorticoids and Prematurity

Although glucocorticoid therapy for the preterm infant has made a significant contribution to the reduction of neonatal respiratory distress syndrome, intraventricular hemorrhage, and infant mortality, there has been a tendency for clinicians to use multiple courses of glucocorticoids. **Studies that have examined the impact of human perinatal glucocorticoid exposure have demonstrated that children exposed to dexamethasone during preterm gestation and who were born at term have increased emotionality, general behavioral problems, and impairments in verbal working memory.**[60,70] Further, offspring of women given multiple doses of antenatal glucocorticoids have reduced head circumference and significantly increased aggressive violent behavior and attention deficits.[71] These findings suggest that fetal exposure to pharmacologic glucocorticoid levels during critical developmental periods (before normal high level in the term neonate) may have adverse consequences, including the programming of the offspring HPA. Preterm babies exposed to antenatal betamethasone had a lower salivary cortisol response to heel stick than matched controls at 3 to 6 days after delivery.[72] Additional studies demonstrate that exposure to antenatal corticosteroids is associated with suppressed cortisol responses to corticotropin-releasing factor during the immediate neonatal period.[73] Salivary cortisol responses to immunization at 4 months of age are significantly correlated with the mean plasma cortisol in the first 4 weeks, independent of maternal glucocorticoid exposure. It is notable that preterm infants have a similar spectrum of developmental and behavioral problems as do babies whose mothers have experienced extreme stress or anxiety during pregnancy, with both groups demonstrating increased levels of attention deficit, hyperactivity, anxiety, and depression.

Although there are consequences of premature exogenous glucocorticoid exposure (via maternal administration), it should be recognized that if actually delivered preterm, infants are exposed to increased endogenous cortisol before that which they would normally experience at term. Several studies demonstrate that LBW is associated with increased resting heart rate and fasting plasma cortisol concentrations in adulthood. Among preterm babies born at less than 32 weeks, newborn plasma cortisol levels are 4 to 7 times higher than would be fetal levels at the same gestational age. As the elevated levels persist through 4 weeks of age, they likely result from a combination of the acute antenatal steroids and postnatal endogenous glucocorticoids. Whether a consequence of prematurity itself, or perhaps premature cortisol exposure, preterm infants (especially born before 28 weeks' gestational age) have significant neurologic impairments, including visual-motor coordination (when measured at 8 years of age). In view of these consequences of exogenous and endogenous glucocorticoids, maternal glucocorticoid use should be directed only at those infants most likely to benefit and those most likely to deliver preterm.

Whereas the effects of glucocorticoids on programming brain development and organ maturation is well accepted, it is less well recognized that glycyrrhiza (a natural constituent of licorice) may also affect fetal programming via a cortisol mechanism. Glycyrrhiza inhibits placental 11β-HSD2, resulting in a potential increased transmission of maternal cortisol to the fetal compartment. In a study of Finnish children 8 years of age, those with high exposure to glycyrrhiza from maternal licorice ingestion had significant detriments in verbal and visual-spatial abilities and in narrative memory, and significant increases in externalizing symptoms and in aggression-related problems. These effects on cognitive performance appear to be related to the degree of licorice consumption.[74] In addition to licorice, glycyrrhiza is often used as flavoring in candies, chewing gum, herbal teas, alcoholic and nonalcoholic drinks, and herbal medications. Although these results suggest that exposure to glycyrrhiza be limited during pregnancy, it more importantly indicates the diversity of foods and drugs that may affect fetal development and programming, perhaps through effects on fetal cortisol exposure.

Prematurely born infants also display abnormalities of insulin resistance, elevated blood pressure, and abnormal retinal vasculature as adults.[75,76] Although much attention has been focused on the effects of LBW on the programming of metabolic syndrome, a study of 49-year-old Swedish men demonstrated that systolic and diastolic blood pressures were inversely correlated with gestational age rather than birth weight, independent of current body mass index.[76] Similar results have been demonstrated in women born preterm.[75] An intergenerational effect may occur, as consequences of elevated blood pressure and abnormal vascularization among women may have a subsequent impact on future pregnancies. Thus, women born before 37 weeks of age demonstrate a 2.5-fold increased risk of developing gestational hypertension.[77]

In a recent study from western North Carolina, boys and girls aged 9 to 16 were tested for depression in relation to birth weight and additional prenatal and perinatal factors. Low birth weight predicted depression in adolescent girls (38.1% versus 8.4% among girls with normal birth weight), though not boys. In addition, LBW was associated with an increased risk of social phobia, posttraumatic stress symptoms, and generalized anxiety disorder, all of which were far more common in girls than in boys.[78] Further studies have demonstrated that LBW is associated with an increased risk of schizophrenia, ADHD, and eating disorders. These findings are consistent with

those of animal studies indicating gender-specific effects of developmental programming.

Immune Function

As noted, prenatal stress may influence the developing immune system, particularly asthma and atopic diseases. Maternal nervousness during gestation correlates with elevated IgE levels in cord blood and may predict atopic diseases in early childhood.[79] **Importantly, pregnant women with prenatal stress have elevated pro-inflammatory cytokine levels,[80] and these levels may affect the risk of allergy in childhood offspring. Although these findings suggest that *enhanced* immunologic responses may occur following maternal stress, LBW may be associated with *reduced* inflammatory responses contributing to increased morbidity.** Young adults born during seasonal famine (and likely growth restricted) are more likely to die from infectious disease.[81] These infants demonstrated reduced thymic size and altered patterns of T-cell subsets with a lower CD4-CD8 ratio, suggestive of lower thymic output. Postpartum maternal influences also may contribute as mothers of these infants express lower levels of maternal breast milk IL7, a putative thymic trophic factor.[82] In support of the impaired inflammation response among LBW infants, antibody responses to typhoid vaccination are positively related to birth weight.[83] These findings suggest that atopy-related immune function may be enhanced in either LBW offspring or offspring associated with maternal prenatal stress, though LBW may well have significant impairment in offspring infectious disease–related immune function. The consequences of LBW and reduced immune function may be a critical factor predisposing to infant mortality in the developing world.

Much as perinatal factors can influence offspring immunity, mothers who are allergic have lower interferon γ responses during pregnancy, which has been postulated to influence the cytokine milieu of the fetus.[84] Similarly, maternal asthma during pregnancy is associated with fetal growth retardation and preterm birth,[85] and placental expression of pro-inflammatory placental cytokines is significantly increased in pregnancies complicated by mild asthma, though only in the presence of a female fetus.[86] There is significant evidence that both the maternal allergic phenotype and maternal environmental exposures during pregnancy affect the risk of subsequent infant allergic disease. Evidence indicates that maternal allergy is a recognized risk factor for infant allergic disease. In regard to maternal environmental exposure, a number of factors may influence fetal immune development and allergic outcomes. Although evidence is inconsistent and mechanisms are unclear, several studies have demonstrated that a Mediterranean diet may protect against early childhood wheezing.[87] Other studies have explored the effects of folate supplementation, polyunsaturated fatty acids, antioxidants, and a range of vitamins and micronutrients, though again with a lack of consistency.

Interestingly, recent evidence suggests that maternal exposure to microbials may influence fetal immune competence. In utero exposure to a farming environment has been demonstrated to protect against the development of childhood asthma and eczema.[88] Similar results have demonstrated that farming environments alter the expression of innate immune genes and modify umbilical cord IgE levels.[89] **In contrast to the potential beneficial effect of microbial exposure, maternal cigarette smoking increases the risk of offspring asthma.** This likely occurs via an allergic sensitization, rather than classic direct pulmonary effects of cigarette smoke. Animal studies also support the premise that innate immune function can be programmed as a result of perinatal challenge to the immune system during development. In rats, neonatal bacterial endotoxin, lipopolysaccharide (LPS) administration influences the adult neuroimmune response to a second LPS challenge through the HPA axis.[90] In addition, undernutrition, particularly during prenatal and postnatal periods, affects offspring immune competence by increasing basal inflammation while reducing cytokine induction to inflammatory stimuli.[91]

Potentially confounding the association of cigarette smoking is a finding that children with a smaller head circumference at 10 to 15 days of age had a markedly increased odds ratio for wheezing at 7 years of age.[92] Thus, factors that determine fetal growth may be associated with wheezing in childhood. Children with both small and large head circumferences at birth (consistent with both undernutrition and overnutrition) have increased atopic sensitization and elevated serum IgE at age 5 to 7.[93] Large head circumference at birth has previously been reported to be associated with elevated IgG in adulthood and with risk of asthma in adolescents.[94] The association of developmental origins with childhood asthma is complex as there are several asthma phenotypes, including those that are associated with atopy as compared to those associated with acute childhood viral infection. Although both these diseases exhibit childhood wheezing and/or are immune modulated, they likely have significant alterations in predisposition. As asthma is associated with an exaggerated T-helper type 2 (TH2) response to both allergic and nonallergic stimuli, it has been proposed that genes involved in IgE synthesis and airway remodeling have failed to be silenced during early infancy. In utero programming of these genes may result in the predisposition to allergic responses.

ENDOCRINE PROGRAMMING

Low birth weight may also be associated with additional endocrine disorders affecting gonadal and adrenal axes. Reduced fetal growth may be associated with exaggerated adrenarche, early puberty, and small ovarian size with the subsequent development of ovarian hyperandrogenism.[95] Children born SGA may have puberty at a normal age or even earlier, but appear to exhibit a more rapid progression, compromising adult ovarian function.[96] SGA as compared to AGA girls displayed increased baseline estradiol, stimulated estradiol, and 17-hydroxyprogesterone at the beginning of puberty,[97] whereas LBW is associated with precocious puberty in girls.[95] Among LBW girls, those who demonstrate postnatal catch-up growth have greater fat mass and central fat. Whether this suggests that early puberty is a consequence of hyperandrogenism or hyperinsulinism associated with the central adiposity is uncertain. **Importantly, children with precocious puberty, particularly those with a history of LBW, have an increased risk of developing ovarian hyperandrogenism and other**

features of polycystic ovary syndrome (PCOS) during early post menarche.[95] Growth restriction may thus program adrenal function, inducing permanent changes in ovarian morphology and function in utero, contributing to PCOS in adult life.

Despite the association with PCOS, women born during famine do not appear to have differences in fertility rates as measured by age at first pregnancy, completed family size, and interpregnancy interval.[98] Recent studies have suggested that the Dutch famine offspring cohort may even have an increased fertility as compared to controls.[99] Furthermore, despite the impact on puberty, LBW does not appear to advance the age of menopause in women.[100] There is evidence, however, of an increased prevalence of anovulation in adolescent girls born SGA as compared with controls (40% vs. 4%),[101] though this may be a consequence of obesity-associated endocrine perturbations. These findings suggest that there are relatively small effects of maternal nutritional status during pregnancy on reproductive performance of offspring.

In the female rat, pubertal timing and subsequent ovarian function is influenced by the animal's nutritional status in utero, with both maternal caloric restriction and maternal high-fat nutrition resulting in early pubertal onset. However, the former leads to a reduction in progesterone levels whereas the latter causes elevated progesterone concentrations in adult offspring.[102] In sheep, reduced lifetime reproductive capacity has been demonstrated in ewes born to mothers undernourished during late pregnancy or the first months of life.[103] Prenatal exposure to testosterone impairs female reproductive capacity in sheep,[104] whereas prepubertal administration of estradiol disrupts ovarian cyclicity in adult rats.[105] Furthermore, exposure of animals to an excess of thyroxine during the neonatal period changes the pituitary-hypothalamic responses linked to the secretion of thyroid-stimulating hormone in later life.[106]

SEXUALITY PROGRAMMING

The following discussion is not meant to imply disease states or opine on issues of normalcy of sexuality, but rather to discuss the developmental processes that result in adult sexual orientation. Among males, sexual orientation is largely dichotomous (heterosexual, homosexual), though there is likely increased bisexual orientation among women. A genetic component for sexual orientation is evident from studies demonstrating increased rates of homosexuality among relatives of homosexuals.[107] Twin studies report moderate hereditability of sexual orientation,[108] though there have been limited advances in the identification of specific genetic loci responsible for sexual orientation. **However, significant research demonstrates a major role for gonadal steroidal androgens in regulating sexual dimorphism in the brain and subsequent behavior.**[109] Animal studies confirm that hormonal signals operating during critical periods may have programming effects on sexuality. The classic example of such a phenomenon is the exposure of female rats at a critical period of fetal life to a single exogenous dose of testosterone, which permanently reoriented sexual behavior. A similar dose of testosterone in 20-day-old females had no effect. Thus, there is a critical time at which the animal's sexual physiology is sensitive and can be permanently changed.[110] Based on early animal models, initial studies resulted in what is likely an oversimplified theory: relative overexposure of females to androgens may contribute to female homosexuality, whereas underexposure to prenatal androgens in men may contribute to male homosexuality. Using proxy markers of prenatal hormonal androgen exposure (ratio of second to fourth finger lengths), several studies have demonstrated that homosexual women have significantly masculine measurements compared to heterosexual women,[111] though one study reported no difference.[112] A further proxy marker is oto-acoustic emissions (OAEs), which represent sounds emitted by the cochlea that are more numerous in females than in males. There is significant evidence that OAEs are influenced by prenatal androgen exposure, with evidence that females with male co-twins have a masculinized OAE pattern.[113] Despite the tendency for homosexual women to be exposed to more prenatal androgens than heterosexual women, there is considerable overlap between the two female groups, indicating that prenatal androgens do not act in isolation.[114] Reports among heterosexual and homosexual men are inconclusive in regard to proxy markers.

In contrast to the stronger correlation of female versus male homosexuality with measures of prenatal androgen exposure, birth order has a more significant effect among males. The paternal birth order effect indicates that homosexual men have a greater number of older brothers than heterosexual men do, with the estimated odds of being homosexual increasing by 33% with each older brother.[114] Of note, homosexual males with older brothers have significantly lower birth weights compared to heterosexual males from older brothers.[115] These findings may suggest an interaction of birth weight and additional developmental factors. Several investigators have suggested a role of immunization of mothers to male-linked androgens, resulting in maternal Y-chromosome linked antibodies that may act on male differentiating receptors within the fetal brain.[114] Further studies demonstrate sexual orientation–related neuronal variation, including hypothalamic and selected cortical regions. Despite these associations, there is little conclusive understanding of specific neurodevelopmental mechanisms that produce homosexuality or heterosexuality.

RENAL PROGRAMMING

In humans, the total number of nephrons ranges between approximately 600,000 and slightly over 1 million, although the factors that determine an individual's glomerular number are unknown. **Nephrogenesis occurs up to approximately 36 weeks of gestation, and both genetic and environmental effects alter or regulate the number of nephrons.** From a genetic perspective, select genes regulating renal signaling and transcription permutation have been associated with renal hypoplasia. Thus, most congenital renal anomalies have an inheritable component.

Environmental exposures/stresses are well demonstrated to alter nephron number. Autopsies of newborn and children have demonstrated a marked association between LBW and reduced nephron number.[116] Importantly, low glomerular number and high glomerular size have been

associated with the development of hypertension, cardiovascular diseases, and an increased susceptibility to renal disease in later life. Reduced nephron number as a result of developmental programming may result in single-nephron glomerular hyperfiltration. The compensatory glomerular hypertrophy that maintains normal glomerular filtration rate (GFR) ultimately may cause glomerular sclerosis, nephron loss, and contribute to later hypertension and chronic renal disease.

Reduced nephron number beginning in the fetal/neonatal period may have effects different from those of adult nephrectomy. In sheep, fetal unilateral nephrectomy at 110 days' gestation leads to offspring hypertension.[117] Similarly, unilateral nephrectomy in the neonatal rat results in adult hypertension and impaired renal function. These findings differ from those of human nephrectomy performed in adults (e.g., renal transplant donors) in which hypertension generally does not develop. The mechanisms that contribute to hypertension resulting from reduced glomerular number occurring during fetal and neonatal life are unclear, but indicate that developmental impact on nephron number may have significant impact on programmed hypertension. These include role of specific genes and growth factors involved in this process (Pax2 and GDNF), as well as apoptotic markers and signaling pathways.

In view of the contribution of renal disease to hypertension, it is notable that very LBW infants exhibit a high rate of hypertension during adolescence.[118] Preterm children also exhibit a higher prevalence of hypertension, occurring in both AGA and SGA offspring.[119] Among both African Americans in the southeastern United States and Australian Aboriginals, LBW is associated with adult-onset renal disease.[116,120,121] As a marker of impending renal disease, microalbuminuria is more than twofold greater in SGA offspring at a young adult age than that occurring in AGA offspring, though not all studies demonstrate this effect. Nutritional insults associated with SGA, LBW, and prematurity are perhaps associated with excess glucocorticoid exposure and secondarily reduced glomerular number.

Pregnant patients are also exposed to a variety of nephrotoxic drugs, including nonsteroidal anti-inflammatories, ampicillin/penicillin, and aminoglycosides. Nonsteroidal anti-inflammatories may lead to renal hypoperfusion during critical nephrogenic periods, resulting in cystic changes in developing nephrons[122] and acute or chronic renal failure in preterm newborns.[123] The impairment in renal development resulting from angiotensin-converting enzyme inhibitors is well documented, likely a result of the critical role of angiotensin in nephrogenesis.

Although less is known regarding offspring of diabetic pregnancies, exposure to transiently high blood glucose concentrations may reduce nephron development in rat pups.[124] In humans, increased urinary albumin excretion has been demonstrated in adult offspring of Pima Indian mothers with diabetes, suggesting an early glomerular injury.[125] Notably, individuals with a history of hypertension contained only 50% as many nephrons as those without hypertension.[126] Nephron number in adult kidneys is correlated to birth weight, with each kilogram increase in birth weight associated with an additional 250,000 nephrons.[116] However, these studies could not differentiate age- or disease-related loss of nephrons as compared to developmental origins. Reduced nephron number has been demonstrated in the absence of hypertension, indicating that additional processes of programmed hypertension may occur independently of a reduction in nephron number. Whether a reduced nephron number is etiologic of hypertension, a consequence of hypertension, or a coincident finding may depend on the individual.

CONCLUSION

As we are beginning to learn of the significance and mechanisms of developmental programming of adult health and disease, the critical consequences of developmental windows are increasingly recognized. Programming effects may have an impact on development by altering organ size, structure, or function. Cellular signaling mechanisms and/or epigenetic consequences may be highly dependent on the magnitude of the exposure and the window of exposure during embryogenesis or organogenesis. Most important, we are only beginning to recognize how consequences of prophylactic treatments may alter programmed phenotypes. Certainly, it appears there is no one single mechanism, nor one single developmental window that affects each organ or system development. Consequently, the ultimate management of fetuses and newborns is likely to be individualized rather than universal. We hope to achieve a greater understanding of the relative risks and benefits of current-day obstetrical decisions, including repeated doses of maternal glucocorticoids, advantages versus disadvantages of early delivery of SGA fetuses, and use of oral hypoglycemic agents that cross the placenta, as well as many other management dilemmas.

KEY POINTS

- Maternal in utero environment (nutrition, hormonal, metabolic, stress, and drugs) is a critical determinant of fetal growth and influences a wide variety of metabolic, developmental, and pathologic processes in adulthood.
- Both ends of growth spectrum (i.e., low and high birth weight newborns) are associated with increased risk of adult obesity, metabolic syndrome, cardiovascular disease, insulin resistance, and neuroendocrine disorders.
- The mechanisms linking early developmental events to later manifestation of disease states involve "programmed" changes in organ structure, cellular responses, gene expression, and epigenome.
- Prenatal care is evolving to reach essential goals of optimizing maternal, fetal, and neonatal health to prevent or reduce adult-onset diseases.
- Guiding policy regarding optimal pregnancy nutrition and weight gain, management of low and high fetal weight pregnancies, use of maternal glucocorticoids, and newborn feeding strategies, among others, has yet to comprehensively integrate long-term consequences on adult health.

Pregnancy and childbirth are major life events. **Preconception and prenatal care are not only part of the pregnancy continuum that culminates in delivery, the postpartum period, and parenthood, but they should also be considered in the context of women's health throughout the life span.**[1,2] This chapter reviews pertinent considerations for prenatal care using the broader definitions espoused by the U.S. Public Health Service and the American College of Obstetrician Gynecologists.[3] Specifically, prenatal care should consist of a series of interactions defined as visits and contacts with caretakers that includes three components: (1) early and continuing risk assessment; (2) health promotion; and (3) medical and psychosocial interventions and follow-up.[4] The overarching objective of prenatal care is to promote the health and well-being not only of the pregnant woman, fetus, and newborn, but also the family. Hence, the breadth of prenatal care does not end with delivery but rather includes preconception care, postpartum care, and up to 1 year after the infant's birth.[3] Importantly, this introduces the concept of interconception care, and the notion that almost all health care interactions with reproductive-age women are opportunities to assess risk, promote healthy lifestyle behaviors, and identify, treat, and optimize medical and psychosocial issues that could affect pregnancy.

Prenatal care is an excellent example of preventive medicine. In 1929, the Ministry of Health of Great Britain issued a memorandum on the conduct of prenatal clinics. In 1942, vitamin tablets were provided for all British women in the last 6 months of pregnancy. United Kingdom maternal mortality rate declined from 319 per 100,000 live births in 1936 to 15 per 100,000 live births in 1985. In the United States, the maternal mortality rate was 13.2 per

100,000 live births in 1999.[4] The decline in maternal mortality rate was partly attributed to prenatal care and partly to medical and public policy advances such as maternal mortality reviews with attention to preventable causes of maternal death, shift to hospital births, improvements in anesthesia, widespread availability of blood transfusions, antibiotics, and access to safe and legal abortion services. Recent guidelines addressing the content and efficacy of prenatal care have focused on the medical, psychosocial, and educational aspects of the prenatal care system. Prenatal care satisfies the definition of primary care from the Institute of Medicine as "integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community." In fact, prenatal care services can be used by obstetricians/gynecologists and other primary care providers as a general model for primary care. Prenatal care satisfies other criteria for primary care in that it is comprehensive and continuous, and provides coordinated health care. Preconception care—planning to ensure the healthiest possible pregnancy outcome—is consistent with this model. We will further argue that the preconception and prenatal care periods—just as labor, delivery, the puerperium, and postgestation and interconceptional periods—must be seen as episodes in a woman's life and that they provide important opportunities to advance wellness and prevention. It must be recognized that for pregnant women all these events are part of a life continuum with birth leading to the multiple challenges of parenting. They are opportunities to introduce and reinforce habits, knowledge, and life-long skills in self-care, health education, and wellness, to inculcate principles of routine screening, immunization, and regular assessment for psychological, behavioral, and medical risk factors.[1,5] Phelan argues that clinicians are not taking advantage of pregnancy as a "teachable moment"—a naturally occurring life transition that motivates people to spontaneously adopt risk-reducing behaviors.[6] Pregnancy qualifies as a teachable moment because it meets the following criteria proposed by McBride and colleagues[7]:

- There is increased perception of personal risk and outcome expectancies.
- The perceptions are associated with strong affective or emotional responses.
- The event is associated with a redefinition of self-concept or social role.

The goal of prenatal care is to help the mother maintain her well-being and achieve a healthy outcome for herself and her infant. Education about pregnancy, childbearing, and childrearing is an important part of prenatal care, as are detection and treatment of abnormalities. This process is best realized when begun even before pregnancy. Many services provided traditionally during the intrapartum hospital stay will be provided at prenatal and postpartum outpatient visits.[8] Too often, hospitalization for childbirth has been seen as an opportunity for education about self-care, child care and parenthood rather than as a time to ensure safe passage. Educational interventions have been targeted for the intrapartum stay, when they can better and more cheaply be performed in the preconceptional, antenatal, or home care environment.[8-10] However, more recently, contemporary models of prenatal and childbirth education have been criticized because research has not shown a strong association between class attendance and childbirth experiences or parenting expectations. In fact, among first-time mothers, there has been a decline in childbirth class attendance from 70% in 2002 to 56% in 2005.[11,12]

MATERNAL MORTALITY

Maternal and neonatal mortality rates are the most widely used indicators of the health of a nation. Maternal death is the demise of any woman from any pregnancy-related cause while pregnant or within 42 days of termination of pregnancy, irrespective of the duration and the site of pregnancy. A direct maternal death is an obstetrical death resulting from obstetrical complications of the pregnancy state, labor, or puerperium. An indirect maternal death is an obstetrical death resulting from a disease previously existing or developing during the pregnancy, labor, or puerperium; death is not directly due to obstetrical causes but may be aggravated by the physiologic effects of pregnancy. A nonmaternal death is an obstetrical death resulting from accidental or incidental causes unrelated to the pregnancy or its management.

The maternal mortality rate is the number of maternal deaths (direct, indirect, or nonmaternal) per 100,000 women of reproductive age but, since this denominator is difficult to determine precisely, most clinical and research entities use the maternal mortality ratio defined as the number of maternal deaths (indirect and direct) per 100,000 live births.

Direct obstetrical deaths have six major causes: hypertensive diseases of pregnancy, hemorrhage, infections/sepsis, thromboembolism, and, in developing countries, obstructed labor and complications from illegal abortion. There are other direct causes of death, such as ectopic pregnancy, complications of anesthesia, and amniotic fluid embolism. The main causes of indirect obstetrical deaths are asthma, heart disease, type 1 diabetes, systemic lupus erythematosus, and other conditions that are aggravated by pregnancy to the point of death.

Maternal mortality has been an underrecognized issue worldwide despite an estimated 600,000 maternal deaths per year from pregnancy-related causes.[13] Put in numerical perspective, this is equivalent to six jumbo jet crashes per day with the deaths of all 250 passengers on board, all of them women in the reproductive years of life. Or, put in a time perspective, every minute of every day a woman dies from pregnancy-related causes.[14] There is also a marked inequity in geographic distribution, because 95% of these deaths occur in developing countries (Figure 6-1). Maternal mortality is the health indicator with the greatest disparity between wealthy and poor countries (and wealthy and poor women in developed countries). Maternal mortality is highest in Africa, Asia, Latin America, and the Caribbean.[15] The World Health Organization estimates that over 80% of maternal deaths could be prevented through actions that have been proven to be effective and affordable. Specifically, providing maternal health services defined as trained birth attendants, aseptic birth environments, identification

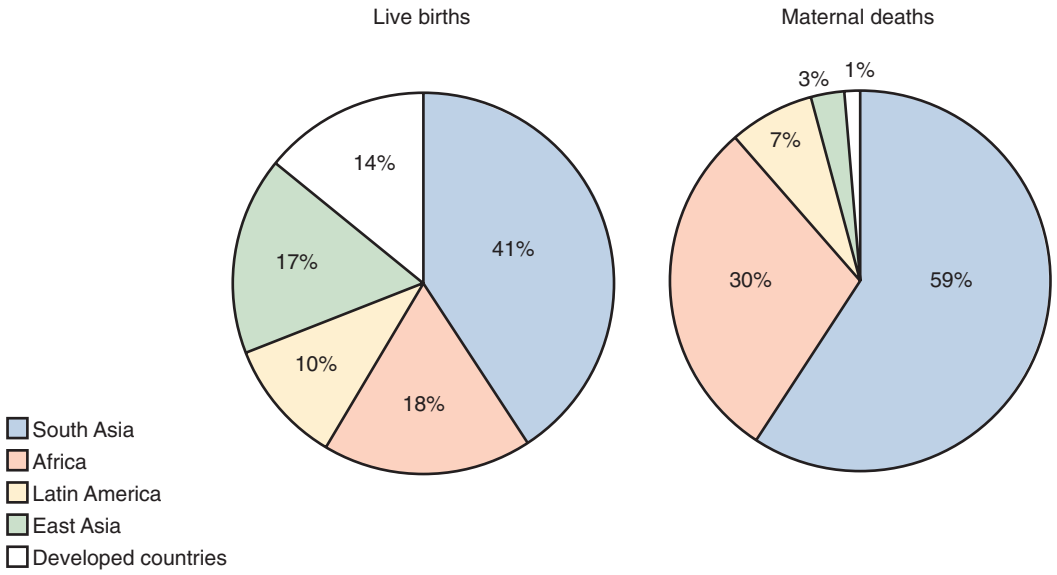

FIGURE 6-1. Worldwide distribution of live births and maternal deaths by region. (From WHO 861663.)

of maternal/fetal/neonatal complications, and transport to a higher level of care when indicated.[14,16] Even in developed countries, the changing demographic profile of childbearing women (e.g., older women and/or women with chronic medical conditions) has contributed to an increase in maternal mortality, and many argue that these too are preventable—requiring rapid recognition and response to treatable emergency conditions.[14] Worldwide, we are far from achieving the international Safe Motherhood goal of reducing maternal mortality by 50%.[16] **Similarly, nationwide, the Centers for Disease Control and Prevention (CDC) reported a maternal mortality rate of 12.1 per 100,000, indicating we have not achieved the *Healthy People 2010* goal of 3.3 per 100,000 and emphasizing that it will take an integrated, multifaceted, multidisciplinary public health approach to achieve these goals for 2020.**[17,18]

The CDC and the American Congress of Obstetricians and Gynecologists (ACOG) have introduced the concept that *pregnancy-associated mortality* is defined as death of a woman, from any cause, while pregnant, or within 1 year of termination of pregnancy.[19] Unfortunately, the United States is seeing an increase in nonmaternal deaths of pregnant women resulting from trauma and violence, many of these related to illegal drugs (Figure 6-2).

In North Carolina from 1992 to 1994, 167 deaths of pregnant and postpartum women were identified through an enhanced surveillance system. When all deaths of pregnant women were categorized, direct and indirect obstetrical deaths (classically defined maternal deaths) accounted for only 37% of deaths of pregnant and postpartum women. Injuries accounted for 38% of deaths with homicide being the most common (36%), followed by motor vehicle accidents (32%), drug-related death (13%), other (11%), and suicide (8%). Acceptance of pregnancy-associated mortality as the appropriate measure will lead to increased recognition of these important problems. The prenatal care provider can play a role in preventing these common causes of death in women by advocating use of seat belts and screening for alcohol use, drug use, depression, and violence.

Significant disparities exist between the maternal mortality rates of white and black women. In the United States, maternal mortality occurs four times more often in black women than in white women. In a *Morbidity and Mortality Weekly Report* review of maternal deaths from 1991 to 1999, the pregnancy-related mortality rate for white women was 8.1; for black women it was 30. On a state-by-state basis, maternal mortality rates for black women were higher in every state.[20,21] Many of the tenets espoused to bring about safe motherhood internationally could arguably be applicable to help understand and eradicate the maternal health disparities seen in poor urban and rural environments in the United States. Specifically, they are health education and promotion, identification of maternal/fetal/neonatal complications, transport to a higher level of care, and rapid responses to acute obstetrical emergencies. For example, one study demonstrated an inverse relationship between the maternal mortality rate and the state density of maternal-fetal medicine specialists after controlling for state-level measures of maternal poverty, education, race, age, and interactions.[22] Similarly, regionalization of perinatal services has been a cornerstone for improved neonatal outcomes.[23]

Last, although much attention has been focused nationally and internationally on maternal mortality, perhaps of greater concern is the less well documented prevalence of maternal morbidity, or "near misses," defined as "pregnant women with severe life-threatening conditions who nearly die but, with good luck or good care, survive." Wen and colleagues found that the overall rate of severe maternal morbidity was 4.4 per 1000 deliveries, but many believe it is significantly underreported.[24] Severe morbidity was defined as thromboembolism, eclampsia, pulmonary, cardiac or central nervous system complications of anesthesia, cerebrovascular disorders, uterine rupture, acute respiratory distress syndrome, pulmonary edema, myocardial

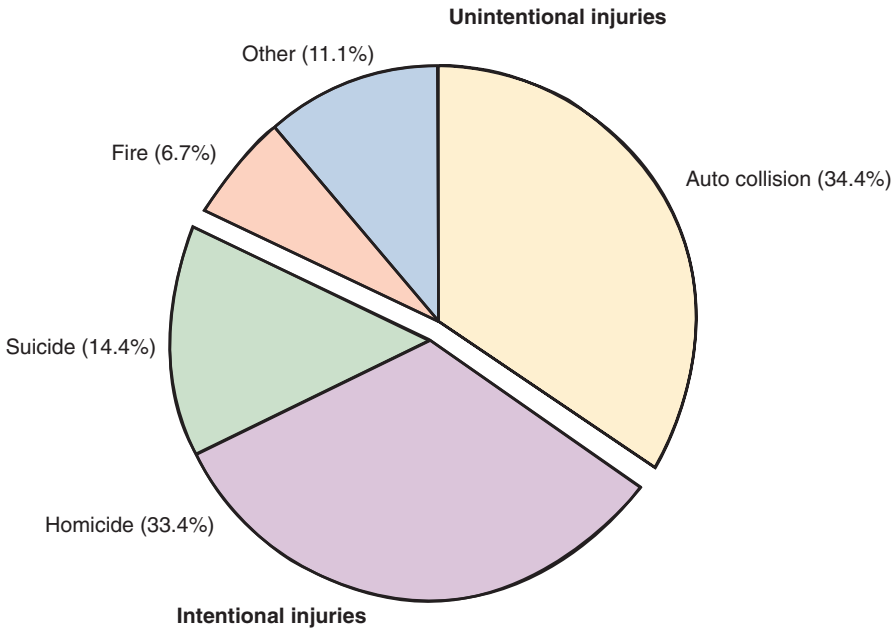

FIGURE 6-2. Distribution of deaths due to injury in the United States, 1980-1985 ($N = 90$). (From MMWR Morb Mortal Wkly Rep 37[SS5]:26, 1988.)

infarction, acute renal failure associated with delivery, cardiac arrest, severe postpartum hemorrhage requiring hysterectomy, and assisted ventilation. Rates of venous thromboembolism, uterine rupture, acute respiratory distress syndrome, pulmonary edema, myocardial infarction, severe postpartum hemorrhage requiring hysterectomy, and assisted ventilation all appear to be increasing in incidence since 1991.[24] The concept of "near misses" and rates of adverse pregnancy-related complications have taken on new significance as payers and providers look for ways to demonstrate safety and quality in health care systems.

Finally, presence of preexisting chronic conditions (e.g., systemic lupus, cystic fibrosis, chronic renal disease, hypertension, diabetes, pulmonary hypertension, and congenital, rheumatic, and ischemic heart disease) also appears to be increasing among pregnant women, and this is significant since the presence of preexisting conditions increases the risk of both maternal morbidity (sixfold increase) and mortality (158-fold increase).[24-27]

NEONATAL MORTALITY AND MORBIDITY

Historically, in developed countries, when decreased maternal mortality was achieved, attention was then turned to infant mortality, and then neonatal mortality and later fetal mortality. The stillbirth rate (fetal death rate) is the number of stillborn infants per 1000 infants born. The neonatal mortality rate is the number of neonatal deaths (deaths in the first 28 days of life) per 1000 live births. The perinatal mortality combines these two—the number of fetal deaths (stillbirths) plus neonatal deaths per 1000 total births.

In 1990, the U.S. infant mortality rate was 9.2 per 1000 live births, ranking the United States 19th internationally.[13] However, there are international differences in the way live births are classified, as some countries exclude infants weighing less than 1 kg and those with fatal anomalies. Final vital statistics data for 2005 indicate that the United States met the *Healthy People 2000* goal of decreasing the infant mortality rate to 7 per 1000 live births, but has not met the 2010/2020 goal of 4.5 per 1000 live births.[17,28] Infant mortality varies by maternal demographic and health characteristics. Rates are higher in the extreme reproductive ages (teens and over 40 years old). Other maternal characteristics associated with increased risk for infant mortality include unmarried, poorly educated, little or no prenatal care, smoking, or illicit substance use. Pregnancy-related complications include but are not limited to multiple births and preterm delivery. There are significant racial differences in infant mortality, with African Americans having a 2.5-fold increased risk.[28] Infant mortality rates in Hispanics are comparable to those of Caucasians; however, variation exists between country of origin and amount of acculturation.

PRENATAL CARE

Historically, the primary goal of prenatal care was to minimize maternal and neonatal mortality. During the past 40 years, new technology has been introduced to assess the fetus antepartum, including electronic fetal monitoring, sonography, amniocentesis, and other in utero interventions, with the fetus emerging as a patient in utero. Prevention of morbidity as well as mortality is now the goal. This has made the task of the prenatal care more complex, since mother and fetus now require an increasingly sophisticated level of care. At the same time, pregnancy is basically a physiologic process, and the normal pregnant patient may not benefit from application of advanced technology.

Prenatal care is provided at a variety of sites, ranging from the private office, to the public health and county hospital clinics, to the patient's home. Obstetricians must optimize their efforts by resourceful use of other

professionals and support groups, including nutritionists, childbirth educators, public health nurses, nurse practitioners, family physicians, nurse-midwives, and specialty medical consultants. Most pregnant women are healthy, with normal pregnancies, and can be followed by an obstetrical team including nurses, nurse practitioners, and nurse-midwives, with an obstetrician available for consultation. These women can be followed by practitioners who have adequate time to spend on patient education and parenting preparation, while physicians can appropriately concentrate on complicated problems requiring their medical skills. This also provides for improved continuity of care, which is recognized as extremely important for patient satisfaction.[29,30]

There have been no prospective controlled trials demonstrating efficacy of prenatal care overall. Two documents addressing the content and efficacy of prenatal care have suggested changes in the current prenatal care system.[2,29-34] Since publication of these recommendations, several well-designed randomized clinical trials and cost-benefit analyses have been reported using alternative visit schedules[33,34] (Table 6-1). There was no difference in outcomes for patients undergoing reduced frequency of visits as measured by rates of preterm birth and low birth weight, and the reduced frequency model has been shown to be cost-effective. However, fewer visits have been associated with decreased maternal satisfaction with care, as well as increased maternal anxiety.[33,34] Some studies support the concept of reduced antenatal visits for selected women.[10,33,34]

Efficacy of prenatal care also depends on the quality of care provided by the caretaker. If a blood pressure is recorded as elevated and no therapeutic maneuvers are recommended, this will not change the outcome. Recommendations must be made and must be carried out by the patient, whose compliance is essential to alter outcome. Kogan and colleagues,[35] using national survey data, reported that women received only 56% of the procedures and 32% of the advice recommended as part of prenatal care content, and that poor women and African American women received fewer of the recommended interventions. Site of care was also an important determinant, suggesting that infrastructure must be geared to address population-specific needs.[35]

RISK ASSESSMENT

The concept of risk in obstetrics can be examined at many levels. All the problems that arise in pregnancy, whether common complaints or more hazardous diseases, convey some risk to the pregnancy, depending on how they are managed by the patient and her care provider. Risk assessment has received detailed attention in the past. It has been shown that most women and infants suffering morbidity and mortality will come from a small segment of women with high-risk factors; by reassessing risk factors before pregnancy, during pregnancy, and again in labor, our ability to identify those at highest risk increases. Most of the emphasis for screening, risk assessment, and associated trials for therapeutic interventions have focused primarily on preeclampsia and preterm birth prevention; Table 6-2 lists representative examples of other clinical conditions that have been proposed to be included as part of routine screening and/or risk assessment during the antepartum period since 1989. Many of these conditions are part of current routine screening programs, but few were implemented as routine care as a result of evidence-based criteria. Most have been implemented as a result of expert or consensus opinion, cost/benefit, and/or risk management decisions. Still others have yet to be commonly accepted and await definitive research trials demonstrating efficacy as a screening test, or more importantly, effective treatment options. For example, cervical length assessment and fetal fibronectin evaluation have been proposed to assess risk of prematurity (see Chapter 28), yet definitive trials proving effectiveness of screening and efficacy of treatment have yet to be done.

Modified from Gregory KD, Davidson E: Prenatal care: who needs it and why? Clin Obstet Gynecol 42(4):725, 1999.

*Current standard of care would likely include offering first trimester screening and/or some multiple marker screening strategy (integrated or sequential) in the second trimester.

TABLE 6-2 EXAMPLES OF CLINICAL CONDITIONS AMENABLE TO ANTENATAL SCREENING AND/OR RISK ASSESSMENT

Clinical Condition SCREENING/DIAGNOSTIC TEST	COMMENT	REFERENCE
Postdates/Multiple Gestation/IUGR		
Early ultrasound	Increased precision of dating; "routine" use unclear benefit yet widely used over 80% of pregnancies	85, 87, 89
IUGR		
Fundal height	Increased identification of small and large infants; fewer ultrasounds, economic benefit	84, 86
Smoking history	Smoking has demonstrated dose-response association with poor fetal growth; smoking cessation/ reduction reverses growth disturbance; likelihood of cessation increased during pregnancy	29, 31, 32, 100-103
Fetal Structural Malformation		
Ultrasound	Ultrasound, MSAFP standard of care for screening for neural tube defects. See text re: prenatal genetic test	104
Maternal serum AFP		
Drug exposure		
Fetal Chromosomal Aberrations		
Multiple marker screening	Combination of specific maternal serum analytes used to screen for Down syndrome, trisomies 13 and 18, with potential detection rate of 60%-90% when used with targeted ultrasound, see text	23, 105
Genetic Conditions		
Cystic fibrosis	Recommended by ACOG	24
Canavan's disease, "Jewish panel"	Recommended by ACOG	106
Preterm Birth (PTB)		
Cervical length	No benefit from routine screening; unclear "best practice" and/or benefit of treatment once identified "at risk"	17, 18, 107, 108
Fetal fibronectin	No clear benefit as screening test to predict PTB (poor sensitivity and specificity); potential benefit from high negative predictive value	107, 109
Periodontal disease	May be independent risk factor for PTB; treatment reduced risk	19
Bacterial vaginosis	Independent risk factor for PTB; inconclusive if treatment alters risk but shown to be beneficial in selected populations	110-116
Preeclampsia		
Uterine Doppler	No effective prevention	15, 85
Serum markers	Nonspecific; no effective prevention	16, 94, 117
Thromboembolic Disease		
Pregnancy history Clinical history Laboratory evaluation for hereditary thrombophilias	Clinically relevant topic due to association with adverse pregnancy outcome; potential for life-threatening thromboembolic event; disseminating into practice; inconclusive data re: treatment efficacy	78
Infections		
Group B streptococcus	Screening and treatment prevents neonatal disease	118
HIV	Routine screening and treatment recommended by ACOG; treatment significantly decreases rate of perinatal transmission	119, 120
Bacterial vaginosis	See PTB	121
Psychosocial Risk		
Demographics	Socioeconomic status, race/ethnicity related to PTB, adverse pregnancy outcomes; not mutable	122-124
Cocaine use	Associated with structural malformations, PTB, abruptions, preeclampsia; comprehensive care deters use	30
Depression		
Screening instruments	Risk/benefit decision re: treatment—not contraindicated; increased likelihood of relapse in postpartum period; related to infection, child development	125
Domestic Abuse		
Screening instruments	Increased likelihood of abuse during pregnancy in women in abusive environment	126

It is important to individualize patient care and to be thorough. The initial visit will include a detailed history and physical and laboratory examinations. The initial history requires that the patient be seen in an office setting. Ideally, she should not be first seen undressed sitting on an examining table.

PRECONCEPTIONAL EDUCATION

We have reached a level of awareness about prenatal care at which the optimal time to assess, manage, and treat many pregnancy conditions and complications is before pregnancy occurs.[36,37] Recognizing that half of pregnancies are unplanned, all reproductive-age women should be asked about their plans for pregnancy at routine gynecologic visits or health maintenance examinations. At that time, much of the risk assessment described later in this chapter can be performed, as well as the basic physical and laboratory evaluations. If there are questions about the history, such as family history of fetal anomaly, or previous cesarean delivery, further details can be obtained from family members or the appropriate medical facility. This is

the time to draw a rubella titer and immunize the susceptible patient. Hepatitis B immunization can be given to appropriate patients and human immunodeficiency virus (HIV) testing offered. Varicella titers or immunization is recommended in women with no history of chickenpox. Patients need to use contraception for up to 3 months following immunizations (see Chapter 50). Toxoplasmosis screening based on risk factors may be indicated at this time because approximately one fourth of the U.S. population is infected.[37] Patients who have negative screens are at risk for congenital toxoplasmosis and should be counseled to avoid risks such as contact with wild felines and ingestion of raw or undercooked meat. Immunocompetent patients who screen positive can be reassured of lack of risk with regard to fetal loss or stillbirth, although rare reports of congenital infection after previous infection have been described. A prospective analysis of the population risks and benefits to substantiate routine screening for and/or education about toxoplasmosis has not been done in the United States. However, proponents argue a theoretical benefit based on treatment availability, extrapolated epidemiologic data from European countries where screening is widespread, and the prevalence of congenital infection that is comparable to other congenital diseases that we currently screen for by mandate (e.g., phenylketonuria, congenital hypothyroidism).

Before pregnancy is the time to screen appropriate populations for genetic disease carrier states such as Tay-Sachs disease, Canavan's disease, cystic fibrosis, or hemoglobinopathies. Resolution of these issues is much easier and less hurried without the time limits placed by an advancing pregnancy. Medical conditions such as anemia, hypothyroidism, hypertension, and diabetes can be fully evaluated and medical treatment can be optimized before pregnancy. If the patient is obese, weight reduction should be attempted before pregnancy. The value of prepregnancy counseling needs to be emphasized to all those who treat women at significant risk for pregnancy problems. Women who are followed by other physicians (family physicians, pediatricians, general internists) for such problems as diabetes, hypertension, or systemic lupus erythematosus should be seen, evaluated, and counseled before pregnancy. Patients in whom risks are very serious are potentially at risk for progressive disease, end-organ damage, or death and should be so counseled, and every attempt should be made to let them make a fully informed decision about pregnancy. Often, significant risk factors can be treated or managed so as to reduce risk during pregnancy.

There is evidence that for some conditions, such as diabetes mellitus and phenylketonuria, medical disease management before conception can positively influence pregnancy outcome. Medical management to normalize the biochemical environment should be discussed with the patient and appropriate management plans outlined before conception. This is also the time to review drug usage and other practices such as alcohol ingestion and smoking (see Chapter 8). Advice can be given about avoiding specific medications in the first trimester (e.g., isotretinoin), and general advice can be given concerning diet, exercise, and occupational exposures.

Periconceptional supplements with folic acid can reduce the incidence of neural tube defects (NTDs) and the use of therapeutic doses to decrease the risk of recurrence has been repeatedly demonstrated. This has resulted in national regulatory mandates for food supplements and national media campaigns to increase public awareness about the importance of this practice. **The CDC recommends that all women of childbearing age who are capable of becoming pregnant should consume 0.4 mg of folic acid daily, which is most easily achieved by taking a supplement. For women with a previously affected child, the recommendation is that the patient take 4 mg daily from 4 weeks before conception through the first 3 months of pregnancy.** The benefits of folic acid supplementation are being investigated with regard to the prevention of other complications of pregnancy, as well as chronic maternal disease states (e.g., preterm birth, cardiac disease), further emphasizing the appropriateness of prenatal care as both a model for primary care and a model for the provision of care in the context of a life span approach. Care provided at each visit affects not only pregnancy outcome, but ultimately long-term health outcomes for the woman and her family.

The importance of seeking care early for confirmation of pregnancy and gestational age dating can be discussed with the patient. Great precision can be achieved with an accurate menstrual calendar predating pregnancy and provide an opportunity for access to first trimester screening for aneuploidy and to prevent ambiguity about postdatism.

THE INITIAL PRECONCEPTIONAL OR PRENATAL VISIT

Social and Demographic Risks

Extremes of age are obstetrical risk factors. The pregnant teenager has particular nutritional and emotional needs. She is at special risk for sexually transmitted diseases; it has been shown that she benefits particularly from education in areas of childbearing and contraception. The pregnant woman over age 35 is at increased risk for a chromosomally abnormal child. Patients should be asked about family histories of Down syndrome, NTDs, hemophilia, hemoglobinopathies, and other birth defects, as well as mental retardation (see Chapter 10). Consultation for genetic counseling and genetic testing, if desired, may be appropriate. Women over 35 are at increased risk for almost all pregnancy-related morbidities, maternal mortality, and neonatal complications, including miscarriage, stillbirth, preterm birth, and neonatal mortality. The age of the father is also important, as there may be genetic risks to the fetus when the father is older than 55 years. Certain diseases may be related to race/ethnicity or geographic origin. Patients of African, Asian, or Mediterranean descent should be screened for the various heritable hemoglobinopathies (sickle cell disease, alpha and beta thalassemia). Patients of Jewish and French Canadian heritage should be screened for Tay-Sachs disease, Canavan's disease, and cystic fibrosis. More recently, it has been suggested that cystic fibrosis screening be offered to all couples planning a pregnancy or seeking prenatal testing.

Low socioeconomic status should be identified and attempts to improve nutritional and hygienic measures undertaken. Appropriate referral to federal programs, such as that for women, infants, and children (WIC), and to

public health nurses can have real benefits. If a patient has a history of previous neonatal death, stillbirth, or preterm birth, records should be carefully reviewed so that the correct diagnosis is made and recurrence risk appropriately assessed. A history of drug abuse or recent blood transfusion should be elicited. The history of medical illnesses should be detailed and records obtained if possible. A rapid procedure for diagnosing mental disorders in primary care may be useful in pregnancy.[38] If appropriate, patients should be screened and treated for depression.

Occupational hazards should be identified. If a patient works in a laboratory with chemicals, for example, she should be advised to identify potential reproductive toxins and limit her exposure. This is an active area of research and there are several online resources for information about potential environmental and occupational teratogens.[39] Patients whose occupations require heavy physical exercise or excess stress should be informed that they may need to decrease such activity later in pregnancy as both have been associated with increased risk of preterm birth and reduced fetal growth in observational studies.[40]

Tobacco, alcohol, and recreational drug use can all adversely affect pregnancy and questions regarding information about their use are a critical part of the history. Specific questions concerning smoking, alcohol, and drugs (prescriptive, over-the-counter, and illicit) should be asked. Regular screening for alcohol and substance use should be carried out using such tools as the T-ACE questionnaire (see Chapter 8) or other simple screening tools, and appropriate directed therapy should be made available to those women who screen positive. Women should be urged to stop smoking before pregnancy and to drink not at all or minimally once they are pregnant. Studies show that smoking cessation counseling by the health care provider works. Pregnancy is an ideal time to initiate this intervention.[41] Drug addiction confers a particularly high risk, and addicted mothers require specialized care throughout pregnancy (see Chapter 8). Discussions about caffeine use should also be addressed, as caffeine is addictive, associated with withdrawal symptoms, and relatively ubiquitous. It is present in coffee, tea, cocoa, cola drinks and other carbonated sodas, chocolate, "energy drinks," and many over-the-counter headache, cold, and flu treatments, as well as diet pills and prescription medications. The average cup of instant or brewed coffee contains 90 to 130 mg of caffeine. High-end coffee from select coffee houses can approach 250 mg.[42] A recent study sponsored by the ACOG suggests that there is considerable variation in assessment and advice related to caffeine consumption in pregnant or reproductive-age women. In a self-reported survey, Anderson and colleagues[42] found that most clinicians did not know the caffeine content of common beverages and were not familiar with scientific data suggesting adverse reproductive consequence. Due to hormonal influences, caffeine metabolism slows during second and third trimester of pregnancy. It crosses the placenta and is distributed to all fetal tissues. Due to immature liver systems, caffeine metabolism is slow in fetuses and neonates, with an extremely long reported half-life ranging from 80 to 100 hours.[43] ACOG[44] concluded that moderate caffeine consumption (less than 200 mg/day) does not appear to be a major contributing factor in miscarriage or preterm birth although a conclusion cannot be made regarding a correlation between higher caffeine intake and miscarriage. The relationship of caffeine to growth restriction is undetermined. **Hence, practice guidelines suggest that pregnant women should be advised to limit their caffeine consumption to 200 mg/day** (2 cups of coffee or cola drinks per day)[43-46] (see Chapter 8).

Violence against women is increasingly recognized as a problem that should be addressed, with reports suggesting that abuse occurs during 3% to 8% of pregnancies. Questions addressing personal safety and violence should be included during the prenatal period, and such tools as the Abuse Assessment Score are recommended.[47] It consists of five questions that assess the pregnant woman's history of abuse (emotional, physical, and sexual). It asks if a woman has ever experienced abuse in her lifetime by a partner or someone close to her and then focuses on questions regarding abuse during the current pregnancy. For example, in cases in which women did experience abuse during their pregnancy, they are asked to "score" each incident according to a scale provided, ranging from mild threats to the dangerous use of a weapon or wound from a weapon.

Medical Risk

Family history of diabetes, hypertension, tuberculosis, seizures, hematologic disorders, multiple pregnancies, congenital abnormalities, and reproductive wastage should be elicited. Often, a family history of mental retardation, birth defect, or genetic trait is difficult to elicit without formal genetic counseling or questionnaires; nonetheless, these areas should be emphasized at the initial history. A better history may be obtained if patients are asked to fill out a preinterview questionnaire or history form. Any significant maternal cardiovascular, renal, or metabolic disease should be defined. Infectious diseases such as urinary tract disease, syphilis, tuberculosis, or herpes genitalis should be identified. Surgical history with special attention to any abdominal or pelvic operations should be noted. A history of previous cesarean birth should include indication, type of uterine incision, and any complications. A copy of the surgical report may be informative. Allergies, particularly drug allergies, should be prominent on the problem list.

Hyperthyroidism

Neonatal hyperthyroidism is rare, with an incidence of 1:4000 to 1:40,000 live births. Fetal thyrotoxic goiter is usually secondary to maternal autoimmune disease, most commonly Graves disease or Hashimoto's thyroiditis (see Chapter 40). As many as 12% of infants of mothers with a known history of Graves disease are affected with neonatal thyrotoxicosis. This can occur even if the mother is euthyroid. The underlying mechanism is transplacental passage of maternal IgG antibodies. These antibodies, known as thyroid-stimulating antibody or thyroid-stimulating immunoglobulin, are predominantly directed against the thyroid-stimulating hormone (TSH) receptor. Often fetal goiter is diagnosed on ultrasound in pregnancies in which the mother has elevated thyroid-stimulating antibodies. In some cases, fetal goiters are incidentally detected on routine ultrasonography. In still others, detection follows scan for polyhydramnios. Untreated fetal hyperthyroidism may be associated with a mortality rate of 12% to 25% owing to high-output cardiac failure.

Hypothyroidism

Congenital hypothyroidism is relatively rare, affecting about 1:3000 to 1:4000 infants. About 85% of the cases are the result of thyroid dysgenesis, a heterogenous group of developmental defects characterized by inadequate thyroid tissue. Congenital hypothyroidism is only rarely associated with errors of thyroid hormone synthesis, TSH insensitivity, or absence of the pituitary gland. Congenital hypothyroidism presenting with a goiter is observed in only about 10% to 15% of cases.

Fetal goiterous hypothyroidism also follows maternal exposure to thyrostatic agents such as propylthiouracil and radioactive iodine-131 used to treat maternal hyperthyroidism. Maternal ingestion of amiodarone or lithium may also cause hypothyroidism in the fetus. Fetal hypothyroidism may also follow transplacental passage of maternal blocking antibodies (known as TBIAb or TBII). Rarely, defects in fetal thyroid hormone biosynthesis may exist.

An enlarged fetal goiter may cause esophageal obstruction and polyhydramnios, leading to preterm delivery or premature rupture of membranes. A goiter may even lead to high-output fetal heart failure. A large fetal goiter can also cause extension of the fetal neck, leading to dystocia. Fetal hypothyroidism itself may be devastating, and without treatment, postnatal growth delay and severe mental retardation ensue. Even with immediate diagnosis and treatment at birth, children with congenital hypothyroidism demonstrate lower scores on long-term perceptual-motor, visuospatial, and language tests.

Obstetrical Risk

Previous obstetrical and reproductive history is essential to optimizing care in subsequent pregnancies. The gravidity and parity should be noted and the outcome for each prior pregnancy recorded in detail. Previous miscarriages (and documentation about the gestational age at the time of the loss) not only confer risk and anxiety for another pregnancy loss but can be associated with an increased risk for genetic disease, as well as preterm delivery.

Previous preterm delivery is strongly associated with recurrence; it is important to delineate the events surrounding the preterm birth. Did the membranes rupture before labor? Were there painful uterine contractions? Was there bleeding? Were there fetal abnormalities? What was the neonatal outcome? All these questions are vital in determining the etiology and prognosis of the condition, although specific recommendations will vary and the efficacy of routine prevention programs is not clear. In patients with a previous premature delivery, after preterm labor or premature rupture of membranes, progesterone administration reduces the recurrence risk.[48,49] Diethylstilbestrol (DES) exposure, incompetent cervix, and uterine anomalies are all conditions that may be known from a previous pregnancy. Previous fetal macrosomia makes glucose screening essential.

After all the specific questions, it is recommended to ask the patient a few simple questions: What important items haven't I asked? What else about you and your pregnancy do I need to know? What problems and questions do you have? Leaving time for open-ended questions is the best way to complete the initial visit.

Physical and Laboratory Evaluation

Physical examination should include a general physical examination, as well as a pelvic examination. Baseline height and weight and prepregnancy weight are recorded. Special attention should be given to the initial vital signs and cardiac examination, because many healthy young women have not had a physical examination immediately before becoming pregnant. Any physical finding that might have an impact on pregnancy or that might be affected by pregnancy should be defined. It is particularly important to perform and record a complete physical examination at this initial visit, because less emphasis will be placed on nonobstetrical portions of the examination as pregnancy progresses in the absence of specific problems or complaints.

The pelvic examination should focus on the uterine size. Before 12 to 14 weeks, size can give a fairly accurate estimate of gestational age in a thin patient. Papanicolaou smear and culture for gonorrhea and chlamydia are done. Bacterial vaginosis should be recognized. The cervix should be carefully palpated, and any deviation from normal should be noted. Clinical pelvimetry should be performed and the clinical impression of adequacy noted. The pelvic examination is limited by examiner and patient variation, as well as by obesity. If there is difficulty in examining the uterus, an ultrasound study is indicated.

Basic laboratory studies are routinely performed (see Table 6-2). Some studies need not be repeated if recent normal values have been obtained, such as at a preconceptional visit or a recent gynecologic or infertility examination. Blood studies should include Rh type and screening for irregular antibodies, hemoglobin level, or hematocrit and serologic tests for syphilis and rubella. A urine sample should be obtained and tested for abnormal protein and glucose levels. Screening for asymptomatic bacteriuria has been traditionally done by urine culture, but screening may be simplified by testing for nitrites and leukocyte esterase.[50] Tuberculosis screening should also be performed in areas of disease prevalence.

First trimester screening, a multiple marker screen, uses sonographic evaluation of nuchal translucency and biochemical markers (PAPP-A and free βhCG) to allow earlier screening for chromosomal aberrations. It is offered between 11 and 14 weeks.[51] The QUAD test (α-fetoprotein, human chorionic gonadotropin [hCG], estriol, and inhibin A) or maternal serum α-fetoprotein screening is offered from 15 to 20 weeks' gestation to screen for NTDs and aneuploidy[52] (see Chapter 10). Patients who undergo first trimester screening require a maternal serum α-fetoprotein level after 15 weeks for NTDs screening. The integrated screen combines first and second trimester screening and gives the result only after the second trimester evaluation is completed.

The laboratory evaluations outlined above are the minimum standard tests. Specific conditions will require further evaluation. A history of thyroid disease will lead to thyroid function testing. Anticonvulsant therapy requires blood level studies to determine adequacy of medication. The importance of compliance with dosing and serial evaluation of serum blood levels should be emphasized as both thyroid medications and anticonvulsant levels are sensitive to the physiologic changes in blood volume that occur

during pregnancy. Adequacy of replacement and/or blood levels will need to be monitored throughout pregnancy. Identification of problems on screening (e.g., anemia, abnormal glucose screen) will mandate further testing. Screening for varicella has been suggested for women with no known history of chickenpox. The ACOG has recommended routine screening of all pregnant women for hepatitis B.[53] HIV screening should also be offered, because maternal therapy with antiretroviral agents can reduce vertical transmission (see Chapter 50).[53] Hepatitis C and CMV screening should be considered for at-risk populations. Recommendations for the content of prenatal care are summarized in Table 6-3. Note that these recommendations are drawn from various sources, most are based on expert opinion, and although similar are not entirely in agreement with regard to all recommendations.[54-58]

ASSESSMENT OF GESTATIONAL AGE

During the course of the prenatal interview, assessment of gestational age begins with the question, "What was the first day of the last menstrual period?" From that point, the establishment of an estimated date of delivery and confirmation of that date by accumulation of supportive information remains one of the most important tasks of good prenatal care.

Human pregnancy has a duration of 280 days, measured from the first day of the last menstrual period (LMP) until delivery. The standard deviation is 14 days. It is important to remember that clinicians are measuring menstrual weeks (not conceptional weeks) with an assumption of ovulation and conception based on day 14 of a 28-day cycle. This gives pregnancy the 40-week gestational period in common clinical use. Much confusion exists among patients who try to measure pregnancy in terms of 9 months, when in fact, it is 10 (40/4 = 10), or who try to measure in conceptional weeks. Another problem exists in women whose menstrual cycles do not follow a 28-day cycle and who therefore do not conceive on day 14 of the menstrual cycle. The commonly used term "4 months' pregnant" has no meaning (one does not know whether this is 16 or 20 weeks) and has no place on a contemporary prenatal record. It is often helpful to explain to patients and their families that their pregnancy will be described in terms of weeks, rather than months, and that the pregnancy can be broken into three trimesters lasting 1 to 14 weeks, 14 to 28 weeks, and 28 weeks to delivery. Every effort should be made to be consistent in usage to prevent

confusion among patients and among clinicians who may assume care of the pregnancy.

Knowledge of gestational age is critical for obstetrical decision making. Generally, in a normal pregnancy, we can extrapolate from gestational age to estimate fetal weight. Throughout pregnancy, these are the two most important determinants of fetal viability and survival. Without accurate knowledge of gestational age, diagnosis of such conditions as postterm pregnancy and intrauterine growth restriction is often impossible. Multiple gestation is most often detected early when the size of the uterine fundus is greater than expected for gestation. Appropriate management of preterm labor or a medically complicated pregnancy depends on an accurate estimate of fetal age and weight. Within regional perinatal systems, records of gestational age are important for flow of information, and rapid access to consistent, clear data is vital. In such situations, and during prolonged hospitalization, it is sometimes helpful to define gestational age further by using the notation of fractional weeks ($27^4/_7$ weeks). It must be remembered, however, that we are describing a biologic system and that such precision is being used more for ease of communication and organization than for any ability to date the pregnancy with such a degree of accuracy.

Clinical Dating

Historically, the most reliable clinical estimator of gestational age is an accurate LMP. Using Naegele's rule, the estimated date of delivery is calculated by subtracting 3 months and adding 1 week from the first day of the LMP. A careful history must be taken from the patient verifying that the date given is the first day of the period, as well as whether the period was normal, heavy, or light. The date of the previous menstrual period will help ascertain the length of the cycle. History should also be taken about previous use of oral contraceptives, which might influence ovulation.

Other clinical tools can be used to confirm and support LMP data and, in cases in which the LMP is inaccurate or unknown, it has been shown that accumulated clinical information from early pregnancy can predict gestational age with an accuracy approaching that of menstrual dating.

The size of the uterus on early pelvic examination, or by direct measurement of the abdomen from the pubic symphysis to the top of the uterine fundus (over the curve), provides useful information. Experienced practitioners can assess the early pregnancy with reproducibility before 12 to 14 weeks. Fundal height measurement in centimeters using the over-the-curve technique approximates the gestational age from 16 to 38 weeks within 3 cm in non-obese patients.

The uterus also tends to reach the umbilicus at about 20 weeks, and this too can be assessed when uterine fundal measurements are made. The uterus may be elevated in early pregnancy in a patient with a previous cesarean delivery or with uterine myomas, making the fundal height appear abnormally high. Considerable variations in the level of the umbilicus and in the height of patients make this clinical marker variable. Quickening, the first perception of fetal movement by the mother, occurs at predictable times in gestation. In the first pregnancy, quickening is usually noted at about 19 weeks; in subsequent pregnancies, probably because of the experience of the observer, it tends to occur about 2 weeks earlier. It is helpful to ask the woman to mark on a calendar the first time she feels the baby move and to report this date.

Audible fetal heart tones, in addition to being absolute evidence of pregnancy, are another marker of gestational age. Using an unamplified Hillis-DeLee fetoscope, they are generally audible at 19 to 20 weeks. Observer experience, acuity, and the time spent listening can all affect this number, so this guideline may need to be adapted individually.

Use of the electronic Doppler device is widespread and permits detection of the fetal heart by 11 to 12 weeks. Practitioners can set a standard individualized to their own equipment, which can be used as a gestational age marker. If fetal heart tones are not heard at the expected time, a sonogram is appropriate to look for date/examination discrepancy, fetal viability, twins, or polyhydramnios.

The conversion of a negative urinary pregnancy test to a positive one may be helpful in assessing gestational age, but the sensitivity of the test used must be known in order to interpret the data accurately. These tests may be negative if they are performed too early.

Comparison of the various clinical estimators shows a known LMP date to be the most precise predictor. The clinical estimators can be ranked according to decreasing order of accuracy as follows: (1) last menstrual period; (2) the uterus reaching umbilicus; and (3) fetal heart tone documentation, fundal height measurements, and quickening. Because of inherent biologic variability and differences in the examiner acuity, the estimated date of confinement can be predicted with 90% certainty only within ±3 weeks by even the best single estimator.

Ultrasound

Ultrasound plays a major role in assessment of size and duration of pregnancy. The National Institutes of Health (NIH) consensus conference in 1984 concluded that in a low-risk pregnancy followed from the first trimester, routine ultrasound examination was not justified for determining gestational age. However, a long list of indications justify an ultrasound examination and studies on resource utilization indicate that at least 70% of women receive an ultrasound at some point in their pregnancy, and, importantly, women have come to expect an ultrasound as part of standard prenatal care. **With the advent of first trimester screening including nuchal translucency measurement, many women are receiving first trimester ultrasounds, and ultrasound is an accurate means of estimating gestational age in the first half of pregnancy.** The crown-rump length, biparietal diameter, and femur length in the first half of pregnancy correlate closely with age. As pregnancy progresses, fetal size varies considerably, and measurement of the fetus is a less reliable tool for estimation of gestational age, especially in the third trimester.

Recognizing that most women are receiving ultrasounds at some time in their pregnancy, the following question arises: What should be done if there is a discrepancy in the clinical dates (based on LMP) and the ultrasound dates? If ultrasound differs more than 7 days from LMP during the first trimester, or more than 10 days between 12 and 20 weeks' gestation, change the estimated due date to the

ultrasound date.[59] Issues arise when the patient is late to care and there is a size/date discrepancy. In general, one can assume an 8% margin of error in the ultrasound (measured in days).[60] Hunter[61] advocates using the "rule of 8's" in this special circumstance. Calculate the difference in dates using days based on LMP and ultrasound. Then multiply the LMP days by 0.08 (margin of error). If the difference is greater than 0.08, use the ultrasound date; if it is less than 0.08, use the LMP dates.[61] It would be prudent to follow up with an interval growth scan to evaluate for growth abnormalities.

Although the benefits of routine ultrasound are widely debated, a randomized trial has shown that the risk of being called overdue was reduced from 8% to 2% for patients who received early ultrasound.[62] Also, twins were detected more often and perinatal mortality was reduced in the ultrasound group. The Routine Antenatal Diagnostic Imaging with Ultrasound (RADIUS) study reported no improvement in perinatal outcome with use of routine ultrasound in normal, low-risk women.[63] However, 61% of women were excluded for many reasons such as an uncertain menstrual history, and only 35% of anomalies were detected in the ultrasound-screened group (only 17% before 24 weeks). The meta-analysis by Bucher and Schmidt indicated that routine scanning can detect many more anomalies. The authors' practice is to perform ultrasound in the first trimester for women requesting integrated serum marker screening or if heart tones are not heard by Doppler by 11 weeks. We screen for fetal abnormality or multiple gestation at 18 to 20 weeks. If ultrasound is not done routinely, the caregiver must be vigilant in detecting problems that are indications for a scan.

REPEAT PRENATAL VISITS

A plan of visits is outlined to the patient. Traditionally, this has been every 4 weeks for the first 28 weeks of pregnancy, every 2 to 3 weeks until 36 weeks, and weekly thereafter, if the pregnancy progresses normally. The Public Health Service suggested that this number of visits can be decreased, especially in parous, healthy women, and studies suggest that this can be done safely[64] (see Table 6-1). If there are any complications, the intervals can be increased appropriately. For example, patients with hypertensive disease or at risk for preterm delivery may require weekly visits. Fetal heart tones can be documented before the 12th week by Doppler devices, and this information can be used for gestational dating purposes.

At regular visits, the patient is weighed, the blood pressure is recorded, and the presence of edema is evaluated (see Intercurrent Problems, following). Fundal height is regularly measured with a tape measure, fetal heart tones are recorded, and fetal position is noted. The goal of subsequent pregnancy visits is to assess fetal growth and maternal well-being. In addition, at each prenatal visit, time should be allowed for the following questions: Do you have any problems? Do you have any questions? Family members should be encouraged to come to prenatal visits, ask questions, and participate to the degree that the patient wishes.

A pelvic examination is usually only performed on the first visit. In patients at risk of prematurity or in those with a history of DES exposure, however, frequent cervical checks or sonographic evaluation of cervical length may reveal premature dilation or effacement.

Further laboratory evaluations are routinely performed at 28 weeks, when the hemoglobin or hematocrit and Rh type and the screen for antibodies, as well as the serologic test for syphilis and possibly HIV testing, can be repeated. If the patient is Rh negative and unsensitized, she should receive Rhesus immune globulin (RhIG) prophylaxis at this time. A glucose screening test for diabetes is also appropriately performed at this time (see Chapter 39), and routine fetal movement counting can begin using an organized system. At 36 weeks, a repeat hematocrit, especially in those women with anemia or at risk for peripartum hemorrhage (multipara, repeat cesarean), may be performed. GBS screening should be done at 35 to 37 weeks and results made available for possible intrapartum prophylaxis. Also, appropriate cultures for sexually transmitted disease (gonorrhea, chlamydia) should be obtained as indicated in the third trimester based on geographic prevalence rates and demographic risk factors.

After 41 weeks from the last menstrual period, the patient should be entered into a screening program for fetal well-being, including electronic monitoring tests and ultrasound evaluation, or offered induction of labor if the dating is accurate (see Chapter 34).

INTERCURRENT PROBLEMS

It is the practice in prenatal care to evaluate the pregnant patient for the development of certain complications. Inherent in these checks is surveillance for intervening problems, an important one being preeclampsia. If a patient shows a blood pressure elevation at 28 weeks, for example, she should be seen again in a week, not a month. Blood pressure will change physiologically in response to pregnancy, but development of hypertension must be recognized and evaluation and hospitalization appropriately instituted.

Weight gain and obesity in pregnancy have been shown to be important predictors of pregnancy outcome. Weight gain is an important correlate of fetal weight gain and is therefore closely monitored. Too little weight gain should lead to an evaluation of nutritional factors and an assessment of associated fetal growth. Excess weight gain is one of the first signs of fluid retention, but it may also reflect increased dietary intake or decreased activity. Sixty-five percent of Americans are overweight (body mass index [BMI] ≥ 25 kg/m^2) or obese (BMI ≥ 30 kg/m^2).[65] Compared to women with normal weight, pregnant obese women are at increased risk of miscarriage, gestational diabetes, preeclampsia, venous thromboembolism, induced labor, cesarean delivery, anesthetic complication, and wound infections. Obese women are less likely to initiate or maintain breastfeeding. Babies of obese mothers are at increased risk of stillbirth, congenital anomalies, prematurity, macrosomia, and neonatal death.[66] Furthermore, weight gain, and weight retention after pregnancy, is a risk factor for subsequent obesity.[6,67] Thus, postpartum weight loss should be encouraged. A study by Rooney and Schauberger[68] demonstrated that women who resumed their prepregnancy weight by 6 months postpartum gained only

2.4 kg over the next 10 years as compared 8.3 kg for women who retained weight after delivery. Whereas clinicians have been inundated with teaching women that appropriate weight gain is important for pregnancy, the concomitant importance of postpartum weight loss has not been given equal attention.[6,12,69] Likewise, interventions and public education based on this knowledge have been poorly addressed. In fact, studies suggest that prenatal care providers are not addressing diet, weight gain, or physical activity, or are giving incorrect advice.[70] Factors that contribute to excessive weight gain during pregnancy include high fat, low fiber intake, high carbohydrate or sugar intake, and decreased physical activity during pregnancy.[71] Several small studies suggest that monitoring weight gain, quantity of food intake, and physical activity, combined with behavioral counseling, can limit weight gain during pregnancy and promote postpartum weight loss. However, larger randomized trials are needed to demonstrate long-term effectiveness.[66,67]

Dependent edema is physiologic in pregnancy, but generalized or facial edema can be a first sign of disease. It is critical here, as in all areas, for the practitioner to understand the normal changes associated with pregnancy not only to accept and explain the normal changes, but also to manage aggressively any abnormal changes.

Proteinuria reflects urinary tract disease, generally either infection or glomerular dysfunction, possibly the result of preeclampsia. Urinary tract infection should be looked for, and the degree of protein quantitated in a 24-hour urine collection.

Glycosuria is common because of increased glucose filtered through the kidney in pregnancy, but warrants evaluation for diabetes with a measurement of capillary glucose when clinical suspicion exists.

Fetal abnormalities are often first detected by deviation from the clinical expectation. In some conditions, risk of fetal anomaly will be so high as to prompt some kind of baseline screening or testing (e.g., amniocentesis, sonography, fetal echocardiography). At other times, risk only becomes evident during the course of prenatal care. Growth restriction and macrosomia can often be suspected clinically, usually on the basis of an abnormality in fundal growth. For the patient who has a history of these conditions or other predisposing factors, such as hypertension, renal disease, or diabetes, particular vigilance is in order. Excess amniotic fluid is another condition that can be clinically detected, and an etiology for the hydramnios should be sought. In addition to maternal conditions, hydramnios may be caused by fetal disease that can also be defined using sonography and that may alter management of the pregnancy.

THE PRENATAL RECORD

The prenatal care record describes in a consistent fashion the comprehensive care that is provided and allows for documentation of coordinated services. Prenatal care should be documented by a prenatal record of good quality designed to systematically capture important clinical and psychosocial information over time. One such example is the antepartum record designed by ACOG. Many of the advances in risk assessment and in regionalization result directly from an improvement in this record and electronic medical records (EMRs) are being developed.[72] Technology allows sophisticated recording, display, and retrieval (often computer-based) of prenatal care records, but quality relies on accurate, consistent compiling and concurrent recording of the information. The record must be complete, yet simple; directive, but flexible; and transmittable, legible, and able to display necessary data rapidly. European nations often have one record for uniform care; many states and regions have adopted records to permit internal consistency.

The commonly used records accurately reflect the following:

1. Demographic data, obstetrical history
2. Medical and family history, including genetic screening
3. Baseline physical examination, with emphasis on gynecologic examination
4. Menstrual history, especially last normal menstrual period with documentation of established due date and reference criteria for dating if other than LMP
5. Record of individual visits
6. Routine laboratory data (e.g., Rh, GBS, rapid plasma reagin (RPR), rubella, hepatitis, and HIV)
7. Problem list
8. Space for special notations and plans (e.g., planned VBAC or repeat cesarean, tubal ligation)

These records must be made available to consultants, and they should be available at the facility where delivery is planned. If transfer is expected, a copy of the prenatal record should accompany the patient.

PRENATAL EDUCATION

Patient education leads to better self-care. As maternal and neonatal outcomes improve, efforts become more sophisticated to improve understanding, involvement, and satisfaction with pregnancy and the perinatal period. In this area, more than any other, the options for paramedical support have expanded. Practitioners and patients have access to a vast array of support persons and groups to assist and advise in the pregnancy and subsequent parenthood. Group prenatal care has recently been proposed and evaluated. The wise practitioner stays abreast of these advances and integrates them into practice. Patients should be educated about care options and participate in decision making. Although not exhaustive, the following section includes common issues or concerns that practitioners should address at some point during successive prenatal visits as part of their health education, promotion, and prevention goals with each patient.

Informed Consent and VBAC

During the educational components of prenatal care there is significant opportunity to accomplish most if not all the informed consent required for the delivery process. There are also advantages to securing documentation of appropriate informed consent for management of labor and associated obstetrical procedures, possible interventions, and risks and benefits when they can be thoroughly reviewed and discussed rather than in the throes of labor. It is our practice to obtain consent, whenever possible, in the third

trimester for "delivery and related procedures including IV fluids, fetal monitoring, labor augmentation, episiotomy, operative vaginal delivery including forceps and vacuum, and cesarean delivery," and this is documented on institutional consent forms and signed by the patient. Consent for anesthesia can also be obtained before admission. Risks such as third- and fourth-degree lacerations with episiotomy and operative delivery are appropriate to discuss, as well as the benefits of birth spacing and contraceptive options. Maternal, newborn, and familial benefits have been associated with optimal birth spacing—estimated to be approximately 2 to 5 years. Short pregnancy intervals are associated with increased low birth weight, preterm birth, and other adverse pregnancy outcomes attributed to decreased maternal reserves, whereas prolonged birth spacing has been associated with increased risk of breast cancer, preeclampsia, and stillbirths. The benefits of intermediate birth spacing needs to be emphasized by health care practitioners and more widely disseminated. It is associated with improved maternal health (decreased risk of uterine rupture, endometritis, antepartum bleeding, anemia, depression), improved child health (decreased childhood illnesses, injuries, death, improved education), and improved family health, functioning, and socioeconomic status.[73,74] Although contraceptive options are numerous, tubal ligation is the most common method in the United States. If tubal ligation is offered, the risks, benefits, and alternatives of postpartum versus interval ligation should be discussed.

The special benefits and risks of vaginal birth after cesarean section are particularly important to discuss before labor, and it is common to document both the components of the informed consent process and the patient's choice with respect to route of delivery.

Smoking Cessation

Smoking has a demonstrated dose-response relationship to impaired fetal growth. Smoking cessation or reduction can reverse this growth disturbance. The likelihood of interventions to stop or reduce smoking are increased during pregnancy. Every effort should be made to identify prepregnancy and pregnant smokers and provide both pharmacologic and psychosocial interventions and programs to maximize likelihood of smoking cessation (see Chapter 8).

Drugs and Teratogens

At the preconceptional or first prenatal visit, recommendations for nonpharmacologic remedies for common ailments can be given. This can often be integrated into a discussion of the common side effects of pregnancy. Because of widespread use of over-the-counter drugs, the patient should be warned to take only those drugs specifically approved or prescribed by her practitioner (see Chapter 8). Likewise, the patient should be advised to inform her practitioner about all natural or herbal supplements that are being used. Practitioners should be aware of current studies estimating that roughly 40% to 87% of women have used complementary and alternative medicines (including herbal therapy).[75]

Radiologic Studies

Elective radiologic studies can safely be delayed until completion of the pregnancy; however, dental and radiologic diagnostic procedures should be performed during pregnancy when they are indicated with proper shielding of the abdomen. Tests to evaluate life-threatening events such as thromboembolic phenomenon, or as needed for trauma evaluation, particularly should not be deferred as this could put the mother's health at undue risk. Judicious use of pulmonary perfusion scans, spiral computed tomography (CT), and magnetic resonance imaging (MRI) have been life-saving for pregnant women with minimal radiation exposure risks. Dental restorative work especially should be performed to allow optimal maternal nutrition (see Chapter 8).

Nutrition

One of the earliest purposes of prenatal care was to counsel and ensure that women received adequate nutrition for pregnancy. The health care provider may be influential in correcting inappropriate dietary habits. Strict vegetarians may need supplemental vitamin B_{12}. Occasionally, consultation with a registered dietitian may be necessary when there is poor compliance or a special medical need such as diabetes mellitus.

Dietary allowances for most substances increase during pregnancy. According to the 1989 recommended dietary allowances (RDAs), only the recommendations for iron, folic acid, and vitamin D double during gestation.[76] The RDA for calcium and phosphorus increase by half; the RDA for pyridoxine and thiamine increase by about one third. The RDA for protein, zinc, and riboflavin increase by about one fourth. The RDA for all other nutrients except vitamin A increase by less than 20% (Tables 6-4 and 6-5) and vitamin A not at all, as that is believed to be stored adequately. All of these nutrients, with the exception of iron, are supplied by a well-balanced diet.

The National Academy of Sciences currently recommends that 30 mg of ferrous iron supplements be given to pregnant women daily, because the iron content of the habitual American diet and the iron stores of many women are not sufficient to provide the increased iron required during pregnancy. For those at high nutritional risk, such as some adolescents, those with multiple gestation, heavy cigarette smokers, and drug and alcohol abusers, a vitamin/mineral supplement should be given. Increased iron is needed both for the fetal needs and for the increased maternal blood volume. Thus, iron-containing foods should also be encouraged. Iron is found in liver, red meats, eggs, dried beans, leafy green vegetables, whole-grain enriched bread and cereal, and dried fruits. The 30-mg iron supplement is contained in approximately 150 mg of ferrous sulfate, 300 mg of ferrous gluconate, or 100 mg of ferrous fumarate. Taking iron between meals on an empty stomach will facilitate its absorption.

Because women of higher socioeconomic status have better reproductive performance and fewer low-birth-weight babies than do women of lower socioeconomic status, and because they also consume more protein, it is probably prudent to continue to recommend a generous amount of dietary protein. However, protein supplementation does not improve pregnancy outcome. Acute caloric restriction in a well-nourished population such as occurred during the Dutch famine of 1944 to 1945 caused the average birth weight to drop about 250 g, yet no adverse effect on long-term outcome was observed. These mothers

ate a calorie-restricted, balanced diet in their second and third trimesters.

Weight Gain

The total weight gain recommended in pregnancy is 25 to 35 lb for normal women.[77] Underweight women may gain up to 40 lb, and overweight women should limit weight gain to 15 lb, although they do not need to gain any weight if they are morbidly obese.[78] About 2 to 3 lb are from increased fluid volume, 3 to 4 lb from increased blood volume, 1 to 2 lb from breast enlargement, 2 lb from enlargement of the uterus, and 2 lb from amniotic fluid. At term, the infant weighs approximately 6 to 8 lb and the placenta 1 to 2 lb. A 4- to 6-lb increase in maternal stores of fat and protein is important for lactation. Usually, 3 to 6 lb are gained in the first trimester and ½ to 1 lb per week in the last two trimesters of pregnancy.

If the patient does not show a 10-lb weight gain by midpregnancy, her nutritional status should be reviewed, unless she is obese. Inadequate weight gain is associated with an increased risk of a low-birth-weight infant (Figure 6-3). Inadequate weight gain seems to have its greatest effect in women who are low or normal weight before pregnancy. Underweight mothers must gain more weight during pregnancy to produce infants of normal weight. Patients should be cautioned against weight loss during pregnancy.

When excess weight gain is noted, patients should be counseled to avoid high fat, high carbohydrate, or sugar intake, and to increase their physical activity. Rapid weight

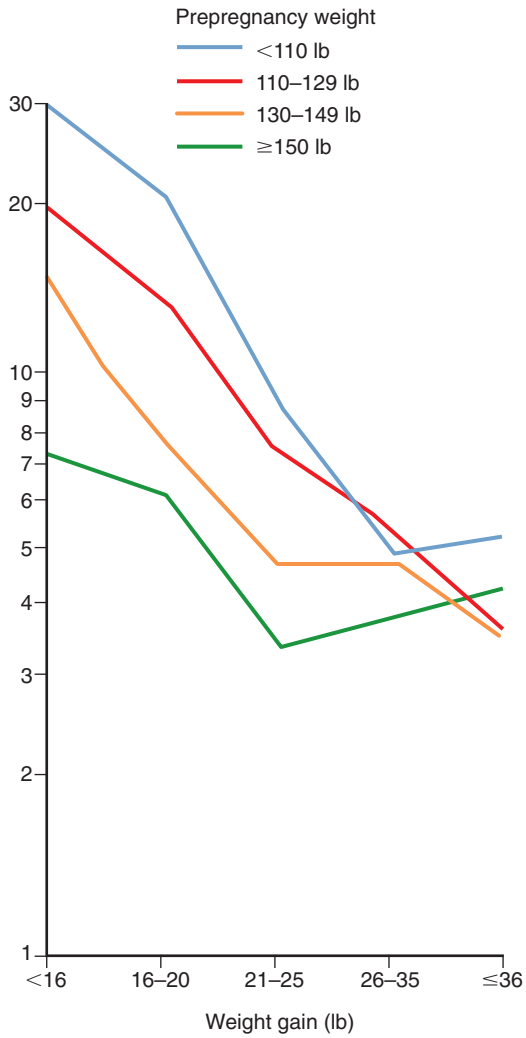

FIGURE 6-3. Percentage of live-born infants of low birth weight by maternal weight gain during pregnancy according to the mother's prepregnancy weight. *Low birth weight* is defined as birth weight of less than 2500 g or 5 lb, 8 oz. (From the National Natality Survey—United States. DHHS Pub No. [PHS] 86-1922, 1980.)

gain requires an assessment for fluid retention. In the assessment of edema, some dependent edema in the legs is normal as pregnancy advances because of venous compression by the weight of the uterus. Elevation of the feet and bedrest on the left side will help correct this problem. Turning the patient from her back to her left side increases venous return from the legs as the pressure on the vena cava is relieved. This maneuver increases the effective circulating blood volume, cardiac output, and thus the blood flow to the kidney. A diuresis will follow, as well as increased blood flow to the uterus.

Limitation of fluids will neither prevent nor correct fluid retention. Salt is not restricted, although patients with hypertension may be advised to decrease salt load.

Activity and Employment

Most patients are able to maintain their normal activity levels in pregnancy. Mothers tolerate pregnancy with considerable physical activity, such as looking after small children, but heavy lifting and excessive physical activity should be avoided. Modification of activity level as the pregnancy progresses is seldom needed, except if the job involves physical danger. Recreational exercises should be encouraged, such as those available in prenatal exercise classes. Unfortunately, many women are routinely told to decrease their physical activity, but research on moderate aerobic activity shows no negative impact on pregnancy outcomes. In the absence of medical or obstetrical complications, current ACOG recommendations advocate for 30 minutes (or more) of moderate exercise daily.[79] A Cochrane review of aerobic exercise in pregnancy indicated improved maternal fitness, but insufficient evidence to determine if there are maternal or neonatal risks or benefits.[40]

Previously sedentary women with no medical contraindications can start with 15 minutes of continuous exercise three times per week and work toward a goal of 30 minutes four times per week. With regard to exercise intensity, a good rule of thumb is the "talk test." If a pregnant, exercising woman cannot maintain a conversation (perceived moderate intensity), she is probably overexercising. Studies suggest that women who engage in regular recreational activity have less gestational diabetes, less preeclampsia, and less low back pain/pelvic pain.[79] The patient should be counseled to discontinue activity whenever she experiences discomfort.

Healthy pregnant women may work until their delivery, if the job presents hazards no greater than those encountered in daily life. Strenuous physical exercise, standing for prolonged periods, and work on industrial machines, as well as other adverse environmental factors, may be associated with increased risk of poor pregnancy outcome, and these should be modified as necessary.[79]

Travel

A pregnant woman should be advised against prolonged sitting during car or airplane travel because of the risk of venous stasis and possible thromboembolism. The usual recommendation is a maximum of 6 hours per day driving, stopping at least every 2 hours for 10 minutes to allow the patient to walk around and increase venous return from the legs. Hydration and support stockings are also recommended.

The patient should be instructed to wear her seat belt during car travel, but under the abdomen as pregnancy advances. It may also be helpful to take pillows along in a car to increase comfort. If the patient is traveling a significant distance, it might be helpful for her to carry a copy of her medical record with her in case an emergency arises in a strange environment. She should also become familiar with the medical facilities in the area or perhaps obtain the name of an obstetrician in the event of a problem.

Immunizations

Because of a theoretical risk to the fetus, pregnant women or women likely to become pregnant should not be given live, attenuated-virus vaccines. Influenza vaccination should be given during flu season.[80] Yellow fever and oral polio may be given to women exposed to these infections. Despite theoretical risks, no evidence of congenital rubella syndrome in infants born to mothers inadvertently given rubella vaccine has been reported. Measles, mumps, and

rubella viruses are not transmitted by those immunized and can be given to children of pregnant women. There is no evidence of fetal risk from inactivated virus vaccines, bacterial vaccines, toxoids, or tetanus immunoglobulin, which should be administered if appropriate. Postdelivery rubella and varicella vaccinations should be encouraged as this remains a substantial missed opportunity. Tdap is given postpartum if the patient has not received it previously, regardless of the interval since the last Td (see Chapter 22).

Nausea and Vomiting in Pregnancy

Nausea and vomiting is a common symptom of pregnancy affecting approximately 75% of pregnancies.[81,82] Hyperemesis gravidarum is an extreme form characterized by unexplained vomiting, dehydration, and weight loss and frequently results in hospitalization.[81] The exact etiology of hyperemesis gravidarum is unknown, but is believed to be related to a product of the placenta, and its occurrence is correlated with human chorionic gonadotropin (hCG) and estradiol concentration. Twin and sibling studies suggest there may be a genetic component.[81] Epidemiologic risk factors include younger age, low prepregnancy body mass, female fetus, and a history of motion sickness or migraines.[81,82] Smoking and obesity are associated with decreased risk of hyperemesis.[81,83] If hyperemesis gravidarum occurs in a first pregnancy, the recurrence risk is approximately 15%, although this can be reduced by a change in paternity.[81,82]

Women with hyperemesis gravidarum can have transient laboratory abnormalities including suppressed TSH or elevated free thyroxine. They can also have elevated liver enzymes, bilirubin, amylase, lipase, and altered electrolytes (loss of sodium, potassium, and chloride).[84] Women with severe hyperemesis can develop rare, severe complications such as Wernicke's encephalopathy, beriberi, central pontine myelinolysis, peripheral neuropathy, hepatic failure, or renal failure. Similarly, severe retching has been associated with Mallory-Weiss tears, esophageal rupture, pneumomediastinum, and retinal detachment.[81]

Fetal effects of hyperemesis gravidarum are unclear. In general, if the problem is corrected or resolves and the patient is able to gain weight, there are no consequences. However, if the woman has poor weight gain (fewer than 15 lb), the fetus is at increased risk for low birth weight and preterm birth.[85]

Treatment of hyperemesis gravidarum is primarily symptomatic. There is no evidence to support an ideal diet in these cases, but women are frequently advised to eat small meals that favor protein over carbohydrates and liquids over solids.[86] **Women admitted to the hospital typically require IV hydration, and most recommend initial supplementation with thiamine (100 mg) for 3 days to prevent the possibility of Wernicke's encephalopathy**.[81,82] Three randomized controlled trials suggest a benefit of vitamin B_6 in reducing nausea.[87] If symptoms persist, adding an antihistamine may be beneficial.[88] In additional to antihistamines, benzamides, phenothiazines, butyrophenones, type 3 serotonin receptor antagonists, and corticosteroids have all been used in the treatment of hyperemesis. Although anecdotally successful, the evidence of efficacy from randomized trials is inconclusive.[81,82] This is important to consider given that some of the agents can cause adverse reactions including but not limited to extrapyramidal symptoms, anxiety, and depression. Alternative therapies that have been described with variable success include acupuncture and acupressure.[81,82] Ginger has been shown in two randomized placebo-controlled trials to be effective.[89,90]

In rare instances, patients do not respond to treatment, are unable to tolerate oral intake, and are unable to maintain or continue to lose weight. These patients may benefit from enteral or parenteral nutrition although significant complications have been described with parenteral nutrition, including infection, thrombophlebitis, and death from infection or pericardial tamponade.[81] A recent study by Holmgren and colleagues[91] described maternal and neonatal outcomes from 94 patients admitted with hyperemesis gravidarum and treated with medication only as compared to nasogastric tube or peripherally inserted central catheter (PICC). They found no difference in neonatal gestational age, mean birth weight, or Apgar scores, but found an increased risk of NICU admission in the PICC line group (9.1% vs. 4.1% or 0%). Of patients managed with medication, 7% (3/42) had an adverse reaction from the medication that resolved after treatment, whereas 11% (2/19) of patients had the nasogastric tube dislodged, and 66% (21/33) of patients with a PICC line required treatment for infection, thromboembolism, or both. Based on their findings, and those of others, the authors suggested that PICC lines should be avoided.[91]

Finally, there are patients who fail treatment and opt to terminate pregnancy. The exact incidence is unknown. However, a Web-based survey of over 800 women who agreed to be part of a hyperemesis gravidarum registry noted that 15% had at least one termination and 6% had more than one termination as a direct or indirect result of severe hyperemesis gravidarum. These women felt they were too sick to care for their family or themselves or they were concerned about the potential adverse consequences of hyperemesis gravidarum on their baby. Further, these women indicated that health care providers were uncaring or did not appear to understand or acknowledge how sick they were, suggesting that further education within the medical community about the physical and psychological burden of hyperemesis gravidarum is needed.[92]

Heartburn

Heartburn is a common complaint in pregnancy because of relaxation of the esophageal sphincter. Overeating contributes to this problem. The patient should be advised to save part of her meal for later if she is experiencing postprandial heartburn and also not to eat immediately before lying down. Pillows at bedtime may help. If necessary, antacids may be prescribed. Liquid antacids coat the esophageal lining more effectively than do tablets. In a subset of patients, H-2 blockers may be helpful (see Chapter 8).

Restless Legs Syndrome

About 1 in 10 women will develop restless legs syndrome (RLS) during the second half of pregnancy. RLS usually occurs as women fall asleep and is characterized by tingling or other uncomfortable sensations in the lower legs, resulting in the overwhelming urge to move the legs. Unfortunately, movement, walking around, or other measures do

not relieve RLS. Iron deficiency anemia has been associated with an increased chance of RLS, and in anemic women, iron supplementation may reduce leg restlessness. Avoiding caffeine-containing drinks such as coffee, tea, or sodas in the last half of the day should also be recommended, as caffeine may increase symptoms.

Sciatica

Sciatica refers to nerve pain that shoots rapidly down from the buttocks and unilaterally down one leg, usually ending in the foot. True sciatica is rare in pregnancy, affecting only about 1% of pregnancies. True sciatica is caused either by a herniated disc or, less commonly, by uterine pressure on the sciatic nerve. In addition to pain, other signs of nerve compression include numbness in the affected leg. True sciatica should prompt referral to a neurologist or an orthopedic surgeon for further evaluation.

Carpal Tunnel Syndrome

The extra fluid retention of pregnancy can exacerbate carpal tunnel syndrome; higher weight gain during pregnancy is also a risk factor. The most common symptoms of carpal tunnel syndrome are pain and numbness in the thumb, index, and middle fingers and weakness in the muscle that moves the thumb. Between 25% and 50% of pregnant women will notice some symptoms of carpal tunnel syndrome. Treatment during pregnancy is usually limited to supportive measures such as nighttime splinting that may help reduce increased pressure on the nerve that occurs when the wrist is bent; about 80% of women will notice reduction in symptoms with splinting alone. Severe cases of carpal tunnel syndrome can be treated with steroid injections into the area around the carpal tunnel to reduce swelling and inflammation. After delivery, symptoms generally resolve within 4 weeks (see Chapter 46).

Hemorrhoids

Hemorrhoids are varicose veins of the rectum. Because straining during bowel movements contributes to their aggravation, avoidance of constipation is preventive, and prolonged sitting should also be avoided. Hemorrhoids will often regress after delivery but usually will not disappear completely.

Constipation

Constipation is physiologic during pregnancy with decreased bowel transit time, and the stool may be hardened. Dietary modification with increased bulk such as with fresh fruit and vegetables and plenty of water can usually help this problem. Constipation is aggravated by the addition of iron supplementation; if dietary measures are inadequate, patients may require stool softeners. Additional dietary fibers such as Metamucil (psyllium hydrophilic muciloid) or surface-active agents such as Colace (docusate) can be used, if indicated. Laxatives are rarely necessary.

Urinary Frequency and Incontinence

Often during the first 3 months of pregnancy, the growing uterus places increased pressure on the bladder. Urinary frequency usually will improve as the uterus rises out of the pelvis by the second trimester. However, as the head engages near the time of delivery, urinary frequency may return as the head presses against the bladder. About 40% to 50% of women will experience urinary incontinence during their pregnancy. The risk of incontinence of urine is highest in the third trimester. The chances of experiencing incontinence are increased in multiparous women, especially those with a history of incontinence. Incontinence during pregnancy is a risk factor for persistent incontinence. If the patient experiences pain with urination or new-onset incontinence, it is appropriate to check for infection.

Round Ligament Pain

Frequently, patients will notice sharp groin pains caused by spasm of the round ligaments associated with movement. This is more frequently felt on the right side as a result of the usual dextrorotation of the uterus. The pain may be helped by application of local heat such as with hot soaks or a heating pad. Patients may awaken at night with this pain after having suddenly rolled over in their sleep without realizing it. During the daytime, however, modification of activity with gradual rising and sitting down, as well as avoidance of sudden movement, will decrease problems with this type of pain. An elastic four-way stretch can minimize movement of the uterus. Analgesics are rarely necessary.

Syncope

Compression of the veins in the legs from the advancing size of the uterus places patients at risk of venous pooling associated with prolonged standing. This may lead to syncope. Measures to avoid this possibility include wearing support stockings and exercising the calves to increase venous return. In later pregnancy, patients may have problems with supine hypotension, a distinct problem when undergoing a medical evaluation or an ultrasound examination. A left lateral tilt position with wedging below the right hip will help keep the weight of the uterus and fetus off the inferior vena cava.

Backache

Back pain is a common complaint in pregnancy affecting over 50% of women. Numerous physiologic changes of pregnancy likely contribute to the development of back pain, including ligament laxity related to relaxin and estrogen, weight gain, hyperlordosis, and anterior tilt of the pelvis. These altered biomechanics lead to mechanical strain on the lower back. Backache can be prevented to a large degree by avoidance of excessive weight gain, and a regular exercise program before pregnancy. Exercises to strengthen back muscles can also be helpful. Posture is important, and sensible shoes, not high heels, should be worn. Scheduled rest periods with elevation of the feet to flex the hips may be helpful. Other successful treatment modalities that have been described include nonelastic maternity support binders, acupuncture, aquatic exercises, and pharmacologic regimens incorporating acetaminophen, narcotics, prednisone, and rarely antiprostaglandins (if remote from term).

Sexual Activity

No restriction need generally be placed on sexual intercourse. However, the patient should be advised that pregnancy may cause changes in comfort and sexual desire.

Frequently, increased uterine activity is noted after sexual intercourse; it is unclear whether this is due to breast stimulation, female orgasm, or prostaglandins in male ejaculate. Fox and colleagues,[93] in a survey of 425 primiparous women, reported that over 60% of women reported sexual activity in the third trimester and up to one third engaged in sexual activity within 2 days of delivery. Studies suggest that sexual activity during pregnancy is rarely discussed, although most women feel the need to receive more information.[94] For women at risk for preterm labor or with a history of previous pregnancy loss and who note increased uterine activity after sex, use of a condom or avoidance of sexual activity may be recommended.

Circumcision

Newborn circumcision is a widely practiced elective procedure with significant variation by race/ethnicity, geographic region, education level, and religious belief. Although the medical benefits have been widely debated, recent studies suggest that circumcision offers protection against urinary tract infections, some sexually transmitted diseases, HIV transmission, cervical cancer, penile cancer, and phimosis. Despite these findings, the American Academy of Pediatrics (AAP) does not recommend routine neonatal circumcision.[95] Education in good personal foreskin hygiene offers many of the advantages of circumcision without the risks.

Circumcision in the newborn is an elective procedure and should be performed only if the infant is stable and healthy. If performed, the AAP recommends a multifaceted approach to pain management in order to reduce the observed physiologic response to the newborn's pain.[95]

Breastfeeding

Breastfeeding as a public policy has been widely endorsed and supported by the Department of Health and Human Services. *Healthy People 2000 and 2010* called for 50% of mothers to breastfeed for at least 6 months. Hence, during prenatal visits, the patient should be encouraged to breastfeed her infant (see Chapter 23). Human milk is the most appropriate nutrient for human infants and also provides significant immunologic protection against infection. Infants who are breastfed have a lower incidence of infection and require fewer sick child office visits and hospitalizations than do infants who are fed formula exclusively. A myriad of other infant benefits have been reported, including but not limited to decreased incidence of sudden infant death syndrome, diabetes, otitis media, respiratory tract disease, tonsillitis, dental caries, and a host of immunologic-mediated conditions such as rheumatoid arthritis, Crohn's disease, multiple sclerosis, eczema, and allergic reactions. These benefits are greatest if the infant is exclusively breastfed for 6 months and the protection decreases in proportion to the amount of supplementation.

Maternal advantages of lactation include economy, convenience, more rapid involution of the uterus, and natural child spacing. Breastfeeding protects the mother from infections, cancer (breast, endometrial, and ovarian), osteoporosis, diabetes, and rheumatoid arthritis. The reasons a woman decides to bottle-feed should be explored, as they may be based on a misconception. For example, preterm birth and medical problems are usually not contraindications for breastfeeding. Practitioner encouragement, liberal use of lactation consultants, and spouse and peer support will sometimes convince a hesitant mother who may then be able to nurse successfully. The American Dietetic Association recommends exclusive breastfeeding for the first 6 months and breastfeeding with complementary foods for at least 12 months as the ideal feeding pattern for infants. Studies on incidence and duration of breastfeeding indicate that U.S. women fall far short of that. Based on survey data, the United States cites initiation rates ranging from 27% to 70% and only 19% to 33% of women reporting duration of breastfeeding for at least 6 months. Initiation and duration of breastfeeding are widely influenced by age, race/ethnicity, cultural, and peer influences.

Working outside the home need not be a contraindication to breastfeeding. Many women who previously would not have considered nursing an option, such as those with careers, are now finding time to breastfeed their infants. Employer-based lactation support programs have demonstrated prolonged breastfeeding duration, as well as specific employer benefits—mothers of breastfed infants were more productive at work, missed fewer days, and used fewer health care benefits because of child care issues. Women should be aware that alternative ways of breastfeeding can be used to correspond with their work schedules. They can decrease the frequency of lactation to a few times a day in most cases and still continue to nurse. Other women may pump their breasts at work, leaving milk for the child's caretaker during the day and thus providing breast milk to the infant even more frequently. The milk may be collected in containers and, if refrigerated, is safe to use for 24 hours. For a longer duration, the milk should be frozen. Because freezing and thawing destroy the cellular content, fresh milk is preferred.

There is no need for specific nipple preparation during pregnancy. In one study, women prepared one nipple and not the other with a variety of techniques, including massage and breast creams, and found no difference in the two. Soap and drying agents should not be used on the nipples, which should be washed only with water.

Preparation for Childbirth

The introduction of childbirth education and consumerism has had significant impact on the practice of obstetrics. Studies have shown that prepared childbirth education can have a beneficial effect on labor and delivery. Although the education can be transmitted by the obstetrician at the initial visit or over a series of shorter return visits, patients have come to expect more personal involvement than to be given a book or handout to read. The appropriate place for such education has evolved to be a series of planned, structured prenatal education classes taught by informed, qualified individuals. These classes can be given in the physician's office, at the hospital, or in free-standing classes. National organizations such as the Childbirth Education Association and the American Society for Psychoprophylaxis in Obstetrics have recognized the need for such instruction and teach prepared childbirth. There are also advantages to office- and hospital-based programs, if the patient volume permits it, since specifics of management and alternatives offered by that practice or

hospital can be discussed in these programs. On the other hand, free-standing classes offer the advantage of open-endedness and of presenting many options to the patient, who can then discuss them with her care provider. Group prenatal care also can apparently serve an important education function. However, attendance at traditional childbirth classes has been waning.[11,12] This has been attributed to various factors such as a growing preference for medicated birth including scheduled inductions and epidurals, increased elective cesareans, and a perception that the content and philosophy of childbirth education classes are not consistent with the changing needs of childbearing women.[11,96] Many advances in family-centered practice (e.g., allowing fathers in the delivery room and operating room) have come from consumer requests and demands. Additional research is needed to understand how clinicians and educators might help inform women and their partners in the current childbirth climate. The prenatal period should be one in which the patient is exposed to information about pregnancy, normal labor and delivery, anesthesia and analgesia, obstetrical complications, and obstetrical operations (e.g., episiotomy, cesarean delivery, and forceps or vacuum delivery). Although the physician, midwife, or childbirth educator is the ideal person to transmit this information, patients have ready access to Internet, media, and peers, all of which can propagate both information and misinformation. Of concern is that many younger women enter pregnancy believing that all technology and medical interventions increase the safety and outcome for both mother and baby.[11]

The primary purpose of childbirth education is to provide the mother with information regarding the range of interventions that could be encountered during childbirth and to empower the patient to participate in shared decision making. Late third trimester is an ideal time to obtain informed consent from the patient for her intrapartum care and management, and to discuss her concerns and preferences about childbirth. A pregnant patient often makes a list of what she would like to discuss with her practitioner in the peripartum period. Thus, the care provider can understand her needs and desires, better address these needs and desires if labor and delivery do not proceed normally or as planned, and explain why certain requests are not possible or reasonable.

Signs of Labor

It is important to instruct the patient about certain warning signs that should trigger a call to her care provider or a visit to the hospital. All women should be informed of what to do if contractions become regular, if rupture of membranes is suspected, or if vaginal bleeding occurs. Patients should be given a number to call where assistance is available 24 hours a day.

Prepared Parenthood and Support Groups

Routine classes on newborn child care and parenting should be part of the prenatal care program. Many parents are completely unprepared for the myriad of changes in their lives, and some idea of what to expect is beneficial. As pregnancy progresses, special needs can arise. Support groups for families with genetic or medical conditions such as Down syndrome, skeletal dysplasias, preterm infants, or maternal support groups for mothers of twins or triplets, and for women who have had cesarean delivery, have all shown that they can meet the special needs of these parents. Unsuccessful pregnancies lead to special problems and needs, for which social workers, clergy, and specialized support groups can be invaluable. Miscarriage, stillbirth, and infant death are particularly devastating events, best managed by a team approach, with special attention to the grieving process. Referral to such groups as Compassionate Friends of Miscarriage, Infant Death, and Stillbirth is recommended. Careful evaluation and follow-up for depression should be part of the routine pregnancy postpartum care.

Postpartum Visit

Most patients should be seen approximately 6 weeks postpartum, sooner for complicated deliveries and/or cesarean deliveries. **The goal of this visit is to evaluate the physical and psychosocial and mental well-being of the mother, provide support and referral for breastfeeding, initiate or encourage compliance with the preferred family planning option, and to initiate preconception care for the next pregnancy.** Current estimates suggest that 82% and 58.5% of commercial and Medicaid enrollees, respectively, obtain a postpartum visit. Data suggest that maternal health after pregnancy is associated with improved child health, and so increasing compliance with postpartum visits has been identified as both a national and an international public health priority.[97-99] Specific attention should be directed toward counseling about weight loss and follow-up for medical complications including heart disease, hypertension, and diabetes (conditions that may have been exacerbated by pregnancy), as well as thyroid disease and epilepsy (conditions in which medication adjustments may be required).

SUMMARY

Prenatal care is effective, if incompletely understood and studied. It provides a model for primary care services for both obstetricians/gynecologists and other primary care providers. It satisfies the Institute of Medicine criteria for primary care, as it is comprehensive and continuous, and provides coordinated services. Preconceptional care has the potential to improve pregnancy outcome if key conditions are recognized and treatment is optimal. Risk assessment, with subsequent elimination or management of risks, health education, advocacy, and disease prevention, as well as appropriate medical management of complications, remain the core of the process. Changes in number of visits and improved understanding of the successful components of prenatal care will improve services and efficiency without altering the substance of what has been developed and achieved. Prenatal care should reinforce the importance of lifelong disease surveillance and prevention, as well as active participation in personal wellness behavior for women and their families. Care providers and patients should embrace pregnancy as a teachable moment and capitalize on the potential

to directly improve the health and well-being of the mother, and indirectly improve the health and well-being of the child and family.

KEY POINTS

- Preconception and prenatal care are not only part of the pregnancy continuum that culminates in delivery, the postpartum period, and parenthood, but they should also be considered in the context of women's health throughout the life span. Importantly, this introduces the concept of interconception care—almost all health care interactions with reproductive-age women are opportunities to assess risk, promote healthy lifestyle behaviors, and identify, treat, and optimize medical and psychosocial issues that could affect pregnancy.
- Maternal mortality is the demise of any woman from any pregnancy-related cause while pregnant or within 42 days of termination of a pregnancy. The United States has not met its *Healthy People 2010* goal of 3.3 per 100,000. The current maternal mortality rate is 12.1 per 100,000 and appears to be rising, with significant ethnic disparity.
- Preconception evaluation should include rubella, hepatitis B, and HIV testing. In selected situations, screening should be extended to varicella, toxoplasmosis, tuberculosis, and hepatitis C. Further tests may be indicated depending on historical genetic risk factors identified.
- Preconception supplementation with folic acid can reduce the incidence of NTDs and other defects. All women of childbearing age should consume 0.4 mg of folic acid daily. Women who have had a child previously affected by an NTD should take 4 mg daily from 4 weeks before conception through the first 3 months of pregnancy.
- Tobacco, alcohol, recreational drugs, and even caffeine have been associated with adverse pregnancy outcomes. Women should be urged to stop smoking, avoid alcohol, and limit caffeine to 2 cups of coffee or cola drinks per day (200 mg/day)
- Accurate dating of pregnancy is essential to optimize screening and to minimize unnecessary interventions for management of postdate pregnancies. Ultrasound evaluation between 16 and 20 weeks allows accurate assessment of gestational age and survey for fetal abnormality and multiple gestation.
- A number of multiple marker tests are available for screening for aneuploidy in the first trimester and/or second trimester. Practitioners should be familiar with the various options and offer them to their patients irrespective of maternal age.
- The total weight gain recommended for healthy women is 25 to 35 lb. Underweight women may gain up to 40 lb, and overweight women should limit weight gain to 15 lb. Women should be monitored on overall weight gain and actively encouraged to return to prepregnancy weight during the postpartum period to minimize long-term risk of subsequent obesity.
- Most patients are able to maintain their normal activity levels in pregnancy. Mothers tolerate pregnancy with considerable physical activity, but heavy lifting and excessive physical activity should be avoided.
- The pregnant woman should be advised against prolonged sitting during car or airplane travel because of the risk of venous stasis and possible thromboembolism.
- Women with hyperemesis gravidarum can have transient laboratory abnormalities including suppressed TSH, elevated liver enzymes, bilirubin, amylase, lipase, and altered electrolytes. Treatment of hyperemesis gravidarum is primarily symptomatic. Recent studies suggest increased risks associated with rare cases requiring parenteral treatment.
- Prenatal care should include information on labor, delivery, possible operative procedures, obstetrical analgesia, breastfeeding, postpartum recovery, and contraception.
- For infant nutrition, "breast is best." The Department of Health and Human Services and *Healthy People 2000 and 2010* called for 50% of mothers to breastfeed for at least 6 months. Human milk is the most appropriate nutrient for human infants, providing significant immunologic protection. Infants who are breastfed have a lower incidence of infection and require fewer office visits and hospitalizations than do infants who are fed formula exclusively. Other reported infant benefits include decreased incidence of sudden infant death syndrome, diabetes, otitis media, respiratory tract disease, tonsillitis, dental caries, rheumatoid arthritis, Crohn's disease, multiple sclerosis, eczema, and allergic reactions. Maternal advantages include economy, convenience, more rapid involution of the uterus, and natural child spacing. Breastfeeding protects the mother from infections, cancer (breast, endometrial, and ovarian), osteoporosis, diabetes, and rheumatoid arthritis.
- Postpartum visits and interconception visits are valuable times for ongoing risk assessment, health promotion, and screening about factors likely to affect the health of women and their families (e.g., diet, exercise, breastfeeding, family planning, substance use, depression, violence and injury prevention). Practitioners should develop the infrastructure within their practices to provide opportunities for patient education about these issues and referral as appropriate.
- Pregnancy is a "teachable moment" (naturally occurring life transition) that motivates people to adopt risk-reducing behaviors. Health care providers should capitalize on this opportunity to educate and facilitate healthy lifestyle changes and primary prevention strategies that may benefit women and their families.

The concept of eating for two when pregnant, along with many other myths of pregnancy, has come under greater scrutiny in the past decade. This is because of the changes in population demographics, as well as alterations in women's lifestyles. In the past 50 years, the number of women of reproductive age who are overweight (body mass index [BMI] greater than 25.0 [kg/m^2] to 29.9) has remained stable at approximately 30%.[1] More concerning is the twofold increase in obesity (BMI ≥30) from 13% to 35% (Figure 7-1).[2] This increase in obesity has occurred disproportionately in minority populations such as Hispanics and African Americans.[1] The increase in obesity in the population has been ascribed to our increased consumption of non-nutritious foods and decreased physical activity. Obstetricians need to assume an important role in preventing the progression of obesity in women.

Excessive weight gain in pregnancy significantly increases the risk of postpartum weight retention[3] and contributes to the accretion of excess adipose tissue in the fetus.[4] Weight management, however, is not the only issue. The importance of specific nutrients is also a critical issue which needs to be considered during gestation, as deficiencies and/or excess of various nutrients can have both short- and long-term consequences in the mother and her fetus. In this chapter, we address the specific nutrient requirements in pregnancy, energy requirements, recommendations for weight gain, and special conditions such as bariatric surgery.

INTEGRATING NUTRITION INTO THE OBSTETRICAL HISTORY

Every woman should have the opportunity to meet with a health care provider for a prepregnancy history and physical examination that includes a nutrition assessment. The purpose of a nutrition assessment is to identify a woman's nutritional risk factors that could jeopardize her health or the health of her fetus and to determine the quality and quantity of nutrients in the mother's diet. Adequate intake of nutrients positively influences the quality of nutritional support for the developing fetus and may reduce fetal risk and improve pregnancy outcome.[5] A thorough evaluation of a woman's nutritional status before and during pregnancy encompasses medical history and weight status, dietary intake, and laboratory data. Pertinent dietary information includes appetite, meal patterns, dieting regimens, cultural or religious dietary practices, vegetarianism, food allergies, and cravings and/or aversions. Information about abnormal eating practices, such as following fad

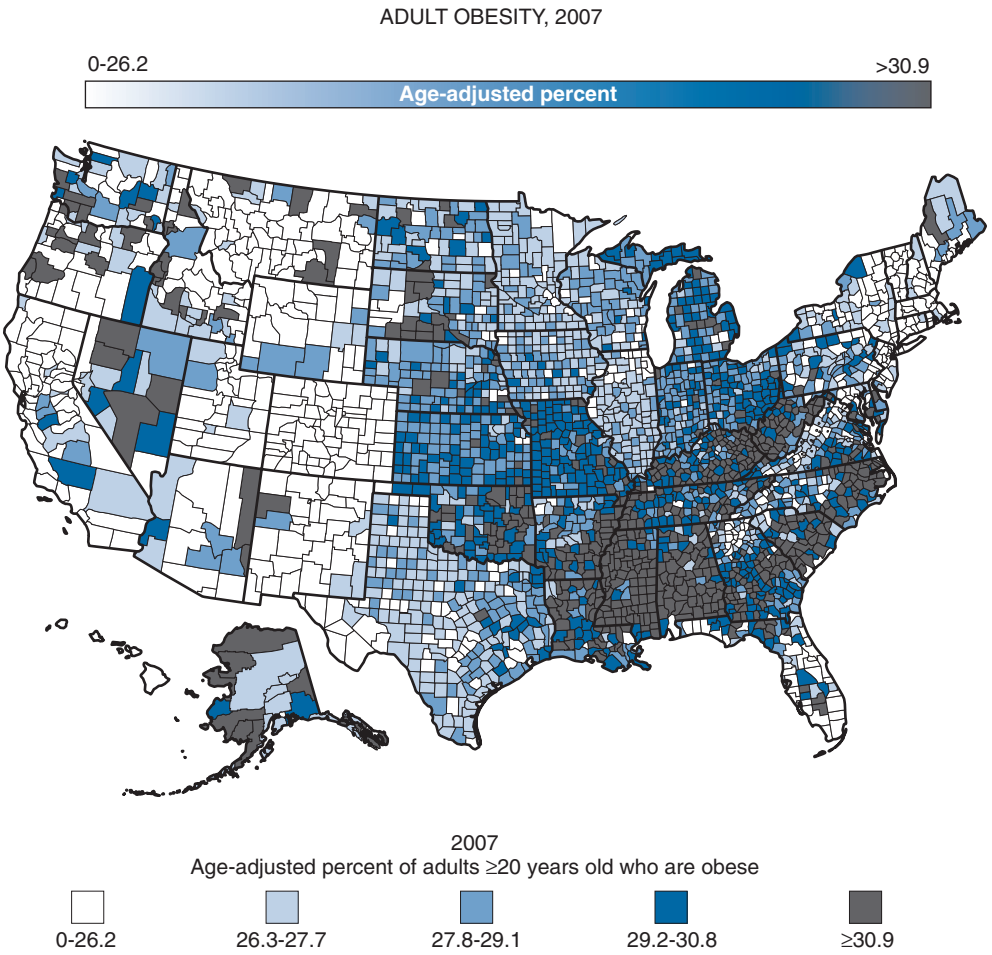

FIGURE 7-1. Adult obesity in the United States 2007, by county. (Modified from CDC Division of Diabetes Translation, National Diabetes Surveillance System. www.cdc.gov/diabetes/statistics)

diets, bingeing, purging, laxative or diuretic use, or pica (eating nonfood items, e.g., ice, detergent, starch, chalk, clay, or rocks), should be ascertained.

Other relevant information includes the habitual use of caffeine-containing beverages, tobacco, alcohol, recreational drug consumption, and any vitamin or herbal supplementation or alternative pharmacologic therapies the woman may be consuming. Dietary supplements may not be volunteered and their use may be inappropriate or dangerous during pregnancy, such as high levels of vitamin A. A woman's current dietary intake can be assessed using the 24-hour recall method, asking her to describe what she ate and drank the day before, or she could complete a diet history questionnaire.

Obtaining a history of previous weight gain patterns during pregnancy; prior history of nausea, vomiting, or hyperemesis during pregnancy; gestational diabetes; eclampsia; anemia; pica; and weight status (BMI) should be determined. The medical history also identifies maternal risk factors for nutritional deficiencies and chronic diseases with nutritional implications (e.g., absorption disorders, cystic fibrosis, eating disorders, metabolic disorders, infections, diabetes mellitus, phenylketonuria, sickle cell trait, or renal disease). Women who have had closely spaced pregnancies (i.e., less than a year between pregnancies) are at increased risk of having depleted nutrient reserves. Maternal nutrient depletion may be associated with an increased incidence of preterm birth, intrauterine growth restriction (IUGR), and maternal mortality/morbidity.

In addition to the medical history, questions regarding professional, social, economic, and emotional stresses and specific religious practices (including dietary restrictions and fasting) that may affect a woman's nutritional status should be asked. Some work environments adversely affect dietary intake, as they may not provide adequate time during the day to eat proper meals or allow access to only nutritionally marginal food. For this reason, it is important to ask pregnant woman about the conditions of their employment, and identify limitations and potential solutions. Women with lower socioeconomic status often need support to obtain nutritious food, and referral to food assistance programs may be appropriate (e.g., Women, Infants and Children Program [WIC]).

Many women are receptive to nutrition counseling just before or during pregnancy, making this an opportune time to encourage the development of good nutritional and physical activity practices aimed at preventing future medical problems such as obesity, diabetes, hypertension, and osteoporosis.[5] Pregnant women with nutritional risk factors may benefit from a referral to a registered dietitian

as shown in the accompanying box, Medical Conditions in Which Consultation with a Registered Dietitian Is Advisable.

Medical Conditions Where Consultation with a Registered Dietitian Is Advisable

- Multiple gestation (twins, triplets)
- Frequent gestations (less than a 3-month interpregnancy interval)
- Tobacco, alcohol, or chronic medicinal or illicit drug use
- Severe nausea and vomiting (hyperemesis gravidarum)
- Eating disorders (anorexia, bulimia, and compulsive eating)
- Inadequate weight gain during pregnancy
- Adolescence
- Restricted eating (vegetarianism, macrobiotic, raw food, vegan)
- Food allergies or food intolerances
- Gestational diabetes mellitus (GDM) or prior history of GDM
- Prior history of low-birth-weight babies or other obstetrical complications
- Social factors that may limit appropriate intake (e.g., religion, poverty)

MATERNAL WEIGHT GAIN RECOMMENDATIONS

In 1990 the Institute of Medicine (IOM) published weight gain recommendations during pregnancy.[6] The guidelines were first proposed to address many issues regarding the role of nutrition in pregnancy, including the prevention of small-for-gestational-age (SGA) and growth-restricted neonates. In view of the recent obesity epidemic, the IOM convened a workshop conference in 2006 to evaluate the available data and reexamine the 1990 IOM guidelines. Shortly thereafter the IOM, at the behest of various federal agencies, organized a committee to evaluate the currently available information regarding weight gain recommendations in pregnancy. These guidelines considered both the short- and long-term outcome for the pregnant woman, as well as her child. Additionally, because of the great importance of achieving appropriate pregravid weight, the 2009 guidelines recommend that women begin pregnancy at a healthy weight. Last, the guidelines call for individualized preconceptual, prenatal, and postpartum care to help women attain a healthy weight gain, within the guidelines, and return to a healthy pregravid weight after delivery. The interested reader is encouraged to access the online report at www.iom.edu/Reports/2009/Weight-Gain-During-Pregnancy-Reexamining-the-Guidelines.aspx in order to understand the complexity of these issues and ensuing recommendations.[7]

Low or Underweight Preconception BMI

The 2009 IOM guidelines use the World Health Organization (WHO) criteria established in 1995 and subsequently adopted by the National Heart, Lung and Blood Institute to characterize pregravid BMI. An underweight BMI is classified as a BMI less than 18.5 kg/m^2. Based on the available data women with low pregnancy BMI and low weight gain during pregnancy appear to be at increased risk for having a small-for-gestational-age infant (less than 10th percentile), preterm birth, and perinatal mortality.[7] In contrast, excessive weight gain in low pregravid BMI women is associated with increased risk for large-for-gestational-age neonates,[7] as well as increased maternal weight retention postpartum[3] (Figure 7-2). The recommended weight gain guidelines and rate of weight gain in the second and third trimesters are provided in Table 7-1.

Table 7-1 New Recommendations for Total and Rate of Weight Gain During Pregnancy, by Prepregnancy BMI*

Pregnancy BMI	BMI (kg/m^2)	Total Weight Gain (lb)	Rates of Weight Gain† 2nd and 3rd Trimester (lb/week)
Underweight	<18.5	28-40	1 (1-1.3)
Normal weight	18.5-24.9	25-35	1 (0.8-1)
Overweight	25.0-29.9	15-25	0.6 (0.5-0.7)
Obese (all classes)	≥30.0	11-20	0.5 (0.4-0.6)

From Rasmussin KM, Yaktin AL (eds): Weight Gain during Pregnancy: Reexamining the Guidelines. Institute of Medicine of the National Academies. Washington, DC, National Academy Press, 2009, Chapter 3, Composition and compound of gestational weight gain: physiology and metabolism, pp 77-83.
*To calculate BMI go to www.nhlbisupport/com/bmi/.
†Calculations assume a 0.5 to 2 kg (1.1 to 4.4 lb) weight gain in the first trimester (IOM, 2009).

Overweight and Obese Preconception BMI

Approximately 60% of women of reproductive age are overweight (BMI >25 kg/m^2) and of these, 50% are obese (BMI >30 kg/m^2). Additionally, 8% meet the criteria for class III obesity, or a BMI greater than 40 kg/m^2. Women who are overweight or obese generally have lower gestational weight gain as compared with a normal-weight population.[8] Data from the Centers for Disease Control and Prevention (CDC) found that 30% of obese women gained within, 46% exceeded, and 24% gained less than the 1990 IOM gestational weight gain guidelines.[6] In obese women, high gestational weight gain during pregnancy was associated with an increased risk for cesarean delivery. High gestational weight gain was also weakly associated with preterm birth, but this may have been related to a possible increased risk of hypertensive disorders such as preeclampsia; however, the evidence again was not sufficient to make definitive conclusions. There was moderate evidence for low gestational weight gain to be associated with failure to initiate breastfeeding. Weight gain in excess of 15 kg was associated with increased postpartum weight retention.[7,9]

The 2009 IOM guidelines recommend a gestational weight gain of between 11 and 20 lb. These recommendations were based primarily on Class 1 obesity. There was a paucity of data regarding the weight gain recommendations for all of the specific classes of obesity. The 11 to 20 lb gestational weight gain primarily represents the obligatory weight gain of pregnancy. This includes approximately 1.0 kg of protein, 7 to 8 kg of water, and a variable amount of adipose tissue (Table 7-2). The potential effects

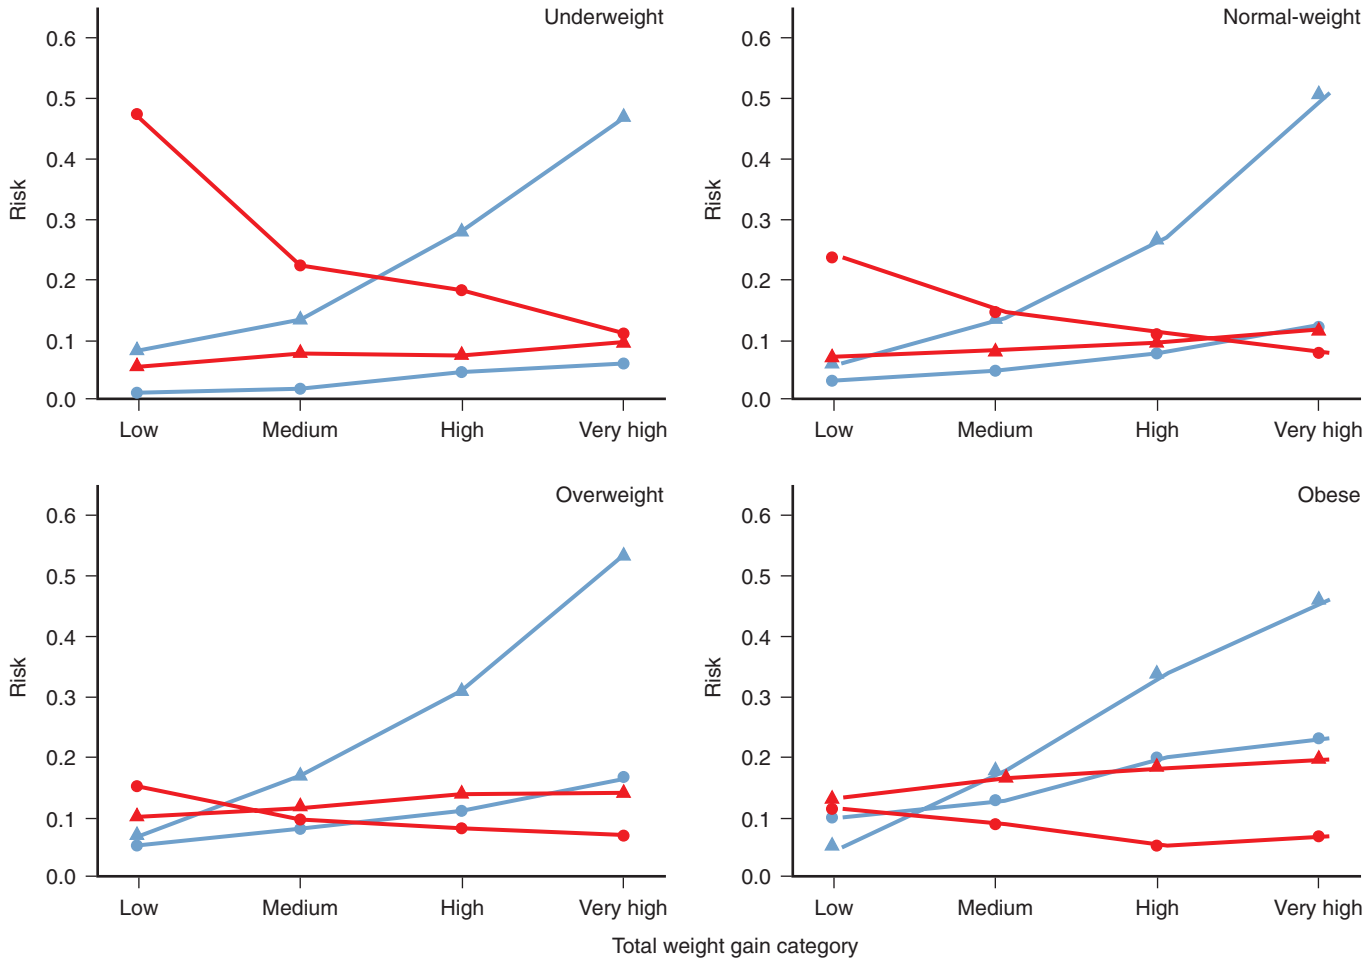

FIGURE 7-2. Adjusted absolute risks for small-for-gestational-age *(red circle),* large-for-gestational-age *(blue circle),* emergency cesarean section *(red triangle),* and postpartum weight retention of ≥5 kg *(blue triangle)* according to prepregnancy BMI (in kg/m^2) and gestational weight gain categories of the World Health Organization. of lack of gestational weight gain or weight loss during pregnancy on maternal metabolism, physiologic function, and long-term effects on the developing fetus were insufficient for the committee to make any recommendations on less gestational weight gain. Epidemiologic data suggest that less weight gain in pregnancy is associated with a decreased risk of preeclampsia.[10,11] Finally, it is recognized that a healthy pregnancy outcome is often achieved by obese women gaining less than the recommended minimal gestational weight gain. However, arbitrary minimal weight gain recommendations in obese women should not be advised. Rather, focus should be on ensuring adequate nutrient intake, avoidance of urinary ketones, and appropriate fetal growth. Further research is needed regarding these issues.

Maternal Weight Gain Recommendations for Special Populations

Multiple Gestation

There is limited evidence-based literature to make specific recommendations regarding weight gain in women who are pregnant with multiple fetuses. However, similar to what is observed in singleton pregnancies, neonatal

outcome appears to vary with gestational weight gain as a function of pregravid BMI.[7] The committee offered provisional gestational weight gain guidelines for women with twin pregnancies based on the work of Luke and others (Table 7-3).[12] These data are based on women delivering beyond 37 weeks and having fetuses greater than 2500 g. There was insufficient data to make recommendations for underweight women with twins or women carrying triplet or higher-order multiples.

Adolescents

Pregnancy in adolescents is associated with an increased risk of preterm delivery and low birth weight,[13] and hence the 1990 IOM report recommended that adolescents gain at the upper end of the gestational weight gain guidelines according to their prepregnancy BMI.[6] The rationale for these recommendations was based on the fact that these young women themselves were growing and there would be a potential competition between the mother and her fetus for nutrients. However, a study by Howie and colleagues reported that adolescents have an increased likelihood of excessive gestational weight gain compared with older women.[14] In addition, adolescents who exceeded the 1990 IOM weight gain recommendations were more likely to become obese 9 years after delivery as compared to those who gained within the guidelines.[15] Based on these data, the 2009 IOM report recommends adolescents gain within the guidelines based on their pregravid BMI.[7]

Other Groups

Based on the available evidence, there were no specific recommendations for gestational weight gain guidelines in women of short stature, various racial or ethnic groups, parity, or smoking status. The IOM report recognized that each of these special groups might possibly benefit from specific gestational weight gain guidelines, but the available evidence was again insufficient to make recommendations.[7]

LABORATORY EVALUATION OF NUTRITIONAL STATUS

The evaluation of nutritional status during pregnancy requires an understanding of the physiologic changes during pregnancy. In particular, the alterations in plasma volume in early gestation may result in hemodilution of various measures but not reflect the total body concentration. Furthermore, the effect of estrogen on hepatic production of certain proteins requires careful interpretation of plasma concentrations. Circulating concentrations of albumin are an example of the potential effects of these physiologic processes on assessment of nutrient status. Reference values for most laboratory measures in pregnancy should be assessed relative to normative pregnancy values and, if available, gestational age or trimester, and are available in a review by Abbassi-Ghanavati and colleagues.[16]

TABLE 7-3 PROVISIONAL GUIDELINES FOR WEIGHT GAIN FOR WOMEN WITH TWIN PREGNANCIES

PREPREGNANCY BMI	BMI (kg/m^2)	TOTAL WEIGHT GAIN (lb)
Normal weight	18.5-24.9	37-54
Overweight	25.0-29.9	31-50
Obese	≥30.0	25-42

From Rasmussin KM, Yaktin AL (eds): Weight Gain during Pregnancy: Reexamining the Guidelines. Institute of Medicine of the National Academies. Washington, DC, National Academy Press, 2009, Chapter 3, Composition and compound of gestational weight gain: physiology and metabolism, pp 77-83.

MATERNAL NUTRIENT NEEDS: CURRENT RECOMMENDATIONS

Energy

Energy expenditure consists of four basic components: resting metabolic rate (RMR), the thermic effect of food (TEF) or dietary-induced thermogenesis, the thermic effect of exercise (TEE), and adaptive or facultative thermogenesis. RMR is the amount of energy or calories used at rest and accounts for approximately 60% of total energy expenditure in normal healthy people. TEF is the caloric cost of eating, digesting, absorbing, resynthesizing, and storing food. The TEF accounts for 5% to 10% of total energy expenditure. TEE is quite variable and in sedentary individuals may account for only 15% to 20% of total energy expenditure. Adaptive or facultative thermogenesis refers to adaptations by an organism to adjust to environmental changes, such as overfeeding, underfeeding, and alterations in ambient temperature. Adaptive thermogenesis accounts for no more that 10% of RMR and varies in individuals (Figure 7-3).[17]

The classic teaching is that the total maternal energy requirement for a full-term pregnancy is estimated at 80,000 kilocalories (kcal). This accounts for the increased metabolic activity of the maternal and fetal tissues, as well as the growth of the fetus and placenta. Maternal energy needs to be increased to move a heavier body and thus provide extra work on the maternal cardiovascular, renal, and respiratory systems. Basal requirements can be determined based on maternal age, stature, activity level, preconception weight, BMI, and gestational weight gain goals.[18] Daily caloric requirements have been estimated by the WHO by dividing the gross energy cost (80,000 kcal) by the approximate duration of pregnancy (250 days after the first month), producing an average additional

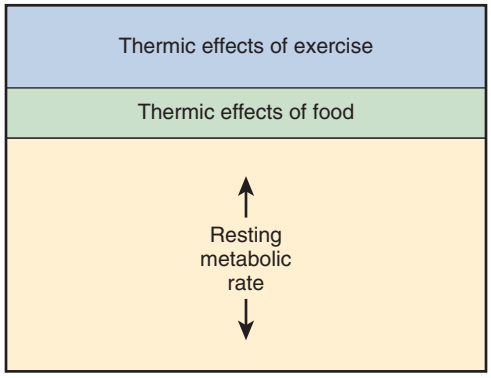

FIGURE 7-3. Components of energy expenditure. (Modified from Catalano PM, Hollenbeck C: Energy requirements in pregnancy. Obstet Gynecol Surv 47:368, 1992.)

300 kcal/day for the entire pregnancy. During the first trimester, total energy expenditure does not change greatly and weight gain is minimal assuming the woman began her pregnancy without depleted body reserves. Therefore, additional energy intake is recommended primarily in the second and third trimesters. Current recommendations are an additional 340 kcal/day above the nonpregnant energy requirements during the second trimester and 452 kcal/day during the third trimester.[19]

A series of prospective studies were conducted in the late 1980s and 1990s in various countries to assess energy expenditure in pregnancy. Many of these studies obtained baseline data before a planned pregnancy and incorporated measurements such as estimates of body composition, energy intake in the diet, RMR, standard measures of exercise, and activity diaries. The conclusion of this research was that the energy cost of pregnancy was much lower than previously estimated (Table 7-4).[20-24]

The introduction of the doubly labeled water method made it possible to estimate total energy expenditure in the free living state. In well-nourished women, RMR usually begins to rise soon after conception and continues to rise until delivery. However, there is considerable interindividual variation and cumulative increases in RMR are positively correlated with prepregnancy weight and the percent body fat.[25] In healthy well-nourished women the average increases in RMR above prepregnancy values were 4.5%, 10.8%, and 24.0% for the first, second, and third trimesters, respectively. Using a room calorimeter, 24-hour energy expenditure averaged 1%, 4%, and 20% above prepregnancy values for the first, second, and third trimesters, respectively. Estimates of total energy expenditure using doubly labeled water increased by 1%, 6%, and 9% and weight increased by 2%, 8%, and 18% over baseline measures in the first, second, and third trimesters, respectively. The TEE averaged –2%, 3%, and 6% relative to baseline. Because of the larger increments in RMR and changes in behavior, physical activity level declined from the time before conception to later in gestation.

Pregnancy also induces changes in fuel utilization. Butte and colleagues reported an increased contribution of carbohydrate to oxidative metabolism in later pregnancy.[26] Using respiratory calorimetry, the 24-hour nonprotein respiratory quotient (NPRQ) was significantly higher in late pregnancy compared with postpartum measures, such that carbohydrate oxidation as a percentage of nonprotein energy expenditure decreased from 66% to 58%. As a consequence the NPRQ was also higher during pregnancy. In summary, there is a large interindividual variability in the energy requirements of pregnancy. These are related to an individual's pregravid metabolic status, her diet, and physical activity. Therefore, these factors should be considered as well as the growth of the fetus when counseling pregnant women about their individualized dietary and nutritional needs.

TABLE 7-4 ESTIMATE OF TOTAL ENERGY EXPENDITURE DURING PREGNANCY

INVESTIGATOR	COUNTRY	CALORIC EQUIVALENTS (MEAN CALORIES)
Lawrence	Gambia	24,000 (unsupplemented) 10,000 (supplemented)
Durnin	Scotland	67,000
Van Raaij	Holland	68,300
Forsum	Sweden	50,300
Goldberg	England	variable

Data from references 20 through 24.

Protein

Additional protein is required during pregnancy for fetal, placental, and maternal tissue development. Maternal protein synthesis increases in order to support expansion of the blood volume, uterus, and breasts. Fetal and placental proteins are also synthesized from amino acids supplied by the mother. The amount of protein deposited during pregnancy for the fetus, placenta, and maternal tissues has been used to determine the increased requirements.[19] Protein retention increases fivefold from the first to the second trimester and about 80% from the second to the third trimester; a total of approximately 925 g of protein are retained during pregnancy.[19] Protein recommendations are therefore increased from 46 g/day for an adult, nonpregnant woman to 71 g/day during pregnancy.[19] This represents a change in protein recommendation from 0.8 g/kg/day for nonpregnant women to 1.1 g/kg/day during pregnancy.

Omega-3 Fatty Acids

The structural and metabolic functions of the body require utilization of polyunsaturated fatty acids (PUFAs). The human body cannot synthesize fatty acids with double bonds three (n-3) or six (n-6) from the n terminus and must be obtained from the diet as either linoleic (18:2 n-6) or alpha linolenic (18:3 n-3). The long-chain PUFA derivatives (LCPUFA) eicosapentaenoic acid (20:6 n-3, EPA) and docosahexaenoic acid (22:6 n-3, DHA) are the most important. Because n-3 PUFAs are essential fatty acids, they can only be obtained through the diet as alpha linoleic acid and converted to DHA and EPA at a rate of between 1% and 4%. The availability of the PUFA/LCPUFA to the fetus depends on maternal dietary intake, as well as placental function.

Although the U.S. expert panel recommends that pregnant women consume at least 300 mg/day of DHA, the mean intake of DHA for pregnant and lactating women was only 52 mg/day and 20 mg/day for EPA.[27] This may in part be explained by the decrease in fish consumption after the Food and Drug Administration (FDA) issued an advisory aimed at pregnant women to avoid consuming fish due to its high levels of mercury, and raw fish, which may contain food-borne illness.[28] With n-3 PUFA supplementation, there is a positive relationship between maternal intake and maternal plasma concentration,[29] as well as between maternal plasma and cord concentrations.[30] Two human studies reported increased plasma levels of DHA in maternal[31] as well as maternal/cord samples in randomized placebo-controlled trials.[32]

There are numerous studies reporting that n-3 PUFA supplementation, especially those derived from fish oils, have beneficial effects on lipid levels, cardiovascular function, and immune function. For example, in rats fed a high-sucrose diet, fish oil protects against visceral fat hypertrophy, hypertriglyceridemia, and hyperglycemia.[27]

In another rodent study, n-3 PUFAs have a protective effect against a high-fat diet inducing insulin resistance. In human studies, Meydani and colleagues reported that 2.4 g of n-3 PUFA supplementation reduced IL-6 and TNF-alpha synthesis between 30% and 58% in young women.[33] In a longitudinal observational study, intake of n-3 PUFA was associated with a reduced risk of islet cell autoimmunity in children at risk for type 1 diabetes.[34]

During pregnancy, Dunstan and colleagues reported that in a randomized controlled trial n-3 PUFA supplementation from the midtrimester resulted in a significant decrease in IL-10 and IL-13.[35,36] Dietary supplementation with n-3 PUFA has been promoted as a means to prolong gestation and prevent prematurity. However, a Maternal Fetal Medicine Network trial did not find any evidence that PUFA supplementation (fish oil) had any beneficial effect in decreasing the risk of preterm delivery in women at risk.[37] Although older trials of n-3 PUFA supplementation purported an increase in birth weight because of a prolongation of gestational age,[38] more recent trials have reported a decrease in birth weight, after adjusting for gestational age.[39,40] Similarly, Groh-Wargo and colleagues reported decreased fat but not lean body mass in infants at 1 year of age whose formulas were supplemented with n-3 PUFA.[41] In summary, although there appears to be a decrease in n-3 PUFA concentrations in pregnant women, the information available regarding the beneficial metabolic effects of supplementation in pregnancy require further evaluation in controlled trials.

VITAMIN AND MINERAL SUPPLEMENTATION GUIDELINES

Dietary Reference Intake

To address the changing nutritional needs of the American population, the Food and Nutrition Board of the IOM established the first Dietary Reference Intakes (DRIs) in 1997. The DRIs moved beyond the traditional Recommended Daily Allowances (RDAs) to focus on the prevention of chronic disease. The DRIs provide a range of safe and appropriate intakes, as well as tolerable upper limits, based on the available research. DRI is a collective term that includes four nutrient-based dietary reference values for every life-stage and gender group. These include estimated average requirement, recommended dietary allowance, adequate intake, and tolerable upper intake level. The tolerable upper intake level is the highest level of daily nutrient intake that is unlikely to pose risks of adverse health effects to the majority (97% to 98%) of individuals in a specified life-stage and gender group. At present, DRIs have been established for vitamin A, carotenoids, the B vitamins, vitamin C, vitamin D, vitamin K, folate, calcium, choline, chromium, copper, fluoride, iodine, iron, magnesium, manganese, molybdenum, phosphorus, biotin, pantothenic acid, selenium, and zinc (Table 7-5).[19,42-45] Recommendations regarding the intake of other nutrients will be available over the next decade as the scientific evidence is evaluated.

Routine vitamin/mineral supplementation for women reporting appropriate dietary intake and demonstrating adequate weight gain (without edema) is not mandatory. However, most health care providers prescribe a prenatal vitamin and mineral supplement because many women do not consume an adequate diet to meet their increased nutritional requirements during the first trimester of pregnancy, especially with regard to folic acid and iron.

Vitamins

Vitamin A

Vitamin A is a fat-soluble vitamin and refers to compounds or mixtures of compounds having vitamin A activity. In animals, vitamin A usually exists as a retinal, retinyl esters, retinol, and retinoic acid. Retinoic acid is the most active form of vitamin A. Retinol is referred to as preformed vitamin A. In plants, vitamin A exists in its precursor form, provitamin A, carotinoids (e.g., beta-carotene), and cryptoxanthin. **Vitamin A is required for cell differentiation and proliferation for the development of the vertebrae, spinal cord, limbs, heart, eyes, and ears, as well as regulation of gene expression.**

Severe vitamin A deficiency is rare in the United States and an adequate intake of vitamin A is readily available in a healthy diet. Women with lower socioeconomic status, however, may consume diets with inadequate amounts of vitamin A. Vitamin A deficiency during pregnancy weakens the immune system, increases risk of infections, and has been linked with night blindness. However, increasing dietary intake of vitamin A, rather than supplements, is advised because excess retinal intake in the first trimester is teratogenic and causes abnormalities of the cranial neural crest cells such as craniofacial and cardiac defects. The DRI for vitamin A during pregnancy is 770 mcg/day, and the tolerable upper intake has been established at 3000 mcg/day.[45] Over-the-counter multivitamin supplements may contain excessive doses of vitamin A and therefore should be discontinued during pregnancy.

Vitamin D

Vitamin D intake is essential for proper absorption of calcium and normal bone health. During pregnancy, vitamin D is also critically important for fetal growth and development, as well as regulation of genes associated with normal implantation and angiogenesis. Low maternal vitamin D status has been associated with reduced intrauterine long bone growth, shorter gestation, reduced childhood bone-mineral accrual, and decreased birth weight. Low maternal vitamin D status may also have consequences for fetal "imprinting" that may affect neurodevelopment, immune function, and chronic disease susceptibility later in life, as well as soon after birth.

Maternal vitamin D status may also be an independent risk factor for preeclampsia; supplementation may be helpful in promoting neonatal well-being and preventing preeclampsia.[46] Vitamin D deficiency is also associated with increased odds of having a primary cesarean section. One study showed that women who were severely vitamin D deficient (25[OH]D ≤37.5 nmol/L) at the time of delivery had almost four times the odds of cesarean birth compared to women who were not deficient.[47] One large study showed an inverse relationship between vitamin D supplementation and spontaneous preterm birth. Higher doses of vitamin D supplementation were associated with decrease in spontaneous preterm birth.

TABLE 7-5 DIETARY REFERENCE INTAKE (DRI): RECOMMENDED INTAKES FOR INDIVIDUALS

VITAMIN/MINERAL	AGE	NONPREGNANT	PREGNANT	UPPER INTAKE LEVELS
Vitamin A (mcg/day)	<18 y/o	700	750	2800
	19-30 y/o	700	770	3000
	31-50 y/o	700	770	3000
Vitamin C (mg/day)	<18 y/o	65	80	1800
	19-30 y/o	75	85	2000
	31-50 y/o	75	85	2000
Vitamin D (mcg/day)	<18 y/o	5	5	50

	31-50 y/o	8	11	40

ND, Not determined.
Modified from references 19 and 42-45.

The DRI for vitamin D for nonpregnant, pregnant, and, lactating women is 5 mcg/day, and the tolerable upper intake has been established at 50 mcg/day.[42] Recent studies, in the United States and other countries, have shown that low maternal vitamin D status is common during pregnancy. Lee and colleagues found that 50% of mothers and 65% of newborns were significantly vitamin D deficient at the time of birth despite mothers taking a prenatal vitamin containing 400 IU of vitamin D and drinking two glasses of vitamin D–fortified milk.[48] In addition, poor vitamin D status has been shown to be significantly more common among African American pregnant women.[49,50]

Vitamin D supplementation is advised for women who are strict vegetarians or for those who avoid sunlight or dairy foods. To evaluate vitamin D levels before and during pregnancy, check serum 25(OH)D levels and aim for vitamin D levels greater than 20 nmol/L and prescribe 1000 to 5000 mg/day of vitamin D_3 depending on the level of deficiency.

Vitamin C

Vitamin C, also known as ascorbic acid, is a water-soluble vitamin with numerous functions, including reducing free radicals and assisting in procollagen formation. Adequate vitamin C is also needed for iron uptake. Women who smoke have an increased need for vitamin C. Current recommendations indicate that pregnant women should consume 85 mg/day, rather than the 75 mg/day recommended for nonpregnant adult women, in order to protect against depleted plasma vitamin C levels and to ensure that adequate vitamin C is transported to the developing fetus. The tolerable upper intake for vitamin C has been established at 2000 mg/day. However, because vitamin C is actively transported from the maternal to the fetal circulation, and no human studies have examined the effects of large doses of vitamin C on fetal growth and development, a tolerable upper intake has been set at 1800 to 2000 mg/day.[44]

Vitamin B_6

Vitamin B_6, also known as pyridoxine, is a water-soluble B-complex vitamin required for protein, carbohydrate, and lipid metabolism. Vitamin B_6 is involved in the synthesis of heme compounds and helps form maternal and fetal red blood cells, antibodies, and neurotransmitters. Research shows that extra vitamin B_6 may be effective at relieving nausea or vomiting for some women during pregnancy.[51] The DRI during pregnancy is 1.9 mg/day. The dose commonly recommended to reduce nausea and vomiting is 10 to 25 mg, three times a day. Because excessive amounts of vitamin B_6 can cause numbness and nerve damage, the tolerable upper intake level for vitamin B_6 is set at 100 mg/day for pregnant women.[43]

Vitamin K

Vitamin K, a fat-soluble vitamin, is required for synthesis of clotting factors VII, IX, and X. Transportation of vitamin K from mother to fetus is limited; nevertheless, significant bleeding problems in the fetus are rare. **However, newborn infants are often functionally deficient in vitamin K and receive parenteral supplementation at birth.** The DRI for vitamin K is 90 mg for pregnant and nonpregnant women, and the tolerable upper intake has not been established.[45]

Folate

Folate and its metabolically active form tetrahydrofolate function as coenzymes involved in one-carbon transfer reactions that include the synthesis of nucleic acids and several amino acids. **Adequate levels of dietary folate are important during pregnancy to support rapid cell growth, replication, cell division, and nucleotide synthesis for fetal and placental development.**[52] Therefore, it is crucial that pregnant women consume adequate folate before and during the first 4 weeks of pregnancy.[43,52] The increased demand for folate during pregnancy is also needed for maternal erythropoiesis, mainly during the second and third trimesters.

Unfortunately, folate deficiency is the most prevalent vitamin deficiency during pregnancy, with well-known associations with birth defects, in particular, neural tube defects (NTDs).[53,54] Folate deficiency in humans is attributed to suboptimal dietary intake, behavioral and environmental factors, and genetic defects. Humans cannot synthesize folate from other sources and are therefore entirely dependent on dietary sources or supplements to meet their requirements. In 1992, the U.S. CDC recommended that all women of childbearing age take 400 mcg/day of supplemental folate, in order to ensure adequate folate levels are present when pregnancy occurs, whether intended or not.[55] The DRI for folate in women of childbearing age is currently 400 mcg/day, and for pregnant women is 600 mcg/day. The tolerable upper intake for folate has been established at 1000 mcg/day.[43] Additionally, evidence suggests that the long-term use of oral contraceptives inhibits folate absorption and enhances folate degradation in the liver.[56] Therefore, folate stores may be more rapidly depleted in women who have used oral contraceptives, which may lead to a higher incidence of folate deficiency in such women if they become pregnant.[43]

Folate and Neural Tube Defects

Spina bifida and anencephaly, the two most common types of NTDs, occur in approximately 3000 pregnancies each year in the United States (0.76 per 1000 births).[55] Prevalence varies according to race and ethnicity, with Hispanic women having the highest rates, while the lowest rates are found among African American and Asian women.[57] Women who have had a previous pregnancy with an NTD or who are personally affected by an NTD are at a higher risk (2% to 3%) for having an offspring with an NTD in a subsequent pregnancy. Other risk factors include a sibling with an NTD, maternal diabetes, and antiseizure medications such as valproic acid or carbamazepine. A higher risk of NTDs is also associated with increased maternal weight.[54] However, 95% of children with NTDs are born to couples without any family history of NTDs.

The etiology of NTDs has been associated with an increased folate demand during pregnancy, combined with a decreased dietary intake of folate. A genetic defect in the production of enzymes involved in folate metabolism has also been linked to NTDs.[53] The neural tube is formed very early in pregnancy, between 18 and 30 days after conception; defects in the formation of the neural tube can include

the absence of formation of most of the brain (anencephaly) and defects in the closure of the lower tube (spina bifida, meningomyeloceles). The early formation and detrimental effects of folate deficiency on neural tube formation form the basis for the recommendation that **folate supplementation should be begun before conception and continued at least through the first trimester of pregnancy.**[52]

Folate Supplementation

In women with a history of a previous pregnancy with an NTD, it has been shown that supplementation with 4000 mcg/day (4 mg/day) of folate per day, initiated 1 month before attempting to conceive and continued throughout the first trimester of pregnancy, reduced the risk of a repeat NTD by 72%.[52] Although there is not yet definitive evidence that other high-risk groups (i.e., women with diabetes, women on antiseizure medications) will benefit from higher levels of supplementation, many experts recommend a higher dose of folate, at least 1000 mcg/day, before conception and in early pregnancy.[53,55] For these women, separate folate supplementation should be prescribed; additional doses of multivitamins should not be used. Additional daily multivitamin consumption could lead to toxicity of other vitamins, particularly vitamin A, which is teratogenic to the developing fetus.[5]

Several controlled and observational trials have shown that periconceptional and early pregnancy consumption of folate supplements can reduce a woman's risk for having an infant with an NTD by as much as 50% to 70%.[53] Since the U.S. government began the Folate Fortification Program in 1998, whereby cereals, pastas, rice, and breads are fortified with folate, NTD rates have declined.[55,57] Using data from eight population-based birth-defect surveillance systems with prenatal diagnosis of NTDs, the CDC reported that the prevalence of NTDs in the United States declined by an estimated 1000 cases from 4000 cases (1995-1996) to 3000 cases (1999-2000).[58] This 26% decrease in pregnancies with NTDs highlights the success of this public health policy. A Canadian study, where the level of folate fortification is similar, showed a 46% reduction in the prevalence of NTDs.[59] The higher baseline rate of NTDs compared to the United States might explain the greater risk reduction.

Minerals

Iron

Iron is an essential component of hemoglobin production and requirements increase significantly during pregnancy. Additional iron is needed to expand maternal red cell mass by 20% to 30%, as well as for fetal and placental tissue production. Throughout pregnancy, an additional 450 mg of iron is delivered to the maternal marrow and 250 mg is lost in blood during delivery. Therefore, approximately 1000 mg is required during pregnancy and the DRI has been established at 27 g/day compared to 18 mg/day for nonpregnant women. The tolerable upper intake for iron has been established at 45 mg/day.[45] Maintaining adequate iron stores is important, but difficult for many women during pregnancy.

According to the CDC, screening for anemia should take place before pregnancy, as well as during the first, second, and third trimesters in high-risk individuals. Iron deficiency anemia increases the risk of maternal and infant death, preterm delivery, and low neonatal birth weight, and has negative consequences for normal infant brain development and function.[60] The prevalence of iron deficiency in pregnancy is higher in African American women, low-income women, teenagers, women with less than a high school education, and women with multiple parity.[61]

Table 7-6 Diagnosis of Anemia in Pregnancy

Laboratory Test	First Trimester	Second Trimester	Third Trimester
Hemoglobin (g/dL)	11	10.5	11
Hematocrit (%)	33	32	<33

From Centers for Disease Control and Prevention (www.cdc.gov).

As shown in Table 7-6, hemoglobin less than 11 g/dL or hematocrit below 33% in the first or third trimester indicates anemia. Hemoglobin less than 10.5 g/dL or hematocrit below 33% in the second trimester also indicates anemia. As the significant increase in maternal blood volume during pregnancy typically reduces hemoglobin levels, serum ferritin and mean corpuscular volume should also be used as a diagnostic criteria because these measures are not affected by the increased blood volume. Serum ferritin is also useful in the assessment of the post–gastric bypass pregnant patient. A serum ferritin level of less than 15 ng/mL warrants aggressive treatment and may require intramuscular injection rather than oral supplementation.

Prenatal care providers generally recommend iron supplementation in the form of a daily supplement of 30 mg of elemental iron in the form of simple salts, beginning around the twelfth week of pregnancy for women who have normal preconception hemoglobin measurements. For women who are pregnant with multiple fetuses or have low preconception hemoglobin measurements, a supplement of between 60 and 100 mg/day of elemental iron is recommended until hemoglobin levels are normal. Once hemoglobin levels become normal, they may decrease their supplemental iron intake to 27 mg/day. Iron supplementation can have gastrointestinal side effects specific to pregnancy, which should be taken into account when prescribing the course of treatment. During the first trimester, nausea is a common problem and can be exacerbated by oral iron supplements. Deferring supplementation until the second trimester, when iron requirements increase and nausea has waned, may be necessary. Nausea resulting from iron supplements can be minimized by taking the supplement following a meal; however, iron absorption may be inhibited if the supplement is ingested immediately following a meal. Oral iron supplements can also cause constipation, which can be effectively treated with bulk laxatives, stool softeners, and increased fiber.

Antacids impair iron absorption and should not be taken concurrently; this is of particular importance during the third trimester, when gastroesophageal reflux is common. Iron is better absorbed if the maternal diet contains adequate amounts of vitamin C. Occasionally, pregnant women develop pica, a craving for nonfood substances such as clay, dirt, or ice. Iron deficiency has been postulated to cause pica but there are also cultural beliefs that lead to these practices. Pregnant women with iron deficiency should be

questioned about pica (the ingestion of nonfood substances), and women experiencing pica should be tested for iron deficiency. Pica is mostly of concern if it prevents the mother from consuming nutrient-rich foods.[62]

Calcium

Large quantities of calcium are essential for the development of the fetal skeleton, fetal tissues, and hormonal adaptations during pregnancy. These include changes in calcium regulatory hormones affecting intestinal absorption, renal reabsorption of calcium, and bone turnover of calcium.[42] The presence of $1,25(OH)_2D_3$ stimulates increased intestinal absorption of calcium during the second and third trimesters, protecting maternal bone, while meeting fetal calcium requirements. In contrast to maternal iron and folate stores, which are relatively small and easily depleted, maternal calcium stores are large and are mostly stored skeletally, allowing for easy mobilization. Fetal calcium needs are highest during the third trimester, when the fetus absorbs an average of 300 mg/day in response to the increased maternal $1,25(OH)_2D_3$.[2] Studies suggest that inadequate calcium during pregnancy is associated with gestational hypertension, preterm delivery, and preeclampsia.[63,64]

The DRI for calcium in women 19 to 50 years old is 1000 mg/day; it is 1300 mg/day for females age 9 to 19.[42] Adolescents may need additional calcium during pregnancy since their own bones still require calcium deposition to ensure adequate bone density as an adult.[65] The tolerable upper intake for calcium during pregnancy is 2500 mg/day.[42] Obtaining adequate dietary calcium is difficult for many women before and during pregnancy and supplementations may be needed, especially for African Americans, Hispanics, and American Indians.[42] Consuming at least three servings of dairy foods every day, including calcium-fortified juices and soy beverages, can help meet these requirements.[5] Women who limit their intake of dairy foods because of lactose intolerance seem to be able to tolerate yogurt and cheese on a daily basis, but may also require a supplement. Calcium carbonate, gluconate, lactate, or citrate may provide 500 to 600 mg/day of calcium to account for the difference between the amount of calcium required and that consumed. The standard prenatal vitamin typically contains 150 to 300 mg/serving. Multivitamins marketed to the nonpregnant population generally have less than 200 mg/serving. Calcium is thought to be absorbed in doses of 600 mg at one time, making it unlikely that pregnant women would reach the tolerable upper intake level.

The data concerning the role of calcium in controlling pregnancy-induced hypertension or preeclampsia remain controversial. Although calcium supplementation has been shown to decrease blood pressure and preeclampsia in smaller studies, larger trials have failed to show an effect.[64,66] Evidence has shown that calcium supplementation reduces the risk of developing hypertension during pregnancy, but only in women who did not have adequate calcium intake before supplementation.[63,64] It is prudent to make sure women are meeting their calcium requirements for their age and to stress the importance of adequate calcium intake before and during pregnancy.

Zinc

Zinc is involved in catalytic, structural, and regulatory functions for nucleic acid and protein metabolism and requirements increase during pregnancy. More than 100 enzymes require zinc and maternal zinc deficiency can lead to prolonged labor, intrauterine growth retardation, teratogenesis, and embryonic or fetal death.[45] The DRI for pregnant women is 11 mg/day and may be higher for vegetarians or vegans because phytates from whole grains and beans bind with zinc and may reduce absorption. The tolerable upper intake for zinc has been established at 40 mg/day for both pregnant and nonpregnant women. Pregnant women eating well-balanced diets do not typically require zinc supplementation. However, if a woman is prescribed elemental iron greater than 60 mg/day, zinc supplementation is recommended, because both iron and copper compete with zinc for absorption. In addition, zinc supplementation should be combined with copper supplement to prevent deficiency.[45] Prenatal vitamin formulations vary and usually include copper and zinc.

NUTRITION-RELATED PROBLEMS IN PREGNANCY

Nausea and Vomiting

Nausea and vomiting during pregnancy commonly occurs between 5 and 18 weeks of gestation and typically improves by 16 to 18 weeks.[67] From 15% to 20% of women may experience these symptoms until the third trimester and 5% of women up until delivery.[68] Between 50% to 90% of women have some degree of nausea, with or without vomiting, but only a small percentage of these women require hospitalization for severe hyperemesis gravidarum.[69] Women with hyperemesis may vomit multiple times throughout the day, lose more than 5% of their prepregnancy body weight, and usually require hospitalization for dehydration.

The causes of pregnancy-related nausea and vomiting are unclear, but may be related to increased levels of human chorionic gonadotropin, which peaks at about 12 weeks' gestation.[68] Studies show that women are more likely to have nausea or vomiting during pregnancy if they have the following:

- Multiple gestation
- Nausea and vomiting in a previous pregnancy
- Nausea or vomiting as a side effect of taking birth control pills
- History of motion sickness
- A relative (mother or sister) who had morning sickness during pregnancy
- History of migraine headaches

Strategies for managing nausea and vomiting during pregnancy are shown in the accompanying box, Strategies for Managing Nausea, Vomiting, Heartburn, and Indigestion in Pregnancy. Vitamin B_6 supplements (10 to 25 mg three times a day) have been used to treat nausea and vomiting during pregnancy. Ginger and acupuncture may also be helpful.[70,71]

Heartburn and Indigestion

Heartburn and indigestion affects two thirds of pregnant women and is usually caused by gastric content reflux that results from both lower esophageal pressure and decreased

Strategies for Managing Nausea, Vomiting, Heartburn, and Indigestion in Pregnancy

- Eat small, low-fat meals and snacks (fruits, pretzels, crackers, nonfat yogurt).
- Eat slowly and frequently.
- Avoid strong food odors by eating room temperature or cold foods and using good ventilation while cooking.
- Drink fluids between meals, rather than with meals.
- Avoid foods that may cause stomach irritation such as spearmint, peppermint, caffeine, citrus fruits, spicy foods, high-fat foods, or tomato products.
- Wait 1 to 2 hours after eating a meal before lying down.
- Take a walk after meals.
- Wear loose-fitting clothes.
- Brush teeth after eating to prevent symptoms.

motility secondary to increased progesterone.[70] Limited gastric capacity, due to a shift of organs to accommodate the growing fetus, contributes to these symptoms in the third trimester of pregnancy. Strategies for managing heartburn or indigestion are shown in the accompanying box, Strategies for Managing Nausea, Vomiting, Heartburn, and Indigestion in Pregnancy.[59,72]

Constipation

Constipation rates during pregnancy range from 16% to 26%.[73] Fifty percent of pregnant women experience constipation at some point during their pregnancy, which is often associated with symptoms of straining, hard stools, and incomplete evacuation, rather than infrequent defecation.[73] Constipation during pregnancy is associated with an increase in water reabsorption from the large intestine, smooth muscle relaxation, and slower gastrointestinal motility. The pregnant woman often notes overall gastrointestinal discomfort, a bloated sensation, an increase in hemorrhoids and heartburn, and decreased appetite. Constipation can also be aggravated by iron supplements. Constipation management strategies are shown in the accompanying box, Strategies for Managing Constipation in Pregnancy.

Food Contamination

Pregnant women have an increased risk of developing food-borne infections secondary to the hormonal changes associated with pregnancy.[74] Pathogens that are a growing concern during pregnancy include *Listeria monocytogenes*, *Toxoplasma gondii*, *Brucella* species, *Salmonella* species, and *Campylobacter jejuni*. Many of these organisms can cross the placenta and therefore increase the fetus's risk of becoming infected.[75]

Strategies for Managing Constipation in Pregnancy

- Increase fluid intake to 2 or 3 quarts per day (water, herbal teas, noncaffeinated beverages).
- Increase daily fiber intake (high-fiber cereals, whole grains, legumes, bran).
- Use psyllium fiber supplement (Metamucil).
- Increase consumptions of fruits and vegetables (fresh, frozen, and dried).
- Participate in moderate physical activity (walking, swimming, yoga).
- Take stool softeners if prescribed iron supplements.

Listeria monocytogenes results from food poisoning during pregnancy and an estimated 14-fold increase in the incidence of listeriosis among pregnant women compared to nonpregnant women has been seen in recent years.[75] In addition, pregnant women make up an estimated 27% of all reported cases of listeriosis.[75] Listeriosis can be found in soil, ground water, plants, and animals.[76] In pregnancy, however, listeriosis can develop into a blood-borne, transplacental infection that can cause chorioamnionitis, premature labor, spontaneous abortion, or fetal demise.[77] Symptoms include fever, chills, headache, muscle and back aches, and gastrointestinal symptoms, which may appear 2 to 3 days after exposure. Blood tests can confirm the diagnosis and women should be treated with antibiotics. To avoid listeriosis, pregnant women should be advised to wash vegetables and fruits well, cook all meats, avoid processed, precooked meats (cold cuts), soft cheeses (brie, blue cheese, Camembert, and Mexican caso-blanco), and only consume pasteurized dairy products.[75] All foods should be handled in a sanitary and appropriate manner to prevent bacterial contamination.[75]

Toxoplasmosis can be passed to humans by water, dust, soil, and eating contaminated foods. Cats are the main host of *T. gondii*. Toxoplasmosis most often results from eating raw or uncooked meat, eating unwashed fruits and vegetables, cleaning the litter box, or handling contaminated soil. Most individuals will not experience any recognizable symptoms and will develop a protective resistance to the parasite. However, if a pregnant woman is exposed during the first few months of gestation, she can pass the parasite on to the fetus. This could result in stillbirth, early prenatal death, or other serious health problems.[76,78]

Salmonellosis infection results in a similar infection, and symptoms include headache, diarrhea, abdominal pain, nausea, chills, fever, and vomiting and usually appear 12 to 36 hours after contamination. *Campylobacter* can cause diarrhea accompanied by fever. These organisms thrive in reduced-oxygen environments. Fetal exposure to *Salmonella* and *Campylobacter* is associated with abortion, stillbirth, and premature labor.[75] Foods that contain these pathogens include raw unpasteurized milk, raw or undercooked meat, poultry, eggs, salads, cream deserts, filling, and untreated water. To avoid these infections, pregnant women should wash their hands often, especially after handling animals or working in the garden, and avoid undercooked food and unpasteurized juices. All surfaces that come into contact with raw meat, fish, or poultry should also be washed with hot soapy water.[75]

Food thought to be contaminated with heavy metals can also produce devastating neurotoxic and teratogenic effects on the developing fetus, which may result in miscarriage, stillbirth, premature labor, or other fetal complications.[79,80] In particular, case reports of teratogenicity or embryotoxicity have been reported with exposure to methyl mercury, lead, cadmium, nickel, and selenium.[81] Consumption of raw fish products and highly carnivorous fish (including tuna, shark, tilefish, swordfish, and mackerel) should be limited or avoided during pregnancy.[82,83] Mercury can be removed from vegetables by peeling or

washing well with soap and water. All dairy foods and juices consumed during pregnancy should be pasteurized.[80]

Pregnancy Following Bariatric Surgery

Because of the increase in obesity in women of reproductive age, obstetricians are seeing many more women who have undergone bariatric surgery. It is estimated that approximately 50,000 women of reproductive age undergo inpatient bariatric surgery per year.[84] Most likely, many more women are undergoing outpatient procedures. How many of these women then go on to become pregnant is not known.

Bariatric surgery may be considered in patients with class III obesity (BMI greater than 40 kg/m^2) or class II (BMI greater than 35 kg/m^2 with comorbid conditions and failure of nonsurgical treatment). There are two major types of bariatric surgical procedures: (1) malabsorptive procedures such as the Roux-en-Y gastric bypass and biliopancreatic diversion (BPD) and (2) restrictive procedures such as laparoscopic adjustable gastric banding (LAGB).

Complications have been associated with both types during pregnancy, including small bowel ischemia[85] and nutritional (folate, vitamin B_{12}) deficiencies.[86] There have also been reported cases of fetal anomalies, SGA neonates, and preterm births.[87,88] Scheiner and colleagues reported malabsorptive and restrictive procedures in a series of 298 pregnant patients after bariatric surgery.[89] Compared with a general population, there was a significant increase in premature rupture of the membranes, labor induction, and macrosomia. Bariatric surgery was also an independent risk factor for cesarean delivery but was not associated with adverse neonatal outcome.

There are no prospective randomized trials of pregnancy outcome in obese women treated by conventional means or bariatric surgery. However, there have been reports using the patient as her own control (i.e., a pregnancy outcome before bariatric surgery and a subsequent pregnancy outcome after having a bariatric procedure)[90-92] or retrospective case-controlled studies.[93] Three of the studies reported a decrease in weight gain during pregnancy in the women who had undergone bariatric surgery; Ducarme and colleagues (5.5 vs. 7.1 kg, $P < 0.05$),[93] Skull and colleagues (3.7 vs. 15.6 kg, $P < 0.0001$),[92] and Dixon and colleagues (9.6 vs. 14.4 kg, $P < 0.001$).[90] Gestational diabetes and hypertensive disorders were also decreased in the bariatric surgery groups. Last, the effect of bariatric surgery on the risk of fetal macrosomia and birth weight are inconclusive. Only two of the four studies reported a decreased risk of macrosomia in women after having bariatric surgery from 14.6% to 7.7% ($P < 0.05$) and 34.8% to 7.7%, respectively.[91,93] Care must be taken in the interpretation of these studies because of their retrospective nature and use of various definitions of outcome measures.

The long-term effects of biliopancreatic diversion (BPD) surgery on the offspring have been addressed in follow-up studies by Kral and colleagues.[94] After maternal bariatric surgery the prevalence of obesity in the offspring decreased by 52% and severe obesity by 45%, with no increase in underweight. The reduction in obesity in the offspring was greater in the male as compared with female offspring. A follow-up study of this same cohort assessing metabolic function was recently published by Smith and colleagues.[95] The offspring of the women who were born after their mothers had BPD had a threefold lower prevalence of severe obesity, greater insulin sensitivity, improved lipid profile, lower C-reactive protein and leptin, and increased ghrelin as compared with their siblings born before maternal BPD surgery. The authors caution in the interpretation of the results as these data do not prove causality but need to be confirmed in other populations with further understanding of potential mechanisms.

ACOG published a Committee Opinion on Obesity and Pregnancy addressing the issue of bariatric surgery and pregnancy.[96] ACOG recommends that obese women who have undergone bariatric surgery receive the following counseling before and during pregnancy:

1. Patients with adjustable gastric banding should be advised that they are at risk of becoming pregnant unexpectedly after weight loss following surgery.
2. All patients are advised to delay pregnancy for 12 to 18 months after surgery to avoid pregnancy during the rapid weight loss phase.
3. Women with gastric banding should be monitored by their general surgeons during pregnancy because adjustments of the band may be necessary.
4. Patients should be evaluated for nutritional deficiencies, including iron, vitamin B_{12}, folate, vitamin D, and calcium, and supplemented with vitamins as necessary.

KEY POINTS

- Pregnant women may need as much as an additional 300 kcal/day for the entire pregnancy, but requirements may be significantly less and vary among individuals and ethnic groups.
- The IOM recommendations for total weight gain during pregnancy are as follows: underweight (BMI <18.5; 28 to 40 lb), normal weight (BMI 18.5 to 24.9; 25 to 35 lb), overweight (BMI 25.0 to 29.9; 15 to 25 lb), and obese (BMI ≥30; 11 to 20 lb) women.
- Protein requirements during pregnancy increase from 0.8 g/kg/day for nonpregnant women to 1.1 g/kg/day during pregnancy.
- Women at high risk of a neural tube defect should be prescribed a higher dose of folate, at least 1000 mcg/day, before conception and in early pregnancy.
- Iron supplementation can have gastrointestinal side effects specific to pregnancy, which should be taken into account when prescribing treatment.
- To evaluate vitamin D levels before and during pregnancy, check serum 25(OH)D levels and aim for vitamin D levels greater than 20 nmol/L. The dietary reference intake (DRI) for vitamin D is 600 IU/day.
- The DRI for calcium in nonpregnant and pregnant women 19 to 50 years old is 1000 mg/day; it is 1300 mg/day for females age 9 to 19.
- Women who have undergone previous bariatric surgery should be evaluated for nutritional deficiencies including iron, vitamin B_{12}, folate, vitamin D, and calcium and supplemented as necessary.

KEY ABBREVIATIONS

Angiotensin-converting Enzyme	ACE
Birth Defect Surveillance Monitoring System	BDMS
Diethylstilbestrol	DES
Electroencephalogram	EEG
Fetal Alcohol Syndrome	FAS
Glucose-6-phosphate Dehydrogenase	G6PD
Neural Tube Defect	NTD
Propylthiouracil	PTU
Sudden Infant Death Syndrome	SIDS
Saturated Solution of Potassium Iodide	SSKI
Thyroid-stimulating Hormone	TSH
U.S. Food and Drug Administration	FDA
Zidovudine	ZDV

The placenta allows for the transfer of many drugs and dietary substances. Lipid-soluble compounds readily cross the placenta, and water-soluble substances pass less well the greater their molecular weight. The degree to which a drug is bound to plasma protein also influences the amount of drug that is free to cross the placenta. **Virtually all drugs cross the placenta to some degree, with the exception of large molecules such as heparin and insulin.**

Developmental defects in humans may result from genetic, environmental, or unknown causes. About 25% are unequivocally genetic in origin; drug exposure accounts for only 2% to 3% of birth defects. About 65% of defects are of unknown etiology but may be from combinations of genetic and environmental factors.

The incidence of major malformations in the general population is 2% to 3%.[1] A major malformation is defined as one that is incompatible with survival, such as anencephaly; one requiring major surgery for correction, such as cleft palate or congenital heart disease; or one producing major dysfunction, such as mental retardation. If minor malformations are also included, such as ear tags or extra digits, the rate may be as high as 7% to 10%. The risk for malformation after exposure to a drug must be compared with this background rate.

There is a marked species specificity in drug teratogenesis. For example, thalidomide was not found to be teratogenic in rats and mice but is a potent human teratogen. Thus, extrapolating from animal studies to humans is hazardous and of limited applicability clinically.

The U.S. Food and Drug Administration (FDA) lists five categories of labeling for drug use in pregnancy. The rating system weighs the degree to which available information has ruled out risk to the fetus against the drug's potential benefit to the patient. The ratings, and their interpretation, are as follows:

A. *Controlled studies show no risk.* Adequate, well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester of pregnancy.
B. *No evidence of risk in humans.* Adequate, well-controlled studies in pregnant women have not shown increased risk for fetal abnormalities despite adverse findings in animals; or in the absence of adequate human studies, animal studies show no fetal risk. The chance of fetal harm is remote but remains a possibility.
C. *Risk cannot be ruled out.* Adequate, well-controlled human studies are lacking, and animal studies have shown a risk to the fetus or are lacking as well. There is a chance of fetal harm if the drug is administered during pregnancy, but the potential benefits may outweigh the potential risk.
D. *Positive evidence of risk.* Studies in humans, or investigational or postmarketing data, have demonstrated fetal risk. Nevertheless, potential benefits from the use of the drug may outweigh the potential risk. For example, the drug may be acceptable if needed in a life-threatening situation or serious disease for which safer drugs cannot be used or are ineffective.
X. *Contraindicated in pregnancy.* Studies in animals or humans, or investigational or postmarketing reports, have demonstrated positive evidence of fetal abnormalities or risk that clearly outweighs any possible benefit to the patient.

The Teratology Society has suggested abandoning the FDA classification,[2] and 15 years later this is still being considered. The categories imply that risk increases from category A to X. However, the drugs in different categories may pose similar risks but be in different categories based on risk and benefit considerations. Second, the categories create the impression that drugs within a category present similar risks, whereas the category definition permits inclusion in the same category drugs that vary in type, degree, or extent of risk, depending on potential benefit.

The categories were designed for prescribing physicians and not to address inadvertent exposure. For example, isotretinoin (Accutane) and oral contraceptives are both category X based on lack of benefit for oral contraceptives during pregnancy, yet oral contraceptives do not have any teratogenic risk with inadvertent exposure. When counseling patients or responding to queries from physicians, we recommend using specific descriptions in teratogen information databases (Table 8-1).

The classic teratogenic period is from day 31 after the last menstrual period in a 28-day cycle to 71 days from the last period (Figure 8-1). **During this critical period, organs are forming, and teratogens may cause malformations that are usually overt at birth.** Timing of exposure is important. Administration of drugs early in the period of organogenesis affects the organs developing at that time, such as the heart or neural tube. Closer to the end of the classic teratogenic period, the ear and palate are forming and may be affected by a teratogen.

Before day 31, exposure to a teratogen produces an all-or-none effect. With exposure around conception, the conceptus usually either does not survive or survives without anomalies. Because so few cells exist in the early stages, irreparable damage to some may be lethal to the entire organism. If the organism remains viable, however, organ-specific anomalies are not manifested because either repair or replacement will occur to permit normal development. A similar insult at a later stage may produce organ-specific defects.

EMBRYOLOGY

During the first 3 days after ovulation, development takes place in the fallopian tube. At the time of fertilization, a pronuclear stage exists during which the nuclei from the egg and the sperm retain their integrity within the egg cytoplasm. After the pronuclei fuse, the fertilized egg begins a series of mitotic cell divisions (cleavage). The two-cell stage is reached about 30 hours after fertilization. With continued division, the cells develop into a solid ball of cells (morula), which reaches the endometrial cavity about 3 days after fertilization. Thereafter, a fluid-filled cavity forms within the cell mass, at which time the conceptus is called a *blastocyst.* The number of cells increases from about 12 to 32 by the end of the third day to 250 by the sixth day.

Until about 3 days after conception, any cell is totipotential, that is, capable of initiating development of any organ system. For this reason, separation of cells during this period gives rise to monozygotic twins, usually each normal. At the blastocyst stage, cells first begin to differentiate. By this stage of development, the embryo is located in the uterus, where implantation occurs 6 to 7 days after conception.

One group of cells forms the inner cell mass that will ultimately develop into the fetus. Different tissues arise from each of the three cell layers. Brain, nerves, and skin develop from the ectoderm, the lining of the digestive tract, respiratory tract, and part of the bladder, as well as the liver and pancreas from the endoderm, and connective tissue, cartilage, muscle, blood vessels, the heart, kidneys, and gonads develop from the mesoderm. The group of cells forming the periphery of the blastocyst is termed the *trophoblast.* The placenta and the fetal membranes develop from this outer cell layer.

The trophoblast continues to grow, and lacunae form within the previously solid syncytiotrophoblast. The lacunae are the precursors of the intervillous spaces of the placenta, and by 2 weeks after conception, maternal blood is found within them. Meanwhile, the cytotrophoblast is forming cell masses that become chorionic villi.

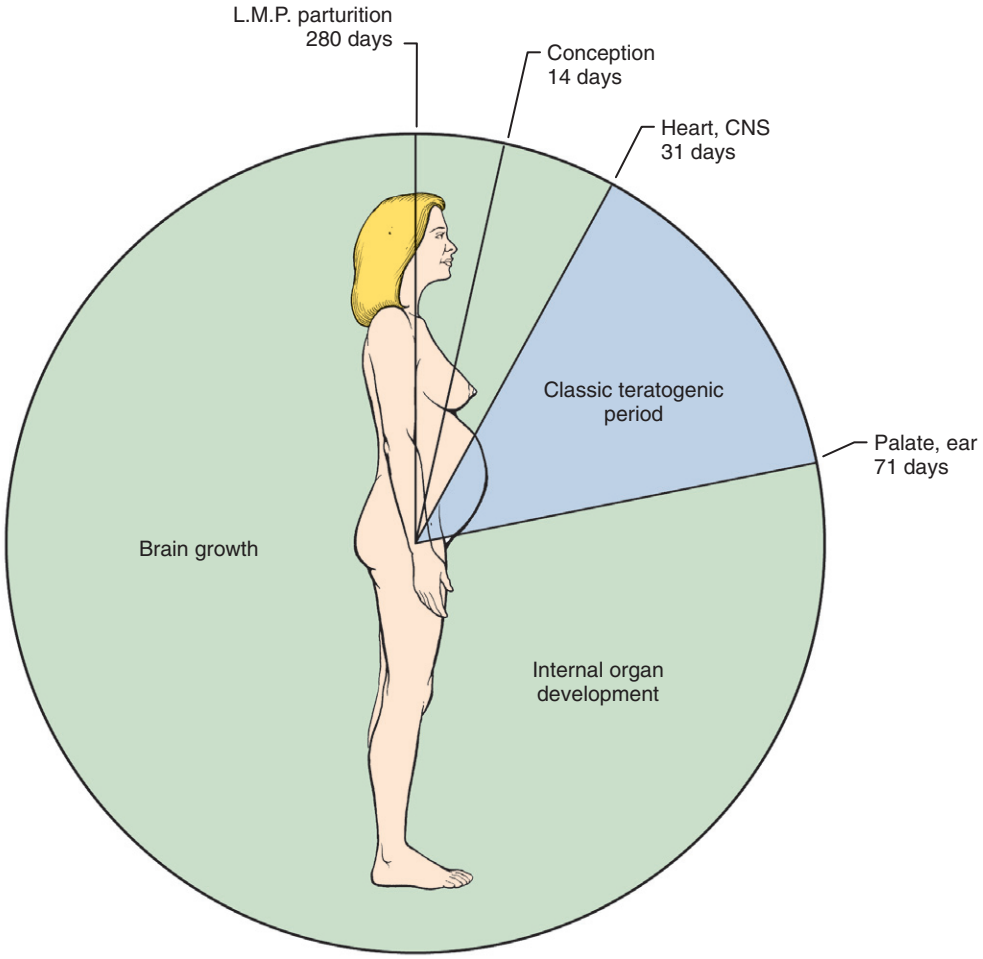

FIGURE 8-1. Gestational clock showing the classic teratogenic period. (From Blake DA, Niebyl JR: Requirements and limitations in reproductive and teratogenic risk assessment. *In* Niebyl JR [ed]: Drug Use in Pregnancy, 2nd ed. Philadelphia, Lea & Febiger, 1988, p 2.)

From the third to the eighth week after conception, the embryonic disk undergoes major developments that lay the foundation for all organ systems. By 4 weeks after conception, the fertilized ovum has progressed from one cell to millions of cells. The rudiments of all major systems have differentiated. The embryo has been transformed into a curved tube about 6 mm long and isolated from the extraembryonic membranes.

Five weeks after conception, the embryo first begins to assume features of human appearance. The face is recognizable, with the formation of discernible eyes, nose, and ears. Limbs emerge from protruding buds; digits, cartilage, and muscles develop. The cerebral hemispheres begin to fill the brain area, and the optic stalk becomes apparent. Nerve connections are established between the retina and the brain. The digestive tract rotates from its prior tubular structure, and the liver starts to produce blood cells and bile. Two tubes emerge from the pharynx to become bronchi, and the lungs have lobes and bronchioles. The heart is beating at 5 weeks and is almost completely developed by 8 weeks after conception. The diaphragm begins to divide the heart and lungs from the abdominal cavity. The kidneys approach their final form at this time. The urogenital and rectal passages separate, and germ cells migrate toward the genital ridges for future transformation into ovaries or testes. Differentiation of internal ducts begins, with persistence of either müllerian or wolffian ducts. Virilization of external genitalia occurs in male embryos. The embryo increases from about 6 to 33 mm in length and increases 50 times in weight.

Structurally, the fetus has become straighter, and the tubular neural canal along which the spinal cord develops becomes filled with nerve cells. Ears remain low on the sides of the head. Teeth are forming, and the two bony plates of the palate fuse in the midline. Disruptions during the latter part of the embryonic period lead to various forms of cleft lip and palate. **By 10 weeks after the last menstrual period, all major organ systems have become established and integrated.**

Development of other organs continues in the second and third trimesters of pregnancy. Therefore, we still need to be concerned about drug use at this time in pregnancy, although the effects may not be recognized until later in life. Some of the uterine anomalies resulting from diethylstilbestrol (DES) occurred with exposure as late as 20 weeks but were not recognized until after puberty. The brain continues to develop throughout pregnancy and the neonatal period. Fetal alcohol syndrome (FAS) may occur with chronic exposure to alcohol in the later stages of pregnancy.

BASIC PRINCIPLES OF TERATOLOGY

To understand the etiology of birth defects, it is important to enumerate the principles of abnormal development (teratogenesis). **Wilson's six general principles of teratogenesis[3] provide a framework for understanding how structural or functional teratogens may act.**

Genotype and Interaction with Environmental Factors

The first principle is that susceptibility to a teratogen depends on the *genotype of the conceptus* and on the manner in which the genotype interacts with environmental factors. This is perhaps most clearly shown by experiments in which different genetic strains of mice have varied greatly in their susceptibility to teratogens that lead to oral clefts. Some of the variability in responses to human teratogens, such as to anticonvulsant drugs like valproic acid and hydantoin, probably relates to genotype of the embryo. The increasing complexity of these potential interactions is illustrated by a series of elegant studies by Musselman and colleagues.[4]

Timing of Exposure

The second principle is that susceptibility of the conceptus to teratogenic agents varies with the developmental stage at the time of exposure. This concept of *critical stages of development* is particularly applicable to alterations in structure. **It is during the second to the eighth weeks of development after conception—the embryonic period—that most structural defects occur.** For such defects, it is believed that there is a critical stage in the developmental process, after which abnormal embryogenesis cannot be initiated. For example, neural tube defects result from the failure of the neural tube to close. Given that this process occurs between 22 and 28 days postconception, any exogenous effect on development must be present at or before this time. The neural tube has five distinct closure sites that may respond differentially to agents and may respond differently in timing. Investigations of thalidomide teratogenicity have clearly shown that the effects of the drug differ as a function of the developmental stage at which the pregnant woman took it.

Mechanisms of Teratogenesis

The third principle is that teratogenic agents act in specific ways *(mechanisms)* on developing cells and tissues in initiating abnormal embryogenesis (pathogenesis). Teratogenic mechanisms are considered separately later.

Manifestation

The fourth principle is that irrespective of the specific deleterious agent, the final manifestations of abnormal development are death, malformation, growth restriction, and functional disorder. The manifestation is thought to depend largely on the stage of development at which exposure occurs; a teratogen may have one effect if exposure occurs during embryogenesis and another if the exposure is during the fetal period. Embryonic exposure is likely to lead to structural abnormalities or embryonic death; fetal exposure is likely to lead to functional deficits or growth restriction.

Despite the importance of teratogen timing on specificity of anomalies, a general pattern usually emerges with respect to any given teratogen. This will be evident throughout this chapter as we consider various agents. If no pattern is evident for a purported teratogen, it increases the suspicion that any purported association is spurious, the observation reflecting confounding variables not recognized and, hence, not taken into account.

Agent

The fifth principle is that access of adverse environmental influences to developing tissues depends on the nature of the influence *(agent)*. This principle relates to such pharmacologic factors as maternal metabolism and placental passage. Although most clearly understood for chemical agents or drugs, the principle also applies to physical agents such as radiation or heat. For an adverse effect to occur, an agent must reach the conceptus, either transmitted indirectly through maternal tissues or directly traversing the maternal body.

Dose Effect

The final principle is that manifestations of abnormal development increase in degree from the no-effect level to the lethal level as *dosage* increases. This means that the response (e.g., malformation, growth restriction) may be expected to vary according to the dose, duration, or amount of exposure. For most human teratogens, this dose-response relationship is not clearly understood, but along with the principle of critical stages of development, these concepts are important in supporting causal inferences about human reproductive hazards. Data regarding in utero exposure to ionizing radiation clearly show the importance of dose on observed effects. The potential complexity of relationships between dose and observed effects for teratogens has been noted.

EPIDEMIOLOGIC APPROACHES TO BIRTH DEFECTS

Teratogens and reproductive toxicants have been identified and are being sought in various ways. Here we enumerate most common approaches, their strengths, and their pitfalls.

Case Reports

Many known teratogens and reproductive toxicants were identified initially through case reports of an unusual number of cases or a constellation of abnormalities. These have often come from astute clinicians, who observed something out of the ordinary. Although the importance of astute observations of abnormal aggregations of cases or patterns of malformations must be recognized, we cannot rely on such methods for identifying health hazards. Furthermore, etiologic speculations based on case reports or case series usually do not lead to a causal agent and are often false-positive speculations. **Whereas case reports may identify a new teratogen, they can never provide an estimate of the risk for disease after exposure.**

Descriptive Studies

Descriptive epidemiologic studies provide information about the distribution and frequency of some outcome of interest, resulting in rates of occurrence that can be compared among populations, places, or times. Defining the population at risk is the first step. The population at risk can be defined geographically, such as residents within a state, or medically, such as being a patient at a particular hospital. Definition of the population at risk includes the time period under consideration. The population at risk constitutes the *denominator* for calculating rates of the occurrence of outcomes of interest.

The second step in a descriptive study is to determine the *numerator* for calculating rates for comparison. This involves two important concepts: (1) case definition (what defines a case to be counted) and (2) case ascertainment (how are cases to be identified).

Relevant examples of descriptive studies are surveillance programs. An at-risk population is identified and then followed over time to detect outcomes of interest. Cases are included in the database. Surveillance programs can develop baseline data and subsequently permit early recognition of potential problems, based on ongoing data collection and analysis. **Birth defect surveillance (monitoring) systems (BDMSs) are designed to identify cases occurring in a defined population, usually by reviewing vital records or hospital record abstracts or charts.** In the past 20 years, there has been a dramatic increase in the number of state-based birth defect surveillance systems. About half the states now have some type of birth defect surveillance system. These programs conduct routine reviews of occurrence rates of specific malformations and attempt to identify increases in rates or clusters of cases.

Case-Control Studies

In a case-control study design, groups of individuals with some outcome or disease of interest (cases) (e.g., a congenital malformation) are compared with controls with regard to a history of one or more exposures. This is the most widely used approach in reproductive outcomes research. Controls are ideally as similar as possible to the cases, except of course lacking the outcome of interest. After cases and controls have been identified, the hypothesis to be tested is whether these two groups differ in exposure as well as outcome. How accurately exposure and its timing are determined may vary greatly among studies, but in any study the same methods must be used to establish the exposure of both cases and controls.

Case-control studies are advantageous in testing outcomes of infrequent occurrence. This can be conducted relatively rapidly and inexpensively. A disadvantage is the potential for several important types of bias, including bias in recalling exposure, in selecting appropriate controls, and in ascertaining cases.

These problems can be addressed in part by use of two control groups, one "normal" and the second "abnormal." Any of several abnormal controls seem equally useful, for example, infants with mendelian or chromosomal disorders as well as infants with no specific malformation.[5] In the former, mothers have incentive to recall, but teratogenesis is not the etiology. Ideally, case-control studies of potential teratogens should follow descriptive studies. After suspecting on the basis of case observations that thalidomide was teratogenic, Lenz[6] conducted a case-control study. **The association between valproic acid use and spina bifida was verified by case-control studies.**[7]

Cohort Studies

In cohort studies, groups are defined by the presence or absence of exposure to a given factor and then are followed over time and compared for rates of occurrence (i.e., incidence rates) of the outcome of interest. Cohort studies have three advantages: (1) the cohort is classified by exposure before the outcome is determined, thereby eliminating exposure recall bias; (2) incidence rates can be calculated among those exposed; and (3) multiple outcomes can be observed simultaneously.

Cohort studies, often called *prospective studies,* require that groups differing in exposure be followed through time, with outcomes observed. Therefore, these studies tend to be time consuming and expensive. In addition, occurrence rates for many adverse reproductive outcomes, such as congenital malformations, are low; thus, large samples must be followed for a considerable period of time. Two main types of cohort studies have been developed: (1) those that identify a cohort and follow it into the future (concurrent cohort study), and (2) those that identify a cohort at some time in the past and follow it to the present (nonconcurrent or historical cohort study). In both cases, risks for adverse outcomes are compared between groups. **Cohort studies enable investigators to calculate incidence rates that provide a measure of risk for an outcome after the exposure.** Risk in the exposed group can be compared with risk in an unexposed group. Most frequently, ratio of the incidence rate among the exposed to the rate among the unexposed is determined. This ratio, referred to as *relative risk*, is a measure of how much the presence of exposure increases the risk for the outcome.

In *historical prospective studies*, one begins by identifying groups that differ in terms of some past exposure and follow them to the present and determine outcomes; exposure groups are defined before outcomes are known. A major advantage is that although the time frame is prospective, investigators do not have to follow the cohort into the future, waiting for events to occur. A disadvantage is that these studies require the ability to determine exposure status retrospectively.

Clinical Trials

Ideally, analytical studies (case control or cohort) are followed by a randomized clinical trial, in which the efficiency of a prevention or treatment regimen is evaluated. That is, subjects are randomly assigned to different treatment groups. The individuals should be as similar as possible in terms of unknown factors that may affect the response before they are randomly assigned to the treatment groups and receive the different regimens.

Clinical trials of both neural tube defect (NTD) recurrence[8] and occurrence[9] have shown a protective effect of periconceptional folic acid supplementation, findings that have led to key public health recommendations regarding the use of folic acid to reduce the risk of these often devastating defects.

FIGURE 8-2. Perineum of a female fetus exposed to danazol in utero. (From Duck SC, Katayama KP: Danazol may cause female pseudohermaphroditism. Fertil Steril 35:230, 1981.)

MEDICAL DRUG USE

Patients should be educated about avenues other than the use of drugs to cope with tension, aches and pains, and viral illnesses during pregnancy. Drugs should be used only when necessary. The risk-to-benefit ratio should justify the use of a particular drug, and the minimal effective dose should be employed. Because long-term effects of drug exposure in utero may not be revealed for many years, caution with regard to the use of any drug in pregnancy is warranted. Also, some drug doses may have a significant effect on the concentrations of analytes routinely used in serum screening for aneuploidy and NTDs.[10] Methadone has been reported to increase screen positive results for trisomy 18. Screen-positive rates for NTDs were higher for those on corticosteroids, antibiotics, and antidepressants.[10]

Effects of Specific Drugs

Estrogens and Progestins

Studies have not confirmed any teratogenic risk for oral contraceptives or progestins. A meta-analysis of first-trimester sex hormone exposure revealed no association between exposure and fetal genital malformations. However, because of the medicolegal climate and the conflicting past literature, it is wise to exclude pregnancy before giving progestins to an amenorrheic patient.

Androgenic Steroids

Androgens may masculinize a developing female fetus. Danazol (Danocrine) has been reported to produce clitoral enlargement and labial fusion after being given inadvertently for the first 9 to 12 weeks after conception (Figure 8-2) in 23 of 57 female infants exposed.

Spermicides

The once-touted increased risk for abnormal offspring in mothers who had used spermicides for contraception has not been confirmed. **A meta-analysis of reports of spermicide exposure concludes that there is no increased risk for birth defects.**[11]

Anticonvulsants

Epileptic women taking anticonvulsants during pregnancy have about double the general population risk for malformations. Compared with the general risk of 2% to 3%, the risk for major malformations in epileptic women on anticonvulsants is about 5%, especially cleft lip with or without cleft palate and congenital heart disease. **Valproic acid (Depakene) and carbamazepine (Tegretol) each carry about a 1% risk for NTDs and other anomalies.** Valproic acid monotherapy significantly increases risk for spina bifida (odds ratio [OR], 12.7), atrial septal defect (2.5), cleft palate (5.2), hypospadias (4.8), polydactyly (2.2), and craniosynostosis (6.8).[12] A high daily dose or a combination of two or three drugs increases the chance of malformations.

Holmes and associates[13] screened 128,049 pregnant women at delivery to identify three groups of infants: those exposed to anticonvulsant drugs, those unexposed to anticonvulsant drugs but with a maternal history of seizures, and those unexposed to anticonvulsant drugs with no maternal history of seizures (control group). The infants were examined systematically for the presence of malformations. The combined frequency of anticonvulsant embryopathy was higher in 223 infants exposed to one anticonvulsant drug than in 508 control infants (20.6% vs. 8.5%; OR, 2.8; 95% confidence interval [CI], 1.1 to 9.7). The frequency was also higher in 93 infants exposed to two or more anticonvulsant drugs than in the controls (28.0% vs. 8.5%; OR, 4.2; 95% CI, 1.1 to 5.1). The greater the number of anticonvulsants, the higher the risk for malformation. The 98 infants whose mothers had a history of epilepsy but took no anticonvulsant drugs during the pregnancy did not have a higher frequency of abnormalities than the control infants.

Phenytoin (Dilantin) decreases folate absorption and lowers the serum folate, which has been implicated in birth defects. Therefore, folic acid supplementation should be given to these mothers, but this may require adjustment of the anticonvulsant dose. Although epileptic women were not included in the Medical Research Council study, most authorities would recommend 4 mg/day folic acid for high-risk women. One study suggested that folic acid at doses of 2.5 to 5 mg daily could reduce birth defects in women on anticonvulsant drugs.[14]

Fewer than 10% of offspring show the fetal hydantoin syndrome,[15] which consists of microcephaly, growth deficiency, developmental delays, mental retardation, and dysmorphic craniofacial features (Figure 8-3). In fact, the risk may be as low as 1% to 2% above background. Although several of these features are also found in other syndromes, such as FAS, more common in the fetal hydantoin syndrome are hypoplasia of the nails and distal phalanges (Figure 8-4) and hypertelorism. Carbamazepine (Tegretol) is also associated with an increased risk for a dysmorphic syndrome.[15] A genetically determined metabolic defect

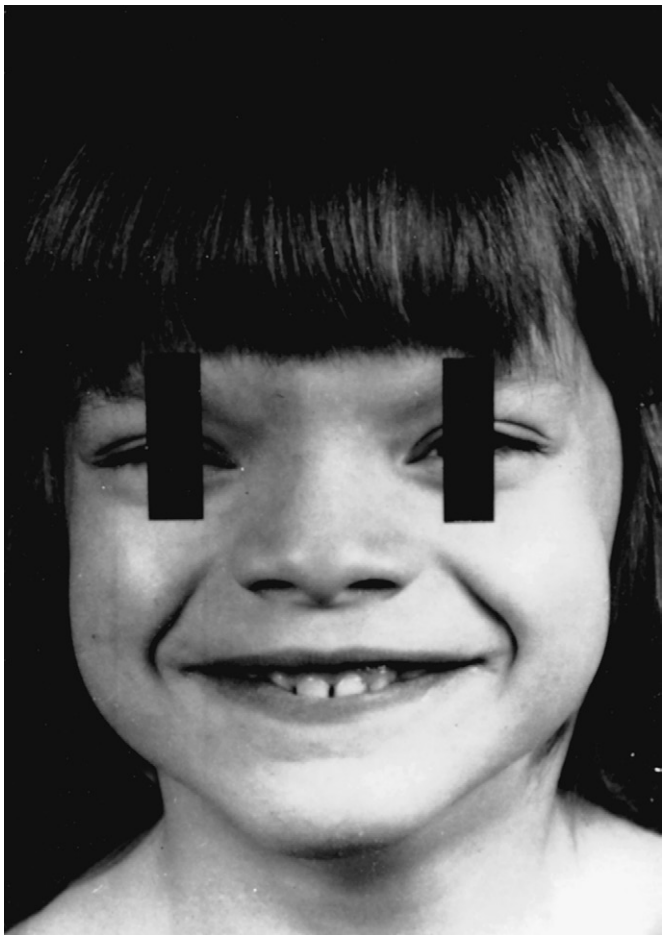

FIGURE 8-3. Facial features of the fetal hydantoin syndrome. Note broad, flat nasal ridge, epicanthic folds, mild hypertelorism, and wide mouth with prominent upper lip. (Courtesy Dr. Thaddeus Kelly, Charlottesville, VA.)

FIGURE 8-4. Hypoplasia of toenails and distal phalanges. (From Hanson JWM: Fetal hydantoin syndrome. Teratology 13:186, 1976.)

in arene oxide detoxification in the infant may increase the risk for a major birth defect. Epoxide hydrolase deficiency may indicate susceptibility to fetal hydantoin syndrome.[16]

In a follow-up study of long-term effects of antenatal exposure to phenobarbital and carbamazepine, there were no neurologic or behavioral differences between the two groups. However, children exposed in utero to phenytoin scored 10 points lower on IQ tests than children exposed to carbamazepine and nonexposed controls. At 3 years of age, children who had been exposed to valproate in utero had significantly lower IQ scores than those exposed to other antiepileptic drugs.[17] **Valproate should not be used as a first choice drug in women of reproductive age.**[17] Also, prenatal exposure to phenobarbital decreased verbal IQ scores in adult men.

Lamotrigine exposures have been compiled in a voluntary registry established by the manufacturer, GlaxoSmithKline. After 1558 exposures in the first trimester, no increased risk for birth defects overall has been observed.[18] Monitoring the risk for specific birth defects will continue. **Of 1532 infant exposures to newer-generation antiepileptic drugs, 1019 were to lamotrigine, and 3.7% had major birth defects. Of 393 infants exposed to oxcarbazepine, the rate was 2.8%, and for 108 exposed to topiramate, the rate was 4.6%. None of these differences was statistically different from controls.** Gabapentin and levetiracetam were used infrequently.

Some women may have taken anticonvulsant drugs for a long period without reevaluation of the need for continuation of the drugs. For patients with idiopathic epilepsy who have been seizure free for 2 years and who have a normal electroencephalogram (EEG), it may be safe to attempt a trial of withdrawal of the drug before pregnancy.

Most authorities agree that the benefits of anticonvulsant therapy during pregnancy outweigh the risks of discontinuation of the drug if the patient is first seen during pregnancy. The blood level of drug should be monitored to ensure a therapeutic level but minimize the dosage. If the patient has not been taking her drug regularly, a low blood level may demonstrate her lack of compliance, and she may not need the drug. Because the albumin concentration falls in pregnancy, the total amount of phenytoin measured is decreased because it is highly protein bound. However, the level of free phenytoin, which is the pharmacologically active portion, is unchanged.

Pediatric care providers need to be notified at birth when a patient has been on anticonvulsants, because this therapy can affect vitamin K–dependent clotting factors in the newborn. Some have recommended vitamin K supplementation at 10 mg daily for these mothers for the last month of pregnancy, but this is not common practice in the United States.

Isotretinoin

Isotretinoin (Accutane) is a significant human teratogen. This drug is marketed for treatment of cystic acne and unfortunately has been taken inadvertently by women who were not planning pregnancy.[19] It is labeled as contraindicated in pregnancy (FDA category X) with appropriate warnings that a negative pregnancy test is required before therapy. Of 154 exposed human pregnancies, there have been 21 reported cases of birth defects, 12 spontaneous abortions, 95 elective abortions, and 26 normal infants in women who took isotretinoin during early pregnancy. **The risk for structural anomalies in patients studied prospectively is now estimated to be about 25%. An additional 25%**

FIGURE 8-5. Infant exposed to Accutane in utero. Note high forehead, hypoplastic nasal bridge, and abnormal ears. (From Lot IT, Bocian M, Pribam HW, Leitner M: Fetal hydrocephalus and ear anomalies associated with use of isotretinoin. J Pediatr 105:598, 1984.)

have mental retardation alone. The malformed infants have a characteristic pattern of craniofacial, cardiac, thymic, and central nervous system anomalies. They include microtia/anotia (small/absent ears) (Figure 8-5), micrognathia, cleft palate, heart defects, thymic defects, retinal or optic nerve anomalies, and central nervous system malformations, including hydrocephalus.[19] Microtia is rare as an isolated anomaly yet appears commonly as part of the retinoic acid embryopathy. Cardiovascular defects include great vessel transposition and ventricular septal defects.

Unlike vitamin A, isotretinoin is not stored in tissue. Therefore, a pregnancy after discontinuation of isotretinoin is not at risk because the drug is no longer detectable in serum 5 days after its ingestion. **In 88 pregnancies prospectively ascertained after discontinuation of isotretinoin, no increased risk for anomalies was noted.** Topical tretinoin (Retin-A) has not been associated with any teratogenic risk.

Vitamin A

There is no evidence that vitamin A itself in normal doses is teratogenic, nor is β-carotene. The levels in prenatal vitamins (5000 IU/day orally) have not been associated with any documented risk. **Eighteen cases of birth defects have been reported after exposure to levels of 25,000 IU of vitamin A or greater during pregnancy.** Vitamin A in doses greater than 10,000 IU/day was shown to increase the risk for malformations in one study but not in another.

Psychoactive Drugs

There is no clear risk documented for most psychoactive drugs with respect to overt birth defects. However, effects of chronic use of these agents on the developing brain in humans is difficult to study, and so a conservative attitude is appropriate. Lack of overt defects does not exclude the possibility of behavioral teratogenesis, and neonatal withdrawal may occur.

Tranquilizers

Conflicting reports of the possible teratogenicity of the various tranquilizers, including meprobamate (Miltown) and chlordiazepoxide (Librium), have appeared, but in prospective studies, no increased risk for anomalies has been shown.

A fetal benzodiazepine syndrome has been reported in seven infants of 36 mothers who regularly took benzodiazepines during pregnancy. However, the high rate of abnormality occurred with concomitant alcohol and substance abuse and may not be caused by the benzodiazepine exposure. In most clinical situations, however, the risk-to-benefit ratio does not justify the use of benzodiazepines in pregnancy. Use of diazepam (Valium) in labor has been associated with neonatal hypotonia, hypothermia, and respiratory depression.

Lithium (Eskalith, Lithobid)

In the International Register of Lithium Babies, 217 infants were listed as exposed at least during the first trimester of pregnancy, and 25 (11.5%) were malformed. Eighteen had cardiovascular anomalies, including six cases of the rare Ebstein anomaly, which occurs in only 1 in 20,000 of the nonexposed population. Of 60 unaffected infants who were followed to age 5 years, no increased mental or physical abnormalities were noted compared with unexposed siblings.

However, two other reports suggest bias of ascertainment in the registry and a risk for anomalies much lower than previously thought. A case-control study of 59 patients with Ebstein anomaly showed no difference in the rate of lithium exposure in pregnancy from a control group of 168 children with neuroblastoma.[20] **A prospective study of 148 women exposed to lithium in the first trimester showed no difference in the incidence of major anomalies compared with controls.**[21] One fetus in the lithium-exposed group had Ebstein anomaly, and one infant in the control group

had a ventricular septal defect. The authors concluded that lithium is not a major human teratogen. **Nevertheless, we recommend that women exposed to lithium be offered ultrasound and fetal echocardiography.**

Lithium is excreted more rapidly during pregnancy; thus, serum lithium levels should be monitored. Perinatal effects of lithium have been noted, including hypotonia, lethargy, and poor feeding in the infant. Also, complications similar to those seen in adults on lithium have been noted in newborns, including goiter and hypothyroidism.

Two cases of polyhydramnios associated with maternal lithium treatment have been reported. Because nephrogenic diabetes insipidus has been reported in adults taking lithium, the presumed mechanism of this polyhydramnios is fetal diabetes insipidus. **Polyhydramnios may be a sign of fetal lithium toxicity.**

It is usually recommended that drug therapy be changed in pregnant women on lithium to avoid fetal drug exposure. Tapering over 10 days delays the risk for relapse. However, discontinuing lithium is associated with a 70% chance of relapse of the affective disorder in 1 year as opposed to 20% in those who remain on lithium. **Discontinuation of lithium may pose an unacceptable risk for increased morbidity in women who have had multiple episodes of affective instability. These women should be offered appropriate prenatal diagnosis with ultrasound, including fetal echocardiography.**

Antidepressants

Imipramine (Tofranil) was the original tricyclic antidepressant claimed to be associated with cardiovascular defects, but the number of patients studied remains small. Of 75 newborns exposed in the first trimester, six major defects were observed, three being cardiovascular, and neonatal withdrawal has been observed.

Amitriptyline (Elavil) has been more widely used, and most of the evidence supports its safety. In the Michigan Medicaid study, 467 newborns had been exposed during the first trimester, with no increased risk for birth defects.

No increased risk for major malformations has been found after first-trimester exposure to fluoxetine (Prozac) in several studies.[22] However, one recent study showed a twofold increased risk for ventricular septal defects.[23] Chambers and associates found more minor malformations and perinatal complications among infants exposed to fluoxetine throughout pregnancy, but this study is difficult to interpret because the authors did not control for depression. When a group whose mothers received tricyclic agents was used as a control for depression, infants exposed to fluoxetine in utero did not appear to have more minor malformations or perinatal complications. One study suggested an increased risk for low-birthweight infants with higher doses of fluoxetine (40 to 80 mg) throughout pregnancy.

Nulman and colleagues evaluated the neurobehavioral effects of long-term fluoxetine exposure during pregnancy and found no abnormalities among 228 children aged 16 to 86 months (average age, 3 years). Theoretically, some psychiatric or neurobehavioral abnormality might occur as a result of exposure, but it would be very difficult to ascertain because of all of the confounding variables.

Current data on other selective serotonin reuptake inhibitor (SSRI) exposures show no consistent teratogenic risk.[24] **However, two studies found an increased risk for cardiac defects after exposure to paroxetine (Paxil),[23,25] and the FDA reclassified the agent as pregnancy category D.** One study showed a twofold increased risk for neural tube defects after citalopram (Celexa).[23]

Studies have described neonatal withdrawal in the first 2 days after in utero exposure to these drugs.[26] Infants exposed during pregnancy exhibited more tremulousness and sleep changes at 1 to 2 days of age. However, no abnormalities were found when children were examined at age 16 to 86 months after prolonged exposure during pregnancy.

A sixfold increased risk for persistent pulmonary hypertension (PPH) in the newborn has been reported in infants exposed to SSRIs after 20 weeks of pregnancy,[27] raising the absolute risk from 1 to 2 per 1000 in unexposed infants to 6 to 12 per 1000 in exposed infants. Another study did not confirm this finding, but confirmed a fivefold increased risk for PPH with cesarean delivery before labor.[28]

No major malformations have occurred in 133 infants exposed to bupropion (Zyban, Wellbutrin).[29]

When considering the use of antidepressant drugs during pregnancy, it should be noted that among women who maintained their medication throughout pregnancy, 26% relapsed, compared with 68% who discontinued medication.[30] Also, fetal alcohol spectrum disorders were 10 times more common in SSRI-exposed offspring than in unexposed.[23]

Anticoagulants

Warfarin (Coumadin) has been associated with chondrodysplasia punctata, which is similar to the genetically determined Conradi-Hünermann syndrome. **Warfarin embryopathy occurs in about 5% of exposed pregnancies and includes nasal hypoplasia, bone stippling seen on radiologic examination, ophthalmologic abnormalities including bilateral optic atrophy, and mental retardation** (Figure 8-6). Ophthalmologic abnormalities and mental retardation may occur even with use only beyond the first trimester. **The risk for pregnancy complications is higher when the mean daily dose of warfarin is more than 5 mg.**

The alternative drug, heparin, does not cross the placenta because it is a large molecule with a strong negative charge. **Because heparin does not have an adverse effect on the fetus when given in pregnancy, it should be the drug of choice for patients requiring anticoagulation, except in women with artificial heart valves.[31]** However, therapy with 20,000 units/day for more than 20 weeks has been associated with bone demineralization. Thirty-six percent of patients had more than a 10% decrease from baseline bone density to postpartum values. The risk for spine fractures was 0.7% with low-dose heparin and 3% with a high-dose regimen.[32] Heparin can also cause thrombocytopenia.

Low-molecular-weight heparins may have substantial benefits over standard unfractionated heparin. The molecules are still relatively large and do not cross the placenta. The half-life is longer, allowing for once-daily administration. **However, enoxaparin (Lovenox) is cleared more rapidly during pregnancy, so twice-daily dosing is advised.**

FIGURE 8-6. Warfarin embryopathy. Note small nose with hypoplastic bridge. (From Shaul W, Hall JG: Multiple congenital anomalies associated with oral anticoagulants. Am J Obstet Gynecol 127:191, 1977.)

Low-molecular-weight heparins have a much more predictable dose-response relationship, obviating the need for monitoring of partial thromboplastin time. There is less risk for heparin-induced thrombocytopenia and clinical bleeding at delivery, but studies suggesting less risk for osteoporosis are preliminary.

Women with mechanical heart valves, especially the first-generation valves, require warfarin anticoagulation because heparin is not safe or effective.[33] Heparin treatment is associated with more thromboembolic complications and more bleeding complications than warfarin therapy.[31]

The risks of heparin during pregnancy may not be justified in patients with only a single remote episode of thrombosis in the past. Certainly, conservative measures should be recommended, such as elastic stockings and avoidance of prolonged sitting or standing.

Thyroid and Antithyroid Drugs

Propylthiouracil (PTU) and methimazole (Tapazole) both cross the placenta and may cause some degree of fetal goiter. In contrast, the thyroid hormones triiodothyronine and thyroxine cross the placenta poorly, so fetal hypothyroidism produced by antithyroid drugs cannot be corrected satisfactorily by administration of thyroid hormone to the mother. Thus, the goal of such therapy during pregnancy is to keep the mother slightly hyperthyroid to minimize fetal drug exposure. By the third trimester, 30% of women no longer need antithyroid medication.[34]

Methimazole has been associated with scalp defects in infants and choanal or esophageal atresia,[34] as well as a higher incidence of maternal side effects. However, PTU and methimazole are equally effective and safe for therapy of hyperthyroidism. **However, in 2009, the FDA released a black box warning highlighting serious liver injury with PTU treatment, to a greater extent than methimazole. Some authors are now advocating treatment with PTU only during the first trimester, and switching to methimazole for the remainder of the pregnancy.**[35]

Radioactive iodine (^{131}I or ^{125}I) administered for thyroid ablation or for diagnostic studies is not concentrated by the fetal thyroid until after 12 weeks of pregnancy. Thus, with inadvertent exposure before 12 weeks, there is no specific risk to the fetal thyroid from ^{131}I or ^{125}I administration.

The need for thyroxine increases in many women with primary hypothyroidism when they are pregnant, as reflected by an increase in serum thyroid-stimulating hormone (TSH) concentrations.[36] Because hypothyroidism in pregnancy may adversely affect the fetus, possibly by increasing prematurity,[37] it is prudent to monitor thyroid function throughout pregnancy and to adjust the thyroid dose to maintain a normal TSH level. **It is recommended that women with hypothyroidism increase their levothyroxine dose by about 30% as soon as pregnancy is confirmed (two extra doses each week) and then have dosing adjustments based on TSH levels.**[36]

Topical iodine preparations are readily absorbed through the vagina during pregnancy, and transient hypothyroidism has been demonstrated in the newborn after exposure during labor.

Digoxin (Lanoxin)

In 194 exposures, no teratogenicity of digoxin was noted. Blood levels should be monitored in pregnancy to ensure adequate therapeutic maternal levels.

Digoxin-like immunoreactive substances may be mistaken in assays for fetal concentrations of digoxin. In one study of fetuses with cardiac anomalies, there was no difference in the immunoreactive digoxin levels whether or not the mother had received digoxin. In hydropic fetuses, digoxin may not easily cross the placenta.

Antihypertensive Drugs

α-Methyldopa (Aldomet) has been widely used for the treatment of chronic hypertension in pregnancy. Although postural hypotension may occur, no unusual fetal effects have been noted. Hydralazine (Apresoline) is used frequently in pregnancy, and no teratogenic effect has been observed. (See also Chapter 35.)

Sympathetic Blocking Agents

Propranolol (Inderal) is a β-adrenergic blocking agent in widespread use for various indications. Theoretically, propranolol might increase uterine contractility. However, this has not been reported, presumably because the drug is not specific for uterine β_2-receptors. No evidence of teratogenicity has been found. Bradycardia has been reported in the newborn as a direct effect of a dose of the drug given to the mother within 2 hours of delivery.[38]

Several studies of propranolol use in pregnancy show an increased risk for intrauterine growth restriction or at least a skewing of the birthweight distribution toward the lower range. Ultrasound monitoring of exposed patients is prudent. Studies from Scotland suggest improved outcome with the use of atenolol (Tenormin) to treat chronic hypertension during pregnancy.

Calcium channel blockers (e.g., nifedipine [Procardia]) have been widely used for chronic hypertension in pregnancy, without evidence of teratogenicity. Magnesium sulfate should be used with caution in women taking these agents.

Angiotensin-Converting Enzyme Inhibitors and Angiotensin Receptor Blockers

Angiotensin-converting enzyme (ACE) inhibitors (e.g., enalapril [Vasotec], captopril [Capoten]) and angiotensin II receptor antagonists (e.g., valsartan [Diovan]) can cause fetal renal tubular dysplasia in the second and third trimesters, leading to oligohydramnios, fetal limb contractures, craniofacial deformities, and hypoplastic lung development.[39] Fetal skull ossification defects have also been described. Fetal exposure in the first trimester is also associated with an increased risk for birth defects. **For these reasons, women taking these medications who plan pregnancy should be switched to other agents.**

Antineoplastic Drugs and Immunosuppressants

Mycophenolate mofetil [CellCept] carries a moderate teratogenic risk.[40] Frequent features include microtia or anotia, cleft lip, cleft palate, heart defects, and dysmorphic facial features. The numbers are too small to determine the actual rate of malformations.

Methotrexate, a folic acid antagonist, appears to be a human teratogen, although experience is limited. Infants of three women known to receive methotrexate in the first trimester of pregnancy had multiple congenital anomalies, including cranial defects and malformed extremities. Two had Tetralogy of Fallot. Eight normal infants were delivered to seven women treated with methotrexate in combination with other agents after the first trimester. When low-dose oral methotrexate (7.5 mg/week) was used for rheumatoid disease in the first trimester, five full-term infants were normal and three patients experienced spontaneous abortions.

Azathioprine (Imuran) has been used by patients with renal transplants or systemic lupus erythematosus. The frequency of anomalies in 375 total women treated in the first trimester was not increased. Some infants had leukopenia, some were small for gestational age, and the others were normal.

No increased risk for anomalies in fetuses exposed to cyclosporine (Sandimmune) in utero has been reported. An increased rate of prematurity and growth restriction has been noted, but it is difficult to separate the contributions of the underlying disease and the drugs given to these transplant patients. The B-cell line may be depleted more than the T-cell line, and one author recommends that infants exposed to immunosuppressive agents be followed for possible immunodeficiency.

Eight malformed infants have resulted from first-trimester exposure to cyclophosphamide (Cytoxan), but these infants were also exposed to other drugs or radiation. Low birthweight may be associated with use after the first trimester, but this may also reflect the underlying medical problem.

Chloroquine (Aralen) is safe in doses used for malarial prophylaxis, and there was no increased incidence of birth defects among 169 infants exposed to 300 mg once weekly.[41] However, after exposure to larger anti-inflammatory doses (250 to 500 mg/day), two cases of cochleovestibular paresis were reported.[42] No abnormalities were noted in 114 other infants.

When cancer chemotherapy must be used during embryogenesis, there is an increased rate of spontaneous abortion and major birth defects. Later in pregnancy, there is a greater risk for stillbirth and intrauterine growth restriction, and myelosuppression is often present in the infant.

Antiasthmatics

Terbutaline (Brethine)

Terbutaline has been widely used in the treatment of preterm labor. It is more rapid in onset, has a longer duration of action than epinephrine, and is preferred for asthma in the pregnant patient. No risk for birth defects has been reported. Long-term use has been associated with an increased risk for glucose intolerance.

Cromolyn Sodium (Intal)

Cromolyn sodium may be administered in pregnancy, and the systemic absorption is minimal. Teratogenicity has not been reported in humans.

Isoproterenol (Isuprel) and Metaproterenol (Alupent)

When isoproterenol and metaproterenol are given as topical aerosols for the treatment of asthma, the total dose

absorbed is usually not significant. With oral or intravenous doses, however, the cardiovascular effects of the agents may decrease uterine blood flow. For this reason, they should be used with caution. No teratogenicity has been reported.

Corticosteroids

All steroids cross the placenta to some degree, but prednisone (Deltasone) and prednisolone are inactivated by the placenta. When prednisone or prednisolone is maternally administered, the concentration of active compound in the fetus is less than 10% of that in the mother. Therefore, these agents are the drugs of choice for treating medical diseases such as asthma. Inhaled corticosteroids are also effective therapy, and very little drug is absorbed. When steroid effects are desired in the fetus to accelerate lung maturity, betamethasone (Celestone) and dexamethasone (Decadron) are preferred because these are minimally inactivated by the placenta. **A meta-analysis of exposure to corticosteroids showed an OR of 3 for cleft lip and/or cleft palate.**[43]

Iodide

Iodide such as found in a saturated solution of potassium iodide (SSKI) expectorant crosses the placenta and may produce a fetal goiter large enough to produce respiratory obstruction in the newborn (Figure 8-7). Before a pregnant patient is advised to take a cough medicine, one should be sure to ascertain that it does not contain iodide.

Antiemetics

Remedies suggested to help nausea and vomiting in pregnancy without pharmacologic intervention include eating crackers at the bedside on first awakening in the morning (before getting out of bed), getting up very slowly, omitting iron tablets, consuming frequent small meals, and eating protein snacks at night. **None of the medications used to treat nausea and vomiting have been found to be teratogenic, except possibly methylprednisolone (Medrol) used before 10 weeks of gestation.**[44]

Vitamin B_6

Vitamin B_6 (pyridoxine), 10 to 25 mg three times a day, has been reported in two randomized placebo-controlled trials to be effective for treating the nausea and vomiting of pregnancy. In several other controlled trials, there was no evidence of teratogenicity.

Doxylamine

Doxylamine (Unisom SleepTabs) is an effective antihistamine for nausea in pregnancy and can be combined with vitamin B_6 to produce a therapy similar to the former preparation Bendectin. Vitamin B_6 (50 mg) and doxylamine (25 mg) at bedtime, and half of each tablet in the morning and afternoon, is an effective combination. The Canadian formulation Diclectin, delayed-release doxylamine 10 mg + pyridoxine 10 mg, is effective and well tolerated.[45]

Figure 8-7. Iodide-induced neonatal goiter. **A,** Appearance on the first day of life. **B,** Appearance at 2 months of age. (From Senior B, Chernoff HL: Iodide goiter in the newborn. Pediatrics 47:510, 1971.)

Meclizine (Bonine)

In one randomized, placebo-controlled study, meclizine gave significantly better results than placebo. Prospective clinical studies have provided no evidence that meclizine is teratogenic in humans. In 1014 patients in the Collaborative Perinatal Project and an additional 613 patients from the Kaiser Health Plan, no teratogenic risk was found.

Dimenhydrinate (Dramamine)

No teratogenicity has been noted with dimenhydrinate, but a 29% failure rate and a significant incidence of side effects, especially drowsiness, have been reported.

Diphenhydramine (Benadryl)

In 595 patients treated in the Collaborative Perinatal Project, no teratogenicity was noted with diphenhydramine. Drowsiness can be a problem.

Phenothiazines

Teratogenicity does not appear to be a problem with the phenothiazines when evaluated as a group. In the Kaiser Health Plan Study, 976 patients were treated, and in the Collaborative Perinatal Project, 1309 patients were treated; in both studies, no evidence of association between these drugs and malformations was noted. In 114 mothers treated with promethazine (Phenergan) and in 877 mothers given prochlorperazine (Compazine), no increased risk for malformations was found.

Metoclopramide

Of 3458 infants exposed to metoclopramide (Reglan) during the first trimester, there was no increased risk for malformations, low birthweight, or preterm delivery.[46]

Ondansetron (Zofran)

Ondansetron is no more effective than promethazine (Phenergan), but less sedating.[47] Ondansetron has not been evaluated in large numbers of patients for teratogenicity.

Methylprednisolone

Forty patients with hyperemesis who were admitted to the hospital were randomized to oral methylprednisolone or oral promethazine, and methylprednisolone was more effective.[48] In a larger study in which all patients received promethazine and metoclopramide as well, methylprednisolone did not reduce the need for rehospitalization. The drug should be used only after 10 weeks of pregnancy because of the potential risk for cleft lip and cleft palate.[43]

Ginger

Ginger has been used with success for treating hyperemesis, and nausea and vomiting in the outpatient setting. A significantly greater relief of symptoms was found after ginger treatment than with placebo. Patients took 250-mg capsules containing ginger as powdered root four times a day.

Acid-Suppressing Drugs

The use of cimetidine, omeprazole, and ranitidine has not been found to be associated with any teratogenic risk in 2261 exposures.[49] Of an additional 3651 infants exposed to proton-pump inhibitors in the first trimester, there was no increased risk for birth defects.[50] Drugs taken were mostly omeprazole but also included lansoprazole, esomeprazole, and pantoprazole.

Antihistamines and Decongestants

No increased risk for anomalies has been associated with most of the commonly used antihistamines, such as chlorpheniramine (Chlor-Trimeton). However, several reports of note are presented in the following section.

Terfenadine (Seldane) has been associated in one study with an increased risk for polydactyly. Astemizole (Hismanal) did not increase the risk for birth defects in 114 infants exposed in the first trimester.

An association between exposure to antihistamines during the last 2 weeks of pregnancy and retrolental fibroplasia in premature infants has been reported.

In the Collaborative Perinatal Project, an increased risk for birth defects was noted with phenylpropanolamine (Entex LA) exposure in the first trimester. In one retrospective study, an increased risk for gastroschisis was associated with first-trimester pseudoephedrine (Sudafed) use. Although these findings have not been confirmed, use of these drugs for trivial indications should be discouraged because long-term effects are unknown. If decongestion is necessary, topical nasal sprays will result in a lower dose to the fetus than systemic medication.

Patients should be educated that antihistamines and decongestants are only symptomatic therapy for the common cold and have no influence on the course of the disease. Other remedies should be recommended, such as use of a humidifier, rest, and fluids. If medications are necessary, combinations with two drugs should not be used if only one drug is necessary. If the diagnosis is truly an allergy, an antihistamine alone will suffice.

Antibiotics and Anti-infective Agents

Because pregnant patients are particularly susceptible to vaginal yeast infections, antibiotics should be used only when clearly indicated. Therapy with antifungal agents may be necessary during or after the course of therapy.

Penicillins

Penicillin, ampicillin, and amoxicillin (Amoxil) are safe in pregnancy. In the Collaborative Perinatal Project, 3546 mothers took penicillin derivatives in the first trimester of pregnancy, with no increased risk for anomalies. Of 86 infants exposed to dicloxacillin in the first trimester, there was no increase in birth defects.

Clavulanate is added to penicillin derivatives to broaden their antibacterial spectrum. Of 556 infants exposed in the first trimester, no increased risk for birth defects was observed. Amoxicillin-clavulanate (Augmentin) was studied in randomized controlled trials as potential therapy for chorioamnionitis in women with preterm premature rupture of membranes.[51] During this trial, amoxicillin-clavulanate was compared with both placebo and erythromycin. An increased incidence of necrotizing enterocolitis was found in the amoxicillin-clavulanate group compared with both the placebo and erythromycin groups. It has been suggested that amoxicillin-clavulanate selects for specific pathogens, which leads to abnormal microbial colonization of the gastrointestinal tract and

ultimately initiation of necrotizing enterocolitis. **Therefore, amoxicillin-clavulanate should be avoided in women at risk for preterm delivery.**[52]

Cephalosporins

In a study of 5000 Michigan Medicaid recipients, there was a suggestion of possible teratogenicity (25% increased birth defects) with cefaclor, cephalexin, and cephradine, but not other cephalosporins. However, another study of 308 women exposed in the first trimester showed no increase in malformations. The consensus is that these drugs are safe.

Sulfonamides

Among 1455 human infants exposed to sulfonamides during the first trimester, no teratogenic effects were noted. However, the administration of sulfonamides should be avoided in women deficient in glucose-6-phosphate dehydrogenase (G6PD) because dose-related hemolysis may occur.

Sulfonamides cause no known damage to the fetus in utero because the fetus can clear free bilirubin through the placenta. These drugs might theoretically have deleterious effects if they are present in the blood of the neonate after birth, however. Sulfonamides compete with bilirubin for binding sites on albumin, thus raising the levels of free bilirubin in the serum and increasing the risk for hyperbilirubinemia in the neonate.[53] Although this toxicity occurs with direct administration to the neonate, kernicterus in the newborn following in utero exposure has not been reported.

Sulfamethoxazole with Trimethoprim (Bactrim, Septra)

Trimethoprim is often given with sulfa to treat urinary tract infections. However, one unpublished study of 2296 Michigan Medicaid recipients suggested an increased risk for cardiovascular defects after exposure in the first trimester. **In one retrospective study of trimethoprim with sulfamethoxazole, the OR for birth defects was 2.3, whereas in another study, it was 2.5 to 3.4.**[54]

Nitrofurantoin (Macrodantin)

Nitrofurantoin is used in the treatment of acute uncomplicated lower urinary tract infections as well as for long-term suppression in patients with chronic bacteriuria. Nitrofurantoin is capable of inducing hemolytic anemia in patients deficient in G6PD. However, hemolytic anemia in the newborn as a result of in utero exposure to nitrofurantoin has not been reported.

No reports have associated nitrofurantoins with congenital defects. In the Collaborative Perinatal Project, 590 infants were exposed, 83 in the first trimester, with no increased risk for adverse effects. Other studies have confirmed these findings.

Tetracyclines

Tetracyclines readily cross the placenta and are firmly bound by chelation to calcium in developing bone and tooth structures. This produces brown discoloration of the deciduous teeth, hypoplasia of the enamel, and inhibition of bone growth.[55] **The staining of the teeth takes place in the second or third trimesters of pregnancy, whereas bone incorporation can occur earlier.** Depression of skeletal growth was particularly common among premature infants treated with tetracycline. First-trimester exposure to doxycycline is not known to carry any risk. **First-trimester exposure to tetracyclines has not been found to have any teratogenic risk in 341 women in the Collaborative Perinatal Project or in 174 women in another study. Alternative antibiotics are currently recommended during pregnancy.**

Aminoglycosides

Streptomycin and kanamycin have been associated with congenital deafness in the offspring of mothers who took these drugs during pregnancy. Ototoxicity was reported with doses as low as 1 g of streptomycin twice a week for 8 weeks during the first trimester. Of 391 mothers who had received 50 mg/kg of kanamycin for prolonged periods during pregnancy, nine children (2.3%) were found to have hearing loss.

Nephrotoxicity may be greater when aminoglycosides are combined with cephalosporins. Neuromuscular blockade may be potentiated by the combined use of aminoglycosides and curariform drugs. Potentiation of magnesium sulfate–induced neuromuscular weakness has also been reported in a neonate exposed to magnesium sulfate and gentamicin. Gentamicin has not been as well studied as the other aminoglycosides.

No known teratogenic effect other than ototoxicity has been associated with aminoglycosides in the first trimester. In 135 infants exposed to streptomycin in the Collaborative Perinatal Project, no teratogenic effects were observed. Among 1619 newborns whose mothers were treated for tuberculosis with multiple drugs, including streptomycin, the incidence of congenital defects was the same as in a healthy control group.

Antituberculosis Drugs

There is no evidence of any teratogenic effect of isoniazid, para-aminosalicylic acid, rifampin (Rifadin), or ethambutol (Myambutol).

Erythromycin

No teratogenic risk for erythromycin has been reported. In 79 patients in the Collaborative Perinatal Project and 260 in another study, no increase in birth defects was noted.

Clarithromycin

Of 122 first-trimester exposures, there was no significant risk for birth defects.

Fluoroquinolones

The quinolones (e.g., ciprofloxacin [Cipro], norfloxacin [Noroxin]) have a high affinity for bone tissue and cartilage and may cause arthralgia in children. However, no malformations or musculoskeletal problems were noted in 38 infants exposed in utero in the first trimester, in 132 newborns exposed in the first trimester in the Michigan Medicaid data, or in 200 other first-trimester exposures.

Metronidazole (Flagyl)

Studies have failed to show any increase in the incidence of congenital defects among the newborns of mothers treated with metronidazole during early or late gestation. Among

1387 prescriptions filled, no increase in birth defects could be determined. A meta-analysis confirmed lack of teratogenic risk.[56]

Antiviral Agents

The Acyclovir Registry has recorded 756 first-trimester exposures, with no increased risk for abnormalities in the infants.[57] Among 1561 pregnancies exposed to acyclovir, 229 exposed to valacyclovir, and 26 exposed to famciclovir, all in the first trimester, there was no increased risk for birth defects.[58] The Centers for Disease Control and Prevention recommend that pregnant women with disseminated infection (e.g., herpetic encephalitis or hepatitis or varicella pneumonia) be treated with acyclovir.

Lindane (Kwell)

After application of lindane to the skin, about 10% of the dose used can be recovered in the urine. Toxicity in humans after use of topical 1% lindane has been observed almost exclusively after misuse and overexposure to the agent. Although no evidence of specific fetal damage is attributable to lindane, the agent is a potent neurotoxin, and its use during pregnancy should be limited. Pregnant women should be cautioned about shampooing their children's hair because absorption could easily occur across the skin of the hands. An alternative drug for lice is usually recommended, such as pyrethrins with piperonyl butoxide (RID).

Antiretroviral Agents

Zidovudine (ZDV) should be included as a component in the antiretroviral regimen whenever possible because of its record of safety and efficacy. In a prospective cohort study, children exposed to ZDV in the perinatal period through Pediatric AIDS Clinical Trials Group Protocol 076 were studied up to a median age of 4.2 years. No adverse effects were observed in these children. The International Antiretroviral Registry was established in 1989 to detect any major teratogenic effect of the antiretroviral drugs. Through January 2004, more than 1000 pregnancies had first-trimester exposures to ZDV and lamivudine, and no teratogenicity was reported.

Concerns have been raised regarding use of other antiretroviral therapies. Efavirenz is not recommended during pregnancy due to reports of significant malformations in monkeys receiving efavirenz during the first trimester and also three case reports of fetal NTDs in women who received the drug.[59] In 2001, Bristol-Myers Squibb issued a warning advising against the use of didanosine and stavudine in pregnant women due to case reports of lactic acidosis, some of which were fatal. These two drugs should only be used if no other alternatives are available.

Antifungal Agents

Nystatin (Mycostatin) is poorly absorbed from intact skin and mucous membranes, and topical use has not been associated with teratogenesis. Clotrimazole (Lotrimin) or miconazole (Monistat) in pregnancy is not known to be associated with congenital malformations. However, in one study, a statistically significantly increased risk for first-trimester abortion was noted after use of these drugs, but these findings were considered not to be definitive evidence of risk. Of 2092 newborns exposed in the first trimester in the Michigan Medicaid data, there was no increased risk for anomalies.

Limb deformities were reported in three infants exposed to 400 to 800 mg/day of fluconazole in the first trimester. However, in systematic studies of 460 patients who received a single 150-mg dose of fluconazole, no increased risk for defects was observed.[60]

Drugs for Induction of Ovulation

In more than 2000 exposures, no evidence of teratogenic risk of clomiphene (Clomid) has been noted, and the percentage of spontaneous abortions is close to the expected rate. Although infants are often exposed to bromocriptine (Parlodel) in early pregnancy, no teratogenic effects have been observed in more than 1400 pregnancies.

Mild Analgesics

Some pains during pregnancy justify the use of a mild analgesic. Pregnant patients should be encouraged to use nonpharmacologic remedies, such as local heat and rest.

Aspirin

There is no evidence of any teratogenic effect of aspirin taken in the first trimester. **Aspirin does have significant perinatal effects, however, because it inhibits prostaglandin synthesis. Uterine contractility is decreased, and patients taking aspirin in analgesic doses have delayed onset of labor, longer duration of labor, and an increased risk for a prolonged pregnancy.**

Aspirin also decreases platelet aggregation, which can increase the risk for bleeding before as well as at delivery. Platelet dysfunction has been described in newborns within 5 days of ingestion of aspirin by the mother. Because aspirin causes permanent inhibition of prostaglandin synthetase in platelets, the only way for adequate clotting to occur is for more platelets to be produced.

Multiple organs may be affected by chronic aspirin use. Of note, prostaglandins mediate the neonatal closure of the ductus arteriosus. In one case report, maternal ingestion of aspirin close to the time of delivery was related to closure of the ductus arteriosus in utero.

Acetaminophen (Tylenol, Datril)

Acetaminophen has also shown no evidence of teratogenicity.[61] With acetaminophen, inhibition of prostaglandin synthesis is reversible; thus, once the drug has cleared, platelet aggregation returns to normal. **Bleeding time is not prolonged with acetaminophen in contrast to aspirin,** and the drug is not toxic to the newborn. Thus, if a mild analgesic or antipyretic is indicated, acetaminophen is preferred over aspirin.

Other Nonsteroidal Anti-inflammatory Agents

No evidence of teratogenicity has been reported for other nonsteroidal anti-inflammatory drugs (e.g., ibuprofen [Motrin,Advil], naproxen [Naprosyn]), but limited information is available. Chronic use may lead to oligohydramnios, and constriction of the fetal ductus arteriosus or neonatal pulmonary hypertension as has been reported with indomethacin might occur.

Codeine

In the Collaborative Perinatal Project, no increased relative risk for malformations was observed in 563 codeine users. In one recent study, maternal treatment with opioid analgesics was associated with an increased risk for heart defects, spina bifida, and gastroschisis. **Codeine can cause addiction and newborn withdrawal symptoms if used to excess perinatally.**

Sumatriptan

Of 479 exposures to sumatriptan (Imitrex) in the first trimester,[62] 4.6% of infants had birth defects. This percentage is not significantly different from the nonexposed population. **For women whose severe headaches do not respond to other therapy, sumatriptan may be used during pregnancy.**[63]

DRUGS OF ABUSE

Smoking

It is not simple to sort out potential confounding factors when comparing smokers with nonsmokers. However, smoking is associated with a fourfold increase in small size for gestational age as well as an increased prematurity rate.[64] **The higher perinatal mortality rate associated with smoking is attributable to an increased risk for abruptio placentae, placenta previa, premature and prolonged rupture of membranes, and intrauterine growth restriction.** The risks for complications and the associated perinatal loss rise with the number of cigarettes smoked. Discontinuation of smoking during pregnancy can reduce the risk for both pregnancy complications and perinatal mortality, especially in women at high risk for other reasons. Maternal passive smoking was also associated with a twofold risk for low birthweight at term in one study.

There is also a positive association between smoking and sudden infant death syndrome (SIDS) and increased respiratory illnesses in children. In such reports, it is not possible to distinguish between apparent effects of maternal smoking during pregnancy and smoking after pregnancy, but both may play a role.

The spontaneous abortion rate may be up to twice that of nonsmokers, and abortions associated with maternal smoking tend to have a higher percentage of normal karyotypes and occur later than those with chromosomal aberrations.[65]

Smoking Cessation During Pregnancy

Tobacco smoke contains nicotine, carbon monoxide, and thousands of other compounds. Although nicotine is the mechanism of addiction to cigarettes, other chemicals may contribute to adverse pregnancy outcomes. For example, carbon monoxide decreases oxygen delivery to the fetus, whereas nicotine decreases uterine blood flow.

Nicotine withdrawal may first be attempted with nicotine fading, switching to brands of cigarettes with progressively less nicotine over a 3-week period. Exercise may also improve quitting success rates. **Nicotine medications are indicated for patients with nicotine dependence.** This is defined as smoking greater than one pack per day, smoking within 30 minutes of getting up in the morning, or prior withdrawal symptoms. Nicotine medications are available as patches, gum, or inhalers. **Although one might question the propriety of prescribing nicotine during pregnancy, cessation of smoking eliminates many other toxins, including carbon monoxide; nicotine blood levels are not increased over those of smokers.**

Congenital anomalies occurred in 5 of 188 infants of women treated with bupropion (Zyban) during the first trimester of pregnancy, not a significant difference from the number expected. There is no knowledge of the safety of varenicline (Chantix) use in pregnancy.[66] However, both of these medications have recently had product warnings mandated by the FDA about the risk for psychiatric symptoms and suicide associated with their use.

Alcohol

Fetal alcohol syndrome (FAS) has been reported in the offspring of alcoholic mothers and includes the features of gross physical retardation with onset prenatally and continuing after birth (Figure 8-8).

In 1980, the Fetal Alcohol Study Group of the Research Society on Alcoholism proposed criteria for the diagnosis of FAS.[67] At least one characteristic from each of the following three categories had to be present for a valid diagnosis of the syndrome:

1. Growth retardation before and/or after birth
2. Facial anomalies, including small palpebral fissures, indistinct or absent philtrum, epicanthic folds, flattened nasal bridge, short length of nose, thin upper lip, low-set and unparallel ears, and retarded midfacial development
3. Central nervous system dysfunction, including microcephaly, varying degrees of mental retardation, or other evidence of abnormal neurobehavioral development, such as attention deficit disorder with hyperactivity

The full FAS occurs in 6% of infants of heavy drinkers, and less severe birth defects and neurocognitive deficits occur in a larger proportion of children whose mothers drink heavily during pregnancy.

Jones and associates compared 23 chronically alcoholic women with 46 controls and compared the pregnancy outcomes of the two groups. Among the alcoholic mothers, perinatal deaths were about eight times more frequent. Growth restriction, microcephaly, and IQ below 80 were considerably more frequent than among the controls. Overall outcome was abnormal in 43% of the offspring of the alcoholic mothers compared with 2% of the controls.

Ouellette and colleagues addressed the risks of smaller amounts of alcohol. Nine percent of infants of abstinent or rare drinkers and 14% of infants of moderate drinkers were abnormal, not a significant difference. **In heavy drinkers (average daily intake of 3 oz of 100-proof liquor or more), 32% of the infants had anomalies.** The aggregate pool of anomalies, growth restriction, and an abnormal neurologic examination were found in 71% of the children of heavy drinkers, twice the frequency in the moderate and rarely drinking groups. In this study, an increased frequency of abnormality was not found until 45 mL of ethanol (equivalent to three drinks) daily were exceeded. The study of Mills and Graubard also showed that total malformation rates were not significantly higher among offspring of women who had an average of less than one drink per day or one to two drinks per day, than among nondrinkers.

FIGURE 8-8. Fetal alcohol syndrome. Patient photographed at birth **(A),** 5 years **(B),** and 8 years **(C).** Note short palpebral fissures, short nose, hypoplastic philtrum, thinned upper lip vermilion, and flattened midface. (From Streissguth AP: CIBA Foundation Monograph 105. London, Pitman, 1984.)

TABLE 8-2 T-ACE QUESTIONS FOUND TO IDENTIFY WOMEN DRINKING SUFFICIENTLY TO POTENTIALLY DAMAGE THE FETUS*

T	How many drinks does it take to make you feel high (can you hold) *(tolerance)*?
A	Have people *annoyed* you by criticizing your drinking?
C	Have you felt you ought to *cut down* on your drinking?
E	Have you ever had to drink first thing in the morning to steady your nerves or to get rid of a hangover *(eye-opener)*?

From Sokol RJ, Martier SS, Ager JW: The T-ACE questions: practical prenatal detection of risk-drinking. Am J Obstet Gynecol 160:863, 1989.

*Two points are scored as a positive answer to the tolerance question and one each for the other three. A score of 2 or more correctly identified 69% of risk drinkers.

Genitourinary malformations increased with increasing alcohol consumption, however, so the possibility remains that for some malformations, no safe drinking level exists.

Heavy drinking remains a major risk to the fetus, and reduction even in midpregnancy can benefit the infant. An occasional drink during pregnancy carries no documentable risk, but no level of drinking is known to be safe.

Sokol and associates have addressed history taking for prenatal detection of risk drinking. Four questions help differentiate patients drinking sufficiently to potentially damage the fetus (Table 8-2). The patient is considered at risk if more than two drinks are required to make her feel "high." The probability of "risk drinking" increases to 63% for those responding positively to all four questions.

Marijuana

No significant teratogenic effect of marijuana has been documented, but the data are insufficient to say that there is no risk. One study finding a mean 73-g decrease in birthweight associated with marijuana use validated exposure with urine assays rather than relying on self-reporting. Other studies have not shown an effect on birthweight or length. Behavioral and developmental alterations have been observed in some studies but not in others.

Cocaine

A serious difficulty in defining the effects of cocaine on the infant is the frequent presence of many confounding variables in the population using cocaine. These mothers often abuse other drugs, smoke, have poor nutrition, fail to seek prenatal care, and live under poor socioeconomic conditions. All of these factors are difficult to take into account in comparison groups. Another difficulty is the choice of outcome measures for infants exposed in utero. The neural systems likely to be affected by cocaine are involved in neurologic and behavioral functions that are not easily quantitated by standard infant development tests.

Cocaine-using women have a higher rate of spontaneous abortion than controls. **Three other studies suggested an increased risk for congenital anomalies after first-trimester cocaine use, most frequently cardiac and central nervous system.** In the study of Bingol and colleagues, the malformation rate was 10% in cocaine users, 4.5% in polydrug users, and 2% in controls. MacGregor and coworkers reported a 6% anomaly rate compared with 1% for controls.

Cocaine is a central nervous system stimulant and has local anesthetic and marked vasoconstrictive effects. Not surprisingly, **abruptio placentae has been reported to occur immediately after nasal or intravenous administration.**[67] Several studies have also noted increased stillbirths, preterm labor, premature birth, and small-for-gestational-age infants with cocaine use.

The most common brain abnormality in infants exposed to cocaine in utero is impairment of intrauterine brain growth as manifested by microcephaly.[68] In one study, 16% of newborns had microcephaly compared with 6% of controls. Somatic growth is also impaired, and the growth restriction may be symmetrical or characterized by a relatively low head-to-abdominal circumference ratio. Multiple other neurologic problems have been reported after cocaine exposure, as well as dysmorphic features and neurobehavioral abnormalities.

Aside from causing congenital anomalies in the first trimester, cocaine has been reported to cause fetal disruption, presumably due to interruption of blood flow to various organs. Bowel infarction has been noted with unusual ileal atresia and bowel perforation. Limb infarction has resulted in missing fingers in a distribution different from the usual congenital limb anomalies. Central nervous system bleeding in utero may result in porencephalic cysts.

Narcotics and Methadone

Menstrual abnormalities, especially amenorrhea, are common in heroin abusers, although they are not associated with the use of methadone. Medical intervention is more likely to involve methadone maintenance, with the goal being a dose of about 20 to 40 mg/day. The dose should be individualized at a level sufficient to minimize the use of supplemental illicit drugs, which represent greater risk to the fetus than even the higher doses of methadone required by some patients. Manipulation of the dose in women maintained on methadone should be avoided in the last trimester because of an association with increased fetal complications and deaths attributed to fetal withdrawal in utero. Because management of narcotic addiction during pregnancy requires a host of social, nutritional, educational, and psychiatric interventions, these patients are best managed in specialized programs. Buprenorphine (Subutex) is also an acceptable treatment, and infants exposed to this drug required less morphine, had shorter hospital stays, and had shorter duration of treatment for neonatal abstinence syndrome than infants exposed to methadone. However, women on buprenorphine were more likely to discontinue treatment.

The pregnancy of the narcotic addict is at increased risk for abortion, prematurity, and growth restriction. Withdrawal should be watched for carefully in the neonatal period.[69]

Caffeine

There is no evidence of teratogenic effects of caffeine in humans.[70] The Collaborative Perinatal Project showed no increased incidence of congenital defects in 5773 women taking caffeine in pregnancy, usually in a fixed-dose analgesic medication. The average cup of coffee contains about 100 mg, and a 12 oz can of soda contains about 50 mg of caffeine. Some conflicting evidence exists concerning the association between heavy ingestion of caffeine and increased pregnancy complications. Early studies suggested that the intake of greater than seven to eight cups of coffee per day was associated with low birthweight infants, spontaneous abortions, prematurity, and stillbirths. However, these studies were not controlled for the concomitant use of tobacco and alcohol. **In one report that controlled for smoking, other habits, demographic characteristics, and medical history, no relationship was found between malformations, low birthweight, or short gestation and heavy coffee consumption.** When pregnant women consumed more than 300 mg of caffeine per day, one study suggested an increase in term low-birthweight infants,[71] less than 2500 g at greater than 36 weeks.

Concomitant consumption of caffeine with cigarette smoking may increase the risk for low birthweight. Maternal coffee intake decreases iron absorption and may contribute to maternal anemia.

Two other studies have shown conflicting results. One retrospective investigation reporting a higher risk for fetal loss was biased by ascertainment of the patients at the time of fetal loss because these patients typically have less nausea and would be expected to drink more coffee. A prospective cohort study found no evidence that moderate caffeine use increased the risk for spontaneous abortion or growth restriction.[72] Measurement of serum paraxanthine, a caffeine metabolite, revealed that only extremely high levels are associated with spontaneous abortions.

The American College of Obstetricians and Gynecologists (ACOG) concluded that moderate caffeine consumption (<200 mg/day) does not appear to be a major contributing factor in miscarriage or preterm birth, but the relationship to growth restriction remains undetermined.[73] High caffeine intake may or may not be related to miscarriage, so limiting intake to 200 mg/day seems prudent.[73]

Aspartame (NutraSweet)

The major metabolite of aspartame is phenylalanine,[74] which is concentrated in the fetus by active placental transport. Sustained high blood levels of phenylalanine in the fetus as seen in maternal phenylketonuria are associated with mental retardation in the infant. However, within the usual range of aspartame ingestion in normal individuals, peak phenylalanine levels do not exceed normal postprandial levels, and even with high doses, phenylalanine concentrations are still very far below those associated with mental retardation. These responses have also been studied in women who are obligate carriers of PKU, and their levels are still normal. **Thus, it seems unlikely that aspartame during pregnancy would cause any fetal toxicity.**

DRUGS IN BREAST MILK

Many drugs can be detected in breast milk at low levels that are not usually of clinical significance to the infant. The rate of transfer into milk depends on the lipid solubility, molecular weight, degree of protein binding, degree of ionization of the drug, and the presence or absence of active secretion. Nonionized molecules of low molecular weight such as ethanol cross easily.[75] If the mother has unusually high blood concentrations such as with increased dosage or decreased renal function, drugs may appear in higher concentrations in the milk.

The amount of drug in breast milk is a variable fraction of the maternal blood level, which itself is proportional to the maternal oral dose. Thus, the dose to the infant is usually subtherapeutic, about 1% to 2% of the maternal

dose on the average. This amount is usually so trivial that no adverse effects are noted. In the case of toxic drugs, however, any exposure may be inappropriate. Allergy may also exist or be initiated. Long-term effects of even small doses of drugs may yet be discovered. Also, drugs are eliminated more slowly in the infant with immature enzyme systems. Short-term effects of most maternal medications on breastfed infants are mild and pose little risk to the infants. The benefits of breastfeeding are well known, and the risk of drug exposure must be weighed against these benefits.

With drug administration in the immediate few days postpartum before lactation is fully established, the infant receives only a small volume of colostrum; thus, little drug is excreted into the milk. It is also helpful to allay fears of patients undergoing cesarean deliveries that analgesics or other drugs administered at this time have no known adverse effects on the infant. For drugs requiring daily dosing during lactation, knowledge of pharmacokinetics in breast milk may minimize the dose to the infant. For example, dosing immediately after nursing decreases the neonatal exposure because the blood level will be at its nadir just before the next dose.

Short-term effects, if any, of most maternal medications on breastfed infants are mild and pose little risk to the infants.[76] Of 838 breastfeeding women, 11.2% reported minor adverse reactions in the infants, but these reactions did not require medical attention. In 19%, antibiotics caused diarrhea; in 11%, narcotics caused drowsiness; in 9%, antihistamines caused irritability; and in 10%, sedatives, antidepressants, or antiepileptics caused drowsiness.[76]

The American Academy of Pediatrics has reviewed drugs in lactation[77] and categorized the drugs as listed below in six categories:

Drugs Commonly Listed as Contraindicated During Breastfeeding

Cytotoxic Drugs That May Interfere with Cellular Metabolism of the Nursing Infant

Cyclosporine (Sandimmune), doxorubicin (Adriamycin), and cyclophosphamide (Cytoxan) might cause immune suppression in the infant, although data are limited with respect to these drugs. In general, the potential risks of these drugs would outweigh the benefits of continuing nursing.[77]

After oral administration to a lactating patient with choriocarcinoma, methotrexate was found in milk in low but detectable levels. Most individuals would elect to avoid any exposure of the infant to this drug. However, in environments in which bottle feeding is rarely practiced or presents practical and cultural difficulties, therapy with this drug would not in itself appear to constitute a contraindication to breastfeeding.

Drugs of Abuse for Which Adverse Effects on the Infant During Breastfeeding Have Been Reported

Drugs of abuse, such as amphetamines, cocaine, heroin, marijuana, and phencyclidine, are all contraindicated during breastfeeding because they are hazardous to the nursing infant and to the health of the mother.[77]

Radioactive Compounds That Require Temporary Cessation of Breastfeeding

The American Academy of Pediatrics[77] suggests consultation with a nuclear medicine physician so that the radionuclide with the shortest excretion time in breast milk can be used. The mother can attempt to store breast milk before the study. She should continue to pump to maintain milk production but discard the milk during therapy. **Radiopharmaceuticals require variable intervals of interruption of nursing.** Recommended intervals are as follows:

1. Gallium-67, 2 weeks
2. ^{131}I, 2 to 14 days
3. Radioactive sodium, 4 days
4. Technetium-99m, 15 hours to 3 days

The physician may reassure the patient by counting the radioactivity of the milk before nursing is resumed.

Drugs for Which the Effect on Nursing Infants Is Unknown but May Be of Concern

The category includes several classes of psychotropic drugs, amiodarone (associated with hypothyroidism), lamotrigine (potential for therapeutic serum concentration in the infant), metoclopramide (potential dopaminergic blocking, but no reported detrimental effects), and metronidazole.[77]

Antianxiety, antidepressant, and antipsychotic agents are sometimes given to nursing mothers. Although there are no data about adverse effects in infants exposed to these drugs through breast milk, they could theoretically alter central nervous system function.[77] Fluoxetine (Prozac) is excreted in breast milk at low levels, so the infant receives about 6.7% of the maternal dose.[78] The level in the breastfed newborn is certainly lower than the level during pregnancy.

Sertraline causes a decline in 5-hydroxytryptamine levels in mothers, but not in their breastfed infants.[79] **This implies that the small amount of drug the infant ingests in breast milk is not enough to have a pharmacologic effect** (Figure 8-9). **Infants of mothers on psychotropic drugs should be monitored for sedation during use and withdrawal after cessation of the drug.**

A bigger problem is postpartum depression, exacerbated by fatigue. **The benefits of breastfeeding should be weighed against the negative effect on bonding resulting from untreated postpartum depression.**

Temporary cessation of breastfeeding after a single dose of metronidazole (Flagyl) may be considered. Its half-life is such that interruption of lactation for 12 to 24 hours after single-dose therapy usually results in negligible exposure to the infant. However, no adverse effects in infants have been reported.

Drugs That Have Been Associated with Significant Effects in Some Nursing Infants and Should Be Given to Nursing Mothers with Caution

Bromocriptine

Bromocriptine is an ergot alkaloid derivative. Because it has an inhibitory effect on lactation, it should be avoided unless the mother has taken it during the pregnancy.

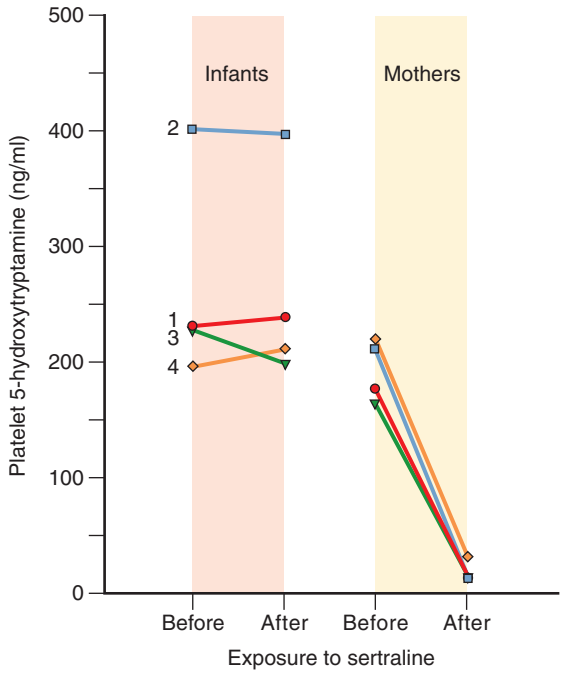

FIGURE 8-9. Effect of sertraline on platelet 5-hydroxytryptamine levels in four breast-fed infants and their mothers. (From Epperson CN, Anderson GM, McDougle CJ: Sertraline and breast-feeding. N Engl J Med 336:1189, 1997. Copyright 1997 Massachusetts Medical Society.)

ERGOTAMINE

Ergotamine, as used by those with migraine headache, has been associated with vomiting, diarrhea, and convulsions in the infant. Administration of an ergot alkaloid for the treatment of uterine atony does not contraindicate lactation.

LITHIUM

Breast milk levels of lithium are one-third to one-half maternal serum levels, and the infant's serum levels while nursing are much lower than the fetal levels that occur when the mother takes lithium during pregnancy. The benefits of breastfeeding must be weighed against the theoretical effects of small amounts of the drug on the developing brain.[77] (See comment above about the need to minimize fatigue in order to mitigate against postpartum psychoses.)

Maternal Medication Usually Compatible with Breastfeeding

NARCOTICS, SEDATIVES, AND ANTICONVULSANTS

In general, no evidence of adverse effect is noted with most of the sedatives, narcotic analgesics, and anticonvulsants. Patients may be reassured that, in normal doses, carbamazepine (Tegretol), phenytoin (Dilantin), magnesium sulfate, codeine, morphine, and meperidine (Demerol) do not cause any obvious adverse effects in the infants because the dose detectable in the breast milk is about 1% to 2% of the mother's dose, which is sufficiently low to have no significant pharmacologic activity.

With diazepam (Valium), the milk-to-plasma ratio at peak dose is 0.68, with only small amounts detected in the breast milk. In two patients who took carbamazepine (Tegretol) while nursing, the concentration of the drug in breast milk at 4 and 5 weeks postpartum was similar, about 60% of the maternal serum level. Accumulation does not seem to occur, and no adverse effects were noted in either infant.

COLD PREPARATIONS

No harmful effects of acetaminophen (Tylenol, Datril) have been noted. Although studies are not extensive, no harmful effects have been noted from antihistamines or decongestants. Less than 1% of a pseudoephedrine dose or triprolidine dose ingested by the mother is excreted in the breast milk.

ANTIHYPERTENSIVES

THIAZIDES

After a single 500-mg oral dose of chlorothiazide (Diuril), no drug was detected in breast milk. In one mother taking 50 mg of hydrochlorothiazide (Hydrodiuril) daily, the drug was not detectable in the nursing infant's serum, and the infant's electrolytes were normal. Thiazide diuretics may decrease milk production in the first month of lactation.[77]

β-BLOCKERS

Propranolol (Inderal) is excreted in breast milk, with milk concentrations after a single 40-mg dose less than 40% of peak plasma concentrations. Thus, an infant consuming 500 mL/day of milk would ingest an amount representing about 1% of a therapeutic dose, which is unlikely to cause any adverse effect.

Atenolol (Tenormin) is concentrated in breast milk to about three times the plasma level. One case has been reported in which a 5-day-old term infant had signs of β-adrenergic blockade with bradycardia (80 beats/minute) with the breast milk dose calculated to be 9% of the maternal dose. Adverse effects in other infants have not been reported. Because milk accumulation occurs with atenolol, infants must be monitored closely for bradycardia. Propranolol is a safer alternative.

Clonidine (Catapres) concentrations in milk are almost twice maternal serum levels. Neurologic and laboratory parameters in the infants of treated mothers are similar to those of controls.

ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

Captopril (Capoten) is excreted into breast milk in low levels, and no effects on nursing infants have been observed.

CALCIUM CHANNEL BLOCKERS

Nifedipine is excreted into breast milk at a concentration of less than 5% of the maternal dose, and verapamil at an even lower level. Neither have caused adverse effects in the infant.

ANTICOAGULANTS

Most mothers requiring anticoagulation may continue to nurse their infants with no problems. Heparin does not cross into milk and is not active orally.

At a maternal dose of warfarin (Coumadin) of 5 to 12 mg/day in seven patients, no warfarin was detected in breast

milk or infant plasma. This low concentration is probably because warfarin is 98% protein bound, and the milk would contain insignificant drug to exert an anticoagulant effect.[80] Another report confirmed that warfarin appears only in insignificant quantities in breast milk.[81] The oral anticoagulant bishydroxycoumarin (Dicumarol) has been given to 125 nursing mothers with no effect on the infants' prothrombin times and no hemorrhages. **Thus, with careful monitoring of maternal prothrombin time so that the dosage is minimized and of neonatal prothrombin times to ensure lack of drug accumulation, warfarin may be safely administered to nursing mothers.**

Corticosteroids

Prednisone enters breast milk in an amount not likely to have any deleterious effect. In a study of seven patients, 0.14% of a sample was secreted in the milk in the subsequent 60 hours, a negligible quantity. Even at 80 mg/day, the nursing infant would ingest less than 0.1% of the dose, less than 10% of its endogenous cortisol.

Digoxin (Lanoxin)

Digoxin enters breast milk in a small amount due to significant maternal protein binding. In 24 hours, an infant would receive about 1% of the maternal dose. No adverse effects in nursing infants have been reported.

Antibiotics

Penicillin derivatives are safe in nursing mothers. With the usual therapeutic doses of penicillin or ampicillin, no adverse effects are noted in the infants. In susceptible individuals or with prolonged therapy, diarrhea and candidiasis are concerns.

Dicloxacillin is 98% protein bound. If this drug is used to treat breast infections, very little will get into the breast milk, and nursing may be continued.

Cephalosporins appear only in trace amounts in milk. In one study after cefazolin 500 mg intramuscularly three times a day (Ancef, Kefzol), no drug was detected in breast milk. After 2 g of cefazolin intravenously, the infant was exposed to less than 1% of the maternal dose.

Tooth staining or delayed bone growth from tetracyclines has not been reported after the drug was taken by a breastfeeding mother. This finding is probably because of the high binding of the drug to calcium and protein, limiting its absorption from the milk. The amount of free tetracycline available is too small to be significant.

Sulfonamides only appear in small amounts in breast milk and are ordinarily not contraindicated during nursing. However, the drug is best avoided in premature, ill, or stressed infants in whom hyperbilirubinemia may be a problem because the drug may displace bilirubin from binding sites on albumin. On the other hand, sulfasalazine was not detected in the breast milk of a mother taking this drug.[82]

Gentamicin (Garamycin) is transferred into breast milk, and half of nursing newborn infants have the drug detectable in their serum. The low levels detected would not be expected to cause clinical effects.

Nitrofurantoin (Macrodantin) is excreted into breast milk in very low concentrations. In one study, the drug could not be detected in 20 samples from mothers receiving 100 mg four times a day.

Erythromycin is excreted into breast milk in small amounts. No reports of adverse effects on infants exposed to erythromycin in breast milk have been noted. Azithromycin (Zithromax) also appears in breast milk in low concentrations. Clindamycin (Cleocin) is excreted into breast milk in low levels, and nursing is usually continued during administration of this drug.

There are no reported adverse effects on the infant of isoniazid administered to nursing mothers, and its use is considered compatible with breast-feeding.[77]

Acyclovir

Acyclovir is compatible with breastfeeding. If a mother takes 1 g/day, the infant receives less than 1 mg/day, a very low dose.

Antifungal Agents

No data are available with nystatin, miconazole, or clotrimazole in breast milk. However, with only small amounts absorbed vaginally, this would not be expected to be a clinical problem. Infant exposure to ketoconazole in human milk was 0.4% of the therapeutic dose, again unlikely to cause adverse effects.

Oral Contraceptives

Estrogen and progestin combination oral contraceptives cause dose-related suppression of milk production. Oral contraceptives containing 50 mcg and more of estrogen during lactation have been associated with shortened duration of lactation, decreased milk production, decreased infant weight gain, and decreased protein content of the milk. Lactation is inhibited to a lesser degree if the pill is started about 3 weeks postpartum and with doses of estrogen lower than 50 mcg. Although the magnitude of the changes is low, the changes may be of nutritional importance, particularly in malnourished mothers.

An infant consuming 600 mL of breast milk daily from a mother using an oral contraceptive containing 50 mcg of the ethinylestradiol receives a daily dose in the range of 10 ng of the estrogen. The amount of natural estradiol received by infants who consume a similar volume of milk from mothers not using oral contraceptives is estimated at 3 to 6 ng during anovulatory cycles and 6 to 12 ng during ovulatory cycles. No consistent long-term adverse effects on growth and development have been described.

Evidence indicates that norgestrel (Ovrette) is metabolized rather than accumulated by the infants, and to date, no adverse effects have been identified as a result of progestational agents taken by the mother. ACOG recommends placement of the etonogestrel contraceptive implant 4 weeks or more after childbirth. Progestin-only contraceptives do not cause alteration of breast milk composition or volume, making them ideal in the breastfeeding mother. When the infant is weaned, the mother should be switched to combined oral contraceptives for maximal contraceptive efficacy.

Alcohol

Alcohol levels in breast milk are similar to those in maternal blood. If a moderate social drinker had two cocktails and

had a blood alcohol concentration of 50 mg/dL, the nursing infant would receive about 82 mg of alcohol, which would produce insignificant blood concentrations. There is no evidence that occasional ingestion of alcohol by a mother is harmful to the infant. However, one study showed that ethanol ingested chronically through breast milk might have a detrimental effect on motor development, but not mental development.[83] Also, alcohol in breast milk has an immediate effect on the odor of the milk, and this may decrease the amount of milk the infant consumes.[84]

Propylthiouracil

PTU is found in breast milk in small amounts. If the mother takes 200 mg PTU three times a day, the child would receive 149 mcg daily, or the equivalent of a 70-kg adult receiving 3 mg/day. Several infants studied up to 5 months of age show no changes in thyroid parameters. **Lactating mothers on PTU can thus continue nursing with close supervision of the infant.** PTU is preferred over methimazole (Tapazole) because of its high protein-binding (80%) and lower breast milk concentrations.

Histamine-2 Receptor Blockers

In theory, histamine-2 (H_2) receptor antagonists (e.g., ranitidine, cimetidine) might suppress gastric acidity and cause central nervous system stimulation in the infant, but these effects have not been confirmed. The American Academy of Pediatrics now considers H_2 receptor antagonists to be compatible with breastfeeding.[77] Famotidine, nizatidine, and roxatidine are less concentrated in breast milk and may be preferable in nursing mothers.

Caffeine

Caffeine has been reported to have no adverse effects on the nursing infant, even after the mother consumes several cups of strong coffee. In one study, the milk level contained 1% of the total dose 6 hours after coffee ingestion, which is not enough to affect the infant. In another report, no significant difference in 24-hour heart rate or sleep time was observed in nursing infants when their mothers drank coffee for 5 days or abstained for 5 days.[85]

Smoking

Nicotine and its metabolite cotinine enter breast milk. Infants of smoking mothers achieve significant serum concentrations of nicotine even if they are not exposed to passive smoking; exposure to passive smoking further raises the levels of nicotine. Women who smoke should be encouraged to stop during lactation as well as during pregnancy.

OCCUPATIONAL AND ENVIRONMENTAL HAZARDS

Ionizing Radiation

The general hazards of radiation exposure are well known. To provide counseling in specific clinical situations, key variables are dose, timing, and temporal sequence.

Acute Exposure

Systematic studies of atomic bomb survivors in Japan showed conclusively that in utero exposure to high-dose radiation increased the risk for microcephaly and mental retardation and growth restriction in the offspring.

Distance from the hypocenter—the area directly beneath the detonated bomb—and gestational age at the time of exposure were directly related to microcephaly and mental retardation and growth restriction in the infant. **The greatest number of children with microcephaly, mental retardation, and growth restriction were in the group exposed at 15 weeks' gestation or earlier.** Exposures were calculated by the distance of the victims from the epicenter. Microcephaly and mental retardation were associated with ionizing radiation at doses of 50 cGy or greater, with 20 cGy being the lowest dose in which microcephaly was observed. It is of note that radiation from the atomic bomb blast differs from the low linear transfer of filtered radiation that is used in diagnostic studies.

Although teratogenic effects have been found in several organ systems of animals exposed to acute, high-dose radiation, the only structural malformations reported among humans exposed prenatally are those mentioned earlier. Using data from animals and from outcomes of reported human exposures at various times during pregnancy, DeKaban[86] constructed a timetable for extrapolating acute, high-dose radiation (>250 cGy) to various reproductive outcomes in humans. Similarities between animal and known human effects support DeKaban's proposal.

Effects of chronic low-dose radiation on reproduction have not been identified in animals or humans. Increased risk of adverse outcomes was not detected among animals with continuous low-dose exposure (<5 rad) throughout pregnancy. The National Council for Radiation Protection[87] concluded that exposures less than 5 rads were not associated with increased risk of malformations.

Exposures are expressed as Gray (Gy): 1 Gy equals 1000 mGy equals 100 cGy (rad) (Table 8-3). Thus 10 mGy equals 1 rad. **Fortunately, virtually no single diagnostic test produces a substantive risk.** Table 8-3 shows mean and maximal fetal exposure. Only multiple computed tomography scans and fluoroscopies would lead to cumulate

Table 8-3 Approximate Fetal Doses from Common Diagnostic Procedures

EXAMINATION	MEAN (mGy)	MAXIMUM (mGy)
Conventional Radiographic Examinations		
Abdomen	1.4	4.2
Chest	<0.01	<0.01
Intravenous urogram	1.7	10
Lumbar spine	1.7	10
Pelvis	1.1	4
Skull	<0.01	<0.01
Thoracic spine	<0.01	<0.01
Fluoroscopic Examinations		
Barium meal (upper gastrointestinal)	1.1	5.8
Barium enema	6.8	24
Computed Tomography		
Abdomen	8.0	49
Chest	0.06	0.96
Head	<0.005	<0.005
Lumbar spine	2.4	8.6
Pelvis	25	79

From Lowe SA: Diagnostic radiography in pregnancy: risks and reality. Aust N Z J Obstet Gynaecol 44:191, 2004.

exposures of 100 mGy or 10 cGy (rad). Internal exposures are 50% less than maternal surface doses.

Female frequent flyers or crew members may be exposed to radiation during frequent long, high-altitude flights. The Federal Aviation Administration recommends limiting exposure to 1 mSv (0.1 cGy) during the pregnancy.[88]

Therapeutic exposures for maternal thyroid ablation with I^{131} are rare but can cause fetal thyroid damage after 12 weeks of pregnancy.

Mutagenesis

Mutagenic effects in the offspring of irradiated women may be manifested years after the birth of the infant. Mutagenic effects presumably explain the 50% increased risk for leukemia in children exposed in utero to radiation during maternal pelvimetry examinations compared with nonirradiated controls. However, clinical consequence is almost nil. The absolute risk is about 1 in 2000 for exposed versus 1 in 3000 for unexposed children.

Lowe[87] estimates one additional cancer death per 1700 10 mGy (1 rad) exposures. If one were to recommend that pregnancies be terminated whenever exposure from diagnostic radiation occurred because of the increased probability of leukemia in the offspring, 1699 exposed pregnancies would have to be terminated to prevent a single case of leukemia. Radiation exposures should be minimized, but fear of radiation should never preclude one from necessary diagnostic procedures. A consent form has been developed for use with pregnant women.[89]

Questions have also been raised about potential risks to children associated with parental (paternal) occupational exposure to low-dose radiation. A case-control study by Gardner and colleagues in the area around the Sellafield Nuclear Facility in the United Kingdom found a statistically significant association between paternal preconception radiation dose and childhood leukemia risk. A similar association had been observed between paternal preconception radiation and risk in workers at the Hanford Nuclear Facility in the United States. The finding regarding childhood leukemia risk is a particularly contentious issue, contradicting studies of the children born to atomic bomb survivors who do not show genetic effects, such as increased risks for childhood cancers. A study in the vicinity of nuclear facilities in Ontario also failed to demonstrate an association between childhood leukemia risk and paternal preconceptional radiation exposure.

Video Display Terminals

Concern about video display terminals linked to adverse reproductive outcomes now seems unwarranted. Early concern grew out of reports of spontaneous abortion clusters among groups of women who used video display terminals at work; some reported clusters included birth defects. Since then, numerous reassuring papers have been published on this topic, along with a number of reviews.[90] **VDT use does not increase the risk for adverse reproductive outcomes.**

Lead

Twenty-five years of public health efforts have produced a striking reduction in lead exposure in the United States. The average blood lead level has decreased to less than 20% of levels measured in the 1970s. However, elevated blood lead (>20 mcg/dL) has a higher incidence among immigrants to Southern California. In Los Angeles, 25 of the 30 cases of elevated blood lead occurred in immigrants.

High lead concentration in maternal blood is associated with an increased risk for delivery of a small-for-gestational-age infant. The frequency of preterm birth was also almost three times higher among women who had umbilical cord levels greater than or equal to 5.1 mcg/dL, compared with those who had levels below that cutoff. One study in Norway found an increased risk for low birthweight and also NTDs.[91]

Lead poisoning has been reported after a pregnant woman ingested Garbhpal ras, an Asian Indian health supplement which contained extremely high levels of lead.[92]

Asking pregnant women about risk factors for lead exposure can aid in assessing prenatal exposure risk. A questionnaire that gathered information on housing conditions, smoking status, and consumption of canned foods had a sensitivity of 89.2% and a negative predictive value of 96.4%.[93] Consumption of calcium and avoidance of the use of lead-glazed ceramics resulted in lowering of blood lead, especially in pregnant women of low socioeconomic status in Mexico City.

Because the nervous system may be more susceptible to the toxic effects during the embryonic and fetal periods than at any other time of life and because maternal and cord blood lead concentrations are directly correlated, lead concentrations in blood should not exceed 25 mcg/dL in women of reproductive age.[94]

Ideally, the maternal blood lead level should be less than 10 mcg/dL to ensure that a child begins life with minimal lead exposure. A dose-response relationship is strongly supported by numerous epidemiologic studies of children showing a reduction in IQ with increasing blood lead concentrations above 10 mcg/dL. Of note, these studies measured blood lead concentrations over time (often 2 years or more) and reported averaged values. **Other neurologic impairments associated with increased blood lead concentrations include attention deficit disorder ("hyperactivity"), hearing deficits, learning disabilities, and shorter stature.** Thus, for public health purposes, childhood lead poisoning has been defined as a blood lead level of 10 mcg/dL or higher.

In occupational settings, federal standards mandate that women should not work in areas where air lead concentrations can reach 50 mcg/cm, because this may result in blood concentrations above 25 to 30 mcg/dL.[95] Subtle but permanent neurologic impairment in children may occur at lower blood lead concentrations.

Mercury

Fish and shellfish are an important part of a healthy diet, but some large fish contain significant amounts of mercury. **Mercury in high levels may harm the unborn baby or young child's developing nervous system.**[96]

Women who may become pregnant, pregnant women, and nursing mothers should avoid shark, swordfish, king mackerel, and tile fish because they contain high levels of

mercury.[97] They may eat up to 12 oz a week of shrimp, canned light tuna, salmon, pollock, and catfish, all of which are very low in mercury. Albacore (white) tuna and tuna steaks have more mercury than canned light tuna, but 6 oz per week is allowed.

THE OBSTETRICIAN'S ROLE IN EVALUATING DRUG AND REPRODUCTIVE RISKS IN AND BEYOND THE WORKPLACE

Clinical questions about adverse reproductive outcomes of potential drug teratogens or environmental or occupational exposures are difficult to answer. Answers are seldom as clearcut as the obstetrician would like. Even if the exposure were known, there is often not a study of similar exposure with a sufficient sample size. Without this, a physician cannot give a reliable estimate of risk.

For drugs and other exposures discussed in this chapter, the threshold is unknown below which no adverse reproductive outcome can be expected. Except for ionizing radiation, maximal recommended exposure levels are difficult to quantify. Epidemiologic studies, when available, often have limitations in design, execution, analysis, or interpretation. Thus, often the questions must be answered on the basis of reasoned judgments in the face of inadequate data.

In addition to traditional genetic referral sources, a variety of teratology information services and computer databases are available to physicians who counsel pregnant women (see Table 8-1). The options include personal computer software (Grateful Med, commercial services) and CD-ROM copies in medical libraries or leased from commercial versions. Information is available from a TOXNET representative, National Library of Medicine, Specialized Information Services, 8600 Rockville Pike, Bethesda, MD 20894, 301-496-6531.

The National Library of Medicine in Bethesda, Maryland, maintains several files on the TOXNET database system, including reproductive and developmental toxicology information in bibliographic or text form. Examples include Developmental and Reproductive Toxicology, GEN-TOX (genetic toxicology), and Environmental Mutagen Information Center. Other very useful sources are Reprotox [http://reprotox.org] and TERIS [depts.washington.edu/%7Eterisweb/teris/index.html].

SUMMARY

Many medical conditions during pregnancy and lactation are best treated initially with nonpharmacologic remedies. Before a drug is administered in pregnancy, the indications should be clear, and the risk-to-benefit ratio should justify drug use. If possible, therapy should be postponed until after the first trimester. In addition, patients should be cautioned about the risks of social drug use such as smoking, alcohol, and cocaine during pregnancy. Most drug therapy does not require cessation of lactation because the amount excreted into breast milk is sufficiently small to be pharmacologically insignificant.

KEY POINTS

- The critical period of organ development extends from day 31 to day 71 after the first day of the last menstrual period.
- Infants of epileptic women taking anticonvulsants have double the rate of malformations of unexposed infants; the risk for fetal hydantoin syndrome is less than 10%.
- The risk for malformations after in utero exposure to isotretinoin is 25%, and an additional 25% of infants have mental retardation.
- Heparin is the drug of choice for anticoagulation during pregnancy except for women with artificial heart valves, who should receive Coumadin despite the 5% risk for warfarin embryopathy.
- Angiotensin-converting enzyme inhibitors and angiotensin receptor blockers can cause fetal renal failure in the second and third trimesters, leading to oligohydramnios and hypoplastic lungs.
- Vitamin B_6, 25 mg three times per day, is a safe and effective therapy for first-trimester nausea and vomiting; doxylamine (Unisom), 12.5 mg three times per day, is also effective in combination with B_6.
- Most antibiotics are generally safe in pregnancy. Trimethoprim may carry an increased risk in the first trimester, and tetracyclines taken in the second and third trimesters may cause tooth discoloration. Aminoglycosides can cause fetal ototoxicity.
- Aspirin in analgesic doses inhibits platelet function and prolongs bleeding time, increasing the risk for peripartum hemorrhage.
- Fetal alcohol syndrome occurs in infants of mothers drinking heavily during pregnancy. A safe level of alcohol intake during pregnancy has not been determined.
- Cocaine has been associated with increased risk for spontaneous abortions, abruptio placentae, and congenital malformations, in particular, microcephaly.
- Most drugs are safe during lactation because subtherapeutic amounts appear in breast milk, about 1% to 2% of the maternal dose.
- Only a small amount of prednisone crosses the placenta, so it is the preferred corticosteroid for most medical illnesses. In contrast, betamethasone and dexamethasone readily cross the placenta and are preferred for acceleration of fetal lung maturity.
- Exposure to high-dose ionizing irradiation during gestation causes microcephaly and mental retardation; however, diagnostic exposures of less than 5 cGy do not pose increased teratogenic risks. Mutagenic effects presumably are responsible for the 50% increased risk for leukemia in children exposed in utero to radiation during maternal pelvimetry; the absolute risk is very low.
- Lead levels in blood have decreased in recent years in all except immigrant populations, making

it easier to achieve blood levels less than 25 mcg/dL in women of reproductive age; this low level minimizes fetal growth restriction.

- Mercury in high levels deleteriously affects the fetal nervous system. For this reason pregnant and nursing women should avoid shark, swordfish, king mackerel, and tile fish; exposures to mercury can further be limited by restricting ingestion of certain other seafood (shrimp, canned tuna, salmon, pollock, catfish) to 12 oz/week.

Thermal Index for Soft Tissues	TIs
Three Dimensional	3-D
Time-Gain Compensation	TGC

Over the past several decades, the clinical use of ultrasound imaging in obstetrics has expanded remarkably. It is now considered by many to be the most valuable diagnostic tool in the field. Ultrasound was first used clinically in pregnancy in the early 1960s to measure the biparietal diameter—the distance between spikes on an oscilloscope screen. Since then, the technology has progressed to the point that even relatively inexpensive ultrasound machines yield detailed real-time images of the fetus. This chapter addresses general aspects of ultrasound use in pregnancy. More detailed discussions of the use of ultrasound to evaluate specific pregnancy problems, such as multiple gestation, third-trimester bleeding, and incompetent cervix, are covered in other chapters.

BIOPHYSICS OF ULTRASOUND

The underlying basis of ultrasound image production is the piezoelectric effect. When electrical impulses are applied to certain ceramic crystals, mechanical oscillations are induced. Conversely, induced vibrations of piezoelectric crystals generate a detectable electric current. In diagnostic ultrasound applications, the ultrasound machine sends an electric signal of the desired frequency to piezoelectric crystals embedded in the ultrasound probe. When the probe is placed in contact with a patient's skin, the skin and underlying tissues begin to vibrate, generating a sound or pressure wave. As this pulse of energy encounters an interface between materials of different impedance, a small amount of the energy is reflected as an echo. The pulses returning to the patient's skin cause the crystals in the probe to vibrate, generating an electric current that is passed back to the ultrasound machine. The pulses of energy that are emitted are very brief—about 1 microsecond. The number of pressure peaks produced in 1 second is the frequency of the sound waves. Ultrasound machines used in obstetrics operate at frequencies of between about 2 and 9 MHz. Sound frequencies above 20 KHz cannot be detected by the human ear, hence the term *ultrasound*.

Between each emitted sound pulse, the probe "listens" for an echo. Because of this alternating send-receive function, the piezoelectric crystal serves as both the transmitter and receiver of the ultrasonic waves.

To produce an image, the ultrasound machine needs to sense the intensity and the time elapsed from send to receive of returning echoes. Highly reflective tissues (e.g., bone) generate relatively more intense echoes. The deeper an object lies, the longer it will take for the return echo to be registered. Because the velocity of sound in tissues is known, the return time can be used to calculate the distance of the object from the transducer. Intensity and depth characteristics are registered in the machine's computer memory, and this information is then used by the computer to activate pixels on the monitor with the appropriate location and intensity.

Modern ultrasound transducers used in obstetrics have a curved face, within which are embedded a row of crystals. The linear arrangement of the crystals on the transducer allows the mechanical oscillations generated by each crystal to be combined into to a wedge-shaped beam. The shape of the transducer face and the resultant beam is depicted on the ultrasound monitor display. In older machines, an unwieldy flat-faced transducer was used to mount this linear array of crystals, but the curved face of current transducers provides a more convenient "footprint" for optimal contact with the patient's skin across the entire transducer. With endovaginal probes, the crystals are mounted on a smaller surface with a tighter curvature. This is apparent on the display as well.

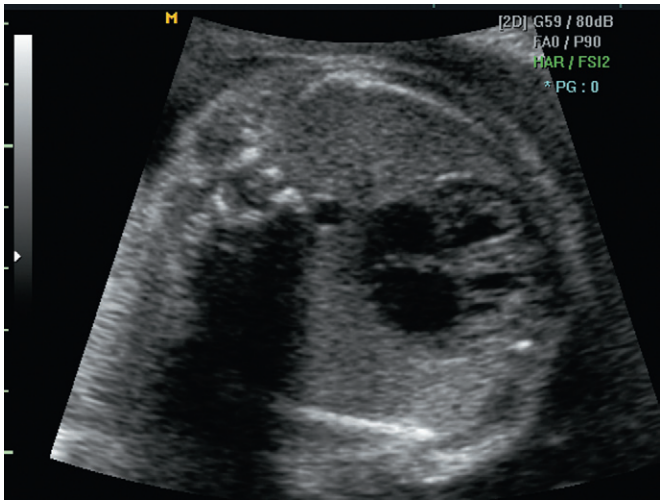

FIGURE 9-1. Transverse four-chamber view of the fetal heart showing appropriate gain settings. The image has a uniform brightness from top to bottom and is neither too light nor too dark.

OPTIMIZING THE ULTRASOUND IMAGE

Power

Ultrasound machines have the capability of delivering varying amounts of voltage to the transducer elements. Increasing the power output increases the amplitude of energy waves in the ultrasound beam and results in stronger returning echoes. This can be advantageous in that it can improve the signal-to-noise ratio and improve imaging capabilities. However, energy is required to create oscillations in the molecules of insonated tissues. Because this energy is absorbed into the tissues, delivering an unnecessarily high energy dose raises safety concerns. The safety of diagnostic ultrasound will be discussed later in this chapter. Suffice it to say that it is good practice to operate at as low power as is consistent with adequate ultrasound penetration. Current ultrasound machines have a preset power level that is sufficient for most situations, and a higher power setting is usually not needed.

Gain

Signals from the weak echoes returning to the transducer elements must be amplified before being used for display. This amplification process is referred to as *gain*. Because of attenuation, echoes returning from deeper within the body have a lower intensity, and the machine must boost the amplification from these echoes. This built-in processing feature is known as *time-gain compensation* (TGC), meaning that echoes with a greater time delay automatically have greater amplification. The amount of amplification, or gain, can be controlled by the sonographer in two ways. Machines come with a gain control knob that adjusts the overall gain up or down. The brightness level of the image can be changed to optimize visualization of anatomic details. When an image is too bright or too dark, much diagnostic information is lost (Figures 9-1 and 9-2). Because tissue characteristics vary from patient to patient, penetration of sound waves at different depths may vary, so the gain at different depths may be adjusted. This is done using the TGC controls—a set of sliders on the instrument control panel (Figures 9-3 and 9-4). A uniform scale across the brightness values should be sought.

Attenuation

Attenuation of ultrasound waves is affected by the medium through which the sound waves pass. Virtually no pulses pass through gas. This is why there must be a coupling agent applied between the transducer face and the patient's skin. For several reasons, ultrasound waves lose intensity as they pass through tissues. The pressure waves gradually diverge from the central beam, they are scattered by reflection from small structures within the tissue, and part of the sound energy is absorbed within tissues. Some tissues, such as bone, strongly attenuate sound waves. The thicker the tissues through which sound waves must pass before arriving at the target, the more the attenuation, and the greater the difficultly in retrieving good information from the echoes. Because of attenuation, obstetrical ultrasound imaging is greatly affected by patient obesity. In patients with a thick, dense abdominal wall, image quality is greatly reduced. In such patients, attention to equipment controls and scanning technique is essential.

Focus

As stated, a linear array transducer makes an ultrasound beam by firing a row of crystals placed along the surface of the probe. When adjacent crystals fire, the pressure waves reinforce one another by a process called *constructive*

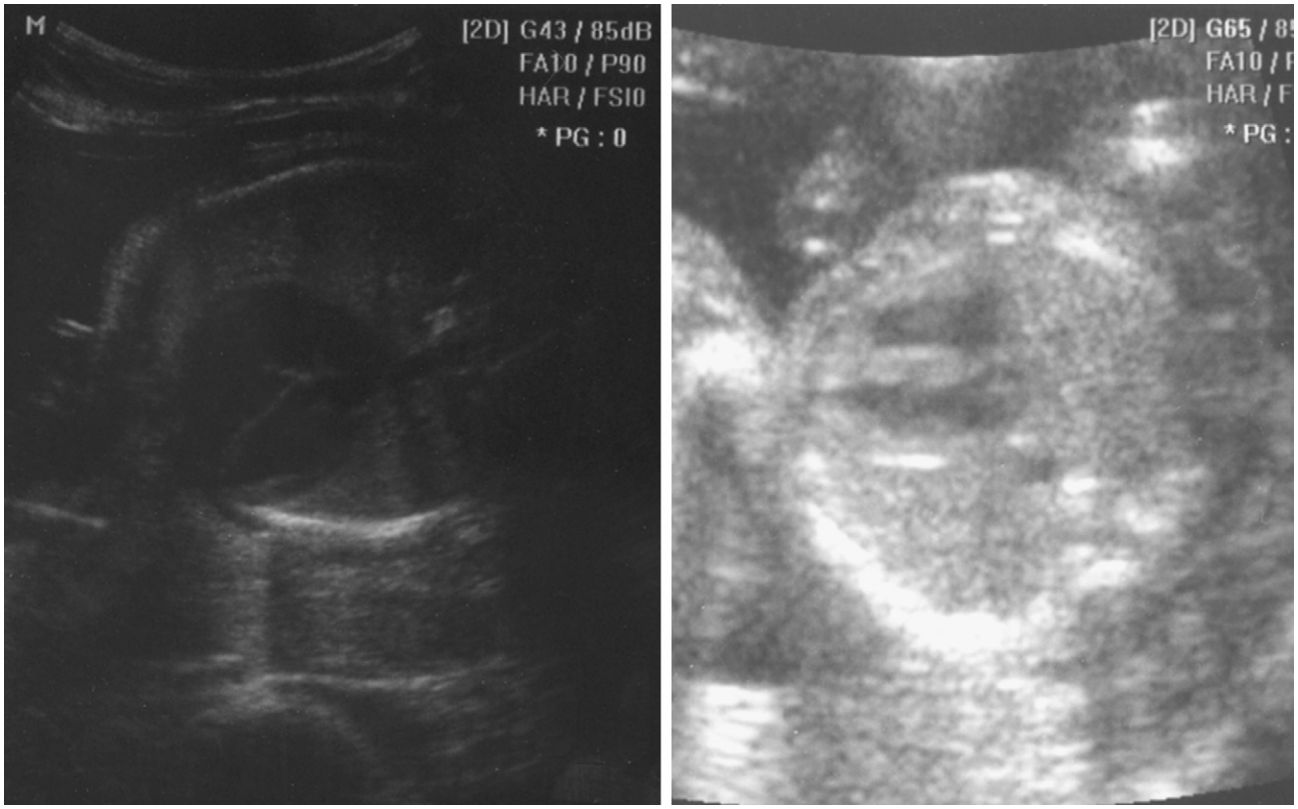

FIGURE 9-2. In the image on the left, the overall gain is too low, yielding a dark image. The image on the right has too much gain. In both cases, diagnostic detail is lost.

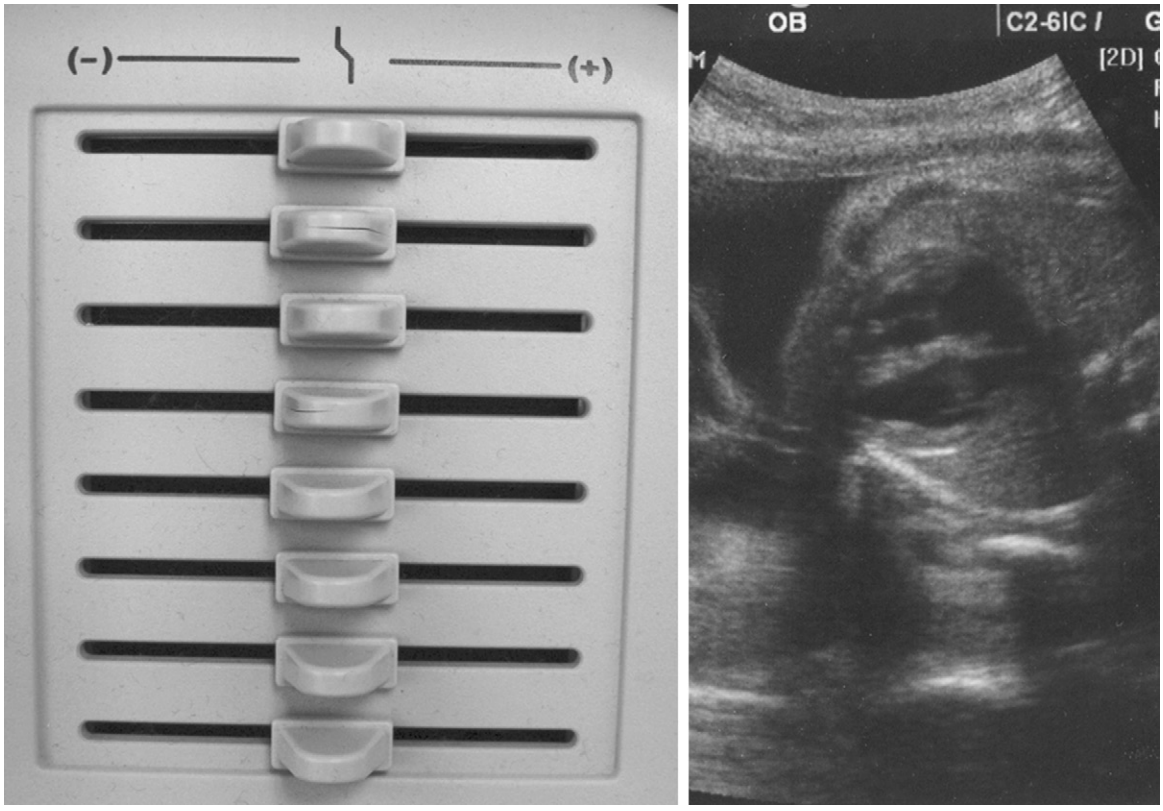

FIGURE 9-3. The photograph on the left shows the slide bars comprising the time-gain compensation controls. In this case, the fact they are lined up in the center indicates that no adjustment for different depths was needed.

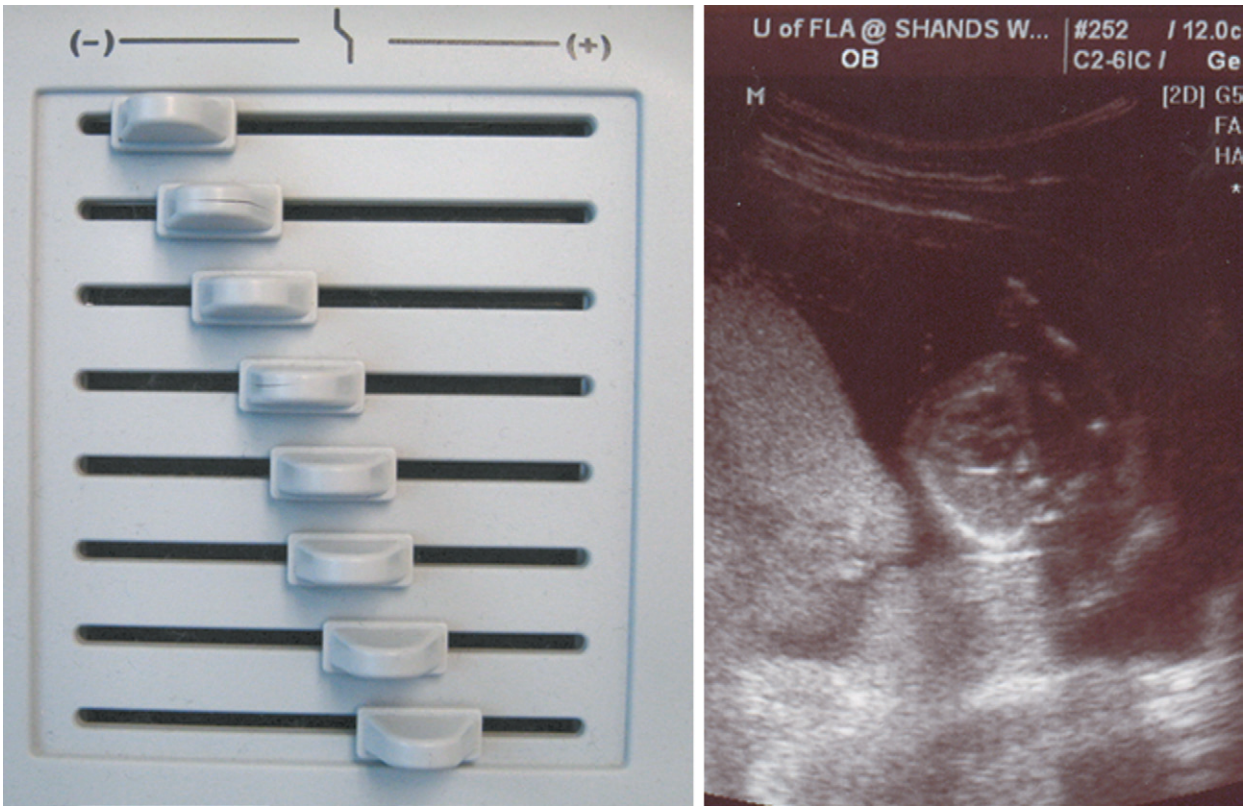

FIGURE 9-4. Incorrect time-gain compensation settings. The slide bars are inappropriately shifted to the left in the near field, making the corresponding area of the image too dark.

interference. This phenomenon creates the central ultrasound beam that extends out from the probe. Electronic control of the timing and order that crystals are activated can work to focus this beam at a certain depth within the tissues. Image resolution is optimal when the structure of interest lies within this zone of optimal focus (Figure 9-5). Using the focus control on the machine console, the user can adjust the depth of this zone for best focus. Many machines allow the operator to set multiple focal zones. With this setting, the computer successively focuses at different depths. It then stores echo information from each zone in turn while filtering echoes from outside the zone, finally displaying the collated information. This can improve clarity over a wider depth range, but at the cost of higher sound exposure, and, more importantly, an appreciably slower frame rate. The focal depths are indicated by small triangles or arrows at the edge of the screen (Figure 9-6). Many sonographers fail to note and adjust the focal depth—an oversight that significantly decreases the quality of images.

Depth and Zoom

Structures of interest vary in depth from the skin surface. When scanning, you should strive to demonstrate important structures without filling the screen with irrelevant material. Extraneous structures at the bottom of the image can be deleted by simply adjusting the depth of insonation. The zoom control is a little more sophisticated because it magnifies a box within the image rather than just removing information from the bottom of the image (Figures 9-7 and 9-8).

Proper depth and zoom are important for several reasons. First, eliminating unnecessary clutter draws the sonographer's attention to important detail within the scanned area. It also makes pertinent detail stand out in the stored images. Decreasing the size of the scanned area allows a higher frame rate and resolution.

Harmonic Imaging

Many high-quality ultrasound machines now have a feature that is called *tissue harmonic imaging*. With this modality, a standard frequency (e.g., 3 MHz) is transmitted and propagated in the usual manner. Because a relatively low frequency wave is emitted, good penetration is preserved. However, in the receive part of the cycle, the ultrasound machine listens for the reflection of the first harmonic wave (e.g., 6 MHz). This higher frequency wave only has to travel one direction; thus, some of the resolution benefit of high-frequency scanning is retained. This process also reduces noise in the image by removing various forms of artifact, making cystic structures appear free of echoes (Figure 9-9). Harmonic imaging often significantly improves image quality and should be used liberally when it is available.

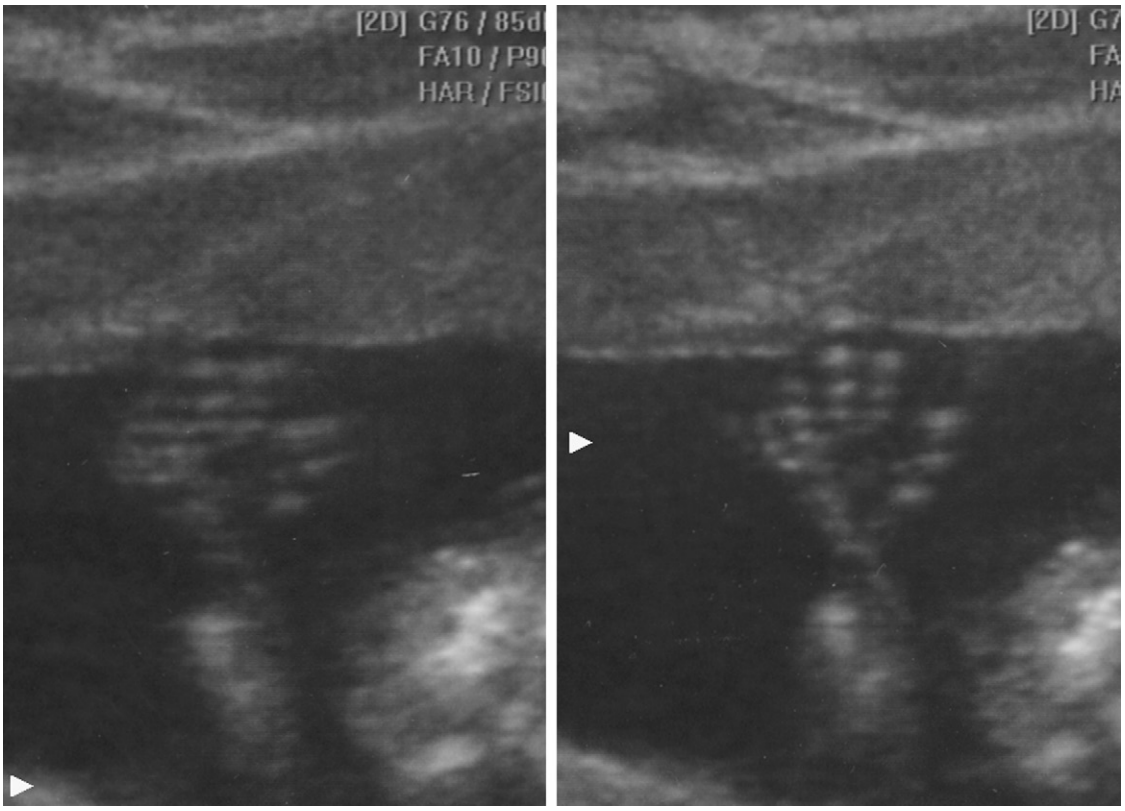

FIGURE 9-5. In the image on the left, the focus was set too low (indicated by the *triangle* on the left), whereas it is at the appropriate level in the image on the right.

FIGURE 9-6. For this illustration, four focal zones were selected (*triangles* on the left of the image). This setting slowed the frame rate from 35 frames per second with one focal zone to a very noticeable 9 frames per second.

FIGURE 9-7. Ultrasound image before zoom is applied. The area within the box will be expanded to fill the entire screen.

SPECIAL ULTRASOUND MODALIES

M-Mode

For most obstetrical applications, the familiar two-dimensional (2-D) gray-scale real-time ultrasound is used. This is formally known as B-mode ultrasound. Another ultrasound modality that is available on most machines is referred to as *M-mode* (meaning "motion mode"). M-mode ultrasound shows changes along a single ultrasound beam over time. The depth of the echo-producing structures is shown on the y-axis, and time is shown on the x-axis. It is useful for documenting the presence of fetal cardiac activity (Figure 9-10) and can be valuable for specialized echocardiography applications.

Color and Pulse-Wave Doppler

Over the past 15 years, Doppler ultrasound imaging has assumed a key role in obstetrics. With this modality, the ultrasound machine detects shifts in the frequency of echoes returning from a specific location in the image. This frequency shift—the Doppler shift—is caused by motion of the insonated material toward or away from the transducer. Doppler ultrasound is primarily used to demonstrate the presence, direction, and velocity of blood flow.

FIGURE 9-8. Appearance after zoom is applied. Compared with Figure 9-7, the cardiac structures are more easily seen. Additionally, because a smaller area is being scanned, the frame rate increased from 25 to 58 frames per second.

The machine displays moving blood as color superimposed on the 2-D gray-scale image. By convention, flow toward the ultrasound transducer is displayed in red and flow away in blue. Pulse-wave Doppler measures the relative velocity of flow within a designated gate inside a vessel. For most obstetrical applications, absolute blood flow velocity is not required. Rather, pulse-wave Doppler is used to generate a waveform showing relative flow velocity over a cardiac cycle. These flow velocity waveforms are primarily used to assess downstream resistance in the vessel being interrogated. This technique has many uses in obstetrics—most importantly as a way to assess placental function. This is done by interrogating the flow within the umbilical artery (Figure 9-11). For some applications, such as fetal echocardiography, the absolute velocity is measured. To do this, the angle of insonation must be very nearly in line with the direction of blood flow. In screening for fetal anemia, the absolute velocity of flow in the middle cerebral artery of the fetus is measured with pulse-wave Doppler ultrasound. To give meaningful results, it is absolutely essential that the Doppler angle (theta) is zero (Figure 9-12).

Three-Dimensional Ultrasound

High-performance computers have allowed the development of ultrasound machines and probes that can acquire, process, and display a three-dimensional (3-D) volume, as opposed to the single plane that is displayed with 2-D ultrasound. To obtain this volume, the transducer uses an internal mechanical sweep mechanism that summates contiguous 2-D planes. This volume data can either be stored

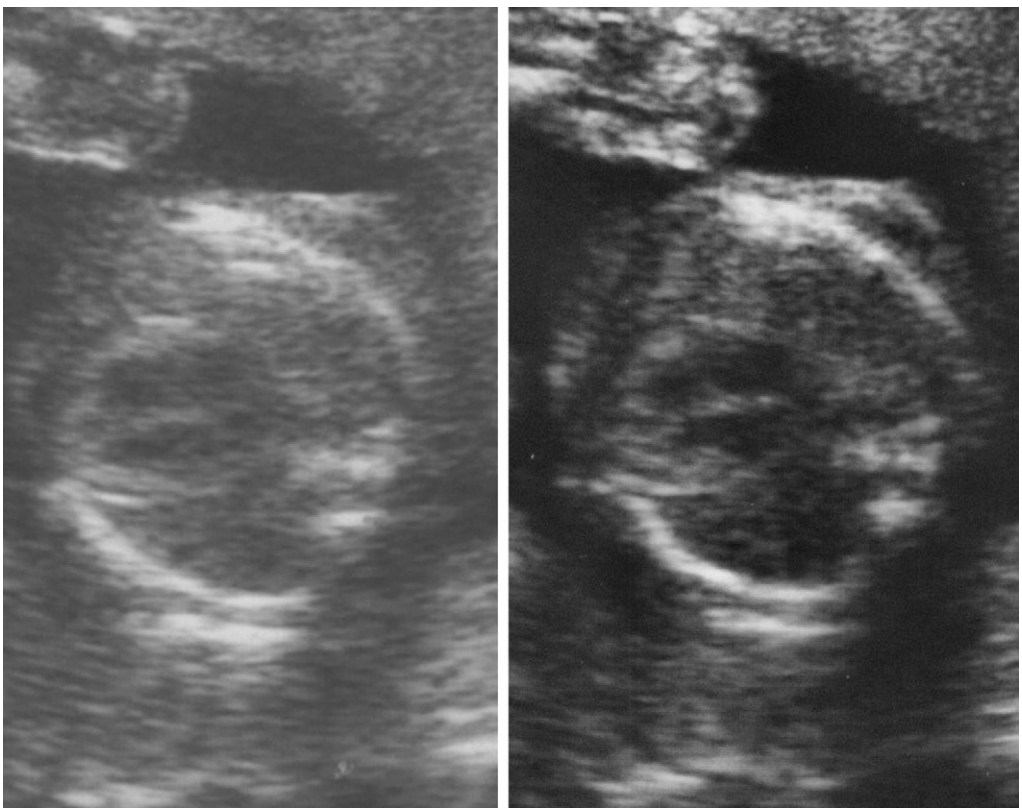

FIGURE 9-9. These figures show the difference that harmonic imaging can have in an obese patient.

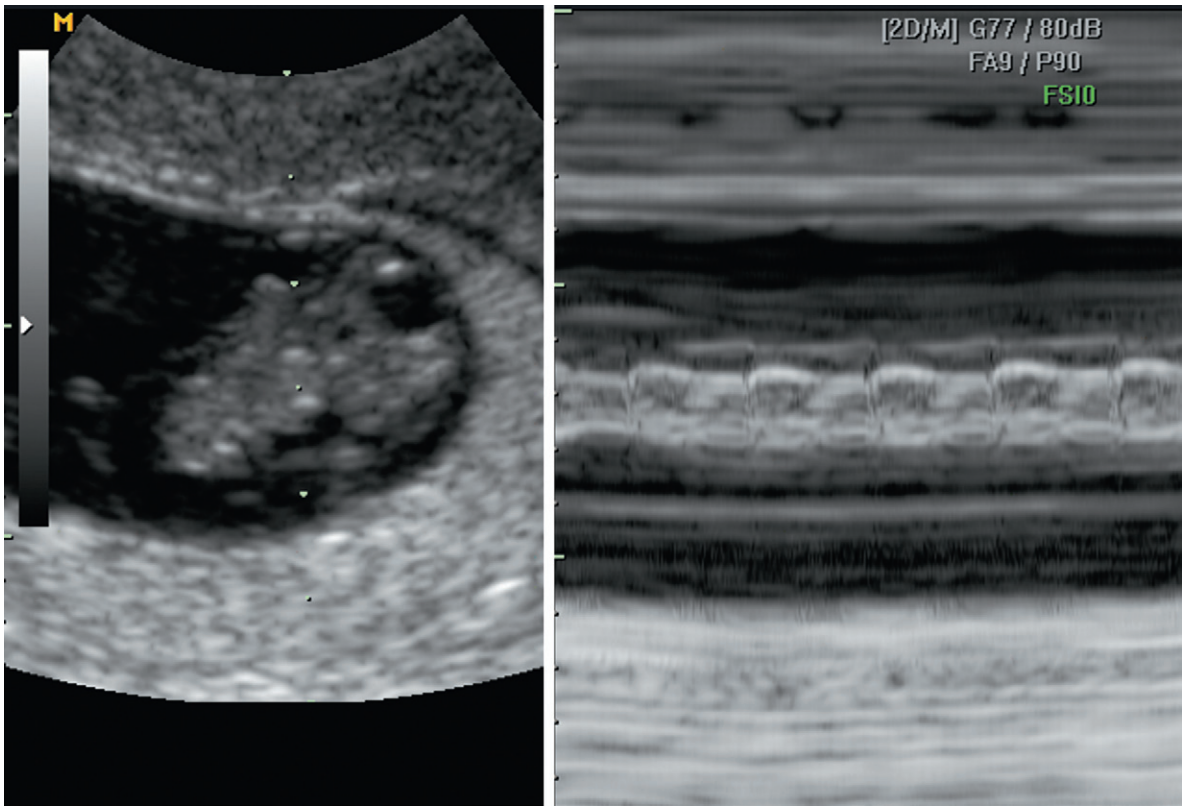

FIGURE 9-10. M-mode application in an 8-week fetus. The *row of dots* in the left panel indicates the line of information (in this case cardiac pulsations) that is being displayed over time in the right panel. Note the prominent brain vesicle in the fetal head.

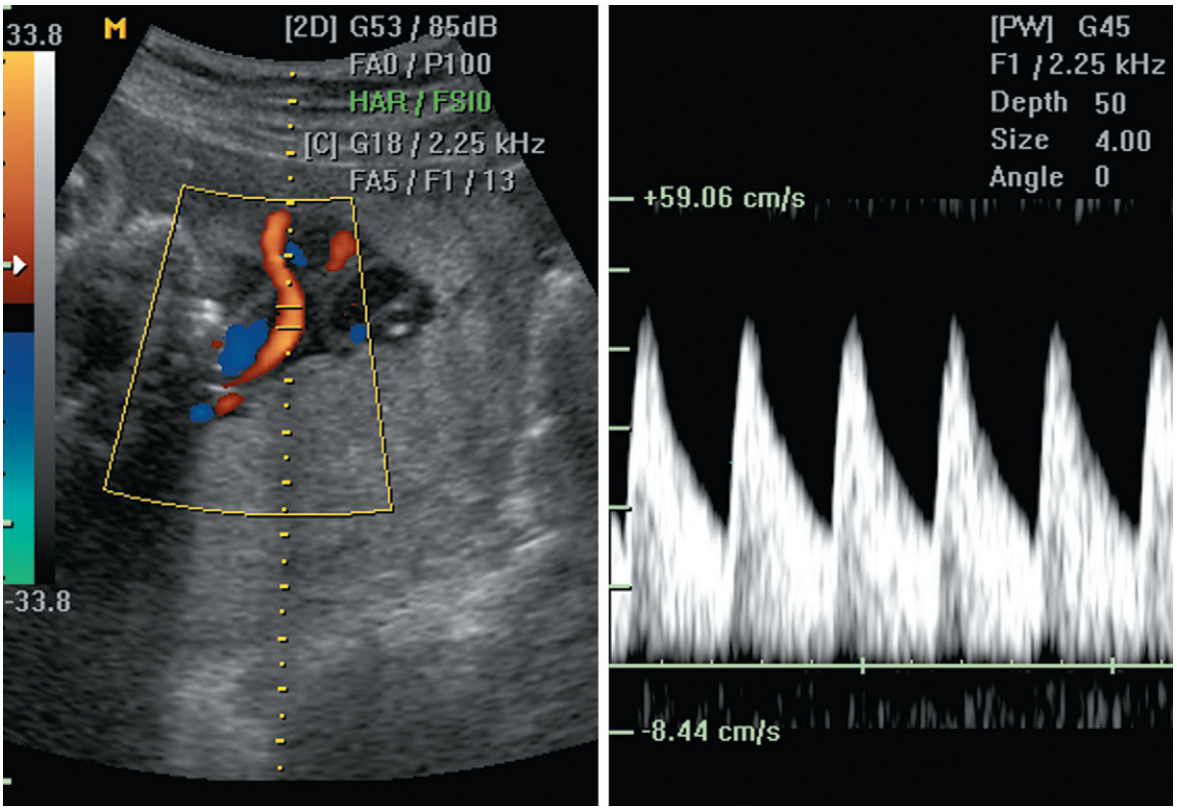

FIGURE 9-11. Color and spectral Doppler evaluation of the umbilical artery. In the left panel, the coiling arteries and vein are shown. Red indicates flow toward the transducer and blue is flow away. The sample gate for the pulse Doppler is superimposed. On the right is the result of the pulse Doppler, depicting a normal flow velocity waveform.

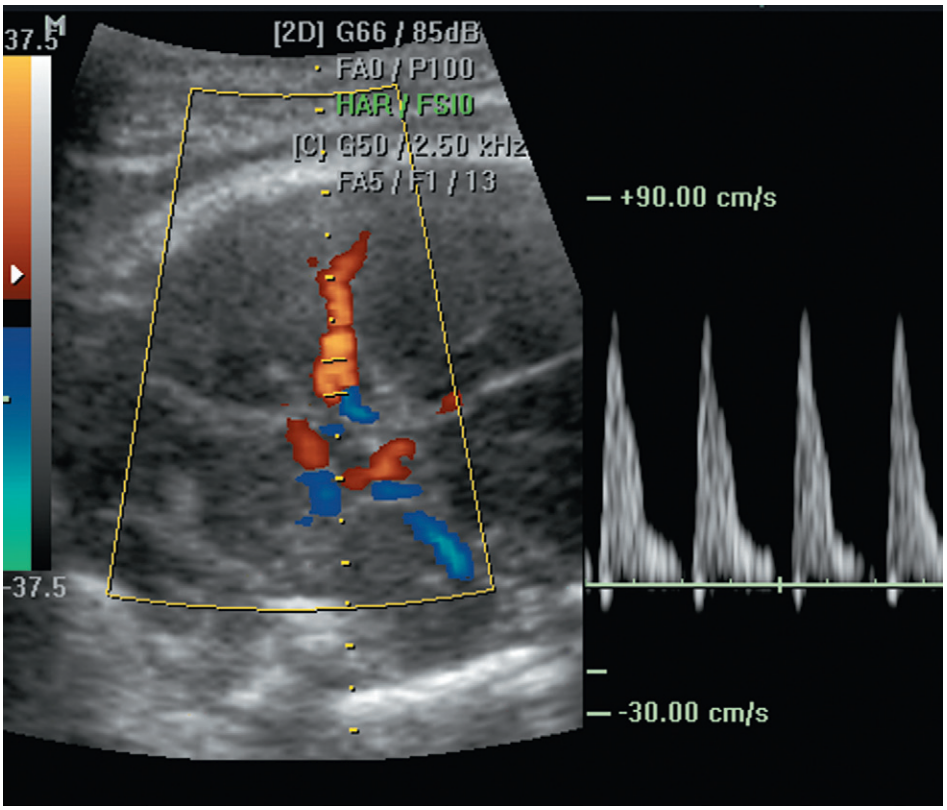

FIGURE 9-12. Color and spectral Doppler interrogation of the middle cerebral artery. Abnormally high peak velocity is an indicator of moderate to severe fetal anemia. Because the actual velocity is being measured, the angle of insonation has to line up with the vessel.

for analysis or updated and displayed on a continuous basis. Adding a real-time updating of a rendered image is commonly referred to as four-dimensional ultrasound.

Three-dimensional ultrasound may be useful for diagnosing certain birth defects. Information from an acquired volume may be processed in such a way that the fetal surface is displayed in a lifelike manner. Surface abnormalities, such as facial cleft, can be well demonstrated with this approach.[1] In addition to being a possible aid in the diagnosis of these and other abnormalities that distort the surface of the fetus, 3-D images may be more readily understood by patients and other professionals who will participate in care of the baby. Software in 3-D ultrasound machines can be used to manipulate stored volume data off-line to show any desired plane through the scanned area. Some of these planes may be very difficult to obtain with standard 2-D imaging. For example, manipulating the 3-D ultrasound volume data can generate an ideal plane for measuring the first-trimester nuchal translucency or for visualizing the nasal bone.[2] Despite these demonstrated capabilities of 3-D ultrasound, there is no proof of an advantage of this technology over standard 2-D imaging for prenatal diagnosis. A 2009 American College of Obstetricians and Gynecologists (ACOG) practice bulletin states that **"three dimensional ultrasonography may be helpful in diagnosis as an adjunct to, but not a replacement for, two dimensional ultrasonography."**[3]

Another suggested use of a stored 3-D volume data set is that it could allow evaluation of a fetus by an expert who is not physically present at the time and place in which the scan is performed.[4] Presumably, the initial volume data set could be obtained by a less-expert examiner, who would perhaps not have sufficient skill to obtain images of the 2-D planes that are required. The potential for this remote approach to ultrasound interpretation has yet to be realized.

Another promising feature of 3-D ultrasound is its ability to calculate tissue and fluid volumes. For example, lung volume measurements have been used to try to better predict pulmonary hypoplasia.[5] In a novel application, Lee and colleagues added measurement of the fetal thigh volume to an equation to improve fetal weight estimation.[6] Although they raise intriguing possibilities, these and similar uses of 3-D ultrasound have not yet found their way into widespread clinical use.

SCANNING TECHNIQUE

Orientation

Every effort should be made to perform the scan with the sonographer and the patient in a standard position. In most settings, the ultrasound machine and the sonographer are on the patient's right, with the sonographer comfortably seated facing the head of the patient. The probe is held in such a way that the image on the screen is properly oriented. By convention, the probe surface is shown at the top of the screen. For sagittal views, the right of the screen corresponds to the inferior aspect of the patient (Figure

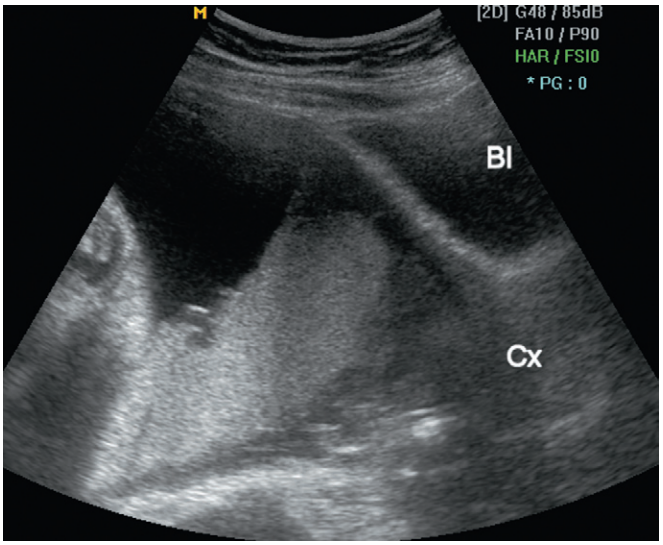

FIGURE 9-13. Transabdominal sagittal view of the lower uterus. The maternal bladder *(Bl)* and location of the cervix *(Cx)* are labeled. By convention, the right side of the ultrasound screen corresponds to the inferior aspect of the patient. Note that placenta previa is present.

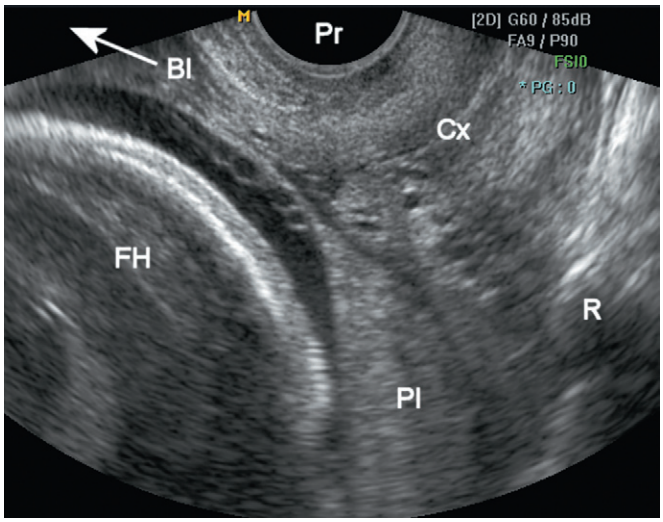

FIGURE 9-14. Transvaginal sagittal view showing proper orientation. The left of the screen is "up" on the patient, that is, toward the bladder *(Bl)*. The probe tip *(Pr)*, fetal head *(FH)*, cervix *(Cx)*, placenta *(Pl)*, and rectum *(R)* are labeled. Note how transvaginal ultrasound provides the ultimate "window," showing very clear views of structures that are close to the vaginal apex. Also note the presence of vasa previa.

9-13). For transverse views, the patient's right is shown on the left of the screen. With transvaginal ultrasound, transverse views also show the patient's right side to the left of the screen. In transvaginal sagittal views, "up" is to the left of the screen (i.e., toward the bladder), and "down" (toward the sacrum) is to the right of the screen (Figure 9-14). Ultrasound transducers have a notch or mark of some type that demarcates the side of the probe that will correspond to the left side of the monitor. Thus, with transabdominal work, this mark would be toward the patient's head for sagittal views and toward the patient's right for transverse views. With transvaginal scanning, the mark is up for sagittal views and to the patient's right for transverse views. Thus, in going from sagittal to transverse, the probe is always rotated counterclockwise, and clockwise to move from transverse to sagittal.

If the sonographer sits or stands on the wrong side of the patient or holds the probe backward, standard orientation of the images cannot be maintained. This is clearly unacceptable for diagnostic and documentation purposes and for performance of invasive procedures. Also, a casual approach to probe orientation will prevent the sonographer from developing the hand-eye coordination needed to quickly steer the probe. With improper probe orientation, the principle probe movements—sliding, rotation, and angulation—will not give predictable results as the sonographer tries to produce the desired image. If the sonographer must scan from the patient's left side, the same considerations for a standardized approach should be maintained, especially with regard to the orientation of the image on the ultrasound screen.

To establish the position of the fetus, the orientation of the probe must obviously be correct. This is important not only when deciding whether the fetus is cephalic or breech, but also when determining the right and left side of the fetus. For example, when the image shows the fetal spine to the right side of the uterus, the fetal left will be up in a cephalic presentation and down with a breech. It is important to mentally go through this orienting exercise at the start of each fetal examination, and not to "cheat" and define left as the side of the stomach or apex of the heart, which could result in missing disorders of sidedness, such as situs inversus (Figure 9-15).

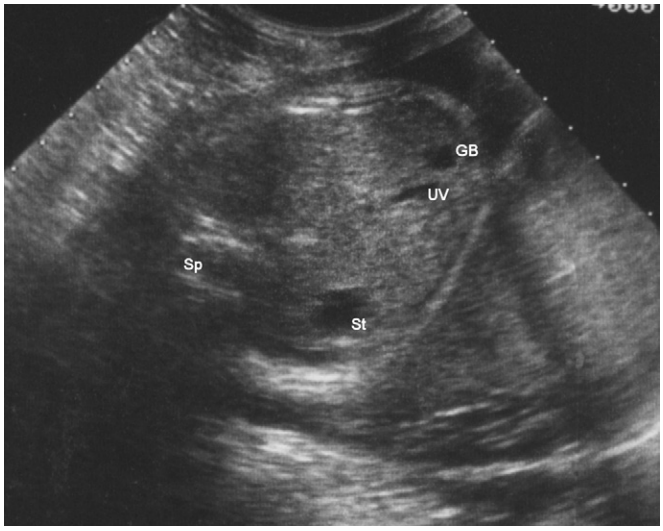

FIGURE 9-15. This view would be normal if the fetus were in a breech presentation. Because the fetus is in a cephalic presentation, with the spine *(Sp)* to the maternal right, the right side of the fetus is down on the image. This indicates that situs inversus is present. You cannot decide which side is right or left based on the sidedness of the viscera. The stomach *(St)*, umbilical vein *(UV)*, and gallbladder *(GB)* are also labeled.

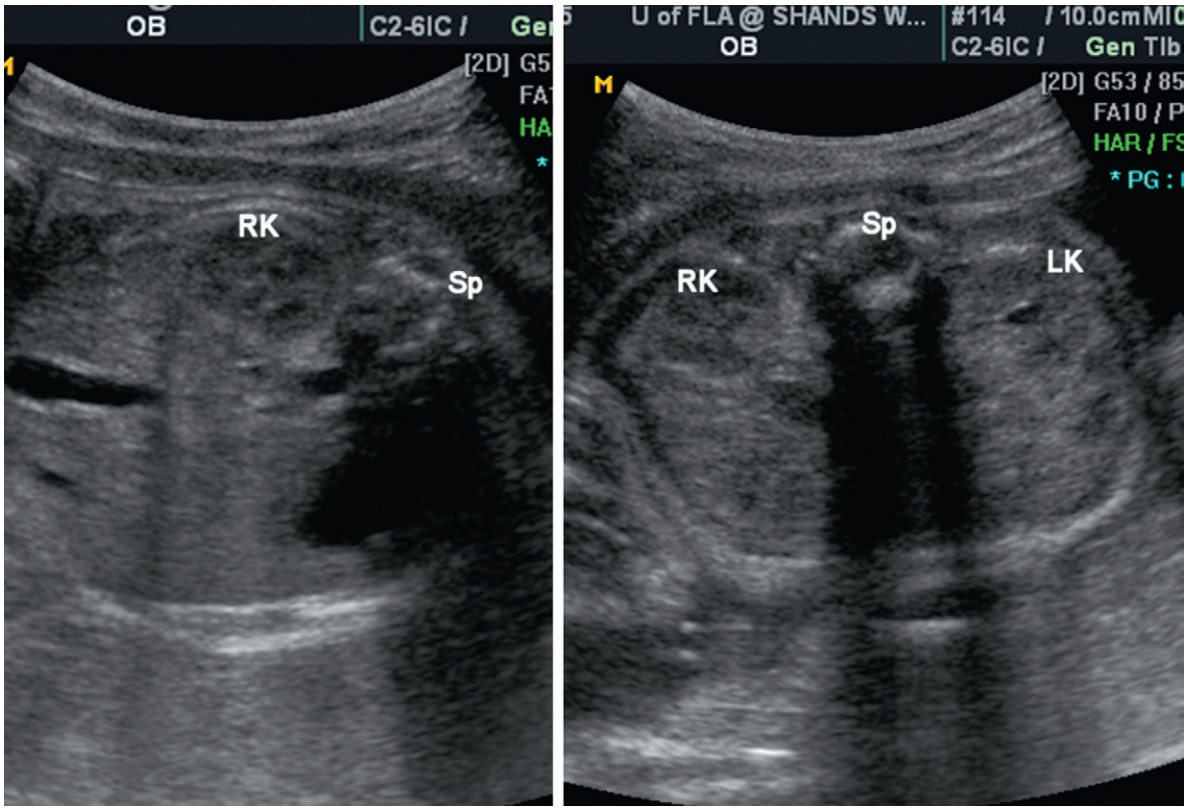

FIGURE 9-16. In the image to the left, shadowing by the spine precludes visualization of the left kidney. By sliding the transducer to a different location on the maternal abdominal wall, a more favorable angle of insonation is possible. The spine *(Sp)*, right kidney *(RK)*, and left kidney *(LK)* are denoted.

Angle of Insonation

Novice sonographers often try to look straight down on a structure to be visualized, as if looking down into a room from a skylight. Actually, the uterus can be thought of as a glass house, and the fetus can be looked at from a wide variety of angles. For many structures, there is a best angle with which to view the structure. For example, a lateral view of the fetus may result in shadowing of one kidney by the spine (Figure 9-16). Sliding the transducer across the mother's abdomen to change the angle of insonation by 90 degrees allows a posterior-anterior view that avoids the spine and shows the kidneys much more clearly. Sometimes, significant pressure with the transducer is needed to get the probe into position for optimal visualization. If the fetal position precludes clear visualization of a structure, a good strategy is to move forward with the examination, then come back to the troublesome area. The fetus will often have moved in such a way that adequate views can be obtained.

Using Natural Windows

As previously noted, increasing the power of ultrasound impulses can overcome some of the effects of attenuation in maternal tissues. Although it is tempting to use higher-power settings for obese patients, other methods should be attempted first. As a starting point, the proper probe frequency and gain setting should be employed. **Even more effective, however, is to avoid attenuation altogether by scanning though one of the natural "windows" in the maternal abdominal wall.** The abdominal wall thickness in obese women is substantially less near the umbilicus and in the suprapubic area. To a lesser extent, thickness is also decreased lateral to the central pannus. Using these windows can often improve the quality of images dramatically (Figure 9-17). Of course, in early pregnancy, or when structures of interest are low in the pelvis, the problem of attenuation is reduced considerably by the use of an endovaginal probe (see Figure 9-14). The reduction of attenuation with transvaginal ultrasound allows the use of a higher frequency probe, resulting in significantly improved resolution. Another natural window is amniotic fluid. Scanning through amniotic fluid improves the image quality below or deep to the amniotic fluid. This is especially true for imaging the surface of the fetus.

FIRST-TRIMESTER ULTRASOUND

Transvaginal ultrasound is almost always superior to transabdominal ultrasound for evaluation of the very early pregnancy and fetus. The fact that the uterus is still within the pelvis makes the developing pregnancy accessible to visualization with the vaginal probe. Because the distance between the probe and pregnancy structures is often just a few centimeters, there is very little attenuation of sound waves, and high-frequency probes may be used. As previously noted, this allows better resolution of detail. Although basic information can be obtained transabdominally (e.g., the presence and size of a gestational sac and presence of

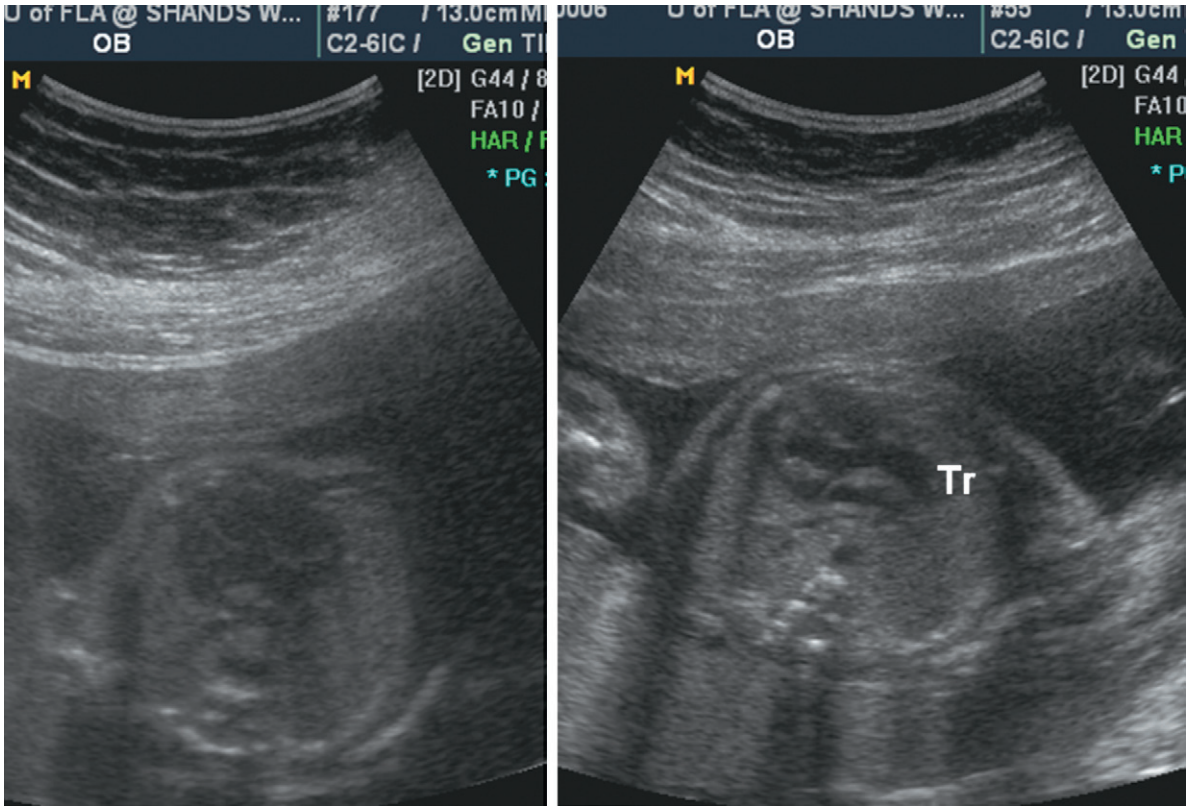

FIGURE 9-17. In the panel on the left, the scan is through the pannus of the woman's abdominal wall. By moving the probe into the thinner area near the maternal umbilicus, the resolution improved dramatically. A similar result can be obtained when scanning below the pannus, in the suprapubic area. Of course, when an object of interest is in the maternal pelvis, transvaginal ultrasound provides an even better window (see Figure 9-14). This fetus has truncus arteriosus *(Tr)*.

fetal cardiac activity), important findings may be missed if transvaginal ultrasound is not performed. In general, structures are visible 1 week earlier with transvaginal ultrasound. At about 12 weeks' gestation, the uterus has grown enough, and the fetus is far enough away from the transducer, that images through the desired fetal plane may be difficult to obtain with transvaginal ultrasound. In these cases, transabdominal ultrasound may give better views, so it should be used instead of or in conjunction with transvaginal ultrasound. The transvaginal probe can be rotated, and there is quite a lot of freedom to angulate up and down, but the tip of the probe is essentially fixed at the apex of the vagina. For this reason, not all scan planes of the fetus and uterine contents are possible. Because of the need for a precise midsagittal plane for the nuchal translucency measurement as part of the first-trimester aneuploidy screen, this scan is usually done transabdominally.

First-Trimester Normal Findings

Knowledge of the time at which embryonic structures normally appear is important for identifying pathologic pregnancies. For the reasons noted earlier, it will be assumed that transvaginal ultrasound is being used for this discussion.

The gestational sac can usually be seen at 4 weeks, the yolk sac at 5 weeks (Figure 9-18), and the fetal pole with cardiac activity by 6 weeks. Cardiac activity can be seen simultaneously with the appearance of a fetal pole as a pulsation at the lateral aspect of the yolk sac. Starting at

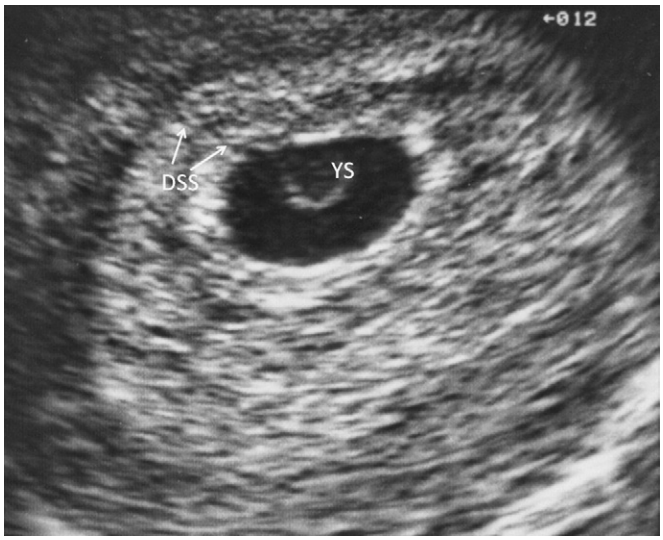

FIGURE 9-18. This image shows a normal yolk sac *(YS)* and the double sac sign *(DSS)*.

7 weeks, the embryo has grown to the point that recognizable features, such as a cephalic pole, can be seen. After this time, a prominent midline brain vesicle, the earliest sonographic manifestation of the five vesicles from which arise the parts of the brain (prosencephalon, mesencephalon, rhombencephalon, telencephalon, and diencephalon)

can be seen (see Figure 9-10). The cerebral falx can be seen at 9 weeks, and the appearance and disappearance of physiologic gut herniation are noted between 8 and 11 weeks (Figure 9-19). Normally, the bowel is seen to lie within the umbilical cord and does not float freely. Obviously, the diagnosis of an abdominal wall defect should be made with great caution at this age. The stomach can consistently be seen by 11 weeks. If conditions are favorable, it is often possible to also visualize the bladder and kidneys at 11 weeks. Using color Doppler, the two umbilical arteries can often be identified at about 12 weeks as they course around the bladder. The fetal heart rate is initially quite slow, averaging 100 beats per minute at 5 to 6 weeks,[7] then it increases steadily to a mean peak of 175 beats per minute at 9 weeks.[8] When the fetal position is favorable, transvaginal ultrasound has the potential for giving good views of the fetal cardiac anatomy in most patients at 13 weeks.[9] Until 13 to 16 weeks' gestation, the amnion has not fused to the chorion and is seen as a separate membrane (see Figure 9-19). Until 12 weeks, the crown-rump length (CRL) should be measured. Care should be taken to measure the full length of the fetus. The gestational age can be significantly underestimated if an oblique plane is taken (Figure 9-20) or if the fetus is in a flexed position.

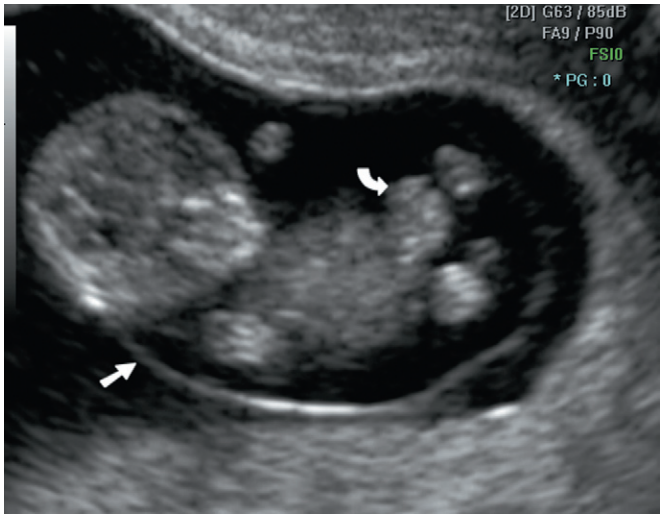

FIGURE 9-19. Nine-week fetus showing the physiologic gut herniation *(curved arrow)*. Note also how the amnion *(straight arrow)* has not yet fused to the chorion at the uterine wall.

First-Trimester Abnormal Findings

Spontaneous abortion occurs in 15% of clinically established pregnancies. **When cardiac activity has been demonstrated, the miscarriage rate is reduced to 2% to 3% in asymptomatic low-risk women.**[10] It is important to note, however, that in some groups at very high risk for miscarriage, such as women over the age of 35 years who are undergoing infertility treatments, early visualization of cardiac activity does not provide quite as much

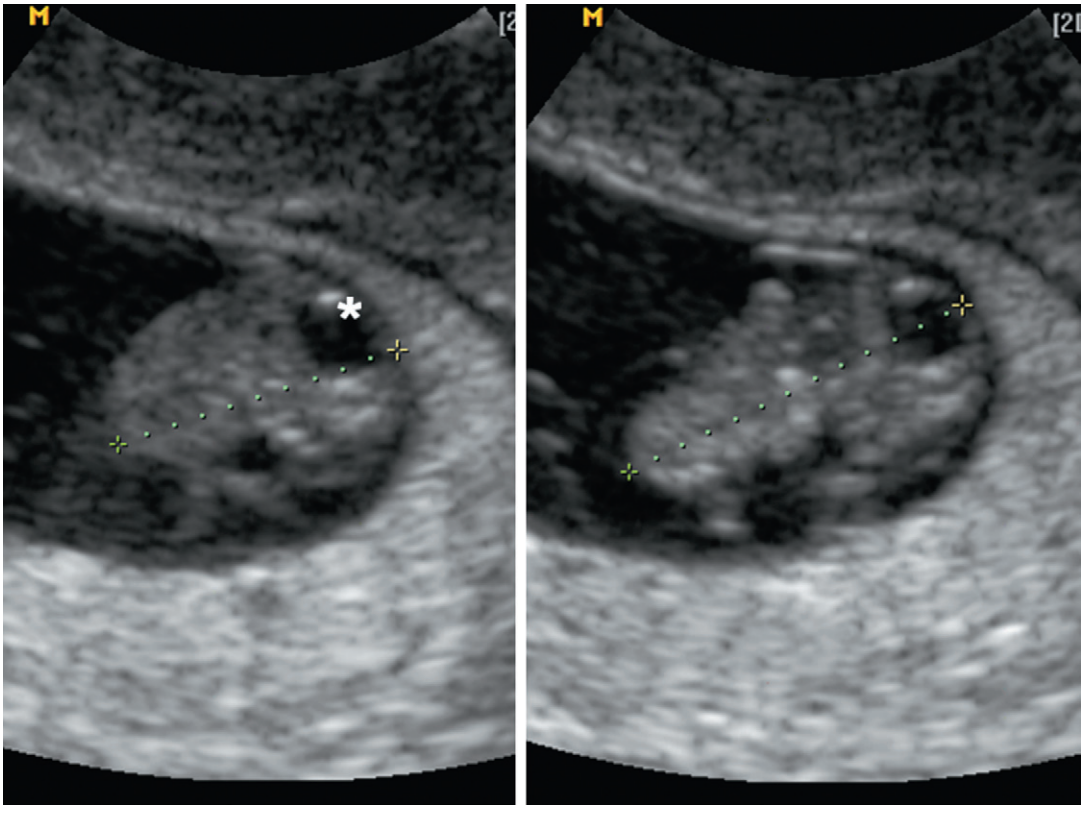

FIGURE 9-20. In the image on the left, the fetus is cut obliquely, and the CRL is inappropriately short. It is measured correctly on the right. There was a difference of 5 days in the calculated gestational age from these two measurements. The normal brain vesicle *(*)* is again denoted.

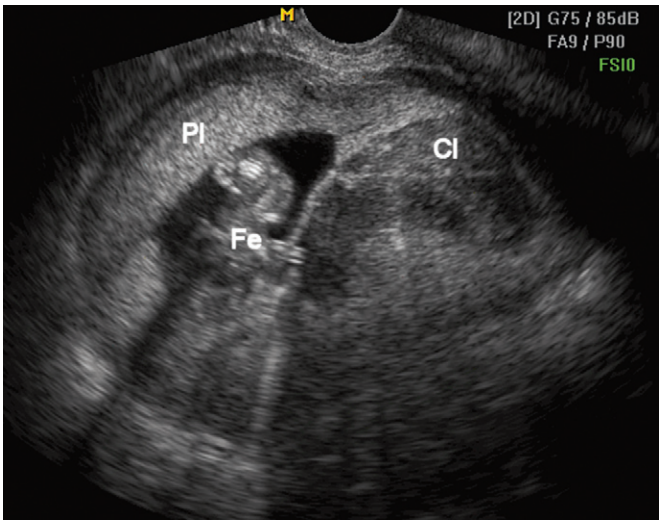

FIGURE 9-21. This patient presented with vaginal bleeding. A subchorionic clot *(Cl)* was present in the lower uterine segment. This patient carried the pregnancy successfully. The fetus *(Fe)* and placenta *(Pl)* are shown.

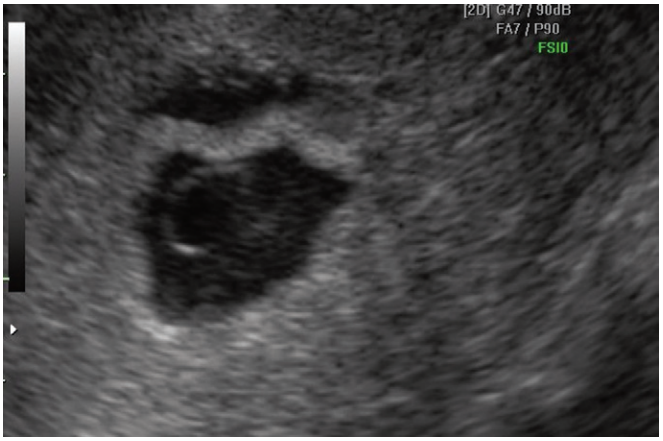

FIGURE 9-22. Irregular gestational sac from an anembryonic gestation.

reassurance. In one study involving such women, the miscarriage rate in asymptomatic women was still 16% after a heartbeat was documented.[11] In younger women who present with bleeding, only 5% miscarry if the ultrasound is normal and shows a live embryo.[12] If there is an intrauterine clot present (Figure 9-21), coexistent with an otherwise normal appearing pregnancy, the miscarriage rate is 15%.[12]

In most pregnancies destined to abort, the embryo does not develop, and ultrasound shows an empty gestational sac (Figure 9-22). Such a pregnancy is termed an *anembryonic gestation*. When there is no yolk sac seen and the mean sac diameter is at least 13 mm or there is no embryo seen with mean sac diameter of at least 20 mm, it is almost certain that the pregnancy is nonviable.[3,13] The absence of cardiac activity when the fetal pole measures greater than 5 mm reliably diagnoses embryonic death.[14] Other findings that are somewhat predictive of spontaneous abortion include a yolk sac that is unusually large or small for gestational age[15] (Figure 9-23), a relatively small gestational

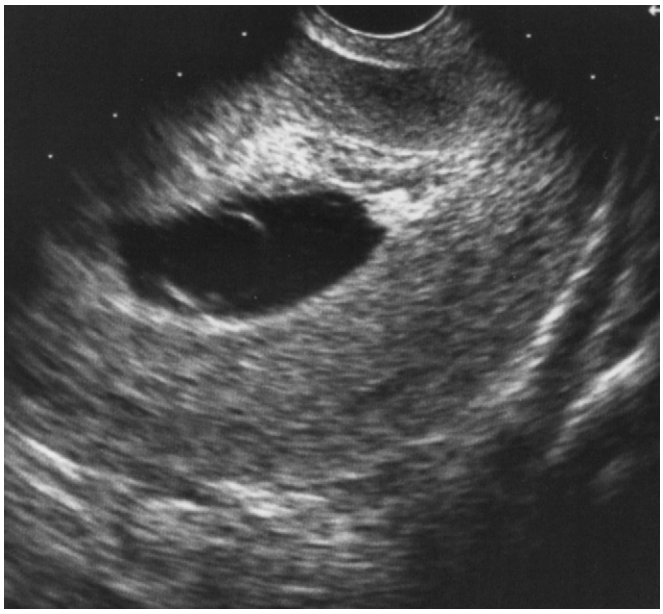

FIGURE 9-23. Compared with Figure 9-18, the yolk sac in this image is relatively large for gestational age. An embryo was never seen with this pregnancy.

sac (mean sac diameter/CRL difference <5 mm),[16] or fetal bradycardia.[7] **If there are borderline findings and uterine evacuation is being considered, it is prudent to repeat the ultrasound in 1 week to be absolutely sure that a viable pregnancy is not interrupted.**[16] Although this is a trying time for the patient, there is no significant medical risk in waiting. Of course, spontaneous abortion may occur during this time. Although a quantitative human chorionic gonadotropin value that does not show an appropriate rise indicates a likely abnormal pregnancy, a decision to terminate a pregnancy is most often based on the failure of development of normal findings by ultrasound.

First-trimester ultrasound findings including thick nuchal translucency, absent nasal bone, abnormally fast or slow fetal heart rate, and some structural malformations, can be very useful for predicting the risk for a chromosome abnormality.[17] The use of ultrasound for aneuploidy screening is discussed in detail in Chapter 11.

SECOND- AND THIRD-TRIMESTER ULTRASOUND

Types of Examinations

The American Institute of Ultrasound in Medicine (AIUM), in conjunction with the ACOG and the American College of Radiology, have defined a set of criteria for standard obstetrical ultrasound examinations performed in the second and third trimesters.[18] Components of a standard obstetrical examination are shown in Table 9-1. Components of the fetal anatomic survey are listed in Chapter 11. A complete description of the AIUM guidelines can be found in the listed reference.

These guidelines recognize that not all ultrasound examinations have the same purpose. For this reason, types of fetal sonographic evaluations have been defined. Components of the first-trimester ultrasound examination

TABLE 9-1 IMAGING PARAMETERS FOR A STANDARD FETAL EXAMINATION

1. Fetal cardiac activity
2. Fetal number
   a. Chorionicity, amnionicity
   b. Comparison of fetal sizes
   c. Estimation of amniotic fluid volume
   d. Fetal genitalia
3. Presentation
4. Qualitative or semiquantitative estimate of amniotic fluid volume
5. Placental location, appearance, and relationship to the internal os
6. Umbilical cord visualized and number of vessels determined, if possible
7. Gestational age assessment
8. Fetal measurements
   a. Crown-rump length in the first trimester
   b. Biparietal diameter
   c. Head circumference
   d. Abdominal circumference
   e. Femur length
9. Fetal weight estimation
10. Maternal anatomy
    a. Uterus
    b. Adnexal structures
    c. Cervix
11. Fetal anatomic survey

were described previously. A *standard* second- or third-trimester examination, as defined in Table 9-1, can be performed by any appropriately qualified sonographer. It is recognized that certain scans should be performed by individuals with special training in the recognition and management of unusual or serious fetal conditions. These scans are referred as *specialized* examinations. This category of examination is considered more complex than the complete standard examinations performed in the course of routine pregnancy care. This designation (and the appropriate billing code) is intended to be used for referral practices with special expertise in the identification of, and counseling about, fetal anomalies.

Another examination category is the *limited* examination. Limited ultrasound examinations are appropriate when needed to obtain specific information about the pregnancy, but only when performed by a trained examiner, and when a complete standard examination has been previously performed. The importance of restricting limited examinations to those cases in which a complete examination has previously been performed should be self-evident. Consider the consequences if a brief ultrasound is performed to answer a question such as "what is the fetal presentation?" or "is placenta previa present?" and critically important information, such as the fact that the fetus has a severe malformation, is missed. Unfortunately, it is all too common for practitioners to perform limited examinations in a manner that is not consistent with good medical practice. For example, in some clinics, practitioners perform an ultrasound at the first prenatal visit to document viability, but without measuring the fetus or recording the results of the examination. Such a practice can create problems later in pregnancy when the gestational age is in doubt.

All the aspects of the standard obstetrical examination listed in Table 9-1 are important for clinical management and should not be neglected. For example, it is obvious that there could be serious consequences if an ultrasound fails to reveal the presence of placenta previa, multiple gestation, or an ovarian tumor. The diagnosis and management of these and other conditions are discussed in detail elsewhere in this book, but a brief description of the importance of the components of the standard ultrasound examination to screen for these conditions will be given here.

Qualifications for Interpreting Diagnostic Ultrasound Examinations

The AIUM recently published guidelines on the training and experience needed for physicians to perform or interpret ultrasound examinations. In brief, these guidelines recommend that licensed physicians have completed an equivalent of 3 months training dedicated to ultrasound in the context of an approved residency, fellowship, or other postgraduate training. In the absence of a formal training program, physicians can qualify through having 100 American Medical Association Category I credits dedicated to diagnostic ultrasound. Along with participation in either a formal training program or by taking postgraduate courses, physicians should have been involved with the performance, evaluation, and interpretation of at least 300 appropriately supervised sonograms.[19] The full text of the guidelines are in the referenced document.

COMPONENTS OF THE EXAMINATION

Cardiac Activity

Obviously, the presence of absence of cardiac activity should be documented. As noted previously, after about 6 weeks' gestation, the diagnosis of fetal life is rarely difficult. Even though fetal death may be obvious with B-mode imaging, confirming the absence of a heart beat with color or pulse-wave Doppler is recommended. Absence of color signal in the fetal chest, contrasted with demonstration of flow in the surrounding uterine tissues, can increase the confidence that fetal death has indeed occurred. Throughout pregnancy, an abnormally fast, slow, or irregular heartbeat can be detected by visual inspection with gray-scale ultrasonography. The abnormal rate can be quantified and documented with M-mode or pulse-wave Doppler ultrasound.

Number of Fetuses

When a multiple pregnancy is diagnosed, the number of amnions and chorions should always be determined. Determination of chorionicity is most easily accomplished in early pregnancy. The presence of unlike sex twins, separate placentas, or a thick membrane dividing the sacs with a "lambda sign" all indicate the presence of two chorions. It is well-recognized that the level of fetal risk is much higher when fetuses share chorions.[20] The risk is extremely high if there is a single amnion. Monochorionic pregnancies require early referral for a specialized ultrasound. In all twin pregnancies, periodic ultrasound examinations should be performed to assess fetal growth. Twins are at significantly increased risk for growth abnormalities, and it

is not possible to assess the growth of the twins individually by abdominal palpation.

Presentation

The assessment of presentation is not merely a matter of determining whether the fetus is head down or breech. A more precise ultrasound analysis of presentation is important in certain circumstances. If a transverse lie is diagnosed, it is important to diagnose whether the fetus is back down (i.e., back toward the cervix) because this may require a vertical incision for cesarean delivery. If the patient has preterm labor or ruptured membranes, a back-up transverse lie indicates a high risk for cord prolapse. The attitude of the fetal head, especially the presence of a face presentation, can be important in assessing progress in labor. In cases in which a breech vaginal delivery is contemplated, ultrasound can show the position of the legs and feet as well as the degree of flexion of the head—all factors that can predict the safety of vaginal birth. In cases in which there is marked caput or molding in late labor, it is often difficult to determine the position of the fetal head by palpation of the cranial sutures. Under these circumstances, ultrasound can be used to readily identify fetal cranial landmarks to clarify the position of the fetal head.[21]

Amniotic Fluid Volume

Every ultrasound examination should include an assessment of the amniotic fluid volume. It is acceptable for an experienced examiner to make this determination subjectively.[18] However, to aid in communication and to provide criteria for management protocols, several semiquantitative methods have been devised. A popular method is the amniotic fluid index (AFI)—the sum of the measurements of the deepest vertical pocket of fluid in each of the uterine quadrants. The limits of the quadrants are the maternal midline and a horizontal line through the maternal umbilicus. The line between the calipers should not cross through loops of cord or fetal parts. Polyhydramnios and oligohydramnios can be defined either by an AFI outside of a fixed range (usually >25 cm and <5 cm)[22] or a value that is greater or less than the 95th or 5th percentile for gestational age.[23] A simpler semiquantitative method is to diagnose polyhydramnios when the single deepest pool measures greater than 8 cm, and oligohydramnios when the shallowest pool measures less than 2 cm.[24]

The actual volume of amniotic fluid can be determined by dye-dilution techniques performed at the time of amniocentesis. The semiquantitative ultrasound methods described previously correlate somewhat with actual fluid volume, but their accuracy for predicting abnormal fluid volume is limited.[24] **Although there are some differences in the predictive ability of the different ultrasound methods, no system has been clearly shown to be superior to another.** However, when the ultrasound amniotic fluid assessment is to be used to guide clinical management, it seems reasonable to employ methods that have been used in studies that correlate outcomes with ultrasound assessment. Most of the studies correlating ultrasound-diagnosed oligohydramnios with clinical outcomes have used an AFI of less than 5 or, for specific use as part of the biophysical profile, a deepest single pocket measuring less than 2 cm. It is less critical to have a standard definition of polyhydramnios because clinical decision making is only affected by the presence of moderate to severe polyhydramnios, when the excess fluid would be recognized by any of the commonly used systems or cut-offs.

Severe polyhydramnios is usually indicative of a fetal problem and requires a specialized ultrasound to determine the cause. It is often caused by malformations that can greatly affect neonatal management or prognosis. For many of these conditions, the excess amniotic fluid is a result of poor fetal swallowing—from neurologic abnormalities, genetic syndromes, or gastrointestinal malformations. Other serious causes of severe polyhydramnios include twin-to-twin transfusion syndrome and fetal hydrops. Mild polyhydramnios may simply be a variant of normal, but may be associated with maternal diabetes or fetal macrosomia.

The absence of amniotic fluid before labor is never normal and can indicate fetal malformations, rupture of membranes, or placental insufficiency. Malformations causing absence of fluid usually involve the urinary tract. This may be from complete bladder outlet obstruction or from bilateral renal anomalies in which no urine is produced. Examples include bilateral renal agenesis, bilateral multicystic dysplastic kidneys, or autosomal recessive polycystic kidney disease. **The outcome with anhydramnios is generally poor but depends on the cause and the gestational age at which it is first present.** Onset of anhydramnios before the middle of the second trimester usually results in lethal pulmonary hypoplasia.[25]

For many years, it has been recognized that less extreme alterations of amniotic fluid volume can be important. Chamberlain and associates found that when there was less than a 1-cm pocket of fluid, there was a 40-fold increase in perinatal mortality.[26] The incidence of intrauterine growth restriction (IUGR) was also much higher when this degree of oligohydramnios was found. These findings led to the inclusion of the amniotic fluid volume assessment as part of the biophysical profile. More recently, researchers have shown that isolated ultrasound-diagnosed oligohydramnios is not as predictive of perinatal outcome as was previously thought. In a review of the available literature, Ott found that **although polyhydramnios helped diagnose macrosomia and anomalies, oligohydramnios was a weak predictor of poor outcome.**[27] Chauhan and coworkers performed a meta-analysis that showed an AFI of less than 5 was linked to an increased risk for cesarean delivery for distress and low Apgar scores, but argued against using a low AFI as the sole criterion for delivery.[28]

Placenta and Umbilical Cord

One of the principal advantages of routine ultrasound is that serious problems of placentation, such as placenta previa, placenta accreta, and vasa previa, can be diagnosed in a timely manner. At the time of a screening ultrasound, it should be definitely determined whether the placenta covers the internal cervical os. **If the placenta and the cervix are not seen clearly, or if it appears that the edge of the placenta is close to the cervix, vaginal ultrasound should be used liberally to clarify this relationship.**[29] The terms "complete" and "partial" placenta previa date from the pre-ultrasound era, when the relationship of the placenta to

the partially dilated cervix was determined by digital examination. A preferred method for use with ultrasound is to measure and report the distance from the edge of the placenta to the internal os. Positive numbers are used to denote an overlap, whereas negative numbers describe a placenta edge that ends short of the cervix.[30]

It is common for placenta previa that is diagnosed early in pregnancy to resolve as pregnancy progresses. In a 1998 study by Taipale and associates, the edge of the placenta extended to or over the internal os of the cervix in 1.5% of patients between 18 and 23 weeks' gestation.[31] The rate of persistence of placenta previa depended on the degree of overlap. When the degree of overlap was 15 mm or greater, 19% persisted, whereas when the overlap was 25 mm or greater, 40% covered the cervix at term. Dashe and colleagues found that when placenta previa was present at 15 to 19 weeks, only 12% persisted. The rate of persistence gradually increased as the gestational age advanced; up to 73% persistence if placenta previa was present at 32 to 35 weeks. This study also showed that the degree of overlap was helpful in predicting persistence.[32] These results suggest that repeated ultrasound examinations should be performed until the placenta moves well away from the cervix or it becomes clear that the previa will persist. If the placenta previa persists, ultrasound can be very valuable in planning delivery.

The diagnosis of vasa previa is critical because the recognition of this finding at the time of a screening ultrasound greatly affects the chance of fetal survival (see Figure 9-14).[33] There is a high fetal mortality rate when vasa previa is not diagnosed before labor. Conversely, early diagnosis and aggressive obstetrical management of patients with vasa previa almost always result in a live baby, born in good condition. The fetal vessels covering the cervix may not be readily apparent with a routine transabdominal screening examination. Therefore, a high index of suspicion should be maintained, and transvaginal color Doppler ultrasound should be strongly considered in any case in which there is a velamentous cord insertion, when there is a succenturiate lobe, or when portions of umbilical cord are noted to be low in the uterus. The sonographer should also be aware that when placenta previa "resolves," branches of the umbilical vessels on the chorionic plate may still course over the cervix as placental villi degenerate beneath them, resulting in vasa previa. Identifying the cord insertion onto the placenta eliminates the possibility of velamentous cord insertion, but it does not exclude vasa previa from the other placentation abnormalities. Documentation of the cord insertion onto the placenta can be difficult, especially with a posterior placenta, and is not listed by the AIUM statement as a required element of a standard examination.[18]

In addition to determining the placenta's location, its appearance should be assessed. Many changes observed in the placenta are related to calcification, fibrosis, and infarction. There is a general trend for these changes to become more apparent as pregnancy progresses, but their clinical significance is unclear. It has recently been recognized that a "globular" placenta, with a narrow base compared with height, is associated with an increased rate of adverse perinatal events.[34]

An attempt should be made to confirm that there are two arteries and a vein in the umbilical cord. In late pregnancy, this can be easily ascertained by looking at a transverse cut of the cord in a free loop (Figure 9-24). In the second trimester, two umbilical arteries are most easily confirmed by identifying the vessels as they course around the fetal bladder. These can be seen with gray-scale ultrasound but are made much more obvious with color Doppler ultrasound. A single umbilical artery is present in 1% of all newborns. Because of the increased incidence of associated malformations, especially involving the kidneys and heart, this finding should prompt a detailed fetal survey. Fetuses with a single umbilical artery are at increased risk for growth restriction as well.[35]

Uterus and Adnexa

With any obstetrical ultrasound, including those performed in the first trimester, the adnexal and uterine morphology should be evaluated. Many women enter pregnancy without being aware that they have fibroids or a Müllerian malformation. Fibroids are usually readily apparent with transvaginal or transabdominal ultrasound. **A common pitfall is to confuse uterine contractions, which are commonly present in the second trimester, with fibroids** (Figure 9-25). Contractions have a more lenticular shape and blend with the surrounding myometrium, whereas fibroids usually are spherical, have distinct borders, and have a whorled internal echo texture. Pedunculated fibroids, even large ones, can be missed if the sonographer does not examine areas around the periphery of the uterus. Most studies have shown a higher rate of pregnancy complications when fibroids are present. A recent large study reported by Stout showed a statistically significantly increase of a wide variety of pregnancy complications when fibroids were present. However, the odds ratios were modest and differences were of limited clinical importance.[36] It is difficult to predict how fibroids will affect an individual patient's pregnancy because the number, size, and location can vary markedly. Ultrasound mapping of fibroids can help in making a delivery plan. Although large fibroids that fill the pelvis may preclude vaginal birth, it is usually prudent to not predict early in the pregnancy the need for cesarean delivery. Fibroids can rise out of the pelvis, leaving a relatively clear lower uterine segment. Because multiple fibroids in the lower uterus can greatly complicate the performance of a low transverse cesarean delivery, ultrasound may help predict the need for a classic incision. **There is conflicting evidence regarding the growth of fibroids during pregnancy.** Using serial ultrasound measurements, Rosati and associates showed that they tend to grow,[37] whereas a more recent study by Neiger and colleagues did not demonstrate significant growth during pregnancy.[38]

Obviously, it is important for a complete obstetrical ultrasound to include an assessment of the adnexa. Normal-sized ovaries may be difficult or impossible to see in the second or third trimester because of shielding by bowel. In a study of sonographic visualization of normal ovaries, Shalev and coworkers found that although both ovaries were visible in almost all first-trimester scans, both ovaries were visible in only 16% of second- and third trimester scans, and in 60% of these, neither ovary was seen.[39]

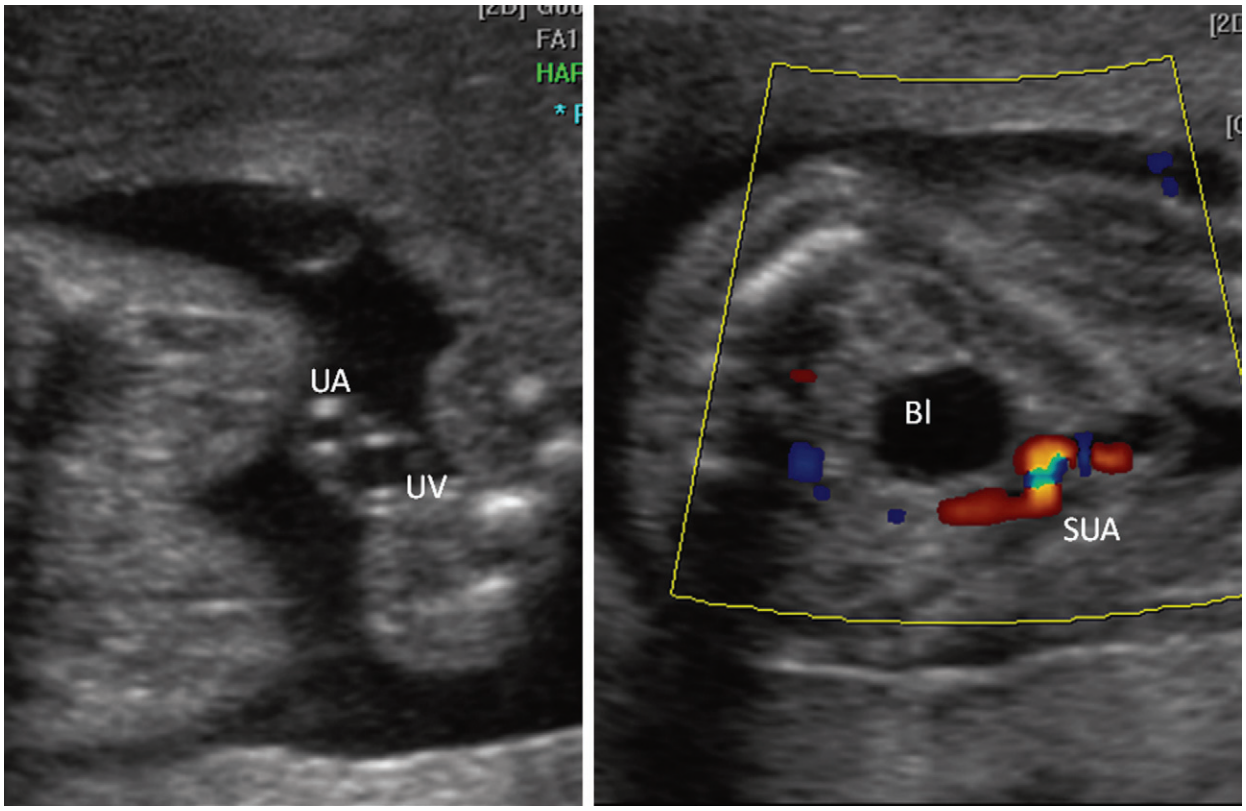

FIGURE 9-24. Two views documenting a single umbilical artery. The view on the left shows the single umbilical artery *(UA)* and the umbilical vein *(UV)* in a transverse section of a free loop of cord. On the right, a transverse view of the fetal pelvis shows a single artery *(SUA)* coursing around the bladder *(Bl)*. Note the absence of a paired artery on the other side. It is easier to document the umbilical arteries in early pregnancy with this color Doppler method.

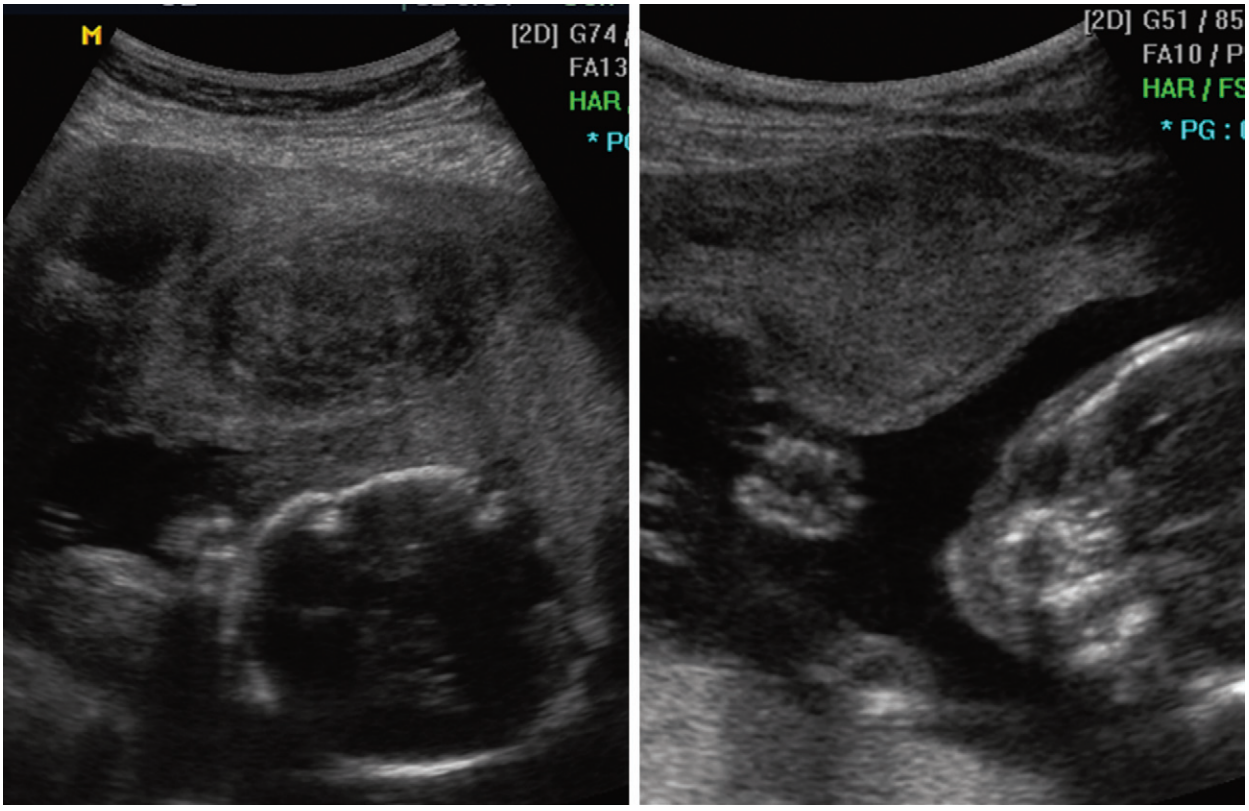

FIGURE 9-25. Two fibroids are seen in the image on the left. They are round and well circumscribed. On the right, a uterine contraction is shown. It is lenticular in shape and does not have a clear border. Contractions such as this are very common in the second trimester.

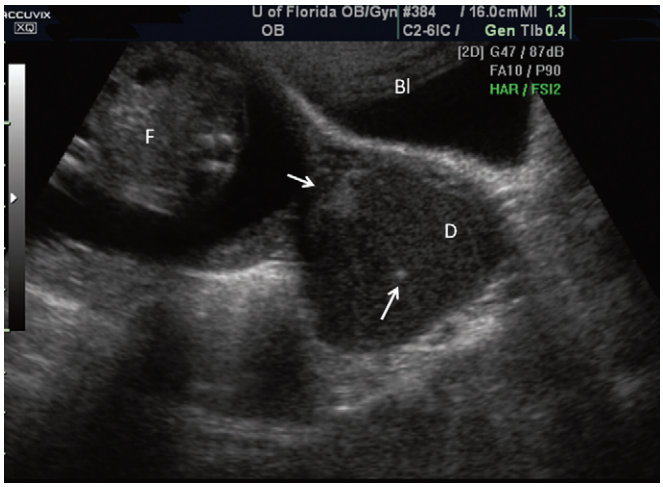

FIGURE 9-26. Transverse view of the maternal uterus and left adnexa in the early second trimester, showing a left ovarian dermoid *(D)*. Note the mixture of homogeneous material with low level echoes and the scattered areas of more echogenic material *(arrows)*. The fetus *(F)* and maternal bladder *(Bl)* are also labeled.

FIGURE 9-27. Measurement of the CRL. This is a sagittal view of the fetus with the crown (the head) to the left and the rump to the right. Errors that could lead to an incorrect CRL measurement would be to obtain an oblique view through the fetus, to measure when the fetus is in a flexed position, or to include the yolk sac with the fetal pole.

However, significant tumors should be visible in most cases. The sonographic appearance of an adnexal mass discovered during pregnancy guides decision making regarding the need for surgical removal. Masses consisting of simple cysts usually represent benign processes and do not require surgical removal during pregnancy. Masses with features of malignancy (large size, multiple cystic cavities, thick septae, internal papillae, or solid areas) require careful evaluation and may require operative removal. The most common neoplasm in pregnancy is a benign cystic teratoma (Figure 9-26). These can usually be identified by their sonographic characteristics.

Anatomic Survey

Systematic evaluation of fetal anatomy is critical. It is a good idea to proceed with an examination in a consistent order so that important parts are not forgotten. **Although there are many well-recognized maternal risk factors for congenital anomalies, most birth defects occur in fetuses of low-risk women.**[40] For this reason, it is important that anyone who performs obstetrical ultrasound have familiarity with the appearance of normal fetal anatomy in order to recognize deviations from normal. **As mentioned previously, although more advanced detailed sonograms (specialized examinations) are appropriate for patients with identified risk factors, all standard examinations should include a full anatomic survey.**

Documentation

Documentation of ultrasound findings is important not only for good patient care but also for quality review and legal defense. AIUM guidelines regarding record keeping state: **"Adequate documentation of the study is essential for high-quality patient care.** This should include a permanent record of the sonographic images, incorporating whenever possible … measurement parameters and anatomic findings."[18] Additionally, it is considered standard practice to include a written report in the patient's medical record.

ULTRASOUND FOR DETERMINING GESTATIONAL AGE

Determination of the correct gestational age is one of the most important aspects of prenatal care. Making correct management decisions for conditions such as preterm labor, postdates pregnancy, and preeclampsia depends heavily on knowledge of the gestational age of the fetus. Without early confirmation of the expected date of confinement (EDC), it is very difficult to diagnose growth disorders in the fetus. Biochemical screening for open fetal defects and chromosomal anomalies likewise requires accurate dating. For these and other reasons, it has become routine in developed countries to offer at least one ultrasound examination in the first half of pregnancy to accurately establish the gestational age.

Standard Measurements

Ian Donald first demonstrated the clinical use of ultrasound in obstetrics in the early 1960s with the measurement of the biparietal diameter BPD.[41] Since that time, a large number of publications have correlated this parameter with gestational age. The BPD can be measured from 12 to 13 weeks' gestation, when the skull has become ossified.

In the early 1970s, static scanners had advanced to the point that the gestational age could be determined in the first trimester by measuring the CRL.[42] With modern transvaginal ultrasound, the embryo can be measured when it is only a few millimeters long, between 5 and 6 weeks' gestation.[43] From 6 to 10 weeks' gestation, the maximal length of the embryo is measured. After about 10 weeks, the head, trunk, and extremities are visible, and the measurement is literally from the well-visualized "crown" to the "rump." Views of the CRL such as those shown in Figure 9-27 are obtained. Measurement of the

TABLE 9-2 DESCRIPTION OF IMAGES FOR FETAL BIOMETRY

Head
- Imaged from side, not front or back
- Head oval rather than round
- Midline structures centered, not displaced to the side
- Measured at level of thalamus and cavum septum pellucidum
- Should not include the top of orbits or any part of the brainstem or cerebellum
- Measured outer edge of the proximal skull to the inner edge of the distal skull
- Head circumference measured at the same level as the biparietal diameter, around the outer perimeter of the skull

Abdomen
- Abdomen nearly round, not oval or squashed
- True transverse image (not oblique)
- Images of ribs should be symmetrical on both sides
- Measured at the level where the umbilical vein joins the portal sinus
- Calipers all the way to the skin surface; not rib, liver, or spine edge

Femur
- Femur should be perpendicular to direction of insonation
- Ends should be sharply visible, not tapered or fuzzy
- Measurement should exclude the distal epiphysis

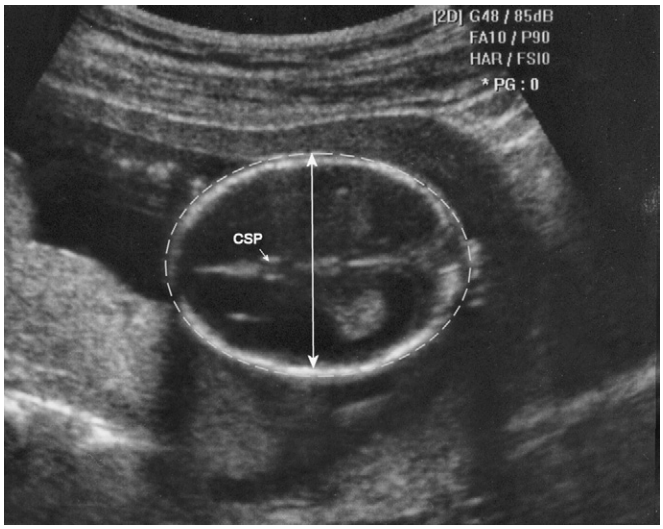

FIGURE 9-28. Image of fetal head for biparietal diameter and head circumference measurements. The cavum septum pellucidum *(CSP)* is indicated. Criteria for an appropriate image are listed in Table 9-2.

femur length (FL) for growth assessment was first described by Queenan and coworkers in 1980 and was enabled by the development of real-time ultrasound.[44] Using real-time linear array transducers, measurement of the FL is straightforward after the first trimester. It is possible to measure virtually any body part on a fetus. However, a standard set of measurements has been accepted as being the most useful for gestational age prediction. In addition to the BPD, CRL, and FL, the standard set now includes the head circumference (HC) and abdominal circumference (AC). Unless these are measured according to standard criteria (Table 9-2), their value in defining the age or growth of a fetus is limited. Optimal views for obtaining measurements are shown in Figures 9-28 to 9-32. Common errors to be avoided are also shown. With experience, a sonographer learns to slide the transducer to the proper position on the maternal abdominal wall, then angulate and rotate the transducer until the precise plane for biometry or anatomic assessment is obtained. Making these adjustments becomes second nature with practice.

Gestational Age Determination

An intrauterine pregnancy can first be identified with transvaginal ultrasound at 4 weeks from the last menstrual period. From this time until the embryo can be seen and measured at 5½ to 6 weeks, formulas using the sac diameter can give a fairly close approximation of the gestational age.[45] The mean sac diameter increases by about 1 mm per day during this interval, and the gestational age (in days) can be figured by adding 30 to the mean sac diameter (in millimeters).[46] **Because the range of error in age prediction from sac measurement is significantly greater than for the CRL and other standard measurements, the sac size should not be used as the final gestational age determinant.**[47] The measurement of the early embryo, either as the maximal embryo length or CRL, is commonly accepted as the best sonographic method for gestational age determination. Using a static scanner in pregnancies dated by "good" menstrual dates, Robinson found that the 95% confidence intervals for gestational age prediction using the CRL was ±4.7 days.[42] Later studies, in which gestational age was determined by in vitro fertilization, showed an even smaller random error.[48] The small random dating error found in early embryos is explained by their high weekly percentage change in size and the fact that there is very little variation among early embryos in their growth rates. However, in the late first trimester, flexion and extension of the fetus can significantly alter the CRL, making it less accurate for dating purposes. MacGregor and colleagues found in a study of patients with known ovulation dates that the 95% confidence intervals for CRL gestational age determination reached ±9.1 days at 14 weeks' gestation.[49] In comparison, Hadlock and others have shown that the 95% confidence intervals for gestational age prediction using the BPD as a single parameter between 14 and 21 weeks is ±7 days.[50,51] In a study of pregnancies dated by in vitro fertilization, Chervenak and colleagues found that in this period of pregnancy, all of the single parameters considered (BPD, HC, FL) performed quite well, with 95% confidence intervals for the gestational age ranging between ±7.5 days for the HC and ±8.7 days for the FL.[52] These studies demonstrate that a dating ultrasound performed between 14 and 22 weeks is comparable to one performed in the first trimester, and that the obstetrician need not refer a patient for ultrasound in the first trimester for the sole purpose of obtaining optimal dates.

Before the mid-1980s, second- or third-trimester gestational age assignment at the time of ultrasound was typically done by consulting a chart that had BPD or FL as the independent variable and gestational age as the dependent variable. This method did not allow for incorporation of multiple measurements in the gestational age assessment, unless ad hoc averaging of the age from different parameters was done. Starting in the late 1980s, computer programs that calculated a composite gestational age from multiple

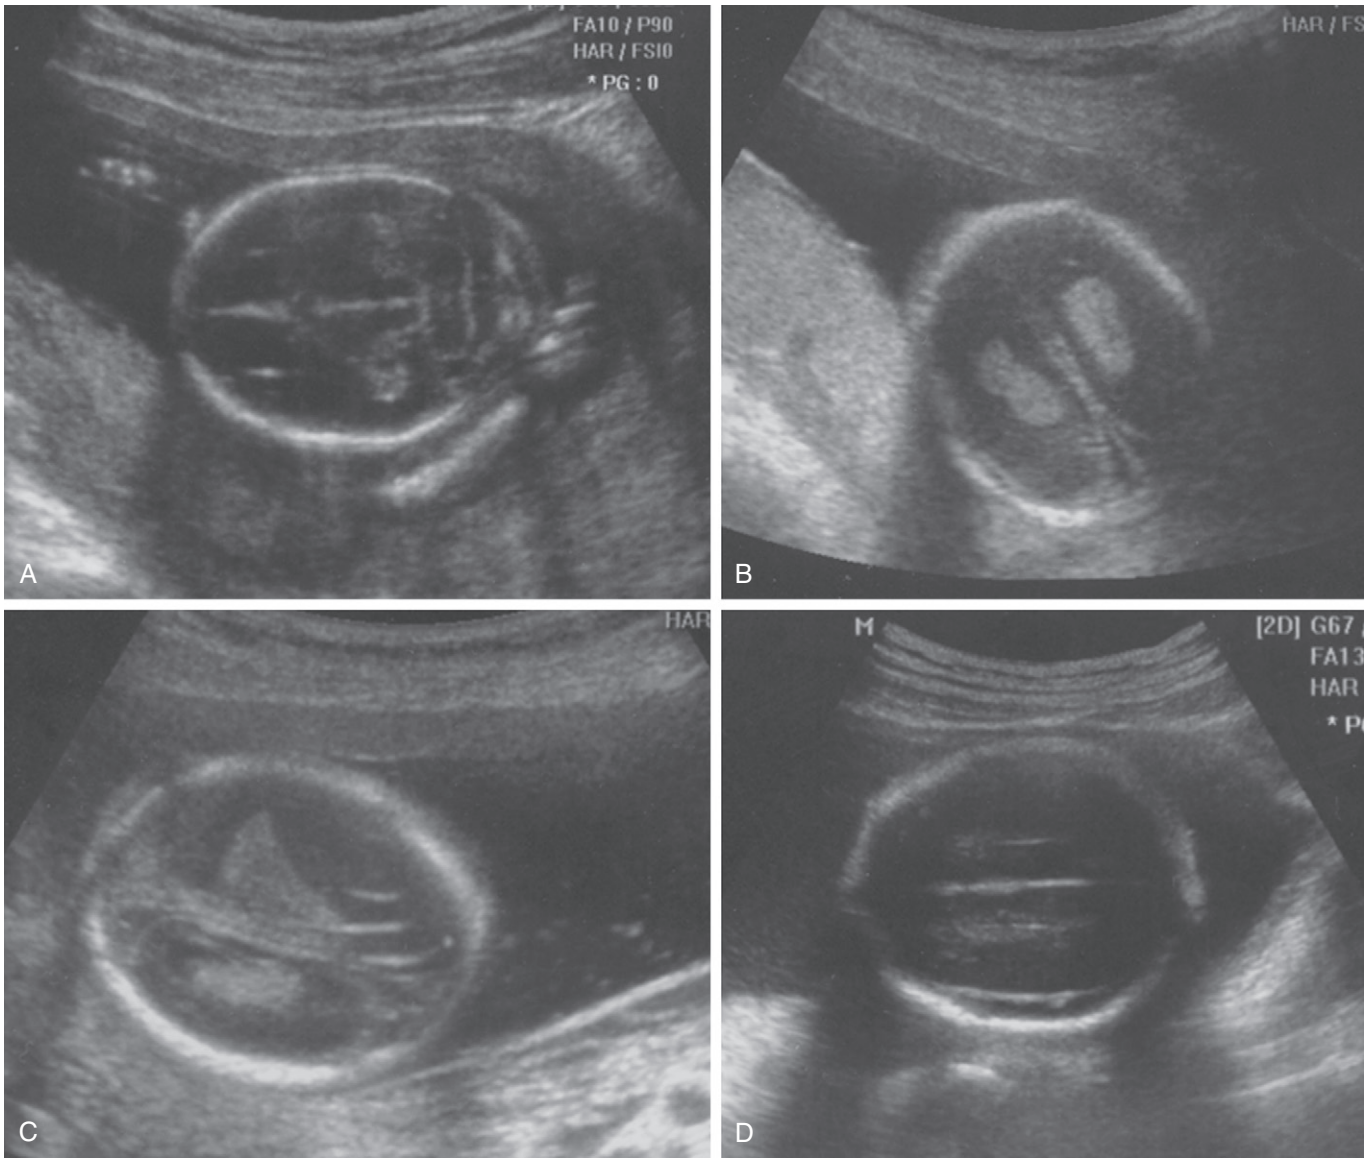

FIGURE 9-29. Examples of head views that are inappropriate for biparietal diameter and head circumference measurements. **A,** The transducer is rotated in such a way that the image includes the cerebellum. **B,** The head is imaged from the back and not from the side. **C,** The scan plane goes though the head obliquely. Note how the brain structures are asymmetrical. **D,** This true axial image is too high on the head. The cavum septum pellucidum is not seen.

measurements became available. These are now routinely used by ultrasound reporting software. Several studies have shown a significant reduction in variability of gestational age estimates when mathematical modeling from multiple parameters (BPD, HC, AC, and FL) is employed.[50,52] This technique reduces the impact of technical errors in measurement and smooths out effects from body part variations. Composite gestational age assessment using mathematical modeling from multiple parameters is now the most accepted method of ultrasound dating after the first trimester. The studies previously cited show that **gestational age calculation using a combination of standard parameters before 22 weeks is accurate to within ±7 days and is comparable to CRL measurement in the first trimester. As pregnancy progress beyond this range, variability in fetal size grows considerably, and ultrasound prediction of gestational age becomes progressively less accurate.**[50] **In one study, the composite gestational age assessment has a variability (±2 standard deviations) of 1.8 weeks at 24 to 30 weeks, and 2 to 3 weeks beyond 30 weeks.**[50]

These variability figures represent a statistical description of the variability of the gestational age calculations in the studied population. Assuming a normally growing fetus, it is likely that the gestational age of a pregnancy falls within the bounds described. However, there is no guarantee that the gestational age of a particular fetus is "at least" or "not more than" the lower or upper limit of the variability estimate. In the third trimester, growth disorders in fetuses are relatively common and can bring about marked size variation. For this reason, the obstetrician must exercise caution when basing management decisions on third-trimester ultrasound dates.

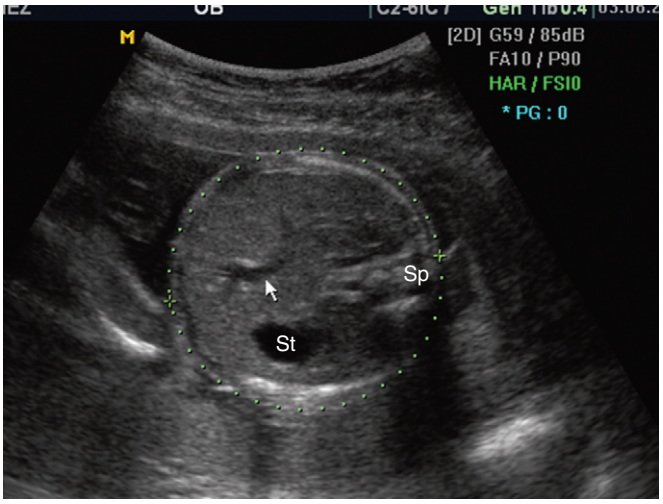

FIGURE 9-30. Proper image for measuring the abdominal circumference. Criteria for an appropriate image are listed in Table 9-2. The *arrow* shows the junction between the umbilical vein and portal sinus. The stomach *(St)* and spine *(Sp)* are labeled.

When to Use Ultrasound Dating

Since the time of Nägele in the early 1800s, obstetricians have routinely used menstrual dates for determining the EDC. In pregnancies in which the menstrual dates are unsure or thought to be unreliable because of a history of irregular cycles, recent hormonal contraception use, or an abnormally light last menstrual period (LMP), dates derived from ultrasound biometry are always preferred. It is now common practice in many countries for ultrasound to be performed routinely in the first half of all pregnancies, even those with good menstrual dates. In these cases in which both menstrual dates and ultrasound dates are available, which should be used? Possible strategies would be to always retain the menstrual dates, to use the menstrual dates unless the ultrasound size is out of the expected size range and thus "contradicts" the menstrual dates, or to ignore the menstrual dates altogether and use the ultrasound dates. A common practice is for ultrasound dates to take precedence over the menstrual dates if an ultrasound performed before about 22 weeks' gestation shows a gestational age more than 1 week different from the menstrual dates.[53]

Changing the dates in favor of the ultrasound dates can lead to an incorrect age assignment if the fetus has an early-onset significant growth disorder that accounts for the discrepancy. In the absence of maternal risk factors for early growth restriction or ultrasound signs suggesting a genetic syndrome or placental insufficiency, most sonographers feel safe in changing to ultrasound dates when a discrepancy exists. Delayed ovulation and incorrect recall of the LMP are common, whereas early-onset severe growth disorder is rare; thus, this is usually a good policy. However, **in the third trimester, aberrant growth is relatively common, so changing certain menstrual dates in favor of a late ultrasound date risks masking the presence of a significant growth disorder.** Uncertainties are best avoided by a policy that encourages routine early prenatal care so that firm dates can be established and risk factors for altered fetal growth can be recognized.

There is growing evidence that a dating ultrasound performed before 22 weeks should be used in preference to menstrual dates, regardless of the reliability or closeness of fit with menstrual dates. In 1996, Mongelli and associates evaluated 34,249 patients who had both "certain" menstrual dates and an ultrasound performed in the first half of pregnancy.[53] Using ultrasound exclusively led to a 70% reduction in the number of pregnancies considered postterm and more accurately predicted the onset of spontaneous labor. A policy of changing dates only when there was a significant discrepancy between menstrual dates and ultrasound gave inferior results compared with the exclusive use of ultrasound dates. Other studies using the same end points have similarly shown that there is no advantage of taking menstrual dates into account if a relatively early dating sonogram is available.[54] Exclusive use of ultrasound dating has also been shown to improve the predictive accuracy of serum screening for Down syndrome.[55] In first-trimester nuchal translucency assessment, measurements are correlated with the CRL, with no consideration of the claimed menstrual dates. The current practice in many developed countries of performing ultrasound in the first half of almost all pregnancies and the apparent superiority of ultrasound dating make it likely that in the future menstrual dating will become obsolete in these settings.

ASSESSING FETAL GROWTH

The first ultrasound examination is generally considered to be a dating examination; that is, the measurements are used to determine the gestational age. An accurate knowledge of gestational age determined by or confirmed by the first ultrasound examination forms the basis for subsequent clinical and sonographic assessment of fetal growth. Because insufficient or excessive growth can be associated with significant fetal morbidity, recognition of growth abnormalities is one of the primary aims of prenatal care and is an important aspect of ultrasound examinations. In most obstetrical practices, growth ultrasound examinations are obtained when abdominal palpation and fundal height measurement raise the suspicion of abnormal growth.[56] A lagging fundal height, combined with the knowledge of clinical risk factors for IUGR, is commonly used as a "screening test" for insufficient fetal growth, whereas ultrasound is considered the "diagnostic test." This scheme for the prenatal detection of growth-restricted fetuses has met with mixed results. In 1987, Pearce and Campbell showed that fundal height measurement in the third trimester had a sensitivity of 76% for detecting small-for-gestational-age births, with a specificity of 79% and positive predictive value of 36%.[57] In contrast, other studies in low- and high-risk pregnancies showed the sensitivity of this stepwise screening for IUGR (defined as birthweight lower than the 10th percentile) to be only 15% to 26%, whereas the positive predictive value was only in the range of 50%.[58,59] The sensitivity of schemes for the antenatal diagnosis of small fetuses is significantly better if clinical risk factors are taken into account.[59]

Serial ultrasound examinations have been shown to be superior to physical examination for diagnosing insufficient growth.[60] For this reason, some European countries have established formal policies requiring a third-trimester

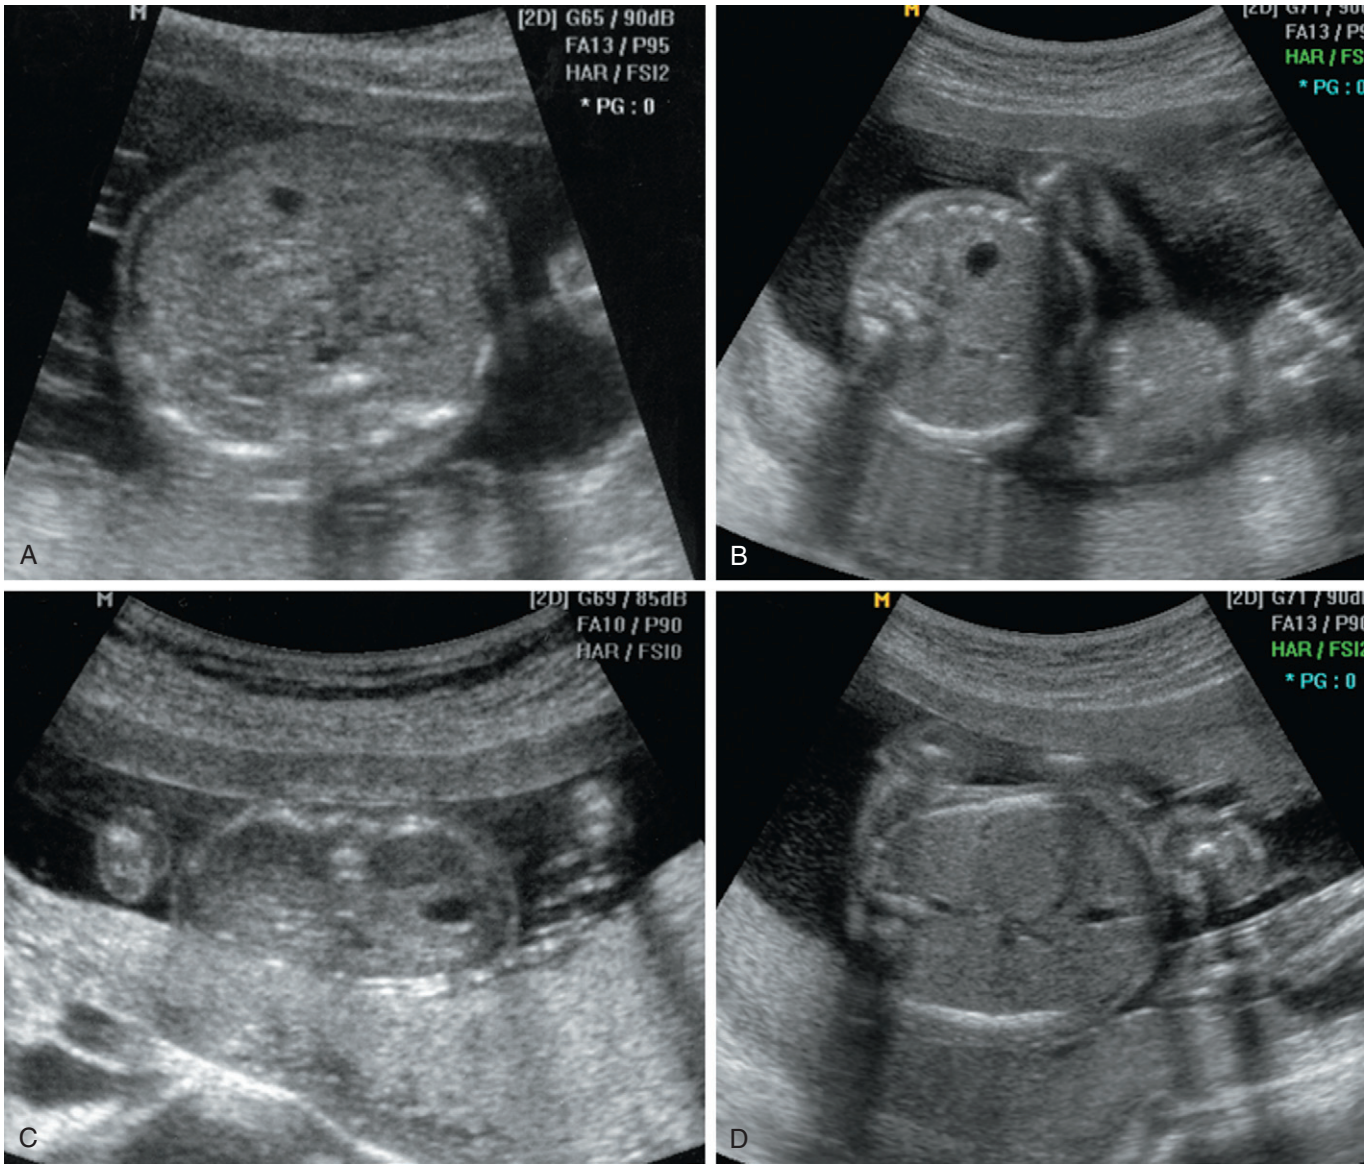

FIGURE 9-31. Examples of abdominal views that are inappropriate for abdominal circumference measurements. **A,** This true axial image is too low on the abdomen. The umbilical vein is seen close to the anterior abdominal wall. **B,** This is an oblique cut through the abdomen. Note the asymmetrical appearance of the ribs. **C,** The abdomen is squashed because the sonographer has applied too much pressure to the maternal abdominal wall. **D,** The transducer is rotated in such as way that an oblong view of the abdomen is obtained. This gives an artificially elongated anterior-posterior dimension.

ultrasound examinations to screen for growth abnormalities, even in low-risk pregnancies. Studies have shown, however, that this policy has little or no impact on perinatal morbidity and mortality.[61,62] **Because of the high cost and unproven benefit of such a screening program, routine ultrasound examinations for growth are generally not a part of prenatal care in the United States.** Because of the high rates of morbidity associated with growth restriction, it is still accepted that **ultrasound should be ordered when clinical examination is suspicious and when there are significant risk factors for a growth abnormality.** Such risk factors include diabetes, maternal hypertension, previous small or large baby, multiple gestation, or poor maternal weight gain. A risk-based approach is particularly appropriate in cases such as multiple gestation or marked maternal obesity, in which clinical evaluation of fetal size is difficult or impossible.

Estimating Fetal Weight

A large number of formulas for calculating the estimated fetal weight (EFW) have been proposed. The most popular of these have been compiled in a review by Nyberg and colleagues.[63] All incorporate the abdominal circumference because this is the standard measurement most susceptible to the variations in fetal soft tissue mass. Although the abdominal circumference alone is a fairly good marker for detecting abnormal fetal growth, the addition of other standard measurements to estimated weight formulas increases their accuracy.[64] It has been shown that the addition of measurements beyond the standard set (BPD, HC,

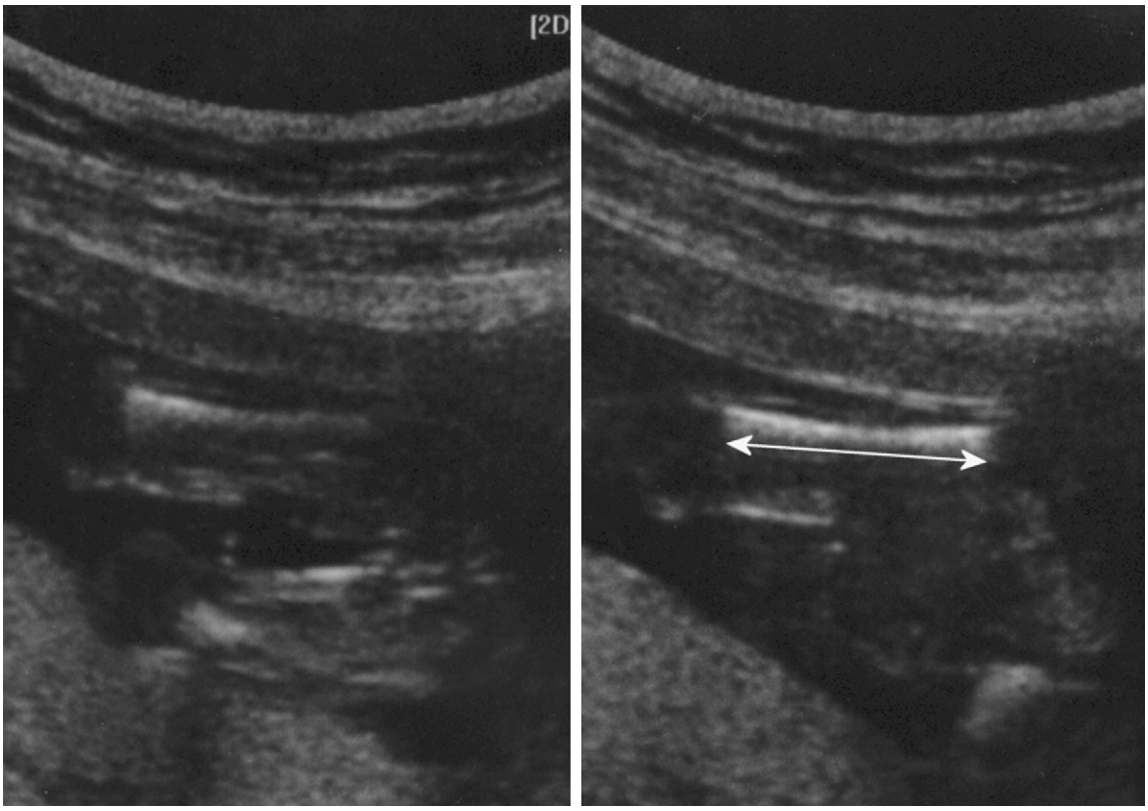

FIGURE 9-32. In the left image, the entire diaphysis of the femur is not clearly shown. This will give an inappropriately short measurement. The ends should be distinct, as shown in the image on the right.

AC, and FL) does not significantly improve weight estimations. It appears that the error inherent in obtaining the basic measurements (especially the AC) is great enough to obscure any refinement in accuracy that might be gained from additional measurements.

Because procedures for standard biometry are well defined, and formulas using these measurements yield seemingly precise weight predictions, some clinicians place more confidence in ultrasound weight estimates than is warranted. There have been a large number of studies in which the accuracy of ultrasound for predicting birthweight has been evaluated.[63,65] It has been claimed in some publications that one formula is better than another when statistically significant differences in accuracy are seen. **However, the differences in accuracy are usually of limited clinical significance, and no formula has been consistently shown to be superior to another.**[65] When scans are done by well-trained sonographers, most studies show a mean absolute error in birthweight prediction of about 8% to 10% of the birthweight. Perhaps a more telling statistic is that in about 30% of cases, the absolute error in estimated weight is greater than 10% of the birthweight. In most of the remaining cases, the error is less than 20% of the birthweight. The rate of clinically significant errors is greater if an inexperienced person performs the ultrasound examination.[66]

It is often assumed that ultrasound is more objective than clinical examination and therefore that ultrasound estimates of fetal weight are more reliable. Most studies have not shown this to be true. In a review by Sherman of 12 studies in which ultrasound was compared with clinical examination for weight estimation, ultrasound was shown to be clearly superior in only one; this involved a subgroup of patients in which the birthweight was less than 2500 g. In three studies, clinical estimates were superior, and in the remaining eight, the two methods either were equivalent or had mixed results depending on the specific formula used.[65] One small study showed that the estimate by the patient was only marginally less accurate than an ultrasound estimate.[66]

There have been several strategies aimed at improving the performance of ultrasound for estimating fetal weight. One is to develop formulas based on subpopulations of fetuses, such as those who are preterm or are thought to be small or large for gestational age. Although this approach seems reasonable, most studies have not shown an improvement in the accuracy of weight estimates compared with traditional "one-size-fits-all" formulas.[67]

Diagnosing Abnormal Growth

The most accepted way of diagnosing abnormal growth in a fetus is to calculate the EFW using standard ultrasound measurements, then to compare the estimated weight with an accepted standard. Some tables still in use were based on the birthweight distribution at different gestational ages of children born in the 1960s or 1970s.[68] Kramer questioned the reliability of these and many subsequent studies. Problems he identified were that patients often had an unconfirmed gestational age, infants were included with implausible birthweight, there was

insufficient sample size at low gestational ages, the samples were not population based, and the studies used inadequate statistical modeling techniques. He and his colleagues published sex-specific growth standards that avoided these problems.[69]

If the EFW is less than the 10th or greater than the 90th percentile, the fetus is said to be small or large for the gestational age. Defining abnormal growth using these percentile cut-offs includes many babies who are healthy and are constitutionally large or small. Using a more restrictive definition such as a birthweight less than the 3rd or greater than the 97th percentile is much more predictive of a poor neonatal outcome. Of course, with this approach, many less severely affected fetuses are not detected. Additionally, some infants have a birthweight within the normal range but have not grown to their genetic potential. For this reason, some have argued that individual birthweight percentile limits that incorporate such characteristics as maternal weight, height, ethnic group, parity, and fetal sex should be used.[70] Claussen and colleagues found that about one fourth of fetuses judged to be abnormally small using conventional limits were within normal limits with adjusted percentiles. Conversely, one fourth of babies identified as small or large with adjusted percentiles would have been missed by conventional assessment. In another study from the same institution, it was demonstrated that the risk for stillbirth, neonatal death, and low Apgar scores can be better predicted by the customized weight percentiles.[71]

In 1977, Campbell and colleagues described the HC/AC ratio as a useful marker for detecting fetal growth restriction.[72] This is based on the observation that growth of the soft tissues in the fetal abdomen is more likely to be compromised than the head when there is nutritional deprivation. This understanding led to the concept that asymmetrical growth restriction is virtually pathognomonic for nutritional deprivation, whereas symmetrical growth restriction signifies an underlying condition such as aneuploidy. This categorization has some utility, but it should be recognized that **there is a great deal of overlap between body ratios of fetuses that are growth restricted from either nutritional or intrinsic factors.** However, because a very high HC/AC ratio is uncommon in normal fetuses, a **high HC/AC ratio points away from constitutional smallness.**[73] Additionally, it has been shown in newborns that a low weight-to-length ratio is associated with an increase in several markers of morbidity even if the birthweight is greater than the 10th percentile; perhaps indicating these infants also experienced growth restriction.[74] Currently, there is no consensus concerning the level of surveillance appropriate for a fetus with a high HC/AC ratio but normal estimated weight.

When a patient presents late for prenatal care and the gestational age is uncertain, diagnosis of a growth disorder is particularly difficult. In these cases, a high or low HC/AC ratio can raise the suspicion of a growth disorder. Other ultrasound findings may be useful to help confirm the suspicion. For example, IUGR is often associated with oligohydramnios, abnormal Doppler flow studies, or an abnormal-appearing placenta. Macrosomic fetuses may demonstrate obviously thickened subcutaneous fat pads. In suspected cases, as long as the fetus is stable, serial ultrasound examinations to evaluate growth are appropriate. The rate of growth can be valuable for predicting adverse outcome. Formulas defining rates of normal growth have been published, but most clinicians rely on an observation of progressively increasing or decreasing weight percentiles to evaluate the severity of an ongoing growth disorder.

It has been hoped by many that ultrasound could aid in the difficult decisions faced by obstetricians when macrosomia is suspected. One of the most feared complications in obstetrics is shoulder dystocia because it can lead to permanent neurologic injury in the fetus. **Unfortunately, ultrasound for fetal weight estimation has proved to be of limited usefulness for the prevention of shoulder dystocia and other complications associated with fetal macrosomia.** A study by Gonen and colleagues demonstrated several explanations for this.[75] In a review of 4480 deliveries, only 17% of infants weighing over 4500 grams were detected by an ultrasound ordered because of a clinical suspicion of macrosomia. Only 1 of the 23 infants who weighed over 4500 grams had a brachial plexus injury. Additionally, 93% of infants who had shoulder dystocia weighed less than 4500 grams. For these reasons, these and other authors have concluded that most cases of injury resulting from shoulder dystocia cannot be predicted by ultrasound, and that if cesarean delivery were routinely performed when macrosomia was suspected, the cesarean rate would be increased with very little benefit.

SAFETY OF ULTRASOUND

Ever since diagnostic ultrasound was introduced for clinical use, attention has appropriately been given to ensuring its safety. It has been recognized that the energy from sound waves is converted into heat as sound waves are attenuated. Mechanical energy from the sound waves can cause the formation of microbubbles, resulting in a phenomenon called *cavitation*. Because cavitation occurs only under high ultrasound intensities in areas in which air is present, it is not of significant concern with diagnostic ultrasound of the fetus.

Quantifying Machine Power Output

As of 1976, trials had indicated that there were no clinically significant biologic effects from diagnostic ultrasound. It was subsequently recognized that it would be impractical to repeat safety studies for each new generation of ultrasound machines, operating with different modalities and power outputs. The U.S. Food and Drug Administration (FDA) decided that approval for equipment marketed after 1976 would require acoustic outputs less than that of equipment that existed at that time, which was 94 mW/cm^2 spatial-peak temporal-average (SPTA). However, it has become apparent that improvements in ultrasound imaging could be obtained with higher power levels than was allowed under this regulation. The FDA agreed to relax this standard if machines provided users with real-time information that indicated the potential for fetal harm from the higher power outputs now allowed. An *output display standard* was adopted, which showed the required information on the ultrasound monitor. The numbers that are pertinent to users of obstetrical ultrasound are the TIs and TIb values, which are the thermal indices for

ultrasound in soft tissues and bone, respectively. The thermal index denotes the potential for increasing the temperature of tissue that is being insonated with that power output. It is determined by the settings and ultrasound modalities that are being used. A TI of 1.0 indicates that the temperature of the tissue may be increased by 1° C. Because there is little bone formation in the first trimester, the TIs is more relevant. Later in pregnancy, as ossification occurs, sounds waves have a greater impact on bone, so the TIb becomes more important. If the output display standard is followed, the new regulations allow the ultrasound intensity to be as high as 720 mW/cm^2. Machines that do not have the output display still must operate with a maximal sound intensity of less than 94 mW/cm^2.[76]

A 2008 official statement from the AIUM on ultrasound bioeffects states that no effects have been observed from unfocused beam SPTA intensities below 100 mW/cm^2, or thermal index values of less than 2.[77] In 2009, the World Health Organization sponsored a systematic review and meta-analysis to evaluate the safety of human exposure to ultrasonography in pregnancy. This study showed no adverse maternal or perinatal effects, impaired physical or neurologic development, increased risk for malignancy in childhood, subnormal intellectual performance, or mental diseases. **This analysis concluded that according to the available evidence, exposure to diagnostic ultrasonography during pregnancy appears to be safe.**[78] Taking into account the many studies that have been done to date, an official statement from the AIUM on prudent use and clinical safety states, "No independently confirmed adverse effects caused by exposure from present diagnostic ultrasound instruments have been reported in human patients in the absence of contrast agents."[79] **Nevertheless, researchers in the field caution about the possibility that unrecognized harm exists. For this reason, the AIUM position remains that ultrasound should be used by qualified health professionals to provide medical benefit to the patient. In another official statement, the AIUM propounds the ALARA principle (as low as reasonably achievable).**[80] This means that the potential benefits and risks of each examination should be considered, and equipment controls should be adjusted to reduce as much as the possible the acoustical output from the transducer.

In general, ultrasound energy and the potential for temperature elevation become progressively greater from B-mode to color Doppler to spectral Doppler. For this reason, M-mode ultrasound is preferred for documenting fetal viability in the first trimester[81] (see Figure 9-10). However, Doppler modes should be used liberally to confirm fetal death.

"Entertainment" Ultrasound Examinations

It has been proposed that natural-appearing 3-D ultrasound images of the fetus could improve patient-fetal bonding. Given the recognized importance of maternal-child bonding immediately postpartum, it seems reasonable that extending this bonding experience into the fetal period could be beneficial. However, **a psychological benefit of viewing fetal photos has not been proven, and obtaining such images largely remains in the realm of "entertainment."**

The use of ultrasound for nondiagnostic purposes has been condemned by the AIUM and the ACOG.[79,81,82] Concerns that were raised in their policy statements include possible adverse bioeffects of ultrasound energy, the possibility that an examination could give false reassurance to women, and the fact that abnormalities may be detected in settings where personnel are not prepared to discuss and provide follow-up for concerning findings. The 2007 statement by the AIUM regarding the prudent use of ultrasound in obstetrics states: **"The AIUM advocates the responsible use of diagnostic ultrasound and strongly discourages the non-medical use of ultrasound for entertainment purposes.** The use of ultrasound without a medical indication to view the fetus, obtain a picture of the fetus or determine the fetal gender is inappropriate and contrary to responsible medical practice. Ultrasound should be used by qualified health professionals to provide medical benefit to the patient."[79]

KEY POINTS

- Sonographers should become familiar with basic physics of ultrasound, equipment controls, and scanning techniques to optimize ultrasound images.
- All of the elements of the standard obstetrical ultrasound examination are important for clinical management and should not be neglected.
- Because most birth defects occur in fetuses of low-risk women, all standard examinations should include a full anatomic survey.
- Limited obstetrical ultrasound examinations are only appropriate when a complete standard examination has previously been performed.
- Physicians performing and interpreting obstetrical ultrasound examinations should have appropriate training and experience.
- Appropriate documentation of ultrasound studies is important for good medical care.
- There is evidence that a dating ultrasound performed before 22 weeks' gestation may be more accurate than menstrual dates. Beyond this time, variability in fetal size grows considerably, and ultrasound prediction of gestational age becomes progressively less accurate.
- Clinical estimate of fetal weight is as accurate as an ultrasound estimate. Ultrasound for fetal weight estimation is of limited usefulness for the prevention of shoulder dystocia and other complications associated with fetal macrosomia.
- Exposure to diagnostic ultrasonography during pregnancy appears to be safe for the fetus.
- Ultrasound should be used by qualified health professionals to provide medical benefit to the patient. Because of the possibility of unrecognized harm, exposing the fetus to ultrasound should follow the ALARA (as low as reasonably achievable) principle.
- The AIUM and ACOG strongly discourage the non-medical use of ultrasound for entertainment purposes.

Genetic counseling and screening for common inherited conditions, chromosomal abnormalities, and congenital defects are an integral part of routine obstetrical care. Approximately 3% of liveborn infants have a major congenital anomaly. About one half of these anomalies are detected at birth; the remainder become evident later during childhood or, less often, during adult life. Although nongenetic factors may cause malformations, genetic factors are usually responsible. In addition, more than 50% of first trimester spontaneous abortions and at least 5% of stillborn infants exhibit chromosomal abnormalities (see Chapter 26). In this chapter we focus on identifying pregnancies in which the couple is at increased risk for abnormal offspring compared to the general population. We review the principles of genetic counseling, common chromosome abnormalities including aneuploidy, and the value of screening for selected single-gene disorders and neural tube defects. Screening the general population to identify at-risk individuals can be followed by definitive diagnosis, using genetic approaches and ultrasound examination covered in Chapter 11.

FREQUENCY AND ETIOLOGY OF GENETIC DISEASE

Phenotypic variation—normal or abnormal—may be considered in terms of several etiologic categories: (1) chromosomal abnormalities, numeric or structural; (2) single-gene or mendelian disorders; (3) polygenic and multifactorial disorders, polygenic implying an etiology resulting from cumulative effects of more than one gene and multifactorial implying interaction as well with environmental factors; and (4) teratogenic disorders, caused by exposure to exogenous factors (e.g., drugs) that deleteriously affect an embryo otherwise destined to develop normally. Principles of these mechanisms are reviewed elsewhere in detail.[1]

Chromosomal Abnormalities

The incidence of chromosomal aberrations is 1 in 160 newborns. Table 10-1 shows the incidence of individual abnormalities.[2] The chromosomal abnormalities that generate the greatest attention are the autosomal trisomies. Autosomal trisomy usually arises as a result of abnormalities of

Data from Hook EB: Rates of chromosome abnormalities at different maternal ages. Obstet Gynecol 58:282, 1981; and Hook EB, Cross PK, Schreinemachers DM: Chromosomal abnormality rates at amniocentesis and in live-born infants. JAMA 249:2034, 1983.
*Because sample size for some intervals is relatively small, confidence limits are sometimes relatively large. Nonetheless, these figures are suitable for genetic counseling.
†47,XXX excluded for ages 20 to 32 (data not available).

meiosis, nondisjunction producing a gamete with 24 rather than the expected 23 chromosomes. This results in a zygote having 47 chromosomes. **This error most commonly occurs during maternal meiosis, and is associated with the well-known maternal age effect.** Table 10-2 shows the year-to-year (maternal age) increase in frequency of Down syndrome and other aneuploidies.[3] Another calculation has shown that the progressive increase with advancing maternal age plateaus around age 45, but this is of relatively little clinical significance.[4] The frequency is about 30% higher in midpregnancy than at term, reflecting lethality throughout pregnancy.[5] Some trisomies, for example, trisomy 16, arise almost exclusively in maternal meiosis, usually maternal meiosis I. For a few chromosomes, there is a relatively higher frequency of errors in meiosis II (e.g., trisomy 18), and in yet others, errors in paternal meiosis are not uncommon (e.g., trisomy 2). Autosomal trisomy can also recur, the recurrence risk being approximately 1% following either trisomy 18 or 21. This suggests that genetic factors perturb meiosis, a phenomenon that serves as justification for offering prenatal genetic screening or testing after one aneuploid conception.

In addition to numeric abnormalities, structural chromosomal abnormalities occur. In a balanced interchange (translocation) between two or more chromosomes, individuals are phenotypically normal. However, such individuals are at increased risk for offspring with unbalanced gametes. This topic is also discussed in Chapter 26 in the context of repeated pregnancy loss. Small, often submicroscopic, deletions and duplications of chromosomal material occur that can result in recognizable syndromes such as the 22q11.2 deletion syndrome.

Single-Gene Disorders

Approximately 1% of liveborn infants are phenotypically abnormal as result of a single-gene mutation. Mendelian or single-gene disorders thus account for 40% of the congenital defects seen in liveborn infants.

The human genome has now been sequenced and shown to contain approximately 22,000 human genes. In addition, posttranscriptional modifications result in perhaps three times as many proteins (gene products). Perturbation of each gene (deoxyribonucleic acid [DNA] sequence) or protein should theoretically result in a mendelian disorder. However, function is known for only a few thousand genes. Moreover, even the most common single-gene disorder is individually rare except in its predominant ethnic group: cystic fibrosis (CF) in whites of European or Ashkenazi Jewish origin; sickle cell anemia in blacks; β-thalassemia

in Greeks and Italians; α-thalassemia in Southeast Asians; and Tay-Sachs disease, Canavan disease, and familial dysautonomia in Ashkenazi Jews. Carrier screening for these disorders is discussed later in this chapter.

Polygenic/Multifactorial Disorders

Approximately 1% of neonates are abnormal but have an apparently normal chromosomal complement and have not ostensibly undergone mutation at a *single* genetic locus. It is postulated that several different genes are responsible (polygenic/multifactorial inheritance) and possibly gene-environmental interactions.[1]

Disorders in this etiologic category include most common malformations limited to a single organ system. These include hydrocephaly, anencephaly, and spina bifida (neural tube defects); facial clefts (cleft lip and palate); cardiac defects; pyloric stenosis; omphalocele; hip dislocation; uterine fusion defects; and club foot (Table 10-3). **After the birth of one child with a birth defect involving only one organ system, the recurrence risk in subsequent progeny is 1% to 5%.**[1] This frequency is less than would be expected if only a single gene were responsible but greater than that for the general population. The recurrence risks for malformations are also 1% to 5% for offspring of affected parents. Recurrence risks are similar for both siblings and offspring, which diminishes the likelihood that environmental causes are the exclusive etiologic factor because it is highly unlikely that households in different generations would be exposed to the same teratogen. Further excluding environmental factors as exclusive etiologic agents are observations that monozygotic twins are much more often concordant (similarly affected) than dizygotic twins, despite the fact that both types of twins share a common intrauterine environment.

Teratogenic Disorders

The perhaps 20 proved teratogens are reviewed in Chapter 8. Although many other agents are suspected teratogens, the quantitative contribution of known teratogens to the incidence of anomalies is thought to be relatively small (with the possible exception of alcohol).

TABLE 10-3 POLYGENIC/MULTIFACTORIAL TRAITS*

Hydrocephaly (excepting some forms of aqueductal stenosis and Dandy Walker syndrome)
Neural tube defects (anencephaly, spina bifida, encephalocele)
Cleft lift, with or without cleft plate
Cleft lip (alone)
Cardiac anomalies (most types)
Diaphragmatic hernia
Pyloric stenosis
Omphalocele
Renal agenesis (unilateral or bilateral)
Ureteral anomalies
Posterior urethral values
Hypospadias
Müllerian fusion effects
Müllerian aplasia
Limb reduction defects
Talipes equinovarus (clubfoot)

*Relatively common traits considered to be inherited in polygenic/multifactorial fashion. For each, normal parents have recurrence risks of 1% to 5% after one affected child. After two affected offspring, the risk is higher.

CLINICAL SPECTRUM OF CHROMOSOMAL ABNORMALITIES

A basic fund of knowledge about common chromosomal disorders may be helpful to the obstetrician, who may encounter abnormal fetuses or infants during prenatal genetic studies or at delivery. In this section, we briefly review the clinical and cytogenetic features characteristic of the common numeric chromosomal abnormalities. Standard genetic texts, some geared for the obstetrician-gynecologist,[1] cover the broader spectrum of rare (often mosaic) trisomies and autosomal duplication or deficiency syndromes.

Autosomal Trisomy

Trisomy 21

Trisomy 21 (Down syndrome) is the most frequent autosomal chromosomal syndrome, occurring in 1 of every 800 liveborn infants (see Table 10-1). The relationship of Down syndrome to advanced maternal age is well known (see Table 10-2). Consistent with this maternal age effect, approximately 95% of cases arise in maternal meiosis, usually meiosis I. Characteristic craniofacial features include brachycephaly, oblique palpebral fissures, epicanthal folds, broad nasal bridge, a protruding tongue, and small, low-set ears with an overlapping helix and a prominent antihelix (Figure 10-1). The mean birth weight in Down syndrome, 2900 g, is decreased compared to normal infants but less so than in other autosomal trisomies. At birth, Down syndrome infants are usually hypotonic. Other features include iridial Brushfield spots, broad short fingers (brachymesophalangia), clinodactyly (incurving deflections resulting from an abnormality of the middle phalanx), a single flexion crease on the fifth digit, and an

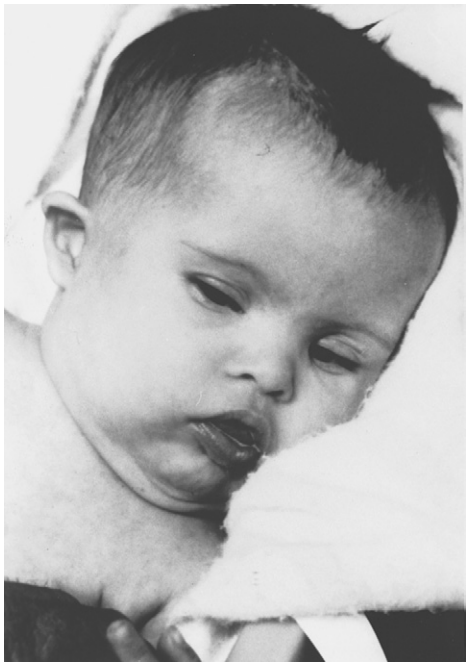

FIGURE 10-1. An infant with trisomy 21. (From Simpson JL, Elias S: Genetics in Obstetrics and Gynecology, ed 3. Philadelphia, WB Saunders, p 24, 2003.)

unusually wide space between the first two toes. A single palmar crease (simian line) is not pathognomonic, being present in only 30% of individuals with trisomy 21 and in 5% of normal individuals. Relatively common anomalies include cardiac defects and duodenal atresia. Cardiac anomalies and increased susceptibility to both respiratory infections and leukemia contribute to reduced life expectancy. However, mean survival extends into the fifth decade.

Individuals with Down syndrome who survive beyond infancy invariably exhibit mental retardation. Mean intelligence quotient (IQ) ranges approximately from 25 to 70. Mosaicism for chromosome 21 should be suspected in Down syndrome individuals with IQs in the 70 to 80 range. Women with Down syndrome are fertile. Although relatively few trisomic mothers have reproduced, about 30% of their offspring are also trisomic. Men are not considered fertile.

Several cytogenetic mechanisms may be associated with Down syndrome. **The cause of Down syndrome is triplication of a small portion of chromosome 21, namely, band q22.** Triplication may be caused either by the presence of an entire additional chromosome 21 or the addition of only band q22. Of all cases of Down syndrome, 95% have primary trisomy (47 instead of the normal 46 chromosomes) (Figure 10-2). It is these cases that show the well-known relationship to both maternal age effect and to errors in maternal meiosis.

Structural chromosomal abnormalities—translocations—show no association to parental age. They may be either sporadic or familial. The translocation most commonly associated with Down syndrome involves chromosomes 14 and 21. With translocation Down syndrome, one parent may have the same translocation (rearrangement), that is, 45,t(14q;21q), referred to as a Robertsonian translocation. Empiric risks are approximately 10% for offspring of female Robertsonian translocation carriers and 2% for offspring of male translocation carriers. A potential concern is that diploid (46,XX or 46,XY) cases actually show uniparental disomy (UPD), both chromosomes originating from the same parent. In 65 Robertsonian translocation carriers [44 t(13q;14q), 11 t(14q;21q), 4 t(14q;22q), 6 others], only 1 UPD case was observed (0.6%).[6] The authors also surveyed 357 inherited and 102 de novo published cases, and concluded overall UPD risk for UPD 14 or 15 was 3%.

Other structural rearrangements resulting in Down syndrome include t(21q;21q), t(21q;21q), and translocations involving chromosome 21 and other acrocentric chromosomes (13 to 15) or G (21 to 22). In t(21q;21q)carriers, normal gametes do not ordinarily form. Thus, only trisomic or monosomic zygotes are produced, the latter presumably appearing as preclinical embryonic losses. Parents having the other translocations have a low empiric risk of having offspring with Down syndrome.

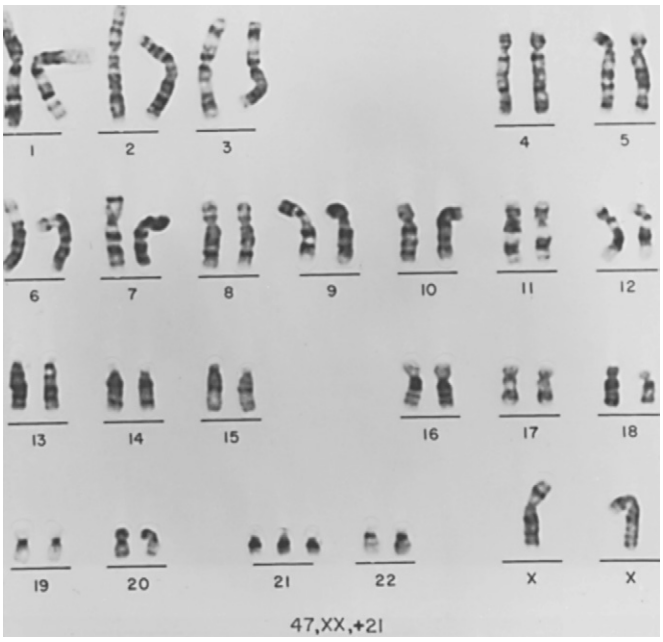

FIGURE 10-2. Karyotype of a trisomy 21 cell. Trypsin-Giemsa (GTG) banding. (From Simpson JL, Elias S: Genetics in Obstetrics and Gynecology, ed 3. Philadelphia, WB Saunders, 2003.)

Trisomy 13

Trisomy 13 occurs in about 1 per 20,000 live births. Intrauterine and postnatal growth restrictions are pronounced, and developmental retardation is severe. Nearly 50% of affected children die in the first month, and relatively few survive past 3 years of age. Characteristic anomalies include holoprosencephaly, eye anomalies (microphthalmia, anophthalmia, or coloboma), cleft lip and palate, polydactyly, cardiac defects, and low birth weight. Other relatively common features include cutaneous scalp defects, hemangiomata on the face or neck, low-set ears with an abnormal helix, and rocker-bottom feet (convex soles and protruding heels).

Trisomy 13 is usually associated with nondisjunctional (primary) trisomy (47,XX,+13 or 47,XY,+13). As in trisomy 21, a maternal age effect exists, and most cases are maternal in origin. Translocations are responsible for less than 20% of cases, invariably associated with two group D (13 to 15) chromosomes joining at their centromeric regions (Robertsonian translocation). If neither parent has a rearrangement, the risk for subsequent affected progeny is not increased. If either parent has a balanced 13q;14q translocation, the recurrence risk for an affected offspring is increased but only to 1% to 2%. The exception is a 13q;13q parental translocation, which carries the same dire prognosis as a 21q;21q translocation.

Trisomy 18

Trisomy 18 occurs in 1 per 8000 live births. Among liveborn infants, girls are affected more often than boys (3:1). Among stillborns and abortuses, however, the sex distribution is more equal.

Facial anomalies characteristic of trisomy 18 include microcephaly, prominent occiput, low-set and pointed "fawn-like" ears, and micrognathia. Skeletal anomalies include overlapping fingers (V over IV, II over III), short sternum, shield chest, narrow pelvis, limited thigh abduction or congenital hip dislocation, rocker-bottom feet with protrusion of the calcaneum, and a short dorsiflexed hallux ("hammer toe"). Cardiac and renal anomalies are common.

Mean birth weight is 2240 g. Fetal movement is feeble, and approximately 50% develop fetal distress during labor.

The mean survival is months. Liveborn infants show pronounced developmental and growth retardation. Trisomy 18 is not uncommonly detected among stillborn infants.

Approximately 80% of trisomy 18 cases are caused by primary nondisjunction (47,XX,+18 or 47,XY,+18). Errors usually arise in maternal meiosis, frequently meiosis II. Recurrence risk is about 1%.

Other Autosomal Trisomies

All autosomes show trisomies, but usually these end in abortuses. In addition to numbers 13, 18, and 21, only a few other trisomies are detected in liveborns (8, 9, 14, 16, and 22), and often in mosaic forms. All cases show mental retardation, various somatic anomalies, and intrauterine growth restriction. The extent of retardation and the spectrum of anomalies vary.

Monosomy has been claimed for trisomy 21,[7] although undetected mosaicism is always difficult to exclude.

Autosomal Deletions or Duplications

Deletions or duplications of portions of autosomal chromosomes also exist. Well-described genetic disorders have been associated with deletions or duplications of chromosomes 4p, 5p, 16q, 17p, 15q, 16p, 20p, and 22q. Specific clinical features vary, but may include learning difficulties, mental retardation, neurologic and behavioral disorders, psychiatric disorders, and various congenital anomalies.

If a chromosomal deletion or duplication is detected, a parental chromosomal rearrangement should be suspected. If a parent has a balanced translocation, duplication or inversion risks are increased in subsequent pregnancies as discussed in Chapter 11.

Availability of chromosomal microarrays (CMAs) (see Chapter 11) enable detection of duplication or deletions (copy number variants) far smaller than the 5Mb (5,000,000 base pairs) possible by conventional karyotypes. A major problem is determining clinical significance, especially in a prenatal setting. A CMA finding that can de deduced logically (if not certainly) as clinically significant in the postnatal setting cannot be so readily implicated in the prenatal state. In a postnatal setting one can compare frequency of microduplication or microdeletion in an abnormal (case) group versus a control group. A collaborative registry, the International Standards for Cytogenetic Array (ISCA) consortium, is compiling data on postnatal cases. However, changes associated involve anomalies less than conditions such as autism. Case and control groups in ISCA have not yet been stratified by de novo versus familial CMA status. For a de novo change in chorionic villi or amniotic fluid cells, clinical significance is more likely, especially if of sufficient size (e.g., 1Mb). If genes are known to be present in the region in question, the likelihood of clinical significance is reinforced. If a normal parent has the same duplication or deletion as a fetus, however, a CMA finding is not typically considered clinically significant. This complex topic is being evaluated in a large NICHD study with results expected in 2012. Thereafter, guidelines can be expected. At present regions that seem most likely to be implicated with phenotypic change, especially if de novo deletions, include 1q21.1, 15q13.2-q13.3, 16p11.2, 17q11.2-q13, and 22q11.2.;[8] all data have been derived from postnatal ascertainment.[8]

Sex Chromosomal Abnormalities

Monosomy X (45,X)

The incidence of 45,X in liveborn girls is about 1 in 10,000. Because monosomy X accounts for 10% of all first trimester abortions, it can be calculated that more than 99% of 45,X conceptuses must end in early pregnancy loss. The error usually (80%) involves loss of a paternal sex chromosome.

A common feature is primary ovarian failure due to gonadal dysgenesis. Structural abnormalities of the X chromosome may also result in premature ovarian failure. Mosaicism is frequent, usually involving a coexisting 45,X cell line. Both the long arm and the short arm of the X chromosome contain determinants necessary for ovarian differentiation and for normal stature, as discussed in detail elsewhere.[1]

45,X individuals not only have streak gonads and absent pubertal development but invariably are short (less than 150 cm). Growth hormone treatment increases the final adult height 6 to 8 cm. Low-dose estrogen therapy is needed to induce puberty, and long-term hormone replacement is needed in adulthood. Pregnancy may be achieved with the use of donor egg but requires careful monitoring of cardiovascular status before and throughout pregnancy and in the postpartum period. Various somatic anomalies including renal and cardiac defects, skeletal abnormalities such as cubitus valgus and clinodactyly, vertebral anomalies, pigmented nevi, nail hypoplasia, and a low posterior hairline. Performance IQ is lower than verbal IQ, but overall IQ is considered normal. Adult-onset diseases include hypertension, coronary artery disease, hypothyroidism, and type 2 diabetes mellitus. Comprehensive guidelines for evaluation and clinical management of Turner syndrome are available.[9,10]

Klinefelter Syndrome

About 1 in 1000 males are born with Klinefelter syndrome, the result of two or more X chromosomes. Characteristic features include small testes, azoospermia, elevated follicle-stimulating hormone and luteinizing hormone levels, and decreased testosterone. The most common chromosomal complement associated with this phenotype is 47,XXY; 48,XXXY and 49,XXXXY are less common.

Mental retardation is uncommon in 47,XXY Klinefelter syndrome, but behavioral problems and receptive language difficulties are common. Mental retardation is invariably associated with 48,XXXY and 49,XXXXY. Skeletal, trunk, and craniofacial anomalies occur infrequently in 47,XXY but are commonly observed in 48,XXXY and 49,XXXXY. Regardless of the specific chromosomal complement, patients with Klinefelter syndrome all have unquestioned male phenotypes. The penis may be hypoplastic, but hypospadias is uncommon. With intracytoplasmic sperm injection and other assisted reproductive technologies, siring a pregnancy is now possible. Simpson and colleagues[11] and Graham and colleagues[12] provide guidelines on evaluation and clinical management.

Polysomy X in Girls (47,XXX; 48,XXXX; 49,XXXXX)

About 1 in 800 liveborn girls has a 47,XXX complement. The IQ of 47,XXX individuals is 10 to 15 points lower than that of their siblings. The absolute risk for mental

retardation does not exceed 5% to 10%, and even then, IQ is usually 60 to 80. Most 47,XXX patients have a normal reproductive system. The theoretical risk of 47,XXX women delivering an infant with an abnormal chromosomal complement is 50%, given half of the maternal gametes carry 24 chromosomes (24,XX). Empiric risks are much less. Somatic anomalies are not common in 47,XXX individuals but anomalies may occur and have been observed in some prenatally detected cases.[13] However, 48,XXXX and 49,XXXXX individuals are invariably retarded and more likely to have somatic malformations than 47,XXX individuals.

Polysomy Y in Boys (47,XYY and 48,XXYY)

Presence of more than one Y chromosome is another frequent chromosomal abnormality in liveborn boys (1 in 1000). 47,XYY are more likely than 46,XY boys to be tall and are at increased risk for learning disabilities, speech and language delay, and behavioral and emotional difficulties. These males have normal male phenotype and sexual development.

GENETIC HISTORY

Obstetricians/gynecologists should attempt to take a thorough personal and family history to determine whether a woman, her partner, or a relative has a heritable disorder, birth defect, mental retardation, or psychiatric disorder that may increase their risk of having an affected offspring. To address this question, some obstetricians find it helpful to elicit genetic information through the use of questionnaires or checklists (Figure 10-3).

One should inquire into the health status of first-degree relatives (siblings, parents, offspring), second-degree relatives (nephews, nieces, aunts, uncles, grandparents), and third-degree relatives (first cousins, especially maternal). A positive family history of a genetic disorder may warrant referral to a clinical geneticist or genetic counselor who can accurately assess the risk of having an affected offspring and review genetic screening and testing options. In some cases, it may be straightforward enough for the well-informed obstetrician to manage. For example, if a birth defect (e.g., cleft lip and palate or neural tube defect) exists in a second- or third-degree relative, the risk for that anomaly will usually not prove substantially increased over that in the general population. In contrast, identification of a second-degree relative with an autosomal recessive disorder such as cystic fibrosis increases the risk for an affected offspring. Adverse reproductive outcomes such as repetitive spontaneous abortions, stillbirths, and anomalous liveborn infants should be pursued. Couples having such histories should undergo chromosomal studies in order to exclude balanced translocations (see Chapter 26).

Parental ages should also be recorded. Advanced maternal age confers an increased risk for aneuploidy (see Table 10-2). A few studies indicate an increased frequency of aneuploidy in sperm in the sixth and seventh decades. However, risks are only marginally increased above background, and there remains no indication that a liveborn pregnancy risk is increased. **A paternal age effect is associated with a small increased risk (0.3% to 0.5% or less in men over 40 years of age) for sporadic gene mutations** for some autosomal dominant conditions such as achondroplasia and craniosynostosis. There are no specific screening tests for advanced paternal age, although some of these conditions may be detected by ultrasonography (see Chapter 11). The American College of Medical Genetics (ACMG) recommends that a pregnancy sired by an older father be treated in no special way, save anatomic ultrasound scan.[14] This can detect certain autosomal dominant disorders (e.g., achondroplasia) that may often arise as de novo mutations.

Ethnic origin should also be recorded because certain genetic diseases are increased in selected ethnic groups (see Genetic Screening, later in this chapter). Such queries also apply to gamete donors.

GENETIC COUNSELING

Although situations exist in which referral to a clinical geneticist or genetic counselor is indicated, it is impractical for obstetricians to refer all patients with genetic inquiries. Obstetricians should be able to counsel patients before performing screening tests for aneuploidy and neural tube defects, carrier screening, and diagnostic procedures such as amniocentesis. Therefore, salient principles of the genetic counseling process are described.

Communication

Pivotal to counseling is communicating in terms that are readily understood by most patients. It is useful to preface remarks with a few sentences recounting the major causes of genetic abnormalities, such as cytogenetic, single-gene, polygenic/multifactorial ("complex"), and environmental (teratogens) causes. Writing unfamiliar words and using tables or diagrams to reinforce important concepts is helpful. Repetition is essential. Allow the couple not only to ask questions but to talk with one another to formulate their concerns.

Written information (letters or brochures) can serve as a couple's permanent record, allaying misunderstanding and assisting in dealing with relatives. Preprinted forms describing common problems (e.g., advanced maternal age) have the additional advantage of emphasizing that the couple's problem is not unique. More complicated scenarios require a detailed letter.

Irrespective of how obvious a diagnosis may seem, confirmation is always obligatory. Accepting a patient's verbal recollection does not suffice, nor would accepting a diagnosis made by a physician not highly knowledgeable about the condition. Medical records should be requested and reviewed. It may be necessary for an appropriate specialist to examine the affected individual and order confirmatory diagnostic tests; examining first-degree relatives may be required as well to detect subtle findings. This is particularly applicable for autosomal dominant disorders such as neurofibromatosis or Marfan syndrome, for which variable expressivity is expected. If a definitive diagnosis cannot be established, the physician should not hesitate to acknowledge this. Accurate counseling requires a definitive diagnosis.

Nondirective Counseling

In genetic counseling, one should provide accurate genetic information yet ideally dictate no particular course of

Prenatal Genetic Screen

Name _____ Patient# _____ Date _____

1. Will you be 35 years or older when the baby is due? Yes ___ No ___
2. Have you, the baby's father, or anyone in either of your families ever had any of the following disorders?
   Down syndrome (mongolism) Yes ___ No ___
   Other chromosomal abnormality Yes ___ No ___
   Neural tube defect, i.e., spina bifida (meningomyelocele or open spine), anencephaly Yes ___ No ___
   Hemophilia Yes ___ No ___
   Muscular dystrophy Yes ___ No ___
   Cystic fibrosis Yes ___ No ___
   If yes, indicate the relationship of the affected person to you or to the baby's father:
   _____
3. Do you or the baby's father have a birth defect? Yes ___ No ___
   If yes, who has the defect and what is it? _____
4. In any previous marriages, have you or the baby's father had a child born, dead or alive, with a birth defect not listed in question 2 above? Yes ___ No ___
5. Do you or the baby's father have any close relatives with mental retardation? Yes ___ No ___
   If yes, indicate the relationship of the affected person to you or to the baby's father:
   _____
   Indicate the cause, if known: _____
6. Do you, the baby's father, or a close relative in either of your families have a birth defect, any familial disorder, or a chromosomal abnormality not listed above? Yes ___ No ___
   If yes, indicate the condition and the relationship of the affected person to you or to the baby's father:
   _____
7. In any previous marriage, have you or the baby's father had a stillborn child or three or more first-trimester spontaneous pregnancy losses? Yes ___ No ___
   Have either of you had a chromosomal study? Yes ___ No ___
8. If you or the baby's father is of Jewish ancestry, have either of you been screened for Tay-Sachs disease, Canavan disease, or cystic fibrosis? Yes ___ No ___
   If yes, indicate who and the results: _____
9. If you or the baby's father is black, have either of you been screened for sickle cell trait? Yes ___ No ___
   If yes, indicate who and the results: _____
10. If you or the baby's father is of Italian, Greek, or Mediterranean background, have either of you been tested for β–thalassemia? Yes ___ No ___
    If yes, indicate who and the results: _____
11. If you or the baby's father is of Philippine or Southeast Asian ancestry, have either of you been tested for α–thalassemia? Yes ___ No ___
    If yes, indicate who and the results: _____
12. Irrespective of ethnic group, have you or the baby's father been screened for cystic fibrosis? Yes ___ No ___
13. Excluding iron and vitamins, have you taken any medications or recreational drugs since becoming pregnant or since your last menstrual period? (include nonprescription drugs)
    If yes, give name of medication and time taken during pregnancy: _____
    _____
14. Have you currently been taking folic acid supplements? Yes ___ No ___

FIGURE 10-3. Questionnaire for identifying couples having increased risk for offspring with genetic disorders. (Modified from a form recommended by the American College of Obstetricians and Gynecologists: Antenatal Diagnosis of Genetic Disorders. Technical Bulletin No. 108. Washington, DC, ACOG, 1987.)

action. Of course, completely nondirective counseling may be considered unrealistic. For example, a counselor's unwitting facial expressions may expose his or her unstated opinions. Merely offering antenatal diagnostic services implies approval. Despite the difficulties of remaining truly objective, one should attempt to provide information in a nondirective manner and then support the couple's decision.

Psychological Defenses

If not appreciated, psychological defenses can impede the entire counseling process. Anxiety is low in couples counseled for advanced maternal age or for an abnormality in a distant relative. So long as anxiety remains low, comprehension of information is usually not impeded. However, couples who have experienced a stillborn infant, an anomalous child, or multiple repetitive abortions are inherently more anxious. Their ability to retain information may be hindered.

Couples experiencing abnormal pregnancy outcomes manifest the same grief reactions that occur after the death of a loved one: denial, anger, guilt, bargaining, and resolution. One should pay deference to this sequence by not attempting definitive counseling immediately after the

TABLE 10-4 GENETIC SCREENING IN VARIOUS ETHNIC GROUPS

ETHNIC GROUP	DISORDER	SCREENING TEST
All ethnic groups	Cystic fibrosis	DNA analysis of selected panel of 23 CFTR mutations (alleles present in 0.1% of the general U.S. population)
Black	Sickle cell anemia	Mean corpuscular volume (MCV) <80%, followed by hemoglobin electrophoresis
Ashkenazi Jewish	Tay-Sachs disease	Decreased serum Hexosaminidase-a or DNA analysis for selected alleles
	Canavan disease	DNA analysis for selected alleles
	Familial dysautonomia	DNA analysis for selected alleles
Cajuns	Tay-Sachs disease	DNA analysis for selected alleles
French-Canadians	Tay-Sachs disease	DNA analysis for selected alleles
Mediterranean people (Italians, Greek)	β-thalassemia	MCV <80%, followed by hemoglobin electrophoresis if iron deficiency excluded
Southeast Asians (Filipinos, Chinese, African, Vietnamese, Laotian, Cambodian, Filipino)	α-thalassemia	MCV <80%, followed by hemoglobin electrophoresis if iron deficiency excluded

CFTR, Cystic fibrosis transmembrane conductance regulator.

birth of an abnormal neonate. The obstetrician should avoid discussing specific recurrence risks for fear of adding to the immediate burden. By 4 to 6 weeks, the couple has begun to cope and is often more receptive to counseling.

An additional psychological consideration is that of parental guilt. One naturally searches for exogenous factors that might have caused an abnormal outcome. In the process of such a search, guilt may arise. Conversely, a tendency to blame the spouse may be seen. Usually, guilt or blame is not justified, but occasionally the "blame" is realistic (e.g., in autosomal dominant traits). Fortunately, most couples can be assured that nothing could have prevented a given abnormality in their offspring.

Appreciating the psychological defenses helps one to understand the failure of ostensibly intelligent and well-counseled couples to comprehend genetic information.

GENETIC SCREENING

The goal of genetic screening is to identify individuals or couples at risk for having a child with an inherited condition, chromosomal abnormality, or birth defect. Ideally, screening to identify individuals who are carriers of genetic disorders based on ethnicity or family history should take place before conception, to ensure that couples are fully informed of their reproductive options, or as early as possible in pregnancy to allow couples the opportunity to have prenatal diagnostic testing (see Chapter 11). Screening is now offered routinely to all individuals of certain ethnic groups to identify those individuals heterozygous for a given autosomal recessive disorder (see Table 10-3). Noninvasive screening during pregnancy for aneuploidy and neural tube defects is offered to all women, regardless of age. Ultrasound screening for fetal abnormalities during pregnancy is reviewed in Chapter 11.

Carrier Screening for Heritable Conditions

Carrier screening is performed to determine if an individual has a mutation in one of two copies (heterozygous carrier) of the gene of interest. Screening is voluntary and informed consent is recommended. Ideally, individuals should be provided with information about the condition, prevalence, severity, and treatment options in addition to information about the test, including detection rates and the limitations. When the detection rate is less than 100%, it is important to explain that a negative screening test reduces the likelihood that an individual is a carrier and at risk for having an affected offspring but does not eliminate the possibility. Individuals should also be assured that their test results are confidential. For some individuals, genetic counseling may assist with the decision-making process. It may be helpful to provide individuals with disease-specific educational material. Further, it is prudent to document in the medical record that screening tests were offered and the individual's decision.

A cost-effective approach to carrier screening begins with testing the partner at risk (e.g., family history of the disease of interest) or the mother. However, it is also acceptable to test both concurrently. If one member of the couple has a mutation for an autosomal recessive disorder, the next step is to test the partner. When both parents are carriers for an autosomal recessive disorder, the risk of having an affected offspring is 25%. Genetic counseling is recommended, and the couple is informed of the availability of prenatal diagnostic testing, preimplantation genetic diagnosis, donor gametes (eggs or sperm), and adoption to avoid the risk for having an affected child (see Chapter 11). In addition, the parents should be informed that their relatives are at risk and also informed of the availability of carrier screening. Infrequently, a screening test may identify an individual with two mutations who is so mildly affected that the mutations escaped medical attention. In this situation, the individual may benefit from a referral to a specialist for further evaluation.

ACOG recommends population carrier screening for selected disorders in families in which no previously affected individual has been born.[15-19] These autosomal recessive disorders are amenable to prenatal diagnosis and are listed in Table 10-4. DNA-based tests also exist for fragile X mental retardation; however, ACOG and ACMG do not recommend screening the normal population for these conditions, save at the patient's request.[20] Fragile X testing is recommended with a family history of unexplained mental retardation, autism, a motor movement disorder,[21] premature ovarian failure, and, of course, fragile X syndrome itself.

TABLE 10-5 GENETIC SCREENING FOR SELECTED DISORDERS IN THE ASHKENAZI JEWISH POPULATION

DISORDERS	HETEROZYGOTE FREQUENCY	HETEROZYGOTE DETECTION RATE (%)
Tay-Sachs	1/25	99
Canavan	1/40	97
Familial dysautonomia	1/35	99.5
Cystic fibrosis	1/25	96
Niemann-Pick	1/70	95
Fanconi anemia, type C	1/90	95
Bloom syndrome	1/100	95
Mucolipidosis type IV	1/125	96
Gaucher disease, type I	1/19	95

ACOG also does not recommend population screening for spinal muscular atrophy (SMA), formerly called Werdnig-Hoffman disease.[22] On the other hand, the American College of Medical Genetics (ACMG) recommends SMA screening, reasoning that 95% of carriers can be detected for a disorder in which the pan-ethnic population incidence is comparable to systemic fibrosis.[23]

Ashkenazi Jewish Genetic Diseases

A number of genetic conditions are very prevalent among individuals of Ashkenazi Jewish ancestry (Table 10-5). Heterozygote or carrier detection rates for each condition are 95% to 99%, the sensitivity reflecting only a few mutations being responsible for each disorder. In aggregate, the likelihood of an Ashkenazi Jewish individual being heterozygous for one of the autosomal recessive disorders listed in this section is 1 in 4.[16] In the United States, Jewish individuals may be uncertain whether they are of Ashkenazic or Sephardic descent (90% are Ashkenazi); thus, obstetricians should offer screening to all Jewish couples. Applying criteria long in place for screening for Tay-Sachs disease, **ACOG also recommends that screening "be offered" for Ashkenazi couples for cystic fibrosis, Canavan disease, and familial dysautonomia.**[16] **For less common diseases prevalent in this ethnic group, ACOG**[16] **notes that carrier screening is available and that couples may inquire.**[16] It is recommended by ACOG that educational material should be available and couples could benefit from genetic counseling. These disorders include mucolipidosis IV, Niemann-Pick disease type A, Fanconi anemia type C, Bloom syndrome, and Gaucher disease.[16] The Genetic Disease Foundation recommends inquiring about screening for a total of 18 disorders for those of Ashkenazi Jewish ancestry (www.geneticdiseasefoundation.org).

Screening usually involves molecular testing for common selected mutations. In all the disorders listed in Table 10-4, screening only a few mutations (alleles for the mutant gene) will detect a very high percentage of heterozygotes. In Tay-Sachs disease, for example, molecular testing in Ashkenazi Jews detects 94% of heterozygotes; screening by the more laborious biochemical methods (based on ratio of hexosaminidase A to total hexosaminidase—A plus B) detects 98%.[15] If only one partner is Ashkenazi, ACOG[15,16] suggests screening that individual first. In low-risk populations (e.g., non-Ashkenazi Europeans), carrier frequency is only 1 in 300.[15] Given molecular heterogeneity being so prevalent, biochemical testing is often necessary in testing individuals who are not Ashkenazi Jews.

With the exception of Tay-Sachs disease and CF, the carrier rate and the detection rate applicable for the non-Jewish partner has not been established and, hence, screening is of limited value. It may thus not be possible to provide the couple with an accurate assessment of their risk to have an affected child.

Hemoglobinopathies

Sickle cell disease occurs most commonly among individuals of African origin but is also found in high frequency in Greeks, Italians (Sicilians), Turks, Arabs, Southern Iranians, and Asian Indians. Classic sickle cell disease is caused by homozygosity for a single base pair mutation in the β-globin gene (hemoglobin S) (see Chapter 42). **Approximately 1 in 12 African Americans are carriers of a single copy (heterozygous) of the mutation and have sickle cell trait.** Hemoglobin electrophoresis is the recommended[17] screening test because it can detect other abnormal forms of hemoglobin and thalassemia.

Thalassemia is caused by the reduced synthesis of either α- or β-globin (see Chapter 42) and is more common among individuals of Southeast Asian, African, or West Indian and Mediterranean (Greek, Italian), Asian, and Middle Eastern origin. Initial screening relies on mean corpuscular volume (MCV).[17] MCV of greater than 80% excludes heterozygosity for α- or β-thalassemia. Values less than 80% are more likely to reflect iron deficiency anemia than thalassemia heterozygosity; thus, tests to exclude the former are indicated. If iron deficiency is not found, hemoglobin electrophoresis showing elevated hemoglobin A_2 and hemoglobin F will confirm β-thalassemia. DNA-based testing is necessary to detect α-globin deletions, which cause α-thalassemia.[17] **ACOG recommends a complete blood count (MCV) and hemoglobin electrophoresis to detect thalassemia.**[17]

Cystic Fibrosis

Since 2001, screening for CF has been recommended by ACOG and ACMG.[18,19,24] CF caused by homozygosity or compound heterozygosity for mutations in the CF gene is more common in whites of Northern European and Ashkenazi Jewish ancestry. **Classic CF affects pulmonary and pancreatic function. The disorder usually is manifested early in childhood; 10% to 20% are detected at birth because of meconium ileus.** Increasing accumulation of viscous secretions progressively leads to chronic respiratory obstruction. Malnutrition and poor postnatal growth arise secondary to blockage of pancreatic ducts, producing insufficient pancreatic enzymes that interfere with intestinal absorption. Almost all men with CF have azoospermia, the result of congenital bilateral absence of the vas deferens (CBAVD). Sometimes CBAVD is the only manifestation of CF. In these cases, the mutant alleles are less deleterious than those causing severe CF. Individuals

without pancreatic involvement have a milder course and longer survival (median survival 56 years compared to 30 years).[25] **CF may be diagnosed by the chloride sweat test or suspected on a newborn screening test, but mutation testing or DNA sequencing is used to confirm the diagnosis.** Once a mutation is identified in a given family, genetic studies are indicated to detect other carriers (heterozygotes) and affected relatives.

The CF gene is relatively large (27 exons), and its gene product is a chloride channel. Since the initial report localizing the CFTR gene[26] and its value recognized for screening, ACOG provided educational material for providers caring for couples both of whom are carriers.[27] Over 1300 disease-causing mutations have been identified, but one mutation (del F 508) deletion phenylalanine [F] at codon 508 accounts for about 75% of CF mutations in non-Ashkenazi Jewish whites and 97% in the Ashkenazim.[28] **ACOG and ACMG recommend using a panethnic panel of 23 mutations (Table 10-6)[29] as a screening test to identify CF carriers.** Detection rates vary depending on ethnic origin. Screening for other alleles is optional because there is only minimal increase in sensitivity. Vendors offer expanded panels of up to nearly 100 mutations and even sequencing of the entire gene. Neither approach is recommended for routine carrier screening. However, an expanded panel or sequencing may be considered if a family member is affected and routine panels have failed to reveal molecular basis. Even if the entire gene is sequenced, not all CF mutations will be identified. Those not identified presumably act in promoter regions or perturb posttranslational modification.

Although the initial ACOG/ACMG recommendation was to offer CF carrier screening to non-Jewish whites and Ashkenazi Jews, obstetricians usually offer screening regardless of ethnicity because it can be unwieldy to assign a single ethnicity to a given patient.[19,29,30] The carrier frequency and detection rates in various ethnic groups and under varying scenarios are shown in Tables 10-7 and 10-8, respectively. Individuals without a family history of CF, an affected partner, or a male partner with CBAVD may benefit from genetic counseling, expanded screening, and, possibly, gene sequencing.

Newborn Screening

Newborn screening is mandated by each state; ACMG and the March of Dimes have recommended screening for a core panel of 29 to 30 conditions, including inborn errors of metabolism amenable to treatment such as phenylketonuria, galactosemia, homocystinuria; endocrine conditions such as hypothyroidism and 21-hydroxylase deficiency; and sickle cell anemia. Information by state is available at www.marchofdimes.com/professionals/580.asp

Table 10-6 Recommended Panel of 23 Mutations in the Cystic Fibrosis Transmembrane Conductance Regulator (CFTR) Gene That Should Be Sought in Carrier Detection Programs[29]*

DF508	DI507 N1303K	G542X	G551D	W1282Z
R533X	621 + 1G > T	R117H	1717 – 1G > A	A455E
	R560T			
R1162X	G85E	R334W	R347P	711 + 1G > T
	1898 + 1G > A			
2184delA	3120 + 1G > A	3849 + 10kbC > T	2789 + 5G > A	3659delC

*The panel is applicable in all ethnic groups. If R117H is detected, status of the 5T-7T-9T polymorphism should be determined reflexly. After originally consisting of 25 mutations,[24] two mutations were removed. 1078delT was removed because of its rarity, whereas I148T was removed because the causative gene was actually a second mutation (3199del6) in linkage disequibrium. However, this mutation (3199del6) is alone too rare to justify screening.

Table 10-7 Detecting Cystic Fibrosis (CF) Heterozygotes (23 Mutation Panel)[19]

ETHNIC GROUP	HETEROZYGOTE CARRIER FREQUENCY	PERCENT OF HETEROZYGOTES DETECTABLE (%)	LIKELIHOOD OF BEING HETEROZYGOUS DESPITE NEGATIVE SCREEN
Ashkenazi Jewish	1/24	94	1/380
European non-Hispanic white	1/25	88	1/200
Hispanic-white	1/58	72	1/200
African American	1/61	64	1/170
Asian American	1/94	49	1/180

Data of ACOG Committee Opinion 486 (2011). The current panel encompasses 23 mutations,[29] rather than the original 25.[24]

Table 10-8 Likelihood of Affected Fetus After Concurrent (Father and Mother) Versus Sequential (Single Partner Initially) Screening for Cystic Fibrosis

	NON-HISPANIC EUROPEAN WHITES	ASHKENAZI JEWISH
No screening	1/2500	1/2304
Both partners negative (concurrent)	1/173,056	1/640,000
One partner negative, one untested (sequential)	1/20,800	1/38,400
One partner positive, one negative (concurrent)	1/832	1/1600
One partner positive, other untested	1/100	1/96
Both partners positive	1/4	1/4

These calculations are based on the frequencies shown in Table 10-6.

or at the National Newborn Screening and Genetics Resource Center's website at genes-r-us.uthsca.edu.

Considerable recent attention is being given to newborn screening for hearing loss. More than 70 genes related to hearing are already known. Mutations in gap junction B *(GJB2)*, the gene that codes connexin 26, and the neighboring gene *GJB6* (connexin 30) account for 50% of deafness in the newborn.[31] The heterozygote frequency for *GJB2* alone is 3% in North American whites.[32] Screening the neonate is standard of care but parents may decline testing and in some states need to consent. These screening tests may also identify couples who are carriers and may benefit from genetic counseling to learn about their options in subsequent pregnancies.

Screening for Aneuploidy

Noninvasive screening for chromosomal disorders such as trisomy 21 and 18 is routinely offered to women during pregnancy regardless of maternal age. Currently available noninvasive screening tests have high detection rates and can decrease the need for diagnostic testing and potential loss of a normal pregnancy; however, there are also limitations to screening, namely false-negative and false-positive results. This section focuses on first and second trimester screening tests; Chapter 11 discusses invasive diagnostic tests and prenatal ultrasonography as a screening and diagnostic tool. The strategy underlying currently employed aneuploidy screening involves deriving likelihood ratios. Likelihood risks for multiple informative markers are taken into account to yield an overall ratio, which is multiplied by the a priori age-related risk. If a marker reveals a likelihood ratio for having a fetus with Down syndrome of 2.6 for MSAFP (a second trimester aneuploidy marker) (Figure 10-4) and the a priori (age-specific) risk was 1 in 581, the recalculated risk after taking into account PAPPA becomes 1 in 148. One calculates likelihood ratio for each analyte tested, each value contributing to an overall likelihood that can be translated into the specific aneuploidy risk for a given patient.

First Trimester Screening

First trimester screening is best performed between 11 and 14 weeks. **The most effective first trimester biochemical markers are PAPP-A and free β-hCG, and the ultrasound measurement of nuchal translucency (NT), a sonolucent space present in all fetuses behind the fetal neck.** PAPP-A levels are reduced, hCG increased, and the NT measurement increased in trisomy 21. NT measurement alone has about a 70% detection rate with a false-positive rate of about 5%.[33] A critical necessity is the requirement for a robust quality NT assurance program. In combination with biochemical markers, the detection rate is greater than 80% with a false-positive rate of 5%. **First trimester screening is comparable or superior to second trimester screening alone and, more important, provides women with the option of earlier diagnostic testing in the event the screen indicates that the fetus is at high risk for aneuploidy.**

Several large collaborative, prospective studies have validated the clinical application of first trimester screening. In the first U.S. large-scale prospective study, 10,251 women of all ages were screened with PAPP-A and free β-hCG using a dried blood spot method; 5809 also had an NT measurement.[34] **Using both ultrasound (NT) and serum analytes (PAPP-A, free β-hCG), the detection rate for trisomy 21 was 87.5% (7 of 8 cases) in women younger than 35 years of age; in women older than 35 years, the detection rate was 92%** (23 of 25), albeit with a higher false-positive or invasive procedure rate. For trisomy 18, detection rates were 100% in both age groups. These impressive results validated the application of first trimester screening for aneuploidy.

In 2003, an NICHD multicenter cohort study, the Blood Ultrasound Nuchal (BUN) Study, reported results in 8514 women screened between 74 and 97 days' gestation[35] (Table 10-9). Applying the traditional midtrimester screen positive cutoff of 1 in 270, 85.2% of trisomy 21 pregnancies were identified at a false-positive rate of 9.4%. The high false-positive rate was predictable, given the higher mean maternal age of the sample. Stratifying by age, the detection rate for trisomy 21 was 66.7% for patients younger than age 35 years at a 3.7% false-positive rate and 89.8% in patients older than age 35 years with a 15.2% false-positive rate. The detection rate for trisomy 18 was 90.9%. Modeling for the general population (with a lower mean age) and setting a false-positive procedures rate of 5%, sensitivity for trisomy 21 would still be 78.7%; at a false-positive rate of 1%, the sensitivity would be 63.9%. These findings were consistent with other studies.

Two other large collaborative studies have also provided results comparable to the NICHD BUN Study. SURUSS (*S*erum *UR*ine and *U*ltrasound *S*creening *S*tudy) was a 25-center European trial[36] in which 47,000 patients were evaluated in both the first and second trimester. Results of

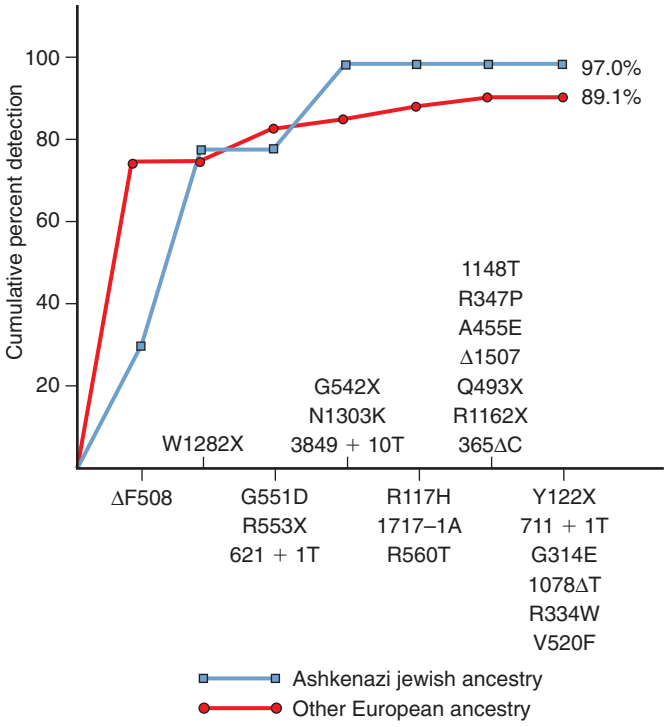

FIGURE 10-4. Increasing detection rate in northern European white and Ashkenazi Jewish populations as increasing numbers of CF-causing alleles are sought. (From Cystic Fibrosis Foundation Annual Report. New York, 1996.)

TABLE 10-9 Detection Rates in the NICHD BUN Study of Wapner and Colleagues[35]*

MATERNAL AGE	DETECTION TRISOMY 21 RATE (%)	FALSE-POSITIVE (PROCEDURE) (%)
<35 yr	66.7	3.7
≥35 yr	89.8	15.2
Total	**85.2**	**9.4**
Modeling for U.S.		
Population (mean)	78.7	5
(Maternal age 27 yr)	63.9	1

*The NICHD first trimester only screening (NT, PAPP-A, free β-hCG) cohort of Wapner and colleagues.[35] The sample of 8515 pregnancies prospectively applied a cut off of 1/270. Detection rate increases with prevalence (increased maternal age), albeit at the cost of more procedures. Because the mean maternal age was 34.5 years, data were then modeled to apply to the U.S. population (whose mean maternal age is 27) at a 5% to 1% false-positive rate.
BUN, Blood ultrasound nuchal translucency; *NICHD,* U.S. National Institute of Child Health and Human Development.

TABLE 10-10 Detection Rates in the NICHD FASTER Trial of Malone and Colleagues[37]

TESTS*	TRISOMY 21 DETECTION (%)
First Trimester (free β-hCG, PAPP-A, NT)	
11 wk	87
12 wk	85
13 wk	82
Second Trimester (15-18 wk)	
AFP, uE_3, total hCG ("triple test")	69
AFP, uE_3, total hCG, inhibin A ("quad test")	81
First Plus Second Trimester (PAPP-A, NT, AFP, uE_3, hCG, inhibin A)	
Disclosure of first trimester results	95
Nondisclosure of first trimester results	96
Serum screening only	88

*If first trimester ultrasound revealed septated cystic hygromas, intervention was taken (CVS offered). Otherwise results were not disclosed until after second trimester screening. Compiled data were then used to compare detection rates that would have occurred given various approaches, all at 5% false-positive (procedure) rates for each.
AFP, Alpha-fetoprotein; *CVS,* chorionic villus sampling; *FASTER,* First and Second Trimester Evaluation of Risk; *hCG,* human chorionic gonadotropin; *NICHD,* U.S. National Institute of Child Health and Human Development; *NT,* nuchal translucency; *PAPP-A,* pregnancy-associated placental protein; *uE_3,* unconjugated estriol.

first trimester assays were not disclosed to patients; thus, there could be no intervention. Nonetheless, setting the detection rate at 85% and using first trimester PAPP-A, hCG, and NT would have required procedures in 5.6% of women screened. Using a similar design, Malone and colleagues[37] studied 38,167 women in 15 U.S. centers in the NICHD FASTER trial. Detection rates were 87% for Down syndrome at 11 weeks and 85% at 12 weeks (Table 10-10). In this study, 134 women having a fetus with a septated cystic hygroma were removed from the cohort; 51% had a chromosomal abnormality and 34% had other major abnormalities.[38] The group[31] later stratified their data and found that NT greater than 4 mm was never associated with a normal noninvasive screen and, therefore, women should be offered diagnostic testing. In fact, only 8% of pregnancies with NT greater than 3 mm had a screen negative value.

Nicolaides[33] tabulated that NT, PAPP-A, and hCG detected 87% of 215 trisomy fetuses at a false-positive rate of 5%. Later results of Avgidou and colleagues[40] reported superior results from the same U.K. group. This group screened 30,564 women with NT, PAPP-A, and hCG, providing results the same day and detecting 93% of trisomy 21 cases. The incorporation of the other sonographic markers such as the presence of a nasal bone have been proposed to increase the detection rates further. However, at present these are not routinely employed.

When an increased NT measurement is associated with a normal karyotype, fetal loss rates are increased, and other fetal anomalies and genetic syndromes are observed, in particular, congenital heart defects.[41] **A targeted ultrasound examination during the second trimester and fetal echocardiography are recommended when the NT measurement is 3.5 mm or greater and the fetal karyotype is normal.**

Second Trimester Serum Screening

Multiple marker serum screening is used between 15 and 22 weeks' gestation to screen for both aneuploidy and open neural tube defects. **The most widely used second trimester aneuploidy screening test is the "quad screen," which utilizes four biochemical analytes—alpha-fetoprotein (AFP), hCG, unconjugated estriol (uE_3), and dimeric inhibin-A. The detection for trisomy 21 is about 75% in women who are less than 35 years of age and over 80% in women 35 years of older, with a false-positive rate of 5%.** For trisomy 18, using only the first three markers the detection rate is about 70%. Screening does not detect other age-related forms of aneuploidy such as Klinefelter syndrome, 47,XXY. Women with a positive screening test or a risk equal to or greater than a 35-year-old woman (e.g., 1 in 270) are referred for genetic counseling and offered diagnostic testing (see Chapter 11).

Use of all four analytes increases the second trimester detection rate for trisomy 21. The most informative single second trimester analyte is human chorionic gonadotropin (hCG). Levels of hCG rise from implantation to 8 weeks' gestation, plateau between 8 and 12 weeks' gestation, decrease from 12 to 18 weeks, and then plateau again until term. Serum hCG levels are increased in women carrying fetuses with Down syndrome.[42] Controversy exists as to whether the free β subunit of hCG is preferable to total hCG in Down syndrome screening, especially in the second trimester. The analyte unconjugated estriol (uE_3) is synthesized from dehydroepiandrosterone sulfate following conversion to 16 alpha-hydroxydehydroepiandrostenedione sulfate in the fetal liver and then to uE_3 in the placenta. Levels of uE_3 in maternal serum are lower (25%) in pregnancies affected with Down syndrome compared with those in unaffected pregnancies.[43] Like hCG, inhibin A (INHA) is elevated in Down syndrome pregnancies. This dimeric glycoprotein has an α-subunit and a βA-subunit linked by a disulfide bond. During pregnancy, inhibin is produced by the corpus luteum and then the placenta. Serum inhibin A levels from women carrying fetuses with Down syndrome have a median multiples of the median (MoM) of about 1.8[44] and do not change significantly with gestational age, unlike most other serum markers.

Typically, levels of AFP, uE_3, and hCG are reduced in trisomy 18. A simple approach to detect trisomy 18 is to offer invasive prenatal diagnostic testing whenever serum

screening for each of these three markers falls below certain thresholds (MSAFP 0.6 MoM; hCG 0.55 MoM; uE_3 0.5 MoM).[45] Using these thresholds would detect 60% to 80% of trisomy 18 fetuses, with a 0.4% amniocentesis rate. Calculating individual risk estimation on the basis of three markers and maternal age, Palomaki and colleagues[46] reported that 60% of trisomy 18 pregnancies can be detected with a low false-positive rate of 0.2%. The value of individual risk estimates is that one in nine pregnancies identified as being at increased risk for trisomy 18 by serum screening would actually be affected.

First and Second Trimester Screening

Several different approaches have been proposed to use both first and second trimester screening to increase the detection rate over that achieved by screening in either trimester alone, with detection rates of 88% to 96% with false-positive rates of 5% reported. A caveat is that independent screening (i.e., using both first and second trimester screening tests to assess separately and independently the risk) is not recommended because of the unacceptably high false-positive rates. The best screening approaches combine first and second trimester approaches.

Sequential screening begins with first trimester screening. A woman is informed of the adjusted risk for aneuploidy based on the first trimester results. If her risk is high (greater than 1 in 50), she is offered genetic counseling and diagnostic testing (see Chapter 11). If the risk is low or moderate, a second trimester screening test is performed with results of both the first and second trimester screening tests used to generate a final adjusted risk for trisomy 21 and 18. This is called the stepwise approach. With contingency screening not all women will even proceed to second trimester screening. This occurs only with an intermediate risk; if the risk is low after the first trimester screen, no further testing is indicated. The detection rates are about 90% with low positive screening rates (2% to 3%). Malone and colleagues[47] compared several different first plus second trimester contingent sequential approaches (see Table 10-9). They concluded that the optimal method was contingency screening in which patients were divided into three groups: women whose calculated (NT, PAPP-A, hCG) first trimester risk was greater than 1/30 would undergo CVS; women whose risk was less than 1/1500 would undergo no further testing; all other women would undergo second trimester serum testing. Using this approach, only 21.8% of the cohort would need second trimester testing in order to detect 93% of trisomy 21 cases at a 4.3% false-positive rate; 65% would be detected in the first trimester with only 1.5% of patients having CVS procedures.

Integrated screening has the highest theoretical (modeling) detection rate (93% to 96%), but with this approach the first trimester screening results are withheld until the second trimester screen is completed. The individual receives only a single adjusted risk for trisomy 21 and trisomy 18 based on the results of both the first and second trimester screen. The obvious disadvantage with this approach is that the individual does not have an option of early diagnostic testing in the event that the first trimester screen would have indicated a high risk for trisomy 21 or 18. Another is that patients may not return for their second trimester screen. In the SURUSS trial, one third of patients failed to return for second trimester testing, despite being requested to do so and part of a study protocol.[25] Fortunately, integrated screening is not necessary; Cuckle and colleagues[48,49] showed that disclosure of first trimester results could be made with very little loss in sensitivity. Conversely, detection rates need not be diminished at all if procedure rates were increased only slightly (1% to 2%).

Lastly, serum integrated screening is useful when an NT measurement cannot be obtained or in communities where NT measurement is not available. With this approach, the first trimester PAPP-A and the second trimester analytes are used to adjust the risk for trisomy 21 and the individual receives one adjusted risk after the second trimester screen is completed. With this approach, sensitivity was 88% in the FASTER trial.[37]

In conclusion, **sequential (first plus second trimester) screening increases the detection rates over first trimester screening alone, but by no more than perhaps 5%.** This difference may shrink if other sonographic markers such as nasal bone are incorporated into the screening process (see Chapter 11). Both ACOG and ACMG recommend that women be offered either first trimester screening alone; sequential (stepwise or contingency) or integrated first and second trimester screening; or second trimester screening alone. **The only screening option not recommended by ACOG is second trimester screening independent of first trimester screening; both first and second trimester screening, should, if pursued, be done in the context of the integrated test, stepwise sequential test, or contingent sequential test.**[50]

Factors Confounding Detection Rates

Maternal Age

Detection rates vary according to sample characteristics, an important caveat in comparing studies. In particular, sensitivity for noninvasive screening is age dependent. Software is constructed such that the proportion of cases detected at a given age is greater for older women than for younger women; the "false-positive" (procedure) rate also increases with maternal age. **More than 90% of cases of Down syndrome will be identified by noninvasive screening in women aged 35 or older, whereas a considerably lower proportion will be identified in much younger women. Therefore, women should be given precise answers as to proportion of trisomy 21 cases excluded by screening.** In particular, one should not counsel a 25-year-old to expect the same proportion of trisomy 21 fetuses to be detected as in the general population (70% or 80%). Although the proportion of cases detected in younger women is lower, the absolute risk remains very low in the screen-negative 25-year-old. Detection rates also depend on *week* (not just trimester) of gestation and on the arbitrarily set procedure rate (false-positive rate). If one accepts more procedures (higher false-positive rate), detection rates increases. The converse is also true.

Maternal Weight and Ethnicity

Confounding factors influence serum screening, and adjustments may be necessary. **Adjustments for maternal weight and ethnic group are routinely employed.** The initial MSAFP assay should be performed at 15 to 20 weeks' gestation. When MSAFP is used for aneuploidy screening,

corrections for gestational age, maternal weight, diabetes, ethnicity, and number of fetuses are necessary. Weight adjustment is needed because without adjustment, dilutional effects would result in heavier women having a spuriously low value, whereas thinner women would have a spuriously elevated value. In women with type 1 diabetes mellitus, a population at increased risk for a neural tube defect (NTD), the median MSAFP is 15% lower than in nondiabetic women. In women of black ethnicity, who have a lower risk for a fetal NTD, the median MSAFP is higher than in other ethnic groups.

With increased maternal weight, decreased levels of AFP, uE_3, and hCG levels all occur. Type 1 diabetes mellitus is associated with decreased uE_3 and hCG. Maternal smoking increases MSAFP by 3% but decreases maternal serum uE_3 and hCG levels by 3% and 23%, respectively.[51] Maternal serum hCG is higher and MSAFP lower in pregnancies conceived in vitro, compared with pregnancies conceived spontaneously.[51] A claim has been made that adjustments should be made for prior aneuploidy; β-hCG is reported to be 10% higher in a pregnancy after aneuploidy, whereas pregnancy-associated placental protein A (PAPP-A) is increased 15% in the first trimester.[52]

Multiple Gestation

Down syndrome occurs 20% more often in twin pregnancies than in singleton pregnancies, as expected given the known positive correlation between twinning and maternal age. Unfortunately, Down syndrome screening using multiple serum markers is less sensitive in twin pregnancies than in singleton pregnancies. **Using singleton cutoffs**, one study showed that 73% of monozygotic twin pregnancies were detected but **only 43% of dizygotic twin pregnancies with Down syndrome, given a 5% false-positive rate.**[53] Decreased sensitivity in detecting trisomy 21 in dizygotic twins reflects the blunting effect of the concomitant presence of one normal and one aneuploid fetus. Thus, patients with twins should be informed that the detection rate by serum screening is less than in singleton pregnancies. First trimester screening identifies about 70% of Down syndrome pregnancies; NT measurement alone has been shown to be as effective as a screening test for higher-order multiple gestation. Addition of the nasal bone assessment increased the detection rate to 87% to 89% in a retrospective study of twin pregnancies. First trimester screening provides the option of early diagnostic testing if the risk is increased and if selective reduction is an option.

MATERNAL SERUM ALPHA-FETOPROTEIN SCREENING FOR NEURAL TUBE DEFECTS

Screening for NTDs was the first application of maternal serum analyte to screening. Because relatively few (5%) NTDs occur in families who have had previously affected offspring, a method other than a positive family history was needed to identify couples in the general population at risk for offspring with an NTD. MSAFP and ultrasound examination (see Chapter 11) are now both useful screening tests.

MSAFP screening for NTD detection should be performed at 15 to 20 weeks' gestation. As with aneuploidy screening, corrections must be made for gestational age, multiple gestations, presence of diabetes mellitus, and maternal age. However, correction for maternal age is not necessary. Maternal serum values above either 2.0 or 2.5 MoM are usually considered elevated with respect to NTD, but exact values are less important than maintaining a consistent policy in the screening program. Values above 2.0 MoM are considered elevated in women with type 1 diabetes, whereas in twin gestations MSAFP is considered abnormal only at 4.5 to 5.0 MoM or greater. Irrespective, threshold values are used for NTD detection in contrast to likelihood ratios derived for aneuploidy screening.

Approximately 3% to 5% of women have an elevated MSAFP depending on threshold set and accuracy of pregnancy dating, and these are mostly false-positive results. If gestational age assessment is determined accurately (e.g., by first trimester sonogram), the number of women having an abnormal serum value is relatively lower. If MSAFP is elevated, a repeat sample may or may not be necessary according to the established protocol, usually based on the accessibility of ultrasound evaluation. In our opinion, there is value in repeating the MSAFP if the value lies between 2.50 and 2.99 MoM and if gestational age is 18 weeks or less.

MSAFP is greater than 2.5 MoM in 80% to 90% of pregnancies in which the fetus has an NTD: 90% in anencephaly and 80% in open spina bifida.[54] With ultrasound alone, one should be able to achieve very high detection rates for anencephaly, but there may be limitations to the detection of small spinal defects and ultrasound examination can confirm gestational age, confirm multiple gestation, and detect other anomalies. In some cases, amniocentesis to measure the amniotic fluid AFP and acetylcholinesterase levels may be necessary (see Chapter 11).

MSAFP may be spuriously elevated (with respect to NTD) in other circumstances, such as (1) underestimated gestational age, inasmuch as MSAFP increases as gestation progresses; (2) unrecognized multiple gestation (60% of twins and almost all triplets having MSAFP values that would be elevated if judged on the basis of singleton values); (3) fetal demise, presumably reflecting fetal blood extravasating into the maternal circulation; (4) Rh isoimmunization, cystic hygroma, and other conditions associated with fetal edema; and (5) other anomalies, mainly abdominal wall defects such as gastroschisis and omphalocele. Follow-up for the conditions cited is obviously necessary.

Absent ultrasound, approximately 1 in 15 women having an unexplained elevated serum AFP will have a fetus with a NTD. The sensitivity for detection of an NTD in twin gestations is predictably lower than in singleton gestations, being only about 30% for spina bifida given a threshold of 4.5 MoM. The lower sensitivity exists because twins are usually discordant for an NTD. Liberal use of ultrasound is recommended in twin gestations.

If aneuploidy screening is performed in the second trimester, an MSAFP value will already be available as part of three (triple) or four (quad) analyte screening for aneuploidy. First trimester MSAFP is, however, not a sensitive method for detecting NTDs. If first trimester aneuploidy

screening alone is performed, second trimester MSAFP screening or ultrasound is still necessary to detect NTDs.

Obstetrical Significance of Unexplained Elevated Maternal Serum Alpha-Fetoprotein

Often, no evident cause is detected after a comprehensive assessment of a patient with an elevated MSAFP. This group of patients has been consistently described to be at higher risk of adverse perinatal outcome: spontaneous abortion, preterm birth, small for gestational age, low birth weight, and infant death. On the other hand, extremely low MSAFP values (less than 0.25 MoM) have also been associated with an increased morbidity: spontaneous abortion, preterm birth, stillbirth, and infant death.[55,56]

Interestingly, in a large prenatal screening database in western Scotland a direct association between MSAFP and the risk of sudden infant death syndrome (SIDS) has been observed.[57]

KEY POINTS

- The frequency of major birth defects is 2% to 3%, based on the definition of a defect causing death, a severe dysfunction, or a structural malformation requiring surgery.
- Major etiologic categories include chromosomal abnormalities (1 in 160 live births), single-gene or mendelian disorders, polygenic/multifactorial disorders, and disorders caused by exogenous factors (teratogens).
- The frequency of autosomal trisomies is higher in midtrimester (30% for Down syndrome) than at term, and many trisomies are so lethal that they are found only in abortuses.
- Single-gene disorders in aggregate result in major defects in 1% of neonates, with additional disorders manifested later in life. However, individual disorders are uncommon, rarely exceeding 1 per 4000.
- Genetic counseling requires adequate communication, appreciation of psychological defenses, and adherence to the principle of nondirective counseling.
- Genetic screening to detect heterozygotes in the nonpregnant and, if not already evaluated, in the pregnant population is appropriate for the following autosomal recessive disorders: Tay-Sachs disease, Canavan disease, familial dysautonomia in Jewish populations; Tay-Sachs disease in Cajun and French-Canadian populations; cystic fibrosis in all populations; α-thalassemia in Asians; β-thalassemia in Mediterranean populations (Greek and Italians); and sickle cell disease in blacks. ACOG does not currently recommend screening for spinal muscular atrophy (SMA), although the American College of Medical Genetics (ACMG) does.
- Carriers for β-thalassemia and α-thalassemia can be inexpensively detected on the basis of MCV less than 80% followed by hemoglobin electrophoresis, once iron deficiency is excluded. Alternatively, ACOG recommends hemoglobin electrophoresis for screening.
- Cystic fibrosis is found in all ethnic groups, but the heterozygote frequency is higher in non-Hispanic whites of northern European (1 in 25) or Ashkenazi Jewish origin (1 in 24) than in other ethnic groups (black 1/61, Hispanic 1/58, Asian 1/94). In the former two groups incidence is approximately 1 in 3600. ACOG and the ACMG originally recommended that CF screening be offered to whites and "made available" to other groups. In 2005, the ACOG acknowledged the difficulty in assigning a single ethnicity and stated that it was reasonable to offer screening to all pregnant women.
- The cystic fibrosis transmembrane regulatory (CFTR) gene is large (27 exons), and more than 1500 disease-causing mutations have been recognized. Screening is obligatory only for a specified panel of 23 mutations. In northern European white and Ashkenazi Jewish individuals, the heterozygote detection rate using the specified panel is 88% and 94%, respectively. In other ethnic groups detection rates are lower (64% blacks, 72% Hispanics, 49% Asian Americans).
- Noninvasive screening for trisomies can be offered at any age, providing patient-specific aneuploidy risks (trisomy 21; trisomy 18). If the calculated risk is greater than a given threshold risk (that of a 35-year-old in midgestation), an invasive procedure is offered. Comparing different methods is usually done by assuming a given number of procedures (false-positive rates) (5%). Detection rates vary if a different false-positive rate is applied.
- First trimester noninvasive screening uses serum free hCG, PAPP-A, and nuchal translucency (NT) measurements. The detection rate is at least 87% at 11 weeks and 85% at 12 weeks at a false-positive (procedure) rate of 5%.
- Second trimester noninvasive screening with three analytes (hCG, AFP, uE3) has a 70% detection rate, whereas screening with four analytes (hCG, AFP, uE3,inhibin A) has an 80% detection rate. Thus, second trimester screening has a lower detection rate than first trimester screening.
- In sequential screening, one performs first followed by second trimester screening. In contingency screening, one discloses first trimester results, offering CVS to high-risk women, and performing second trimester screening only on low-risk women. Alternatively, first trimester results can be withheld (nondisclosure or integrated), with only a single result provided in the second trimester. The two approaches show almost identical detection rates (95% and 96%); thus, offering nondisclosure is usually unnecessary. If pursued, nondisclosure screening necessitates rigorous patient follow-up to ensure compliance.

Prenatal genetic diagnosis is an important process used to evaluate the fetus at risk for a chromosomal abnormality, genetic disorder, or a congenital anomaly. Amniotic fluid, placental tissue, and cord blood can be readily obtained and analyzed during the first and second trimester. It is also possible to diagnose chromosomal abnormalities and genetic disorders from fetal cells or DNA recovered from the maternal blood and cells from embryos obtained through in vitro fertilization. The detection of many congenital malformations is possible using ultrasonography and fetal echocardiography.

In this chapter, we review the indications for prenatal diagnosis and specifically discuss the procedures used to obtain fetal tissue and cells for prenatal diagnosis and to visualize congenital anomalies. This chapter complements Chapter 10 on genetic counseling, which discusses noninvasive screening for aneuploidy and neural tube defects.

DIAGNOSTIC PROCEDURES FOR PRENATAL GENETIC DIAGNOSIS

Prenatal detection of chromosomal abnormalities and many genetic conditions requires an invasive procedure such as amniocentesis or chorionic villus sampling (CVS) to obtain fetal or placental tissue for chromosomal and genetic testing. Less frequently, cordocentesis is performed to obtain fetal blood. In this section, we review these techniques and their safety.

As a common feature of any prenatal invasive procedure, the patient should receive genetic counseling and be fully informed about the nature of the procedure. It is essential in clinical practice to obtain formal consent before an invasive procedure. Written or oral information should include nature, accuracy, and possible results; how, when, and by whom it is performed; safety of the procedure; culture failure rates; reporting time; and postprocedure recommendations.

Amniocentesis

Genetic amniocentesis was first performed in the 1950s. Analytes such as α-fetoprotein (AFP) can be measured in the amniotic fluid, and amniocytes can be cultured for cytogenetic and molecular analyses. Amniocentesis is probably the most widely used prenatal diagnostic invasive procedure.

Technique

Genetic amniocentesis is usually performed after 15 weeks' gestation. A 20- or 22-gauge spinal needle with the stylet is introduced percutaneously into the amniotic cavity under continuous ultrasound guidance taking care to avoid the fetus, cord, and whenever possible, the placenta. A local anesthetic in the site of puncture may be given, but a randomized trial showed that local anesthetic did not reduce pain scores reported by women undergoing amniocentesis.[1] Approximately 20 to 30 mL of amniotic fluid is aspirated and the first 1 or 2 mL usually discarded in order to avoid maternal cell contamination. Rh immune globulin should be administered to the Rh-negative, Du-negative, unsensitized patient who has an Rh-positive fetus (or if fetal Rh status is not known, through cell free fetal DNA studies).

Continuous visualization of the needle by ultrasound significantly reduces the incidence of bloody amniotic fluid, dry taps, and the need for multiple insertions. Bloody amniotic fluid is occasionally aspirated; however, the blood is almost always maternal in origin and does not adversely affect amniotic cell growth. Brown, dark red, or wine-colored amniotic fluid indicates that intra-amniotic bleeding has occurred earlier in pregnancy and hemoglobin breakdown products are persistent in the fluid. Pregnancy loss eventually occurs in about one third of such cases. If the abnormally colored fluid is associated with an elevated AFP level, then the outcome is almost always unfavorable (fetal demise or fetal abnormality). Greenish amniotic fluid is the result of meconium staining and is apparently not associated with poor pregnancy outcome.

After amniocentesis, the patient may resume all normal activities. Common sense dictates that strenuous exercise such as jogging or aerobic exercise is deferred for a day or so. Deferring sexual activity for 24 to 48 hours seems prudent. The patient should report persistent uterine cramping, vaginal bleeding, leakage of amniotic fluid, or fever; however, physician intervention is almost never required, unless of course overt abortion occurs.

Amniocentesis in Twin Pregnancies

In multiple gestations, amniocentesis can usually be performed on all fetuses. It is important to assess and record chorionicity, placental location, fetal viability, anatomy, and gender and to carefully identify each sac should selective termination be desired at a later date. A simple and reliable technique to ensure that the same sac is not sampled twice is to inject 2 to 3 mL of indigo carmine following aspiration of amniotic fluid from the first sac, before the needle is withdrawn. A second amniocentesis is then performed at a site determined after visualizing the membranes separating the two sacs. Aspiration of clear fluid confirms that the second (new) sac was entered. Gestations greater than two can be managed similarly, sequentially injecting dye into successive sacs. Cross-contamination of fetal cells in multiple gestations appears rare, but confusion may sometimes arise in interpreting amniotic fluid acetylcholinesterase (AchE) or AFP results. Some obstetricians aspirate the second sac without dye injection, use a single-puncture technique, or perform simultaneous visualization of the two inserted needles in each sac.[2,3]

If only one fetus in a multiple gestation is abnormal, parents should be prepared to choose between aborting all fetuses or continuing the pregnancy with one or more normal fetuses and one abnormal fetus. Selective termination in the second trimester is possible but is associated with a higher rate of complications (fetal loss and prematurity); therefore, CVS should be considered the preferred test for multiple gestations.

Safety

Any procedure that involves entering the pregnant uterus carries some risk to the fetus. **However, the risk for amniocentesis is very low in experienced hands, approximately 1 in 400 procedure-related losses, or less.**[4] The risk for pregnancy loss has decreased since the large collaborative studies to assess safety were first done in the 1970s.[5,6] In none of these early collaborative studies, nor others of that

era, was high-quality ultrasonography as defined by today's standards available, nor was concurrent ultrasonography ever universally applied.[3] By contrast, studies conducted within the past decade universally employ high-quality ultrasound and have shown no statistical difference between outcomes following amniocentesis groups and controls. Increased risks logically should be increased even further when amniocentesis is performed in twins. However, even this is difficult to prove.

Maternal risks are low, with symptomatic amnionitis occurring only rarely (0.1%). Minor maternal complications such as transient vaginal spotting or minimal amniotic fluid leakage occur in 1% or less of cases, but these complications are almost always self-limited in nature. Other complications include intra-abdominal viscus injury or hemorrhage. The most serious is fulminant sepsis (*Escherichia coli* or clostridia) resulting in maternal mortality, but this is extraordinarily rare.[7]

Early Amniocentesis

The American College of Obstetricians and Gynecologists (ACOG) states that amniocentesis before 14 weeks' gestation, especially before 13 weeks' gestation, should not be performed for genetic indications.[8] The basis for this strong statement is four large studies all showing untoward results including higher rates of pregnancy loss, talipes equinovarus (TE), and amniotic fluid leakage.

Amniocentesis in Women with Hepatitis B, Hepatitis C, and Human Immunodeficiency Virus

Blood-borne viruses constitute a risk factor for maternal-fetal transmission. Available evidence is limited, but the risk for transmission for hepatitis B seems to be very low.[9] Knowledge of the maternal hepatitis B "e" antigen status is valuable in the counseling of risks associated with amniocentesis. There is less information about hepatitis C, but to date there is no evidence that transmission is increased following amniocentesis.[10] **Invasive prenatal testing can be carried out in women who carry hepatitis B or C; however, the patient should be informed of the limited data on transmission.**

In HIV-positive women, noninvasive testing is preferable, and invasive testing should be avoided, particularly in the third trimester when the relative risk for transmission is 4 when an invasive procedure is performed.[10,11] Some authors have suggested that procedures early in pregnancy would carry a very low risk provided that antiretroviral therapy is administered and the maternal viral load is low.[12]

The Society of Obstetricians and Gynaecologists of Canada states that for women infected with hepatitis B, hepatitis C, or HIV, the use of noninvasive methods for prenatal screening, (e.g., nuchal translucency [NT] measurement, maternal serum screening, and anatomic ultrasound) may help reduce that age-related risk to a level below the threshold for genetic amniocentesis. For those who insist on amniocentesis, every effort should be made to avoid traversing the placenta.

Chorionic Villus Sampling

CVS allows diagnosis in the first trimester of pregnancy. If desired, pregnancy termination can be performed earlier, when it is much safer for the mother. For example, the maternal death rate is 1 per 100,000 early in pregnancy compared with 7 to 10 per 100,000 in midpregnancy.[13] Early diagnosis also makes it feasible to perform selective fetal reduction in multiple gestations, a relatively safe procedure in the first trimester but decidedly less so in the second trimester. Early termination also protects patient privacy. Both chorionic villi analysis and amniotic fluid cell analysis offer the same information concerning chromosomal status, enzyme levels, and gene mutations. CVS is not useful for the few assays requiring amniotic fluid liquor, such as AFP for neural tube defects.

Technique

CVS is performed between 10 and 13 weeks' gestation. Before performing a CVS, an ultrasound evaluation is necessary to determine gestational age, uterine anatomy, placental location, chorionicity, number of fetuses, fetal status, and potential aneuploidy markers, such as cystic hygroma and increased NT measurement. When abnormal ultrasound findings are detected, it is useful to reevaluate the indication and to discuss it with the patient before performing the CVS.

CVS can be performed by either a transcervical or transabdominal approach. Transcervical CVS (TC-CVS) is usually performed with a flexible polyethylene catheter with a metal obturator, which is introduced through the cervical canal toward the placenta under direct ultrasonographic visualization (Figure 11-1). After withdrawal of the obturator, 10 to 25 mg of villi is aspirated by negative pressure into a 20- or 30-mL syringe containing tissue culture media.

TA-CVS is performed by introducing an 18- or 20- gauge spinal needle percutaneously into the long axis of the placenta (Figure 11-2), under ultrasound guidance. After removal of the stylet, villi are aspirated into a 20-mL syringe containing about 5 mL of tissue culture media,

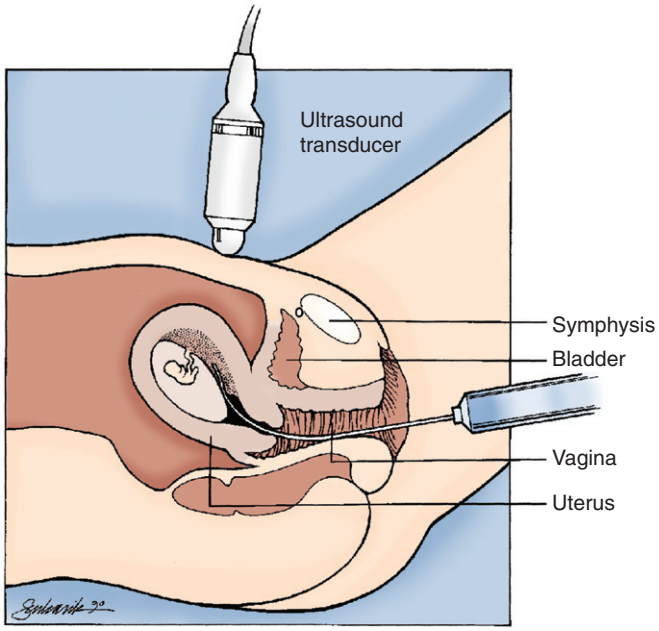

FIGURE 11-1. Transcervical chorionic villus sampling.

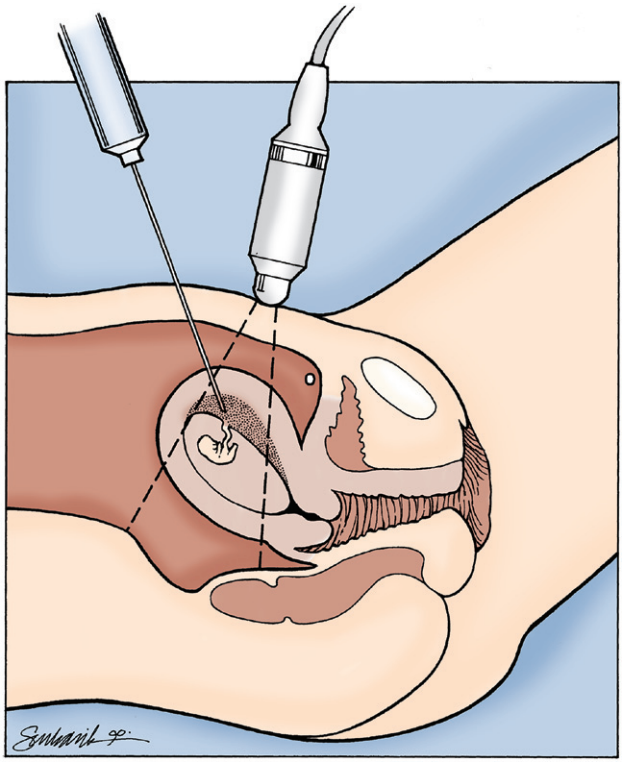

FIGURE 11-2. Transabdominal chorionic villus sampling.

keeping negative pressure and performing a gentle, longitudinal, back-and-forth movement of the needle. TA-CVS is typically performed at 10 to 13 weeks' gestation but can be performed later in gestation for rapid fetal karyotyping or when there is severe oligohydramnios. After the first trimester, this procedure is better known as *late CVS* or *placental biopsy*. Placental biopsy has now replaced cordocentesis for rapid fetal karyotyping during the second and third trimesters in many centers, given that it carries a lower risk, is technically easier, and can yield cytogenetic results within 24 to 48 hours.[14]

In many cases, either TA-CVS or TC-CVS is acceptable. However, there are situations in which one approach may be preferable. For example, cervical myomas or sharply angulated uteri may preclude transcervical passage of the catheter, whereas TA-CVS would permit sampling. The transabdominal approach is preferable in the presence of genital herpes, cervicitis, or bicornuate uteri.

With either approach, Rh immune globulin should be administered to the Rh-negative, Du-negative, unsensitized patient unless the fetus is known (cell free fetal DNA studies) to be Rh-negative. Sampling women sensitized to Rh(D) should probably be deferred until later in gestation.

Safety

CVS is a relatively safe procedure. In experienced hands, the risk for pregnancy loss is similar to second trimester amniocentesis. The prevalence of intrauterine growth restriction, placental abruption, and premature delivery is no higher in women undergoing CVS than expected in the general population.[15]

The U.S. Cooperative Clinical Comparison of Chorionic Villus Sampling and Amniocentesis study[16] and the Canadian Collaborative CVS-Amniocentesis Trial Group study[17] reported that pregnancy losses after CVS were no different than loss rates after second-trimester amniocentesis. A systematic review assessing comparative safety between TA-CVS and TC-CVS, and EA and second-trimester amniocentesis concluded that second-trimester amniocentesis and TA-CVS are safer than TC-CVS and EA.[18] Randomized studies in the United States and in Italy found no difference between TC-CVS and TA-CVS. In the second phase of the U.S. National Institute of Child Health and Human Development (NICHD) collaborative study, 1194 patients were randomized to TC-CVS and 1929 patients to TA-CVS. Loss rates in cytogenetically normal pregnancies through 28 weeks were 2.5% and 2.3%, respectively.[19] Of interest, the overall loss rate (i.e., background plus procedure related) during the randomized trial was 0.8% lower than rates observed during the mid-1980s, probably reflecting increasing operator experience as well as availability of both transcervical and transabdominal approaches.

In contrast, a multicenter randomized study in the United Kingdom compared second-trimester amniocentesis and CVS, as performed in any fashion deemed suitable by the obstetrician. The outcome assessed was completed pregnancies. The 4.4% fewer completed pregnancies in the U.K. CVS cohort reflected both unintended and intended pregnancy terminations.[17] The operators in this study were also considerably less experienced than in the U.S. trials. The only requirement for participation in the U.K. study was 30 "practice" CVS procedures. Greater experience is clearly necessary to become facile with CVS.

Another important factor in assessing safety is the indication for CVS. If CVS is performed because of an increased NT measurement, a cystic hygroma, or any other anomaly, the risk for miscarriage is increased. Thus, simple comparison to amniocentesis is not always valid.

In the early 1990s, controversy about the safety of CVS focused on the risk for limb reduction defects. Severe limb reduction deformity (LRD), transverse limb defects, and oromandibular-limb hypogenesis following transcervical CVS were reported in the United Kingdom, United States, and Taiwan. The U.S. Centers for Disease Control and Prevention conducted a case-control study of 131 infants with nonsyndromic limb deficiency, identified in seven population-based birth defects surveillance programs, compared with 131 controls with other birth defects matched to cases by the infant year of birth, mother's age, race, and state of residence.[20] The odds ratio (OR) for all limb deficiencies after CVS during 8 to 12 weeks' gestation was only 1.7, not significantly increased given the 95% confidence interval (CI) of 0.4 to 6.3. However, the authors found a significant association for transverse digital deficiency (OR, 6.4; 95% CI, 1.1 to 38.6) when stratified by anatomic subtypes.

The consensus of other studies is, however, that LRD is not a major concern when CVS is performed by experienced individuals at 10 to 13 weeks of gestation.[21,22] The types of limb defects and calculation of overall incidences have failed to reveal a difference between the

CVS and background populations. Nonetheless, teratogenic mechanisms by which CVS might cause LRDs can be hypothesized. These include (1) decreased blood flow caused by fetomaternal hemorrhage or pressor substances released by disturbing villi or chorion and (2) embolization of chorionic villus material or maternal clots into the fetal circulation. It has been suggested that at least some of the LRDs associated with CVS could result from disruption of the amniotic membrane due to incorrect sampling.[23]

A possible association between late first-trimester CVS (13 to 14 weeks) and a higher risk for hypertension and preeclampsia was reported,[24] but other reports have not confirmed this.[25] It could be hypothesized that focal placental disruption is the involved mechanism, supporting the theory that disturbances of early placentation lead to maternal hypertension.[24]

In summary, patients should be informed that in experienced hands, the fetal loss rates are comparable in CVS and second-trimester amniocentesis. When the CVS procedure is performed after 9 completed weeks, the risk for limb reduction problems is low, and no higher than the general population risk of 6 per 10,000.

Chorionic Villus Sampling in Twin Pregnancies

In experienced hands, CVS is safe in multiple gestations. In a U.S. study, the total loss rate of chromosomally normal fetuses (spontaneous abortions, stillborns, neonatal deaths) was 5%,[26] only slightly higher than the 4% absolute rate observed in singleton pregnancies.[16] A critical issue in counseling twin pregnancies for prenatal diagnosis is to establish chorionicity. In providing genetic risk figures and considering technical issues, monochorionic or dichorionic twin pregnancies may imply significant differences. Monochorionic twins are monozygotic and, therefore, carry the same genetic constitution, with a few exceptions. Thus, if there are not any significant sonographic differences in both fetuses, only one sample need be obtained. For dichorionic twin pregnancies, both placentas must be sampled. When the placentas appear to be fused, it can be helpful to identify the cord insertion sites to avoid the cross-contamination of chorionic tissue, leading to either false-positive or false-negative results. Alternatively, amniocentesis may be the preferred test.

CVS is widely used before selective reduction in multiple gestations. Here, it is especially desirable to sample the inferiorly lying fetus (usually retained to minimize risk for ascending infection) as well as at least two or three of the other fetuses potentially slated to be retained.

Fetal Blood Sampling

Ultrasound-directed percutaneous umbilical blood sampling (PUBS), also termed *cordocentesis* or *funipuncture*, can be used to obtain fetal blood for cytogenetic or molecular analyses. One of the most common indications for PUBS is a fetal malformation detected during the second and third trimesters. However, as previously described, placental biopsy is a safer, easier, and faster alternative and has replaced fetal blood sampling in many centers. Further, improvements in cytogenetic and molecular diagnostic testing have decreased the need for fetal blood sampling. For instance, fetal blood sampling was once frequently performed for diagnostic reasons in regions with a high prevalence of hemoglobinopathies. Now, most of those diagnoses are made by DNA-based analysis of chorionic villi.

Fetal blood samples may still be used to help clarify chromosome mosaicism detected in cultured amniotic fluid cells or chorionic villi or for the prenatal evaluation of fetal hematologic abnormalities. The fetal hematocrit can be measured to assess anemia resulting from Rh or other blood antigen isoimmunization states. Fetal blood has been used for the diagnosis of blood factor abnormalities (gene products) like hemophilia A, hemophilia B, or von Willebrand disease. Recovery of fetal blood is important in the assessment of viral, bacterial, or parasitic infections of the fetus. Serum studies of fetal blood permit quantification of antibody titers, and serum can be used to initiate viral, bacterial, or parasitic cultures. PUBS is also a valuable diagnostic approach in cases of nonimmune hydrops fetalis because a single procedure provides the opportunity to assess different hematologic, genetic, and infectious etiologies.

Technique

Cordocentesis is usually performed from 18 weeks onward, although successful procedures have been reported as early as 12 weeks. Ultrasonographic examination before the procedure is necessary to assess fetal viability, placental and umbilical cord location, fetal position, and presence or absence of fetal or placental anomalies. Color-flow Doppler imaging is an important tool in evaluating the cord and placenta. Maternal sedation is not usually required, but oral benzodiazepine before the procedure may be of benefit. Although there is no good evidence, many centers use prophylactic antibiotics.

Under continuous ultrasound guidance, a 21- or 22-gauge spinal needle with stylet is inserted percutaneously and directed into the umbilical vein. The needle may be inserted using a freehand technique or using a needle-guiding device fixed to the transducer. Most experienced maternal-fetal medicine specialists use the freehand technique.[27] The umbilical vein is preferred over the artery because the former is larger and less likely to be associated with fetal bradycardia and significant hemorrhage when punctured. Puncture of the umbilical cord at the placental insertion site is technically easier but is associated with a higher rate of maternal blood contamination. Free loops of cord and the intrahepatic vein are alternatives.[28] Cardiocentesis has also been described for fetal blood sampling, but obviously it carries a higher risk for fetal loss, about 6%.[29]

Once the needle is positioned in the umbilical vein, the stylet is removed, and a small amount of blood is aspirated into a heparin-coated syringe. It is crucial to confirm that the sample is fetal in origin; thus, a small amount is used for a complete blood count to assess the mean corpuscular volume. Fetal blood cells (140 fL) are larger than maternal cells (80 fL). The mean corpuscular volume of a sample of fetal blood should be higher than 100. A useful alternative when a complete blood analysis cannot be performed at once is the "Apt test" or hemoglobin alkaline denaturation test, especially before 28 weeks of gestation. Based on the ability of fetal hemoglobin to resist denaturation in

alkaline conditions, the Apt test is a rapid, inexpensive, and simple bedside alternative.

Fetal movements can interfere with the procedure and sometimes can dislodge the needle, with the risk for complications (bleeding, cord hematoma) and the necessity of further cord punctures. In some situations, it may be helpful to perform a fetal neuromuscular blockade as is done in therapeutic cordocentesis. An intravascular injection as part of the cordocentesis or intramuscular administration of pancuronium bromide (0.1 to 0.3 mg/kg of estimated fetal weight) can achieve fetal paralysis.[30]

In at least 1% of pregnancies, a single umbilical artery (usually having a larger diameter than normal umbilical cord arteries) is present. The fetal loss risk associated with puncture of a single umbilical artery (two vessel cord) appears to be no different from that with a normal three-vessel cord.[31] Nevertheless, the use of Doppler color-flow mapping to guide the procedure and an experienced operator is recommended.

Safety

Loss rates for patients undergoing PUBS vary greatly by indication and by operator experience, more so than with amniocentesis or CVS. No randomized clinical trial has been reported. The ACOG[8] suggests "less than 2%" as the procedure-related loss risk, citing Ghidini and colleagues.[32] Data from several large perinatal centers similarly estimate the risk for in utero death or spontaneous abortion to be 3% or less following PUBS.[33] Collaborative data from 14 North American centers sampling 1600 patients at varying gestational ages for a variety of indications found an uncorrected fetal loss rate of 1.6%.[34] Tongsong and associates[34] compared a cohort of 1281 women with a singleton gestation without a fetal anomaly and undergoing cordocentesis between 16 and 24 weeks of gestational age with a control group matched for maternal and gestational age; the fetal loss rate was 3.2% in the study group compared with 1.8% in the controls. In another series of 2010 cordocentesis procedures in singleton pregnancies, the procedure-related fetal loss rates within 2 weeks were 1% when performed before 24 weeks and 0.8% after 24 weeks.[35] Cordocentesis can be successfully performed in multifetal gestation; limited data suggest a higher overall fetal loss rates (10.5%) with no increase in the procedure-related loss rates.[36] **Cordocentesis is thus a relatively safe procedure, although fetal loss rates vary with indication (preexisting fetal status) and operator experience.**

Other complications associated with cordocentesis include cord hematomas, bleeding from the puncture site in the umbilical cord, transient fetal bradycardia, and fetomaternal hemorrhage. Bleeding from the cord puncture is the most common complication and may be seen in 30% to 41% of cases.[37] Duration of bleeding is significantly longer after arterial than umbilical vein puncture. However, usually the blood loss is not clinically significant in either case. Van Kamp and coworkers[38] also describe bleeding from the puncture site significantly more often and of longer duration after transamniotic cord puncture than after transplacental puncture. Transient fetal bradycardia occurs in approximately 10% of procedures. Both umbilical artery puncture and severe, early-onset growth restriction were associated with increased rates of bradycardia. Finally, the extent of fetomaternal hemorrhage or transfusion depends on the duration of the procedure, bleeding time, puncture site, and use of a transplacental approach.[39]

Maternal complications are rare but include amnionitis (>1%) and transplacental hemorrhage.[38] In general, these complications do not significantly compromise maternal health status. However, there are case reports of severe sepsis.[38,40]

INDICATIONS FOR PRENATAL GENETIC STUDIES

Indications for prenatal genetic studies arise from those clinical situations associated with an increased risk for a diagnosable prenatal genetic condition. Some of these risk factors are present preconceptionally and are discussed in Chapter 10. These include maternal age, parental chromosome rearrangements, and parents both heterozygous for the same mendelian disorders. Other risk factors become evident only during the pregnancy. These include positive results for aneuploidy screening, unexpected ultrasound detection of fetal structural anomalies, and intrauterine growth restriction (IUGR).

Cytogenetic Disorders

Every chromosomal disorder is potentially detectable in utero. Thus, any pregnant woman could if desired undergo an invasive procedure to exclude these conditions, with near 100% certainty. However, for most couples, the risk for an invasive procedure outweighs the diagnostic benefits, as discussed earlier in this chapter. The most common indications that justify prenatal cytogenetic diagnosis are the following:

- Advanced maternal age, resulting in increased risk for autosomal trisomy
- Parental chromosome rearrangements
- Previous pregnancy with autosomal trisomy
- Abnormal ultrasound findings during the current pregnancy: fetal structural anomalies, IUGR, amniotic fluid volume abnormalities
- Increased risk, as calculated from noninvasive screening results: nuchal translucency and maternal serum analytes (see Chapter 10)

Advanced Maternal Age

Antenatal prenatal cytogenetic studies (screening or invasive procedures) are most commonly pursued because of advanced maternal age. A procedure may be requested at any age, as stated by ACOG.[41] The incidence of trisomy 21 is 1 per 800 live births in the United States. A commonly used table showing age-specific risks is provided in Table 11-1.[42] Other calculations exist. Trisomy 13, trisomy 18, 47,XXX, and 47,XXY also increase with advanced age.

Risk figures shown in Table 11-1 are applicable for live-born infants. The prevalence of chromosomal abnormalities when amniocentesis is performed is higher than that at birth by approximately 30%.[43] It follows that the risk at the time of noninvasive screening (10 to 15 weeks) is higher. In using noninvasive screening protocols, the likelihood of Down syndrome is usually set at 1 per 270 (screen positivity), the midtrimester risk for a 35-year-old woman

Data from Hook EB, Cross PK, Schreinemachers DM: Chromosomal abnormality rates at amniocentesis and in live-born infants. JAMA 249:2034, 1983; and Schreinemachers DM, Cross PK, Hook EB: Rates of trisomies 21, 18, 13 and other chromosome abnormalities in about 20,000 prenatal studies compared with estimated rates in live births. Hum Genet 61:318, 1982.

*Because sample size for some intervals is relatively small, confidence limits are sometimes relatively large. Nonetheless, these figures are suitable for genetic counseling.

†47,XXX excluded for ages 20 to 32 yr (data not available).

(Chapter 10). There is a further increase (50%) in prevalence at CVS compared with amniocentesis.[43,44] The frequency of aneuploidy in the first trimester is 5% higher than in the second trimester. That the frequency of chromosomal abnormalities is lower in liveborn infants than in first- or second-trimester fetuses reflects the disproportionate likelihood that fetuses lost spontaneously will have chromosomal abnormalities. Some abnormal fetuses would have died spontaneously in utero had iatrogenic intervention not occurred in the second trimester. In fact, 8% to 13% of stillborn infants show chromosomal abnormalities (see Chapter 26), more if the stillborn has overt malformations.

In January 2007, ACOG published new recommendations concerning prenatal cytogenetic screening.[41] Before this, it was standard medical practice in the United States to offer invasive chromosomal diagnosis to all women who at their expected delivery date will be 35 years or older and have singleton pregnancies, but not necessarily to those younger. The cutoff of age 35 years was, however, always largely arbitrary, chosen at a time when risk figures were available only in 5-year intervals (i.e., 30 to 34 years, 35 to 39 years, 40 to 44 years) (see Simpson[45]). In twin gestations, it had been recommended that an invasive procedure be offered at age 32 or 33 years.[46,47] The rationale was that most twins being dizygotic, the likelihood that either one of the two would be aneuploid is the sum of the individual risks. At age 33, this combined risk for either liveborn infant being trisomic was 1 in 347, comparable to the singleton risk at age 35 (1 in 375) (see Table 11-1). The same reasoning applies to all chromosomal aneuploidies: 1 in 176 versus 1 in 202.

The 2007 ACOG[41] guidelines state unequivocally that neither age 35 years nor any specific age should be used as a threshold for invasive or noninvasive screening. ACOG stated: "All women, regardless of age, should have the option of invasive testing." ACOG[41] specifically elaborates that "patients informed of the risks, especially those at increased risk for having an aneuploid fetus, may elect to have diagnostic testing without first having screening." Relatively younger women who elect an invasive procedure directly may do so because of the ability to detect not only trisomies but also microdeletions and microduplication syndromes. This is possible through chromosomal microarrays based on comparative genome hybridization (CGH), a topic discussed later.

If an invasive procedure is not selected initially, first- or second-trimester noninvasive screening is now considered by ACOG[41] as appropriate to offer all women who present before 20 weeks of gestation, irrespective of age. As discussed in Chapter 10, only those who are "screen positive" are offered an invasive procedure. If a noninvasive screening program has been instituted in a population in which women older than maternal age 34 years were previously offered an invasive procedure, potential litigious hazard exists if counseling is not lucid. Detection rates for Down syndrome are good (80% to 93%) with noninvasive screening but less than the near 100% achieved with an invasive diagnostic test. Noninvasive screening is most likely to be applicable to women ages 33 to 37 years, after which most women will be screen positive and still require a procedure.

Previous Child with Chromosomal Abnormality

After the occurrence of one child, stillborn fetus, or abortus with autosomal trisomy, the likelihood that subsequent progeny will have autosomal trisomy is increased, even if parental chromosomal complements are normal. Recurrence risks are approximately 1%.[48] Invasive antenatal chromosomal studies should be offered for couples with a prior trisomic pregnancy. Recurrence risk data following trisomy 18 are comparable.[48] Describing a risk of 1% for either the same or a different chromosomal abnormality seems appropriate in women younger than 40 years. Risk for recurrence applies also if the trisomy was detected in a spontaneous abortion.

Parental Chromosomal Rearrangements

An uncommon but important indication for prenatal cytogenetic studies is presence of a parental chromosomal abnormality. A balanced translocation is the most common indication, but inversions and other chromosomal rearrangements exist. See Chapter 10 for a more detailed

discussion and figures. A mother or father having a balanced translocation is at risk for offspring with an unbalanced translocation and, hence, abnormal offspring. Fortunately, empirical data show that theoretical risks for abnormal (unbalanced) offspring are greater than empirical risks, but miscarriages are common. It is for this reason that preimplantation genetic diagnosis (see later) can be especially helpful; otherwise, time to achieve pregnancy could be delayed beyond that realistic for an older woman. The risk for having a liveborn infant with an unbalanced chromosomal complement varies by rearrangement, sex of the carrier, and method of ascertainment.[49] Pooled empirical risks tabulated at CVS or amniocentesis approximate 12% risk for clinically abnormal offspring of either male or female translocation carriers with reciprocal translocations.[49] For Robertsonian (centric fusion) translocations, risks vary according to the chromosomes involved. For t(14q;21q), risks are 10% for offspring of heterozygous mothers and 2% for offspring of heterozygous fathers.[50] For other nonhomologous Robertsonian translocations, empirical risks for liveborn infants are less than 1%. Later in this chapter, we discuss the different percentages observed at preimplantation genetic diagnosis (PGD).

For homologous translocations (e.g., 21q;21q), all liveborn offspring should have trisomy 21. For other homologous Robertsonian translocations (13q;13q or 22q;22q), almost all pregnancies result in abortions.

In Robertsonian translocations, risk also exists for uniparental disomy (UPD). In UPD, both homologous chromosomes are derived from a single parent. UPD has been observed in offspring of a carrier having a balanced robertsonian translocation. Excluding UPD is most appropriately performed in prenatal cases in which a chromosome with known UPD clinical effect is involved (e.g., chromosomes 7, 11, 14, 15).

Assisted Reproduction through Intracytoplasmic Sperm Injection

Intracytoplasmic sperm injection (ICSI) is used in assisted reproduction technology (ART) when the male partner is subfertile. Empirical data have showed an increased frequency of aneuploidies, mainly sex chromosome anomalies (1% to 2%).[51] The excess risk appears not related to the ICSI technique but rather to the underlying male infertility that necessitated ICSI.

Accuracy of Prenatal Cytogenetic Diagnosis

The obstetrician-gynecologist should be aware of the common pitfalls associated with analysis of chorionic villi or amniotic fluid cells and may be called on to interpret or explain these findings to patients. One obvious problem is that cells may not grow, or growth may be insufficient for proper analysis. Analysis of maternal rather than fetal cells is another problem, fortunately uncommon. In amniocentesis, maternal cell contamination can be minimized by discarding the first 1 to 2 mL of aspirated amniotic fluid. In CVS, examination under a dissecting microscope allows one to distinguish villi from maternal decidua.

A more vexing concern is that chromosomal abnormalities detected in villi or amniotic fluid may not reflect fetal status. Chromosomal aberrations may arise in culture (in vitro) or may be confined to placental tissue. This possibility should be suspected when mosaicism (more than one cell line) is restricted to only one of the several culture flasks or clones initiated from a single amniotic fluid or CVS specimen, or when an abnormal karyotype with a known severely anomalous phenotype does not correlate with a normal ultrasound. Although the reference laboratory and clinical geneticists are naturally expected to have requisite expertise, the obstetrician should be prepared to discuss certain common dilemmas with the patient.

Numerical

Cells containing at least one additional structurally normal chromosome are not uncommonly detected (1% to 2%) in amniotic fluid or CVS specimens.[52] If these abnormal cells are found in a single culture or clone, the phenomenon is termed *pseudomosaicism*. Usually no clinical significance is attached. Defined by the presence of the same abnormality in more than one clone or culture flask, true fetal mosaicism is rarer but more significant. True mosaicism is confirmed by studies of the abortus or liveborn infant in 70% to 80% of cases[53] and actually can never truly be excluded because the abnormality could be restricted to a tissue not readily accessible.

Numerical problems are more frequent in short-term cultures, which can be performed on chorionic villi but not on amniotic fluid cells. However, array CGH (chromosomal microarrays), discussed later, can be performed on uncultured DNA from either villi or amniotic fluid cells). Metaphases from the trophoblasts or villi can accumulate within hours of sampling, allowing rapid answers. In CVS, discrepancies may arise between short-term trophoblast cultures and long-term cultures, which are initiated from the mesenchymal core of villi.[54] Discrepancies may further exist between CVS preparations and the embryo. If CVS results seem at odds with clinical findings, it is reasonable to track interval growth and, if normal, perform a follow-up amniocentesis. Several rare trisomies (+16, +22, +7)[54] in particular may not be confirmed. Sometimes mosaicism is present in the placenta but not in the embryo; this is called *confined placental mosaicism* (CPM). In this circumstance, the likelihood of anomalies is considered low.[55] However, the U.S. NICHD Collaborative CVS Trial observed increased late loss rates (8.6%) in pregnancies showing CPM compared with pregnancies without mosaicism (3.4%). Although CPM usually does not have clinical significance,[54] two potential adverse effects associated with CPM should be considered: IUGR and UPD. UPD, the inheritance of both homologous chromosomes from a single parent, may result from a reduction to disomy from a trisomic embryo rescue.[57] The phenotypic effect of UPD depends on the chromosome involved.[58] Imprinted genes that have phenotypic effects with regard to UPD include chromosomes 7 (Russell-Silver syndrome), 11 (Beckwith-Wiedemann syndrome), 14 (mental retardation and multiple anomalies), and 15 (Prader-Willi and Angelman syndromes).

Potential technical problems notwithstanding, amniotic fluid analysis and chorionic villi analysis are highly accurate. The U.S. NICHD Collaborative CVS Trial evaluated 11,473 chorionic villus samples by direct methods, long-term culture, or both. There were no incorrect sex

predictions.[54] No diagnostic errors occurred among 148 common autosomal trisomies (+13, +18, +21), 16 sex chromosomal aneuploidies, and 13 structural aberrations; no normal cytogenetic diagnosis with CVS has ever been followed by birth of a trisomic infant. Overall, accuracy of CVS is comparable to that of amniocentesis.

Structural

If an ostensibly balanced inversion or translocation is detected in the fetus but not found in either parent, the rearrangement arose de novo. In this situation, there is increased likelihood that the neonate will be phenotypically abnormal at birth. The inversion or translocation may not actually be balanced; there may be genes around breakpoints deleted and unappreciated by cytogenetic analysis whose resolution is 5 million base pairs (5 Mb). The risk for the fetus being abnormal has been tabulated at 6% for a de novo reciprocal inversion and 10% to 15% for a de novo translocation.[59] Risks are not chromosome specific but represent pooled data involving many chromosomes. These risks also apply only to anatomic or developmental abnormalities evident at birth, not taking into account abnormalities that become evident only later in life. In ostensibly balanced de novo translocations, more subtle changes responsible for risks may be detected by chromosomal microarrays (array CGH), whose resolution is much better than standard karyotypes. Thus, more precise counseling is now possible, but normalcy cannot be promised even if array CGH shows no abnormality.

Marker chromosomes, also called *supernumerary chromosomes*, by definition cannot be fully characterized on the basis of standard cytogenetic analyses. These small chromosomes usually contain a centromere, a high proportion derived from the short arms of acrocentric chromosomes (13, 14, 15, 21, and 22). Marker chromosomes are observed in approximately 0.06% of the population.[60] Analogous to translocations and inversions, the risk for phenotypic abnormality in a fetus with a marker chromosome then depends on whether the marker is de novo or familial. Risk is higher when de novo markers are encountered. With FISH or chromosomal microarrays, the chromosome from which the marker chromosomes originated can now usually be established.

In reviewing 15,522 prenatal diagnostic procedures, Hume and colleagues[61] ascertained 19 marker chromosomes, 5 from CVS specimens and 14 from amniotic fluid samples. Monitoring these pregnancies with high-resolution ultrasonography revealed an association between de novo marker chromosomes and anomalies. When ultrasound examination was normal, the likelihood of a phenotypically normal offspring was high. Analogous to de novo translocations, array CGH can characterize the marker and elucidate whether gain or loss of genetic material exists.

Newer Cytogenetic Approaches

A plethora of cytogenetic advances has become available within the past decade, and the obstetrician may encounter patients whose diagnostic studies have used these technologies. A brief summary of those tests, some alluded to already, is therefore provided. Standard genetic texts provide additional information.

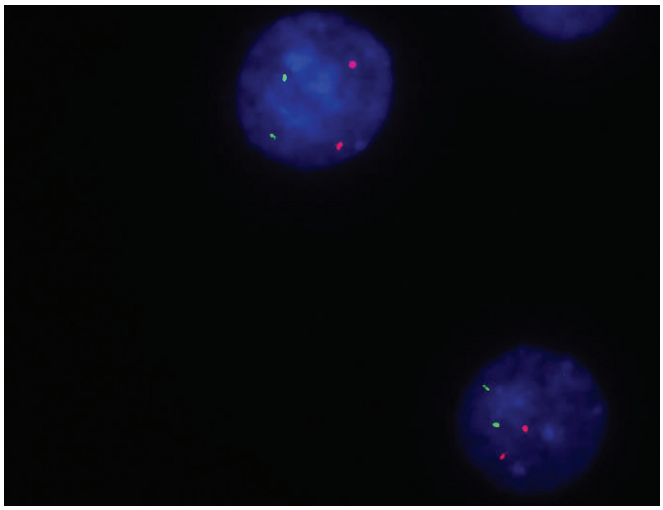

Figure 11-3. Fluorescence in situ hybridization *(FISH)* performed on interphase nuclei obtained from peripheral blood lymphocytes. Dual-color FISH has been performed using Vysis (Abbot Molecular, Abbott Park, IL) locus-specific probes *(LSI)* for chromosome 13 (green) and chromosome 21 (red). Chromosomal DNA is stained with DAPI (blue). Two signals for each indicates disomy (normal numbers) for these two chromosomes. (Courtesy Helen Tempest, Florida International University, Miami, FL.)

Fluorescence in Situ Hybridization

Available for 20 years now, fluorescence in situ hybridization (FISH) merges molecular genetics with cytogenetics. Using DNA sequences unique to the chromosome in question, chromosome-specific probes (e.g., chromosomes 13, 18, 21, the X, or the Y) can be created (Figure 11-3). The probe is then labeled with a fluorochrome and used to challenge unknown DNA that is denatured. Now single-stranded, this DNA becomes amenable to hybridization to its complementary sequence, whether from the same individual or reference (normal) DNA. Disomic cells (metaphase or interphase) should show two separate signals; trisomic cells show three signals. Because of geometric vicissitudes (e.g., one chromosome overlying another and unappreciated in a two-dimensional scan), not every trisomic cell shows three signals; however, the modal count is readily indicated. A single cell can be interrogated for up to five chromosomes. FISH uses interphase cells, thus permitting rapid or same-day diagnosis of aneuploidy. This becomes particularly important when a rapid diagnosis is needed to aid in the management of a fetus at high risk, such as one with multiple anomalies detected by ultrasound. FISH can also be used on preserved tissue (e.g., paraffin blocks), when culture for metaphase analysis is obviously not possible.

Quantitative Fluorescent Polymerase Chain Reaction

Polymerase chain reaction (PCR) is a widely used test that permits a small amount of DNA (e.g., one cell) to be amplified to generate an amount sufficient for a diagnostic test. In quantitative PCR (QPCR), the rapidity with which the exponential increase in DNA occurs allows rapid and accurate detection of major numerical chromosomal disorders in CVS.[62] This technique can be a powerful

adjunct to conventional cytogenetics and in some venues (Europe) has replaced the traditional karyotype in prenatal diagnosis.

Comparative Genomic Hybridization and Chromosomal Microarrays

Comparative genomic hybridization (CGH) is an exciting molecular cytogenetic technique that, as alluded to already, allows comprehensive analysis of the entire genome at a finer resolution than banded karyotypes. The principle is based on single-stranded DNA annealing (hybridizing) with a complementary single-stranded DNA. Hybridization occurs whether from the same individual or from different individuals. Initially, normal (control) DNA in the form of a metaphase was labeled with a fluorochrome of one color (e.g., green), whereas test (patient) DNA was labeled with a fluorochrome of a different color (e.g., red). When both test and control DNA are denatured (single stranded), the test DNA hybridizes to the control metaphase. If equal amounts of control and test DNA are present, one would expect the color of the hybridized mixture to be yellow. If the test DNA were in excess (e.g., trisomy), the mixture for the relevant chromosome region would be relatively more of the color used to connote test (patient) DNA. This would be red in the previous example. For trisomy, this would apply to the entire chromosome. For duplications or deficiencies of chromosomal regions, only a portion of the chromosome would be red or green. The converse would apply for deletions or monosomy. Metaphase CGH has evolved into more sensitive chromosome microarrays, but the same principle applies.

The principles discussed earlier can be applied to smaller portions of DNA, even several thousand bases. Small amounts of single-stranded DNA (cDNA) of known sequence are placed by photolithography onto a platform (array) in ordered fashion. The amount of DNA in each spot is small (i.e., micro). Compared with karyotypes, the ability to detect deletions or duplications is greatly increased. Conventional karyotypes can only detect abnormalities of 5 to 10 Mb, whereas chromosomal microarrays easily detect abnormalities 200 kilobases (200,000) in size and if desired, 20 to 50 bases. The number of sequences is set in advance but is expected to encompass the entire genome, one sequence overlaying the adjacent one ("tiling"). The "control" DNA embedded by photolithography is labeled with a fluorochrome of one color (e.g., green). Exposure is then made to single-stranded test DNA (e.g., patient), now labeled with a fluorochrome of different color (e.g., red). If control and test DNA are quantitatively equal for a given sequence, the color is yellow. If test DNA is excess (trisomy), the color is more red; if test DNA is deficient, the color is more green. One thus detects deletion or excess (gain) of DNA, de facto generating a "molecular karyotype" (Figure 11-4).

Several different commercial platforms are available, but all interrogate sequences of DNA along every chromosome. "Coverage" varies slightly based on sensitivity sought, and in all there is redundancy, that is, a given region is interrogated more than once to ensure replicability before making a diagnosis. The smaller the copy number variants (CNVs) the less likely a pathogenic effect,

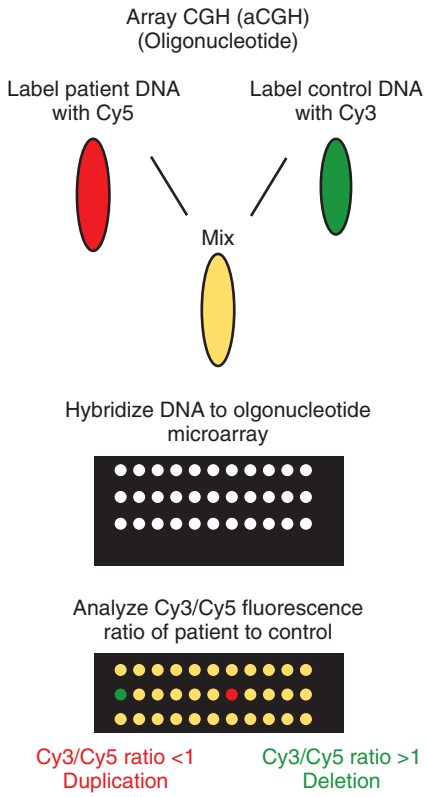

FIGURE 11-4. Schematic diagram illustrating principles of array comparative genome hybridization *(CGH)*. Patient DNA is labeled in red *(CY5)*, whereas references (normal control) are labeled in green *(Cy3)*. When denatured into single-stranded DNA, patient DNA and control DNA hybridize with DNA of the same type that is embedded on a platform *(circles)*. The diagram shows only 33 "spots" of similar sequence, whereas in actual practice, a diagnostic platform would consist of thousands of embedded sequences. If the region being interrogated shows equal amounts of patient DNA and control DNA, the signal is yellow. A green signal indicates deficiency of test DNA (deletion or mosaicism), whereas a red signal indicates excess of test DNA (duplication or trisomy). Array CGH detects trisomies just like a karyotype; smaller deletions or duplications (<5,000,000 base pairs) are detected only by array CGH. (Courtesy Ron J. Wapner, Columbia University, New York).

but even small CNVs can be significant. At the 50- to 200-base level, CNVs (duplications or deletions) are often polymorphisms, inherited from a clinically normal parent and without clinical significance. Some 70 CNVs can be confidentially predicted to have pathogenic consequences and readily detected by CMAs but not by traditional karyotype. In aggregate these occur in perhaps 1 per 1500 births in the general population, but this number is higher in selected populations. An estimated 5% to 7% of children with developmental delay have CNVs, and array CGH is now considered a standard part of evaluation in such cases.[63]

In prenatal studies, determining case and effort is more arguable. In postnatal cases, array CGH is usually requested only if a clinical abnormality is obvious in a liveborn child. This is not so in prenatal cases, and even if so (e.g., ultrasound), the extent of abnormalities is never clear. It is thus more difficult to predict the significance of a CNV detected in villi or amniotic fluid cells. Several principles are,

however, applicable. A large CNV present in a fetus but in neither parent (de novo) warrants the most attention, and a deletion is more consequential than a duplication. The region involved is also important; some sequences of DNA are relatively "gene poor," whereas others contain genes known to be deleterious if perturbed. Familial heritable transmission of CNVs may be clinically significant. Exceptions exist because CNVs may display incomplete penetrance with respect to phenotypic effect.

The recently reported NICHD prenatal cytogenetic array study involved 4401 women having varying indications (46% maternal age; 26% ultrasound anomaly) All trisomies and sex chromosome aneuploidies detected by karyotypes were also detected by array CGH.[64] All microdeletions and microduplications predicted to be detected (e.g., DiGeorge syndrome) were in fact detected. A difficulty is that additional CNVs of uncertain clinical significance were also detected. A Clinical Advisory Committee independent of laboratory directions considered one third of CNVs to be benign based on extant data, not warranting disclosure to parents.[65] Of the remaining, 1.6% were considered to be potentially significant and for a variety of reasons required disclosure. Sometimes disclosure was considered on the basis of potential termination, sometimes because follow-up ultrasound seemed warranted and would otherwise not have been pursued, and sometimes on the basis of relevance to a family history of abnormalities. The manner in which disclosure and counseling are conveyed is thus crucial.[65,66]

In summary, prenatal array CGH promises to be a major addition to the diagnostic armamentarium, but providers need to be prepared for anxiety in deciding when to disclose variants of uncertain clinical significance.

One disadvantage of array CGH compared with the traditional karyotype is that chromosomal microarrays cannot distinguish between balanced translocations and normal; unbalanced (duplication, deficiency) rearrangements are readily detected. Another is difficulty in detecting low-level mosaicism in which one of the two cell lines is infrequent. In some platforms, triploidy cannot be excluded. On the other hand, array CGH can be performed on uncultured DNA, including circumstances (e.g., stillborn fetuses) in which cell cultures for chromosomal abnormalities are not often successful.

MENDELIAN DISORDERS

The combination of sequencing the human genome (2001) and subsequently developing molecular diagnostics has completely changed the approach to prenatal genetic diagnosis for single gene disorders. Previously, many different approaches had to be applied, as recounted in earlier editions of this text. This reflected the reality that for a very few disorders was the actual molecular basis (e.g., missense or nonsense mutations) known. Rarely was the gene's location even known. Only a relatively small proportion of at-risk couples could thus be tested for a disorder of interest. The prototype exception was sickle cell anemia, in which virtually almost all cases result from a point mutation in codon 6 of β-globin. Prenatal diagnosis more often required measuring the presence or absence of the deficient gene product (proteins), an accumulated substrate (e.g., inborn errors of metabolism) in chorionic villus of amniotic fluid cells. Although this was readily possible for inborn errors of metabolism (e.g., galactosemia), it was not for disorders lacking a known metabolic basis. Imaging (ultrasound or radiographic) was the preferred approach for mendelian disorders like skeletal dysplasias. Cytogenetic studies could be used for chromosomal breakage syndromes like Bloom syndrome and Fanconi anemia. Fetal skin biopsy for histologic studies was required for epidermolysis bullosa and genodermatosis, and fetal muscle biopsy for Duchenne muscular dystrophy. With sequencing of the human genome, the paradigm has completely changed. Indirect approaches like those enumerated above are used less frequently for definitive diagnosis, and theoretically not at all if the location of the causative gene is known.

Molecular Approach to Diagnosis

Sequencing the human genome has revealed approximately 22,000 genes (based on certain established sequencing criteria defining a gene). The function of many genes is still unknown, but increasingly, mendelian disorders of potential prenatal genetic diagnosis interest are being identified and their molecular perturbations known. The illustration of cystic fibrosis discussed in Chapter 10 is paradigmatic. Molecular basis of recognized single gene disorders varies—point mutations leading to a single nucleotide and hence a single amino acid change (e.g., sickle cell anemia), premature stop codon truncating the protein gene product, deletions of three nucleotides leading to loss of an entire amino acid, deletion of one or two nucleotides leading to a frame shift that results in an altered reading frame with all subsequent amino acids being coded erroneously.

In a given disorder, it is exceptional for a single molecular perturbation to be responsible, as is the case in sickle cell anemia and achondroplasia. One or more perturbations may account for a significant proportion, at least within a given ethnic group; however, the molecular basis is typically heterogeneous. In the near future, we can expect panels to be available for genes likely to result in, say, the most common forms of skeletal dysplasia. An array of mutations or targeted sequencing of such genes can be constructed. If the cost of sequencing the entire genome decreases as expected, diagnosis may become conceptually straightforward for the obstetrician (albeit with considerable pitfalls for the interpreting geneticist). Still, the molecular basis may not always be evident for every affected individual, even in well-studied disorders like cystic fibrosis. If sequencing the coding regions of the gene in question does not reveal a perturbation, the assumption is that pathogenesis involves the promoter region or post-transcriptional processes (e.g., translation). However, diagnosis is still possible by linkage analysis.

The general approach for detecting single gene disorders involves directly determining presence of a known molecular perturbation. Alternatively, if the actual mutation is not known, linkage analysis can still be used to identify affected cases if the chromosomal location has been determined. Suppose a couple is at risk for a known disorder, but the molecular basis in their family is unknown. Recall that the chromosomal location may still be known, even if no

perturbation is evident. In linkage analysis, one relies on polymorphic markers upstream and downstream from the mutation site. These polymorphisms are without clinical significance but can serve as markers (short tandem repeats of nucleotides; single nucleotide polymorphisms). At every locus (polymorphic or mutant), one marker allele is of paternal origin and one is maternal. A panel of markers can be identified that coexist (in phase) with the chromosome having the mutation, said to be *cis* and in contrast to those markers on the chromosome having the normal allele *(trans)*. That is, given two chromosomes, one set of markers will be on the chromosome containing the mutant allele for the disorder in question (dominant or recessive), whereas the other will lie on the "normal" chromosome. Studying affected and unaffected family members will allow one to determine the "phase" of markers unique to that family. If there are no surviving affected family members, one may still be able to deduce phase (*cis* versus *trans*) by analyzing individual sperm, should the disorder have arisen de novo in a male. Regardless, the principle is that a diagnosis can be deduced without knowledge of the precise nucleotide perturbations.

A molecularly based diagnosis can thus be readily achieved for patients at risk for hundreds of disorders. Any nucleated fetal cell (chorionic villus, amniotic fluid cell, blastomere from an embryo) will suffice. Technical details are beyond the purview of this text, save appreciation that molecular diagnosis is highly accurate in good laboratories, and none is perfect.

Mendelian Disorders Without Known Molecular Basis

There remain disorders whose genetic basis is not yet elucidated. If the causative gene is not known, linkage analysis is not applicable. Whether the concern originates in a previously affected child or the current pregnancy, one may have to resort to imaging, assuming cytogenetic findings (including microarrays) are normal in the previously affected child and structural anomalies are present. The spectrum of disorders detectable by imaging studies is discussed later in this chapter, including sensitivity at varying stages of gestation.

MULTIFACTORIAL DISORDERS

Although some progress has been made, the genetic basis of isolated birth defects involving a single organ system remains elusive. These are listed in Chapter 10 (see Table 10-1). Thus, even with a history of a prior affected offspring, no specific genetic tests are available. Prenatal diagnosis depends on ultrasound (see later), although for disorders in which fetal skin is discontinuous (e.g., myelomeningocele, omphalocele), nonspecific measures like amniotic fluid AFP are useful.

ULTRASOUND DIAGNOSIS OF FETAL MALFORMATIONS

Over the past few decades, many publications have described the ultrasound diagnosis of fetal malformations. A catalog of the diseases that are now considered detectable with prenatal ultrasound is beyond the scope of this chapter. In this section, we discuss the use of ultrasound as a screening test, outline the role of ultrasound in aneuploidy screening, and describe the relatively common birth defects that may be diagnosed with a standard ultrasound examination.

Ultrasound as a Screening Test for Birth Defects

With improvements of ultrasound equipment in the past few decades, many patients and clinicians have come to assume an ultrasound examination will likely detect all serious fetal anomalies. Indeed, in the 1980s and early 1990s, several individual centers reported detection rates of greater than 75% in referral[65] and low-risk[66] patients. However, serious questions regarding the sensitivity of routine ultrasound examinations in more general settings were raised by a large multicenter trial published in 1993.[67] The Routine Antenatal Diagnostic Imaging with Ultrasound Study (RADIUS)[67] was a randomized trial that included standardized ultrasound examinations of more than 15,000 women between 16 and 20 weeks of gestation, then again at 31 to 33 weeks. Patients were selected to be at low risk for pregnancy complications. In this study, only 17% of major anomalies were diagnosed by ultrasound before 24 weeks' gestation, and only 35% were detected overall. The study's authors concluded that routine ultrasound to screen for birth defects in low-risk women was not efficacious. A subsequent large study of ultrasound screening for birth defects, the "Eurofetus" study, included more than 200,000 women screened with routine ultrasound in 61 hospital units in 14 European countries.[68] In contrast to the low rate of detection of anomalies in the RADIUS trial, 61% of malformed fetuses were detected; sensitivity was much higher for major malformations (74%), albeit with a significant difference in detection rates according to the particular malformation or organ system involved. Defects of the central nervous system and urinary tract were detected 88% of the time, whereas only 18% of cases of cleft lip and palate were diagnosed. Eighteen percent of minor musculoskeletal malformations and 21% of minor cardiac malformations were detected, whereas sensitivities were 74% and 39%, respectively, for major anomalies of these two organ systems.

In the hands of a well-trained examiner, the detection rate of some anomalies should approach 100%. For example, anencephaly, abdominal wall defects, and anomalies involving an abnormal accumulation of fluid within a body cavity (i.e., hydronephrosis, hydrocephalus) will rarely be missed. Spina bifida, which itself may be difficult to see, is almost always accompanied by easily recognized intracranial findings, making the detection rate of this defect quite high. The growing awareness that **a screening ultrasound should include not only the four-chamber view of the heart** (Figure 11-5) **but also views of the outflow tracts** (Figures. 11-6 and 11-7**)** has resulted in a significant increase in detection rate of heart defects. DeVore reviewed three studies from the 1990s in which only the four-chamber view was obtained as a part of a screening ultrasound in low-risk populations.[69] In that 1998 report, only 8 of 151 cases were detected with the four-chamber screening, a detection rate of 5%. In contrast, a 2006 Norwegian study of more than 30,000 unselected patients screened

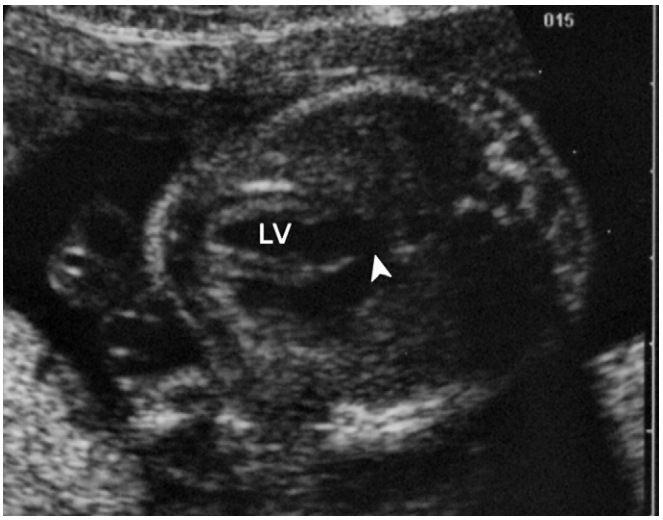

FIGURE 11-5. Normal four-chamber view of the heart. Note that the heart's position is central in the chest, and the axis is about 45 degrees to the left of the midline. The ventricles are approximately equal in size, while the left ventricle *(LV)* extends further into the apex. The intraventricular septum is intact, and the foramen ovale *(arrowhead)* is seen.

using not only the four chamber but also the great vessel views achieved a 57% detection rate.[70] Because of studies such as this that show the importance of outflow tract visualization for the detection of many heart defects, the American Institute of Ultrasound in Medicine (AIUM) recommends that attempts should be made to obtain these views in all second- and third-trimester scans.[71]

It is well recognized **that adequate training is essential to the proper performance and interpretation of obstetric ultrasound examinations.** In the RADIUS trial,[67] the detection rate for anomalies was almost three times higher when the examinations were performed at a tertiary center compared with a general practice setting (13% versus 35%), presumably because of greater experience of sonographers at the tertiary centers. Although qualifications for those performing ultrasound examinations to screen for birth defects have not been standardized, the AIUM has made recommendations regarding the training and experience needed for physicians to perform obstetrical ultrasound. These include the completion of an approved training program with the equivalent of 3 months of ultrasound experience and the involvement in the performance of at least 300 examinations, continuing education in the field (at least 30 hours every 3 years), and ongoing practice consisting of at least 170 obstetrical or gynecologic ultrasound examinations performed annually.[72]

The nature of the population being screened and the thoroughness of postnatal ascertainment of birth defects also affect the sensitivity of ultrasound for detecting defects. The detection rate has been shown to be higher in high-risk populations screened at centers with extensive experience at diagnosing birth defects. In studies that did not include rigorous prospective neonatal evaluation, subtle anomalies may not have been noted, and a sonographic "miss" of these defects would not be counted. This would give a falsely optimistic detection rate. The

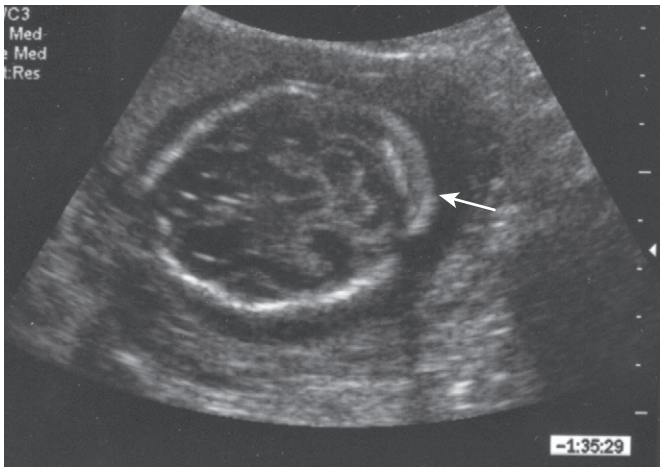

FIGURE 11-7. An 18-week fetus with trisomy 21, showing a thick nuchal fold *(arrow)*.

gestational age at which ultrasound is performed can influence the sensitivity of anomaly screening. Although many defects can now be recognized in the late first trimester (i.e., anencephaly and large abdominal wall defects), many are not visible until later. Some defects may become more readily apparent late in pregnancy. Although multiple examinations in each pregnancy would undoubtedly increase the pick-up rate of malformations, resource and financial constraints make this impractical. **It is generally agreed that the most cost-effective approach for screening low-risk pregnancies is to perform a standard examination between 18 and 20 weeks.** At this gestational age, adequate visualization of major organs is possible for most women.

False-positive results must be taken into account when considering the effectiveness of ultrasound screening for birth defects. Falsely abnormal results can cause patients and families considerable anguish and result in unnecessary follow-up tests. Fortunately, in both the RADIUS[67] and the Eurofetus[68] trials, fewer than 1 in 500 women was erroneously told that her healthy fetus had a malformation. However, of the nearly 3000 suspected malformations in the Eurofetus study, 10% were false-positive diagnoses, and 6% involved fetuses in which an initial concern was resolved on a subsequent ultrasound examination.[68]

Ultrasound Screening for Aneuploidy

Second Trimester

As discussed earlier in this chapter, well-established diagnostic tests for fetal aneuploidy include amniocentesis and CVS. In the past two decades, it has increasingly been possible to diagnose with ultrasound specific birth defects that are associated with aneuploidy, such as duodenal atresia and certain heart defects. In 1985, Benacerraf showed that there was **a significant association between the thickness of the fetal skinfold (see Figure 11-7) and the presence of trisomy 21**.[73] For the first time, a "marker," as opposed to an actual birth defect, could be used to assess the likelihood that Down syndrome was present. **Other markers that are now commonly used in the genetic sonogram include the nasal bone length, short femur or humerus, echogenic intracardiac focus, echogenic bowel, and pyelectasis.** The use of these markers has gradually become common clinical practice. Most of the markers perform poorly as individual predictors of Down syndrome, with a very low sensitivity and a high rate of false-positive results.[74] However, as markers were studied in larger numbers of women, it became possible to assign likelihood ratios to each marker and to do a formal risk adjustment from the a priori risk to an ultrasound-adjusted risk.[75] Most women undergoing a genetic sonogram have no markers. Therefore, most who are initially considered to be at high risk because of maternal age, a family history, or serum screening have an ultrasound-adjusted risk that places them in the low-risk category, such as a trisomy 21 risk less than that of a 35-year-old woman. **With patients increasingly relying on ultrasound and serum screening methods, the rate of women choosing invasive testing has decreased considerably.**[76]

There are problems with the use of these soft markers. First, some women may assume that the genetic sonogram is a diagnostic test that accurately identifies fetuses with aneuploidy. Women should be made to understand that although a genetic sonogram may reduce the chance that her fetus is affected, **the absence of markers does not rule out the possibility of Down syndrome or other chromosome abnormalities.** Second, it is difficult to assign a definite detection rate for the genetic sonogram because the test performs differently in the hands of different sonographers. Possible reasons include different skill levels of examiners and the subjective assessment required for several markers, particularly echogenic intracardiac focus and echogenic bowel.

The incidental finding of soft markers in otherwise low-risk pregnancies can cause a great deal of anxiety in the expectant parents. Opinions vary as to what to do when so-called minor markers, such as, echogenic intracardiac focus or pyelectasis, are noted in a low-risk patient. A reasonable approach is to refer such a patient for a consultation by an expert to evaluate for the presence of other markers. This individual can then use published likelihood ratios to adjust the patient's prior risk. In most cases, the patient's ultrasound-adjusted risk will be less than that of a 35-year-old woman. She can then be reassured that the finding is probably a variant of normal and that she remains in a low-risk category.

First Trimester

As discussed in detail in Chapter 10, ultrasound assessment is an important part of first-trimester aneuploidy screening. Discussion of the role of ultrasound for this application is much more straightforward because there is good standardization of the imaging and measurement techniques. The most important sonographic component of first-trimester screening is the nuchal translucency measurement. The presence or absence of a visible nasal bone is another important ultrasound finding (Figure 11-8). Other ultrasound findings have been described, such as reverse ductus venosus flow and tricuspid regurgitation,

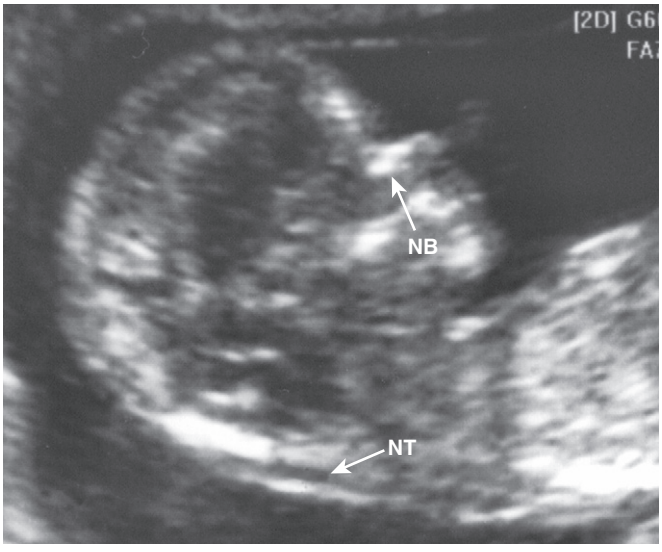

FIGURE 11-8. Midsagittal view of a 12-week fetus showing the nuchal translucency *(NT)* and nasal bone *(NB)*.

but they are not in general use.[77] There are rigorous criteria for appropriate nuchal translucency and nasal bone images. **Individuals who wish to perform the ultrasound component of the first-trimester screen must be trained and certified.** The standardization that comes through certification allows much greater confidence in the risk estimates for aneuploidy than is possible with the second-trimester genetic sonogram.

Screening for Anomalies with the Standard Ultrasound Examination

The AIUM has published specific components of a standard ultrasound examination performed in the second or third trimester (see box, Suggested Components of the Standard Obstetrical Ultrasound Performed in the Second and Third Trimesters). Careful attention to each of these components will allow detection of many, if not most, serious birth defects. In the following sections, normal structures will be demonstrated, and the alterations expected with different birth defects will be shown. The conditions described are those for which the general obstetrician should have familiarity, and that might reasonably be detected with a standard screening ultrasound examination. **Most of the associated images with these conditions are found in the on-line version of this book.**

Suggested Components of the Standard Obstetrical Ultrasound Performed in the Second and Third Trimesters

- Standard biometry
- Fetal cardiac activity (present or absent, normal or abnormal)
- Number of fetuses (if multiples, document chorionicity, amnionicity, comparison of fetal sizes, estimation of amniotic fluid normality in each sac, fetal genitalia)
- Presentation
- Qualitative or semiquantitative estimate of amniotic fluid volume
- Placental location, especially its relationship to the internal os
- Evaluation of the uterus (including fibroids) and adnexal structures
- Anatomic survey to include:
  - Head and neck
    - Cerebellum
    - Choroid plexus
    - Cisterna magna
    - Lateral cerebral ventricles
    - Midline falx
    - Cavum septum pellucidum
  - Chest
    - Four-chamber view of the heart
    - Outflow tracts (if possible)
  - Abdomen
    - Stomach (presence, size, and situs)
    - Kidneys
    - Bladder
    - Umbilical cord insertion into the abdomen
    - Number of umbilical cord vessels
  - Spine
  - Extremities (presence or absence of legs and arms)

Head and Neck

General Appearance

On axial views the head should have an oval appearance. Elongation of the head (termed *dolichocephaly*) is often caused by lateral compressive forces associated with oligohydramnios, especially if the fetus is in a breech presentation. An abnormally round shape (termed *brachycephaly*) can be an important indicator of fetal abnormalities, especially holoprosencephaly and aneuploidies.

Neural Tube Defects

Anencephaly is often first suspected when a proper image for measuring the biparietal diameter cannot be obtained. The absence of the cranial vault can be diagnosed after 10 weeks' gestation. Although the skull is missing, lobulated disorganized brain tissue can be prominent between 9 and 11 weeks. This tissue degenerates by 15 weeks, leaving the characteristic appearance in which there is there is no cortex or cranium and the fetal eyes appear at the top of an intact lower face. Meningomyelocele extending varying distances from the base of the skull down the neck and body may be present with the anencephaly. Fetuses with anencephaly do not swallow normally, so polyhydramnios usually develops in pregnancies that are allowed to continue.

Whenever anencephaly is seen, especially if there are additional clefts or amputations in the fetus, a careful search should be made for strands of membranes attached to the fetus, which are diagnostic of the amniotic band sequence. When there are major skull deficits caused by amniotic bands, there is typically some remaining cerebral cortex, although this is not the case with anencephaly.

Encephalocele is the least common type of neural tube defect and is manifested by a protrusion of the meninges and sometimes brain tissue through a midline defect in the cranium. Ultrasound shows a midline sac protruding though the skull, most often in the occiput. The outcome is very poor if there is brain tissue within the encephalocele sac or there are other significant associated anomalies. When there is an isolated defect with no brain involvement, most children have a good neurologic outcome.

The sensitivity of ultrasound for diagnosing spina bifida increased dramatically in the 1980s when it was discovered that fetuses with this condition have readily apparent secondary changes in the brain and skull.[78] These include frontal narrowing of the skull (the *lemon sign*), ventriculomegaly, and an abnormal cerebellum and posterior fossa. The cerebellum is deformed and drawn backward to obliterate the posterior fossa. This finding, the Chiari type II malformation, is referred to as the *banana sign*.

Cystic Hygroma

A cystic hygroma is a loculated accumulation of fluid in the skin of the posterior neck. In fetuses with this finding, edema may be widespread and is often associated with full-blown hydrops. These fetuses do not survive into the third trimester. When a cystic hygroma is present, there is more than a 60% chance that the fetus has a chromosome abnormality, most commonly Turner syndrome.[79]

Cleft Lip and Palate

While not specifically listed as an AIUM required component of the standard exam, a coronal view of the fetal face

is usually readily obtainable. This view shows the presence of cleft lip. Approximately two-thirds of those with cleft lip also have cleft palate. Cleft palate may be demonstrated with oblique views showing a defect in the maxillary ridge. An isolated cleft palate is rarely diagnosed with prenatal ultrasound.

Micrognathia

A midsagittal view of the face is the best in which to detect micrognathia. Micrognathia may be an important marker for genetic syndromes, such as trisomy 18. Severe hypoplasia of the mandible, such as is seen with Pierre Robin sequence, can cause breathing difficulties at birth; therefore, prenatal diagnosis is invaluable in planning neonatal management.

Cerebellum and Cisterna Magna

The cerebellum and posterior fossa should always be visualized in order to diagnose spina bifida, as described previously, and the Dandy-Walker malformation. In the latter condition, there is a posterior fossa cyst continuous with the fourth ventricle, complete or partial absence of the cerebellar vermis, and varying degrees of hydrocephalus. About 50% of affected fetuses have other intracranial malformations, 35% have extracranial abnormalities, and 15% to 30% have aneuploidy.[80] Many infants with the Dandy-Walker syndrome die after birth, usually as a result of associated malformations. Most survivors have some degree of mental handicap.

Choroid Plexus

Cysts within the choroid plexus are noted in about 1% of normal fetuses.[81] They generally are benign and resolve before 26 weeks without sequelae. Because their presence indicates a seven-fold increase in risk that the fetus has trisomy 18, referral to a specialty center or ultrasonographer is indicated.[82]

Lateral Ventricles

Hydrocephalus is a general term used to describe a head in which the cerebral ventricles are dilated. There are many causes, including spina bifida, stenosis of the aqueduct of Sylvius, normal pressure hydrocephalus, agenesis of the corpus callosum, fetal TORCH (*t*oxoplasmosis, *o*ther infections, *r*ubella, *c*ytomegalovirus, and *h*erpes simplex) infections, and other serious developmental malformations of the brain. In some cases, particularly those caused by aqueductal stenosis, the head can be markedly enlarged. The lateral and third ventricles may be very dilated with marked thinning of the cerebral cortex. With atraumatic delivery and appropriate neurosurgical treatment, more than half of infants with aqueductal stenosis survive, but about 75% of survivors have moderate to severe developmental delay.[83] The degree of hydrocephalus and the thickness of the remaining cerebral cortex are weak predictors of the neurologic outcome.

The appearance of the choroid plexus can assist in the diagnosis of less obvious hydrocephalus. With hydrocephalus, this structure, which usually fills this portion of the lateral ventricle from side to side, is compressed and "dangles." The accepted upper limit of the transverse diameter of the lateral ventricles at the atrium is 10 mm. When the ventricles measure between 10 and 12 mm, there is a 96% chance of a normal neurologic outcome, and an 86% chance with a measurement between 12 and 15 mm.[84] Whenever any degree of hydrocephalus is seen, a careful search for other malformations is essential because their presence strongly influences the prognosis. Agenesis of the corpus callosum should be considered when there is modest ventricular dilation that is primarily confined to posterior horns. Although fetuses with spina bifida usually have dilation of the lateral ventricles, the head size is usually not increased.[85]

A unilateral cystic lesion adjacent to the cerebral cortex most likely represents an arachnoid cyst. These generally are associated with a good prognosis but can reach considerable size, causing symptoms such as seizures or hydrocephalus. Porencephalic cysts are unilateral cystic lesions in the brain that have a much worse outcome. These arise from intracerebral infarcts or hemorrhages with subsequent liquefaction of the brain tissue or clot. The resultant cystic cavity within the brain parenchyma may be in communication with the subarachnoid space or a cerebral ventricle.

Midline Falx

Absence or abnormality of midline structures of the brain should point to a diagnosis of holoprosencephaly. This condition results from incomplete division of the cerebral hemispheres. With the "alobar" form of holoprosencephaly, the head is usually small and brachycephalic. There is no midline echo dividing the cerebral cortex, and there is a single crescent-shaped ventricle anterior to the bulbous-appearing thalamus. Many fetuses with holoprosencephaly have facial abnormalities as well, which may include hypotelorism or cyclopia, facial clefts, absent nose or single nostril, and presence of a proboscis above the eye or between the eyes. Chromosome abnormalities (especially trisomy 13) and other malformations are present in one third of cases. Regardless of the karyotype or presence of other malformations, alobar holoprosencephaly is associated with a dismal neurologic prognosis; death almost always occurs either before or shortly after birth. When there is partial division of the brain, the fetus may have "semilobar" or "lobar" holoprosencephaly, both of which have a somewhat more favorable prognosis.

Chest

Chest Masses

Displacement of the heart away from the midline is often a sign of a diaphragmatic hernia or a lung mass such as congenital pulmonary adenomatoid malformation (CPAM) or pulmonary sequestration. The presence of these conditions can be life-threatening to the fetus because vital chest structures are compressed or displaced. Space-occupying chest lesions can severely impair lung growth. Compression of the esophagus by a lung mass may cause symptomatic polyhydramnios. Similar pressure on the central veins and lymphatics may cause fetal death from generalized hydrops.

With diaphragmatic hernia, the heart is displaced to the side opposite the location of the defect, which is on the left in 75% of cases. The condition can be distinguished from other chest masses by the appearance of bowel, stomach, and other abdominal organs in the chest at the level of the

four-chamber view of the heart. In the midabdominal view, the stomach is typically not seen with left-sided hernias and is shifted toward the right in right-sided lesions. The intrahepatic umbilical vein is usually shifted toward the side of the defect, and variable amounts of liver will sometimes be seen prolapsed into the chest. Ultrasound does not usually demonstrate significant lung tissue on the affected side. The contralateral lung can be very small. Displacement of the gastrointestinal tract often results in swallowing abnormalities, and half of cases develop polyhydramnios.

CPAM appears as a solid or cystic lung mass that is almost always unilateral and confined to one lobe. Frequently, there is a shift in the mediastinum with compression of the contralateral lung. Nonimmune hydrops can develop, and this finding is associated with a poor prognosis. Because an apparently very large CPAM can appear to regress as a pregnancy advances the clinician should be cautious about predicting a poor outcome.[86] Most affected children require nonemergent surgical resection.

Pulmonary sequestration is a congenital anomaly in which a mass of lung tissue arises from the foregut independently of the normal lung. It does not communicate with the tracheobronchial tree, and it receives its blood supply directly from the aorta. Ultrasound shows an echogenic intrathoracic or intra-abdominal mass, usually just above or just below the diaphragm. Color Doppler ultrasound can sometimes show the aberrant blood supply, thus distinguishing a pulmonary sequestration from CPAM. A pulmonary sequestration usually must be removed in childhood but rarely causes prenatal complications.[87]

Four-Chamber View of the Heart

In addition to the position of the heart within the chest, the axis should be carefully noted. The sonographer must identify the fetal right and left side based on the position of the fetus, not the position of the organs. Otherwise, abnormalities of sidedness, such as situs inversus, would be missed.

The starting place for diagnosing congenital heart defects is the four-chamber view (see Figure 11-5). Examples of defects that present with an abnormal four-chamber view include many septal defects and hypoplastic left heart syndrome. Ventricular septal defects account for 20% to 30% of congenital heart defects. Although large defects can often be seen in the four-chamber view, small defects are commonly missed, even by experienced examiners. Some significant defects are in the anterior, membranous portion and are not visible with the four-chamber view. The most obvious septal defect visible with prenatal ultrasound consists of an atrioventricular canal defect. With this, there is a large defect in the atrial and ventricular septum and a common atrioventricular valve. This particular lesion has a strong association with Down syndrome, which is present in about half of cases. In about half of the cases of ventricular septal defects there are other, more complex malformations. It is difficult to distinguish an atrial septal defect from a normal patent foramen ovale.

Hypoplastic left heart syndrome is suspected when the left ventricle, which should be similar in size to the right ventricle, appears very small with a four-chamber view. To better characterize such defects, visualizing the outflow tracts is critical (see Figure 11-6). In hypoplastic left heart syndrome, the ascending aorta and aortic arch are very narrow in comparison with the pulmonary artery and ductus arteriosus.

Outflow Tracts

Many relatively common serious congenital heart defects may be missed entirely unless the outflow tracts are assessed. One example of such a condition is tetralogy of Fallot, which consists of a ventricular septal defect (VSD), pulmonary stenosis, and aorta that overrides the VSD. The fourth finding is hypertrophy of the right ventricle, which develops postnatally. Transposition of the great arteries may also present with a completely normal four-chamber view. This disorder is recognized with the outflow tract views when the aorta and pulmonary artery run parallel to each other instead of crossing. The aorta, which can be recognized from the shape of the arch, arises from the right ventricle and runs anterior to the main pulmonary, which arises posteriorly from the left ventricle. A ventricular septal defect is found in 40% of cases.

Abdomen

The fetal stomach should always be visualized after the first trimester. If the stomach is small or absent and does not fill after 30 to 60 minutes of observation, esophageal atresia should be suspected. In most cases, polyhydramnios will also be present, resulting from an inability of the fetus to swallow amniotic fluid normally. An empty stomach in a fetus with anhydramnios is not suggestive of gastrointestinal pathology but simply reflects that absence of fluid available for the fetus to swallow.

Duodenal atresia is usually easily diagnosed by third trimester fetal ultrasound. The diagnosis is based on the demonstration of the double-bubble sign in which adjacent fluid filled structures are seen, representing the fluid-filled dilated stomach and proximal duodenum. Polyhydramnios is a consistent feature in these cases; trisomy 21 is found in about 30%. Small bowel obstruction further along the intestinal tract is less common than duodenal atresia. Ultrasound in these cases shows multiple actively peristalsing loops of distended small bowel. The degree of polyhydramnios depends on the proximity of the obstruction.

Kidneys

Bilateral renal agenesis is usually first suspected when there is absent amniotic fluid and nonvisualization of the fetal bladder. The diagnosis is confirmed by the absence of kidneys in the renal fossae. The diagnosis is sometimes difficult because the absent amniotic fluid makes adequate visualization of the fetal anatomy difficult and because the discoid-shaped adrenals can be confused with fetal kidneys. Transvaginal scanning can be very helpful because with absent amniotic fluid the fetus is often close to the upper vagina. Bilateral agenesis is invariably associated with pulmonary hypoplasia, which is the cause of death in live-born infants. In this setting, ultrasound shows a small, bell-shaped chest.

Infantile polycystic kidney disease is an autosomal recessive disorder characterized by bilateral symmetrical enlargement of the kidneys. In this condition, normal parenchyma is replaced by dilated collecting tubules, which measure less than 2 mm in diameter. These cysts are not seen macroscopically with ultrasound but rather

give the kidneys a markedly echogenic appearance. In most cases, these kidneys are nonfunctioning in the fetus, and there is no bladder filling or amniotic fluid production. Neonates die of pulmonary hypoplasia.

Multicystic dysplasia is a disorder with sporadic occurrence characterized by noncommunicating cysts of various sizes scattered randomly through the kidneys. The renal parenchyma between the cyst has an echogenic appearance. The disorder can be bilateral, unilateral, or segmental. Affected kidneys may become quite large. This condition should be differentiated from hydronephrosis, in which the parenchyma is normal, and a dilated renal pelvis communicates with dilated calyces. In bilateral multicystic dysplasia, there is nonproduction of urine, so the bladder is not visualized and there is no amniotic fluid. As with renal agenesis, unilateral disease is associated with normal bladder filling and amniotic fluid volume and has an excellent prognosis.

With hydronephrosis, there are varying degrees of dilation of the renal pelvis and calices. The degree of dilation is recorded as the anteroposterior diameter of the renal pelvis. If this measurement is greater than 4 mm up to 32 weeks or greater than 7 mm beyond 32 weeks, follow-up ultrasound is indicated.[88] These cut-offs were set to ensure a sensitivity of nearly 100% for detecting any postnatal compromise or the need for surgery. Using these cut-offs, 20% to 50% of cases have normal kidneys at postnatal evaluation. Persistent hydronephrosis is most often caused by ureteropelvic junction obstruction or vesicoureteral reflux. Dilated ureters signify the presence of severe vesicoureteral reflux, bladder outlet obstruction, or ureterovesical junction obstruction. The latter condition is often associated with a duplicated collecting system. A ureterocele may form at the point of ureteral implantation into the bladder.

Bladder

Bladder outlet obstruction is most commonly seen in male fetuses and is usually caused by posterior urethral valves. These are membrane-like structures in the posterior urethra that cause varying grades of urethral obstruction. More complex malformations involving the urogenital tract may also cause bladder outlet obstruction and are more common when the affected fetus is a female. Sonographically, bladder outlet obstruction is diagnosed when the bladder is abnormally enlarged, and normal emptying is not seen. When the obstruction is severe, other findings include oligohydramnios, dilated ureters, hydronephrosis, and cystic dysplasia of the kidneys. When complete urethral obstruction has been present from early in pregnancy, anhydramnios causes lethal pulmonary hypoplasia, and ureteral reflux results in irreversible damage to the kidneys. Prune-belly syndrome occurs in male fetuses and has the same sonographic appearance as bladder outlet obstruction. With this condition, however, the impairment of bladder emptying is thought to result from a neuromuscular defect in the bladder and not physical obstruction of the urethra.

Umbilical Cord Insertion into the Abdomen

Omphalocele is a ventral wall defect characterized by a membrane-covered herniation of the intra-abdominal contents into the base of the umbilical cord. Bowel loops, stomach, and liver are the most frequently herniated organs. With omphalocele, there is a 75% likelihood of associated birth defects; the karyotype is abnormal in 20%.[89] These associated problems account for most of the mortality associated with this condition.

Gastroschisis is a right paraumbilical defect of the anterior abdominal wall associated with evisceration of the abdominal organs. Gastroschisis is distinguished from omphalocele by the fact that the umbilical cord inserts normally into the abdominal wall and there is no membrane covering the herniated viscera. Most commonly, only bowel loops are involved, but liver, stomach, and bladder may be outside the abdomen. Because of associated atresias or obstruction at the small abdominal wall ring, bowel loops and the stomach may be dilated inside or outside the abdomen. Gastroschisis is rarely associated with chromosome abnormalities and usually does not involve abnormalities outside of the gastrointestinal tract.[90]

Number of Umbilical Cord Vessels

An attempt should be made to confirm that there are two arteries and a vein in the umbilical cord. In late pregnancy, this can be easily ascertained by looking at a transverse cut of the cord in a free loop. In the second trimester, two umbilical arteries are most easily confirmed by identifying the vessels as they course around the fetal bladder. These can be seen with gray-scale ultrasound but are made much more obvious with color Doppler ultrasound. A single umbilical artery (two-vessel cord) is present in 1% of all newborns. Because of the 20% incidence of associated malformations, this finding should prompt a detailed fetal survey.

Spine

With spina bifida, transverse views of the spine show widening of the lateral echocenters. In longitudinal images, the ossification centers, which usually run a parallel course down the back, are widened in the area of the defect. A meningomyelocele sac is usually present. The presence of clubfoot and absence of movement of the lower extremities signify a poor prognosis for motor function of the lower extremities.

Extremities

In most cases of confirmed skeletal dysplasia, the long bones are obviously abnormal, with measurements far below the normal range. Concern sometimes arises when routine measurement of the femur gives a result several weeks less than expected for the gestational age. For most long bone nomograms, the lower confidence limit corresponds to "2 weeks behind" up to 28 weeks, and "3 weeks behind" beyond 28 weeks. For this reason, when the femur is more than 2 or 3 weeks less than expected, a detailed survey of fetal anatomy, especially the long bones, is advisable. A femur-to-foot ratio close to 1 usually implies that the fetus is normal or merely constitutionally small.

Achondroplasia is the most common form of skeletal dysplasia and is associated with a normal life span. Ultrasound shows severe shortening of the long bones, a relatively large head with a protruding forehead, and polyhydramnios. Although this condition exhibits autosomal

dominant inheritance, 80% of cases result from new mutations.

Thanatophoric dysplasia is the most common lethal skeletal dysplasia. In this condition, there is extreme shortening of the long bones. The femur is often bowed, resembling an old-fashioned telephone receiver. The fetus has a small, narrow chest that results in lethal pulmonary hypoplasia. The abdomen and head appear relatively enlarged. In about one of six cases, the head has a cloverleaf shape. Hydrocephalus and polyhydramnios are common.

There are more than a dozen discrete forms of osteogenesis imperfecta, all characterized by abnormalities of the biochemical composition of the bone matrix. The more severe forms are lethal, manifesting very short limbs and the prenatal occurrence of multiple fractures. More mild forms may show few or no fractures, bowing of the femurs, and limb lengths close to the normal range.

Clubfoot is best diagnosed with a coronal view of the lower leg, with the tibia and fibula both seen in a lengthwise section. A normal foot is perpendicular to this plane, but a clubfoot is turned down and in and is seen falling within the coronal plane. It may be very difficult to diagnose clubfoot in the third trimester or in the presence of oligohydramnios.

Hydrops

The term *hydrops* refers to generalized edema in the neonate, manifested by skin edema and accumulations of fluid in body cavities, including the pleural spaces, pericardium, and peritoneal cavity. Before the introduction of Rh immune prophylaxis, most hydrops resulted from erythroblastosis fetalis. Currently, most cases of hydrops are from nonimmune causes. With improvement in diagnostic methods, the etiology of most cases of nonimmune hydrops can be determined. See the box, Causes of Hydrops Fetalis, for the more common causes of nonimmune hydrops. In recent years, it has become apparent that parvovirus infection is responsible for many of the cases of hydrops, which were previously classified as idiopathic.

Causes of Hydrops Fetalis

- Twin-to-twin transfusion
- Chromosomal abnormalities
- Structural cardiac defects
- Cardiac arrhythmia (especially tachyarrhythmia)
- Cardiac tumor
- High-output failure from vascular malformation or tumor
- Sacrococcygeal teratoma
- Vein of Galen malformation
- Placenta chorangioma
- Twin reverse arterial perfusion sequence
- Fetal anemia
  - Parvovirus infection
  - α-Thalassemia
  - Fetomaternal hemorrhage
- Other infections
  - TORCH infection
  - Syphilis
- Chest mass
  - Congenital cystic adenomatoid malformation
  - Pulmonary sequestration

Effect of Prenatal Ultrasound on Neonatal Outcome

It is initially surprisingly difficult to prove that prenatal ultrasound reduces morbidity or mortality in newborns with birth defects. The RADIUS trial demonstrated similar outcomes in the control group and the group with routine screening.[67] A randomized trial of routine ultrasound conducted in Finland demonstrated a decrease in perinatal mortality when routine ultrasound was used, but this was because most pregnancies with serious malformations were terminated, not because offspring from continued pregnancies did better.[91] However, more **recent studies have shown improved outcome when congenital heart defects were diagnosed with prenatal ultrasound**. This has been shown for hypoplastic left heart syndrome[92] and transposition of the great arteries.[93] Although less critical, the prenatal diagnosis of urinary tract malformations can also lead to proper postnatal evaluation and treatment, presumably leading to improved long-term prognosis.[94]

Although definitive proof remains scarce for most conditions, it seems self-evident that there are advantages to prenatal diagnosis. For one, it gives parents the option of pregnancy termination when serious malformations are diagnosed. Another advantage is that it allows families and caregivers time to gather complete information about the fetal problem so that practical and emotional preparations can be made. Plans can be made for delivery at the proper time at a high-risk perinatal center where the newborn can receive optimal care. When the mother delivers at the tertiary care center, there is no need to transport a potentially unstable newborn, and the mother and baby are not separated.

Routine ultrasound to screen for birth defects involves significant costs, but the cost per defect diagnosed are not out of line with other accepted screening tests. It has been shown that the cost-to-benefit ratio is much more favorable when examinations are performed by sonographers with good detection rates.[95] Ideally, in offering a screening ultrasound, the obstetrician should inform the patients in general terms of the sensitivity of this test in the setting in which it is to be performed. **Most importantly, ultrasound to screen for birth defects should always be performed by a well-qualified examiner, following a standardized approach**.

CELL FREE FETAL DNA AND INTACT FETAL CELLS IN MATERNAL BLOOD: DEFINITIVE NONINVASIVE DIAGNOSIS

As currently practiced, noninvasive screening for detecting chromosomal aneuploidy (see Chapter 10) is *not definitive*. A screen-positive result must be followed by an invasive procedure (CVS or amniocentesis) to determine whether fetal aneuploidy is present. In fact, only 1 per 15 to 20 procedures will reveal aneuploidy. Thus, most women undergo procedures unnecessarily.

The holy grail of prenatal genetic diagnosis is *definitive noninvasive prenatal diagnosis*, that is, a blood sample to detect fetal aneuploidy (or other disorders) without a subsequent invasive procedure. CVS or amniocentesis might then be performed only to exclude rare confounding circumstances that would result in false-positive noninvasive

results. (An example would be excluding a vanishing twin, which could lead to unrepresentative results.) If a definitive noninvasive test were robust, one would expect that invasive procedures would almost always confirm abnormal findings.

The goal of definitive noninvasive prenatal diagnosis has been pursued for decades, since the first detection of fetal trisomy 18 in 1991 using intact fetal cells (nucleated fetal red blood cells) recovered from maternal blood.[96] Subsequent confirmation detected trisomy 21.[97-99] However, clinical utility is still lacking with respect to detecting fetal trisomy. By contrast, mendelian disorders can be confidentially detected in certain families. Both cell free fetal DNA and intact fetal cells using maternal blood.

Cell Free Fetal DNA in Maternal Blood

Maternal blood contains cell free fetal DNA in plasma and whole blood.[100] Approximately 5% of cell free DNA in maternal blood is fetal. Fetal DNA fragments are smaller (50 to 200 base pairs), providing the basis for separation from the more plentiful maternal cell free DNA. The goal is to isolate and interrogate fetal DNA sequences but not maternal DNA sequences. Confirmation of success is presence of DNA that cannot be of maternal origin. The obvious example is a Y-sequence, connoting presence of a male fetus. The mother has no Y-sequences; thus, Y DNA must be fetal in origin.

Y-Sequences

Detection of Y-sequence in maternal blood is well documented. A meta-analysis of 792 reports research clinical series resulted in 52 publications suitable for analysis.[101] In pregnancies with a male fetus, Y sequences are detected with 95.4% sensitivity and 98.5% specificity. Sensitivity increased with gestational age: 75.8%, less than 7 weeks; 95.1%, 7 to 12 weeks; 95.6%, 13 to 20 weeks; and 99%, after 20 weeks. Sensitivity was comparable using SRY, DYS14, DYS, DA2, and DY23. Reverse-transcriptase PCR outperformed conventional PCR (96.1% vs. 93.7%). Although these studies were not being designed for clinical application and in fact were usually done in research laboratories, scientific consensus is that validity should be achievable for clinical application.

Single Gene Disorders

Certain mendelian disorders can be detected from cell free DNA, usually when the father has a mutation not present in the mother. If the father has a DNA sequence that the mother lacks and that mutant sequence is detected in the mother, it must be of fetal origin. An example is a father with an autosomal dominant disorder (i.e., polycystic kidney disease or Marfan syndrome). Presence of the paternal (mutant) DNA sequence causing the disorder in *maternal* blood indicates the paternal mutant allele must have been transmitted to the fetus. Another example arises when the father is heterozygous (Aa) and the mother homozygous abnormal (aa) for an autosomal recessive trait. If the normal allele is found in mother, it must have come from a heterozygous fetus inheriting the normal paternal allele.

There exist a host of disorders in which noninvasive definitive diagnosis has been made by this method. Case reports amply validate proof of principle, and series concerning selected disorders (i.e., hemophilia) are now accumulating.[101-103]

Rhesus (D)

Analysis of cell free fetal DNA is already used to assess fetal rhesus status (D). By analysis of maternal blood, fetal Rh(D) can be determined without amniocentesis. The molecular basis of Rh(D) negativity (dd) is usually a gene deletion, the *d* allele representing lack of the DNA sequence that if present would encode *D*. One can distinguish Rh(D)-positive (DD or Dd) from Rh(D)-negative (dd) fetuses by molecular techniques. If the mother is Rh negative and the father heterozygous for Rh(D) (Rh positive), the likelihood is only 50% that the fetus would inherit his Rh(D) gene and, hence, place the pregnancy at risk for isoimmunization; the other 50% of pregnancies would not be at risk for Rh isoimmunization and would not require Rh immune globulin. However, if fetal Rh status were not known, Rh immune globulin would need to be administered, in retrospect, unnecessarily. By contrast, if Rh(D) sequences are found in a pregnant Rh-negative woman (dd), their origin must be fetal, meaning the fetus is Dd and that Rh immune globulin is needed. In many European countries, cell free DNA testing for this purpose is available, and interest is increasing in adopting this technology in the United States.

Trisomy 21

Cell free DNA in maternal blood is being actively pursued for detection of fetal aneuploidy, specifically trisomy 21. At present, cell free fetal DNA testing for aneuploidy is not offered clinically, but promising reports presage introduction. The task here is more difficult than for single gene disorders because detecting fetal trisomy must reflect quantitative differences between affected and unaffected pregnancies. Current strategies are based on counting the total number of chromosome 21 transcripts in maternal blood, using techniques called *massive parallel genomic sequencing*. A pregnancy carrying a trisomy 21 fetus will have more chromosome 21 transcripts than one carrying a normal fetus; the trisomic fetus has three chromosomes 21, whereas the latter only two. Assume 5% of cell free DNA in maternal blood is of fetal origin; thus, a trisomy 21 pregnancy should contain 2.5% more fetal chromosome 21 transcripts than a euploid pregnancy. However, the mother contributes 95% of the total cell free DNA. Thus, the task is to distinguish the 2.5% overall difference. Table 11-2 illustrates the underlying principle on the assumption that maternal blood cell free DNA consists of 95% that is her own (maternal) and 5% that is from her fetus. Various biotechnology companies and academic partners are seeking to exploit this small but finite difference, using various approaches but all fundamentally quantitative in nature. Obtaining a relatively enriched portion of fetal DNA is the universal goal, using microfluidic approaches (fetal DNA size) or selected characteristics by which fetal DNA differ from maternal DNA (e.g., methylated genes). The most straightforward approach is simply to compare quantitatively the total number of targeted sequences compared with expectations.[102] Another is to place greatly diluted cell free fetal DNA transcripts in wells. Simply counting (digital PCR) the number of wells with a chromosome

TABLE 11-2 TOTAL CHROMOSOME 21 CELL FREE DNA IN MATERNAL BLOOD: DISOMIC VERSUS TRISOMIC FETUSES

	DISOMIC FETUS	TOTAL 21 TRANSCRIPTS	TRISOMIC FETUS	TOTAL 21 TRANSCRIPTS
Mother	2	95	2	95
Fetus	2	5	3	7.5
		100		102.5
			2.5%	

Assume 95% of cell free DNA in maternal (pregnant) blood is derived from the mother and 5% from the fetus. The 5% of fetal origin will have 50% more 21 transcripts if that fetus is trisomic. Thus, the total (maternal and fetal) 21 transcripts will be 2.5% higher if the fetus is trisomic.

21 signal should reveal a greater number in trisomy 21 pregnancies.[103]

Although the validity of cell free fetal DNA to detect fetal trisomies is proved in principle, a problem is obtaining an answer consistently. For clinical applications, a robust test must be able to provide a definitive answer in a specified percentage of cases. The "call rate" should be high and well defined, but not necessarily 100%. By contrast, false-negative cases must be near zero if analysis of cell free fetal DNA on fetal cues is to be a *test* and not merely another *method of screening*.

Several promising series have been recently reported, and ability to detect fetal trisomy 21 is no longer in doubt.[104] Ehrich and associates[104a] assessed 480 cases (some samples prospective, others archived); 13 had "insufficient volume," and 18 failed quality control parameter. Of the remaining 449, all 39 trisomy 21 samples were correctly identified, but 1 false-positive case was observed. Papageorgiou and colleagues[104] used certain genes that were methylated in the fetus but not in the mother. In 40 "blind" samples, euploid versus trisomy 21 maternal blood samples could be discriminated. Chiu and coworkers[105] studied a mixed sample consisting of prospective pregnant women and archived plasma samples. Of the 576 pregnant women, 1.7% "did not meet recruitment criteria," and 5.6% samples "did not pass the specimen quality requirements." All trisomy 21 cases were detected with 97.9% specificity when a two-plex approach was applied, meaning two cases were sequenced and analyzed concurrently. On the other hand, testing eight samples concurrently (eight-plex) resulted in unacceptable (79.1%) sensitivity. The rationale for an eight-plex approach is to decrease the cost of a given diagnostic test. The same research team has detected trisomy 13 and trisomy 18, but only after a complex bioinformatics approach applying statistical correction.[106] An additional salutary report (39 trisomy 21 cases detected with one false positive) was reported in early 2012.[107]

Intact Fetal Cells

Intact fetal cells are rare but present in 1 per million to 10 million maternal cells. Original efforts toward definitive noninvasive prenatal diagnosis involved recovering intact fetal cells from maternal blood.

Given the rarity of fetal cells in maternal blood (one fetal cell per 10^7 nucleated maternal cells), it has long been accepted that one must enrich the sample for these rare fetal cells. This process first requires targeting a specific fetal cell type: fetal trophoblasts, lymphocytes, granulocytes, or nucleated red blood cells.

Analyzing interphase cells by FISH with chromosome-specific probes, Elias, Simpson, and colleagues were the first to detect fetal aneuploidy (trisomy 18)[96] in maternal blood. This 1991 advance was soon followed by noninvasive detection of trisomy 21.[97,98] Diagnosis was made on the basis of one to three trisomic and, hence, fetal cells recovered from a 20- to 30-mL maternal specimen and studied by FISH with chromosome-specific probes. The major problem was that the expected number of fetal cells were not recovered, presumably lost in processing and thus impeding sensitivity. An NICHD collaborative study toward this goal assessed the accuracy of intact fetal cell recovery in four centers, using two different methods. Overall, 74% of aneuploidies were detected (32 of 43) cases.[108] This approach was, however, laborious and hindered by lack of consistent recovery. Subsequent attempts focused on recovering *intact* fetal cells using microelectronic mechanism devices or analyzing cells for FISH signals through automated microscopy. Neither has provided consistent results to date.

The most promising current approach appears to involve recovery of fetal trophoblasts in maternal blood. Paterlini-Brechot and colleagues demonstrated proof of principle for recovery and diagnosis of both cystic fibrosis (ΔF508)[109] and spinal muscular atrophy (SMA).[110] Individual trophoblasts can be recovered on a filter, with individual trophoblasts laser-microdissected and analyzed molecularly to confirm first fetal origin (based on parental polymorphisms) and then fetal genotype. Fetal cells can thus be distinguished from maternal cells. All pregnancies having a fetus affected with cystic fibrosis or SMA were correctly detected; results were identical to those obtained by CVS, the study that was performed concurrently in "blind" fashion. In a recent report from this group, 63 consecutive cases of cystic fibrosis and SMA impressively showed 100% cellular and clinical sensitivity and specificity,[109] a sine que non typically lacking in studies involving either intact fetal cells or cell free fetal DNA.

Intact fetal cells retain considerable advantages over cell free fetal DNA. Recovery of intact fetal cells would allow ready diagnosis of not only aneuploidy but also many other conditions concurrently. This approach would be analogous to that already routinely performed on blastomeres or polar bodies in PGD (see later). Analyzing intact fetal cells rather than cell free fetal DNA should facilitate provision of information on not only trisomy 21 but also all chromosomes and selective mendelian traits.

PREIMPLANTATION GENETIC DIAGNOSIS

Preimplantation genetic diagnosis (PGD) is not simply "earlier" prenatal genetic diagnosis but rather a technology

also with novel application. PGD requires access to embryonic DNA—gametes or embryos before 6 days of conception, when implantation occurs. **There are three potential approaches for obtaining embryonic DNA for PGD: (1) polar body biopsy, (2) blastomere biopsy (aspiration) from the 3-day six- to eight-cell cleaving embryo, and (3) trophectoderm biopsy from the 5- to 6-day blastocyst.**

Obtaining Embryonic and Gamete DNA

Initial work in most centers involved blastomere biopsy, the zona pellucida being traversed by mechanical, laser, or chemical means to extract a cell. This is not without risk: removal of cell is believed to reduce embryo survival by 10%; removal of two cells reduces the pregnancy rate further and is generally not performed.[110]

Initially, PGD predominantly used blastomeres from the cleavage stage embryo. Polar body biopsy has recently become accepted as the most accurate method for chromosomal analysis. A polar body is extruded at both first and second meiotic divisions as the number of chromosomes is first reduced (46 to 23), and then each chromosome is divided into single chromatids. The underlying principle is illustrated by considering a heterozygous individual. Absent recombination, a mutant maternal allele in the first polar body should be complemented by a primary oocyte having the normal allele. Oocytes deduced to be genetically normal can be allowed to fertilize in vitro and be transferred for potential implantation. Conversely, a normal polar body indicates an abnormal oocyte; thus, fertilization would not be allowed. If the first polar body fails to show chromosome 21, the oocyte is presumed to have two 21 chromosomes and, hence, once fertilized, leads to a trisomic zygote. Maternal meiotic error is actually now recognized to involve chromatids in both meiotic I and II, the result of premature chromatid separation. Thus, segregation patterns are more complex; however, the general principle holds, deducing oocyte status as the complement of the second polar body. Polar body biopsy has special value in detecting chromosomal abnormalities because maternal meiotic errors account for 95% of numerical chromosomal abnormalities. Surprisingly, polar body biopsy detects maternal meiotic errors more robustly than blastomeres of the actual embryo because polar body biopsy correlates with greater fidelity to embryonic status. The explanation is that a single abnormal blastomere in a cleavage stage embryo may merely reflect a mitotic error that will not persist; thus, one would erroneously deduce the entire embryo to be aneuploidy and lose the opportunity to transfer a normal embryo.

The obvious disadvantage of polar body biopsy is inability to assess paternal genotype, precluding application if the father has an autosomal dominant disorder and making analysis less efficient in managing couples at risk for autosomal recessive traits. See Simpson[111] for additional details, in particular concerning how to handle recombination observed in the first polar body.

Biopsy of the trophectoderm is the third approach. In the 5- to 6-day blastocyst, there are 120 or more cells. The greater number of cells potentially facilitates diagnosis. Another advantage is that the trophectoderm forms the placenta; thus, cells detained to produce the embryo are not removed, an advantage shared with polar body biopsy. The additional 2 to 3 days in culture for blastocysts beyond that required for an eight-cell embryo further allows self-selection against nonthriving embryos. Approximately one third of embryos with chromosomal abnormalities are selected against (lost) between days 3 and 5; however, PGD remains necessary to exclude the remaining aneuploidies. The value of trophectoderm biopsy has been enhanced by the recent development of new techniques (vitrification) by which cryopreservation of biopsied embryos has become possible. Cryopreservation has long been routine to generate ART pregnancies using nonbiopsied embryos, but not until recently was it possible to do so using cryopreserved biopsied embryos. Thought to minimize formation of intracellular ice crystals, vitrification can be used following blastocyst biopsy, thawing available embryo at a later time for transfer. In the intervening period, CGH based on single nucleotide polymorphisms (SNPs)[112] or array CGH can be performed.

Chromosomal Indications

The most common indication for PGD is detection of chromosomal abnormalities, most often selected aneuploidies. It is not possible to obtain a karyotype on a single cell reliably, for which reason preimplantation cytogenetic analysis (numerical or structural) traditionally relied on FISH using chromosome-specific probes.[111,112] PGD for detecting unbalanced translocations is also applicable, also using FISH. In Chapter 26, we describe how most translocations predispose to unbalanced genetics. This unavoidably delays the time needed to achieve a normal pregnancy, for some women beyond the age realistic to achieve pregnancy.

Sensitivity for detecting aneuploidy naturally increases as the number of chromosomes tested increases. Usually 5 to 9 chromosomes were studied. Approximately 70% to 80% of aneuploidy embryos can be detected using 9 to 12 chromosomes (e.g., X, Y, 13, 18, 21, 16, 17, 15, 22).[113] A single cell can be interrogated over two to three hybridization cycles to reach that number. The current preference is, however, to obtain information on all 24 chromosomes. One approach is simply to perform additional hybridization cycles, eventually covering all chromosomes. Actually, 90% of aneuploidy can be detected by studying only 10 to 12 chromosomes because rarer trisomies are often found to be trisomic concomitant with another trisomy (double trisomy). Thus, screening for 10 chromosomes predicts correctly 89% (382 of 427) of embryos to be either normal or abnormal[114]; testing 12 chromosomes predicts 91% (389 of 427).

FISH for PGD aneuploidy testing is now being replaced by genome-wide molecular approaches, namely SNPs from all chromosomes[112] or array CGH (chromosomal microarrays).[114] The microarrays used in PGD are different from those used in prenatal array CGH on amniocentesis or chronic villi. In PGD, bacterial artificial chromosomes are used, producing large sequences that in aggregate detect only major abnormalities like aneuploidy, in either chromosomes (blastomeres) or polar bodies (chromatids). Thus, the dilemma of disclosing or not disclosing polymorphic CNVs of uncertain clinical significance does not arise.

Single Gene Disorders

Approximately one fourth of PGD cases are performed for disorders caused by a single mutant gene.[111,115] Like other

forms of single gene prenatal genetic diagnosis, PGD can be performed whenever the chromosomal location is known, even if the causative mutation is not. Linkage analysis can still be performed and, in fact, is routinely employed in PGD. The Reproductive Genetics Institute has tested more than 220 different conditions, the most frequent being hemoglobinopathies, cystic fibrosis, fragile X syndrome, and Duchenne muscular dystrophy. See Verlinsky and Kuliev[115] for a list of disorders tested. The implantation rate per embryo in their series of more than 2000 cases was 27.1% (gestational sacs per embryos transferred). A pitfall is that amplification rates do not exceed 90% to 95% per allele, even in experienced hands.[116] This phenomenon—allele dropout (ADO)—probably reflects stochastic phenomena (failure of probes to locate patient DNA) or in turn perhaps exacerbated by embryo damage that has resulted in loss of embryonic DNA. Linkage data are obligatory in single gene PGD for mitigating against erroneous or noninformative results in ADO that involves the mutant allele itself. The Reproductive Genetics Institute has observed only three errors in 2300 single gene PGD cycles, which resulted in more than 500 babies.[111,115] In Brussels, Liebaers and colleagues[117] reported 0.6% misdiagnosis in 581 PGD pregnancies studied in Brussels. That the rate of diagnostic accuracy is so high, despite 5% to 10% unavoidable ADO, probably reflects the policy in experienced PGD centers of transferring only the most diagnostically robust and morphologically normal embryos, which presumably are less likely to have ADO.

Novel Indications

Preimplantation genetic diagnosis is not simply early prenatal genetic diagnosis. PGD allows unique applications not possible using traditional prenatal diagnosis (CVS or amniocentesis).

Avoiding Clinical Termination

Couples may wish to avoid an abnormal fetus yet are opposed to pregnancy termination for religious or other reasons. The considerable disquiet of any couple undergoing pregnancy termination becomes exacerbated when repeated pregnancy terminations are necessary because of consecutively affected offspring. Moreover, the first polar body is present before fertilization; thus, its analysis offers the unique possibility of *preconceptional* diagnosis. The second polar body is, however, not extruded until the mature oocyte is fertilized; thus, its analysis would not truly be preconceptional.

Nondisclosure of Parental Genotype

PGD is the only practical prenatal diagnostic approach when a person at risk for an adult-onset disorder wishes to remain unaware of his or her genotype, yet not transmit the mutation to his or her offspring. Prototypic indications involve Huntington disease and autosomal dominant Alzheimer disease. Using PGD, multiple embryos can be screened with only unaffected embryos transferred; the patient can remain oblivious to diagnostic methods underway. A caveat is that the scenario must be repeated in subsequent cycles, even if the (undisclosed) patient proves unaffected. Otherwise, all at-risk patients could readily deduce his or her genotype.

Cancer and Other Adult-Onset Disorders

Performing prenatal genetic diagnosis for adult-onset mendelian conditions had been considered arguable before application through PGD. In the United States, relatively little controversy now exists. However, there remains reticence in Europe (see Chapter 54). The first case of PGD performed for adult-onset cancer involved Li-Fraumeni syndrome, a disorder caused by a *p53* perturbation.[118] *BRCA1*, multiple endocrine neoplasia, familial adenomatous polyposis (FAP), retinoblastoma, and von Hippel-Lindau syndrome are other common indications.[119]

HLA-Compatible Embryos

Having a human leukocyte antigen (HLA) compatible sibling is invaluable if an older, moribund sibling with a lethal disease requires stem cell transplantation to repopulate his or her bone marrow. The ideal source of stem cells is an HLA-matched sibling because among siblings, one in four is HLA compatible (identical). Sufficient cells can be obtained from its umbilical cord blood. Stem cell transplantation using cord blood is very successful (95%) if the cord blood is HLA compatible, but much less so (65%) if not HLA compatible. Given the risk for a single gene disorder usually coexisting when HLA matching is requested, the couple can not only avoid another genetically abnormal child but also take advantage of the possibility of a normal offspring who is HLA compatible with the affected child. **HLA-compatible umbilical cord blood contains stem cells that if transplanted could allow their older, moribund offspring to survive.** Success rates using HLA-compatible stem cells are more than 90% compared with much less (60% to 65%) if not HLA compatible. If the pregnancy is at risk for an autosomal recessive disorder, the likelihood of a genetically normal, HLA-compatible embryo is 3 in 16 (1 in 4 for the desired HLA-compatible embryo multiplied by the 3 in 4 likelihood of also being unaffected = 3/16).

PGD for the purpose of transferring HLA-compatible embryos was first performed by Verlinsky and colleagues in a couple at risk for Fanconi anemia.[120] By 2004, 45 cycles for HLA typing had been performed[121]; 17.5% embryos were genetically suitable for transfer, very near the expected 18.7% (3/16). The most common genetic indication worldwide for HLA testing is β-thalassemia.[111,115]

In the United States and Turkey, testing for HLA-compatible embryos *without* risk for genetic disease[121] is well accepted. A prime indication is an older sibling with leukemia. In the United States, approximately one third of HLA PGD cases are performed for this purpose; this indication is uncommon in the United Kingdom.[111]

Aneuploidy Testing to Improve Pregnancy Rates

In addition to excluding aneuploidy in couples at increased risk who wish to avoid clinical pregnancy termination or must undergo ART for other reasons, PGD has been pursued to improve the low (30 to 40%) pregnancy rates in ART. The success rate for ART declines precipitously beginning late in the fourth decade. The primary reason is the high embryonic loss due to aneuploidy; endometrial factors are not paramount, as witnessed by successful pregnancies following use of donor oocytes for women in their fifth decade or beyond. Not only does aneuploidy increase

with increasing maternal age, but so, too, do miscarriage rates. This is logical given most early pregnancy losses resulting from aneuploidy (Chapter 26), and a maternal age effect existing for aneuploidy. Thus, an obvious strategy is to perform PGD, transfer euploid embryos and increase the proportion of potentially viable pregnancies.

By 2000, larger PGD and ART centers in the United Stated and Europe increasingly were offering PGD to improve pregnancy rates in older women. However, these centers were not able to conduct a randomized clinical trial (RCT). RCTs in smaller centers, mostly in Europe, were conducted and did not show salutary benefits. These RCTs have methodologic flaws, however, and PGD aneuploidy testing is still pursued. Still, lack of a RCT providing benefit has understandably impeded acceptance. This controversy, discussed elsewhere,[122] is ongoing and unresolved.

The current recommendation worldwide largely mirrors that of the European Society of Human Reproduction and Embryology (ESHRE) Consortium.[123] In PGD aneuploidy testing one should interrogate embryonic tissues *other* than blastomeres (the traditional method), namely polar body biopsy. One should also use methods other than FISH, namely array CGH. A RCT to test this approach is underway in Europe. While awaiting results, the following seems appropriate counsel for couples considering PGD aneuploidy testing: (1) Pursue PGD only in women of relatively advanced maternal age, perhaps >37 years old. (2) Proceed only if there are at least 6 morphologically normal embryos; two to three chromosomally normal embryos can thus be reasonably expected. If fewer embryos exist, PGD should not be pursued without parental consent. (3) Use only highly skilled embryologists, and if unavailable do not proceed. (4) Interrogate at least 8 and preferably 10 to 12 chromosomes by FISH, or preferably all 24 chromosomes either by FISH or array CGH.

Safety of Preimplantation Genetic Diagnosis

Removal of any embryonic cell logically might decrease survival or implantation and, hence, reduce pregnancy rates. This appears true at least with respect to removal of blastomeres.[110] If viability is reduced by 10% when a single blastomere is removed, PGD aneuploidy must first overcome this 10% decrease and then generate another 10% or more improvement in pregnancy rate in order to show clinical utility.

Viability aside, the totipotential nature of embryonic cells confers safety against organ-specific anomalies in resulting liveborn infants. Loss of one or more cells prior to irrevocable differentiation into a specific embryologic developmental pathway is obviated if another cell has capacity to accomplish the same purpose. In determining safety of PGD in liveborn infants, it is relevant that the birth defects rate in ART is 30% over background.[124] A **30% increase in birth defects associated with ART is not likely the result of ART per se but rather a reflection of the underlying infertility that necessitated ART. This can be deduced because the frequency of birth defects is above background not only in ART pregnancies but in pregnancies spontaneously conceived but only after 12 months of trying to conceive (the traditional definition of infertility).**[125] Irrespective, available data indicate no increased rate of birth defects in liveborn infants previously subjected to PGD. Liebaers et al.[117] conducted a thorough, systematic study of PGD offspring assessed by physical examination 2 months after birth. Frequencies of anomalies in 563 PGD liveborn infants, 18 stillborn fetuses, and 9 neonatal deaths were compared to those in a previously reported cohort study of ICSI offspring not undergoing PGD.[126] Approximately half the PGD cases were at risk for a single gene disorder, whereas the others underwent aneuploidy testing. Structural malformations were found in 2.13% for PGD alone and 3.38% for ICSI.[117] There were no differences between offspring resulting from single gene PGD versus PGD aneuploidy testing. The anomaly rate observed in PGD cases in Brussels[117] was also similar to that tabulated by the Reproductive Genetics Institute in the U.S.[111] PGD appears safe for resulting liveborns.[127]

Current Utility

Single embryonic cells can be transported to referral centers; thus, PGD is widely available. The many different testable conditions have shown high accuracy. The obstetrician should be aware that PGD has certain unique indications, foremost being HLA testing to identify a compatible embryo whose umbilical cord blood can be used for stem cell transplantation for an older, moribund sibling. Other indications applicable only by PGD include nondisclosure testing and avoidance of clinical pregnancy terminations. PGD can be applied for any mendelian disorder whose location is known, using linkage analysis even when the causative mutation is not known.

PGD for translocations is also well accepted, and PGD to avoid repeated pregnancy losses in couples having recurrent aneuploidy is known to be efficacious. Controversy exists concerning whether PGD aneuploidy testing improves pregnancy rates.

KEY POINTS

- All invasive prenatal diagnostic procedures are accurate but carry risks. Amniocentesis at 15 weeks and later carries a procedure-related risk of 1 in 400 to 500. Amniocentesis before 13 weeks is not recommended because of an unacceptable risk for clubfoot (talipes equinovarus).
- Chorionic villus sampling (CVS) is, in experienced hands, equal to amniocentesis in safety (loss rates) and diagnostic accuracy. Transcervical and transabdominal CVS are equivalent in safety and accuracy.
- Newer molecular diagnostic methods (array CGH) provide greater sensitivity for detecting gains or losses of chromosomal regions than the traditional karyotype.
- The precise complication rate associated with fetal blood sampling is undefined, but the loss rate is considered to be 1% to 2%. Rates depend greatly on the associated fetal status.
- Most single-gene disorders can now be detected by molecular methods if fetal tissue is available, given location of the causative mutant gene being known for most disorders. Linkage analysis can be

applied if the gene has been localized but not yet sequenced or if the mutation responsible for the disorder in a given family remains unknown despite sequencing. This option represents a transformational improvement over previous methods, which relied on a number of different indirect approaches.

- Multifactorial disorders most often use ultrasound for detection, but many single gene disorders (e.g., skeletal dysplasias) can be detected as well and then confirmed by molecular tests. Sensitivity of ultrasound for the detection of birth defects depends on the level of training of examiners and the maintenance of a structured approach to the fetal examination.
- In experienced hands, the use of the "genetic sonogram" is a noninvasive way to adjust the likelihood that a fetus has trisomy 21. However, patients should understand that the genetic sonogram is used only to a*djust* risk estimates and cannot definitively diagnose aneuploidy. Sensitivity is never 100%.
- Cell free fetal DNA can be recovered from maternal blood and has allowed *definitiv*e noninvasive diagnosis for fetal Rh(D), fetal sex, and certain paternally transmitted single gene disorders. Screening ror aneuploidy is possible.
- Definitive noninvasive prenatal diagnosis using intact fetal cells (nucleated red blood cells) was the initial approach for detecting fetal disorders, and more recently fetal trophoblasts have been recovered to make diagnosis. However, detection of fetal trisomy by analysis of maternal blood is not yet available or able to yield the near 100% detection following an invasive procedure (amniocentesis or CVS). Promising results are being achieved using cell-free DNA.
- Preimplantation genetic diagnosis (PGD) requires removal of one or more cells (polar body blastomere, trophectoderm) from the embryo. Diagnosis uses molecular techniques to detect single gene disorders and either FISH or chromosomal array CGH to detect chromosomal abnormalities (trisomy). Safety does not seem to be a major concern among resulting live born infants.
- PGD has certain unique indications not possible with traditional prenatal diagnosis. These include avoidance of clinical pregnancy termination, fetal (embryonic) diagnosis without disclosure of parental genotype (e.g., Huntington disease), and desire to select HLA-compatible unaffected embryos. In the latter, cord blood of resulting HLA compatible babies can be used for stem cell transplantation in an older, moribund sibling who has a bone marrow infiltrative condition.

Antepartum fetal evaluation is an ever-growing and changing science. **The goal of evidence-based antepartum fetal evaluation is to decrease perinatal mortality and permanent neurologic injury through judicious use of reliable and valid methods of fetal assessment, without acting prematurely to modify an otherwise-healthy pregnancy or providing a false sense of well-being in cases of impending morbidity.** The opportunity for obstetrical care providers to participate in this delicate balance has been made possible by continued advances in our ability to assess the physiologic well-being of the fetus, concurrent with great improvement in neonatal care and survival.[1] However, despite these advances in antepartum fetal surveillance and the widespread use of antepartum testing programs, the ability of these techniques to prevent intrauterine injury or death remains unproved in many cases.[2] The focus of this chapter is on antepartum evaluation in the United States and similarly technologically advanced and resource-rich countries, noting that the worldwide problem of stillbirth is a vast and compelling area of international interest.[3]

DEFINING THE PROBLEM OF PERINATAL MORTALITY

Identification of fetuses at risk for perinatal mortality has historically been the goal of antepartum fetal assessment. Our emerging understanding that long-term neurologic disability is an integrally related and often competing entity to perinatal mortality makes this goal more complex.[2]

The National Center for Health Statistics (NCHS) provides two different definitions for perinatal mortality, acknowledging that variation in definitions and reporting rates both among states in the United States and throughout different countries worldwide makes comparisons difficult; an agenda to develop a classification consensus has been the focus of a number of international committees,

including the National Institute for Child Health and Development (NICHD).[3] The NCHS National Vital Statistics Report (NVSR) on fetal and perinatal mortality describes two different definitions for perinatal mortality rate (PMR). PMR definition I includes infant deaths of less than 7 days of age and fetal deaths of 28 weeks of gestation or more per 1000 live births plus fetal deaths, whereas PMR definition II is more comprehensive, including infant deaths of less than 28 days of age and fetal deaths of 20 weeks or more per the same denominator.[4,5] The definitions of PMR provided by the World Health Organization (WHO) and the American College of Obstetricians and Gynecologists (ACOG) differ slightly, including the number of fetuses and live births weighing at least 500 g rather than using a gestational age cut-off.[6,7] According to the NCHS, "Fetal death means death prior to the complete expulsion or extraction from its mother of a product of human conception, irrespective of the duration of pregnancy and which is not an induced termination of pregnancy. The death is indicated by the fact that after such expulsion or extraction, the fetus does not breathe or show any other evidence of life such as beating of the heart, pulsation of the umbilical cord, or definite movement of voluntary muscles."[4] The term *fetal death* is used in these definitions and hereafter rather than stillbirth, spontaneous abortion, or miscarriage.

In 2005, there were about 26,000 fetal deaths in the United States. **Although the PMR has fallen steadily in the United States since 1965, the number of fetal deaths has not changed substantially in the past decade** (Figure 12-1).[4,5,8] Using NCHS definition I, the PMR reported in 2005 was 6.6 per 1000, with fetal deaths accounting for about 50% of all perinatal mortality in the United States.[4] The PMR varies greatly by maternal race and ethnicity (Figure 12-2). In 2005, rates (per 1000) were lowest for Asian/Pacific Islander women (4.96), followed by non-Hispanic white (5.36), Hispanic (5.89), and American Indian/Alaskan Native women (6.29). The rate for non-Hispanic black women (12.19) was the highest among the racial and ethnic groups and was 2.3 times the rate for non-Hispanic white women. The significantly greater PMR in blacks results from higher rates of *both* neonatal and fetal deaths.[4]

Characteristics of Fetal Death

Another way to consider the contribution of fetal events on PMR is to look at the infant mortality rate (Figure 12-3).[8] Although the infant mortality rate includes all deaths of infants younger than 1 year of age, 50% of all infant deaths occur in the first week of life, and 50% of these losses result during the first day of life.[7] The infant mortality rate has fallen progressively and even more steeply over time than the fetal death rate, from 47 per 1000 in 1940 to 6.8 per 1000 in 2005, although the rate has remained largely unchanged from 2000 to 2005.[6,9,10] In 2005 there were about 28,000 infant deaths (7 per 1000 live births), including 19,000 (4.7 per 1000 live births) neonatal deaths, 15,000 of which were in the first week of life.[6,9,10] In 2005, the leading causes of infant mortality were congenital malformations (19.5%); disorders relating to short gestation and low birthweight, not elsewhere classified (16.5%); sudden infant death syndrome (7.4%); newborn affected by maternal complications of pregnancy (maternal complications) (6.3%); and newborn affected by complication of placenta, cord, and membranes (4%).[10] Clearly, **perinatal events play an important role in infant mortality.**

Causes of Fetal Deaths

In addition to declining frequency in PMR over time, the overall pattern of perinatal deaths in the United States has changed considerably during the past 40 years. Manning and associates[11] suggest that antepartum deaths may be divided into four broad categories: (1) chronic asphyxia of diverse origin; (2) congenital malformations; (3) superimposed complications of pregnancy, such as Rh isoimmunization, placental abruption, and fetal infection; and (4) deaths of unexplained cause. Fretts and colleagues[12,13] analyzed the causes of deaths, confirmed by autopsy, in fetuses weighing more than 500 g in 94,346 births at the Royal Victoria Hospital in Montreal from 1961 to 1993. The population studied was predominantly white, participated in prenatal care, and included patients from all socioeconomic groups. Overall, the fetal death rate in this group declined by 70%, from 11.5 per 1000 in the 1960s to 3.2 per 1000 during 1990 to 1993.[13] The decline in the fetal death rate in this cohort was attributed to the prevention of Rh sensitization, antepartum and intrapartum fetal surveillance, improved detection of intrauterine growth restriction (IUGR) and fetal anomalies with ultrasound, and improved care of maternal diabetes mellitus and preeclampsia. The role of antenatal diagnosis and management of congenital malformations and aneuploidy is obviously critical to a goal of reducing perinatal morbidity and mortality and will be discussed separately (see Chapters 9, 10, and 11).

Fretts and colleagues[12,13] noted that most of the deaths in the Canadian cohort occurred between 28 and 36 weeks' gestation and that the diagnosis of IUGR was rarely identified before death. In addition to IUGR, leading causes of fetal death after 28 weeks' gestation included abruptio placentae and unexplained antepartum losses. Despite a marked fall in unexplained fetal deaths, from 38.1 to 13.6 per 1000, this category was used for more than 25% of all stillbirths. Fetal-maternal hemorrhage may occur in 10% to 15% of cases of unexplained fetal deaths. Fetal deaths caused by infection, most often associated with premature rupture of the membranes before 28 weeks' gestation, did not decline over the 30 years of the study and accounted for about 19% of fetal deaths. Further population-based analyses of the causes of fetal death have confirmed these findings.

In summary, based on available data, about 30% of antepartum fetal deaths may be attributed to asphyxia (IUGR, prolonged gestation), 30% to maternal complications (placental abruption, hypertension, preeclampsia, and diabetes mellitus), 15% to congenital malformations and chromosomal abnormalities, and 5% to infection. **At least 20% of fetal deaths have no obvious fetal, placental, maternal, or obstetrical etiology, and this percentage increases with advancing gestational age.** Late-gestation stillbirths are more likely to have no identifiable etiology.[6] The ability of our current methods of surveillance to make an impact on the perinatal mortality will depend on the ability of available tests to predict and predate injury and on use of obstetrical interventions to prevent adverse outcomes. In one British series, obstetrical and pediatric assessors reviewed the circumstances surrounding each case of perinatal death to identify any *avoidable* factors contributing to the death.[14] Of the 309 perinatal deaths in this population (half fetal and half in the first week of life), 59% were considered to have had avoidable factors, including 74% of normal-birthweight infants with no fetal abnormalities and no maternal complications. Most avoidable factors were found to be obstetrical rather than pediatric or maternal and social. The failure to respond appropriately to abnormalities during pregnancy and labor, including results from the monitoring of fetal growth or intrapartum fetal well-being, significant maternal weight loss, or reported reductions in fetal movement, constituted the largest groups of avoidable factors. This characterization of avoidable factors contributing to perinatal death has been confirmed in additional studies.

Timing of Fetal Death

Another way to classify fetal deaths may be to differentiate those that occur during the antepartum period and those that occur during labor, or intrapartum deaths. **Antepartum fetal death is much more common than intrapartum fetal death,[15] and unexplained fetal death occurs far more commonly than unexplained infant death.**[4,10] In a population-based study in the United States in 2007, the antepartum fetal death rate was 3.7 per 1000, compared with 0.6 per 1000 intrapartum fetal deaths.[15] Although most fetal deaths occur before 32 weeks' gestation, in planning a strategy for antepartum fetal monitoring, one must examine the risk for fetal death in the population of women who are still pregnant at that point in pregnancy.[16] When this approach is taken, the data would suggest that fetuses at 40 to 41 weeks are at a threefold greater risk and those at 42 or more weeks are at a 12-fold greater risk for intrauterine death than fetuses at 28 to 31 weeks. The risks are even higher in multiple gestations, as pregnancy progresses. For twin gestations, the optimal time for delivery to prevent late gestation perinatal deaths is by 39 weeks, and for triplets, 36 weeks.[17]

Identifying Those at Risk

Some risk factors have a clear etiologic relationship to fetal compromise and death, such as exposures to teratogens or maternal conditions that alter the fetal environment or blood supply or content. Other risk factors, such as epidemiologic factors including maternal age, race, and body habitus, have a perhaps more complex and less well-understood link to fetal death risk (Figure 12-4).[3] Common risk factors for fetal death in the United States are listed in Table 12-1.[2,18] Many of these conditions may coexist in individual patients, making assessment of the contribution of each factor to perinatal mortality a challenge. Additionally, the contribution of these conditions to fetal injury resulting in liveborn children with permanent neurologic compromise has yet to be determined but is an important alternative outcome to perinatal mortality that, as mentioned previously, deserves further study.[2]

DETAILS ON SELECT MATERNAL CONDITIONS

Obesity: Prepregnancy obesity is associated with increased perinatal mortality, especially in late gestation. This has been demonstrated in several large series, including a meta-analysis of nine studies that included

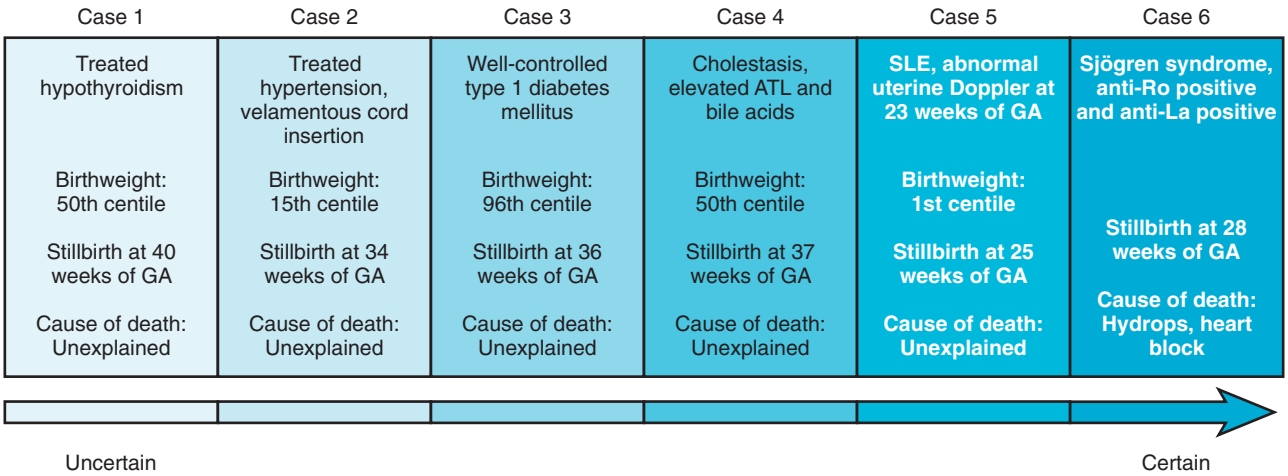

FIGURE 12-4. Continuum of certainty in pathophysiology of cause of fetal death. As one progresses from left to right on the continuum, there are increasing levels of certainty as to the role of the pathophysiology of a particular condition in causing the fetal death. *ALT,* Alanine aminotransferase; *GA,* gestational age. (Courtesy Professor Gordon Smith. Modified from Reddy UM, Goldenberg R, Silver R, et al: Stillbirth classification: developing an international consensus for research. Executive summary of a National Institute of Child Health and Human Development workshop. Stillbirth Classification of Cause of Death. Obstet Gynecol 114:901-914, 2009.)

more than 325,000 women.[19] The connection between obesity and fetal death is still under investigation and is made more complex by the frequent comorbidities encountered in patients with prepregnancy obesity. Theoretical contributors to adverse perinatal outcomes in this group include placental dysfunction, sleep apnea, metabolic abnormalities, and difficulty in clinical assessment of fetal growth.[18]

Parity: Nulliparity and high parity have both been associated with fetal death, in contrast to women having their second child. This association has not been fully explored and may be subject to significant confounding influences, including advanced maternal age, related conditions in nulliparous women with delayed childbearing in developed nations, and other medical and socioeconomic comorbidities in women with high parity.[8,18]

Maternal age: Fretts and coworkers and others[2,13,20] have found that, after controlling for risk factors such as multiple gestation, hypertension, diabetes mellitus, placenta previa and abruption, previous abortion, and prior fetal death, women 35 years of age or older have a greater risk for fetal death than women younger than 30 years, and women 40 years or older have an even further increased risk. **Data from other countries and other investigators have confirmed a J-shaped curve relationship between maternal age and fetal deaths, with the highest rates in teenagers and women older than 35 years of age** (Figure 12-5). The interplay of fetal death, maternal age, and gestational age was demonstrated in a population-based 2006 study in the United States of almost 5.5 million births.[21] In this cohort, compared with their counterparts aged 30 to 34 years at 41 weeks of gestation, women older than 35 to 39 years had the same risk for fetal death at 40 weeks, and women older than 40 years had the same risk at 39 weeks of gestation. Only 10% of the women older than 35 years had medical comorbidities, and the results of this study did not change when those women were excluded, highlighting the point that the increase in fetal death risk exists in otherwise healthy older gravidas compared with younger women.

Multiple gestation: **The higher rate of perinatal mortality in multiple gestations compared with singletons is related both to complications unique to multiple gestations (such as twin-to-twin transfusion syndrome) and to more general complications such as fetal abnormalities and growth restriction.**[18,22] Additionally, many women carrying more than one fetus have maternal risk factors for increased perinatal mortality, including advanced maternal age and use of assisted reproductive technologies (ART), and are subject to development of complications such as preeclampsia and preterm delivery.[2,23] Optimal timing of delivery between 37 and 38 weeks has been considered for twins, compared with 39 to 40 weeks among singletons, because of increased rate of late fetal death in this group. Chorionicity is of paramount importance in determining fetal risk, with higher rates of adverse outcomes among monochorionic twins.[2,23]

Diabetes mellitus: **Although historically insulin-dependent diabetes has been a major risk factor for fetal death, the fetal death rate in women with optimal glycemic control now approaches that of women without diabetes.**[2,24] However, the relationship between glycemic control and fetal death remains uncertain. Poor glycemic control remains associated with increased perinatal mortality, in large part as a result of congenital anomalies, indicated preterm deliveries, and sudden unexplained fetal death. There is no evidence that gestational diabetes controlled by diet alone is associated with increased rates of adverse perinatal outcomes.[2,25]

Serum markers: First- and second-trimester serum markers for aneuploidy, when abnormally low or elevated, have been associated to varying degrees with adverse perinatal outcomes even in the absence of aneuploidy. Regarding fetal death after 24 weeks,

TABLE 12-1 COMMON RISK FACTORS FOR FETAL DEATH IN THE UNITED STATES

RISK FACTOR	PREVALENCE (%)	ODDS RATIO
All pregnancies	—	1.0
Low-risk pregnancies	80	0.86
Obesity		
BMI 25-29.9	21-24	1.4-2.7
BMI >30	20-34	2.1-2.8
Nulliparity compared with second pregnancy	40	1.2-1.6
Fourth child or greater compared with second	11	2.2-2.3
Maternal age (reference <35 yr)		
35-39 yr	15-18	1.8-2.2
≥40 yr	2	1.8-3.3
Multiple gestation		
Twins	2.7	1.0-2.2
Triplets or greater	0.14	2.8-3.7
Oligohydramnios	2	4.5
Assisted reproductive technologies (all)	1-3	1.2-3.0
Abnormal serum markers		
First-trimester PAPP-A <5%	5	2.2-4.0
Two or more second-trimester markers	0.1-2	4.2-9.2
Intrahepatic cholestasis	<0.1	1.8-4.4
Renal disease	<1	2.2-30
Systemic lupus erythematosus	<1	6-20
Smoking	10-20	1.7-3.0
Alcohol use (any)	6-10	1.2-1.7
Illicit drug use	2-4	1.2-3.0
Low education and socioeconomic status	30	2.0-7.0
Antenatal visits <4*	6	2.7
Black (reference white)	15	2.0-2.2
Hypertension	6-10	1.5-4.4
Diabetes	2-5	1.5-7.0
Large for gestational age (>97% without diabetes)	12	2.4
Fetal growth restriction (%)		
<3	3.0	4.8
3-10	7.5	2.8
Previous growth-restricted infant	6.7	2.0-4.6
Previous preterm birth with growth restriction	2	4.0-8.0
Decreased fetal movement	4-8	4.0-12.0
Previous stillbirth	0.5	2.0-10.0
Previous cesarean section	22-25	1.0-1.5
Postterm pregnancy compared with 38-40 wk		2.0-3.0
41 wk	9	1.5
42 wk	5	2.0-3.0

Obstet Gynecol 113:687-701, 2009; and Fretts RC: Stillbirth epidemiology, risk factors, and opportunities for stillbirth prevention. Clin Obstet Gynecol 53:588-596, 2010.

*For stillbirths 37 weeks' gestation.

BMI, Body mass index; PAPP-A, pregnancy associated plasma protein A.

markers of interest include first-trimester levels of pregnancy-associated plasma protein A (PAPP-A) of less than the 5th percentile (0.415 multiples of the median [MoM]), and second trimester free β-human chorionic gonadotropin (free β-hCG), α-fetoprotein (AFP), and inhibin A of more than 2 MoM. The sensitivity and positive predictive value of these markers for fetal death have yet to be determined. The pathophysiologic link between these markers and adverse outcomes is under investigation but most plausibly involves abnormal placental attachment or function.[26]

Thrombophilia: In general, there has been no demonstrable link between inherited thrombophilia and risk for fetal death.[3,27] Although initial reports seemed to support an association between thrombophilias, such as factor V Leiden mutation and prothrombin gene mutation, and fetal death, large prospective trials have failed to substantiate this association. The presence of circulating maternal antiphospholipid antibodies, in particular lupus anticoagulant, anticardiolipin antibodies, and anti-β_2-glycoprotein-I antibodies, in the antiphospholipid antibody syndrome (APLAS) has been associated with a variety of adverse pregnancy outcomes, including fetal loss. The mechanism of these adverse outcomes remains unclear but likely includes inflammation, thrombosis, and placental infarction.[3] However, the link between these antibodies or presence of APLAS and fetal death in particular is still under investigation, with insufficient evidence to conclude that there is an increased risk for fetal death.[28]

Maternal race: The variation in fetal death risk in the United States by maternal race is complex, making ascertainment of biologic risk factors related to race difficult.[18] Factors contributing to increased rates of fetal death among black women compared with white women include disparities in socioeconomic status, access to health care, and preexisting medical conditions. A 2009 population-based study of more than 5 million U.S. births demonstrated that the greatest black and white disparity is in preterm perinatal death, with a hazard ratio at 20 to 23 weeks of 2.75, which decreases to 1.57 at 39 to 40 weeks. Lower education levels and higher rates of medical, pregnancy, and labor complications contributed more to the adverse outcomes in blacks compared with whites, with congenital anomalies more contributory in whites.[29]

Hypertensive disorders: Studies have shown conflicting evidence regarding whether fetal death rates with well-controlled preexisting hypertension are comparable to those in the general population, or increased. The increased risk for perinatal mortality associated with hypertension is most often related to complicated hypertension, with sequelae of placental insufficiency including IUGR and oligohydramnios. Proteinuric hypertension, including especially severe preeclampsia or eclampsia, may be associated with fetal death through placental and coagulation-related pathways, including placental abruption.[3,30]

Fetal growth restriction (IUGR): IUGR is a well-known risk factor for perinatal death but historically has been under-recognized before fetal death. Placental dysfunction is commonly implicated in nonmalformed and chromosomally normal IUGR fetuses. This topic is reviewed in further detail in Chapter 31.

Amniotic fluid abnormalities: The predictive value of either oligohydramnios or polyhydramnios for adverse pregnancy outcomes, in particular fetal death, typically lies in their association with other abnormal conditions,

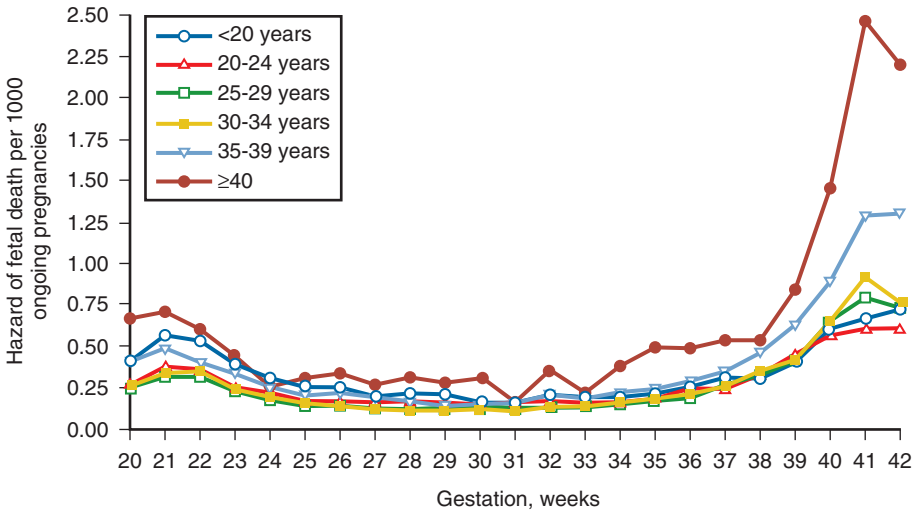

FIGURE 12-5. Relationship of fetal death and maternal age across gestation. (From Reddy UM, Ko CW, Willinger M: Maternal age and the risk of stillbirth throughout pregnancy in the United States. Am J Obstet Gynecol 195:764-770, 2006.)

such as maternal diabetes mellitus, hypertensive disorders, rupture of membranes, fetal growth restriction, or fetal anomalies. Isolated oligohydramnios and polyhydramnios have not been conclusively linked to increased risk for fetal death; nevertheless, evaluation of amniotic fluid volume as a marker of long-term fetal health status is a mainstay of antepartum fetal evaluation.[2,31]

Prior obstetrical and fertility history ART: Multiple aspects of a woman's obstetrical and fertility history may contribute to risk for fetal death in a current pregnancy, including parity, use of assisted reproductive technologies, and history of prior adverse obstetrical outcomes. Both nulliparity and high parity are associated with an increased risk for fetal death compared with "low multiparity" (one, two, or three prior births).[32] This association is likely mediated through a variety of sociodemographic risk factors related to overall health and interconception health status, although studies have confirmed the association between parity and fetal death after controlling for several social and medical comorbidities. History of prior adverse pregnancy outcomes, including fetal growth restriction, preterm birth, and fetal death marks a current pregnancy at risk for fetal death. However, the association with preventable recurrent fetal death is complex and is modified by coexistence of other high-risk conditions. Recurrence risk for fetal death in particular has received recent scrutiny because rates vary dramatically by study population and presence of other risk factors. Given that many fetal deaths occur in pregnancies with no identifiable risk factors and that well-designed studies with appropriate comparison groups (i.e., low-risk women without identifiable risk factors) are lacking, clinician and patient perception of increased risk in a pregnancy subsequent to a fetal death will likely continue to drive management of these patients.[33] Regarding use of ART and risk for fetal death, several systematic reviews have confirmed an independent association between the use of in vitro fertilization in particular and fetal death. However, whether the association is mediated through the technologies themselves or the underlying infertility or through other undetermined mechanisms remains unclear.[34]

Postdates: The definition of postterm pregnancy has been reevaluated in the past decade, based on reappraisal of the peak time of fetal risk in relation to the 40-week mark. The pathophysiology of increased fetal death risk in the postterm pregnancy is thought to be mediated by impaired placental gas exchange and is often associated with oligohydramnios. Traditionally oligohydramnios has been as a marker for increased risk in the postterm pregnancy for which intervention in the form of delivery is thought to be necessary, although as described previously, whether oligohydramnios is independently associated with fetal death in pregnancies after 40 weeks' gestation is unclear.[35]

Socioeconomic factors, prenatal care, and substance use: Poor access to prenatal care and poor underlying health and nutrition have been linked to increase risk for fetal death both in developing and in developed nations. As with other sociodemographic risk factors, these potential influences on fetal death risk are difficult to quantify and may be additive to other high-risk conditions.[36] Smoking and use of alcohol and other substances, along with obesity, represent potentially modifiable risk factors for fetal death. Although these behaviors are attractive candidates for fetal death prevention through counseling and modification of intake, prospective trials of behavioral modification strategies have generally been underpowered to detect a difference in fetal death with these interventions.[18]

Intrahepatic cholestasis: **The cause of fetal death in women with gestational cholestasis remains unknown, and timing and predictive features of impending fetal death remain unpredictable.** Fetal deaths in these pregnancies are not preceded by signs of placental insufficiency such as growth restriction or abnormal

placental pathology, and normal fetal heart rate tracings proximal to fetal death (i.e., within 24 hours) have often been reported. It has also not been established whether maternal serum levels of bile acids, liver enzymes, or pharmacologic therapy modify or predict fetal death risk.[37]

Renal disease, systemic lupus erythematosus (SLE): With chronic maternal renal disease, perinatal outcome is largely associated with degree of renal dysfunction and presence of coexisting hypertension or diabetes. Although data are limited by lack of prospective studies with appropriate control groups, the greatest risk for fetal death appears to be in those with severe renal impairment (i.e., serum creatinine levels >2.4 to 2.8 mg/dL).[38] As with maternal renal disease, the prognosis for fetal outcome in women with SLE is dependent on disease state and comorbid conditions, including hypertension, circulating autoantibodies, and renal involvement.[39] Prognosis for fetal survival in pregnancies complicated by both maternal renal disease and maternal SLE has improved over time, with advances in therapies promoting disease quiescence for both of these conditions.

The best use of available antenatal testing modalities may vary according to the risk profile of each individual pregnancy. Discussion of condition-specific testing will be undertaken after review of the individual testing modalities described later.

POTENTIAL UTILITY OF ANTEPARTUM FETAL TESTING

Can antepartum fetal deaths and injury be prevented? Before using antepartum fetal testing, the obstetrician must ask several important questions:

1. Does the test provide information not already known by the patient's clinical status?
2. Can the information be helpful in managing the patient?
3. If an abnormality is detected, is there a treatment available for the problem?
4. Could an abnormal test result lead to increased risk for the mother or fetus?
5. Will the test ultimately decrease perinatal morbidity and mortality?

A large body of clinical and research experience suggests that antepartum fetal assessment can have a significant impact on the frequency and causes of antenatal fetal deaths.[1] However, according to several recent reviews of the benefits and costs of antenatal testing, "strong evidence for the efficacy of antepartum testing is lacking."[40] **Unfortunately, few of the antepartum tests commonly employed in clinical practice today have been subjected to large-scale prospective and randomized evaluations that can speak to the true efficacy of testing.**[27,41] In most cases, when the test has been applied and good perinatal outcomes observed, the test has gained further acceptance and has been used more widely. In such cases, one cannot be sure whether it is actually the information provided by the test that has led to the improved outcomes or the total program of care that has made the difference. When prospective randomized investigations are conducted, large numbers of patients must be studied because many adverse outcomes, such as intrauterine death, are uncommon even in high-risk populations. For example, although several controlled trials have failed to demonstrate improved outcomes with nonstress testing, the study populations ranged from only 300 to 530 subjects.

To determine the clinical application of antepartum diagnostic testing, the predictive value of the tests must be considered. The sensitivity of the test is the probability that the test will be positive or abnormal when the disease is present. The specificity of the test is the probability that the test result will be negative when the disease is not present. Note that the sensitivity and specificity refer not to the actual numbers of patients with a positive or abnormal result but to the proportion or probability of these test results. The predictive value of an abnormal test would be that fraction of patients with an abnormal test result who have the abnormal condition, and the predictive value of a normal test would be the fraction of patients with a normal test result who are normal.

Antepartum fetal tests may be used to screen a large obstetrical population to detect fetal disease. In this setting, a test of high sensitivity is preferable because one would not want to miss patients whose fetus might be compromised. One would be willing to overdiagnose the problem, that is, accept some false-positive diagnoses. In further evaluating the patient whose fetus may be at risk and when attempting to confirm the presence of disease, one would want a test of high specificity. One would not want to intervene unnecessarily and deliver a fetus that was doing well. In this setting, multiple tests may be helpful. When multiple test results are normal, they tend to exclude disease. When all are abnormal, however, they tend to support the diagnosis of fetal disease.

The prevalence of the abnormal condition has great impact on the predictive value of antenatal fetal tests and the number needed to evaluate with testing and to treat with interventions (delivery) to presumably prevent fetal death. The impact of these parameters on the utility of testing was illustrated in a decision analysis of the risks and benefits of antepartum testing late in pregnancy for women 35 years or older using the McGill Obstetrical Neonatal Database to obtain risk estimates.[42] In this model, as in practice, the relative benefit of antenatal testing lies in the balance of number of fetal deaths prevented with number and type of interventions required to prevent them. At an estimated risk for unexplained fetal death of 5.2 per 1000 pregnancies (nulliparas ≥35 years of age in the McGill cohort), 863 additional antenatal tests, 71 additional inductions of labor, and 14 additional cesarean deliveries would be required to prevent one additional fetal death using this model. Comparatively, using the same model, at an estimated risk for 1 to 2 per 1000 pregnancies, 2862 additional antenatal tests, 233 additional inductions, and 44 additional cesarean deliveries would be required to prevent one additional fetal death. Thus, the number needed to evaluate and treat to prevent one fetal death decreases as risk for fetal death increases in the population being tested.

In interpreting the results of studies of antepartum testing, the obstetrician must consider the application of that test to his or her own population. If the study has been done in a population of patients at great risk, it is more

likely that an abnormal test will be associated with an abnormal fetus. If the obstetrician is practicing in a community with patients who are, in general, at low risk, an abnormal test result would more likely be associated with a false-positive diagnosis.

For most antepartum diagnostic tests, a cut-off point used to define an abnormal result must be arbitrarily established. The cut-off point is selected to maximize the separation between the normal and diseased populations (Figure 12-6). Changing the cut-off will have a great impact on the predictive value of the test. For example, suppose that 10 accelerations in 10 minutes were required for a fetus to have a reactive nonstress test (NST) (threshold A). The fetus who fulfilled this rigid definition would almost certainly be in good condition. However, many fetuses who failed to achieve 10 accelerations in 10 minutes would also be in good condition, but would be judged to be abnormal by this cut-off. In this instance, the test would have many abnormal results. It would be highly sensitive and capture all of the abnormal fetuses, but it would have a low specificity. If the number of accelerations required to pass an NST were lowered to 1 in 10 minutes, it would decrease the sensitivity of the test (threshold C). That is, one might miss a truly sick fetus. At the same time, however, one would improve the specificity of the test or its ability to predict that percentage of the patients who are normal. Using the criterion of two accelerations of the fetal heart rate in 20 minutes for a reactive NST (threshold B), one hopes to have a test with both high sensitivity and high specificity.

WHAT DO THESE TESTS TELL US ABOUT THE FETUS?

Fetal State

To be able to diagnose suspected fetal compromise using tests of fetal biophysical state, blood flow, and heart rate, we must be able to appreciate how these parameters appear under normal conditions and in response to suboptimal conditions.

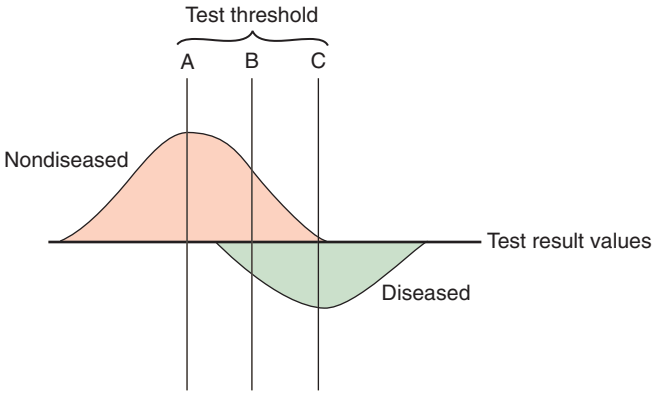

FIGURE 12-6. Hypothetical distribution of test results in a normal and diseased population, demonstrating the differences in test sensitivity and specificity with a change in test threshold. Making it more difficult for the fetus to pass the test by raising the test threshold *(A)* will increase the sensitivity but decrease the specificity, of the test. On the other hand, making the test easier to pass by decreasing the test threshold *(C)* will increase the specificity of the test but decrease the sensitivity. (Modified from Carpenter M, Coustan D: Criteria for screening tests for gestational diabetes. Am J Obstet Gynecol 144:768, 1982.)

Regarding fetal biophysical characteristics, one must appreciate that, during the third trimester, the normal fetus may exhibit marked changes in its neurologic state.[43] Four fetal states have been identified. The near-term fetus spends about 25% of its time in a quiet sleep state (state 1F) and 60% to 70% in an active sleep state (state 2F). Active sleep is associated with rapid eye movement (REM). In fetal lambs, electrocortical activity during REM sleep is characterized by low-voltage, high-frequency waves. The fetus exhibits regular breathing movements and intermittent abrupt movements of its head, limbs, and trunk. The fetal heart rate in active sleep (state 2F) exhibits increased variability and frequent accelerations with movement. During quiet, or non-REM, sleep, the fetal heart rate slows, and heart rate variability is reduced. The fetus may make infrequent breathing movements and startled movements. Electrocortical activity recordings at this time reveal high-voltage, low-frequency waves. Near term, periods of quiet sleep may last 20 minutes, and those of active sleep about 40 minutes.[43] The mechanisms that control these periods of rest and activity in the fetus are not well established. External factors such as the mother's activity, her ingestion of drugs, and her nutrition may play a role. Specific factors that may decrease fetal movement in the third trimester include fetal anomalies, particularly central nervous system (CNS) anomalies; maternal exposures, including corticosteroids, sedatives, and smoking; low amniotic fluid volume; and decreased placental blood flow due to placental insufficiency.[44]

When evaluating fetal condition using the NST or the biophysical profile (BPP), one must ask whether a fetus that is not making breathing movements or shows no accelerations of its baseline heart rate is in a quiet sleep state or is neurologically compromised. In such circumstances, prolonging the period of evaluation usually allows a change in fetal state, and more normal parameters of fetal well-being appear.

Regarding regulation of fetal heart rate and blood flow, **fetal adaptation to hypoxemia is mediated through changes in heart rate and redistribution of cardiac output.** However, changes in fetal cardiac output are generally observed during hypoxemia only when there is coexisting acidemia. In response to sudden hypoxemia, one can initially observe fetal heart rate slowing and increased variability, through vagally mediated chemoreceptor responses. With prolonged hypoxemia (30 to 60 minutes), increasing levels of circulating adrenergic agonists and modulation of vagal activity by endogenous opiates lead to a fetal heart rate return to or rise from the previous baseline.[45] Development of acidemia on top of hypoxemia can accelerate the rate of fetal deterioration and amplify the hypoxemia, by a shift of the oxyhemoglobin dissociation curve to the right, further reducing oxygen carrying capacity of fetal blood and eventually leading to redistribution of cardiac output that can be appreciated as a "brain-sparing" effect in evaluation of fetal blood flow. Redistribution of blood flow in the compromised fetus preferentially preserves perfusion to not only the brain but also the heart and adrenal glands.[45]

Fetal movement is a more indirect indicator of fetal oxygen status and CNS function, with decreased fetal

movements in response to hypoxemia.[2] However, gestational development of fetal movement must be considered when evaluating fetal well-being as marked by fetal activity. Periods of absent fetal movement become more prolonged as gestation advances, with normal fetuses progressively exhibiting longer periods of quiescence as the late second and third trimesters advance. Up to and perhaps longer than 40 minutes of fetal inactivity at 40 weeks may be a normal finding, compared with less than 10 minutes at 20 weeks and less than 20 minutes at 32 weeks.[45] Keeping these trends in mind, abnormal degree or absence of fetal movement can be an appropriate marker for fetal hypoxemia. Fetal activity levels have been seen in animal studies to adapt to inducement of hypoxemia, however, with a resumption of fetal breathing and body movements after a prolonged period of hypoxemia, especially if induced gradually. Therefore, observation of these fetal states during antenatal testing does not guarantee a normoxic fetus.

BIOPHYSICAL TECHNIQUES OF FETAL EVALUATION

Description of the predictive value of several commonly performed antenatal tests of fetal well-being is presented in Table 12-2,[2] with detail on each methodology in the following sections.

Maternal Assessment of Fetal Activity

Studies performed using real-time ultrasonography have demonstrated that during the third trimester, the human fetus spends 10% of its time making gross fetal body movements and that 30 such movements are made each hour.[46] Periods of active fetal body movement last about 40 minutes, whereas quiet periods last about 20 minutes. Patrick and colleagues[46] noted that the longest period without fetal movements in a normal fetus was about 75 minutes. The mother is able to appreciate about 70% to 80% of gross fetal movements. The fetus does make fine body movements such as limb flexion and extension, hand grasping, and sucking, which probably reflect more coordinated CNS function. However, the mother is generally unable to perceive these fine movements. Fetal movement appears to peak between 9:00 PM and 1:00 AM, a time when maternal glucose levels are falling.[43,46] In a study in which maternal glucose levels were carefully controlled with an artificial pancreas, Holden and coworkers[47] found that hypoglycemia was associated with increased fetal movement. Fetal activity does not increase after meals or after maternal glucose administration.[48]

The decrease in fetal movement with hypoxemia makes maternal assessment of fetal activity a potentially simple and widely applicable method of monitoring fetal well-being. However, prospective trials of this method for prevention of perinatal mortality have failed to conclusively show benefit.[2] Neldam demonstrated a 73% reduction in avoidable fetal deaths in a prospective trial of more than 1500 women instructed to count fetal movements.[49] In contrast, a subsequent international trial of more than 68,000 women randomized to routine fetal movement assessment versus no formal assessment of fetal activity failed to show a significant reduction in fetal deaths in the group randomized to routine movement counting (weighted mean difference between groups, 0.23; 95% confidence interval [CI], 0.61 to 1.07).[50] There were significant differences in method of fetal movement counting, definition of abnormal fetal movements, patient compliance with the intervention, and provider response to patients who presented to care as a result of an abnormal fetal movement count in the latter compared with the former trial, as well as throughout the literature on this topic. This illustrates the difficulties in validating and reproducing the results of these trials and the uncertain clinical benefit that may be derived from introducing maternal assessment of fetal movement into routine clinical practice. A 2007 Cochrane review of four trials involving more than 71,000 women in 2007 concluded that there is insufficient evidence to recommend routine fetal movement counting to prevent fetal death.[51]

Despite these results, there may be some advantages to this type of fetal assessment. Although there will be a wide but normal range in fetal activity, with fetal movement counting, each mother and her fetus serve as their own control.[16] Factors affecting maternal perception of fetal movement are not well understood. Fetal and placental factors that may contribute include placental location, the length and type of fetal movements, and amniotic fluid volume (AFV), although whether AFV affects maternal perception or actual fetal movement is not clear.[44] Maternal factors that may influence the evaluation of fetal movement include maternal activity, parity, obesity, medications, and psychological factors, including anxiety. Studies of these associations have demonstrated conflicting results.[44] **About 80% of all mothers are able to comply with a program of counting fetal activity.**[16]

Several methods have been used to monitor fetal activity in research and clinical practice. These methods include fetal movement counting over a prescribed time period, such as 30 to 60 minutes one to three times daily, or conversely a target number of fetal movements to be counted over a variable time range. A variety of "normal" and "abnormal" fetal movement count results or thresholds have been proposed, to which the patient should be instructed to respond by presenting for further evaluation of fetal condition (Figure 12-7). These potential triggers for further evaluation include fewer than three movements in 1 hour or no movements for 12 hours, Sadovsky's "movement alarm signal"[52]; fewer than three movements an hour for 2 consecutive days[53]; or inability to

TABLE 12-2 COMPARISON OF SELECTED ANTENATAL TESTS

TEST	FALSE-NEGATIVE RATE (%)	FALSE-POSITIVE RATE (%)
Contraction stress test (CST)	0.04	35-65
Nonstress test (NST)	0.2-0.8	55-90
Biophysical profile (BPP)	0.07-0.08	40-50
Modified biophysical profile (mBPP)	0.08	60

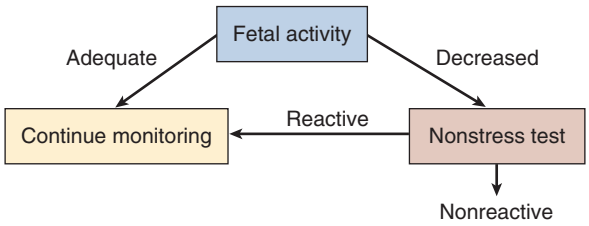

FIGURE 12-7. Maternal assessment of fetal activity is a valuable screening test for fetal condition. Should the mother report decreased fetal activity, an NST is performed. In this situation, most NSTs are reactive.

count 10 movements in a 12-hour period, the Cardiff count-to-10 method advocated by Pearson and Weaver.[54] Although the count-to-10 method has received wide scrutiny and is used perhaps most frequently in clinical practice, the use of this technique as a screening tool has most recently been reexamined by Froen and associates, who found in a cohort of 1200 women instructed to start their fetal movement count at the first convenient time of the day that the mean time to count to 10 was less than 10 minutes, compared with significantly longer and more variable average times reported in previous investigations.[55] Noting the variation in defining normal and abnormal patterns and maternal perception of fetal movement as mentioned previously, Froen and associates concluded that significant research is needed to better define the changes in fetal activity patterns and perception that are associated with good and adverse perinatal outcomes.

Potential negative impacts of maternal assessment of fetal activity include maternal anxiety as well as potential increase in utility of other testing modalities and antepartum admissions.[56] However, given the likely low impact of false-positive fetal movement count results, and the fact that this has been the only form of antenatal testing to be compared with no testing and found to have a favorable impact on fetal death, it seems reasonable to continue to prescribe some form of maternal assessment of fetal movement to patients until more conclusive evidence can be generated. As stated by Froen and associates in a 2008 review, "the fact that FMC versus no counting seems to be beneficial irrespective of the chosen definition of Decreased Fetal Movement (DFM) would support the hypothesis that benefit was derived from increased maternal vigilance regarding FM. When awareness, vigilance, and fetal movement counting is to be promoted, we have suggested that a maternal perception of significant and sustained reduction in fetal activity should remain the main definition of DFM. Any alarm limits, as '10 FM in 2 hours,'[57] should only be for guidance as a 'rule of thumb.'"[55]

Contraction Stress Test

The contraction stress test (CST), also known as the oxytocin challenge test (OCT), was the first biophysical technique widely applied for antepartum fetal surveillance. It was well known that uterine contractions produced a reduction in blood flow to the intervillous space. Analyses of intrapartum fetal heart rate monitoring had shown that a fetus with inadequate placental respiratory reserve would demonstrate recurrent late decelerations in response to hypoxia, in particular a fetal arterial oxygen pressure below 20 mm Hg (see Chapter 16). This drop in fetal heart rate in response to transient hypoxia is mediated, as noted earlier, by a vagal response to transient systemic fetal vascular reactivity provoked by hypoxia. The CST extended these observations to the antepartum period. The response of the fetus at risk for uteroplacental insufficiency to uterine contractions formed the basis for this test.

To perform the CST, the patient is placed in the semi-Fowler's position at a 30- to 45-degree angle with a slight left tilt to avoid the supine hypotensive syndrome. Continuous external fetal heart rate and uterine contraction monitoring is recorded, obtaining a baseline before stimulating uterine activity. Maternal blood pressure is determined every 5 to 10 minutes to detect maternal hypotension. In some cases, adequate uterine activity occurs spontaneously, and additional uterine stimulation is not necessary. An adequate CST requires uterine contractions of moderate intensity lasting about 40 to 60 seconds with a frequency of three in 10 minutes. These criteria were selected to approximate the stress experienced by the fetus during the first stage of labor. If uterine activity is absent or inadequate, intravenous oxytocin is begun to initiate contractions and increased until adequate uterine contractions have been achieved.[27] Several methods of nipple stimulation have been used to induce adequate uterine activity, and the success rate at achieving adequate contractions and test results is comparable to that of oxytocin infusion.[23,27] After the CST has been completed, the patient should be observed until uterine activity has returned to its baseline level. Contraindications to the test include a high risk for premature labor, such as in patients with premature rupture of the membranes, multiple gestation, and cervical incompetence, although the CST has not been associated with an increased incidence of premature labor.[58] The CST should also be avoided in conditions in which uterine contractions may be dangerous, such as placenta previa and a previous classic cesarean delivery or uterine surgery.

Most clinicians use the definitions proposed by Freeman and colleagues to interpret the CST[58,59] (detail in Table 12-3):

Negative: No late or significant variable decelerations
Positive: Late decelerations with at least 50% of contractions
Suspicious: Intermittent late or variable decelerations
Hyperstimulation: Decelerations with contractions longer than 90 seconds' duration or 2-minute frequency
Unsatisfactory: Fewer than three contractions per 10 minutes or an uninterpretable tracing

Predictive Value of the Contraction Stress Test

A negative CST has been consistently associated with good fetal outcome. Studies have shown the incidence of perinatal death within 1 week of a negative CST (i.e., the false-negative rate) to be less than 1 per 1000.[2,23,60,61] Many of these deaths, however, can be attributed to cord accidents, malformations, placental abruption, and acute deterioration of glucose control in patients with diabetes. Thus, the CST, like most methods of antepartum fetal surveillance, cannot predict acute fetal compromise. If the CST is negative and reactive, a repeat study is usually scheduled in 1 week (Figure 12-8). A negative but nonreactive

TABLE 12-3 INTERPRETATION OF THE CONTRACTION STRESS TEST

INTERPRETATION	DESCRIPTION	INCIDENCE (%)
Negative	No late decelerations appearing anywhere on the tracing with adequate uterine contractions (three in 10 min)	80
Positive	Late decelerations that are consistent and persistent, present with the majority (>50%) of contractions without excessive uterine activity; if persistent late decelerations seen before the frequency of contractions is adequate, test interpreted as positive	3-5
Suspicious	Inconsistent late decelerations	5
Hyperstimulation	Uterine contractions closer than every 2 min or lasting >90 sec, or five uterine contractions in 10 min; if no late decelerations seen, test interpreted as negative	5
Unsatisfactory	Quality of the tracing inadequate for interpretation, or adequate uterine activity cannot be achieved	5

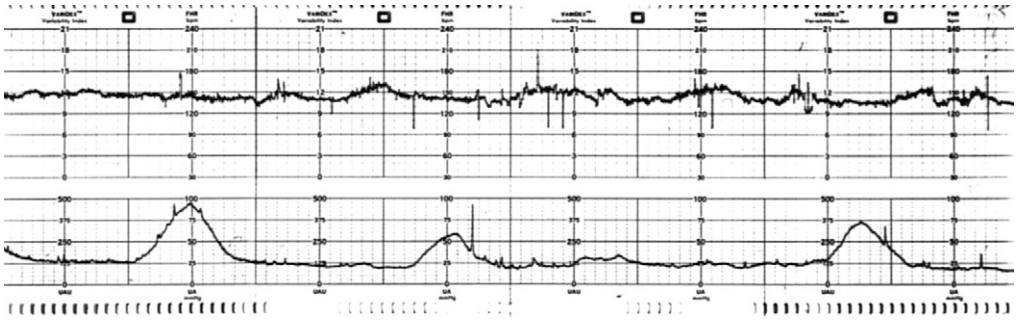

FIGURE 12-8. A reactive and negative CST. With this result, the CST would ordinarily be repeated in 1 week.

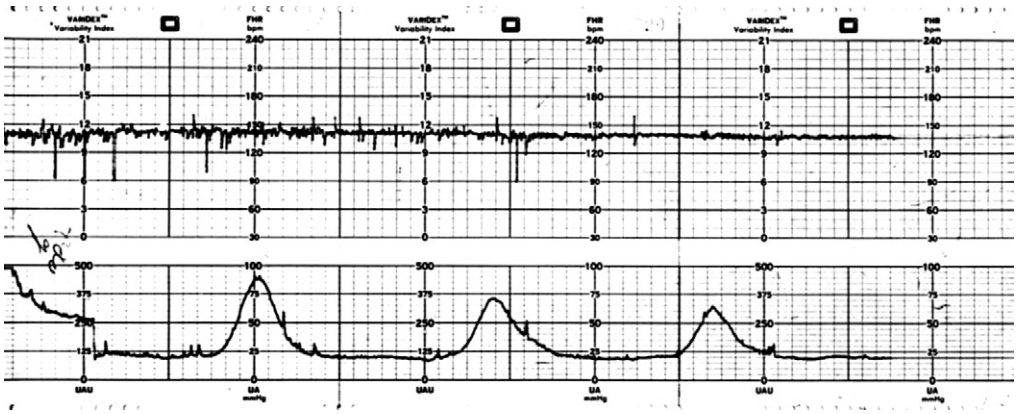

FIGURE 12-9. A nonreactive and negative CST. After this result, the test would ordinarily be repeated in 24 hours.

CST is not suggestive of acute fetal compromise, but cannot be seen as constituting the same low false-negative rate over the course of 1 week as a negative reactive CST. A negative nonreactive CST is usually repeated in 24 hours (Figure 12-9). Changes in the patient's clinical condition may warrant more frequent studies. A positive CST has been associated with an increased incidence of intrauterine death, late decelerations in labor, low 5-minute Apgar scores, IUGR, and meconium-stained amniotic fluid (Figure 12-10),[60] with an overall likelihood of perinatal death after a positive CST ranging from 7% to 15%. On the other hand, there has been a significant incidence of false-positive CSTs that, depending on the end point used, can be between 35% and 65%.[2,61] The positive CST is more likely to be associated with fetal compromise if the baseline heart rate lacks accelerations and the latency period between the onset of the uterine contractions and the onset of the late deceleration is less than 45 seconds.

The high incidence of false-positive CSTs is one of the greatest limitations of this test because such results could lead to unnecessary premature intervention. False-positive CSTs may be attributable to misinterpretation of the tracing; supine hypotension, which decreases uterine perfusion; uterine hyperstimulation, which is not appreciated using the tocodynamometer; or an improvement in fetal condition after the CST has been performed. The high false-positive rate also indicates that a patient with a positive CST need not necessarily require an elective cesarean delivery. If a trial of labor is to be undertaken after a positive CST, the cervix should be favorable for induction so that direct fetal heart rate monitoring and careful assessment of uterine contractility with an intrauterine pressure

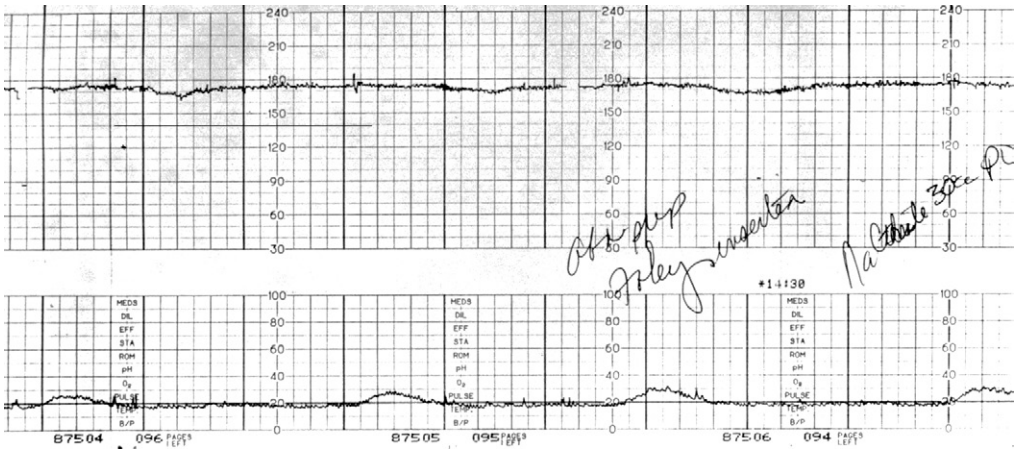

FIGURE 12-10. A nonreactive and positive CST with fetal tachycardia. At 34 weeks, a poorly compliant patient with type 1 diabetes mellitus reported decreased fetal activity. The NST revealed a fetal tachycardia of 170 beats/minute and was nonreactive. The CST was positive, and a BPP score was 2. The patient's cervix was unfavorable for induction. The patient underwent a low transverse cesarean delivery of a 2200-g male infant with Apgar scores of 1 and 3. The umbilical arterial pH was 7.21.

catheter can be performed. False-positive results are not increased when the CST is used early in the third trimester, between 28 and 33 weeks' gestation. A suspicious or equivocal CST or one that is unsatisfactory or shows hyperstimulation should be repeated in 24 hours. In one series, 7.5% of patients with an initially suspicious CST exhibited positive tests on further evaluation, 53.7% became negative, and 38.8% remained suspicious.[62] In follow-up studies of children who demonstrated a positive CST, few have exhibited abnormalities in neurologic and psychological development.[63] An important determinant in the long-term outcome for these children would be the early recognition of nonreassuring fetal heart rate patterns and the prevention of intrapartum compromise.

Nonstress Test

Mid-20th-century observations that **accelerations of the fetal heart rate in response to fetal activity, uterine contractions, or stimulation reflect fetal well-being formed the basis for the NST.** The NST is the most widely applied technique for antepartum fetal evaluation, despite the uncertainty regarding its reliability and reproducibility as a test of fetal assessment and that the basic technology that underlies its performance and application has changed little since its introduction and wide acceptance into antenatal practice.[64]

In late gestation, the healthy fetus exhibits an average of 34 accelerations above the baseline fetal heart rate each hour.[65] These accelerations, which average 20 to 25 beats/minute in amplitude and about 40 seconds in duration, require intact neurologic coupling between the fetal CNS and the fetal heart.[65] Fetal hypoxia disrupts this pathway. At term, fetal accelerations are associated with fetal movement more than 85% of the time, and more than 90% of gross movements are accompanied by accelerations. Fetal heart rate accelerations may be absent during periods of quiet fetal sleep. Studies by Patrick and associates[65] demonstrated that the longest time between successive accelerations in the healthy term fetus is about 40 minutes. However, the fetus may fail to exhibit heart rate accelerations for up to 80 minutes and still be normal.

Although an absence of fetal heart rate accelerations is most often attributable to a quiet fetal sleep state, CNS depressants such as narcotics and phenobarbital, as well as the β-blocker propranolol, can reduce heart rate reactivity.[66,67] Chronic smoking is known to decrease fetal oxygenation through an increase in fetal carboxyhemoglobin and a decrease in uterine blood flow. Fetal heart rate accelerations are also decreased in smokers.[68]

The NST is usually performed in an outpatient setting. In most cases, only 10 to 15 minutes are required to complete the test. It has virtually no contraindications, and few equivocal test results are observed. The patient may be seated in a reclining chair, with care being taken to ensure that she is tilted to the left to avoid the supine hypotensive syndrome.[27] The patient's blood pressure should be recorded before the test is begun and then repeated at 5- to 10-minute intervals. Fetal heart rate is monitored using the Doppler ultrasound transducer, and the tocodynamometer is applied to detect uterine contractions or fetal movement. Fetal activity may be recorded by the patient using an event marker or noted by the staff performing the test.

Fetal Heart Rate Patterns Observable on the Nonstress Test

REACTIVE

The most widely applied definition of a reactive test requires that at least two accelerations of the fetal heart rate, each with a peak amplitude of 15 beat/minute and total duration of 15 seconds, be observed in 20 minutes of monitoring (Figure 12-11).[69] Gestational age affects reactivity criteria because sympathetic and parasympathetic influences on fetal heart rate change with advancing gestational age. Increased frequency and amplitude of fetal heart rate accelerations are seen after 30 weeks of gestation compared with early third trimester; although half of normal fetuses demonstrate accelerations with fetal movements at 24 weeks, nearly all fetuses will do so after 30 weeks. Similarly, before 30 to 32 weeks' gestation, acceptable criteria for a reactive fetal heart rate tracing include accelerations with a peak of only 10 beats/minute

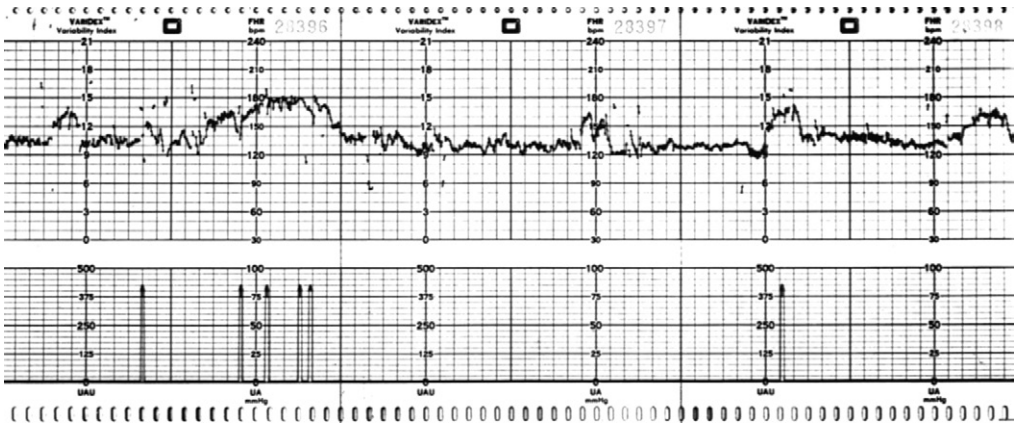

FIGURE 12-11. A reactive NST. Accelerations of the fetal heart that are greater than 15 beats/minute and last longer than 15 seconds can be identified. When the patient appreciates a fetal movement, she presses an event marker on the monitor, creating the *arrows* on the lower portion of the tracing.

FIGURE 12-12. An NST. No accelerations of the fetal heart rate are observed. The patient has perceived fetal activity as indicated by the *arrows* in the lower portion of the tracing.

amplitude and 10 seconds' duration rather than the 15 and 15 mentioned previously.[69]

NONREACTIVE

If the criteria for reactivity are not met, the test is considered nonreactive (Figure 12-12). The most common cause for a nonreactive test is a period of fetal inactivity or quiet sleep. Therefore, the test may be extended for an additional 20 minutes with the expectation that fetal state will change and reactivity will appear. Keegan and colleagues[70] noted that about 80% of tests that were nonreactive in the morning became reactive when repeated later the same day. In an effort to change fetal state, some clinicians have manually stimulated the fetus or attempted to increase fetal glucose levels by giving the mother orange juice. There is no evidence that such efforts will increase fetal activity.[71,72] If the test has been extended for 40 minutes, and reactivity has not been seen, a BPP or CST should be performed. Of those fetuses that exhibit a nonreactive NST, about 25% will a positive CST on further evaluation.[73-75] Reactivity that occurs during preparations for the CST has proved to be a reliable index of fetal well-being.

Overall, on initial testing, 85% of NSTs are reactive, and 15% are nonreactive (Figure 12-13).[73] Fewer than 1% of NSTs prove unsatisfactory because of inadequately recorded fetal heart rate data.

The likelihood of a nonreactive test is substantially increased early in the third trimester. Between 24 and 28 weeks' gestation, about 50% of NSTs are nonreactive. Fifteen percent of NSTs remain nonreactive between 28 and 32 weeks.[76] After 32 weeks, the incidences of reactive and nonreactive tests is comparable to that seen at term. **In summary, when accelerations of the baseline heart rate are seen during monitoring in the late second and early third trimesters, the NST has been associated with fetal well-being.**

When nonreactive, the NST is extended in an attempt to separate the fetus in a period of prolonged quiet sleep from those who are hypoxemic or asphyxiated. Most fetuses exhibiting a nonreactive NST are not compromised but simply fail to exhibit heart rate reactivity during the 40-minute period of testing. Malformed fetuses also exhibit a significantly higher incidence of nonreactive NSTs.[77] Vibroacoustic stimulation (VAS) may be used to change fetal state from quiet to active sleep (Figure 12-14).

Auditory brainstem response appears to be functional in the fetus at 26 to 28 weeks' gestation. Thus, VAS may significantly increase the incidence of reactive NSTs after 26 weeks' gestation and reduce the testing time, making this a potentially useful adjunct to antepartum fetal testing.[76,78] Most studies of VAS have employed an electronic artificial larynx that generates sound pressure levels measured at 1 m in air of 82 dB with a frequency of 80 Hz and a harmonic of 20 to 9000 Hz. Whether it is the acoustic or vibratory component of this stimulus that alters fetal state is unclear. VAS may produce a significant increase in the mean duration and amplitude of heart rate accelerations, fetal heart rate variability, and gross fetal body movements, within 3 minutes of stimulation.[79] Several studies using VAS have shown a decreased incidence of nonreactive NSTs from 13% to 14% down to 6% to 9%. A reactive NST after VAS stimulation appears to be as reliable an index of fetal well-being as spontaneous reactivity. However, those fetuses that remain nonreactive even after VAS may be at increased risk for poor perinatal outcome with increased rates of intrapartum fetal distress, growth restriction, and low Apgar scores in fetuses that are nonreactive after acoustic stimulation.

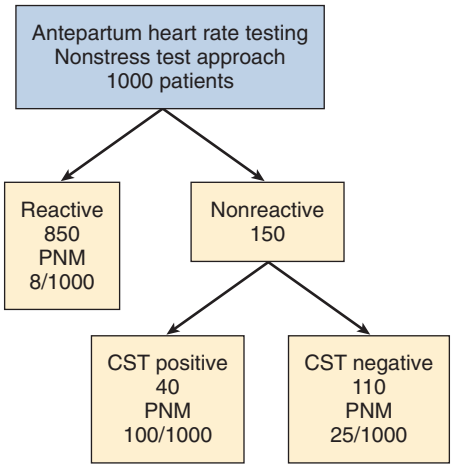

FIGURE 12-13. Results of NST in 1000 high-risk patients. In general, 85% of the NSTs are reactive, and 15% are nonreactive. Of those patients with a nonreactive NST, about 25% have a positive CST on further evaluation. The highest perinatal mortality (PNM) is observed in patients with a nonreactive NST and positive CST. Patients with a nonreactive NST and negative CST have a perinatal mortality rate higher than that found in patients whose NST is initially reactive. (PNM rates based on data from Evertson L, Gauthier R, Schifrin B, et al: Antepartum fetal heart rate testing. I. Evolution of the nonstress test. Am J Obstet Gynecol 133:29, 1979.)

In most centers that use VAS, the baseline fetal heart rate is first observed for 5 minutes. If the pattern is nonreactive, a stimulus of 3 seconds or less is applied near the fetal head. If the NST remains nonreactive, the stimulus is repeated at 1-minute intervals up to three times. If there continues to be no response to VAS, further evaluation should be carried out with a BPP or CST. **In summary, VAS may be helpful in shortening the time required to perform an NST and may be especially useful in centers where large numbers of NSTs are done.**

Could the sound generated by an electronic artificial larynx damage the fetal ear? Using intrauterine microphones, Smith and colleagues[80] documented baseline intrauterine sound levels of up to 88 dB during labor. Transabdominal stimulation with an electronic artificial larynx increased these levels minimally, up to 91 to 111 dB. Sound vibrations and intensity are attenuated by amniotic fluid.[81] Therefore, a 90-dB sound pressure produced by VAS in air results in exposure of the fetal ear to the equivalent of 40 dB, the level of normal conversation at about 3 feet. Arulkumaran and associates[81] concluded that intrauterine sound levels from VAS were not hazardous to the fetal ear. Studies have confirmed the safety of VAS use during pregnancy, with no long-term evidence of hearing loss in children followed in the neonatal period and up to 4 years of age.[82]

Other Nonstress Test Patterns or Findings

SINUSOIDAL

On rare occasions, a sinusoidal heart rate pattern may be observed, as described in Chapter 16. This undulating heart rate pattern with virtually absent variability has been

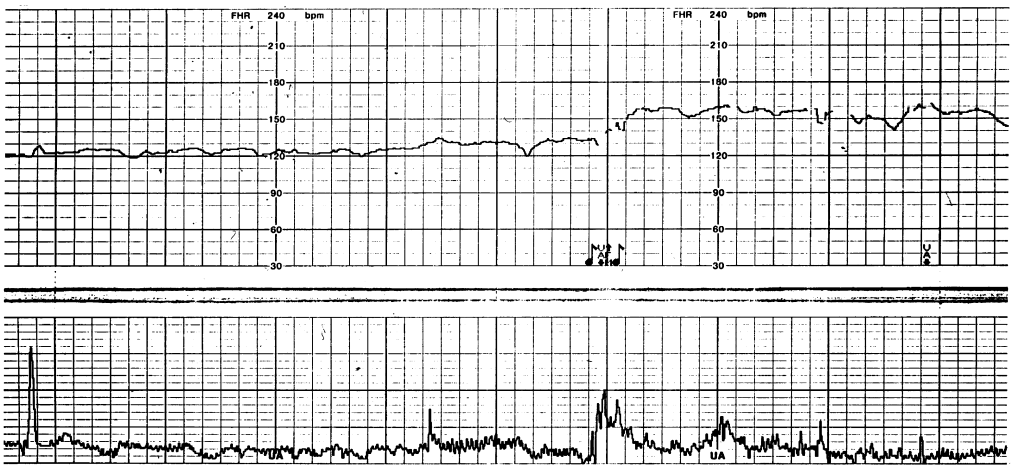

FIGURE 12-14. Reactive NST after VAS. The stimulus was applied in panel 54042, at the point marked by the musical notes. A sustained fetal heart rate acceleration was produced.

associated with fetal anemia, fetal asphyxia, congenital malformations, and medications such as narcotics. In one of the earliest reports on the use of the NST, Rochard and coworkers[83] described a sinusoidal pattern in 20 of 50 pregnancies complicated by Rh isoimmunization. One half of these pregnancies ended in a perinatal death, and 40% of the surviving infants required prolonged hospitalization. Only 10% of the babies with a sinusoidal pattern had an uncomplicated course.

Bradycardia

Before 27 weeks' gestation, the normal fetal heart rate response to fetal movement may in fact be a bradycardia. However, in some settings such as IUGR associated with antiphospholipid syndrome, bradycardia at a gestational age of 26 to 28 weeks may be a predictor of fetal compromise and impending fetal death. Druzin and associates[84] reported three cases in which antenatal steroid administration and elective premature delivery led to good perinatal outcome. In these challenging cases, the entire clinical situation needs to be evaluated, and a full discussion with the patient, including neonatal consultation, should be initiated before intervention and delivery of the very preterm fetus exhibiting fetal heart rate decelerations.

Significant fetal heart rate bradycardias have been observed in 1% to 2% of all NSTs, defined as a fetal heart rate of 90 beats/minute or a fall in the fetal heart rate of 40 beats/minute below the baseline for 1 minute or longer (Figure 12-15). In a review of 121 cases, bradycardia was associated with increased perinatal morbidity and mortality, particularly antepartum fetal death, cord compression, IUGR, and fetal malformations.[85] Although about one half of the NSTs associated with bradycardia were reactive, the incidence of a nonreassuring fetal heart rate pattern in labor leading to emergency delivery in this group was identical to that of patients exhibiting nonreactive NSTs. Clinical management decisions should be based on the finding of bradycardia, *not* on the presence or absence of reactivity. Bradycardia has a higher positive predictive value for fetal compromise (fetal death or fetal intolerance of labor) than does the nonreactive NST. In this setting, antepartum fetal death is most likely due to a cord accident.

If a bradycardia is observed, an ultrasound examination should be performed to assess amniotic fluid volume and to detect the presence of anomalies such as renal agenesis. Expectant management in the setting of a bradycardia has been associated with a PMR of 25%. Therefore, several reports have recommended that delivery be undertaken if the fetus is mature. When the fetus is premature, one might elect to administer corticosteroids to accelerate fetal lung maturation before delivery. Continuous fetal heart rate monitoring is necessary if expectant management is followed.

Tachycardia

Fetal heart rate baseline evaluation must also take gestational age into account, as with fetal heart rate reactivity. Vagal activity has a greater influence on fetal heart rate at baseline as gestation advances; thus, baseline fetal heart rate will decrease from an average of 155 beats/minute at 20 weeks to 145 beats/minute at 30 weeks. The most common etiology of fetal tachycardia is maternal-fetal fever, secondary to maternal-fetal infection such as chorioamnionitis. Other causes include chronic hypoxemia, maternal hyperthyroidism, and fetal tachyarrhythmia. Fetal heart rates above 200 beats/minute, and certainly above 220 beats/minute, should increase the index of suspicion of fetal tachyarrhythmia and lead to further fetal cardiac evaluation with a targeted fetal echocardiogram. For fetal heart rates between 160 and 180 beats/minute, the presence or absence of baseline variability is an important indicator of fetal acid-base status. Fetal acidosis is more likely if baseline variability is absent.[69]

Arrhythmia

Among fetal arrhythmias, most (about 90%) are tachyarrhythmias. Fetal tachyarrhythmia is most often diagnosed when the fetal ventricular heart rate is faster than 180 beats/minute. Common causes of fetal tachyarrhythmias are paroxysmal supraventricular tachycardia and atrial flutter. The administration of antiarrhythmic therapy to the pregnant mothers of fetuses with sustained supraventricular tachycardia represented the first examples of successful prenatal cardiac therapy. Multiple publications

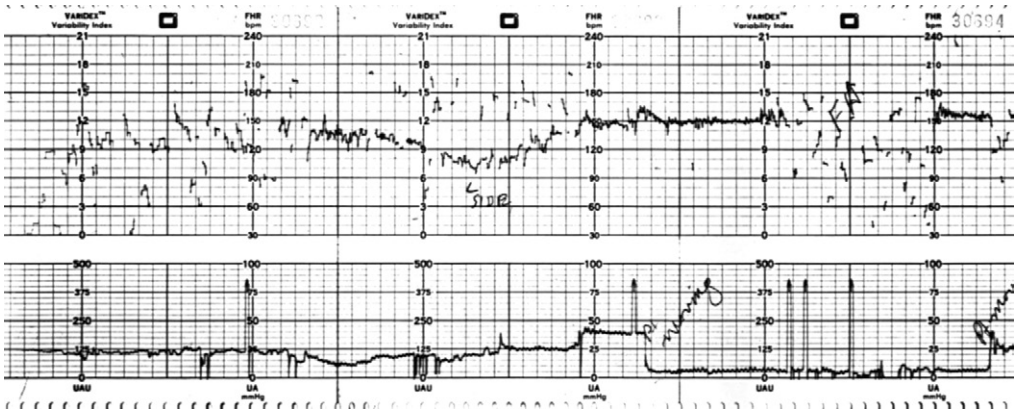

Figure 12-15. An NST in this primigravid patient of 43 weeks' gestation reveals a spontaneous bradycardia (panel 30692). The fetal heart rate has fallen from a baseline of 150 to 100 beats/minute. Upon induction of labor, the patient required cesarean delivery for fetal distress associated with severe variable decelerations. The amniotic fluid was decreased in amount and was meconium stained.

described treatment protocols for this arrhythmia. Characteristics of fetuses needing treatment include hydrops fetalis in the face of a sustained arrhythmia and a gestational age too early to preclude safe delivery and postnatal treatment. In such cases, therapy is best initiated with medications that have a relatively broad therapeutic margin and a low risk for proarrhythmia (unwanted precipitation or exacerbation of the arrhythmia) for fetus or mother.[86,87] Digoxin is the most commonly used first-line agent but is rarely effective in the presence of fetal hydrops, for which sotalol or flecainide are typical first-line choices.[88]

Fetal bradyarrhythmia is diagnosed when the fetal ventricular heart rate is slower than 100 beats/minute, mainly due to atrioventricular block. About half of all cases are caused by fetal cardiac anomalies, and of the remaining cases with normal cardiac structure, many are related to maternal antibodies. These antibodies, which include SS-A and SS-B, may directly target the fetal atrioventricular node or the myocardium, resulting in heart block and myocarditis. Fetuses with bradyarrhythmia may develop hydrops fetalis, particularly with sustained bradycardia at a rate less than 55 beats/minute. In utero heart failure with congenital heart block, with or without congenital heart disease, represents an absolute indication for electrical pacemaker therapy in surviving neonates.[87] This condition is less often successfully treated antenatally than fetal tachyarrhythmia. Available therapies include maternal administration of β-agonists, which have been shown to increase fetal ventricular rate by 10% to 20%, and steroid or immunoglobulin administration, which may be effective in cases of fetal heart block caused by maternal antibodies. Potential improved fetal outcome includes reversal of hydrops in several reports.[88]

Deceleration

In most cases, mild variable decelerations are not associated with poor perinatal outcome. Meis and associates[89] reported that variable decelerations of 20 beats/minute or more below the baseline heart rate but lasting less than 10 seconds were noted in 50.7% of patients undergoing an NST. Whereas these decelerations were more often associated with a nuchal cord, they were not predictive of IUGR or a nonreassuring fetal heart rate pattern, or more severe variable decelerations during labor. When mild variable decelerations are observed, even if the NST is reactive, an ultrasound examination should be performed to rule out oligohydramnios. A low amniotic fluid index (AFI) and mild variable decelerations increase the likelihood of a cord accident. If late decelerations in response to contractions are observed in the performance of an NST, criteria for interpretation of CST should then be implemented.

Predictive Value of Nonstress Test

The NST is most predictive when normal or reactive. The reported false-negative rate over multiple studies ranges from 0.2% to 0.8%, corresponding to a fetal death rate of 3 to 8 per 1000 within 1 week of a reactive NST. The false-positive rate is considerably higher, ranging from 50% to more than 90% in various studies.[2,23]

A 2010 Cochrane review integrated the results of six randomized controlled trials including 2105 women; four studies with 1636 women compared NST (or NST with results revealed) to no NST (or NST with results concealed), and two studies with 469 women compared NST with computerized analysis to traditional (visually analyzed) NST.[64] The six included studies only recruited high-risk women, and none provided information about singleton and multiple pregnancies. Of note, all four of the studies comparing NST with no NST were performed in the 1980s. In the studies comparing NST with no NST, there were no significant differences identified in the risk for perinatal mortality (risk ratio [RR], 2.05; 95% CI, 0.95 to 4.42; 2.3% versus 1.1%). There were also no differences identified in rates of cesarean delivery, "potentially preventable perinatal mortality," Apgar scores, neonatal intensive care admissions, gestational age at birth, or neonatal seizures. However, in the two studies comparing computerized analysis to visual analysis, there was a significant reduction in perinatal mortality with computerized analysis (RR, 0.20; 95% CI, 0.04 to 0.88; 0.9% versus 4.2%).[64] The authors concluded that the analysis was underpowered to detect possible important differences in perinatal mortality and pointed out that many aspects of antenatal and postnatal care may have changed since the included trials were performed. They called for new studies to assess the effects of traditional and computer-analyzed NST in order to assess the true impact on perinatal mortality and other outcomes.

In selected high-risk pregnancies, the false-negative rate associated with a weekly NST may be unacceptably high, in particular those pregnancies complicated by diabetes mellitus, IUGR, and prolonged gestation. In these cases, increasing frequency of the NST to twice weekly may be considered.[90,91]

Fetal Biophysical Profile

The use of real-time ultrasonography to assess antepartum fetal condition has enabled the obstetrician to perform an in utero physical examination and evaluate dynamic functions reflecting the integrity of the fetal CNS.[92] As emphasized by Manning and colleagues,[93] "fetal biophysical scoring rests on the principle that the more complete the examination of the fetus, its activities, and its environment, the more accurate may be the differentiation of fetal health from disease states."

Fetal breathing movements (FBMs) were the first biophysical parameter to be assessed using real-time ultrasonography. It is thought that the fetus exercises its breathing muscles in utero in preparation for postdelivery respiratory function. With real-time ultrasonography, FBM is evidenced by downward movement of the diaphragm and abdominal contents and by an inward collapsing of the chest. FBMs become regular at 20 to 21 weeks and are controlled by centers on the ventral surface of the fourth ventricle of the fetus.[94] They are observed about 30% of the time, are seen more often during REM sleep, and, when present, demonstrate intact neurologic control. Although the absence of FBMs may reflect fetal asphyxia, this finding may also indicate that the fetus is in a period of quiet sleep.[43] Several factors other than fetal state and hypoxia can influence the presence of FBM. As maternal glucose levels rise, FBM becomes more frequent, and during periods of maternal hypoglycemia, FBM decreases. Maternal smoking reduces FBM, probably as a result of

fetal hypoxemia.[95] Narcotics that depress the fetal CNS also decrease FBM.

Regarding other observable fetal states as markers of fetal oxygen status and well-being, Vintzileos and coworkers[94] stressed that **those fetal biophysical activities that are present earliest in fetal development are the last to disappear with fetal hypoxia.** The fetal tone center in the cortex begins to function at 7.5 to 8.5 weeks. Therefore, fetal tone would be the last fetal parameter to be lost with worsening fetal condition. The fetal movement center in the cortex-nuclei is functional at 9 weeks and would be more sensitive than fetal tone. As noted earlier, FBM becomes regular at 20 to 21 weeks. Finally, fetal heart rate control, residing within the posterior hypothalamus and medulla, becomes functional at the end of the second trimester and early in the third trimester. An alteration in fetal heart rate would theoretically be the earliest sign of fetal compromise.

Using these principles, Manning and colleagues[96] developed the concept of the fetal BPP score. These workers elected to combine the NST with four parameters that could be assessed using real-time ultrasonography: FBM, fetal movement, fetal tone, and AFV. FBM, fetal movement, and fetal tone are mediated by complex neurologic pathways and should reflect the function of the fetal CNS at the time of the examination. On the other hand, AFV should provide information about the presence of chronic fetal asphyxia. Finally, the ultrasound examination performed for the BPP has the added advantage of detecting previously unrecognized major fetal anomalies. A BPP score was developed that is similar to the Apgar score used to assess the condition of the newborn.[96] The presence of a normal parameter, such as a reactive NST, was awarded 2 points, whereas the absence of that parameter was scored as 0. The highest score a fetus can receive is 10, and the lowest score is 0. The BPP may be used as early as 26 to 28 weeks' gestation. The time required for the fetus to achieve a satisfactory BPP score is closely related to fetal state, with an average of only 5 minutes if the fetus is in a 2F state but over 25 minutes if it is in a 1F state.[97]

The criteria proposed by Manning and colleagues,[96] and the clinical actions recommended in response to these scores, are presented in Tables 12-4 and 12-5. Regardless of a low score on the BPP, Manning and colleagues have emphasized that vaginal delivery is attempted if other obstetrical factors are favorable.

In a prospective blinded study of 216 high-risk patients, Manning and colleagues[96] found no perinatal deaths when all five variables described earlier were normal, but a PMR of 60% in fetuses with a score of zero. Fetal deaths were increased 14-fold with the absence of fetal movement, and the PMR was increased 18-fold if FBM was absent. Any single test was associated with a significant false-positive rate ranging from 50% to 79%. However, combining abnormal variables significantly decreased the false-positive rate to as low as 20%. The false-negative rate, that is, the incidence of babies who were compromised but who had normal testing, was low, ranging from a PMR of 6.9 per

TABLE 12-4 TECHNIQUE OF BIOPHYSICAL PROFILE SCORING

BIOPHYSICAL VARIABLE (SCORE = 0)	NORMAL (SCORE = 2)	ABNORMAL
Fetal breathing movements	At least one episode of ≥30 sec duration in 30-min observation	Absent or no episode of ≥30 sec duration in 30 min
Gross body/limb movement	At least three discrete body/limb movements in 30 min (episodes of active continuous movement considered a single movement)	Up to two episodes of movements in 30 min
Fetal tone	At least one episode of active extension with return to flexion of fetal limb or trunk; opening and closing of hand considered normal tone	Either slow extension with return to partial flexion, or movement of limb in full extension, or absent fetal movement
Reactive fetal heart rate	At least two episodes of acceleration of ≥15 beats/min and 15 sec duration associated with fetal movement in 20 min*	Fewer than two accelerations or acceleration <15 beats/min in 20 min
Amniotic fluid volume	At least one pocket of amniotic fluid measuring ≥2 cm in two perpendicular planes	Either no amniotic fluid pockets or a pocket <2 cm in two perpendicular planes

Modified from Manning FA: Biophysical profile scoring. *In* Nijhuis J (ed): Fetal Behaviour. New York, Oxford University Press, 1992, p 241.
*For gestational age >30 weeks.

TABLE 12-5 MANAGEMENT BASED ON BIOPHYSICAL PROFILE

SCORE	INTERPRETATION	MANAGEMENT
10	Normal; low risk for chronic asphyxia	Repeat testing at weekly to twice-weekly intervals
8	Normal; low risk for chronic asphyxia	Repeat testing at weekly to twice-weekly intervals
6	Suspect chronic asphyxia	If ≥36-37 wk gestation or <36 wk with positive testing for fetal pulmonary maturity, consider delivery; if <36 wk and/or fetal pulmonary maturity testing negative, repeat biophysical profile in 4 to 6 hr; deliver if oligohydramnios is present
4	Suspect chronic asphyxia	If ≥36 wk gestation, deliver; if <32 wk gestation, repeat score
0-2	Strongly suspect chronic asphyxia	Extend testing time to 120 min; if persistent score ≤4, deliver, regardless of gestational age

Modified from Manning FA, Harman CR, Morrison I, et al: Fetal assessment based on fetal biophysical profile scoring. Am J Obstet Gynecol 162:703, 1990; and Manning FA: Biophysical profile scoring. *In* Nijhuis J (ed): Fetal Behaviour. New York, Oxford University Press, 1992, p 241.

1000 for infants with normal amniotic fluid volume to 12.8 per 1000 for fetuses demonstrating a reactive NST. These investigators found that, in most cases, the ultrasound-derived BPP parameters and NST could be completed within a relatively short time, each requiring about 10 minutes.

Manning and colleagues presented their experience with 26,780 high-risk pregnancies followed with the BPP. In their protocol, a routine NST is not performed if all of the ultrasound parameters are found to be normal for a score of 8.[98] An NST is performed when one ultrasound finding is abnormal. The corrected PMR in this series was 1.9 per 1000, with fewer than 1 fetal death per 1000 patients within 1 week of a normal profile. Of all patients tested, almost 97% had a score of 8, which means that only 3% required further evaluation for scores of 6 or less. In a study of 525 patients with scores of 6 or less, poor perinatal outcome was most often associated with either a nonreactive NST and absent fetal tone or a nonreactive NST and absent FBM.[99] A significant inverse linear relationship was observed between the last BPP score and both perinatal morbidity and mortality (Figures 12-16 and 12-17).[100] The false-positive rate, depending on the end point used, ranges from 75% for a score of 6 to less than 20% for a score of 0. Manning has summarized the data reported in eight investigations using the BPP for fetal evaluation. Overall, 23,780 patients and 54,337 tests were reviewed. The corrected PMR, excluding lethal anomalies, was 0.77 per 1,000.

The BPP correlates well with fetal acid-base status. Vintzileos and associates[94] studied 124 patients undergoing cesarean birth *before* the onset of labor. Deliveries were undertaken for severe preeclampsia, elective repeat cesarean delivery, growth restriction, breech presentation, placenta previa, and fetal macrosomia. Acidosis was defined as an umbilical cord arterial pH less than 7.20. The earliest manifestations of fetal acidosis were a nonreactive NST and loss of FBM. With scores of 8 or more, the mean arterial pH was 7.28, and only 2 of 102 fetuses were acidotic. Nine fetuses with scores of 4 or less had a mean pH of 6.99, and all were acidotic.

Some studies have demonstrated that antenatal corticosteroid administration may have an effect on the BPP, decreasing the profile score. Because corticosteroids are used in cases of anticipated premature delivery (24 to 34

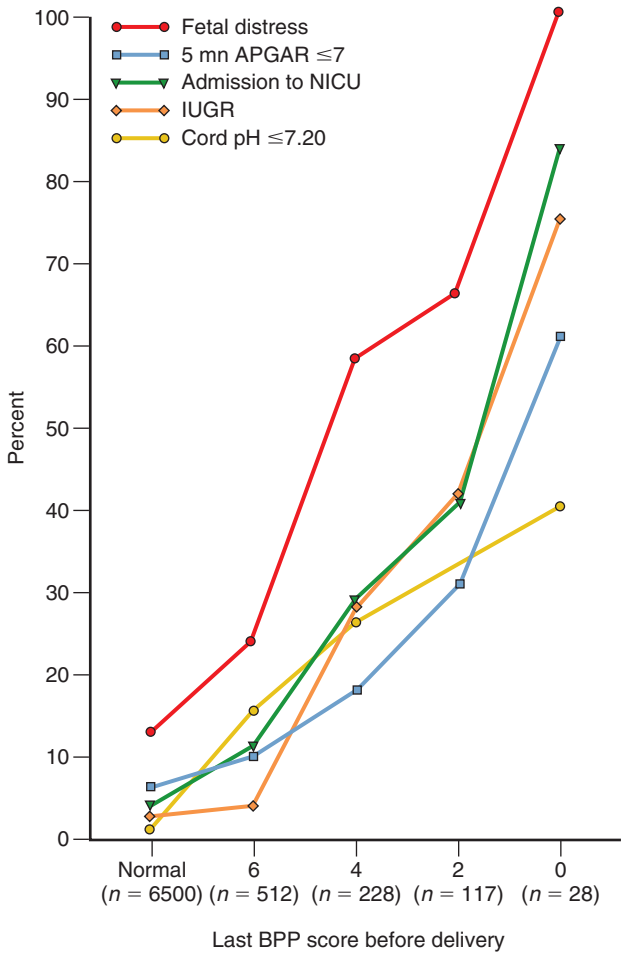

FIGURE 12-16. The relationship between five indices of perinatal morbidity and last BPP score before delivery. A significant inverse linear correlation is observed for each variable. (From Manning FA, Harman CR, Morrison I, et al: Fetal assessment based on fetal biophysical profile scoring. Am J Obstet Gynecol 162:703, 1990.)

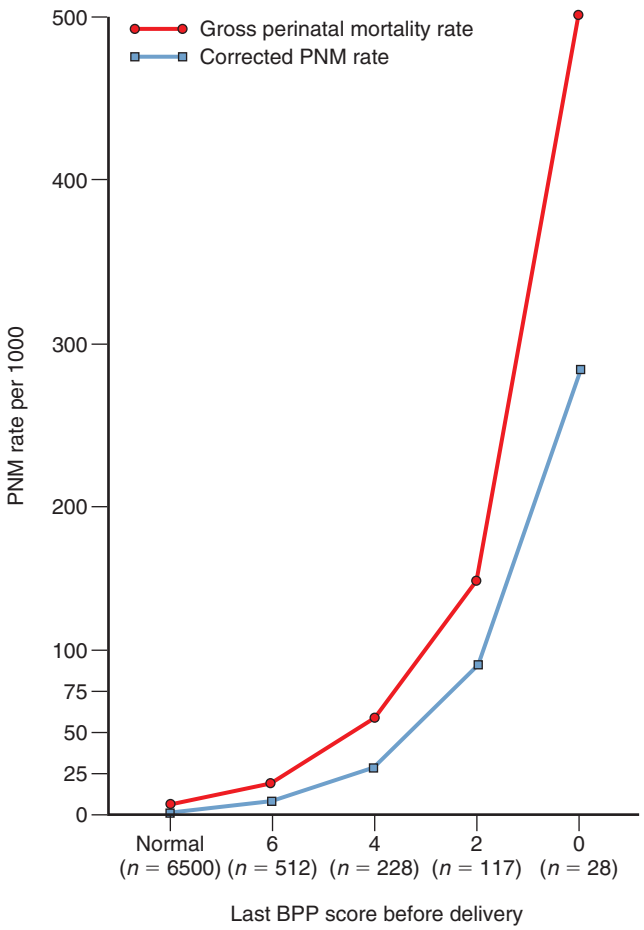

FIGURE 12-17. The relationship between perinatal mortality, both total and corrected for major anomalies, and the last BPP score before delivery. A highly significant inverse and exponential relationship is observed. (From Manning FA, Harman CR, Morrison I, et al: Fetal assessment based on fetal biophysical profile scoring. Am J Obstet Gynecol 162:703, 1990.)

weeks), any false-positive results on biophysical testing may lead to inappropriate intervention and delivery. Kelly and coworkers reported that BPP scores were decreased in more than one third of the fetuses tested at 28 to 34 weeks' gestation. This effect was seen within 48 hours of corticosteroid administration. Neonatal outcome was not affected. Repeat BPPs within 24 to 48 hours were normal in cases in which the BPP score had decreased by 4 points. The most commonly affected variables were FBM and the NST. Other investigators have reported transient suppression of FBM and heart rate reactivity after corticosteroid administration at less than 34 weeks' gestation, with return of these parameters to normal by 48 to 96 hours after corticosteroid treatment. This effect must be considered at institutions where daily BPPs are used to evaluate the fetus in cases of preterm labor or preterm premature rupture of the membranes.

There has been some controversy concerning the utility of the BPP in predicting chorioamnionitis in pregnancies complicated by preterm labor or preterm premature rupture of the membranes. Sherer and colleagues reported that the absence of FBM is associated with histologic evidence of fetal inflammation and intrauterine infection in patients with preterm labor and intact membranes before 32 weeks' gestation. However, they recommend that this finding not be used to guide clinical management because of the low positive predictive value of absent FBM. Lewis and associates performed a randomized trial of daily NSTs versus BPP in the management of preterm premature rupture of the membranes. They concluded that neither daily NSTs nor BPPs had high sensitivity in predicting infectious complications in these patients. Daily BPPs increased cost without apparent benefit.

Manning and colleagues have described the correlation between biophysical scoring and the incidence of cerebral palsy in Manitoba. In patients referred for a BPP, there was an inverse, exponential, and highly significant relationship between last BPP score and the incidence of cerebral palsy. Scores of 6 or less had a sensitivity of 49%. The more abnormal the last BPP, the greater the risk for cerebral palsy. Gestational age, birthweight, or assumed timing of the injury were not related to the incidence of cerebral palsy. The incidence of cerebral palsy ranged from 0.7 per 1000 live births, for a normal BPP score; to 13.1 per 1000 live births, for a score of 6; and 333 per 1000 live births, for a score of 0.

Is an NST needed if all ultrasound parameters of the BPP are normal? Prospective and blinded studies by and Manning and others using both the BPP and NST have demonstrated that each of these tests is a valuable predictor of normal outcome. In the experience of Manning and colleagues, an NST was needed in less than 5% of tests. As emphasized by Eden and associates, however, the NST allows the detection of fetal heart rate decelerations. In the presence of reduced amniotic fluid, these decelerations may be associated with a cord accident. Eden and associates reported that when spontaneous fetal heart rate decelerations lasting at least 30 seconds with a decrease of at least 15 beats/minute are seen in the presence of normal amniotic fluid, there is an increased likelihood of late decelerations in labor and cesarean delivery for fetal distress.

Several drawbacks of the BPP should be considered. Unlike the NST and CST, an ultrasound machine is required, and unless the BPP is videotaped, it cannot be reviewed. If the fetus is in a quiet sleep state, the BPP can require a long period of observation. The present scoring system does not consider the impact of hydramnios. In a pregnancy complicated by diabetes mellitus, the presence of excessive amniotic fluid is of great concern.

Predictive Value of Biophysical Profile

To summarize the results of multiple studies, the false-negative rate of a normal BPP is less than 0.1%, or fewer than 1 fetal death per 1000 within 1 week of a normal BPP.[2]

The false-positive rate of a particular test has always been of concern because of the possibility of unnecessary intervention (usually delivery) and subsequent iatrogenic complications. The BPP was developed in part to address the issue of the high false-positive rate of the CST and the NST. There has been little attention paid to the possible false-positive rate of the abnormal or equivocal BPP. This is particularly relevant because the BPP is most commonly used as the final backup test in the NST and CST sequence of testing and is critically important when dealing with the premature fetus. As noted earlier, the false-positive rate of a score of 0 is less than 20%, but for a score of 6, it is up to 75%. Inglis and coworkers used VAS to define fetal condition with BPP scores of 6 or less in 81 patients at 28 to 42 weeks. Obstetrical and neonatal outcomes of 41 patients whose score improved to normal after VAS were compared with those of 238 patients who had normal scores without VAS. The obstetrical and neonatal outcomes were not significantly different between the two groups. VAS improved the BPP in about 80% of cases. Use of VAS for an equivocal BPP did not increase the false-negative rate and may reduce the likelihood of unnecessary obstetrical intervention.

A 2008 Cochrane review included evaluation of 2829 women randomized to BPP versus NST. The majority were term pregnancies. No differences were found in perinatal mortality, cesarean delivery rate, Apgar scores, or admission to the neonatal intensive care unit. As with the 2010 Cochrane review of NST, mentioned earlier, this analysis was underpowered to detect a significant difference in perinatal mortality between BPP and other modalities. The authors also note that, "It is regrettable that since the introduction of the BPP in the 1980s, and following reports of observational studies of tens of thousands of pregnancies, less than 3000 women have been enrolled into randomised trials."

Modified Biophysical Profile

A variety of modifications of the full BPP have been evaluated, in an attempt to simplify and reduce the time necessary to complete testing, by focusing on the components of the BPP that are most predictive of perinatal outcome. The NST, an indicator of present fetal condition, may be combined with the AFI (see Chapter 33), a marker of long-term status, in a modified BPP (mBPP). In this setting, an AFI greater than 5 cm is usually considered normal, although different criteria have been applied. VAS may be used to shorten the time required to achieve a reactive NST. **Multiple investigators**, including a trial by

Miller of 56,617 antepartum tests in 15,482 women, **have demonstrated comparable results of the mBPP to the full BPP, namely a false-negative rate (or rate of fetal death within 1 week of a normal mBPP) of 0.8 per 1000.** Nageotte and associates demonstrated that the mBPP was as good a predictor of adverse fetal outcome as a negative CST. Additional evaluation for abnormal mBPP is required in about 10% of patients. If the NST is nonreactive despite VAS or extended monitoring, or if the AFI is abnormal, either a full BPP or CST is performed. The CST as a backup test is associated with a higher rate of intervention for an abnormal test than the use of a complete BPP as a backup test. Overall, the modified BPP has a false-positive rate comparable to the NST but higher than the CST and full BPP. The low false-negative rate and ease of performance of the modified BPP make it an excellent approach for the evaluation of large numbers of high-risk patients. As such, although potentially still a useful test, the CST has becoming less frequently used in current practice.

Whether to use a full AFI for AFV assessment, or an abbreviated measure, the single deepest vertical pocket (DVP), has been under investigation. Trends have varied over time, without substantial evidence to reliably link either method to perinatal outcomes. Chauhan and colleagues performed a randomized trial of more than 1000 women and found that the AFI led to more diagnoses of oligohydramnios and a higher rate of intervention, including iatrogenic prematurity, but offered no advantage in detecting or preventing adverse outcomes. Similarly, a 2009 Cochrane review of five trials including more than 3200 women concluded that there were no differences in perinatal outcomes. However, the use of AFI did result in increased rate of diagnosis of oligohydramnios and rate of induction of labor compared with DVP. This review could not comment on the relative ability of AFI compared with DVP for prevention of perinatal death because there were no deaths reported in the included trials. Clearly, further study of these modalities is warranted with regard to their utility in preventing perinatal mortality.

Doppler Ultrasound

The advent of Doppler ultrasound has permitted noninvasive assessment of the fetal, maternal, and placental circulations. With Doppler ultrasound, we can obtain information about uteroplacental blood flow and resistance, which may be markers of fetal adaptation and reserve. This method of fetal assessment has only been demonstrated to be of value in reducing perinatal mortality and unnecessary obstetrical interventions in fetuses with suspected IUGR and possibly other disorders of uteroplacental blood flow.[2] A detailed description of the underlying principles and use of Doppler ultrasound for fetal assessment is available in Chapter 31 on IUGR. For the purposes of this chapter on antenatal fetal assessment, Doppler interrogation of fetal vascular flow and resistance can be conceptualized as a follow-up test to determine fetal reserve in cases of suspected IUGR, and not as a primary method of antenatal fetal surveillance for either high-risk or low-risk pregnancies.

Perhaps ironically, however, Doppler ultrasound has been more stringently evaluated in randomized trials than other antenatal testing methods, as has been summarized in an editorial by Divon and Ferber. The most recent summary of the available evidence comes from a 2010 Cochrane review of 18 randomized trials including more than 10,000 high-risk women, in which the use of Doppler ultrasound was associated with decreased perinatal deaths (RR, 0.71; 95% CI, 0.52 to 0.98) as well as significantly fewer inductions of labor and cesarean deliveries. Studies of low-risk pregnancies have not shown a benefit from the use of Doppler ultrasound, as has been most recently described in a 2010 systematic review of five studies including more than 14,000 women.

CLINICAL APPLICATION OF TESTS OF FETAL WELL-BEING

Our ability to detect and prevent impending fetal death or injury depends not only on the predictive value of the tests employed and the population selected for testing, but also on our ability to respond to abnormal test results. In order to have an impact on testing outcomes and the overall fetal death rate, we must consider available strategies to deal with abnormal test results. These strategies would ideally include a series of antenatal evaluations and interventions short of premature delivery, with premature delivery ultimately reserved for cases when it is ascertained that intrauterine injury or death can no longer be delayed or prevented. Figure 12-18 presents a practical testing scheme that has been used successfully by several centers.[92] This strategy would include using combinations of antepartum tests in an organized sequence to evaluate the fetus further; administration of antenatal steroids; potentially modified maternal activity level; and correction of maternal metabolic, cardiopulmonary, or other medical disorders. In some cases, fetal therapy may be indicated, such as intrauterine transfusion for anemia, removal of fluid from body cavities, diagnostic procedures, and direct administration of medication to the fetus.

Testing can be initiated at early gestational ages in high-risk pregnancies (25 to 26 weeks) to identify the fetus at risk. Maternal and fetal interventions can then be considered. Obviously, safe prolongation of intrauterine life is the primary goal, and better understanding of the pathophysiology of the premature fetus and the use of combinations of tests will allow this to be accomplished.

The question of routine antepartum fetal surveillance must be carefully examined. Antepartum fetal testing can more accurately predict fetal outcome than antenatal risk assessment using an established scoring system. Patients judged to be at high risk based on known medical factors but whose fetuses demonstrated normal antepartum fetal evaluation had a lower PMR than did patients considered at low risk, whose fetuses had abnormal antepartum testing results. Routine antepartum fetal evaluation would be necessary to detect the considerable proportion of fetuses destined for fetal death or injury with no identifiable risk factors. It would seem reasonable, therefore, to consider extending some form of antepartum fetal surveillance to all obstetrical patients, such as maternal assessment of fetal activity as described previously.

How, therefore, to combine antenatal tests in clinical practice, and in which patients? **The approach to**

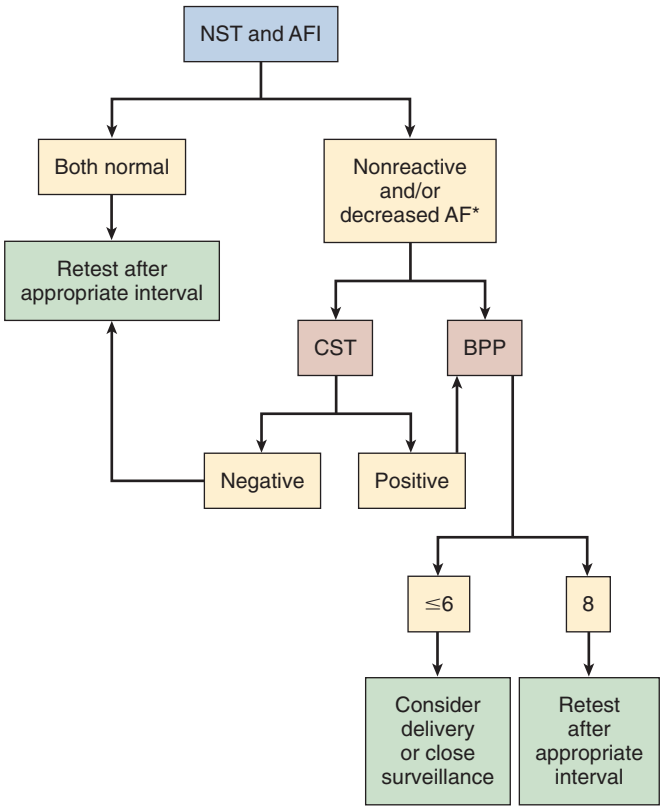

FIGURE 12-18. Flow chart for antepartum fetal surveillance in which the NST and AFI are used as the primary methods for fetal evaluation. A nonreactive NST and decreased AFI are further evaluated using either the CST or the BPP. Further details regarding the use of the BPP are provided in Table 12-6.
*If the fetus is mature and amniotic fluid volume is reduced, delivery should be considered before further testing is undertaken. (Modified from Finberg HJ, Kurtz AB, Johnson RL, et al: The biophysical profile: a literature review and reassessment of its usefulness in the evaluation of fetal well-being. J Ultrasound Med 9:583, 1990.)

prescribing testing modalities must take into account gestational age, medical comorbidities, and sociodemographic risk factors described in this chapter, in order to prevent fetal injury or death without causing iatrogenic prematurity or an excess of testing and worry. According to a summary by Fretts and Duru in 2008, "The best opportunity for stillbirth reduction is to identify patients who have an increased risk of stillbirth, late in pregnancy, where the downside of antepartum testing and early delivery, if warranted, can be minimized."[20]

The condition-specific use of antenatal testing may be illustrated by the following examples. In a prolonged pregnancy, one would use a parallel testing scheme. In this situation, the obstetrician is not concerned with fetal maturity but rather with fetal well-being. Several tests are performed at the same time, such as antepartum fetal heart rate testing and the BPP. It is acceptable in this high-risk situation to intervene when a single test is abnormal. One is willing to accept a false-positive test result to avoid the intrauterine death of a mature and otherwise healthy fetus. In most other high-risk pregnancies, such as those complicated by diabetes mellitus or hypertension, it is preferable to allow the fetus to remain in utero as long as possible. In these situations, a branched testing scheme is used. To decrease the likelihood of unnecessary premature intervention, the obstetrician uses a series of tests and, under most circumstances, would only deliver a premature infant when all parameters suggest fetal compromise. In this situation, one must consider the likelihood of neonatal respiratory distress syndrome (RDS) as predicted by the evaluation of AFIs and review these risks with colleagues in neonatology.

The comparable performance of the various available antenatal tests, along with their utility in series, has been illustrated by numerous investigators (see Table 12-2).[2] Maternal assessment of fetal activity would appear to be a reasonable first-line screening test for both high-risk and low-risk patients. The use of this approach may decrease the number of unexpected intrauterine deaths in so-called normal pregnancies. The NST and mBPP remain the primary methods used for antepartum fetal evaluation in high-risk patients at most centers, with full BPP and CST to assess fetal condition in patients exhibiting a persistently nonreactive NST or abnormal mBPP. This sequential approach may be particularly valuable in avoiding unnecessary premature intervention. The NST and mBPP can be quickly performed in an outpatient setting and are easily interpreted. In contrast, the CST is usually performed near the labor and delivery suite, may require an intravenous infusion of oxytocin, and may be more difficult to interpret. However, the ability of the CST to stress the fetus and evaluate its response to intermittent interruptions in intervillous blood flow may provide an earlier warning of fetal compromise than the NST or mBPP.

The frequency with which to employ specific tests will depend on a number of features, including the predictive value of the test and the underlying condition prompting the test. Most tests described previously have relatively reliable risk profiles over the course of a week when normal, with decreased intervals between tests recommended for abnormal results. Regarding the underlying condition contributing to risk for adverse outcomes, consideration must be given to whether that condition is stable, worsening, or improving. The gestational age at which to initiate testing has not been clearly defined for most high-risk conditions. Initiating testing at 32 to 34 weeks of gestation has historically been prescribed for most high-risk pregnancies, with earlier testing recommended for cases with multiple comorbidities or particularly worrisome features.

Signore and coworkers, on behalf of the Eunice Kennedy Shriver National Institute of Child Health and Human Development Workshop, have proposed a series of guidelines for condition-specific antenatal testing, based on the available evidence (Table 12-6).[2] In their 2009 publication, they stress that **"the basis for antepartum testing relies on the premise that the fetus whose oxygenation in utero is challenged will respond with a series of detectable physiologic adaptive or decompensatory signs as hypoxemia or frank metabolic academia develop"**—hence the recommendation for the use of antenatal tests in series to follow the changes in observable measures of fetal response to a suboptimal intrauterine environment. Although this proposed strategy is certainly not comprehensive, future

TABLE 12-6 PROPOSED INITIAL TESTING STRATEGY BY SELECTED ANTENATAL CONDITION

RISK FACTOR	TEST	FREQUENCY	START
All pregnancies	FMC	Daily	24-28 wk
Low-risk pregnancies	FMC	Daily	24-28 wk
Insulin-treated diabetes			
Uncomplicated pregestational, or A2	mBPP	Twice weekly	32 wk
with hypertension, renal disease, or IUGR	Above, plus consider CST	Weekly	26-28 wk
Hypertensive disorders			
Uncomplicated	mBPP	Twice weekly	32 wk
With comorbidities	mBPP	Twice weekly	26-28 wk
IUGR	mBPP/Doppler	Once or twice weekly	At diagnosis
Multiple gestation			
Twins			
Concordant growth	mBPP	Weekly	32 wk
Discordant growth or AFV	mBPP	Twice weekly	At diagnosis
Triplets or greater	mBPP	Twice weekly	28 wk
Oligohydramnios	mBPP	Twice weekly	At diagnosis
Intrahepatic cholestasis	mBPP	Weekly	34 wk
Renal disease	mBPP	Weekly	30-32 wk
Decreased fetal movement	mBPP	PRN	At diagnosis
Previous fetal death	mBPP	Once or twice weekly	32-34 wk, or 1 wk before previous fetal death
	Alternative: BPP or CST	Weekly	
Postterm pregnancy	mBPP	Once or twice weekly	≥41 wk
SLE	mBPP	Weekly	26 wk
Renal disease	mBPP	Once or twice weekly	30-32 wk
Intrahepatic cholestasis	mBPP	Weekly	34 wk

See Key Abbreviations box at beginning of chapter for definition of abbreviations used.

research into specific testing strategies stratified by risk category will hopefully enhance our ability to prescribe these tests effectively and safely.

Evidence for Condition-Specific Testing Strategies

For most of the conditions identified as constituting an increased risk for fetal death, insufficient studies exist to permit an evidence-based recommendation for a particular testing scheme. In addition to this limitation, condition-specific testing is problematic as a general strategy for prevention of fetal death, given the many fetal deaths that occur in pregnancies otherwise categorized as low risk, or without identifiable risk factors.[2] However, it is incumbent on care providers to consider all conditions associated with an increased risk for fetal death or other adverse outcomes as a potential indication for some form of antenatal surveillance[2,27] and perhaps to individualize antenatal testing plans based on specific underlying conditions. This strategy is outlined in an excellent 2004 summary by Kontopoulos and Vintzileos, in which several pathophysiologic mechanisms are explored as potentially distinct etiologies for risk of fetal death in different populations. **The authors acknowledge that there is no ideal single test or testing strategy for all high-risk pregnancies but that clinician judgement and logic, as well as evidence from observational trials, should guide testing strategies for each patient.**

Difficulty in generating evidence-based recommendations for condition-specific testing schemes in cases of identified risk factors can be illustrated by considering the example of hypertensive disorders. Well-designed prospective trials providing evidence for any specific testing strategy are not available, despite the very frequent use of a variety of antenatal testing schemes employed in clinical practice for hypertensive disorders. The heterogeneity of pathophysiologic mechanisms at play in the general category of hypertensive disorders contributes to the difficulty in generating specific recommendations. Freeman summarized the situation in a 2008 review.[30] He noted that despite previous testing guidelines recommending a more wide application of antenatal testing in women with varying degrees of hypertension, the most recent expert recommendations do not support antepartum fetal testing for mild to moderate blood pressure abnormalities and in the absence of preeclampsia or IUGR. However, for many practitioners, the evidence that all forms of chronic hypertension constitute an increased risk for fetal death and adverse outcomes prompts broad use of testing modalities for these patients.

ASSESSMENT OF FETAL PULMONARY MATURATION

This section reviews those techniques that enable the obstetrician to predict accurately the risks of RDS for the infant requiring premature delivery and to avoid the unnecessary complications of iatrogenic prematurity. It is the risk of iatrogenic prematurity for the neonate, balanced against the risk of continued antepartum assessment of the potentially compromised fetus, that determines ultimate management strategies. As such, incorporation of the discussion of assessment of fetal pulmonary maturity with that of antepartum assessment is critical.

RDS is caused by a deficiency of pulmonary surfactant, an antiatelectasis factor that is able to maintain a low stable surface tension at the air-water interface within alveoli. Surfactant decreases the pressure needed to distend the lung and prevents alveolar collapse (see Chapter 21). The type II alveolar cell is the major site of surfactant synthesis. Surfactant is packaged in lamellar bodies, discharged into

the alveoli, and carried into the amniotic cavity with pulmonary fluid.

Phospholipids account for more than 80% of the surface active material within the lung, and more than 50% of this phospholipid is dipalmitoyl lecithin. The latter is a derivative of glycerol phosphate and contains two fatty acids as well as the nitrogenous base choline. Other phospholipids contained in the surfactant complex include phosphatidylglycerol (PG), phosphatidylinositol, phosphatidylserine, phosphatidylethanolamine, sphingomyelin, and lysolecithin. PG is the second most abundant lipid in surfactant and significantly improves its properties.

Important differences in neonatal adaptation, including development of RDS, have been demonstrated not only between preterm and term neonates but also with each advancing gestational week from 37 to 39 weeks. This places even more responsibility on the physician to judiciously assess indications for and timing of delivery before 39 weeks. In weighing the risks and benefits of effecting delivery as a result of antenatal testing results before 39 weeks, assessment of fetal pulmonary maturity may in some cases be indicated. At the same time, it is important to recognize that many perinatal processes contribute to the prognosis for neonatal respiratory function, including surfactant deficiency, immaturity, and intrapartum complications, which are prime factors in determining the pathogenesis of RDS and may not be predicted by fetal pulmonary maturity testing.

Tests of Fetal Pulmonary Maturity

Available methods for evaluating fetal pulmonary maturity rely generally on either presence or quantitation of components of pulmonary surfactant, or measurement of surfactant function. The former category has become the most common and reliable in current practice, although no data show that one method is preferable to the others with regard to prediction of pulmonary maturity. In general, a test that is positive for fetal pulmonary maturity will much more accurately predict the absence of RDS than a negative test will predict the presence of RDS.

With the exception of amniotic fluid specimens obtained from the vaginal pool, the evaluation of fetal pulmonary maturation requires that a sample of amniotic fluid be obtained by amniocentesis. This is generally a low-risk procedure, with few potential adverse outcomes, including unsuccessful amniocentesis (1.6% to 4.4%) and complications requiring same-day delivery (0.7% to 3.3%).

Quantitation of Pulmonary Surfactant

The lecithin-to-sphingomyelin (L/S) ratio was the first reliable assay for the assessment of fetal pulmonary maturity. The amniotic fluid concentration of lecithin increases markedly at about 35 weeks' gestation, whereas sphingomyelin levels remain stable or decrease. Thus, by comparing the ratio of these two components, rather than measuring them, variations in amniotic fluid volume will not affect the outcome of the test. Amniotic fluid sphingomyelin exceeds lecithin until 31 to 32 weeks, when the L/S ratio reaches 1. Lecithin then rises rapidly, and an L/S ratio of *2* is observed at about 35 weeks. Wide variation in the L/S ratio at each gestational age has been noted. Nevertheless, a ratio of *2* or greater has repeatedly been associated with pulmonary maturity. In more than 2100 cases, a mature L/S ratio predicted the absence of RDS in 98% of neonates. With a ratio of 1.5 to 1.9, about 50% of infants will develop RDS. Below 1.5, the risk for subsequent RDS increases to 73%. Thus, the L/S ratio, like most indices of fetal pulmonary maturation, rarely errs when predicting fetal pulmonary maturity but is frequently incorrect when predicting subsequent RDS. Many neonates with an immature L/S ratio do not develop RDS.

Several important variables must be considered in interpreting the predictive accuracy of the L/S ratio, including presence of blood or meconium. Blood has been reported both to increase and decrease the ratio, and meconium can produce falsely mature results. The presence of PG in a bloody or meconium-stained amniotic fluid sample remains a reliable indicator of pulmonary maturity. PG is not normally found in blood, and meconium generally does not interfere with the identification of PG. PG, which does not appear until 35 weeks' gestation and increases rapidly between 37 and 40 weeks, is a marker of completed pulmonary maturation. Most infants who lack PG but who have a mature L/S ratio fail to develop RDS. However, PG may provide further insurance against the onset of RDS despite intrapartum complications. A rapid immunologic semiquantitative agglutination test (AmnioStat-FLM) can be used to determine the presence of PG. This assay can detect PG at a concentration greater than 0.5 mcg/mL of amniotic fluid. The test takes 20 to 30 minutes to perform and requires only 1.5 mL of amniotic fluid.

Visual inspection of amniotic fluid can give some information about the presence of pulmonary surfactant components. During the first and second trimesters, amniotic fluid is yellow and clear. It becomes colorless in the third trimester. By 33 to 34 weeks' gestation, cloudiness and flocculation are noted, and as term approaches, vernix appears. Amniotic fluid with obvious vernix or fluid so turbid it does not permit the reading of newsprint through it will usually have a mature L/S ratio.

The TDx analyzer is an automated fluorescence polarimeter that is used to detect the ratio of surfactant to albumin in amniotic fluid. The test requires 1 mL of amniotic fluid and can be run in less than 1 hour. The surfactant-to-albumin ratio is determined with amniotic fluid albumin used as an internal reference. With the newer FLM-II test, 55 mg/g is the mature cut-off. A mature value reliably predicts the absence of RDS requiring intubation in infants of diabetic mothers. The TDx test correlates well with the L/S ratio and has few falsely mature results, making it an excellent screening test. The TDx assay proved to be reliable in predicting fetal lung maturity in vaginal pool specimens from patients with preterm premature rupture of the membranes at 30 to 36 weeks. About 50% of infants with an immature TDx result develop RDS. The test has gained wide popularity because of its ease, low cost, and reproducibility and is commonly available in practice.

Measurements of Surfactant Function

Lamellar bodies are the storage form of surfactant released by fetal type II pneumocytes into the amniotic fluid. Because they are the same size as platelets, the amniotic fluid concentration of lamellar bodies may be determined using a commercial cell counter. The test requires less

than 1 mL of amniotic fluid and takes only 15 minutes to perform. A lamellar body count greater than 30,000 to 55,000/μL is highly predictive of pulmonary maturity, whereas a count below 10,000/μL suggests a significant risk for RDS. Lewis and associates have reported that a lamellar body count of less than 8000 predicted an immature L/S and PG assay in all cases, whereas a value greater than 32,000 predicted a mature L/S or PG assay in 99% of cases. The cut-off used to predict fetal pulmonary status depends on the type of cell counter used and the speed of centrifugation of the amniotic fluid specimen. Neither meconium nor lysed blood has a significant effect on the lamellar body count. The ease and relatively low cost of this test have contributed to its popularity, although poor concordance among various instruments for the assay of lamellar body counts has been noted.

The manual foam stability index (FSI) is a variation of the shake test. The kit currently available contains test wells with a predispensed volume of ethanol. The addition of 0.5 mL of amniotic fluid to each test well in the kit produces final ethanol volumes of 44% to 50%. A control well contains sufficient surfactant in 50% ethanol to produce an example of the stable foam end point. The amniotic fluid and ethanol mixture is first shaken, and the FSI value is read as the highest value well in which a ring of stable foam persists.

This test appears to be a reliable predictor of fetal lung maturity. Subsequent RDS is very unlikely with an FSI value of 47 or higher. The methodology is simple, and the test can be performed at any time of day by persons who have had only minimal instruction. The assay appears to be extremely sensitive, with a high proportion of immature results being associated with RDS, as well as moderately specific, with a high proportion of mature results predicting the absence of RDS. Contamination of the amniotic fluid specimen by blood or meconium invalidates the FSI results. The FSI can function well as a screening test, but has lost popularity in current practice to other more reliable and convenient tests.

Determination of Fetal Pulmonary Maturation in Clinical Practice

A large number of techniques are now available to assess fetal pulmonary maturation. Several rapid screening tests, including the TDx test and lamellar body count, appear to be highly reliable when mature. In an uncomplicated pregnancy, when a screening test such as the TDx demonstrates fetal pulmonary maturation, one can safely proceed with delivery. The more complicated, expensive, and timely L/S ratio may be reserved for those borderline TDx or lamellar body count results in the clinical circumstance of a fetus that may benefit from delivery if maturity is ultimately confirmed with advanced testing. This sequential approach is also extremely cost-effective. When the screening test is immature, the L/S ratio and PG assessment should be considered.

As data have been assimilated in recent years related to lung maturity assessment and its role in high-risk pregnancy management, new important paradigms are emerging. Traditionally, lung maturity tests have been interpreted in categorical fashion, usually as either "positive," indicating lung maturity and a low risk for RDS, or "negative," indicating the absence of maturity and a higher risk for RDS. However, the presence of RDS in neonates is associated with both gestational age and lung maturity assessments. As further information has been gathered, it is now possible to stratify risk for RDS based on both gestational age and lung maturity assessment. This represents a more appropriate use of the lung maturity tests. For instance, the risk for RDS given an FLM result of 30 to 40 mg/g is about 50% at 28 weeks, about 25% at 32 weeks, and only about 10% at 36 weeks. **In assessing the risk for RDS complicating subsequent delivery, results from fetal lung maturity testing are most appropriately correlated with the gestational age at the time of fluid retrieval.**

CONCLUSIONS AND FUTURE DIRECTIONS

We must be aware of our limited understanding of the pathophysiology of fetal death and injury in many occasions and attempt judicious use of antenatal testing measures with the hope of preventing some adverse outcomes and the goal of doing no harm. As Scifres and Macones state in a 2008 review of costs and benefits of antenatal testing, although we assume that by testing and intervening with delivery for abnormal test results we are contributing to a good outcome, "in the absence of data we cannot be assured that our interventions, even if they prevent stillbirth, may not involve a tradeoff between long term neurologic dysfunction and fetal death."[40] Additionally, aside from potential unknown medical sequelae of antenatal testing and interventions, monetary, time, and psychological costs must also be considered, but these are difficult to quantify in both research settings and in practice.

As clinicians aim to implement evidence-based strategies to screen for and prevent fetal injury and death, the limitations of existing research must be considered. Because it is in many ways impractical and perhaps unethical to carry out placebo-controlled trials of antenatal testing methodologies in high-risk pregnancies, we must acknowledge that this type of rigorous evidence is not likely to be imminently forthcoming.[2] Nevertheless, we propose that biologic plausibility and clinician judgment prevail over therapeutic nihilism in clinical practice, and that future research efforts embrace a creative approach to both condition-specific and apparently unpredictable fetal death and injury.

KEY POINTS

- Although the PMR has fallen steadily in the United States since 1965, the number of fetal deaths has not changed substantially in the past decade.
- Perinatal events play an important role in infant mortality and long-term disability of survivors, in addition to their contribution to fetal death.
- At least 20% of fetal deaths have no obvious fetal, placental, maternal, or obstetrical etiology, and this percentage increases with advancing gestational age.

- The prevalence of an abnormal condition (i.e., fetal death) has great impact on the predictive value of antepartum fetal tests.
- Few of the antepartum tests commonly employed in clinical practice today have been subjected to large-scale prospective and randomized evaluations that can speak to the true efficacy of testing.
- Fetal adaptation to hypoxemia is mediated by changes in heart rate and redistribution of cardiac output.
- The decrease in fetal movement with hypoxemia makes maternal assessment of fetal activity a potentially simple and widely applicable method of monitoring fetal well-being. However, prospective trials of this method for prevention of perinatal mortality have failed to conclusively show benefit.
- The CST has a low false-negative rate but a high false-positive rate and is cumbersome to perform and thus is used less frequently in common practice than other testing modalities.
- The observation that accelerations of the fetal heart rate in response to fetal activity, uterine contractions, or stimulation reflect fetal well-being is the basis for the NST.
- Use of VAS for a nonreactive NST or equivocal BPP does not increase the false-negative rate and may reduce the likelihood of unnecessary obstetrical intervention.
- The NST has a low false-negative rate, although higher than that of CST, and a high false-positive rate.
- Fetal biophysical activities can be evaluated with real-time ultrasonography by BPP, and those fetal biophysical activities that are present earliest in fetal development are the last to disappear with fetal hypoxia.
- The modified BPP performs comparably to the full BPP. Both modalities have a false-negative rate, or rate of fetal death within 1 week of a normal test, of 0.8 per 1000.
- Most amniotic fluid tests of fetal pulmonary maturation accurately predict maturity, but improved accuracy in predicting subsequent RDS is noted when the indices are correlated with gestational age.
- Condition-specific testing involves modifying the frequency, type, and initiation of antenatal tests according to maternal high-risk conditions.

LABOR: DEFINITION AND PHYSIOLOGY

Labor is defined as the process by which the fetus is expelled from the uterus. **More specifically, labor requires regular, effective contractions that lead to dilation and effacement of the cervix.** This chapter describes the physiology and normal characteristics of term labor and delivery.

The physiology of labor initiation has not been completely elucidated, but the putative mechanisms have been well reviewed by Liao and colleagues.[1] Labor initiation is species-specific, and the mechanisms in human labor are unique. The four phases of labor from quiescence to involution are outlined in Figure 13-1.[2] The first phase is quiescence and represents that time in utero before labor begins when uterine activity is suppressed by the action of progesterone, prostacyclin, relaxin, nitric oxide, parathyroid hormone–related peptide, and possibly other hormones. During the activation phase, estrogen begins to facilitate expression of myometrial receptors for prostaglandins (PGs) and oxytocin, which results in ion channel activation and increased gap junctions. This increase in the gap junctions between myometrial cells facilitates effective contractions.[3] In essence, the activation phase readies the uterus for the subsequent stimulation phase, when uterotonics, particularly PGs and oxytocin, stimulate regular contractions. In the human, this process at term may be protracted, occurring over days to weeks. The final phase, uterine involution, occurs after delivery and is mediated primarily by oxytocin. The first three phases of labor require endocrine, paracrine, and autocrine interaction between the fetus, membranes, placenta, and mother.

The fetus has a central role in the initiation of term labor in nonhuman mammals; in humans, the fetal role is not completely understood (Figure 13-2).[2-5] In sheep, term labor is initiated through activation of the fetal hypothalamic-pituitary-adrenal axis, with a resultant increase in fetal adrenocorticotrophic hormone and cortisol.[4,5] Fetal cortisol increases production of estradiol and decreases production of progesterone by a shift in placental metabolism of cortisol dependent on placental 17α-hydroxylase. The change in the progesterone/estradiol ratio stimulates placental production of oxytocin and PG, particularly $PGF_{2\alpha}$.[4] If this increase in fetal adrenocorticotrophic hormone and cortisol is blocked, parturition is delayed.[5] In contrast, humans lack placental 17α-hydroxylase and there is no increase in fetal cortisol near term. Rather, in humans, uterine activation may be potentiated in part by increased fetal adrenal production of dehydroepiandrostenedione, which is converted in the placenta to estradiol and estriol. Placental estriol stimulates an increase in maternal (likely decidual) $PGF_{2\alpha}$, PG receptors, oxytocin receptors, and gap junctions. In humans, there is no documented decrease in progesterone near term and a fall in progesterone is not necessary for labor initiation. However, some research suggests the possibility of a "functional progesterone withdrawal" in humans: Labor is accompanied by a decrease in the concentration of progesterone receptors, as well as a change in the ratio of progesterone receptor isoforms A and B in both the myometrium[6,7] and membranes.[8] More research is needed to elucidate the precise mechanism through which the human parturition cascade is activated. Fetal maturation may play an important role, as well as maternal

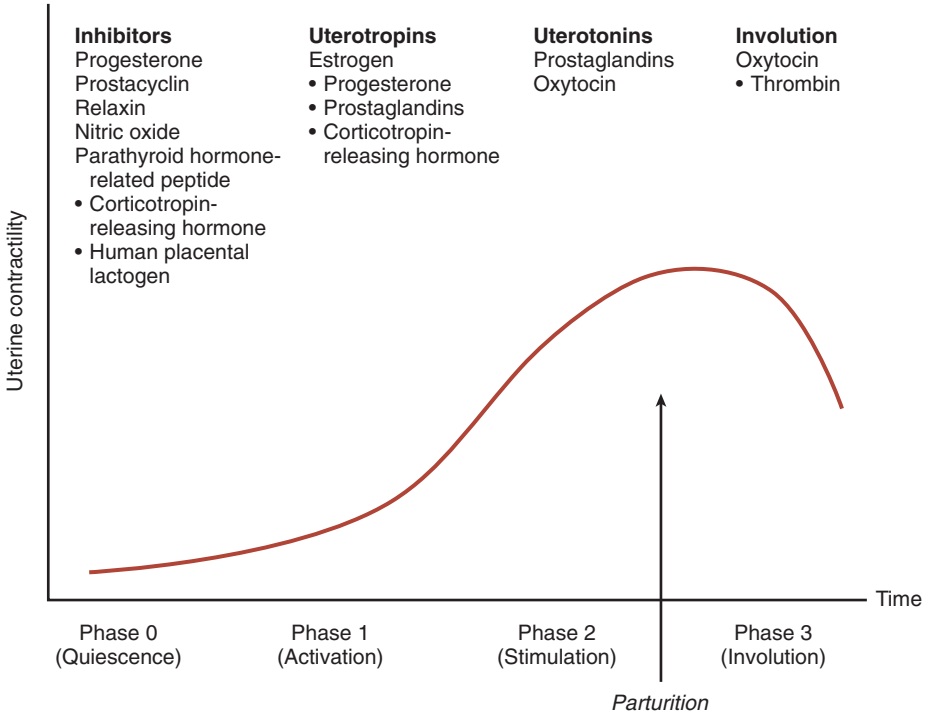

FIGURE 13-1. Regulation of uterine activity during pregnancy and labor. (Modified from Challis JRG, Gibb W: Control of parturition. Prenat Neonat Med 1:283, 1996.)

cues that affect circadian cycling. There are distinct diurnal patterns of contractions and delivery in most species, and in humans, the majority of contractions occur at night.[2,9]

Oxytocin is used commonly for labor induction and augmentation; a full understanding of the mechanism of oxytocin action is helpful. **Oxytocin is a peptide hormone synthesized in the hypothalamus and released from the posterior pituitary in a pulsatile fashion. At term, oxytocin is a potent uterotonic agent that is capable of stimulating uterine contractions at intravenous infusion rates of 1 to 2 mIU/min.**[10] **Oxytocin is inactivated largely in the liver and kidney, and during pregnancy, it is degraded primarily by placental oxytocinase. Its biologic half-life is approximately 3 to 4 minutes, but appears to be shorter when higher doses are infused.** Concentrations of oxytocin in the maternal circulation do not change significantly during pregnancy or before the onset of labor, but they do rise late in the second stage of labor.[10,11] Studies of fetal pituitary oxytocin production and the umbilical arteriovenous differences in plasma oxytocin strongly suggest that the fetus secretes oxytocin that reaches the maternal side of the placenta.[10,12] The calculated rate of active oxytocin secretion from the fetus increases from a baseline of 1 mIU/min before labor to around 3 mIU/min after spontaneous labor.

Significant differences in myometrial oxytocin receptor distribution have been reported, with large numbers of fundal receptors and fewer receptors in the lower uterine segment and cervix.[13] Myometrial oxytocin receptors increase on average by 100- to 200-fold during pregnancy, reaching a maximum during early labor.[10,11,14,15] This rise in receptor concentration is paralleled by an increase in uterine sensitivity to circulating oxytocin. Specific high-affinity oxytocin receptors have also been isolated from human amnion and decidua parietalis but not decidua vera.[10,13] **It has been suggested that oxytocin plays a dual role in parturition.** First, through its receptor, oxytocin directly stimulates uterine contractions. Second, oxytocin may act indirectly by stimulating the amnion and decidua to produce PG.[13,16,17] Indeed, even when uterine contractions are adequate, induction of labor at term is successful only when oxytocin infusion is associated with an increase in PGF production.[13]

Oxytocin binding to its receptor activates phospolipase C. In turn, phospholipase C increases intracellular calcium both by stimulating the release of intracellular calcium and by promoting the influx of extracellular calcium. Oxytocin stimulation of phospholipase C can be blocked by increased levels of cyclic adenosine monophosphate. Increased calcium levels stimulate the calmodulin-mediated activation of myosin light-chain kinase. Oxytocin may also stimulate uterine contractions via a calcium-independent pathway by inhibiting myosin phosphatase, which in turn increases myosin phosphorylation. **These pathways ($PGF_{2\alpha}$ and intracellular calcium) have been the target of multiple tocolytic agents: indomethacin, calcium channel blockers, beta mimetics (through stimulation of cyclic adenosine monophosphate), and magnesium.**

MECHANICS OF LABOR

Labor and delivery are not passive processes in which uterine contractions push a rigid object through a fixed aperture. The ability of the fetus to successfully negotiate the pelvis during labor and delivery depends on the complex interactions of three variables: uterine activity,

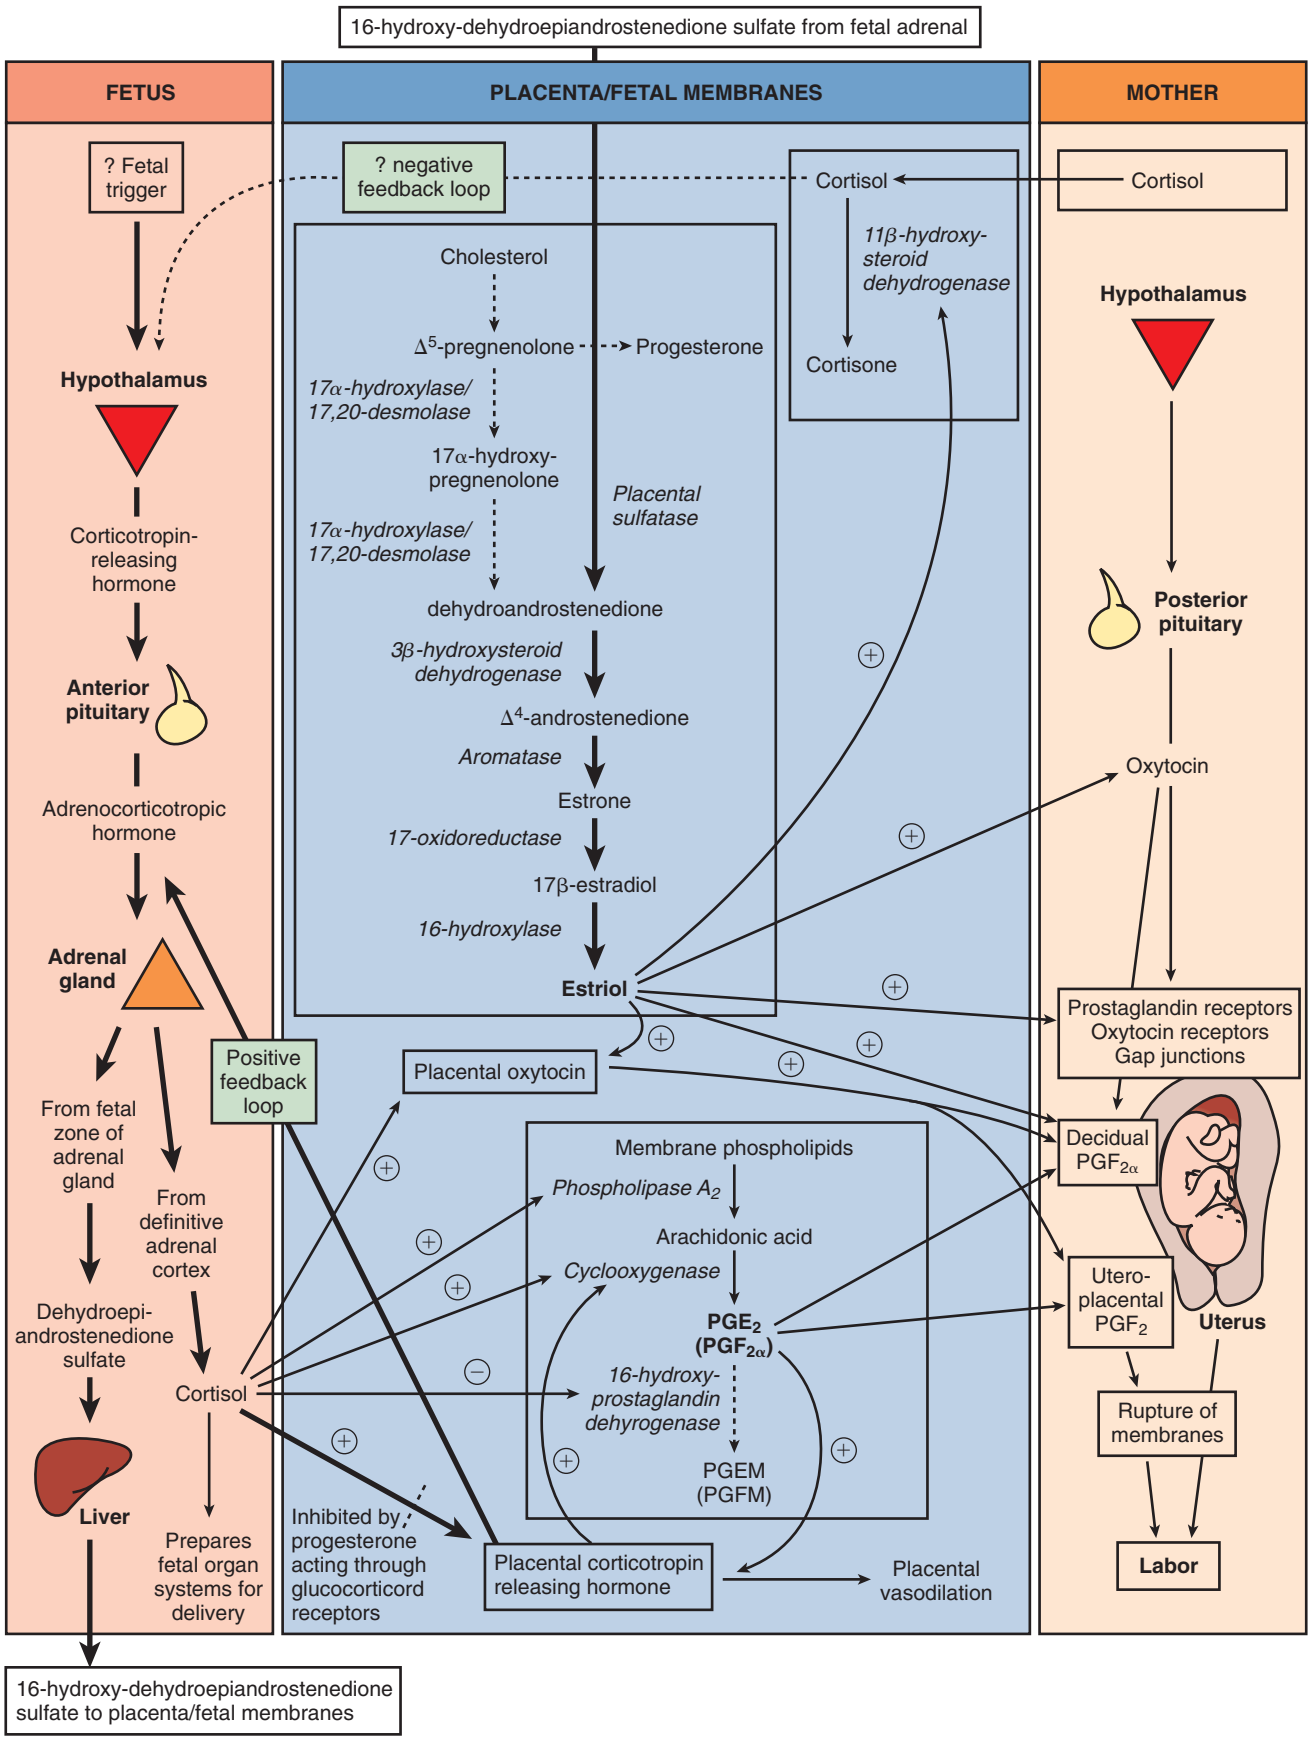

FIGURE 13-2. Proposed "parturition cascade" for labor induction at term. The spontaneous induction of labor at term in the human is regulated by a series of paracrine/autocrine hormones acting in an integrated parturition cascade responsible for promoting uterine contractions. *PGE_2,* Prostaglandin E_2; *PGEM,* 13, 14-dihydro-15-keto-PGE_2; *$PGF_{2\alpha}$,* prostaglandin $F_{2\alpha}$; *PGFM,* 13, 14-dihydro-15keto-$PGF_{2\alpha}$. (Modified from Norwitz ER, Robinson JN, Repke JT: The initiation of parturition: a comparative analysis across the species. Curr Prob Obstet Gynecol Fertil 22:41, 1999.)

the fetus, and the maternal pelvis (*Powers*, *Passenger*, *Passage*).

Uterine Activity (Powers)

The powers refer to the forces generated by the uterine musculature. Uterine activity is characterized by the frequency, amplitude (intensity), and duration of contractions. Assessment of uterine activity may include simple observation, manual palpation, external objective assessment techniques (such as external tocodynamometry), and direct measurement via an internal uterine pressure catheter (IUPC). External tocodynamometry measures the change in shape of the abdominal wall as a function of uterine contractions and, as such, is qualitative rather than quantitative. Although it permits graphic display of uterine activity and allows for accurate correlation of fetal heart rate patterns with uterine activity, external tocodynamometry does not allow measurement of contraction intensity or basal intrauterine tone. The most precise method for determination of uterine activity is the direct measurement of intrauterine pressure with an IUPC. However, this procedure should not be performed unless indicated given the small but finite associated risks of uterine perforation, placental disruption, and intrauterine infection.

Despite technologic improvements, the definition of "adequate" uterine activity during labor remains unclear. Classically, three to five contractions per 10 minutes has been used to define adequate labor; this pattern has been observed in approximately 95% of women in spontaneous labor. In labor, patients usually contract every 2 to 5 minutes, with contractions becoming as frequent as every 2 to 3 minutes in late active labor, as well as during the second stage. Abnormal uterine activity can also be observed either spontaneously or resulting from iatrogenic interventions. ***Tachysystole* is defined as more than five contractions in 10 minutes, averaged over 30 minutes. If tachysytole occurs, documentation should note the presence or absence of fetal heart rate (FHR) decelerations. The term *hyperstimulation* should no longer be used.**[18]

Various units have been devised to objectively measure uterine activity, the most common of which is the *Montevideo unit* (MVU), a measure of average frequency and amplitude above basal tone (the average strength of contractions in millimeters of mercury multiplied by the number of contractions per 10 minutes). Although 150 to 350 MVU has been described for adequate labor, 200 to 250 MVU is commonly accepted to define adequate labor in the active phase of labor.[19,20] There are no data that identify adequate forces during latent labor. Although it is generally believed that optimal uterine contractions are associated with an increased likelihood of vaginal delivery, there are limited data to support this assumption. If uterine contractions are "adequate" to effect vaginal delivery, one of two things will happen: either the cervix will efface and dilate, and the fetal head will descend, or there will be worsening caput succedaneum (scalp edema) and molding of the fetal head (overlapping of the skull bones) without cervical effacement and dilation. The latter situation suggests the presence of cephalopelvic disproportion (CPD), which can be either absolute (in which a given fetus is simply too large to negotiate a given pelvis) or relative (in which delivery of a given fetus through a given pelvis would be possible under optimal conditions, but is precluded by malposition or abnormal attitude of the fetal head), or pelvic outlet obstruction such as with uterine fibroids.

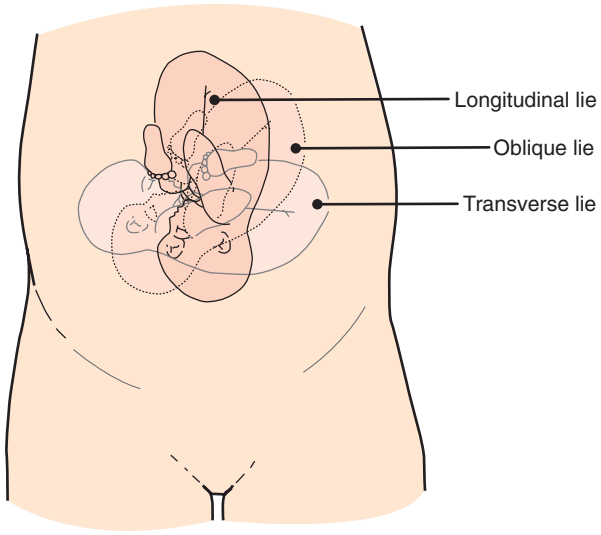

FIGURE 13-3. Examples of different fetal lie.

The Fetus (Passenger)

The passenger, of course, is the fetus. Several fetal variables influence the course of labor and delivery.

1. Fetal *size* can be estimated clinically by abdominal palpation or with ultrasound, but both are subject to a large degree of error. **Fetal macrosomia (defined by the American College of Obstetricians and Gynecologists [ACOG] as actual birth weight greater than 4500 g[21])** is associated with an increased likelihood of failed trial of labor and may be associated with labor abnormalities.[22]
2. ***Lie* refers to the longitudinal axis of the fetus relative to the longitudinal axis of the uterus**. Fetal lie can be longitudinal, transverse, or oblique (Figure 13-3). In a singleton pregnancy, only fetuses in a longitudinal lie can be safely delivered vaginally.
3. ***Presentation* refers to the fetal part that directly overlies the pelvic inlet.** In a fetus presenting in the longitudinal lie, the presentation can be cephalic (vertex) or breech. Compound presentation refers to the presence of more than one fetal part overlying the pelvic inlet, such as a fetal hand and the vertex. Funic presentation refers to presentation of the umbilical cord and is rare at term. In a cephalic fetus, the presentation is classified according to the leading bony landmark of the skull, which can be either the occiput (vertex), the chin (mentum), or the brow (Figure 13-4). *Malpresentation*, referring to any presentation other than vertex, is seen in approximately 5% of all term labors.
4. ***Attitude* refers to the position of the head with regard to the fetal spine (the degree of flexion and/or extension of the fetal head).** Flexion of the head is important to facilitate *engagement* of the head in the maternal pelvis. When the fetal chin is optimally

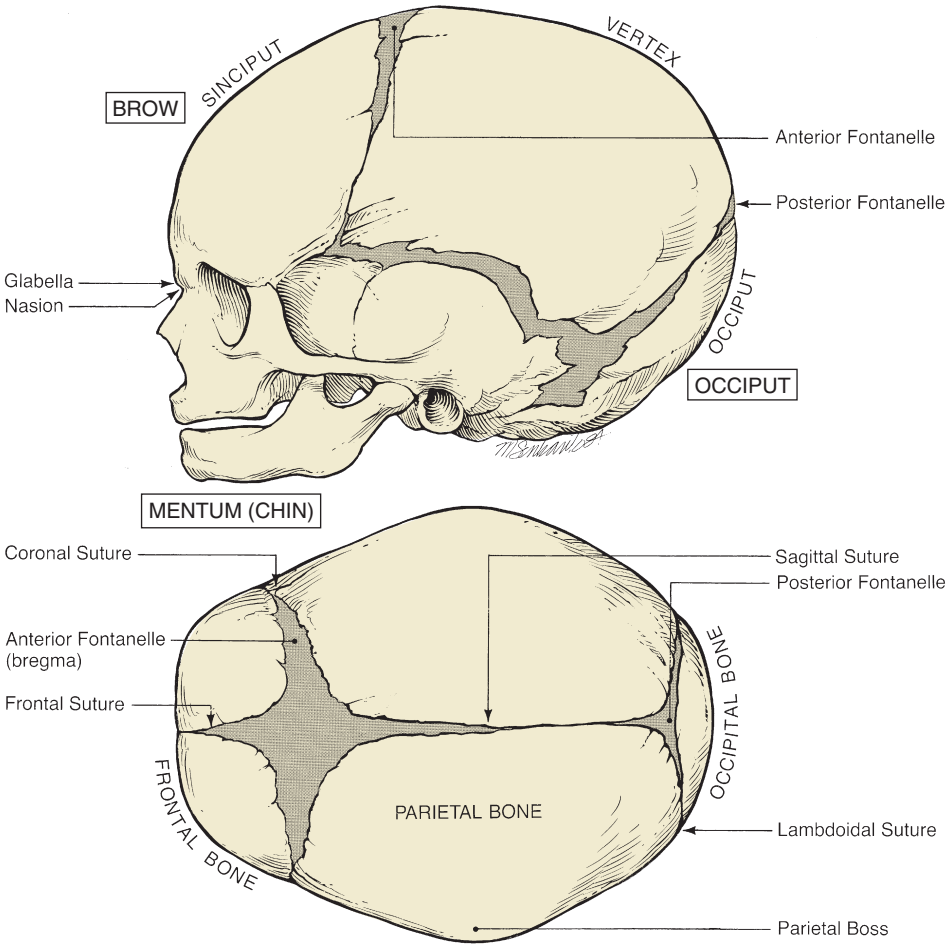

FIGURE 13-4. Landmarks of fetal skull for determination of fetal position.

flexed onto the chest, the suboccipitobregmatic diameter (9.5 cm) presents at the pelvic inlet (Figure 13-5). This is the smallest possible presenting diameter in the cephalic presentation. As the head deflexes (extends), the diameter presenting to the pelvic inlet progressively increases even before the malpresentations of brow and face are encountered (see Figure 13-5), and may contribute to failure to progress in labor. The architecture of the pelvic floor along with increased uterine activity may correct deflexion in the early stages of labor.

5. ***Position* of the fetus refers to the relationship of the fetal presenting part to the maternal pelvis, and it can be assessed most accurately on vaginal examination.** For cephalic presentations, the fetal occiput is the reference. If the occiput is directly anterior, the position is occiput anterior (OA). If the occiput is turned toward the mother's right side, the position is right occiput anterior (ROA). In the breech presentation, the sacrum is the reference (right sacrum anterior). The various positions of a cephalic presentation are illustrated in Figure 13-6. In a vertex presentation, position can be determined by palpation of the fetal sutures. The sagittal suture is the easiest to palpate. Palpation of the distinctive lamdoid sutures should identify the position of the fetal occiput. The frontal suture can also be used to determine the position of the front of the vertex. Most commonly, the fetal head enters the pelvis in a transverse position and, then as a normal part of labor, rotates to an OA position. Most fetuses deliver in the OA, LOA, or ROA position. In the past, less than 10% of presentations were occiput posterior (OP) at delivery.[23] However, epidural analgesia is associated with an increased risk of OP presentation (observed in 12.9% of women with epidural analgesia).[24]

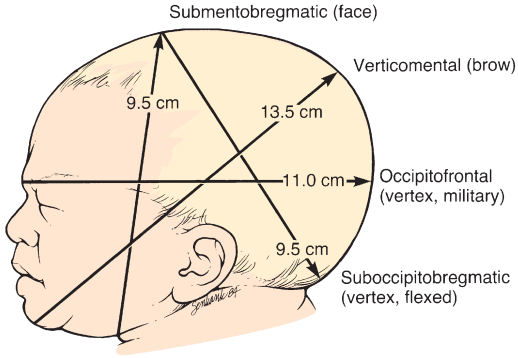

FIGURE 13-5. Presenting diameters of the average term fetal skull.

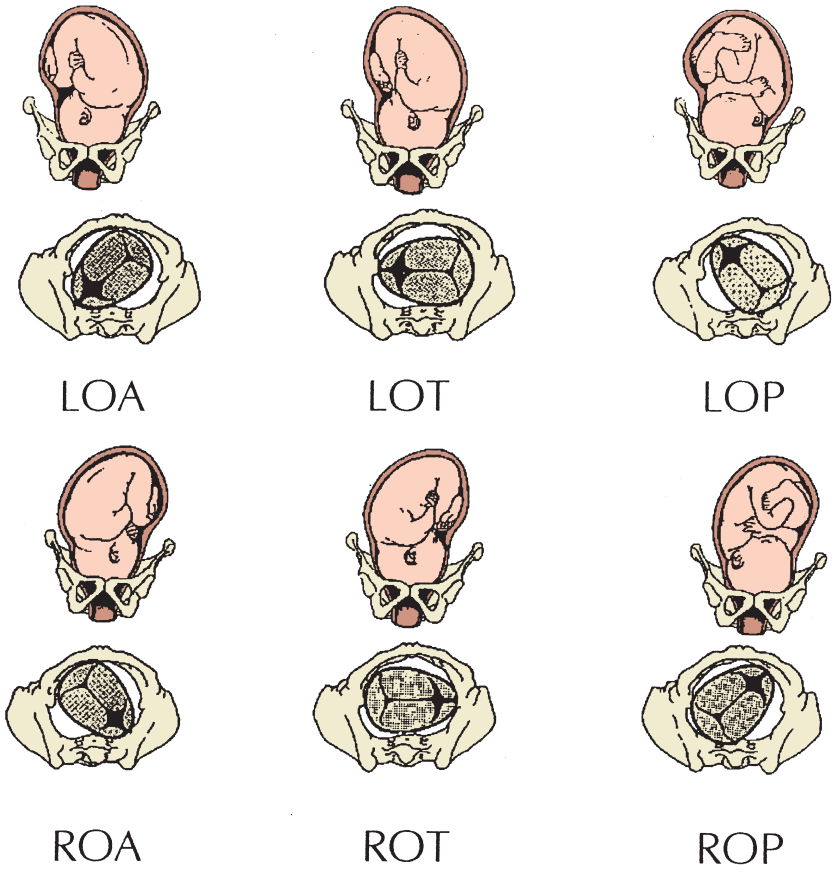

FIGURE 13-6. Fetal presentations and positions in labor. *LOA,* Left occiput anterior; *LOP,* left occiput posterior; *LOT,* left occiput transverse; *ROA,* right occiput anterior; *ROT,* right occiput transverse; *ROP,* right occiput posterior. (Modified from Norwitz ER, Robinson J, Repke JT: The initiation and management of labor. *In* Seifer DB, Samuels P, Kniss DA [eds]: The Physiologic Basis of Gynecology and Obstetrics. Philadelphia, Lippincott Williams & Wilkins, 2001.)

Asynclitism occurs when the sagittal suture is not directly central relative to the maternal pelvis. If the fetal head is turned such that more parietal bone is present posteriorly, the sagittal suture is more anterior and this is referred to as posterior asynclitism. Anterior asynclitism occurs when there is more parietal bone presenting anteriorly. The occiput transverse (OT) and OP positions are less common at delivery and more difficult to deliver. *Malposition* refers to any position in labor that is not ROA, OA, or LOA.

6. ***Station* is a measure of descent of the bony presenting part of the fetus through the birth canal** (Figure 13-7). The current standard classification (–5 to +5) is based on a quantitative measure in centimeters of the distance of the leading bony edge from the ischial spines. The midpoint (0 station) is defined as the plane of the maternal ischial spines. The ischial spines can be palpated on vaginal examination at approximately 8 o'clock and 4 o'clock. For the right-handed person, they are most easily felt on the maternal right.

An abnormality in any of these fetal variables may affect both the course of labor and the likelihood of vaginal delivery. For example, OP presentation is well known to be associated with longer labor.[25]

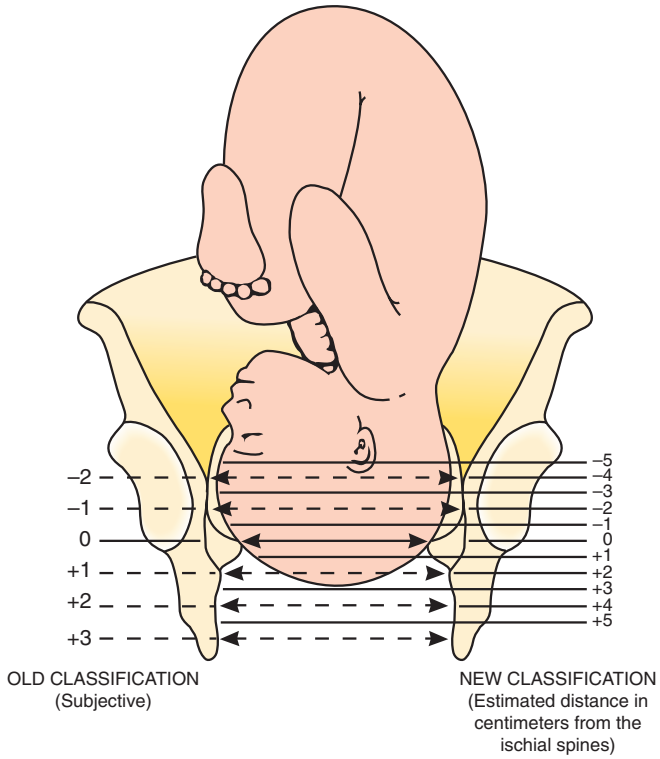

FIGURE 13-7. The relationship of the leading edge of the presenting part of the fetus to the plane of the maternal ischial spines determines the station. Station +1/+3 (old classification) or +2/+5 (new classification) is illustrated.

The Maternal Pelvis (Passage)

The passage consists of the bony pelvis (composed of the sacrum, ilium, ischium, and pubis) and the resistance

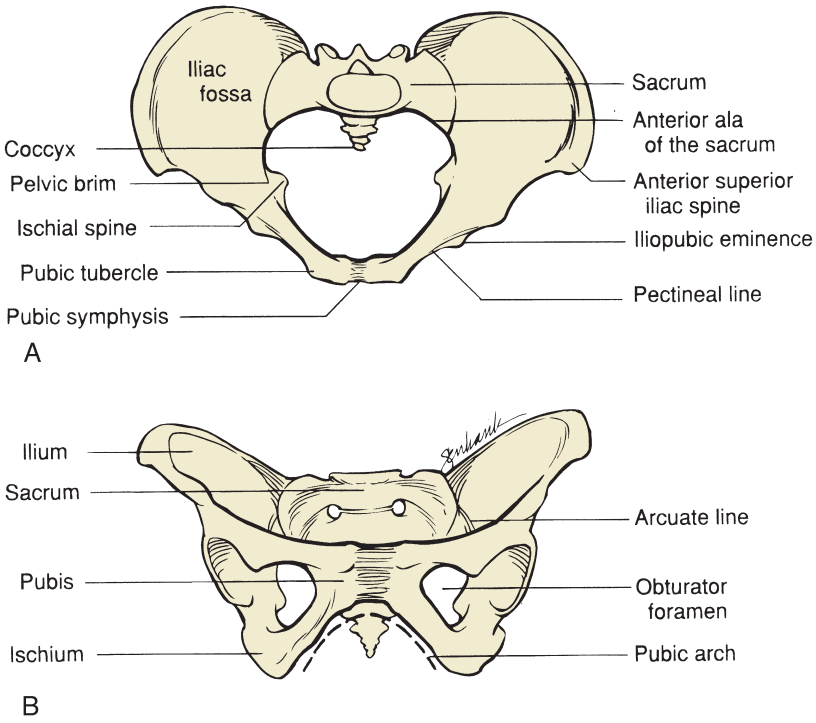

FIGURE 13-8. Superior **(A)** and anterior **(B)** view of the female pelvis. (From Repke JT: Intrapartum Obstetrics. New York, Churchill Livingstone, 1996, p 68.)

provided by the soft tissues. The bony pelvis is divided into the false (greater) and true (lesser) pelvis by the pelvic brim, which is demarcated by the sacral promontory, the anterior ala of the sacrum, the arcuate line of the ilium, the pectineal line of the pubis, and the pubic crest culminating in the symphysis (Figure 13-8). Measurements of the various parameters of the bony female pelvis have been made with great precision, directly in cadavers and using radiographic imaging in living women. Such measurements have divided the true pelvis into a series of planes that must be negotiated by the fetus during passage through the birth canal, which can be broadly classified into the pelvic inlet, midpelvis, and pelvic outlet. X-ray pelvimetry and computed tomography (CT) have been used to define average and critical limit values for the various parameters of the bony pelvis (Table 13-1).[26,27] Critical limit values are measurements that are associated with a significant probability of CPD.[26] **However, CT and x-ray pelvimetry are rarely used, having been replaced by a clinical trial of the pelvis (labor).** The remaining indications for x-ray or CT pelvimetry are evaluation for vaginal breech delivery or evaluation of a woman who has suffered a significant pelvic fracture.[28]

Clinical pelvimetry is currently the only method of assessing the shape and dimensions of the bony pelvis in labor. A useful protocol for clinical pelvimetry is detailed in Figure 13-9 and involves the assessment of the pelvic inlet, midpelvis, and pelvic outlet. The inlet of the true pelvis is largest in its transverse diameter (usually greater than 12.0 cm). The *diagonal conjugate* (the distance from the sacral promontory to the inferior margin of the symphysis pubis as assessed on vaginal examination) is a clinical representation of the anteroposterior diameter of the pelvic inlet. The *true conjugate* (or *obstetric conjugate*) of the pelvic inlet is the distance from the sacral promontory to the superior aspect of the symphysis pubis. This measurement cannot be made clinically but can be estimated by subtracting 1.5 to 2.0 cm from the diagonal conjugate. This is the smallest diameter of the inlet, and it usually measures approximately 10 to 11 cm. The limiting factor in the midpelvis is the interspinous diameter (the measurement between the ischial spines), which is usually the smallest diameter of the pelvis but should be greater than 10 cm. The pelvic outlet is rarely of clinical significance. The anteroposterior diameter from the coccyx to the symphysis pubis is approximately 13 cm in most cases, and the transverse diameter between the ischial tuberosities is approximately 8 cm.

The shape of the female bony pelvis can be classified into four broad categories: gynecoid, anthropoid, android, and platypelloid (Figure 13-10). This classification, based

TABLE 13-1 AVERAGE AND CRITICAL LIMIT VALUES FOR PELVIC MEASUREMENTS BY X-RAY PELVIMETRY

DIAMETER	AVERAGE VALUE	CRITICAL LIMIT*
Pelvic Inlet		
Anteroposterior (cm)	12.5	10.0
Transverse (cm)	13.0	12.0
Sum (cm)	25.5	22.0
Area (cm^2)	145.0	123.0
Pelvic Midcavity		
Anteroposterior (cm)	11.5	10.0
Transverse (cm)	10.5	9.5
Sum (cm)	22.0	19.5
Area (cm^2)	125.0	106.0

on the radiographic studies of Caldwell and Moloy, separates those with more favorable characteristics (gynecoid, anthropoid) from those that are less favorable for vaginal delivery (android, platypelloid).[29] In reality, however, many women fall into intermediate classes, and the distinctions become arbitrary. The gynecoid pelvis is the classic female shape. The anthropoid pelvis with its exaggerated oval shape of the inlet, largest anterioposterior diameter, and limited anterior capacity is more often associated with delivery in the OP position. The android pelvis is male in pattern and theoretically has an increased risk of CPD, and the platypelloid pelvis with its broad, flat pelvis theoretically predisposes to a transverse arrest. Although the assessment of fetal size along with pelvic shape and capacity is still of clinical utility, it is a very inexact science. An adequate trial of labor is the only definitive method to determine whether a given fetus will be able to safely negotiate a given pelvis.

Pelvic soft tissues may provide resistance in both the first and second stages of labor. In the first stage, resistance is offered primarily by the cervix, whereas in the second stage, it is offered by the muscles of the pelvic floor. In the second stage of labor, the resistance of the pelvic musculature is believed to play an important role in the rotation and movement of the presenting part through the pelvis.

CARDINAL MOVEMENTS IN LABOR

The mechanisms of labor, also known as the cardinal movements, refer to the changes in position of fetal head during its passage through the birth canal. Because of the asymmetry of the shape of both the fetal head and the maternal bony pelvis, such rotations are required for the fetus to successfully negotiate the birth canal. **Although labor and birth comprise a continuous process, seven discrete cardinal movements of the fetus are described: engagement, descent, flexion, internal rotation, extension, external rotation or restitution, and expulsion** (Figure 13-11).

Engagement

Engagement refers to passage of the widest diameter of the presenting part to a level below the plane of the pelvic inlet (Figure 13-12). In the cephalic presentation with a well-flexed head, the largest transverse diameter of the fetal head is the biparietal diameter (9.5 cm). In the breech, the widest diameter is the bitrochanteric diameter. Clinically, engagement can be confirmed by palpation of the presenting part both abdominally and vaginally. With a cephalic presentation, engagement is achieved when the presenting part is at 0 station on vaginal examination. Engagement is considered an important clinical prognostic sign because it demonstrates that, at least at the level of the pelvic inlet,

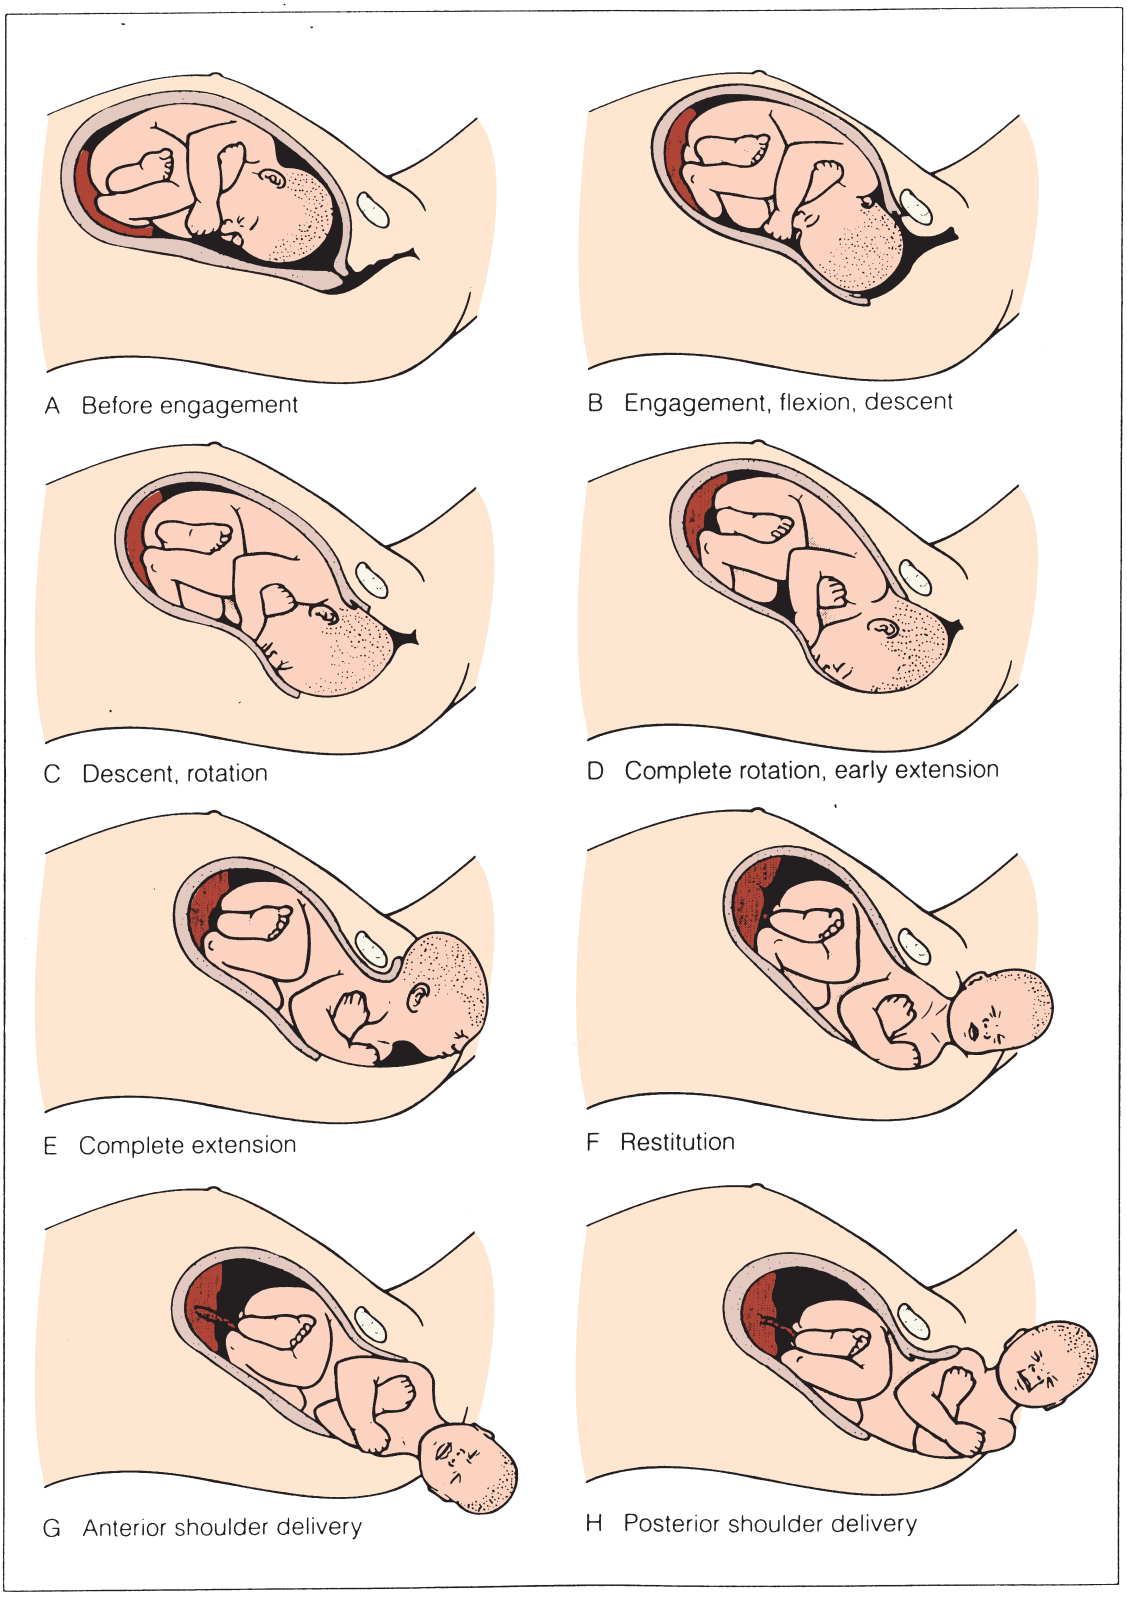

FIGURE 13-11. Cardinal movements of labor.

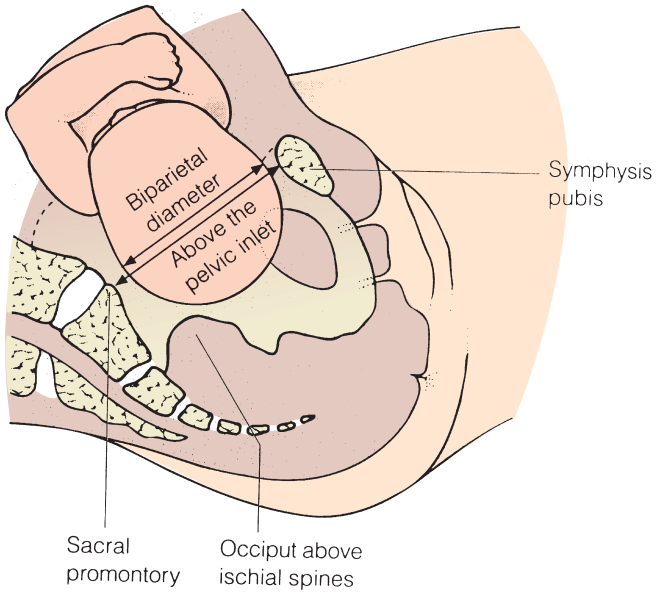

FIGURE 13-12. Engagement of the fetal head.

the maternal bony pelvis is sufficiently large to allow descent of the fetal head. In nulliparas, engagement of the fetal head usually occurs by 36 weeks' gestation. In multiparas, however, engagement can occur later in gestation or even during the course of labor.

Descent

Descent refers to the downward passage of the presenting part through the pelvis. Descent of the fetus is not continuous; the greatest rates of descent occur during the deceleration phase of the first stage of labor and during the second stage of labor.

Flexion

Flexion of the fetal head occurs passively as the head descends owing to the shape of the bony pelvis and the resistance offered by the soft tissues of the pelvic floor. Although flexion of the fetal head onto the chest is present to some degree in most fetuses before labor, complete flexion usually occurs only during the course of labor. The result of complete flexion is to present the smallest diameter of the fetal head (the suboccipitobregmatic diameter) for optimal passage through the pelvis.

Internal Rotation

Internal rotation refers to rotation of the presenting part from its original position as it enters the pelvic inlet (usually OT) to the anteroposterior position as it passes through the pelvis. As with flexion, internal rotation is a passive movement resulting from the shape of the pelvis and the pelvic floor musculature. The pelvic floor musculature, including the coccygeus and ileococcygeus muscles, forms a V-shaped hammock that diverges anteriorly. As the head descends, the occiput of the fetus rotates toward the symphysis pubis (or, less commonly, toward the hollow of the sacrum), thereby allowing the widest portion of the fetus to negotiate the pelvis at its widest dimension. Owing to the angle of inclination between the maternal lumbar spine and pelvic inlet, the fetal head engages in an asynclitic fashion (i.e., with one parietal eminence lower than the other). With uterine contractions, the leading parietal eminence descends and is first to engage the pelvic floor. As the uterus relaxes, the pelvic floor musculature causes the fetal head to rotate until it is no longer asynclitic.

Extension

Extension occurs once the fetus has descended to the level of the introitus. This descent brings the base of the occiput into contact with the inferior margin at the symphysis pubis. At this point, the birth canal curves upward. The fetal head is delivered by extension and rotates around the symphysis pubis. The forces responsible for this motion are the downward force exerted on the fetus by the uterine contractions along with the upward forces exerted by the muscles of the pelvic floor.

External Rotation

External rotation, also known as restitution, refers to the return of the fetal head to the correct anatomic position in relation to the fetal torso. This can occur to either side depending on the orientation of the fetus. This is again a passive movement resulting from a release of the forces exerted on the fetal head by the maternal bony pelvis and its musculature and mediated by the basal tone of the fetal musculature.

Expulsion

Expulsion refers to delivery of the rest of the fetus. After delivery of the head and external rotation, further descent brings the anterior shoulder to the level of the symphysis pubis. The anterior shoulder is delivered in much the same manner as the head, with rotation of the shoulder under the symphysis pubis. After the shoulder, the rest of the body is usually delivered without difficulty.

NORMAL PROGRESS OF LABOR

Progress of labor is measured with multiple variables. With the onset of regular contractions, the fetus descends in the pelvis as the cervix both effaces and dilates. The clinician must assess not only cervical effacement and dilation but fetal station and position with each vaginal examination to judge labor progress. This assessment depends on skilled digital palpation of the maternal cervix and the presenting part. In labor, the cervix shortens (becomes more effaced). Cervical effacement refers to the length of the remaining cervix and can be reported in length or as a percentage. If percentage is used, 0% effacement refers to at least a 2 cm long or a very thick cervix, and 100% effacement refers to no length remaining or a very thin cervix. Most clinicians use percentage to follow cervical effacement during labor. Generally, 80% or greater effacement is required for the diagnosis of active labor. Dilation, perhaps the easiest assessment to master, ranges from closed (no dilation) to complete (10 cm dilated). For most people, a cervical dilation that accommodates a single index finger is equal to 1 cm and 2 index fingers dilation is equal to 3 cm. If no cervix can be palpated around the presenting part, the cervix is 10 cm or completely dilated. The assessment of station (see earlier) is important for documentation

TABLE 13-2 Summary of Means and 95th Percentiles for Duration of First- and Second-Stage Labor

PARAMETER	MEAN	95th PERCENTILE
Nulliparas		
Latent labor	7.3-8.6 hr	17-21 hr
First stage	7.7-13.3 hr	16.6-19.4 hr
First stage, epidural	10.2 hr	19 hr
Second stage	53-57 min	122-147 min
Second stage, epidural	79 min	185 min
Multiparas		
Latent labor	4.1-5.3 hr	12-14 hr
First stage	5.7-7.5 hr	12.5-13.7 hr
First stage, epidural	7.4 hr	14.9 hr
Second stage, F2	17-19 min	57-61 min
Second stage, epidural	45 min	131 min

*An interval-censored regression model with a log normal distribution was fitted to adjust for maternal age, prepregnancy BMI, and gravidity.

of progress, but it is also critical when determining if an operative vaginal delivery is feasible. Fetal head position should be regularly determined once the woman is in active labor and ideally before significant caput has developed, obscuring the sutures. Like station, knowledge of the fetal position is critical before performing an operative vaginal delivery.

Labor has two categorizations: phases and stages. Phases are divided into latent and active. The *latent phase* of labor is defined as the period between the onset of labor and the point when labor becomes active. The onset of labor is difficult to identify objectively. Usually, it is defined by the initiation of regular painful contractions. Women are frequently at home at this time; therefore, the identification of labor onset depends on patient memory, and hence the length of latent labor is difficult to truly quantify. The beginning of active labor is a retrospective diagnosis because the definition of the active phase of labor is when the slope of cervical dilation accelerates. **In general, active labor requires ≥80% effacement and ≥4 cm dilation of the cervix, but the dilation at which active labor begins is particularly variable.**

In addition, there are three stages of labor. The first stage is from labor onset until full dilation. The second stage is from full dilation until delivery of the baby, and the third stage is from the delivery of the baby until the delivery of the placenta.

The work of Dr. Emanuel Friedman in the 1950s and 1960s was seminal to the current knowledge of labor progress. He analyzed labor progress in 500 nulliparous and multiparous women, and reported normative data that are still useful today.[30,31] Of note, Friedman's second-stage lengths are somewhat artificial because most nulliparous women in that era had a forceps delivery once the duration of the second stage reached 2 hours. More recent data evaluating women in spontaneous labor without augmentation or operative delivery from multiple countries are amazingly similar in the means, suggesting that these normative data are reliable and useful (Table 13-2).[32-35] Of interest, epidural use appears to add about 2 hours to the first stage and about 20 minutes to the second stage in both multiparous and nulliparous women.[35] Friedman's data popularized the use of the labor graph, first depicting only cervical dilation and then modified to include descent and dilation.[37] **Rates of 1.5 cm and 1.2 cm dilation per hour in the active phase for multiparous and nulliparous women, respectively, represent the 5th percentile for rates of dilation[31] and have led to the general concept that in active labor, dilation of at least 1 cm per hour should occur** (Table 13-3). More recent analysis of data from the National Collaborative Perinatal Project, the same data evaluated by Friedman, suggested that progress in active labor in women who ultimately have a vaginal delivery is in fact faster but that these women enter active labor later than initially described.[36] Specifically, most nulliparous women were not in active labor until approximately 5-6 cm and the slope of labor progress did not really increase until after 6 cm. This is an important finding and suggests that clinicians may be diagnosing active phase arrest too early, which could result in unnecessary cesarean deliveries[36,37] (see Chapter 14). The time when an individual patient enters the active phase becomes obvious only retrospectively, as noted earlier, and is more difficult to recognize in nulliparous women.[36]

A more practical approach to following labor progress was introduced by Schulman and Ledger, when they published a modified labor graph that evaluated labor progress focused on latent and active phase only, and this is the graph most commonly used today (Figure 13-13).[38] When evaluating labor progress, it is extremely important to understand that progress in latent phase is slower and less predictable both in multiparas and nulliparas. Factors affecting the duration of labor include parity, maternal body mass index, fetal position, maternal age, and fetal size. Longer labors are associated with increased maternal body mass index,[39] fetal position other than OA,[40] and older maternal age.[41,42] **Factors significantly associated with a prolonged second stage included induced labor, chorioamnionitis, older maternal age, non–African American ethnicity, and parity ≥5.**[41,43] Limits of lengths of first and second stages incorporating the effect of epidural use are helpful in identifying those women who may benefit from interventions (see Table 13-2).[32,34,35]

Mean lengths of the third stage of labor are not affected by parity. In a case series of nearly 13,000 singleton vaginal deliveries greater than 20 weeks' gestation, the median

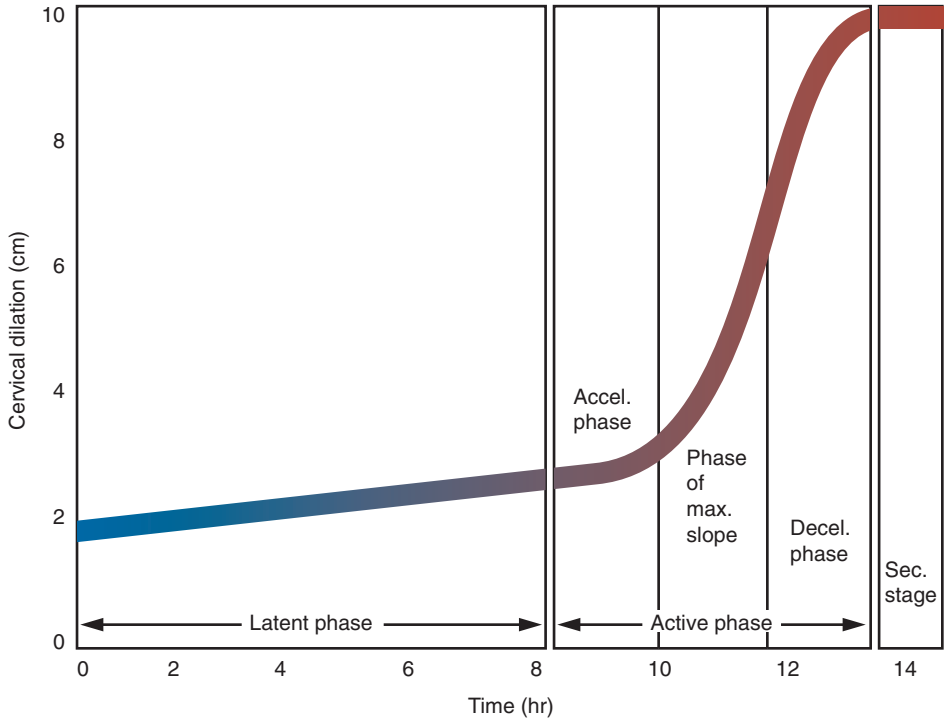

FIGURE 13-13. Modern labor graph. Characteristics of the average cervical dilation curve for nulliparous labor. (Modified from Friedman EA: Labor: Clinical Evaluation and Management, ed 2. Norwalk, CT, Appleton-Century-Crofts, 1978.)

third stage duration was 6 minutes and exceeded 30 minutes in only 3% of women.[44] A threshold of 30 minutes was associated with a significantly increased risk of a greater than 500 mL blood loss, a drop in postdelivery hematocrit by greater than or equal to 10%, or a need for dilation and curettage.[44] This suggests that manual removal and/or extraction of the placenta is indicated after 30 minutes.

Interventions Affecting Normal Labor Outcomes

Various interventions have been suggested to promote normal labor progress, including maternal ambulation during active labor (Figure 13-14). However, a well-designed randomized trial of over 1000 women in active labor comparing ambulation with usual care found no differences in the duration of the first stage, need for oxytocin, use of analgesia, or route of delivery.[45] In contrast, upright rather than recumbent positioning during labor was associated with significantly shorter first stage of labor and less epidural use.[46] In addition, the presence of a labor doula compared with no support was associated with a significant reduction in use of analgesia, oxytocin, and operative or cesarean delivery and an increase in satisfaction by the woman.[47] These data were compelling enough for doula support in labor to receive an A rating, meaning that it should be recommended for use during labor.[48] **In a randomized trial of nulliparas in active labor, IV administration at 125 mL/min of D_5NS was associated with a significant reduction in labor length and in second stage length compared to NS.**[49]

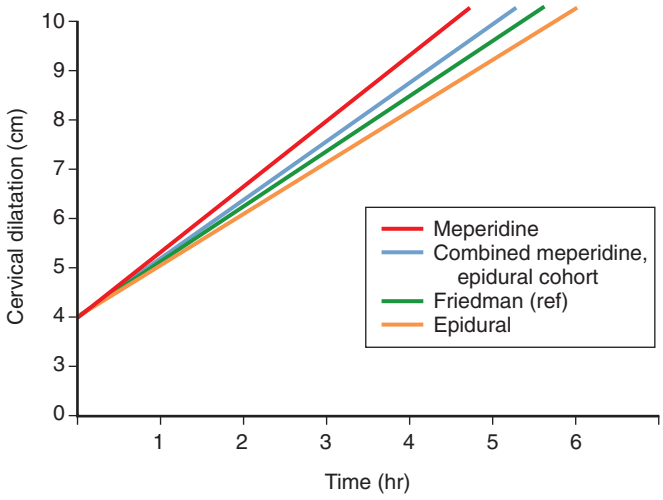

FIGURE 13-14. Comparison of the rates of cervical dilation during the active phase of labor originally reported by Friedman and now reported for the women who received patient-controlled intravenous meperidine, patient-controlled epidural analgesia, and the combined cohort. (From Alexander JM, Sharma SK, McIntire DD, Leveno KJ: Epidural analgesia lengthens the Friedman active phase of labor. Obstet Gynecol 100:46, 2002.)

Active Management of Labor

Dystocia is lack of progress of labor for any reason and is the second most common indication for cesarean delivery, following previous cesarean delivery. In the late 1980s, in an effort to reduce the rapidly rising cesarean delivery rate, active management of labor was popularized in the United States based on findings in Ireland, where the routine use

of active management was associated with very low rates of cesarean delivery.[50] Protocols for active management included admission only when labor was established (painful contractions and spontaneous rupture of membranes, 100% effacement, or passage of blood-stained mucus); artificial rupture of membranes on diagnosis of labor; aggressive oxytocin augmentation for labor progress of less than 1 cm/hr with high-dose oxytocin (6 mIU/min initial dose, increased by 6 mIU/min every 15 minutes to a maximum of 40 mIU/min); and patient education.[50] Observational data suggested that this management protocol was associated with rates of cesarean delivery of 5.5% and delivery within 12 hours in 98% of women.[50] Only 41% of the nulliparas actually required oxytocin augmentation. Multiple nonrandomized studies were subsequently published attempting to duplicate these results in the United States and Canada.[51-54] Two of these reported a significant reduction in cesarean delivery when compared with historical controls.[51,53] However, in two of three randomized controlled trials (RCTs), there was no significant decrease in the rate of cesarean delivery with active compared with routine management of labor.[55,56] In the third RCT, the overall cesarean delivery rate was not significantly different; however, when confounding variables were controlled, cesarean delivery was significantly lower in the actively managed group.[54] In all randomized trials, labor duration was significantly decreased by a range of 1.7 to 2.7 hours, and neonatal morbidity was not different between groups. A recent Cochrane review concluded that early oxytocin augmentation in women with spontaneous labor was associated with a significant decrease in cesarean delivery. In addition, early amniotomy with oxytocin augmentation was associated with a significantly shortened labor.[57] Of note, amniotomy alone did not affect labor length or cesarean. This reduction in labor duration has significant cost and bed management implications, especially for busy labor and delivery units. Perhaps the most important factor in active management is delaying admission until active labor has been established.

Second Stage of Labor

Abnormal progress in fetal descent is the dystocia of the second stage. For practical purposes, second-stage durations of greater than 1 hour for multiparous women without an epidural, 2 hours for multiparous women with an epidural and nulliparous women without an epidural, and 3 hours for nulliparous women with an epidural identify women who are outliers, representing only 5% of women in these categories (see Table 13-2).[35] In nulliparous women vaginal delivery decreased, and chorioamnionitis, severe tears, and uterine atony increased significantly with second stages longer than 3 hours. However, neonatal outcome was not altered.[58] Although there is no indication that these limits should be used arbitrarily to justify ending the second stage, they identify a subset of women who require further evaluation.[58]

Other models include prospectively determined second-stage partograms in which the median second-stage lengths are similar to those outlined in Table 13-2.[59] Women with a prolonged second stage by these criteria should be evaluated for potential interventions. As with active labor, poor progress may be related to inadequate contractions; initiating oxytocin in the second stage may be effective if contraction frequency is diminished. If malposition is diagnosed, rotation to OA (either manually or by forceps) may be indicated in the second stage. If neither uterine forces nor fetal position are abnormal, the default diagnosis is cephalopelvic disproportion. No excess neonatal morbidity has been reported in association with a prolonged second stage in the absence of nonreassuring fetal heart rate tracings. Therefore, if steady progress is observed, there is no need for arbitrary time cut-offs.[60-64] In contrast, maternal morbidity, including perineal trauma, postpartum hemorrhage, and chorioamnionitis, is significantly higher in women with a second stage lasting longer than 2 or 3 hours.[58,64] However, it is important to note that performing an instrument-assisted vaginal delivery is unlikely to reduce perineal trauma and morbidity. If the fetal heart rate tracing is reassuring, continuing the second stage beyond 3 hours is reasonable. After 4 hours, the likelihood of vaginal delivery declines and maternal morbidity increases. The incidence of a vaginal delivery, including operative delivery, in nulliparous women with a second stage length of less than 2 hours, 2 to 4 hours, and longer than 4 hours is 98%, 81%, and 45%, respectively.[58]

Multiple factors influence the duration of the second stage, including epidural analgesia, nulliparity, older maternal age, longer active phase, larger birth weight, and excess maternal weight gain.[58,59] Modifiable factors that have been evaluated in the management of the second stage include maternal position, decreasing epidural analgesia (see Chapter 17), and delayed pushing. Two of three RCTs of decreased second-stage epidural analgesia found no difference in outcome or second-stage length.[65-67] One reported a decrease in second-stage length and operative delivery in the group that was randomized to reduced levels of epidural analgesia.[65] Epidural analgesia is clearly associated with an increased rate of operative delivery and associated perineal injury.[67,68] Delayed pushing has also been studied in nulliparas with epidural analgesia to determine if this strategy reduces the need for operative delivery, but little benefit has been demonstrated.[68-71] Only one trial reported a significant decrease in operative deliveries, and that was limited to midpelvic deliveries.[69] Conversely, the risk of delayed pushing appears to be negligible. Finally, the effect of maternal position has been evaluated.[72,73] Randomization to squatting using a birth cushion was associated with a significant reduction in operative deliveries and a significantly shorter second stage in nulliparas compared with delivery in the lithotomy position.[72] In a second trial randomizing women to either a routine delivery position or any upright position (squatting, kneeling, sitting, or standing per patient choice), no difference in operative deliveries was noted between groups but a significant increase in the percent of women with an intact perineum was noted in the upright group.[73] Therefore, allowing women to choose alternative positions during the second stage may be beneficial, especially in nulliparas.

SPONTANEOUS VAGINAL DELIVERY

Preparation for delivery should take into account the patient's parity, the progression of labor, fetal presentation, and any labor complications. Among women for whom

delivery complications are anticipated (shoulder dystocia risk factors or multiple gestation), transfer to a larger and better equipped delivery room, removal of the foot of the bed, and delivery in the lithotomy position may be appropriate. If no complications are anticipated, delivery can be accomplished with the mother in her preferred position. Common positions include the lateral (Sims) position or the partial sitting position.

The goals of clinical assistance at spontaneous delivery are the reduction of maternal trauma, prevention of fetal injury, and initial support of the newborn, if required. When the fetal head crowns and delivery is imminent, gentle pressure should be used to maintain flexion of the fetal head and to control delivery, potentially protecting against perineal injury. Once the fetal head is delivered, external rotation (restitution) is allowed. If a shoulder dystocia is anticipated, it is appropriate to proceed directly with gentle downward traction of the fetal head before restitution occurs. During restitution, nuchal umbilical cords should be identified and reduced; in rare cases in which simple reduction is not possible, the cord can be doubly clamped and transected. **There is no evidence that DeLee suction reduces the risk of meconium aspiration syndrome in the presence of meconium; thus this should not be performed.**[74] The anterior shoulder should then be delivered by gentle downward traction in concert with maternal expulsive efforts. The posterior shoulder is delivered by upward traction. These movements should be performed with the minimal force possible to avoid perineal injury and traction injuries to the brachial plexus. The timing of cord clamping is usually dictated by convenience and commonly performed immediately after delivery. However, an ongoing debate exists about the benefits and risks of late cord clamping to the newborn. One meta-analysis of trials comparing late (greater than 2 minutes) to immediate cord clamping in term babies showed a significant increase in infant hematocrit, ferrintin, and stored iron levels at 2 to 6 months.[75] However, there was also a significant increase in neonatal polycythemia in the delayed group. After delivery, the infant should be wiped dry and kept warm while any mucus remaining in the airway is suctioned. Keeping the infant warm is particularly important, and, because heat is lost quickly from the head, placing a hat on the infant is appropriate. If possible all of these steps can best be done with the infant on the mother's abdomen.

DELIVERY OF THE PLACENTA AND FETAL MEMBRANES

The third stage of labor can be managed either passively or actively. Passive management is characterized by patiently waiting for the classic signs of placental separation: (1) lengthening of the umbilical cord, and (2) a gush of blood from the vagina signifying separation of the placenta from the uterine wall. In addition, two techniques of controlled cord traction are commonly used to facilitate separation and delivery of the placenta: the *Brandt-Andrews maneuver* (in which an abdominal hand secures the uterine fundus to prevent uterine inversion while the other hand exerts sustained downward traction on the umbilical cord) or the *Créde maneuver* (in which the cord is fixed with the lower hand while the uterine fundus is secured and sustained upward traction is applied using the abdominal hand). Care should be taken to avoid avulsion of the cord. Active management with uterotonic agents such as oxytocin administered at delivery hasten delivery of the placenta and may reduce the incidence of postpartum hemorrhage and total blood loss.[76] Conversely, other studies have shown no benefit to active management in the second stage.[77]

After delivery, the placenta, umbilical cord, and fetal membranes should be examined. Placental weight (excluding membranes and cord) varies with fetal weight, with a ratio of approximately 1:6. Abnormally large placentae are associated with such conditions as hydrops fetalis and congenital syphilis. **Inspection and palpation of the placenta should include the fetal and maternal surfaces and may reveal areas of fibrosis, infarction, or calcification.** Although each of these conditions may be seen in the normal term placenta, extensive lesions should prompt histologic examination. Adherent clots on the maternal placental surface may indicate recent placental abruption; however, their absence does not exclude the diagnosis. A missing placental cotyledon or a membrane defect (suggesting a missing succenturiate lobe) suggests retention of a portion of placenta and should prompt further clinical evaluation. There is no need for routine manual exploration of the uterus after delivery unless there is suspicion of retained products of conception or a postpartum hemorrhage.

The site of insertion of the umbilical cord into the placenta should be noted. Abnormal insertions include marginal insertion (in which the cord inserts into the edge of the placenta) and membranous insertion (in which the vessels of the umbilical cord course through the membranes before attachment to the placental disk). The cord itself should be inspected for length, the correct number of umbilical vessels (normally two arteries and one vein), true knots, hematomas, and strictures. The average cord length is 50 to 60 cm. A single umbilical artery discovered on pathologic examination is associated with other fetal structural anomalies in 27% of cases.[78,79] Therefore, this finding should be relayed to the attending neonatologist or pediatrician. Any abnormalities of the placenta or cord should be noted in the mother's chart.

EPISIOTOMY, PERINEAL INJURY, AND PERINEAL REPAIR

Following delivery of the placenta, the vagina and perineum should be carefully examined for evidence of injury. If a laceration is seen, its length and position should be noted and repair initiated. Adequate analgesia (either regional or local) is essential for repair. Special attention should be paid to repair of the perineal body, the external anal sphincter, and the rectal mucosa. Failure to recognize and repair rectal injury can lead to serious long-term morbidity, most notably fecal incontinence. The cervix should be inspected for lacerations if an operative delivery was performed or if there is significant bleeding with or after the delivery.

Perineal injuries, either spontaneous or with episiotomy, are the most common complications of spontaneous or operative vaginal deliveries. **A first-degree tear is defined as a superficial tear confined to the epithelial layer and may**

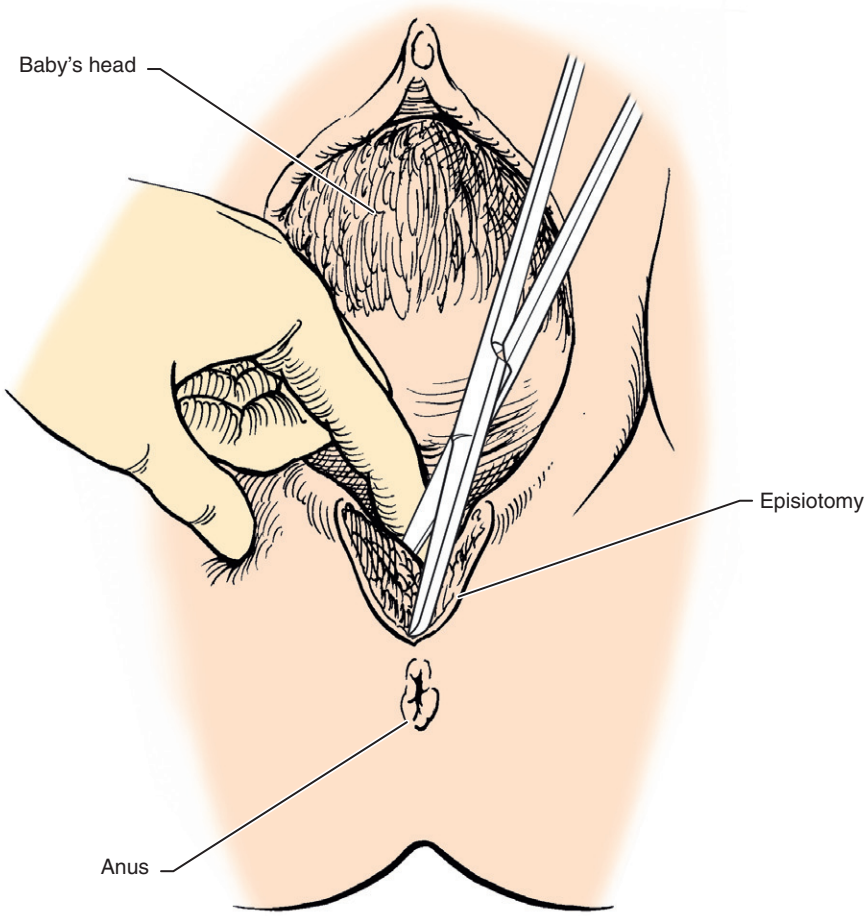

FIGURE 13-15. Cutting a midline episiotomy.

or may not need to be repaired generally depending on amount of bleeding. Second-degree tears extend into the perineal body, but not into the external anal sphincter. Third-degree tears involve superficial or deep injury to the external anal sphincter, whereas a fourth-degree tear extends completely through the sphincter and the rectal mucosa. All second-, third-, and fourth-degree tears should be repaired. Significant morbidity is associated with third- and fourth-degree tears, including risk of flatus and stool incontinence, rectovaginal fistula, infection, and pain. Primary approximation of perineal lacerations affords the best opportunity for functional repair, especially if there is evidence of rectal sphincter injury. The external anal sphincter should be repaired by direct apposition or overlapping the cut ends and securing them using interrupted sutures.

Episiotomy is an incision into the perineal body made during the second stage of labor to facilitate delivery. It is by definition a second-degree tear. Episiotomy can be classified into two broad categories: median (midline) and mediolateral. Median episiotomy refers to a vertical midline incision from the posterior forchette toward the rectum (Figure 13-15). After adequate analgesia, either local or regional, has been achieved, straight Mayo scissors are generally used to perform the episiotomy. Care should be taken to displace the perineum from the fetal head. The size of the incision depends on the length of the perineum but is generally approximately half of the length of the perineum and should be extended vertically up the vaginal mucosa for a distance of 2 to 3 cm. Every effort should be made to avoid direct injury to the anal sphincter. **Complications of median episiotomy include increased blood loss (especially if the incision is made too early), fetal injury, and localized pain.** With a mediolateral episiotomy, the incision is made at a 45-degree angle from the inferior portion of the hymeneal ring (Figure 13-16). The length of the incision is less critical than with median episiotomy, but longer incisions require lengthier repair. The side to which the episiotomy is performed is usually dictated by the dominant hand of the practitioner. Because such incisions appear to be moderately protective against severe perineal trauma, they are the procedure of choice for women with inflammatory bowel disease, if an episiotomy is needed, because of the critical need to prevent rectal injury. Historically, it was believed that episiotomy improved outcome by reducing pressure on the fetal head, protecting the maternal perineum from extensive tearing, and subsequent pelvic relaxation. However, consistent data since the late 1980s confirm that midline episiotomy does not protect the perineum from further tearing and data do not show that episiotomy improves neonatal outcome.[64,80,81] Midline episiotomy was associated with a significant increase of third- and fourth-degree lacerations in spontaneous vaginal

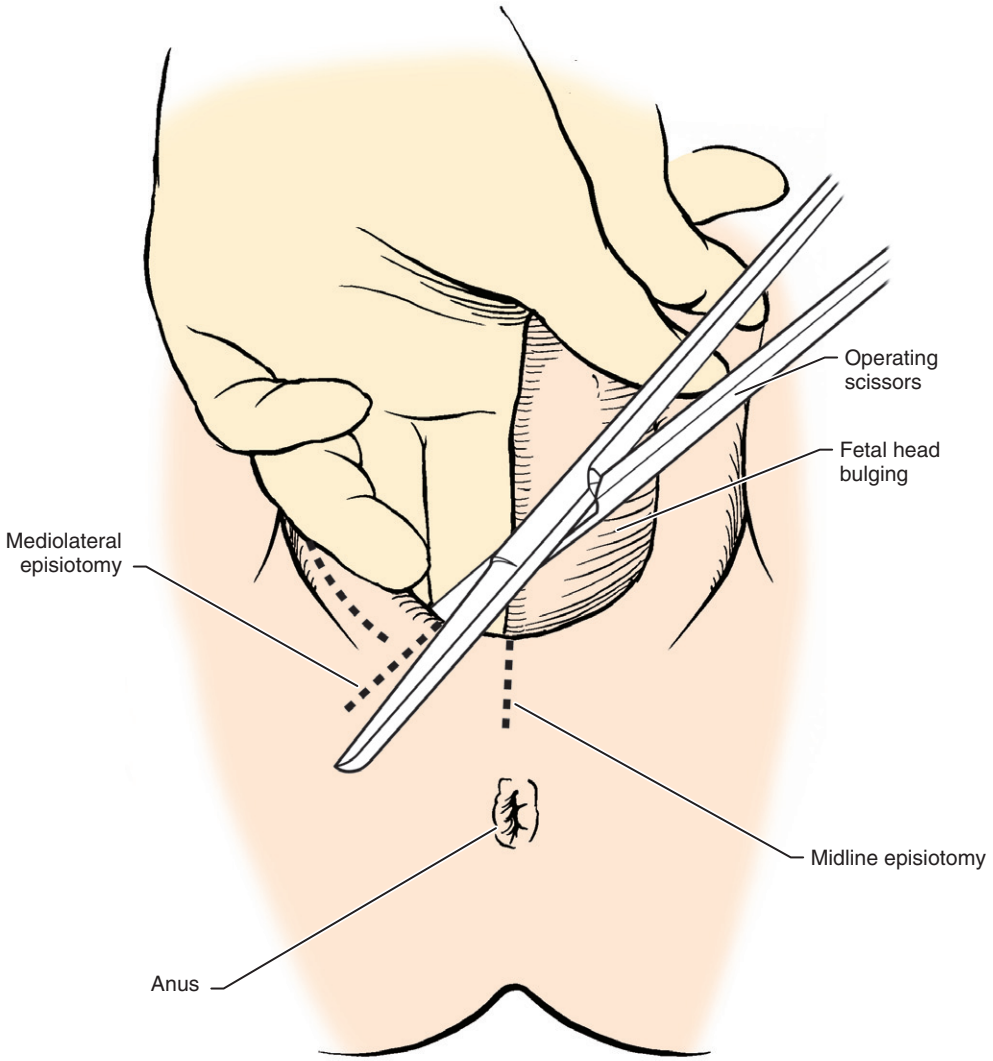

FIGURE 13-16. Cutting a mediolateral episiotomy.

delivery in nulliparous women with both spontaneous and operative vaginal delivery.[81-87] Episiotomy had the highest odds ratio (OR 3.2; CI 2.73-3.80) for anal sphincter laceration in a large study of nulliparous women when compared to other risk factors, including forceps delivery.[88] Fewer papers reported that midline episiotomy was associated with no difference in fourth-degree tears compared to no episiotomy.[89] **Based on the lack of consistent evidence that episiotomy is of benefit, there is no role for routine episiotomy in modern obstetrics.**[80,81,90,91] In fact, a recent evidence-based review recommended that episiotomy should be avoided if possible, based on U.S. Preventive Task Force quality of evidence.[48] Based on these data and ACOG recommendations,[91] rates of midline episiotomy have decreased, although episiotomies are performed in 10% to 17% of deliveries, suggesting that elective episiotomy continues to be performed.[83,92] Decreasing episiotomy rates from 87% in 1976 to 10% in 1994 were associated with a parallel decrease in the rates of third- or fourth-degree lacerations (9% to 4%) and an increase in the incidence of an intact perineum (10% to 26%).[83] Randomized trials comparing routine to indicated use of episiotomy report a 23% reduction in perineal lacerations requiring repair in the indicated group (11% to 35%).[92] Finally, a recent Cochrane review of eight randomized trials comparing restrictive to routine use of episiotomy showed a significant reduction of severe perineal tears, suturing, and healing complications in the restrictive group.[93] Although the restrictive episiotomy group had a significantly higher incidence of anterior tears, there was no difference in pain measures between the groups. All of these findings were similar whether median or mediolateral episiotomy was used.

The relationship of episiotomy to subsequent pelvic relaxation and incontinence has been evaluated, with no studies suggesting that episiotomy reduces risk of incontinence. Clearly, fourth-degree tears are associated with future incontinence.[94] Neither midline nor mediolateral episiotomy was associated with a reduction in incontinence.[95] **Therefore, there are no data to suggest that episiotomy protects the woman from later incontinence and avoidance of fourth-degree tear should be a priority.**

If an episiotomy is deemed indicated, the decision of which type to perform rests on their individual risks. It

does appear that mediolateral episiotomy is associated with fewer fourth-degree tears compared to median episiotomy.[96-98] However, other studies do not show benefit of mediolateral over median for future prolapse.[95] Chronic complications such as unsatisfactory cosmetic results and inclusions within the scar may be more common with mediolateral episiotomies, and blood loss is greater. Finally, it must be remembered that neither episiotomy type has been shown to reduce severe perineal tears compared to no episiotomy.

Although there is no role for routine episiotomy, indicated episiotomy should be performed in select situations and providers should receive training in the skill.[89] Indications for episiotomy include the need to expedite delivery in the setting of fetal heart rate abnormalities or for relief of shoulder dystocia.

KEY POINTS

- Labor is a clinical diagnosis that includes regular painful uterine contractions and progressive cervical effacement and dilation.
- Active labor is diagnosed as the time when the slope of cervical change increases, which is more difficult to identify in nulliparas.
- Active labor and latent labor should be managed differently.
- The fetus likely plays a key role in determining the onset of labor, although the precise mechanism by which this occurs is not clear.
- The ability of the fetus to successfully negotiate the pelvis during labor and delivery is dependent on the complex interaction of three variables: uterine force, the fetus, and the maternal pelvis.
- Labor length is affected by many variables, including parity, epidural use, fetal position, fetal size, and BMI.
- Routine median episiotomy is associated with a significant increase in the incidence of severe perineal trauma and should be avoided.

Labor is the physiologic process by which a fetus is expelled from the uterus to the outside world. A switch from contractures (long-lasting, low-frequency activity) to contractions (frequent, high-intensity, high-frequency activity) occurs before progressive cervical effacement and dilation of the cervix and regular uterine contractions. The timing of the switch varies from patient to patient. The exact trigger for the onset of labor is unknown, but there is considerable evidence to suggest that the fetus provides the stimulus through complex neuronal-hormonal signaling (see Chapter 13).

The mean duration of a human singleton pregnancy is 280 days or 40 weeks from the first day of the last menstrual period assuming a normal 28-day menstrual cycle. *Term* is defined as the period from 36 completed ($37^{0/7}$) to 42 weeks of gestation. *Preterm* labor refers to the onset of labor before 36 completed weeks of gestation. Prolonged or *postterm pregnancy* refers to gestation continuing beyond 42 completed weeks.

DIAGNOSIS

Labor is a clinical diagnosis defined as uterine contractions resulting in progressive cervical effacement and dilation, often accompanied by a bloody discharge referred to as *bloody show*, which results in birth of the baby. The diagnosis of bona fide labor is often elusive. There are wide variations in the clinical spectrum of normal labor, as well as many opinions of the definitions for normal and abnormal labor progress. To gain an understanding of abnormal labor progress and induction of labor, a fundamental understanding of normal spontaneous labor is needed.

ABNORMAL LABOR AT TERM

Most guidelines for normal human labor progress are derived from Friedman's clinical observations of women in labor.[1] Friedman characterized a sigmoid pattern for labor when graphing cervical dilation against time (Figure 14-1). He divided labor into three functional divisions: the *preparatory division*, *dilation division*, and *pelvic division*. The preparatory division is better known as the *latent phase*, during which little cervical dilation occurs but considerable changes are taking place in the connective tissue components of the cervix. The dilation division or *active phase* is the period when dilation proceeds at its most rapid rate to complete cervical dilation. These two phases together make up the *first stage of labor*. The *pelvic division* or *second stage of labor* refers to the time of full cervical

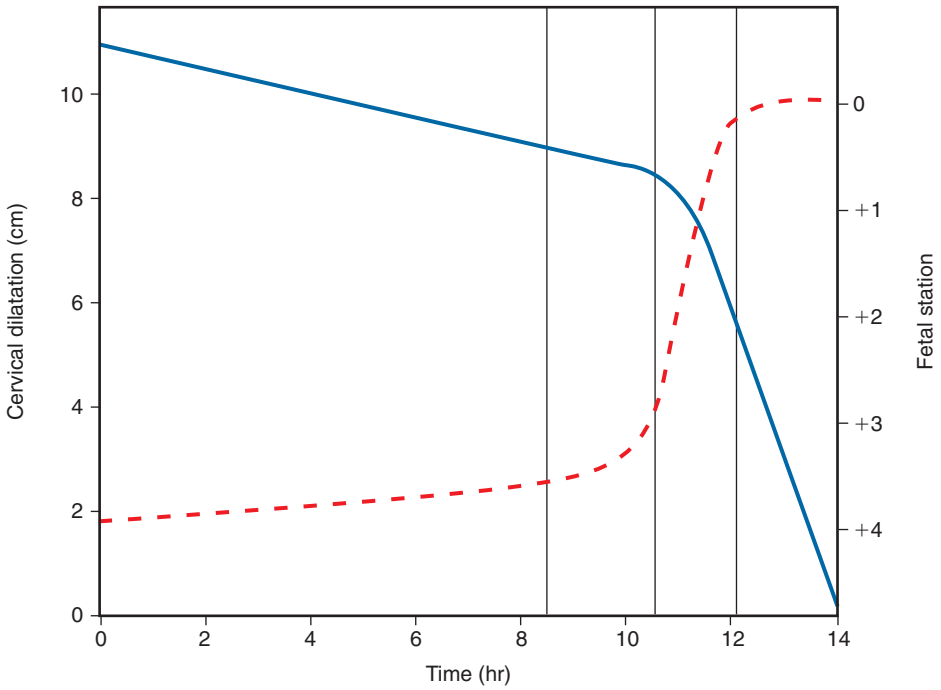

FIGURE 14-1. Characteristics of the average cervical dilation curve for nulliparous labor. (Modified from Friedman EA: Labor: Clinical Evaluation and Management, 2nd ed. Norwalk, CT, Appleton-Century-Crofts, 1978.)

dilation to the delivery of the infant. The *third stage of labor* refers to the time from the delivery of the infant to expulsion of the placenta.

Subsequent observations challenge Friedman's original labor curves. Between 1959 and 1966, the National Collaborative Perinatal Project prospectively observed labor progression, as well as several other factors possibly associated with cerebral palsy. This large multicenter project gathered data at a time when natural labor progress could be evaluated more easily than current obstetrical practices allow. Using these data, Zhang and colleagues for the Consortium for Safe Labor[2] determined that the active phase of labor as described by Friedman may not actually begin until 5 cm dilation in multiparas and even later in nulliparas. As well, before 6 cm of dilation, a 2-hour threshold for diagnosing labor arrest may be too brief whereas a 4-hour threshold may be too lengthy after 6 cm of dilation. Although cervical dilation does accelerate as labor advances, a precipitous dilation as described by Friedman may not necessarily occur, especially in nulliparas. Additional analyses regarding contemporary labor progress are expected from this project. Regardless of those results, a **graduated approach for diagnosis of labor protraction and arrest should be considered, based on the level of cervical dilation** (Table 14-1).

TABLE 14-1 PROGRESSION OF SPONTANEOUS LABOR AT TERM (ZHANG)

CERVICAL DILATION (cm)	PARITY 0	PARITY 1	PARITY 2+
From 3 to 4	1.2 (6.6)		
From 4 to 5	0.9 (4.5)	0.7 (3.3)	0.7 (3.5)
From 5 to 6	0.6 (2.6)	0.4 (1.6)	0.4 (1.6)
From 6 to 7	0.5 (1.8)	0.4 (1.2)	0.3 (1.2)
From 7 to 8	0.4 (1.4)	0.3 (0.8)	0.3 (0.7)
From 8 to 9	0.4 (1.3)	0.3 (0.7)	0.2 (0.6)
From 9 to 10	0.4 (1.2)	0.2 (0.5)	0.2 (0.5)
From 4 to 10	3.7 (16.7)	2.4 (13.8)	2.2 (14.2)

Data presented in hours as median (95th percentile). Data from Zhang J, Troendle J, Mikolajczyk R, et al: The natural history of the normal first stage of labor. Obstet Gynecol 115:705, 2010.

Disorders of the Latent Phase

The onset of latent labor is considered to be the point at which regular uterine contractions are perceived. Friedman found that the mean duration of latent labor was 6.4 hours for nulliparas and 4.8 hours for multiparas. The 95th percentiles for maximum length in latent labor was 20 hours for nulliparous women and 14 hours for multiparous women. These are considered the upper limits for time spent in latent labor (Table 14-2).[1]

Latent phase arrest implies that labor has not truly begun. Prolonged latent phase refers to a latent phase lasting longer than the 95th percentiles.[1] **Because the duration of latent labor is highly variable, expectant management is most appropriate**. Some women can spend days in latent labor; provided there is no indication for delivery, awaiting active labor is appropriate. If expeditious delivery is indicated, augmentation of labor may be initiated with a pharmacologic agent such as oxytocin. Another option is to administer "therapeutic rest," especially if contractions are painful or the patient is exhausted, with an analgesic agent such as morphine. A recommended dosing regimen is a single administration of 15 to 20 mg of morphine subcutaneously or intramuscularly. Often this will help abate

or alleviate painful contractions and allow the patient to rest comfortably until active labor begins. The onset of regular contractions is often unpredictable after amniotomy and, therefore, such therapy is not recommended in nulliparas with prolonged latent phase. Early amniotomy may increase the risk of prolonged membrane rupture and its associated infectious morbidity.

TABLE 14-2 PROGRESSION OF SPONTANEOUS LABOR AT TERM (FRIEDMAN)

PARAMETER	MEDIAN	5th PERCENTILE
Nulliparas		
Total duration	10.1 hr	25.8 hr
Stages		
First	9.7 hr	24.7 hr
Second	33.0 min	117.5 min
Third	5.0 min	30 min
Latent phase (duration)	6.4 hr	20.6 hr
Maximal dilation (rate)	3.0 cm/hr	1.2 cm/hr
Descent (rate)	3.3 cm/hr	1.0 cm/hr
Multiparas		
Total duration	6.2 hr	19.5 hr
Stages		
First	8.0 hr	18.8 hr
Second	8.5 min	46.5 min
Third	5.0 min	30 min
Latent phase (duration)	4.8 hr	13.6 hr
Maximal dilation (rate)	5.7 cm/hr	1.5 cm/hr
Descent (rate)	6.6 cm/hr	2.1 cm/hr

Data from Friedman EA: Primigravid labor: a graphicostatistical analysis. Obstet Gynecol 6:567, 1955; Friedman EA: Labor in multiparas: a graphicostatistical analysis. Obstet Gynecol 8:691, 1956; and Cohen W, Friedman EA (eds): Management of Labor. Baltimore, University Park Press, 1983.

Disorders of the Active Phase

Active labor demarcates a rapid change in cervical dilation. The change to active phase usually occurs when the cervix is dilated between 3 and 5 cm, but the most accurate diagnosis is retrospective. Friedman observed that the mean duration of active phase labor in nulliparas was 4.9 hours, with a standard deviation of 3.4 hours. The active phase begins once cervical dilation progresses at a minimum rate of 1.2 cm/hr for nulliparous women and 1.5 cm/hr for multiparous women, with a maximum duration of active phase reported to be 11.7 hours. Rates of cervical dilation varied greatly, ranging from 1.2 to 6.8 cm/hr.

Active-phase disorders may be divided into *protraction* and *arrest* disorders.[1] *Protraction* is defined as a slow rate of cervical change less than 1.2 cm/hr for the nullipara and less than 1.5 cm/hr for the multipara. These rates represent less than the 5th percentile for most gravidas (Figure 14-2). Whereas protraction disorders reflect slower than normal progress, arrest disorders consist of complete cessation of progress.

The most common cause of a protraction disorder is inadequate uterine activity. External tocodynamometry is used to evaluate the duration of and time interval between contractions but cannot be used to evaluate the strength of uterine contractions. The external monitor is held against the abdominal wall and records a relative measurement of uterine contraction intensity, reflecting the monitor's movement as the uterine shape changes. More precise measurements of uterine activity must be obtained with an intrauterine pressure catheter (IUPC). After amniotomy, an IUPC can be placed into the uterus to measure

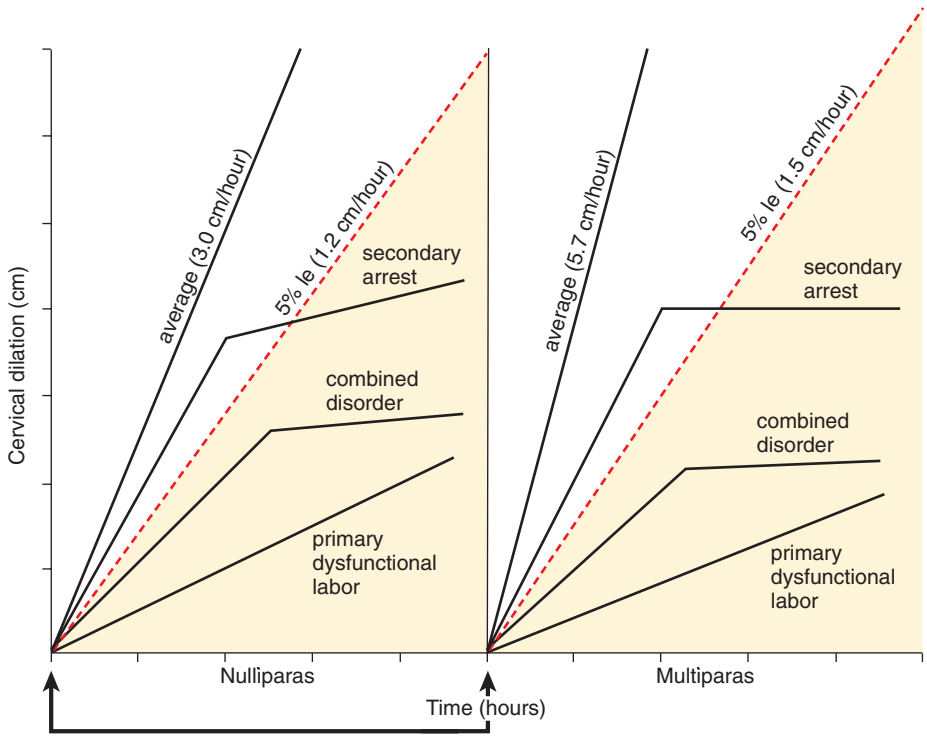

FIGURE 14-2. Disorders of the first stage of labor. Combined disorder implies an arrest in a gravida previously exhibiting primary dysfunctional labor.

the pressure generated during a uterine contraction. **An IUPC is frequently used when inadequate uterine activity is suspected owing to a protraction or arrest disorder. It can also be used to monitor and titrate oxytocin augmentation of labor to desired uterine effect.** The lower limit of contraction pressure required to dilate the cervix is observed to be 15 mm Hg over baseline. Normal spontaneous contractions often exert pressures up to 60 mm Hg.

Once inadequate uterine activity is diagnosed with an IUPC, oxytocin is usually administered. Typically, the dose is increased until there is normal progression of labor, resulting in strong contractions occurring at 2- to 3-minute intervals lasting 60 to 90 seconds, with a peak intrauterine pressure of 50 to 60 mm Hg and a resting tone of 10 to 15 mm Hg, or uterine activity equal to 150 to 350 Montevideo units. Montevideo units are calculated by subtracting the baseline uterine pressure from the peak contraction pressure of each contraction in a 10-minute window and adding the pressures generated by each contraction.

Another common cause of protraction disorders is abnormal positioning of the fetal presenting part. Some examples of malpresentation are an extended (rather than flexed) fetal head, brow or face presentation, and occiput posterior (OP) position. When persistent OP position is present, labor is reported to be prolonged an average 1 hour in multiparous women and 2 hours in nulliparous women. In one series, sonography showed OP position in 35% of women in early active labor, indicating that this may contribute to prolongation of labor in many women. In another investigation, the prevalence of persistent OP position at the time of vaginal delivery regardless of parity was 5.5% (7.2% in nulliparas and 4.0% in multiparas).[3] The OP position was found to be associated with longer first and second stages, and a lower rate of vaginal delivery (26% for nulliparas and 57% for multiparas) when compared with the occiput anterior (OA) position. Most fetuses in the OP position undergo spontaneous anterior rotation during the course of labor, and expectant management is generally indicated. However, approximately 5% remain in persistent OP position or transverse arrest, which often requires either an operative vaginal or cesarean delivery.

Cephalopelvic disproportion (CPD) refers to the disproportion between the size of the fetus relative to the mother and can be the cause of a protraction or arrest disorder. This is a diagnosis of exclusion, often made at the time a protracted labor course is observed. Most frequently, malposition of the fetal presenting part is the culprit rather than true CPD. Unfortunately, there is no way to accurately predict CPD. In a decision analysis, it has been estimated that thousands of unnecessary cesarean deliveries would need to be performed in low-risk pregnancies to prevent one diagnosis of true CPD.[4]

Arrest of labor is defined as cessation of previously normal active phase cervical dilation for a period of 2 hours or more.[1] Evaluation of this disorder includes an assessment of uterine activity with an IUPC, performance of clinical pelvimetry, and evaluation of fetal presentation, position, station, and estimated fetal weight. Amniotomy and oxytocin therapy can be initiated if uterine activity is found to be inadequate. The majority of gravidas respond to this intervention, and resume progression of cervical dilation and achieve vaginal delivery. Although the definition reflects a 2-hour window before diagnosis of arrest, Rouse and colleagues[5] found that at least 4 hours of observation can be undertaken without oxytocin augmentation before making this diagnosis without incurring additional maternal or fetal compromise.

Electromechanical Classification

An alternative classification system for disorders of the active phase of labor is based on the electromechanical state of the uterus regarding uterine tone. This classification reflects an understanding of the propagation of electrical signals through the myometrium. In normal labor, a gradient of myometrial activity sweeps from the fundus and, through the excitation of cellular gap junctions, propagates toward the cervix. *Hypotonic dysfunction* reflects an inefficient generation and propagation of these action potentials through the myometrium or a lack of contractile response of myometrial cells to the initial stimulus. Hypotonic uterine contractions are infrequent, of low amplitude, and accompanied by low or normal baseline intrauterine pressures. Maternal discomfort is minimal. Oxytocin augmentation is usually applied in this clinical situation if active labor has already begun.

Hypertonic dysfunction is primarily a condition of primiparas and usually occurs in early labor. It is characterized by the presence of regular uterine contractions that fail to effect cervical effacement and dilation. Frequent contractions of low amplitude are often associated with an elevated basal intrauterine pressure. Maternal discomfort is usually significant. Therapeutic rest or expectant management can be initiated in this clinical situation if the patient is in latent labor. When diagnosed, the most likely scenario is that the patient will soon enter active labor. If the patient is in active labor and found to have hypertonic dysfunction, amniotomy can be performed with or without concomitant oxytocin administration.

Combined Disorder

A combined disorder of active phase dilation is defined as arrest of dilation or descent occurring when a patient has previously exhibited protracted labor. This pattern is associated with less favorable outcomes with regard to vaginal delivery when compared with patients with secondary arrest alone.[1] If diagnosed, an evaluation of uterine activity is necessary, as is an assessment of pelvic capacity, fetal position, station, and estimated fetal weight.

Disorders of the Second Stage

The second stage of labor begins once the cervix becomes fully dilated and ends with the delivery of the infant. Although fetal descent begins before the cervix becomes fully dilated, the majority of fetal descent occurs once full cervical dilation is achieved. At this time, maternal expulsion efforts may begin.

Protraction of descent is defined as descent of the presenting part during the second stage of labor occurring at less than 1 cm/hr in nulliparous women and less than 2 cm/hr in multiparous women.[1] *Arrest (failure) of descent* refers to no progress in descent. Both diagnoses require prompt evaluation of uterine activity, maternal expulsive efforts, fetal heart rate status, fetal position, clinical pelvimetry,

and a reevaluation of estimated fetal weight. Decisions then may be made regarding interventions, such as increasing or initiating oxytocin infusion to improve maternal expulsion efforts, or proceeding with operative vaginal or cesarean delivery. Management of the second stage of labor can be difficult, and decisions regarding intervention must be individualized.

The median duration of the second stage is 50 to 60 minutes for nulliparas and 20 to 30 minutes for multiparas, but this is highly variable.[6,7] In classic obstetrical teaching, the upper limit for the duration of the second stage of labor was considered to be 2 hours. Factors influencing the length of the second stage include parity, maternal size, birth weight, OP position, fetal station at complete dilation, and, potentially, conduction anesthesia.[8] Currently, the American College of Obstetricians and Gynecologists' (ACOG's) guidelines[9] for the definition of prolonged second stage, provided the fetal heart rate tracing is normal and there is some degree of labor progress, are as follows: For nulliparous women, the diagnosis should be considered when the second stage exceeds 3 hours if regional anesthesia has been administered or 2 hours if no regional anesthesia is used, and in multiparous women, the diagnosis can be made when the second stage exceeds 2 hours with regional anesthesia or 1 hour without. Janakiraman and colleagues compared the second stage in 3139 induced women to that of 11,588 women in spontaneous labor.[10] No differences in the length of second stage or the risk of a prolonged second stage were noted between the groups, although the induced nulliparas appeared to be at increased risk of postpartum hemorrhage and cesarean delivery (4.2% vs. 2.0%, OR 1.62, 95% CI 1.02 to 2.58; 10.9% vs. 7.2%, OR 1.32, 95% CI 1.01 to 1.71, respectively).

Many authors have studied the perinatal and maternal effects of a prolonged second stage. Several studies found no increase in infant morbidity or mortality with a second stage lasting longer than 2 hours,[11] although the rate of vaginal delivery precipitously decreases after 3 hours in the second stage. However, a recent population-based cohort study by Allen and colleagues examined 63,404 nulliparous women and found increased risks of low 5-minute Apgar score, birth depression, and admission to the neonatal intensive care unit (NICU) with increasing duration of the second stage greater than 3 hours.[7] This study is the largest thus far evaluating neonatal and maternal outcomes with prolonged second stage. **In this study, as well as others, there is evidence that maternal morbidities including perineal trauma, chorioamnionitis, instrumental delivery, and postpartum hemorrhage increase with prolonged second stages lasting greater than 2 hours**. Effective management of the second stage should be individualized.

Disorders of the Third Stage

The third stage of labor refers to the period from delivery of the infant to the expulsion of the placenta. Separation of the placenta is the consequence of continued uterine contractions. Signs of placental separation include a gush of blood, lengthening of the umbilical cord, and change in shape of the uterine fundus from discoid to globular with elevation of the fundal height. The interval between delivery of the infant and delivery of the placenta and fetal membranes is usually less than 10 minutes and is complete within 15 minutes in 95% of deliveries.[12] The most important risk associated with a prolonged third stage is hemorrhage; this risk increases proportionally with increased duration.[13] Because of the associated increased incidence of hemorrhage after 30 minutes, most practitioners diagnose retained placenta after this time interval has elapsed. Interventions to expedite placental delivery are usually undertaken at this time.

Management of the third stage of labor may be expectant or active. Expectant management refers to the delivery of the placenta without cord clamping, cord traction, or the administration of uterotonic agents such as oxytocin. Active management consists of early cord clamping, controlled cord traction, and administration of a uterotonic agent. Oxytocin is the usual uterotonic agent given, but others have been used, such as misoprostol or other prostaglandin compounds. **Comparing active to expectant management of the third stage, there appears to be a reduced risk of postpartum hemorrhage when active management is used.**[14] Cochrane reviewers evaluated five studies (6486 women) that compared active and expectant management. They confirmed that active management reduced the average risk of maternal hemorrhage (RR 0.34, 95% CI 0.14 to 0.87), but that significant increases in maternal diastolic blood pressure, afterpains, and analgesia use occurred as well. These adverse events may reflect the side effects of the various uterotonic medications used in different countries.

There is some debate regarding the timing of oxytocin administration when the active management of the third stage is practiced: after the placenta has delivered versus after the anterior shoulder of the fetus has delivered. A randomized controlled trial including 1486 women comparing the effects of oxytocin administration on delivery of the anterior shoulder to administration after delivery of the placenta showed no significant differences in blood loss or retained placenta between the groups.[15]

Retained placenta can usually be treated with measures such as manual removal or sharp curettage. Attempting manual removal can be performed under regional anesthesia or conscious sedation. If this is not successful, a sharp curettage can be performed under sonographic guidance. Prophylactic broad-spectrum antimicrobial agents are often administered when manual removal of the placenta is performed, although there is little evidence to support or refute their use.[16]

Precipitous Labor

Precipitous labor refers to delivery of the infant in less than 3 hours. This occurs in approximately 2% of all deliveries in the United States. Precipitous labor and delivery alone is not usually associated with significant maternal or infant morbidity and mortality. Short labors can be associated with placental abruption, uterine tachysystole, and recent maternal cocaine use—all of which are major contributors to poor outcomes for mothers and infants. Other investigators have looked at intrapartum risk factors associated with permanent brachial plexus injury and found that a precipitous second stage is the most common labor abnormality associated with shoulder dystocia, although the rates of permanent injury did not increase.[17]

Anesthesia Effects on Labor Progress

Conduction regional anesthesia's effects on the rate of cervical change remains controversial. In a recent meta-analysis,[18] 15 randomized controlled trials including 4619 patients compared the effects of epidural anesthesia to parenteral opioid. The incidence of cesarean section was the same between the groups, although the incidence of operative vaginal delivery was increased in the conduction anesthesia group (OR 1.92; 95% CI 1.52 to 1.22). It has been difficult to establish whether this increase in operative vaginal delivery was due to a direct effect of the epidural analgesia on the rate of labor or an indirect effect, such as resident training. No difference in the duration of the first stage was noted; however, the second stage was prolonged by approximately 16 minutes (95% CI 10 to 23 minutes). This statistically significant finding lacks clinical relevance.[18]

It has also been suggested that receiving regional anesthesia during latent labor, as opposed to during the active phase, results in prolongation of the labor, such that many practitioners refrain from administering regional analgesia until the patient reaches 4 cm or more dilation. An investigation including 12,693 nulliparas randomized subjects to receive early epidural analgesia (at first request if cervical dilation was at least 1 cm) compared with late epidural analgesia (parenteral meperidine until cervical dilation of 4 cm was achieved). The median cervical dilation at the time of epidural placement was 1.6 cm for the early group and 5.1 for the late group. These researchers found no difference in the incidence of cesarean birth, operative vaginal delivery, or length of first or second stages of labor.

MANAGEMENT OF ABNORMAL LABOR AND DELIVERY

Pharmacologic Augmentation

When the first stage of labor is protracted or an arrest disorder is diagnosed, an evaluation of uterine activity, clinical pelvimetry, and fetal position, station, and estimated weight should be performed. If uterine activity is found to be suboptimal, the most common remedy is oxytocin augmentation, because once labor is initiated, the uterus becomes more sensitive to oxytocin stimulation. Various oxytocin dosing regimens have been described in the obstetrical literature. Local protocols for oxytocin administration should specify the dose of oxytocin being delivered (milliunits per minute) as opposed to the volume of fluid being infused (milliliters per minute), initial dose, incremental increases with periodicity, and maximum dose. Although oxytocin currently is used in a majority of labors in the United States, it is important for clinicians to recognize that it is also the medication implicated in approximately half of all paid obstetrical litigation claims and is the medication most commonly associated with preventable adverse events during childbirth.[19]

Recently, attention has been turned to misoprostol solution as an alternative augmentation agent. Ho and colleagues[20] evaluated a solution of 200 mcg misoprostol dissolved in 200 mL tap water randomized against intravenous oxytocin in 231 women. This small study yielded promising results with similar rates of vaginal delivery between the two groups and no difference noted in side effects of neonatal outcomes. As well, a recent study by Bleich and colleages compared oral misoprostol tablets (25 mcg) versus intravenous oxytocin for labor augmentation in 350 women, with no differences in maternal or neonatal outcomes. Further research is ongoing in this area.

Side Effects

Uterine Overactivity

The most frequently encountered complication of oxytocin or prostaglandin administration is *uterine overactivity*. Historically, the most commonly used terms to describe this activity were *hyperstimulation*, *tachysystole*, *hypercontractility*, and *hypertonus*. However, there were no uniform definitions for these terms until a recent National Institutes of Child Health and Human Development (NICHD) workshop attempted to provide standardized nomenclature for uterine activity, as well as electronic fetal heart monitoring.[21] These guidelines quantify the number of uterine contractions present in a 10-minute window, averaged over 30 minutes. A *normal* contraction pattern is considered five contractions or less in 10 minutes, averaged over 30 minutes, accounting as well for frequency, intensity, duration, and relaxation time when described. *Tachysystole* is defined as more than five contractions in 10 minutes, averaged over a 30-minute window. Tachysystole can occur in spontaneous or stimulated labor and can be associated with fetal heart rate changes or not. The NICHD guidelines recommend abandoning the terms *hyperstimulation* and *hypercontractility*.[21]

One of the advantages of oxytocin administration is that if uterine overactivity is encountered, the infusion can quickly be stopped. The half-life of oxytocin is approximately 3 minutes; therefore, stopping the infusion usually results in the resolution of such uterine overactivity. In addition, placing the woman in the left lateral position, administering oxygen, and increasing intravenous fluids may be of benefit. If fetal heart rate tracing abnormalities persist and uterine tachysystole is ongoing, the use of a tocolytic, such as terbutaline, may be considered. Oxytocin may then be reinitiated, if appropriate, once uterine tone has returned to baseline and fetal status is reassuring.

Water Intoxication

Oxytocin is structurally and functionally related to vasopressin, or antidiuretic hormone. It binds to vasopressin and oxytocin receptors in the kidney and the brain. Oxytocin can have an antidiuretic effect at high doses and can, in extreme situations, result in water intoxication. Severe symptomatic hyponatremia can result if oxytocin is administered at high concentrations (e.g., 40 mU/min) in large quantities of hypotonic solutions (>3 liters) for prolonged periods of time. Symptoms of severe acute hyponatremia include headache, anorexia, nausea, vomiting, abdominal pain, lethargy, drowsiness, unconsciousness, grand mal seizures, and potentially irreversible neurologic injury. Fortunately, this side effect is extremely rare even with high-dose oxytocin regimens.

If water intoxication occurs, oxytocin and any hypotonic solutions should be stopped. Correction of hyponatremia must be performed carefully and consists of restricting water intake and careful administration of hypertonic saline. Correction of hyponatremia must occur

TABLE 14-3 MATERNAL COMPLICATIONS ASSOCIATED WITH TRIAL OF LABOR AFTER PREVIOUS CESAREAN BIRTH

COMPLICATION	TRIAL OF LABOR (*n* = 17,898)	ELECTIVE REPEAT CESAREAN DELIVERY (*n* = 15,801)	ODDS RATIO (95% CI)	*p* VALUE

*Other adverse events include broad-ligament hematoma, cystotomy, bowel injury, ureteral injury.
DVT, Deep vein thrombosis; *PE,* pulmonary embolism.

slowly and cautiously because overly rapid correction can be deleterious.

Hypotension

Historically, bolus injections of oxytocin were thought to cause hypotension. Current practice for labor management is administration by infusion pump or slow drip. Mean arterial blood pressure and peripheral vascular resistance have been noted to decrease 30% and 50%, respectively, after oxytocin bolus injection of 5 to 10 units. This caused increases of 30% in heart rate, 25% in stroke volume, and 50% in cardiac output when compared with patients receiving slow dilute infusions. Fewer cardiovascular side effects are observed when oxytocin is given as a slow intravenous infusion or intramuscularly, as may be needed for third-stage labor management. However, a report by Davies and colleagues[22] revealed that a 10-IU bolus of oxytocin given in the third stage of labor was not associated with adverse hemodynamic responses compared with oxytocin given as an infusion. Although multiple boluses during labor are not recommended, consideration may be given to its use in the third stage of labor as a single bolus.

Uterine Rupture

Uterine rupture is rare and in most instances occurs in women with prior uterine surgery such as cesarean delivery or myomectomy. Other risk factors for uterine rupture are grand multiparity; marked uterine overdistention either with a macrosomic fetus, multiple gestation, or polyhydramnios; and fetal malpresentation. Although there is no association between maximum dose of oxytocin and risk of uterine rupture, it is likely that some cases of uterine rupture can be avoided by using the lowest dose of oxytocin possible that produces regular contractions and cervical change.

Recent investigations have shed light on the question of labor augmentation and induction for women attempting trials of labor after previous cesarean deliveries. Although randomized trials currently do not exist, a large prospective investigation evaluated more than 17,000 women attempting trials of labor after previous cesarean deliveries.[23] The incidence of uterine rupture was 0.4% for those subjects who spontaneously labored versus 0.9% for those who received augmentation and 1.0% for subjects undergoing induction. The highest risk of rupture was in those patients who received a combination of prostaglandins and oxytocin. Other complications of attempting a trial of labor after a previous cesarean section can be seen in Table 14-3. The ACOG currently recommends the use of oxytocin in augmentation and induction of women undergoing a trial of labor after previous cesarean deliveries, although caution is encouraged in women with unfavorable cervices.[24]

Use of intrauterine pressure catheters does not appear to be helpful in diagnosis of uterine rupture, because the ruptures usually evolve gradually in labor and are often heralded by abnormal fetal heart rate patterns. There is no evidence that amnioinfusion increases the risk of uterine rupture; however, studies to date have been small and retrospective.

Anaphylaxis of Pregnancy (Amniotic Fluid Embolism)

A population-based retrospective cohort study including 3 million deliveries reported that medical induction of labor was associated with an increased risk of amniotic fluid embolism (adjusted OR 1.8; 95% CI 1.2 to 2.7).[25] However, the absolute risk was small: 10.3 per 100,000 births with medical induction versus 5.2 per 100,000 births without medical induction. Moreover, given that these women were induced for medical indications, not inducing labor could potentially result in greater maternal-fetal morbidity and mortality than inducing labor. These findings should be confirmed by others before changes in management of induction are considered.

INDUCTION OF LABOR

Induction of labor is one of the most commonly performed obstetrical procedures in the United States. Induction of labor refers to the iatrogenic stimulation of uterine contractions before the onset of spontaneous labor to accomplish vaginal delivery. Augmentation of labor refers to increasing the frequency and improving the intensity of existing uterine contractions in a patient who is in labor and not progressing adequately, in order to accomplish vaginal delivery.

Indications and Contraindications

Induction of labor should be undertaken when the benefits of prompt delivery to either mother or fetus outweigh

the risks of pregnancy continuation.[26] Many accepted medical and obstetrical indications for labor induction and several relative indications for labor induction exist (Table 14-4). Contraindications are those that preclude vaginal delivery, among others (Table 14-5). "Impending" macrosomia, a favorable cervix, or patients considered to be at increased risk of preeclampsia (such as having a prior history of preeclampsia) or at risk for intrauterine growth restriction (e.g., a fetus with an estimated weight of 19th percentile) are not considered indications for induction.

Careful examination of the maternal and fetal condition is required before undertaking labor induction (Table 14-6). Indications and contraindications for induction should be reviewed, as well as the alternatives. Risks and benefits of labor induction should be discussed with the patient, including the risk of cesarean delivery (to be discussed later). Confirmation of gestational age is critical, and evaluation of fetal lung maturity status should be performed if indicated (Table 14-7).[26] Fetal weight should be estimated and clinical pelvimetry performed. Fetal presentation and position should be confirmed. A cervical examination should be performed and documented as well. In addition, labor induction should be performed at a location where personnel are available who are familiar with the process and its potential complications.

Table 14-4 Indications for Labor Induction

ACCEPTED ABSOLUTE INDICATIONS	RELATIVE INDICATIONS
Hypertensive disorders	**Hypertensive disorders**
• Preeclampsia/eclampsia	• Chronic hypertension
Maternal medical conditions	**Maternal medical conditions**
• Diabetes mellitus	• Systemic lupus erythematosus
• Renal disease	• Gestational diabetes
• Chronic pulmonary disease	• Hypercoagulable disorders
	• Cholestasis of pregnancy
Prelabor rupture of membranes	Polyhydramnios
Chorioamnionitis	Fetal anomalies requiring specialized neonatal care
Fetal compromise	**Logistic factors**
• Fetal growth restriction	• Risk of rapid labor
• Isoimmunization	• Distance from hospital
• Nonreassuring antepartum fetal testing	• Psychosocial indications
	• Advanced cervical dilation
• Oligohydramnios	
Fetal demise	Previous stillbirth
Postdates pregnancy (>42 weeks)	Postterm pregnancy (>41 weeks)

Table 14-5 Contraindications to Labor Induction

ACCEPTED ABSOLUTE CONTRAINDICATIONS	RELATIVE CONTRAINDICATIONS
Prior classical uterine incision or transfundal uterine surgery	Cervical carcinoma
Active genital herpes infection	Funic presentation
Placenta or vasa previa	Malpresentation (breech)
Umbilical cord prolapse	
Transverse or oblique fetal lie	
Absolute cephalopelvic disproportion (as in women with pelvic deformities)	

Uterine activity and electronic fetal monitoring (EFM) are recommended for any gravida receiving uterotonic medications.

Prolonged Pregnancy

Postterm pregnancy (>41 completed weeks) is associated with significant risks to the fetus and mother. Antepartum stillbirths account for more perinatal deaths than either complications of prematurity or sudden infant death syndrome. According to a large epidemiologic study by Hilder and colleagues,[27] the perinatal mortality rate (stillbirths plus early neonatal deaths) at greater than 42 weeks of gestation is approximately twice that at term (4 to 7 deaths vs. 2 to 3 deaths per 1000 deliveries) and increases sixfold

Table 14-6 Evaluation Before Induction of Labor

PARAMETER	CRITERIA
Maternal	Confirm indication for induction
	Review contraindications to labor and/or vaginal delivery
	Perform clinical pelvimetry to assess pelvic shape and adequacy of bony pelvis
	Assess cervical condition (assign Bishop score)
	Review risks, benefits, and alternatives of induction of labor with patient
Fetal/neonatal	Confirm gestational age
	Assess need to document fetal lung maturity status
	Estimate fetal weight (either by clinical or ultrasound examination)
	Determine fetal presentation and lie
	Confirm fetal well-being

Table 14-7 Criteria for Confirmation of Gestational Age and/or Fetal Pulmonary Maturity

	PARAMETERS
Confirmation of Gestational Age	Fetal heart tones have been documented as present for ≥30 weeks by Doppler ultrasound.
	≥36 weeks have elapsed since a positive serum or urine human chorionic gonadotropin pregnancy test.
	Ultrasound measurement at less than 20 weeks of gestation supports gestational age of 39 weeks or greater.
Fetal Pulmonary Maturity	If term gestation cannot be confirmed by two or more of the above obstetrical clinical or laboratory criteria, amniotic fluid analyses can be used to provide evidence of fetal lung maturity. A variety of tests are available. The parameters for evidence of fetal pulmonary maturity are as follows:
	1. Lecithin/sphingomyelin (L/S) ratio >2.1
	2. Presence of phosphatidylglycerol (PG)
	3. TDxFLM assay ≥70 mg surfactant per 1 g albumin present
	4. Presence of saturated phosphatidylcholine (SPC) ≥500 ng/mL in nondiabetic patients (≥1000 ng/mL for pregestational diabetic patients)
	5. Lamellar body count exceeding 30,000/mcL

Modified data from Induction of Labor. ACOG Practice Bulletin No 107. American College of Obstetricians and Gynecologists. Obstet Gynecol 2009:114, 386; and Fetal Lung Maturity. ACOG Practice Bulletin No. 97. American College of Obstetricians and Gynecologists. Obstet Gynecol 112:717, 2008.

and higher at 43 weeks of gestation and beyond. However, several other epidemiologic studies suggested that other risk factors (such as congenital malformations and intrauterine growth restriction) outweighed prolonged pregnancy as the cause of neonatal mortality. Weaknesses of these studies overall included a lack of recording of the actual cause of death for many of the infants, as well as pregnancy dating by last menstrual period rather than early ultrasounds, and possible inequality or poor access to care of the populations evaluated.

Two more recent studies consisted of prospective cohort evaluations of singleton pregnancies based on ultrasound dating.[28,29] Nakling and colleagues[28] found an incidence of postterm pregnancies to be 7.6% in their cohort, with 0.3% of pregnancies progressing to 301 days (43 weeks' gestation) if inductions were not permitted before 43 weeks. This investigation found a significantly increased rate of perinatal mortality after 41 weeks' gestation, although whether the prolonged pregnancy or intrauterine growth restriction was the actual culprit is difficult to ascertain in this study. In contrast, Heimstad and colleagues[29] found an increased trend toward intrauterine fetal demise at 42 weeks' gestation compared to 38 weeks, but this study allowed inductions before 43 weeks and did not calculate the perinatal mortality rates. Factors that may contribute to the increased rate of perinatal deaths are uteroplacental insufficiency, meconium aspiration, intrauterine growth restriction, and intrauterine infection.[30] For these reasons, the tendency has been to deliver by 41 completed weeks of gestation (42 weeks, 294 days, EDD + 14 days).

Postterm pregnancy is also associated with significant risks to the pregnant woman, including an increase in labor dystocia (9% to 12% vs. 2% to 7% at term), which is denoted by an increase in severe perineal injury related to macrosomia (3.3% vs. 2.6% at term), and a doubling in the rate of cesarean delivery.[29,31-35] Cesarean delivery is associated with higher risks of complications, such as hemorrhage, endometritis, and thromboembolic disease. In a recent randomized, controlled trial of women at 41 weeks of gestation, those who were induced would desire the same management 74% of the time, whereas women with serial antenatal monitoring desired the same management only 38% of the time.

Management of low-risk postterm pregnancy is controversial. A recent meta-analysis included 19 studies that compared induction and expectant management for uncomplicated, singleton pregnancies of at least 41 weeks' gestation.[36] There was no difference in cesarean delivery rates (RR 0.92; 95% CI 0.76 to 1.12; RR 0.97; 95% CI 0.72 to 1.31) for women induced at 41 and 42 completed weeks, respectively. There was a small and statistically significant reduction in perinatal mortality rates, but none in neonatal intensive care admission rates, meconium aspiration, or abnormal Apgar scores. In this subset of women, elective labor induction may be justified.

Because delivery cannot always be brought about readily, maternal risks from cesarean delivery resulting from failed inductions or other dystocia, and the impact on future pregnancies from cesarean delivery, need to be considered. Some studies have demonstrated the risks of abnormal placentation from multiple cesarean deliveries.[37] Also, with the declining rates of vaginal birth after cesarean, once the first cesarean has occurred, there is a less than 10% chance that future pregnancies will be delivered vaginally.

In 1954, approximately 20% of postterm fetuses were diagnosed with dysmaturity syndrome, with characteristics resembling chronic intrauterine growth restriction from uteroplacental deficiency. These pregnancies were considered at increased risk of umbilical cord compression from oligohydramnios, meconium aspiration, and short-term neonatal complications (such as hypoglycemia, seizures, and respiratory insufficiency) and had an increased incidence of nonreassuring fetal testing, both antepartum and intrapartum. Whether such infants also are at risk of long-term neurologic sequelae was not apparent. In a large, prospective, follow-up study of children from 1 to 2 years of age, the general physical milestones, intelligence quotient, and frequency of intercurrent illnesses were not significantly different between normal infants born at term and those born postterm. Again, these infants might have increased neonatal complications secondary to intrauterine growth restriction and uteroplacental insufficiency, rather than from prolonged pregnancy itself.

Elective Induction of Labor

Elective induction of labor refers to the initiation of labor for convenience in an individual with a term pregnancy who is free of medical or obstetrical indications. The rate of elective induction in the United States has increased dramatically from 9.5% to 19.4% from 1989 to 1998.[38] Factors associated with higher induction rates are white race, higher education, and early initiation of prenatal care. Although elective induction is not recommended or encouraged, it may be appropriate in specific instances such as a history of very short labors or for patients who live a great distance from the hospital.[26] Also, a patient who has experienced a prior stillbirth at or near term may require labor induction to ease anxiety and fears about the loss of a subsequent pregnancy. In addition, there are certain maternal medical conditions that require multispecialty participation in which the benefit of a planned delivery to have experienced personnel readily available is most appropriate. Examples of such cases are pregnancies with maternal cardiac disease that may require invasive monitoring during labor or those complicated by chronic renal disease in which considerations for hemodialysis may dictate a scheduled birth.

The major risks of elective induction of labor at term are thought to be increased rates of cesarean delivery (especially in nulliparas), increased neonatal morbidity, and cost. The risk of cesarean delivery following elective induction, especially for the nullipara with an unfavorable cervix, was clearly established in the literature with several cohort and case-control studies.[39] These studies revealed an increased risk of cesarean of at least twice the risk of spontaneously laboring patients. Seyb and colleagues also noted in their investigation that the mean time spent on labor and delivery was almost twice as long, and postpartum stays were prolonged if labor induction was undertaken. The total cost associated with hospitalization for elective induction was 17.4% higher than for spontaneous labor, including costs for labor and delivery, pharmacy, and postpartum care. These findings were confirmed by the investigations undertaken by Maslow, Sweeney, and Cammu

and colleagues.[39] These data reinforced the finding that labor induction was a significant predictor of cesarean delivery for both nulliparous and multiparous women and contributed to rising health care costs.

Following these cohort and case-control studies, several randomized controlled trials were undertaken. In a meta-analysis by Caughey and colleagues,[40] nine randomized controlled trials were evaluated. These trials utilized patients undergoing expectant management (rather than spontaneous labor) as the comparison group for the patients being electively induced. The rationale for this change of perspective consists of examining the actual decision made by the clinician when a patient at 38 or 39 weeks' gestation is seen at the office. The clinician and patient do not make a decision at that time between spontaneous labor and induction, but rather, between expectant management and induction. In contrast to the previous reports of the cohort studies, the meta-analysis of randomized controlled trials actually revealed a decreased risk of cesarean in the induction group compared to the expectantly managed group (RR 1.17, 95% CI 1.05 to 1.29). As well, Cochrane reviewers examined 19 trials including 7984 women and found that the women induced at 37 to 40 completed weeks were more likely to have a cesarean with expectant management than those in the labor induction group (RR 0.58, 95% CI 0.34 to 0.99).[36]

Caughey and colleagues[41] also examined the risk of cesarean delivery for each week of gestational age ranging from 38 to 41 weeks. In their retrospective study, again comparing induction to expectant management, cesarean delivery was decreased in the induction groups.

In contrast to these studies, the Consortium of Safe Labor, consisting of 10 U.S. institutions throughout the nation, reviewed their electronic medical record data from 2002 to 2008.[42] In this large study of 115,528 deliveries, the outcomes of mothers and neonates undergoing either spontaneous labor, elective induction, medically indicated induction, or cesarean without labor were evaluated. The incidence of cesarean delivery in this study was again increased in the group undergoing elective induction compared to the spontaneous laboring group, particularly at 37 to 38 completed weeks' gestation and at 41 weeks' gestation. When the outcomes were adjusted for race, maternal age, parity, preeclampsia, eclampsia, chronic hypertension, diabetes, and GBS status, the odds ratio for electively induced patients from 37 to 42 weeks' gestation to undergo cesarean was 1.58 compared to spontaneously laboring patients (95% CI 1.48 to 1.69).

Neonatal respiratory problems, sepsis, and asphyxia are the major pediatric concerns when mothers undergo elective delivery. Respiratory problems can result from inadvertent delivery of a premature infant or transient tachypnea related to cesarean delivery after failed induction. This is counterbalanced by observations that fewer electively induced infants have meconium passage when compared to spontaneously labored infants, and, therefore, likely have reduced incidence of meconium aspiration syndrome.[40] Macrosomia also may be reduced, as noted in an ecological study performed by Zhang and colleagues.[43] This study revealed that the increased induction rate between 1992 and 2003 (14% to 27%) was significantly associated with reduced mean fetal birth weight ($r = -0.54$, 95% CI −0.71 to −0.29) and rate of macrosomia ($r = -0.55$, 95% CI −0.74 to −0.32).

Table 14-8 Neonatal Respiratory Morbidity

Gestational Age (Weeks)	Frequency of NICU Admission per 1000 Deliveries	Odds Ratio (95% CI)
Following Vaginal Delivery		
37 0/7 to 37 6/7	12.6 (7.6-19.6)	2.5 (1.5-4.2)
38 0/7 to 38 6/7	7.0 (4.6-10.2)	1.4 (0.8-2.2)
39 0/7 to 39 6/7	3.2 (1.8-4.5)	0.6 (0.4-1.0)
Following Cesarean Delivery		
37 0/7 to 37 6/7	57.7 (26.7-107.1)	11.2 (5.4-13.1)
38 0/7 to 38 6/7	9.4 (1.9-27.2)	1.8 (0.6-5.9)
39 0/7 to 39 6/7	16.2 (5.9-35.5)	3.2 (1.4-7.4)

Morrison JJ, Rennie JM, Milton PJ: Neonatal respiratory morbidity and mode of delivery at term: influence of timing of elective caesarean section. Br J Obstet Gynaecol 102:101, 1995.

The risk of respiratory morbidity was illustrated in a retrospective review of infants admitted to the neonatal intensive care unit following elective delivery at term.[44] These results support delaying elective delivery until 39 weeks' gestation (Table 14-8). In further support of these findings, Clark and colleagues[45] performed a prospective observational study of 27 hospitals, including 17,794 deliveries. Of these deliveries, 44% were planned, and 73% of those deliveries were considered elective. The percentage of the electively induced infants admitted to the NICU at 37 weeks was 15.2% ($n = 112$), at 38 weeks 7.0% ($n = 678$), and at 39 weeks 6.0% ($n = 2004$). These studies reiterate the importance of considering neonatal morbidity with elective induction before 40 weeks' gestation. However, examining the results of the Consortium of Safe Labor provides a conflicting result for neonatal morbidity in elective inductions. In this study, infants of electively induced mothers were less likely to receive ventilatory support, become septic, or be admitted to the NICU.[42]

On one risk of elective induction, the scientific evidence agrees: Costs with elective induction are increased. Kaufman and colleagues[46] studied the economic consequences of elective induction of labor at term. Using decision analysis, these researchers examined a hypothetical cohort of 100,000 pregnant patients for whom an initial decision was made to either induce labor at 39 weeks' gestation or to follow the patient expectantly through the remainder of pregnancy. All patients in this model underwent elective induction at 42 weeks' gestation. Clinical outcomes of patients undergoing expectant management were evaluated. Using baseline estimates, the investigators concluded that elective induction would result in more than 12,000 excess cesarean deliveries and impose an annual cost to the medical system of nearly $100 million. A policy of induction at any gestational age, regardless of parity or cervical ripeness, required economic expenditures by the medical system. Although never cost saving, inductions were less expensive at later gestational ages, for multiparous patients, and for those women with a favorable cervix. The inductions most costly to the health care system were those performed in nulliparas with unfavorable cervices at 39 weeks. When nulliparous women with favorable cervices undergo labor induction, the estimated

cost is approximately halved, but is still considerably higher than allowing spontaneous labor.

One approach called the Active Management of Risk in Pregnancy at Term (AMOR-IPAT) provides promise for reducing the risk of cesarean delivery following induction of labor.[47] Using a retrospective cohort design, delivery outcomes of 100 women with a tailored approach to prenatal care and individualization of risk of cesarean delivery were compared with 300 nonexposed women. Consideration was given to the most common indications for nonelective cesarean delivery: cephalopelvic disproportion and uteroplacental insufficiency. A hypothetical ceiling for gestational age at delivery, always ≤41 weeks and ≥38 weeks, was set for each subject. Cervical ripening was used for all women with Bishop scores less than 5. Despite an increase in the labor induction rate in the women exposed to AMOR-IPAT (63% vs. 26%, P <0.001), there was a significant reduction in the cesarean births in this same group (4% vs. 17%, P <0.001). In a similar retrospective cohort study from the same authors, a protocol of risk-guided prostaglandin-assisted preventive labor induction with differing intensity was applied. Compared with nonexposed subjects, the exposed group (n = 794) had a significantly higher rate of labor induction (31.4% vs. 20.4%), and use of prostaglandin E_2 (23.3% vs. 15.7%), and a significantly lower cesarean delivery rate (5.3% vs. 11.8%). A small prospective trial of AMOR-IPAT, however, failed to confirm these promising results. Lack of a difference in the cesarean delivery rates (10.3% in the AMOR-IPAT group vs. 14.9% in the conventional management group; $p = 0.25$) may have been because the sample size was too small to reveal a true difference between treatment groups.[48] Larger randomized controlled multicenter investigations are planned.

Prediction of Labor Induction Success

In observational studies, characteristics associated with successful induction include multiparity, tall stature (over 5 feet 5 inches), increasing gestational age, nonobese maternal weight or body mass index, and infant birth weight less than 3.5 kg.[49,50] However, these characteristics are predictive of success even in spontaneous labors, which suggests they are more predictive of the route of delivery than the likelihood that the patient will reach the active phase of labor.

Because of the risk of cesarean delivery and the rising costs of health care associated with labor induction, some researchers have tried to identify, with varying success, biochemical and biophysical assays to predict the probability of vaginal delivery following labor induction.[51] These measures include digital evaluation of the cervix, ultrasonographic cervical length measurements, and use of fetal fibronectin before labor induction.

The modified Bishop score is the system most commonly used in clinical practice in the United States to evaluate the cervix before induction. This system tabulates a score based on the station of the presenting part and four characteristics of the cervix: dilation, effacement, consistency, and position (Table 14-9).[52] If the Bishop score is high (variously defined as ≥5 or ≥8), the likelihood of vaginal delivery is similar whether labor is spontaneous or induced.[53] In contrast, a low Bishop score is predictive that induction will fail and result in cesarean delivery. These relationships are particularly strong in nulliparous women who undergo induction.[54,55] Of note, the relationship between a low Bishop score and failed induction, prolonged labor, and a high cesarean birth rate was first described before widespread use of cervical ripening agents.[56]

TABLE 14-9 MODIFIED BISHOP SCORE

Score	0	1	2	3
Parameter				
Dilation (cm)	Closed	1-2	3-4	5 or more
Effacement (%)	0-30	40-50	60-70	80 or more
Length (cm)*	*>4*	*2-4*	*1-2*	*1-2*
Station	−3	−2	−1 or 0	+1 or +2

Bishop EH: Pelvic scoring for elective induction. Obstet Gynecol 24:266, 1964.
*Modification by Calder AA, Brennand JE: Labor and normal delivery: induction of labor. Curr Opin Obstet Gynecol 3:764, 1991. This modification replaces percent effacement as one of the parameters of the Bishop score.

Cervical length is also predictive of the likelihood of spontaneous onset of labor postterm. Sonographic assessment of cervical length for predicting the outcome of labor induction has been evaluated in numerous studies. A systematic review of 20 prospective studies found that cervical length was predictive of successful induction (likelihood ratio of a positive test, 1.66; 95% CI 1.20 to 2.31) and failed induction (likelihood ratio of a negative test, 0.51; 95% CI 0.39 to 0.67).[57] However, sonographic cervical length performed poorly for predicting vaginal delivery within 24 hours (sensitivity 59%, specificity 65%), vaginal delivery (sensitivity 67%, specificity 58%), achieving active labor (sensitivity 57%, specificity 60%), and delivery within 24 hours (sensitivity 56%, specificity 47%), and did not perform significantly better than the Bishop score for predicting a successful induction. These data are limited by substantial heterogeneity among the studies. The role of ultrasound examination as a tool for selecting women likely to have a successful induction is uncertain.

Two studies examined the use of magnetic resonance imaging (MRI) as a tool for assessing cervical readiness for labor, the idea behind this being that MRI delineates the internal signal changes as well as morphologic alterations of the cervix during pregnancy. Studies have evaluated the cervical hydration status and signal intensities. The largest study published thus far was by Pates and colleagues and examined 93 women undergoing labor induction at term. No correlation was found between MRI T2 relaxation time estimates (measuring cervical hydration) and clinical indicators of ripening (Bishop score) or obstetrical outcome. Practicality and cost concerns abound with any radiographic predictions of labor induction success.

The presence of an elevated fetal fibronectin (fFN) concentration in cervicovaginal secretions has also been used to predict uterine readiness for induction. Elevated fFN is thought to represent a disruption or inflammation of the chorionic-decidual interface. In several studies, women with a positive fFN result had a significantly shorter interval until delivery than those with a negative fFN result and there was reduction in the frequency of cesarean

delivery.[58] Positive fFN results were predictive of a shorter interval to delivery, even in nulliparas with low (<5) Bishop scores. However, other investigations have not confirmed these findings.[59]

Bailit and colleagues[60] used a decision analysis to determine if the vaginal delivery rate is increased in nulliparous women undergoing elective labor induction following fFN testing. In this model, three management strategies were evaluated presuming fFN testing was performed in select groups at 39 weeks of pregnancy: (1) no elective induction of labor for any candidate until 41 weeks' gestation (spontaneous labor), (2) induction only of those patients with a positive fFN result at 39 weeks, and (3) elective induction for every woman at no less than 39 weeks' gestation without performance of a fFN test. The investigators based estimates and assumptions for their statistical model on previous published clinical studies regarding rates of cesarean delivery for women in spontaneous labor, rates of cesarean delivery after an induction for a prolonged pregnancy, distribution of fFN results at 39 weeks' gestation, and percentage of pregnancies beyond 41 weeks. Investigators found that the spontaneous labor strategy had the highest rate of vaginal delivery (90%) and the elective induction strategy had the lowest rate (79%). When fFN test results were used to screen candidates for elective induction, the rate of vaginal delivery was higher than the induction strategy but lower than the spontaneous labor strategy (83%). These investigators concluded that the best approach to improve vaginal delivery rates was to avoid elective induction in nulliparous women. fFN may, however, improve chances of vaginal delivery over nonselective induction. Larger trials are needed to further clarify the role of fFN in predicting the success of labor induction in the nulliparous patient and the cost-effectiveness of this approach.

Cervical Ripening

As discussed earlier, the condition of the cervix greatly influences the success of inducing labor. Cervical ripening is a complex process that results in physical softening and distensibility of the cervix, ultimately leading to partial cervical effacement and dilation.[61] Remodeling of the cervix involves enzymatic dissolution of collagen fibrils, increase in water content, and chemical changes. These changes are induced by hormones (estrogen, progesterone, relaxin), as well as cytokines, prostaglandin, and nitric oxide synthesis enzymes.[61] **Cervical ripening methods fall into two main categories: pharmacologic and mechanical (Table 14-10). Because the state of the cervix plays such a crucial role in labor induction, a cervical examination is essential before determining which method to use for labor induction.**

Although Bishop originally used his scoring system to prevent iatrogenic prematurity in an era before the widespread use of sonography, it is now widely used to assess the state of the cervix before induction, as well as to predict the success of labor induction. The higher the Bishop score, the more "ripe" or "favorable" the cervix is for labor induction. A low Bishop score, usually considered 5 or less, is "unripened" or "unfavorable" and will benefit from cervical ripening. For example, the likelihood of a vaginal delivery after labor induction is similar to that after spontaneous onset of labor if the Bishop score is 8 or higher in multiparous patients. A low Bishop score is particularly predictive of failure in nulliparous women who undergo induction of labor at term. The high risk of cesarean delivery associated with failure of induction in nulliparous women at term with low Bishop scores is well established in the literature.[53,56] The rates of cesarean delivery were compared in 4635 nulliparas women in spontaneous labor with 2647 nulliparas women who underwent induction of labor.[54] Cesarean delivery was performed in 11.5% of the spontaneous labor group and 23.7% of the labor induction group. The most important variable in predicting the risk of cesarean delivery was a Bishop score at the initiation of labor induction, with a 31.5% cesarean section rate among patients with a Bishop score less than 5 versus 18.1% for patients with a Bishop score greater than 5.

Table 14-10 Methods of Cervical Ripening

Pharmacologic Methods	Mechanical Methods
Oxytocin	Membrane stripping
Prostaglandins	Amniotomy
• E_2 (dinoprostone, Prepidil gel and Cervidil time-released vaginal insert)	Mechanical dilators
• E_1 (misoprostol, Cytotec)	• Laminaria tents
Estrogen	• Dilapan
Relaxin	• Lamicel
Hyaluronic acid	• Transcervical balloon catheters
Progesterone receptor antagonists	• With extra-amniotic saline infusion
	• With concomitant oxytocin administration

Failed Induction

Vaginal delivery is the goal of the induction process; however, this occurs less often than when women labor spontaneously. **There are currently no standards of what constitutes a failed induction. It is important for the clinician to recall that cervical ripening itself can take some time, and that the development of an active labor pattern should be achieved before the determination that the induction has failed.** The definitions and durations of labor described by Friedman in the 1950s were in regard to spontaneous labor, not inductions of labor. The importance of allowing enough time to progress from the latent phase of labor to the active phase is illustrated by the following studies.

In one large prospective study, the mean duration of the latent phase of labor (defined as the interval from initiation of induction with either prostaglandins or oxytocin to a cervical dilation of 4 cm) in women with a Bishop score of 0 to 3 was 12 hours in multiparas and 16 hours in nulliparas.[53] In another study, requiring a minimum of 12 hours of oxytocin administration after membrane rupture before diagnosing failed labor induction led to vaginal deliveries in 75% of nulliparas and eliminated failed labor induction as an indication for cesarean birth in parous women.[62] A third series found that 73% of women who ultimately delivered vaginally had a latent phase of up to 18 hours.[63] Latent phase was defined as the interval from initiation of oxytocin or amniotomy to the beginning of the active

phase (i.e., cervical dilation of 4 cm with 80% effacement or 5 cm dilation).

The definition of failed induction should be derived from what is known about the pattern of labor progression in women undergoing induced labor who ultimately achieve vaginal delivery. The goal is to minimize the number of cesarean deliveries performed for failed induction in patients who are progressing slowly because they are still in the latent phase of labor.[53,62,63] Once induced women enter active labor, progression should be comparable to progression in women with spontaneous active labor, or faster.[64]

One group proposed that failed induction be defined as the inability to achieve cervical dilation of 4 cm and 80% effacement or 5 cm (regardless of effacement) after a minimum of 12 to 18 hours of both oxytocin administration and membrane rupture.[65] They also specified that uterine contractile activity should reach five contractions per 10 minutes or 250 Montevideo units, which is the minimum level achieved by most women whose labor is progressing normally. The cervical criteria were based on the observation that most women have entered the active phase when dilation reached 4 to 5 cm; thus, intervention before this dilation is likely to represent a latent phase abnormality rather than a protracted or arrested active phase. The duration of oxytocin administration was based on the observational studies cited previously, which described the maximum duration of latent phase in over 70% of induced women who went on to deliver vaginally. The membrane rupture requirement established a clear time point for "starting the clock," removed the time required for preinduction cervical ripening from the latent phase, and acknowledged the contribution of amniotomy as a method of induction.

An Australian researcher evaluated a group of 978 nulliparous women after either artificial or spontaneous rupture of membranes to determine factors that could predict failed induction.[66] There was a direct correlation between increasing duration of the latent phase and the probability of cesarean birth. After 10 hours of oxytocin administration, the 8% of women not in the active phase of labor had an approximately 75% chance of being delivered by cesarean for failed induction; after 12 hours of oxytocin administration, the chance of cesarean was almost 90%. Multivariable analysis showed that short maternal stature and use of pharmacologic or mechanical methods of cervical ripening contributed to an increased probability of cesarean delivery. Similarly, there was a linear relationship between lack of cervical dilation and cesarean birth. The authors concluded that the continuation of oxytocin after amniotomy for women who had not yet reached at least 4 cm dilation was not unreasonable, but that beyond 12 hours, the benefit was unclear.

TECHNIQUES FOR CERVICAL RIPENING AND LABOR INDUCTION

Oxytocin

Oxytocin is a polypeptide hormone produced in the hypothalamus and secreted from the posterior lobe of the pituitary gland in a pulsatile fashion. It is identical to its synthetic analog, which is among the most potent uterotonic agents known. Synthetic oxytocin is an effective means of labor induction.[67] Exogenous oxytocin administration produces periodic uterine contractions first demonstrable at approximately 20 weeks' gestation, with increasing responsiveness with advancing gestational age primarily due to an increase in myometrial oxytocin binding sites. There is little change in myometrial sensitivity to oxytocin from 34 weeks to term; however, once spontaneous labor begins, the uterine sensitivity to oxytocin increases rapidly. This physiologic mechanism makes oxytocin more effective in augmenting labor than in inducing labor, and even less successful as a cervical ripening agent.

Oxytocin is most often given intravenously. It cannot be given orally because the polypeptide is degraded to small, inactive forms by gastrointestinal enzymes. The plasma half-life is short, estimated at 3 to 6 minutes, and steady-state concentrations are reached within 30 to 40 minutes of initiation or dose change. Synthetic oxytocin is generally diluted by placing 10 units in 1000 mL of an isotonic solution, such as normal saline, yielding an oxytocin concentration of 10 mU/mL. It is given by infusion pump to allow continuous, precise control of the dose administered. A common practice is to make a solution of 60 units in 1000 mL crystalloid to allow the infusion pump setting to match the dose administered (e.g., 1 mU/min equals a pump infusion rate of 1 mL/hr).

Although oxytocin is an effective means of labor induction in women with a favorable cervix as noted earlier, it is less effective as a cervical ripening agent. Many randomized controlled trials comparing oxytocin with various prostaglandin (PG) formulations and other methods of cervical ripening confirm this observation. Lyndrup and colleagues compared the efficacy of labor induction with vaginal PGE_2 with continuous oxytocin infusion in 91 women with an unfavorable cervix (Bishop score <6). They found PGE_2 more efficacious for labor induction in 12 to 24 hours, with fewer women undelivered at 24 hours. However, by allowing the inductions to proceed for 48 hours, they found no difference in vaginal delivery rates after 48 hours between the two groups. In a larger study involving 200 women with an unfavorable cervix undergoing labor induction, vaginally applied prostaglandin E_2 was compared with continuous oxytocin infusion. These investigators found a shorter time interval to active labor, a significantly greater change in Bishop score, fewer failed inductions, and fewer multiple-day inductions with PGE_2 compared with oxytocin. No difference in the rate of cesarean delivery was found between the groups overall. In a Cochrane review of 110 trials including more than 11,000 women comparing oxytocin with any vaginal prostaglandin formulation for labor induction, oxytocin alone was associated with an increase in unsuccessful vaginal delivery within 24 hours (52 vs. 28%, RR 1.85, 95% CI 1.41 to 2.43). There was no difference in the rate of cesarean delivery between groups. When intracervical prostaglandins were compared with oxytocin alone for labor induction, oxytocin alone was associated with an increase in unsuccessful vaginal delivery within 24 hours (51 vs. 35%, RR 1.49, 95% CI 1.12 to 1.99) and an increase in cesarean delivery (19% vs. 13%, RR 1.42, 95% CI 1.11 to 1.82).[67]

In the setting of premature rupture of membranes (PROM) at term (defined as rupture of membranes before

TABLE 14-11 LABOR STIMULATION WITH OXYTOCIN: EXAMPLES OF LOW- AND HIGH-DOSE OXYTOCIN DOSING REGIMENS

REGIMEN	STARTING DOSE (mU/MIN)	INCREMENTAL INCREASE (mU/MIN)	DOSAGE INTERVAL (MIN)
Low-dose	0.5-2.0	1-2	15-40
High-dose	6	3-6*	15-40

Induction of Labor. ACOG Practice Bulletin No 107. American College of Obstetricians and Gynecologists. Obstet Gynecol 114:386, 2009.
*The incremental increase is reduced to 3 mU/min in the presence of hyperstimulation and reduced to 1 mU/min with recurrent hyperstimulation.

the onset of labor), labor induction is recommended if spontaneous labor does not ensue within a reasonable amount of time because, as the time between rupture of membranes and the onset of labor increases, so may the risk of maternal and fetal infection.[68] A series of systematic reviews examined the outcomes of pregnancies with PROM at or near term.[68] One trial accounts for most of the patients included in the analysis. Hannah and colleagues studied 5041 women with PROM at term. Subjects were randomly assigned to receive intravenous oxytocin, vaginal prostaglandin E_2 gel, or expectant management for up to 4 days, with labor induced with either intravenous oxytocin or vaginal prostaglandin E_2 gel. Those randomized to the expectant management group were induced if complications such as chorioamnionitis developed. The rates of neonatal infection and cesarean delivery were not statistically different between the groups. Rates of clinical chorioamnionitis were less in the group receiving intravenous oxytocin. When oxytocin alone was compared with vaginal prostaglandins in 14 trials for labor induction after PROM by Cochrane reviewers, both medications were found to be equally efficacious.[67] Thus, both can be used in this clinical setting. Because the majority of women with PROM enter labor spontaneously, a policy of expectant management for up to 96 hours is not unreasonable. However, active management of PROM does not increase the risk of cesarean delivery and significantly shortens the time until delivery. Therefore, patients should be offered a choice between active and expectant management, although more prefer active management.

The optimal regimen for oxytocin administration is debatable, although success rates for varying protocols are similar. Protocols differ as to the initial dose, incremental time period, and steady state dose (Table 14-11).[26] A maximum oxytocin dose has not been established, but most protocols do not exceed 42 mU/min.

Low-Dose Versus High-Dose Oxytocin

Low-dose protocols mimic endogenous maternal physiology and are associated with lower rates of uterine tachysystole. Low-dose oxytocin is initiated at 0.5 to 1 mU and increased by 1 mU per minute at 40- to 60-minute intervals. Slightly higher doses beginning at 1 to 2 mU/min increased by 1 to 2 mU/min, with shorter incremental time intervals of 15 to 30 minutes, have also been recommended. Pulsatile oxytocin administration, which truly mimics endogenous oxytocin release from the posterior pituitary, at 8- to 10-minute intervals, is considered a variant of low-dose oxytocin administration. It has the advantage of reducing total oxytocin requirements by 20% to 50%.[69] Proponents of low-dose oxytocin administration maintain that a slow rate of oxytocin administration is as effective for inducing labor and labor augmentation as faster rates of increase, while at the same time minimizing oxytocin requirements with lower rates of uterine overactivity.

High-dose oxytocin regimens are often employed in active management of labor protocols. These regimens are largely used for labor augmentation, rather than for labor induction. Examples of these protocols start with an initial oxytocin dose of 6 mU/min increased by 6 mU/min at 20 minute intervals, with a maximum dose of 40 mU/min[69] or start at 4 mU/min with 4 mU/min incremental increases (no maximum dose described).[53] A prospective study involving nearly 5000 women at Parkland Hospital comparing low-dose with high-dose oxytocin regimens for labor induction and augmentation was undertaken.[70] The high-dose protocol allowed for reduction of the dosage to 3 mU/min in the presence of uterine tachysystole. The results indicated that subjects given the high-dose regimen had a significantly shorter mean admission to delivery time, fewer failed inductions, fewer forceps deliveries, fewer cesarean deliveries for failure to progress, less chorioamnionitis, and less neonatal sepsis than subjects given the low-dose regimen. Notably, these subjects had a higher rate of cesarean delivery performed for "fetal distress," but no difference in neonatal outcomes was observed. Merrill and Zlatnik[71] conducted a randomized, double-masked trial including 1307 patients, comparing high-dose (4.5 mU/min initially increased by 4.5 mU/min every 30 minutes) with low-dose (1.5 mU/min initially, increased by 1.5 mU/min every 30 minutes) oxytocin for augmentation and induction of labor. Oxytocin solutions were prepared by a central pharmacy, and infusion volumes were identical to ensure double masking. In the group receiving high-dose oxytocin, labor was significantly shortened when used for induction (8.5 vs. 10.5 hours, $p < 0.001$), and augmentation (4.4 vs. 5.1 hours, $p = 0.3$). There was no significant difference in cesarean section rates between the two regimens (15% vs. 11.3%, $p = 0.17$). There were, however, more decreases or discontinuations of oxytocin in the high-dose group both for uterine tachysystole and fetal heart rate abnormalities. Discontinuation of oxytocin did not appear to have an adverse impact on cesarean section rates or lengthening of labor. Neonatal outcomes were observed to be similar in both groups.

In contemporary obstetrical practice, based on the aforementioned evidence, oxytocin is most often used to augment labor in patients with inadequate uterine activity or to induce labor in a patient with a favorable cervical status. One of many dosing regimens may be used depending on the standard practice in the community or the preference of the individual practitioner. Satin and colleagues[70] studied the differences in outcomes when oxytocin was used to augment as opposed to induce labor. These investigators prospectively studied 2788 consecutive women with singleton pregnancies. Indications for oxytocin stimulation were divided into augmentation ($n = 1676$) and induction ($n = 1112$). The low-dose regimen consisted of a starting dose of 1 mU/min with incremental increases of 1 mU/min at 20-minute intervals until 8 mU/min, then 2 mU/min increases up to a maximum of 20 mU/min, and

was used first for 5 months in 1251 pregnancies. The high-dose regimen consisted of a starting dose of 6 mU/min, with increases of 6 mU/min at 20-minute intervals up to a maximum dose of 42 mU/min, and was used for the subsequent 5 months in 1537 pregnancies. Labor augmentation was more than 3 hours shorter in the high-dose group compared with that of the low-dose group. High-dose augmentation resulted in fewer cesarean deliveries for labor dystocia and fewer failed inductions when compared with the low-dose regimen, although cesarean deliveries for fetal distress were performed more frequently. A literature review of randomized clinical trials of high- versus low-dose oxytocin regimens published from 1966 to 2003 concluded that high-dose oxytocin decreased the time from admission to vaginal delivery, but did not decrease the incidence of cesarean delivery compared with low-dose therapy.[72] Only one double-blinded randomized trial has been published, and had the same findings.[71] High-dose regimens are associated with a higher rate of tachysystole than low-dose regimes, and in some studies this has resulted in a higher rate of cesarean delivery for fetal distress,[70] but no significant difference in neonatal outcomes. When making decisions regarding which oxytocin regimen to use, the risks and benefits need to be carefully considered depending on the ultimate outcome desired.

Oxytocin Dosing Intervals

Varying dosing intervals have also been studied and, in contemporary practice, vary from 15 to 40 minutes. One comparison of the efficacy and outcomes with differing oxytocin dosing intervals included 1801 consecutive pregnancies receiving high-dose oxytocin (starting dose of 6 mU/min with incremental increases of 6 mU/min) at 20- and 40-minute intervals. In this study, 949 women received oxytocin at 20-minute intervals (n = 603 labor augmentations and n = 346 labor inductions) and 852 women received oxytocin at 40-minute dosing intervals (n = 564 labor augmentations and n = 288 labor inductions). The rates of cesarean delivery for dystocia or fetal distress were not statistically different between groups; however, the 20-minute regimen for augmentation was associated with a significant reduction in cesareans for dystocia (8% vs. 12%, p = 0.05). The incidence of uterine tachysystole was greater with the 20-minute regimen compared to the 40-minute regimen (40% vs. 31%; P = 0.02). Neonatal outcomes were unaffected by the dosing interval. The authors concluded that the 40-minute dosing interval offered no clear advantage over the 20-minute interval and that both were safe and efficacious.

Oxytocin Dosing Protocols

Several experts have suggested that implementation of a standardized protocol is desirable to minimize errors in oxytocin administration.[73-75] Clark and colleagues[75] implemented an oxytocin checklist-based protocol at a tertiary facility and evaluated outcomes in 100 women before utilization of the protocol versus another 100 women after the protocol was put into practice. In the checklist-managed group, the maximum dose of oxytocin used to achieve delivery was significantly lower. No differences were noted preprotocol or postprotocol in the length of labor, total time of oxytocin administration, or rate of operative vaginal or abdominal delivery. When the protocol was then implemented throughout the Hospital Corporation of American system (125 obstetrical facilities in 20 states), the rate of cesarean birth was notably decreased from 23.6% to 21.0% and newborn complications requiring NICU admission or Apgar scores less than 8 were improved. Hayes and Weinstein[73] describe a standardized protocol for oxytocin administration based on a literature review, as well as the specific pharmacokinetics of oxytocin (see box, Standardized Oxytocin Regimen). However, at this time, no protocol has been subjected to the scientific scrutiny necessary to demonstrate its superiority in both efficacy and safety over another.

Standardized Oxytocin Regimen

1. Dilution: 10 U oxytocin in 1000 mL normal saline for resultant concentration of 10 mU oxytocin/mL
2. Infusion rate: 2 mU/min or 12 mL/hr
3. Incremental increase: 2 mU/min or 12 mL/hr every 45 minutes until contraction frequency adequate
4. Maximum dose: 16 mU/min or 96 mL/hr

Hayes EJ, Weinstein L: Improving patient safety and uniformity of care by a standardized regimen for the use of oxytocin. Am J Obstet Gynecol 198:622.e1, 2008. Epub Mar 20, 2008.

Prostaglandins

Administration of PG results in dissolution of collagen bundles and an increase in submucosal water content of the cervix. These changes in cervical connective tissue at term are similar to those observed in early labor. PGs are endogenous compounds found in the myometrium, deciduas, and fetal membranes during pregnancy. The chemical precursor is arachidonic acid. PG formulations have been used since they were first synthesized in the laboratory in 1968. Prostaglandin analogs were originally given by intravenous and oral routes. Later, local administration of prostaglandins in the vagina or the endocervix became the route of choice because of fewer side effects and acceptable clinical response. Side effects of all PG formulations and routes may include fever, chills, vomiting, and diarrhea.

The efficacy of locally applied PG (vaginal or intracervical) for cervical ripening and labor induction as compared with oxytocin (alone or in combination with amniotomy) has been demonstrated in a Cochrane review involving more than 10,000 women. Vaginal prostaglandin E_2 compared with placebo reduced the likelihood of vaginal delivery not being achieved within 24 hours, the risk of the cervix remaining unfavorable or unchanged, and the need for oxytocin. There was no difference between cesarean section rates, although there was a trade-off with prostaglandin E_2 use as the risk of uterine tachysystole with fetal heart rate changes was increased. The various administration vehicles (tablet, gel, and timed-release pessary) appear to be equally efficacious. The optimal route, frequency, and dose of prostaglandins of all types and formulations for cervical ripening and labor induction have not been determined. Also, prostaglandin formulations of any kind should be avoided in women with a prior uterine scar such as a prior cesarean delivery or myomectomy because their use

appears to increase the risk for uterine rupture.[76] Uterine activity and fetal heart rate monitoring are indicated for 0.5 to 2 hours after administration of prostaglandins for cervical ripening, and should be maintained as long as regular uterine activity is present.[26]

Prostaglandin E_2

One of the first randomized controlled trials using intravaginal PG was conducted in 1979 by Liggins and colleagues. Eighty-four term women with singleton pregnancies were randomly assigned to three groups receiving placebo, 0.2 mg, or 0.4 mg PGE_2 compound. Labor was established in 48 hours in 9.3% of placebo women, 65.4% of women receiving 0.2 mg PGE_2, and 85.7% of women receiving 0.4 mg PGE_2. Rayburn summarized the experience with more than 3313 pregnancies representing 59 prospective clinical trials in which either intracervical or intravaginal PGE_2 was used for cervical ripening before the induction of labor. He concluded that local administration of PGE_2 is effective in enhancing cervical effacement and dilation, reducing the failed induction rate, shortening the induction to delivery interval, and reducing oxytocin use and cesarean delivery for failure to progress. These findings were confirmed in a meta-analysis of 44 controlled trials performed worldwide using various PG compounds and dosing regimens. Because there appears to be no difference in clinical outcomes when comparing intravaginal or intracervical PGE_2 preparations, and for ease of administration and patient satisfaction, vaginal administration is recommended.[77] A sustained-release vaginal pessary for PGE_2 has been developed. Its use eliminates the need for repeated dosing. Although data are limited, when comparing the efficacy of the intravaginally applied PGE_2 to the sustained-release suppository, there appears to be no difference in rates of vaginal delivery, fetal heart rate abnormalities, or uterine tachysystole.

Currently, there are two PGE_2 preparations approved by the U.S. Food and Drug Administration (FDA) for cervical ripening. There are a variety of other PGE_2 compounds such as suppositories available in the United States and tablets available in Europe, although these latter formulations are not approved for use by the FDA for cervical ripening. Many clinicians and pharmacists may prepare their own formulations of PGE_2 gel by thawing and resuspending 20 mg PGE_2 suppositories in small amounts of methylcellulose gel. The resulting gel preparation is then frozen in plastic syringes in various doses ranging from 1 to 6 mg.

Prepidil (Upjohn Pharmaceuticals, Kalamazoo, Michigan) contains 0.5 mg of dinoprostone in 2.5 mL of gel for intracervical administration. The dose can be repeated in 6 to 12 hours if there is inadequate cervical change and minimal uterine activity following the first dose. The manufacturer recommends that the maximum cumulative dose of dinoprostone not exceed 1.5 mg (three doses) within a 24-hour period. Oxytocin should not be initiated until 6 to 12 hours after the last dose because of the potential for uterine tachysystole with concurrent oxytocin and prostaglandin administration.

Cervidil (Forest Pharmaceuticals, St. Louis, Missouri) is a vaginal insert containing 10 mg of dinoprostone in a timed-release formulation. The vaginal insert administers the medication at 0.3 mg/hr and may be left in place for up to 12 hours. An advantage of the vaginal insert over the gel formulation is that the insert may be removed with the onset of active labor, rupture of membranes, or the development of uterine overactivity. This abnormality of uterine contractions is more often defined as six or more contractions in 10 minutes for a total of 20 minutes with concurrent fetal heart rate tracing abnormalities. Per the manufacturer's recommendations, oxytocin may be initiated 30 to 60 minutes after removal of the insert.

These two preparations are relatively expensive, require refrigerated storage, and become unstable at room temperature.

Prostaglandin E_1

Misoprostol (Cytotec, Searle Pharmaceuticals, Chicago, Illinois) is a synthetic prostaglandin E_1 analog available as 100 mcg and 200 mcg tablets. The current FDA-approved use for misoprostol is for the treatment and prevention of peptic ulcer disease related to chronic nonsteroidal anti-inflammatory use. Administration of misoprostol for preinduction cervical ripening is considered a safe and effective "off-label" use by the College.[78] Misoprostol is inexpensive and is also stable at room temperature. Misoprostol can be administered orally or placed vaginally with few systemic side effects. Although not scored, the tablets are usually divided to provide 25 or 50 mcg doses.

Multiple studies suggest that misoprostol tablets placed vaginally are either superior to or equivalent in efficacy compared with intracervical PGE_2 gel.[79] More recently a meta-analysis of 70 trials revealed the following points regarding the use of misoprostol compared with other methods of cervical ripening and labor induction.[80] Misoprostol improved cervical ripening compared with placebo and was associated with a reduced failure to achieve vaginal delivery within 24 hours (RR 0.36; 95% CI 0.19 to 0.68). There was a trend toward fewer cesarean deliveries that did not reach statistical significance. Compared with other vaginal prostaglandins for labor induction, vaginal misoprostol was more effective in achieving vaginal delivery within 24 hours (RR 0.80; 95% CI 0.73 to 0.87). Compared with vaginal or intracervical PGE_2, oxytocin augmentation was also less common with misoprostol (RR 0.65; 95% CI 0.57 to 0.73). However, uterine tachysystole with fetal heart rate changes (RR 2.04; 95% CI 1.49 to 2.80) and meconium-stained amniotic fluid (RR 1.42; 95% CI 1.11 to 1.81) was more common. Most studies suggested that restricting the dose of misoprostol to 25 mcg every 4 hours significantly reduced the risk of uterine tachysystole with and without fetal heart rate changes and meconium passage. Most important, regardless of misoprostol dose, there were no significant differences in immediate neonatal outcomes.

Although the ACOG, based on its review of the existing evidence, recommends 25 mcg dosing every 3 to 6 hours with vaginally applied misoprostol, the optimal dose and timing interval is not known.[26] Oxytocin may be initiated, if necessary, 4 hours after the final misoprostol dose. A meta-analysis comparing 25 mcg with 50 mcg dosing reported that 50 mcg dosing resulted in a higher rate of vaginal delivery within 24 hours with higher rates of uterine tachysystole and meconium passage but without

compromising in neonatal outcomes.[81] A statistically significant difference in fetal acidosis defined as a umbilical arterial pH of less than 7.16 was found in infants born to mothers given 50 mcg of intravaginally applied misoprostol every 3 hours compared with those born to mothers given 25 mcg every 3 hours. In their Committee Opinions on the use of misoprostol for labor induction, the College concludes that safety using the higher 50 mcg dosing could not be adequately evaluated and suggests the higher dose could be used only in select circumstances. A time-released misoprostol vaginal insert [MVI] is under development. In a three-arm Phase III investigation, an MVI dose of 100 mcg did not have appreciably better clinical outcomes than Cervidil.

Oral administration of misoprostol for cervical ripening has also been studied. Oral administration has the promise for offering more patient comfort, satisfaction, and convenience of administration. Most of these studies compared lower oral doses of misoprostol such as 50 mcg given every 3 to 6 hours and compared them to similar vaginal misoprostol dosing regimens such as 25 to 50 mcg given every 3 to 6 hours. This oral regimen of dosing appears to be no more effective than vaginal administration for achieving vaginal delivery or affecting cesarean rates, but may be associated with less uterine overactivity. There is a clear positive dose-response relationship seen between the dosage of oral misoprostol and rate of tachysystole. With the 25- and 50-mcg dosages, there is a lower tachysystole rate; it is higher in those given 200 mcg.[82] In this meta-analysis, oral misoprostol use was clearly superior to placebo, as women administered oral misoprostol were more likely to deliver vaginally within 24 hours, needed less oxytocin, and had a lower cesarean rate.

Some investigators have described titrating oral misoprostol to its desired effect.[83] This method appears to achieve vaginal delivery rates similar to vaginally administered misoprostol with less uterine overactivity. Low doses of oral misoprostol were achieved by making a solution (e.g., dissolving a 200 mcg tablet in 200 mL tap water), as this was believed to provide more accurate dosing than simply cutting the tablet into pieces. Because oral dosing has a short (2 hours) duration of action, administration was repeated at 2-hour intervals. The authors of this Cochrane review recommend that if clinicians choose to use oral misoprostol, a dose of 20 to 25 mcg in solution is preferred for safety considerations and addresses concerns regarding imprecision of dividing misoprostol tablets for recommended dosages. There are concerns, however, that the pharmacy and nursing administration needed for dose titration is complex.[82] More data are needed to shed light on the optimal dosing, safety, and cost considerations of oral misoprostol for cervical ripening and labor induction.

Other novel approaches include buccal and sublingual misoprostol administration. The theory is that avoiding first-pass hepatic circulation from oral administration will lead to bioavailability similar to that achieved with vaginal administration. This hypothesis has been substantiated by pharmacokinetic studies that have shown that the buccal and sublingual routes of administration are associated with rapid onset of action and greater bioavailability than other routes.[84] In a randomized controlled trial including 250 women admitted for labor induction, 50 mcg of sublingual misoprostol was compared to 100 mcg of orally administered misoprostol given every 4 hours to a maximum of five doses. Sublingual misoprostol appeared to have the same efficacy as orally administered misoprostol to achieve vaginal delivery within 24 hours with no increase in uterine tachysystole. However, the 100 mcg oral dose had higher rates of uterine overactivity than 25 mcg administered vaginally. A randomized controlled trial including 152 women received either 200 mcg of buccal misoprostol every 6 hours or 50 mcg of misoprostol administered vaginally every 6 hours. There was no statistically significant difference in time interval to vaginal delivery, the rate of vaginal delivery, or the rate of uterine tachysystole between the two groups. The buccal route was associated with a trend toward fewer cesarean sections than with the vaginal route. Based on only three small trials included in the Cochrane meta-analysis, sublingual misoprostol appears to be at least as effective as when the same dose is administered orally. There are inadequate data to comment on the relative complications and side effects. More data are needed to clarify not only safety but the efficacy of buccal and sublingual misoprostol use as well.[85] Optimal dosing regimens are yet to be defined, and concern exists because of greater bioavailability associated with these routes of administration when compared to vaginal use.

Outpatient or ambulatory approaches to cervical ripening and labor induction for elective or marginal indications could be useful in reducing the duration of hospitalization and the staffing requirements of labor and delivery. The body of evidence to support this approach, however, is limited.[86-89] Relevant published studies reflect a variety of different approaches to cervical ripening, including local applications of prostaglandin compounds and placement of Foley balloon catheters to the lower uterine segment with or without immediate hospitalization for further labor management. To adequately address safety of any outpatient cervical ripening and labor induction technique, large numbers of subjects will be necessary. For this reason, outpatient cervical ripening and labor induction is not recommended at this time, other than in a research setting.

Alternative Pharmacologic Methods

Researchers have evaluated several other compounds as alternatives for cervical ripening and labor induction in term pregnancies, including RU-486 (mifepristone), estrogen, relaxin, and hyaluronic acid.

RU-486 (mifepristone) is a competitive steroid receptor antagonist and, because of its antiprogestational action, it has been used for early pregnancy termination. It has also been studied as a potential alternative for cervical ripening and labor induction in term pregnancies. Although these studies demonstrate that mifepristone is more effective than placebo, there are no studies to date comparing mifepristone to other agents for cervical ripening and labor induction.[90] At this time, access to this medication limits widespread research and use.

Seminal parturition studies in sheep showed that there is a prelabor rise in estrogen associated with a decrease in progesterone. These changes stimulate prostaglandin production and may help initiate labor. Through this

mechanism, estrogen has been suggested and studied as a cervical ripening agent and labor induction agent. At this time, estrogen is not currently used in common practice as an induction agent, and there is insufficient evidence to draw any conclusions regarding its efficacy.

Relaxin, produced by the corpus luteum in pregnancy, is a protein hormone thought to have a promoting effect on cervical ripening through connective tissue remodeling. Its use was thought to have advantages over other agents that promoted uterine activity by potentially decreasing the risk of uterine tachsystole. Two studies totaling 113 women who received human recombinant relaxin for induction of labor compared with placebo showed no effect on cervical ripening or labor induction. The place of relaxin as an induction or cervical priming agent is unclear, and further trials are needed to determine its place in current clinical practice.

The cervix is a fibrous organ composed principally of hyaluronic acid, collagen, and proteoglycan. Hyaluronic acid increases as pregnancy progresses, peaks after the onset of labor, and decreases rapidly after birth of the infant. The increase in the level of hyaluronic acid is associated with an increase in tissue water content of the cervix, which is one of the mechanisms involved in cervical ripening. In the past, investigators postulated that cervical injection of hyaluronic acid would lead to cervical ripening. Although there is a theoretical physiologic mechanism for hyaluronic acid as a cervical ripening agent, there are no published studies using this agent for this indication.

Mechanical Methods

Mechanical methods are among the oldest approaches used to promote cervical ripening. Advantages of these techniques compared to pharmacologic methods include their low cost, low risk of tachysystole, few systemic side effects, and convenient storage requirements (no refrigeration or expiration).[91] Comparing mechanical methods with placebo or no treatment, tachysystole with fetal heart rate changes was not reported. The risk of cesarean birth was similar between groups (34%; RR 1.00; 95% CI 0.76 to 1.30, n = 416, six studies). There were no reported cases of severe neonatal and maternal morbidity among them. The risk of tachysystole was reduced when compared with all prostaglandins (intracervical, intravaginal, or misoprostol). Compared with oxytocin in women with unfavorable cervix, mechanical methods reduce the risk of cesarean delivery. Disadvantages of mechanical methods include a small increase in the risk of maternal and neonatal infection from introduction of a foreign body,[92] the potential for disruption of a low-lying placenta, and some maternal discomfort on manipulation of the cervix. The most common mechanical methods are stripping (or sweeping) of the fetal membranes, amniotomy, placement of hygroscopic dilators within the endocervical canal, and insertion of a balloon catheter above the internal cervical os (with or without infusion of extra-amniotic saline). All of these methods likely work, at least in part, by causing the release of prostaglandin $F_{2\text{-alpha}}$ from the decidua and adjacent membranes or prostaglandin E_2 from the cervix. The latter two methods physically cause gradual cervical dilation with minimal discomfort to the patient.

Membrane Stripping

Stripping or sweeping of the fetal membranes refers to digital separation of the chorioamniotic membrane from the wall of the cervix and lower uterine segment by inserting the examiner's finger beyond the internal cervical os and then rotating the finger circumferentially along the lower uterine segment. This procedure was first reported for induction of labor at term in 1810 by Hamilton in England. For membrane stripping, the fetal vertex should be well applied to the cervix, and the cervix should be dilated sufficiently to allow introduction of the examiner's finger.

Many investigations have been conducted using routine membrane stripping at 38 or 39 weeks to either prevent prolonged pregnancies or decrease the frequency of more formal inductions occurring after 41 weeks.[93] Two randomized trials compared outcomes of women who underwent membrane stripping or no membrane stripping at initiation of labor induction with oxytocin. The results of these trials suggested that membrane stripping increased the rate of spontaneous vaginal delivery and shortened the induction to delivery interval. However, differences in study design and management of induction preclude definitive conclusions. As an example, in one trial, these benefits were only observed in nulliparas, and, in the other trial, induction was performed using amniotomy or dinoprostone pessary.

Other randomized trials have tried to assess whether membrane stripping hastens the onset of spontaneous labor. In one randomized trial, women assigned to membrane stripping had a significant reduction in the subsequent duration of pregnancy (2 days compared to 5 days in controls) and frequency of induction (8.1% vs. 18.8% in controls), whereas two other randomized trials found no beneficial effects from membrane sweeping. None of these trials reported harmful side effects that could be attributed to the procedure.

Routine membrane stripping is not recommended given that there is no evidence this practice results in an improvement in maternal or neonatal outcome. However, **weekly membrane stripping at term shortens the interval of time to onset of spontaneous labor and reduces the need for formal induction.** For this reason, we offer membrane stripping after 39 weeks of gestation to patients who wish to hasten the onset of spontaneous labor.

Although the existing meta-analysis on the use of membrane stripping[94] was not associated with an increase in either maternal or neonatal infection, it is unclear if the included studies involved carriers of group B streptococcus (GBS). There are no studies currently in the literature specifically designed to address the safety of membrane stripping in known carriers of GBS and, as a result, this is not considered a contraindication to membrane stripping.[95]

Complications that can result from membrane stripping include rupture of membranes, hemorrhage from disruption of an occult placenta previa, and the development of chorioamnionitis. **Most commonly, however, membrane stripping is associated with maternal discomfort and clinically insignificant vaginal bleeding.**

Amniotomy

Amniotomy, artificial rupture of membranes, is a technique involving the perforation of the chorioamniotic

membranes. It is an effective method of labor induction performed in multiparous women with favorable cervices. Before amniotomy is performed, confirmation is essential that the fetal vertex, and not the umbilical cord or other fetal part, is presenting and is well applied to the cervix. These precautions are taken to prevent umbilical cord prolapse, which often necessitates emergent cesarean delivery. The amniotomy procedure usually involves a toothed clamp such as an Allis clamp, or more commonly, a plastic hook that is applied to the membranes and manipulated so as to puncture the membranes. The fetal heart rate status before and after the procedure should be monitored, and the amniotic fluid character and color should be recorded.

Although trials evaluating amniotomy alone versus placebo or no treatment are lacking,[96] combined use of amniotomy and intravenous oxytocin is more effective than amniotomy alone with fewer women undelivered vaginally after 24 hours.[97] In the meta-analysis of amniotomy, 17 trials involving 2566 women were included. Amniotomy and intravenous oxytocin were found to result in (1) fewer women being undelivered vaginally at 24 hours than amniotomy alone (RR 0.03; 95% CI 0.001 to 0.49, $n = 100$, one study); (2) significantly fewer instrumental vaginal deliveries than placebo (RR 0.18; CI 0.05 to 0.58); and (3) more postpartum hemorrhage than vaginal prostaglandins (RR 5.5; CI 1.26 to 24.07). There is also more dissatisfaction with amniotomy and intravenous oxytocin when compared with vaginal prostaglandins (RR 53.0; CI 3.32 to 846.51).[97]

Hygroscopic Dilators

Mechanical dilators placed in the lower uterine segment release endogenous prostaglandins from the fetal membranes and maternal decidua. In addition, the osmotic properties of hygroscopic dilators promote cervical ripening. These hygroscopic dilators absorb endocervical and local tissue fluids that cause swelling and allow for controlled dilation by mechanical pressure. There are two types of hygroscopic dilators: one is made from natural seaweed *(Laminaria japonicum)* and the other is a synthetic product (e.g., Lamicel). Hygroscopic dilators are safe and effective for dilating the cervix, although they are used primarily during pregnancy termination rather than for preinduction cervical ripening of term pregnancies. They function by disrupting the chorioamniotic decidual interface, causing lysosomal destruction and prostaglandin release. These events lead to active stretching of the cervix beyond the passive mechanical stretching provided by the dilator itself.

A meta-analysis of randomized trials comparing hygroscopic dilators to placebo/no treatment found that pregnant women in both groups had similar rates of not achieving a vaginal delivery by 24 hours (RR 0.90; 95% CI 0.64 to 1.26), cesarean deliveries (RR 0.98; 95% CI 0.74 to 1.30), and infection.[91] These data suggest that although hygroscopic dilators can dilate the cervix, they are inadequate for improving the outcome of induction. However, no large trials have been performed and there are no well-designed comparative studies evaluating the optimal use of hygroscopic dilators with other modalities, such as amniotomy, to improve the rate of successful induction. A significant disadvantage of the use of laminaria for cervical ripening is patient discomfort both at the time of insertion and with progressive cervical dilation. With other equally effective agents available, there is no obvious benefit to support their routine use for labor induction at term. In specific clinical circumstances in which prostaglandins should be avoided or are unavailable because of supply or cost, laminaria can be used both safely and effectively.

Transcervical Balloon Catheters

A deflated Foley catheter, usually a 16-French 30-mL balloon, can be passed through an undilated cervix into the extra-amniotic space and then inflated. The balloon is then retracted to rest against the internal os. Some clinicians remove the top of the catheter before insertion although there are no data to suggest that this is necessary. To add more traction, pressure may be applied by attaching a weight such as a liter of intravenous fluid to the end of the catheter and suspending it with the force of gravity or by taping the catheter under tension to the patient's inner thigh. The benefit of traction has not been proven.

Transcervical balloon catheters appear to be as effective for preinduction cervical ripening as prostaglandin E_2 gel and intravaginal misoprostol in most studies. The combination of a balloon catheter plus administration of a prostaglandin does not appear to be more effective than prostaglandins alone. Although the risk of infection may theoretically be associated with the insertion of a foreign object in the cervix, existing meta-analysis data did not show evidence of an increased risk of infectious morbidity. This technique is a superior method of preinduction cervical ripening when compared with intravenous oxytocin and has been associated with a lower rate of cesarean delivery in one investigation.[91] Some studies show more rapid cervical ripening, a shortened induction to delivery interval, and reduced frequency of patients undelivered in 24 hours when combining a transcervical balloon catheter with a pharmacologic method of cervical ripening such as a prostaglandin, whereas others do not. No increased risk of preterm delivery in subsequent pregnancies following the placement of balloon catheters in the lower uterine segment was found by Sciscione and colleagues in 126 women.

The use of the Atad double-balloon device has also been described in a limited group of studies. One investigation included 95 women with Bishop scores no more than 4 and randomly assigned them to vaginally administered PGE_2, Atad balloon dilator technique, or continuous oxytocin for labor induction. They found a significant mean change in Bishop score after 12 hours in the PGE_2 group and Atad balloon dilator group of 5 compared with 2.5 in the oxytocin group. In addition they found a higher rate of failed induction in the oxytocin group (58%) compared with 20% in the PGE_2 and 5.7% in the Atad balloon dilator groups. Vaginal delivery rates in the oxytocin group were 26.7% compared with 77% and 70% in the Atad balloon dilator and PGE_2 groups, respectively.

Extra-Amniotic Saline Infusion

Infusion of isotonic fluid into the extra-amniotic space has been employed as an adjunct to transcervical balloon catheter placement in the lower uterine segment. The

hypothesis for this approach is that this disruption of the fetal-maternal interface will result in added release of endogenous prostaglandins and other parturition-related hormones to facilitate the onset of spontaneous uterine activity. Most commonly, isotonic saline is used (hence the name extra-amniotic saline infusion [EASI]) and is infused continuously at rates of 20 to 40 mL/hr. The use of EASI with a transcervical Foley balloon catheter appears to be effective for cervical ripening when compared with intravaginal prostaglandins, although EASI does not appear to improve induction outcomes over those observed with the use of Foley catheter alone. In three randomized trials, both techniques resulted in similar rates of delivery less than 24 hours, cesarean delivery, and complications, although one small trial reported a shorter induction-to-vaginal-delivery time with the combined method.

A Cochrane review comparing EASI to any prostaglandin for cervical ripening showed that EASI infusion was significantly less likely to result in vaginal delivery within 24 hours (43% vs. 58%, RR 1.33; 95% CI 1.02 to 1.75), had a higher risk of cesarean delivery (31% vs. 22%, RR 1.48; 95% CI 1.14 to 1.90), and did not reduce the risk of tachysystole.[91] From these data, there is little support for the use of EASI as an adjunct to transcervical balloon catheter placement.

The only trials using the transcervical Foley catheter with simultaneous oxytocin infusion compared with vaginally administered misoprostol incorporated EASI along with the transcervical catheter. The largest trial by Buccellato and colleagues included 250 women undergoing labor induction with an unfavorable cervix who were randomly assigned to receive either a transcervical Foley catheter with concomitant oxytocin infusion or vaginally administered misoprostol 50 mcg every 4 hours for a maximum of three doses. There were no significant differences in the rate of cesarean delivery, rate of uterine tachysystole, or time intervals to vaginal delivery, indicating that both methods of labor induction appear to be equally effective. Mullin and colleagues studied 200 women undergoing labor induction with an unfavorable cervix. Subjects were randomized to receive a transcervical Foley catheter with EASI and concomitant oxytocin infusion or vaginally administered misoprostol 25 mcg every 4 hours for a maximum of six doses. They found that subjects receiving misoprostol had a longer average interval from labor induction to delivery of 1323 minutes compared with 970 minutes for subjects receiving the transcervical Foley catheter. There were no differences in cesarean births between the two groups. These data indicate that the transcervical Foley catheter with simultaneous oxytocin infusion may be just as efficacious as the usual dosing regimen for vaginally administered misoprostol for preinduction cervical ripening, and may, in fact, result in shorter induction to delivery time intervals.

MIDTRIMESTER INDUCTION

In particular circumstances, such as when a fetus has died in utero or in cases of termination of pregnancy in which a fetus would not survive or would survive but with significant handicaps, a woman may need to give birth before spontaneous labor. Several delivery options are available for these women, and the decision as to which option is chosen depends on physician expertise, gestational age, clinical circumstances, and the patient's preferences. Many women will desire immediate delivery secondary to the emotional difficulties of continuing to carry a nonviable fetus; however, some would prefer expectant management in order to avoid an induction of labor. In most cases, there is no medical urgency for immediate delivery. Expectant management raises concerns regarding consumptive coagulopathy and intrauterine infection, but these are rarely associated with prolonged expectant management. Some studies report that 80% to 90% of women will spontaneously labor within 2 weeks of a fetal demise, but the latency period may be longer.[98]

Table 14-12 Second Trimester Termination Methods

SURGICAL TECHNIQUES	MEDICAL TECHNIQUES
Dilation and evacuation	Intravenous oxytocin
Laparotomy	Intra-amniotic hyperosmotic fluid
Hysterotomy	20% saline
Hysterectomy	30% urea
	Prostaglandins E_2, $F_{2\alpha}$, E_1, and analogs
	RU-486 (mifepristone)
	Various combinations of above

Options of delivery include induction of labor and dilation and evacuation (D&E), among others (Table 14-12). Again, the decision for which mode of delivery to choose must be individualized by practitioner experience, gestational age, and the patient's desires. The emotional and psychological factors vary with each patient, with one advantage of induction being the delivery of an intact fetus whereas an advantage of D&E may be avoiding a prolonged induction.

Most of the research available regarding modes of delivery for midtrimester delivery are extrapolated from the investigations performed regarding second trimester elective abortions. One study evaluated patients undergoing surgical termination between 14 and 24 weeks of gestation and women undergoing labor induction, which revealed an overall lower rate of complications in those undergoing D&E (4% vs. 29%). The groups were similar, however, in their need for blood transfusion, infection, cervical laceration, maternal organ damage, and hospital readmission. Cochrane reviewers recently concluded that D&E is superior to intra-amniotic instillation of prostaglandin $F_{2\text{-alpha}}$ and may be favored over mifepristone and misoprostol, but larger randomized studies are necessary to confirm these latter findings.[99] At this time, both methods of delivery are considered reasonably safe.

Several methods of labor induction have been used, with no standard protocol currently accepted. In the 1940s, physicians attempted to "salt out" the fetus by injecting hypertonic agents into the amniotic cavity. Hypertonic saline thus became the mainstay of second trimester medical abortion through the 1970s. However, significant risks associated with this method included hypernatremia, coagulopathy, and massive hemorrhage requiring blood transfusions. Instillation regimens using hyperosmolar urea were associated with less coagulopathy and hypernatremia than saline. However, the urea regimens have not

TABLE 14-13 SUGGESTED PROTOCOLS FOR STILLBIRTH DELIVERY

D&E FOR UTERUS BETWEEN 13 AND 22 WK SIZE	INDUCTION OF LABOR
• Admit to hospital, day operating room, or clinic • Obtain hematocrit and type and screen • Give doxycycline 100 mg orally 1 hr before procedure and 200 mg after procedure or postoperative metronidozole 500 mg orally twice a day for 5 days	• Admit to labor and delivery • Obtain complete blood count and type and screen; consider fibrinogen if fetus has been dead for >4 wk
To Facilitate Cervical Dilation • Administer misoprostol 200 mcg in the posterior fornix 4 hr before procedure (may be placed by patient) • Place laminaria in cervix (usually carried out in office on the afternoon before the procedure)	**Induction Protocols** • For uterus <28 wk: misoprostol 200-400 mcg vaginally or orally every 4 hr until delivery of fetus • For uterus >28 wk: misoprostol 25-50 mcg vaginally or orally every 4 hr or oxytocin infusion per usual protocol • Consider transcervical Foley catheter or laminaria for cervical ripening
Operative • Perform D&E under ultrasound guidance	**Intrapartum** • To minimize risk of retained placenta, allow for spontaneous placental delivery, avoid pulling on umbilical cord, consider further doses of misoprostol or high-dose oxytocin • Monitor vital signs as per routine for labor and delivery • Pain management includes epidural, intravenous narcotics via patient-controlled analgesia or intermittent doses • Parents should be encouraged to spend time with the infant and offered keepsake items (pictures, handprints/footprints, etc.)
Postprocedure Instructions • Discharge home after anesthesia has worn off and vaginal bleeding is minimal • Administer RhD immune globulin if patient is Rh negative • Schedule a follow-up visit in 2 wk • Prescribe NSAIDs or mild narcotics • Offer bereavement services	**Postprocedure Instructions** • Discharge home in 6 to 24 hr if vital signs are stable and bleeding is appropriate • Consider postpartum care on a nonmaternity ward • Administer RhD immune globulin if patient is Rh negative • Follow-up visit in 2-6 wk • Offer bereavement services

D&E, Dilation and evacuation; *NSAIDs*, nonsteroidal anti-inflammatory drugs.

been compared to more recent induction protocols. Hyperosmolar regimens often require concomitant use of medical induction agents, such as oxytocin, to stimulate contractions and delivery.

More recent protocols have implemented regimens with gemeprost or misoprostol, both PGE_1 analogs; however, a meta-analysis of randomized trials comparing the two medications reported that misoprostol suppositories were associated with a reduced need for narcotic analgesia and surgical evacuation of the uterus. The application of gemeprost is limited secondary to its expense, instability at room temperature, and narrow routes of administration. It is also not currently available in the United States. At this time, the World Health Organization also recommends the use of mifepristone before PGE_1 analogs for expeditious and safe second trimester abortions. Mifepristone, as an antiprogestin, increases uterine sensitivity to prostaglandins, permitting lower doses and minimizing side effects. However, current studies do not reveal any advantage of pretreatment with mifepristone for induction in second trimester fetal demise.[100]

When planning an induction of labor, gestational age plays a significant role regarding the methods of induction. When the gestational age is less than 28 weeks, the uterus is less sensitive to oxytocin and, therefore, prostaglandins or mechanical devices may be required to commence labor. Current induction protocols vary by dose, route, and gestational age (Table 14-13). It is important to keep in mind that although side effects (uterine tachysystole, nausea, vomiting, diarrhea) and safety remain important considerations for the patient in these circumstances, the fetal well-being is no longer an issue.

Women with a prior cesarean section are candidates for induction of labor in these circumstances as well. A recent review by Berghella and colleagues reported an incidence of uterine rupture of 0.4%, hysterectomy 0%, and transfusion 0.2% for women undergoing second trimester misoprostol terminations. Patients may elect for a repeat cesarean delivery, but the risks and benefits should be carefully considered.

SUMMARY

Induction of labor is one of the most commonly performed procedures in obstetrical medicine, and can be undertaken for a variety of medical and obstetrical indications. The prediction of labor induction success has been studied with focus on a number of clinical, biochemical, and radiographic approaches. Cervical dilation at the time of initiation is the best independent predictor of induction success. A variety of pharmacologic and mechanical methods exist for cervical ripening. The most commonly used approaches include use of prostaglandins such as dinoprostone and misoprostol, as well as transcervical Foley balloon catheter placement. Augmentation of labor is usually accomplished with intravenous oxytocin, which can be administered using either low- or high-dose infusion protocols. In the case of a midtrimester induction, either induction of labor or dilation and evacuation is considered a safe approach.

KEY POINTS

- Labor is a clinical diagnosis defined as uterine contractions resulting in progressive cervical effacement and dilation, often accompanied by a bloody discharge referred to as bloody show, which results in birth of the baby.
- A graduated approach for diagnosis of labor protraction and arrest should be considered, based on the level of cervical dilation.
- Because the duration of latent labor is highly variable, expectant management is most appropriate.
- The most common causes of protraction or arrest disorders are inadequate uterine activity and abnormal positioning of the fetal presenting part.
- An intrauterine pressure catheter is frequently used when inadequate uterine activity is suspected owing to a protraction or arrest disorder. It can also be used to monitor and titrate oxytocin administration.
- There is evidence that maternal morbidities including perineal trauma, chorioamnionitis, instrumental delivery, and postpartum hemorrhage increase with prolonged second stages lasting greater than 2 hours.
- Comparing active to expectant management of the third stage, there is a reduced risk of postpartum hemorrhage when active management is used.
- Complications of oxytocin administration include water intoxication, uterine tachysystole, and uterine rupture. These complications are most commonly seen with high-dose, prolonged infusions. The condition of the cervix at the start of labor induction is critical to the success of the induction attempt. Both pharmacologic and mechanical methods of cervical ripening are available.
- Induction of labor should be undertaken when the benefits of prompt delivery to either mother or fetus outweigh the risks of pregnancy continuation.
- Recent studies have demonstrated that routine induction of labor at 41 weeks' gestation is not associated with an increased risk of cesarean delivery regardless of parity, state of the cervix, or method of induction. This indicates that some target populations may be appropriate for elective induction without incurring the added risks of cesarean delivery.
- The three major potential complications of elective induction of labor are increased neonatal morbidity, increased cost, and increased cesarean delivery resulting from failed induction. However, elective induction between 37 and 39 weeks' gestational age may be associated with a decreased risk of cesarean birth compared to expectant management.
- Cervical ripening methods fall into two main categories: pharmacologic and mechanical. Because the state of the cervix plays such a crucial role in labor induction, a cervical examination is essential before determining which method to use for labor induction.
- There are currently no standards of what constitutes a failed induction. It is important for the clinician to recall that cervical ripening itself can take some time, and that the development of an active labor pattern should be achieved before the determination that the induction has failed.
- Membrane sweeping is effective in reducing the interval to spontaneous onset of labor and the overall duration of pregnancy when performed at term. It is not associated with increased maternal or neonatal infection, but can cause maternal discomfort and vaginal bleeding.
- In women with intact membranes, combined use of amniotomy and intravenous oxytocin is more effective than amniotomy alone, with fewer women undelivered vaginally after 24 hours.
- Induction of labor with intravenous oxytocin, intravaginal prostaglandin compounds, and expectant management (with defined time limits) are all reasonable options for women and their infants in the face of PROM at term, because they result in similar rates of neonatal infection and cesarean delivery.
- There are a variety of different dosing protocols and dosing intervals for the administration of oxytocin for labor induction and augmentation. In general, higher doses are associated with shorter times to delivery, but more uterine tachysystole than are lower doses. Lower doses of oxytocin do not increase operative delivery rates or prolong delivery intervals.
- Options of delivery for midtrimester stillbirth or induction for lethal fetal anomalies include induction of labor and dilation and evacuation (D&E), among others. The decision for which mode of delivery to choose must be individualized by practitioner experience, gestational age, and the patient's desires.

Obstetrical forceps are the one instrument that makes the practice of obstetrical care unique to obstetricians. The proper use of these instruments has afforded safe and timely vaginal delivery to those whose abnormal labor course and/or urgent need for delivery required their use. Following the introduction of forceps by Chamberlin during the 1600s, much discussion about the proper use and timing of forceps application ensued. Following Smellie's retirement from practice in 1760, forceps began to be used very frequently, resulting in an increase in both maternal and neonatal injury owing to the application techniques used at the time. In his 1788 text entitled "An Introduction to the Practice of Midwifery," Thomas Denman stated that "the head of the child shall have rested for 6 hours as low as the perineum before the forceps are applied though the pains should have ceased during that time."[1] Denman's Law then became widely accepted as the standard of this time. However, after the news of Princess Charlotte's death following the birth of a stillborn Prince on November 6, 1817, a review of Denman's Law ensued with much public discussion regarding the timely use of forceps. Princess Charlotte's labor had been managed by one of Denman's students and son-in-law, Sir Richard Croft, whose second-stage labor management during this delivery came into question. Croft had permitted the second stage to last 24 hours, including 6 hours on the perineum, as Denman's Law had advised. However, the Princess delivered a 9 lb stillborn male heir, and within 24 hours of delivery the Princess herself died of a massive postpartum hemorrhage. Disturbed with depression and despair at the blame for the death of both the Princess and the heir to the British throne, Croft shot himself 3 months later. During a lecture delivered at the Royal College of Obstetricians and Gynaecologists on September 28, 1951, Sir Eardley Holland named his lecture on these events "A Triple Obstetric Tragedy" in which he described a mother, baby, and accoucheur all dead, victims of a mistaken system.[2] In a subsequent text in 1817, Denman wrote: "Care is also to be taken that we do not, through an aversion to the use of instruments, too long delay that assistance we have the power of affording them."[3] The debate regarding the use of these instruments continued into the twentieth century with prophylactic forceps delivery advocated by DeLee in 1920.[4] This clinical management strategy resulted in forceps delivery rates in excess of 65% by 1950.

With these lessons in mind, a review of operative vaginal delivery in modern obstetrical practice is extremely important and timely. **Rates of cesarean delivery have risen in**

both the United States and the United Kingdom,[5,6] reaching a rate of approximately 25% of all deliveries in the United States, whereas rates of forceps delivery have declined from 17.7% in 1980 to 4% in 2000[5] in the United States, and from 8.6% in 1989 to 6.2% in 1993 in the United Kingdom.[7] Conversely, the rate of vacuum-assisted vaginal delivery more than doubled in the United States between 1980 and 2000 to 8.4%.[4] Most residency training programs in the United States still expect proficiency in outlet and low forceps (less than or greater than 45-degree rotation), whereas less than 40% expect proficiency in midforceps delivery.[8] **However, to make education and teaching of these procedures even more challenging, new resident work hour restrictions have resulted in a decline in resident experience with both primary cesarean delivery and vacuum-assisted vaginal delivery, despite increased institutional volumes of these procedures.** In a study by Blanchard and colleagues,[9] the decrease in experience with these procedures has been dramatic, noting a 54% decline in experience with primary cesarean delivery and a 56% decline in vacuum-assisted vaginal delivery. Because both forceps and vacuum extractors are acceptable and safe instruments for operative vaginal delivery, operator experience is the determining factor in which instrument should be used in a specific clinical situation.[10] Declining use and resident experience may make it difficult to provide the level of operator experience required for proficiency of this obstetrical art. However, because most women prefer a vaginal delivery, focused experience with the use of these instruments during residency training is crucial to ensure safe, timely, and effective vaginal delivery because women are more likely to achieve a spontaneous vaginal delivery in a subsequent pregnancy after forceps delivery than after cesarean delivery (78% vs. 31%).[11-14] The challenge, therefore, is to ensure that women who experience second-stage labor abnormalities are afforded options for safe and timely delivery.

OPERATIVE VAGINAL DELIVERY

Classification, Prerequisites, and Indications

The use of a well-defined and consistent classification system for operative vaginal deliveries makes comparison of maternal and neonatal outcomes among spontaneous delivery, cesarean delivery, and operative vaginal delivery as well as instruction in these techniques easier. It is intuitive that not all operative vaginal deliveries are the same with respect to degree of difficulty or maternal and fetal risk. Therefore, classification systems have been developed and modified over time. In 1949, Titus created a classification system that permitted general practitioners to perform operative vaginal delivery without consultation from a specialist.[15] This system divided the pelvis into thirds from the ischial spines to the inlet and, in the opposite direction, in thirds to the outlet. Dennen proposed an alternative classification system in 1952 that was based on the four major obstetrical planes of the pelvis with the following definitions: high forceps as the biparietal diameter (BPD) in the plane of the inlet, but above the ischial spines; midforceps as the BPD just at or below the ischial spines and the sacral hollow not filled; low-midforceps as the BPD below the ischial spines, the leading bony part within a fingerbreadth of the perineum between contractions and the hollow of the sacrum filled; and outlet as the BPD below the level of the ischial spines, the sagittal suture in the anteroposterior diameter and the head visible at the perineum during a contraction.[15]

TABLE 15-1 1988 Operative Vaginal Delivery Classification

Outlet
• Scalp visible at introitus without separating labia
• Fetal skull has reached the pelvic floor
• Sagittal suture is in the AP diameter, or left or right occiput anterior or posterior position
• Fetal head is at or on the perineum
• Rotation does not exceed 45°
Low Forceps
• Leading point of fetal skull is at ≥+2 cm and not on the pelvic floor
• Rotation ≤45° (to LOA /ROA to OA, or LOP/ROP to OP), or
• Rotation ≥45°
Midforceps
• Station above +2 cm, but head engaged
High
• Not included in classification

Modified from American College of Obstetricians and Gynecologists, Committee on Obstetrics, Maternal and Fetal Medicine: Obstetric Forceps. Technical Bulletin No. 59, February 1988.

In 1965, the American College of Obstetricians and Gynecologists (ACOG) created a classification system that defined midforceps extremely broadly (from the ischial spines to the pelvic floor and any rotation). This category clearly included many forceps operations that ranged from delivery of a straightforward anteroposterior position of the fetal vertex to complex rotations.[16] The broad category for these operations lead many practicing clinicians to question whether the classification should be narrowed to reflect the clinically significant differences between deliveries such as these. **Therefore, in 1988, ACOG revised the classification of forceps operations to address two significant shortcomings of the previous system, that midforceps was too widely defined and outlet forceps too narrowly defined.**[17] This system was validated in 1991 by Hagadorn-Freathy and colleagues,[18] demonstrating that 25% of deliveries in this study that would have been previously classified as midforceps (but were reclassified into the low-forceps [greater than 45-degree] rotation and midforceps categories) were associated with 41% of episiotomy extensions and 50% of the lacerations in the cohort. Clearly, the outcomes of these operations confounded the relatively low-risk group of low-forceps operations with up to 45-degree rotation (which would also have been classified as midforceps by the previous system). **In short, these investigators validated the 1988 ACOG classification scheme by demonstrating that the higher station and more complex deliveries carried a greater risk of maternal and fetal injury compared with those that were more straightforward.** This differentiation was lost in the 1965 classification scheme owing to the broad definition of low forceps. It is extremely important to appropriately classify operative vaginal delivery based on this system, including accurate determination of fetal station and position. The 1988 classification scheme for operative vaginal delivery is shown in Table 15-1.

TABLE 15-2 PREREQUISITES FOR FORCEPS OR VACUUM EXTRACTOR APPLICATION

Engaged fetal vertex
Ruptured membranes
Fully dilated cervix
Position is precisely known
Assessment of maternal pelvis reveals adequacy for the estimated fetal weight
Adequate maternal analgesia is available
Bladder drained
Knowledgeable operator
Willingness to abandon the procedure, if necessary
Informed consent has been obtained
Necessary support personnel and equipment are present

With respect to operative vaginal delivery of the vertex, station is defined as the relationship of the estimated distance, in centimeters, between the leading bony portion of the fetal head and the level of the maternal ischial spines, and position refers to the relationship of the occiput to a denominating location on the maternal pelvis. Operative vaginal delivery with a fetus in the left occiput anterior (LOA) position, with the leading bony portion of the vertex 3 cm below the ischial spines (+3 station) would be classified as a low forceps, less than 45-degree rotation delivery. It is also important to note that this classification system applies to both forceps and vacuum extraction instruments, and that the precise position and station must be known before the placement of either instrument.

In addition to precise evaluation of the position and station, several other extremely important data are necessary before performing operative vaginal delivery. **The prerequisites for application of either forceps or vacuum extractor are listed in Table 15-2. When these prerequisites have been met, the following indications are appropriate for consideration of either forceps delivery or vacuum extraction:**

- Prolonged second stage
- Nulliparous women: lack of continuing progress for 3 hours with regional analgesia or 2 hours without regional analgesia
- Multiparous women: lack of continuing progress for 2 hours with regional analgesia or 1 hour without regional analgesia
- Suspicion of immediate or potential fetal compromise
- Nonreassuring fetal heart rate tracing
- Shortening of the second stage of labor for maternal benefit (i.e., maternal exhaustion, maternal cardiopulmonary or cerebrovascular disease)

OPERATIVE VAGINAL DELIVERY INSTRUMENTS

Forceps Instruments

Invention and modification have led to a description and use of more than 700 varieties of forceps instruments. Most of them are of historic interest only, but many common features remain among those still in use. **Forceps are paired instruments, except when used at cesarean delivery and are broadly categorized according to their intended use: "classic" forceps, rotational forceps, and specialized forceps designed to assist vaginal breech deliveries.** Each forceps type consists of two halves joined by a lock, which may be sliding or fixed. The key structures of forceps include the blade, shank, lock, finger guards, and handle (Figure 15-1). The toe refers to the tip of the blade and the heel to the end of the blade that is attached to the shank at the posterior lip of the fenestration (if present). The cephalic curve is defined by the radius of the two blades when in opposition and the pelvic curve by the upward (or reverse as in the case of Kielland and Piper forceps) curve of the blades from the shank. The handles transmit the applied force, the screw or lock represent the fulcrum, and the blades transmit the load (Figure 15-2).[19]

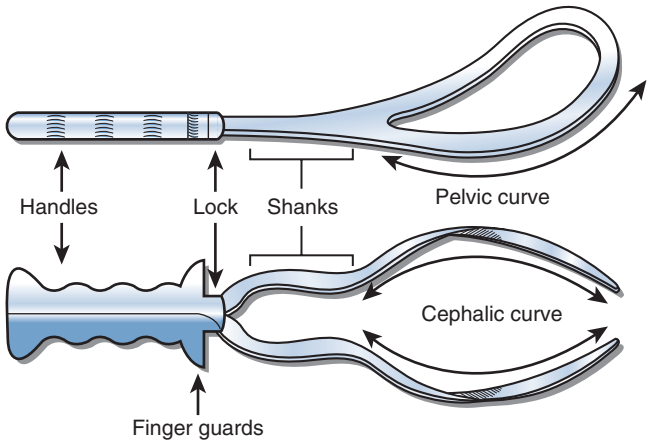

FIGURE 15-1. Anatomy of the forceps.

The pelvic curve permits ease of application along the maternal pelvic axis (Figure 15-3). Forceps have two functions, traction and rotation, both of which can only be accomplished by some degree of compression on the fetal head. The cephalic curvature of the blade is designed to aid in the even distribution of force about the fetal parietal bone and fetal malar eminence. Blades may be solid (Tucker-McLane), fenestrated (Simpson), or pseudofenestrated (Luikart-Simpson). The pseudofenestration modification can be applied to the design of any type of forceps and is known as the Luikart modification. In general, use of solid or pseudofenestrated blades results in less risk of maternal soft tissue injury, especially during rotation, but fenestrated blades provide improved traction in comparison to solid blades.

"Classic" Forceps

Classic forceps instruments are typically used when rotation of the vertex is not required for delivery. However, they may be used for rotations such as the Scanzoni-Smellie maneuver. All classic forceps have a cephalic curve, a pelvic curve, and an English lock, in which the articulation is fixed in a slot into which the shank of the opposite blade fits. The type of classic forceps instrument is determined by its shank, whether overlapping or parallel. Examples of classic forceps with parallel shanks include Simpson, DeLee, Irving, and Hawks-Dennen forceps. Classic forceps with overlapping shanks include Elliott and Tucker-McLane. Because these instruments have a more rounded cephalic curve than the Simpson forceps, they are often used for assisting delivery of the unmolded head, such as that commonly encountered in the multiparous patient. In addition,

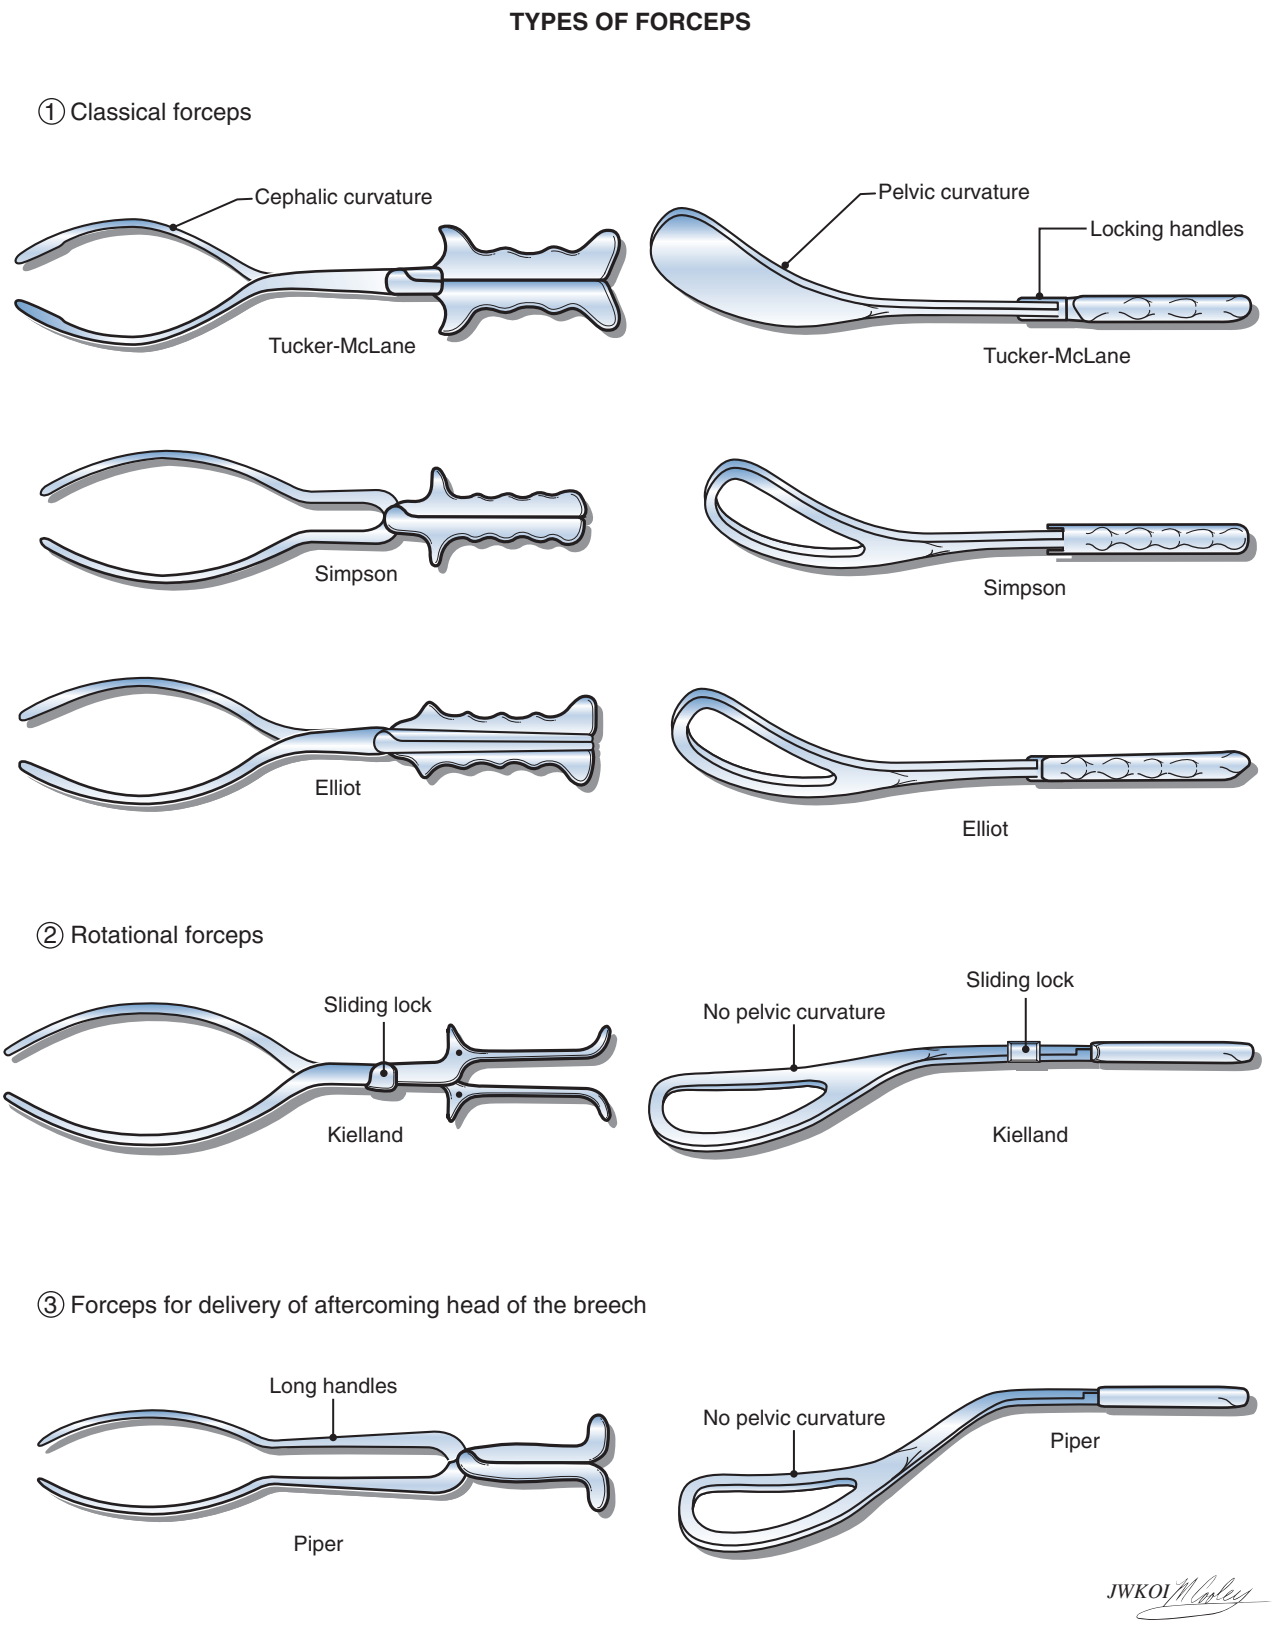

FIGURE 15-2. Classification of forceps.

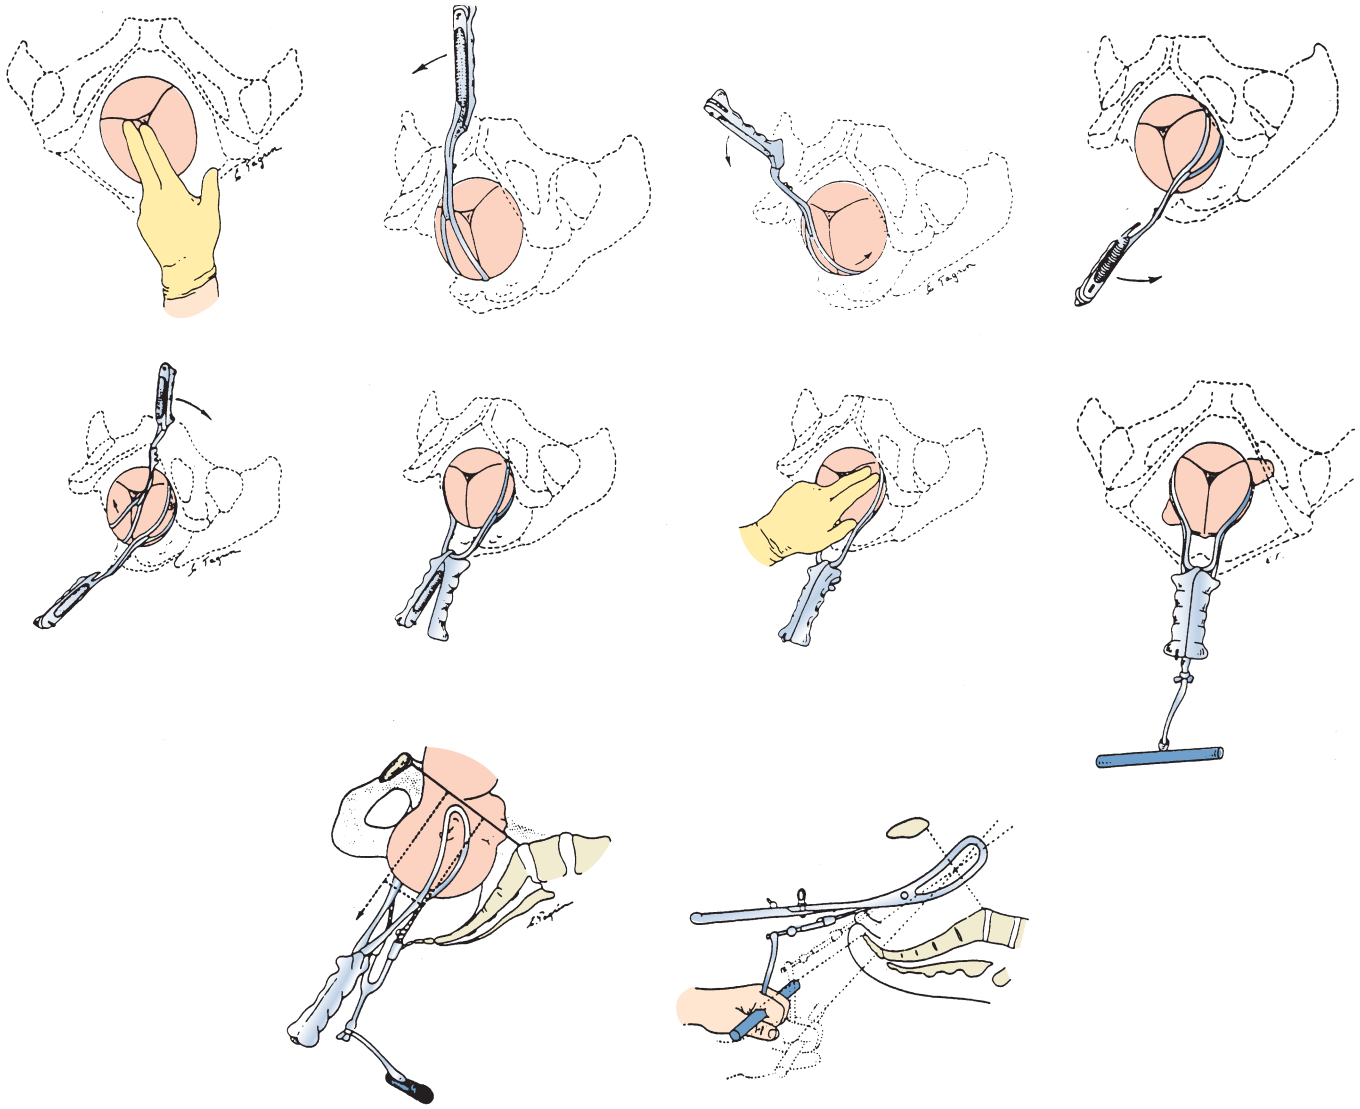

FIGURE 15-3. Stepwise approach to application of obstetrical forceps.

because the Tucker-McLane forceps have a shorter, solid blade and overlapping shanks, they are more often used for rotations than other classic instruments.

Rotational Forceps

Forceps instruments used for rotation are characterized as having a cephalic curve amenable to application to the molded vertex, and either only a slight pelvic curve or none at all. **The absence of a pelvic curve in these instruments facilitates rotation of the vertex without moving the handles of the instrument through a wide arch, as is necessary when using one of the classic instruments to accomplish rotation.** Forceps that may be used for rotation include some of the classic instruments (e.g., Tucker-McLane) and those with minimal pelvic curvature (e.g., Kielland and Leff). In 1916, Christian Kielland of Norway described the rationale for the introduction of his new forceps:

> When the head is high it has to be pulled through a greater length of the birth canal, which is incompletely prepared. The child's head is in such a position that it cannot be grasped by the blades of the forceps in the way which is possible when the head is low and completely rotated. The forceps do not hold the head in the biparietal diameter, but over the occipital and frontal areas which cannot withstand much pressure. These factors are responsible for the difficulties which occur in such a delivery, but they do not entirely explain the amount of force required nor the resistance which is encountered. In the search for an explanation of the chief cause for the remarkable amount of force, which had to be used, it was thought that traction might be in the wrong direction, because the blade of the ordinary forceps is curved to correspond with the birth canal. This type of forceps cannot be depressed sufficiently low against the perineum without the risk of damaging it or losing the good position on the fetal head when an attempt is made to exert traction in the pelvic axis.[20]

Following their introduction, Kielland's forceps have become a frequently used instrument for rotation of the vertex (see Figure 15-1). These forceps have a slightly backward pelvic curve with overlapping shanks and a sliding lock. The advantages of the Kielland's forceps

compared with the classic instruments for rotation include the following:

- A straight design that places the handle and shanks in the same plane as the long axis of the fetal head, permitting the toe to travel through a very small arch during rotation.
- The distance between the heel and the intersecting point of the shanks is long, which accommodates heads of various shapes and sizes associated with unusual molding.
- A slight degree of axis traction is produced by the reverse pelvic curve.
- The sliding lock permits placement of the handles at any level on the shank to accommodate the asynclitic head and subsequent correction of asynclitism.

In 1955, another forceps used for rotation of the vertex was introduced by Leff.[21] These forceps have a locking shank with short, straight, and narrow blades and a smaller cephalic curve than the Kielland's forceps. In a series of 104 consecutive rotational forceps deliveries (>90 degrees) using Leff forceps compared with 163 nonrotational forceps deliveries with traditional instruments, Feldman demonstrated a lower episiotomy (66% vs. 82%) and perineal laceration rate (16% vs. 23%) with the Leff forceps compared with the nonrotational forceps group, attributed to a 40% spontaneous vaginal delivery rate after Leff forceps rotation.[22] In addition, there was no difference in the low incidence of fetal bruising between the groups (3% in each). They concluded that Leff forceps were also a safe option for rotation of the persistent occipitoposterior fetal position.

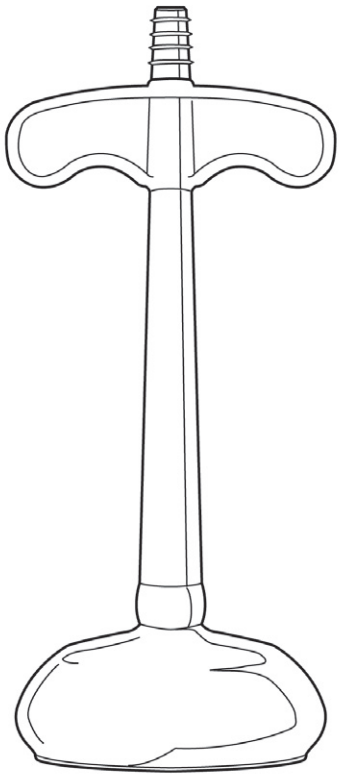

FIGURE 15-4. "M"-style mushroom vacuum extractor cup with a centrally located stem and handle.

Other Specialized Instruments

Forceps to assist with delivery of the aftercoming head during vaginal breech delivery (Piper forceps) have a cephalic curve, a reverse pelvic curve, long parallel shanks, and an English lock (see Figure 15-2). This design provides easy application to the aftercoming head, stabilizing and protecting the fetal head and neck during delivery. The long shanks permit the body of the breech to rest against it during delivery of the head.

Vacuum Extraction Devices

Swedish obstetrician Tage Malmstrom was credited with the introduction of the first successful vacuum cup into the field of modern obstetrics in 1953. It consisted of a metal cup, suction tubing, and a traction chain.[23] Vacuum devices are classified by the material used to make the cup: either stainless steel or plastic (silicone). Plastic ("soft") cups are used much more commonly in the United States than the stainless steel cups owing to the lower rates of scalp trauma associated with these devices.[24] These devices consist of the cup, which is connected to a handle grip and tubing that connects them both to a vacuum source (Figure 15-4). The vacuum generated through this tubing attaches the fetal scalp to the cup and allows traction on the vertex. The vacuum force can be generated either from wall suction or by a hand-held device with a pumping mechanism.

Stainless Steel Devices

The Malmstrom device is the most commonly used instrument for vacuum extraction in the world.[25] This device consists of a mushroom-shaped stainless steel cup, two vacuum hoses, a traction chain and attached metallic disk, a traction handle, and a vacuum source. The cup is available in 40, 50, and 60 mm diameter sizes and is designed such that the diameter of the opening is smaller than the internal diameter of the cup. Therefore, when vacuum is established, the fetal scalp fills the internal dimension of the cup and an artificial caput succedaneum is formed (the "chignon"). This allows for appropriate traction force to be applied to the vertex without a "pop-off" or detachment.

Soft Cup Devices

These devices may be classified into three groups by the shape of the cup: funnel shaped, bell shaped, and mushroom shaped (Figures 15-5 and 15-6). The Kobayashi style funnel-shaped Silastic cup is the prototype and the largest cup available (65 mm). It was designed to fit over the fetal occiput without requiring formation of a chignon. This feature results in a lower rate of scalp trauma and more rapid time to effect delivery compared with the stainless steel devices, but with a slightly higher failure rate owing to pop-off.[24] Bell-shaped cups are available from a number of vendors and include the following brands: Mityvac (Prism Enterprises, San Antonio, Texas), Kiwi (Clinical Innovations, Murray, Utah) and CMI (Utah Medical, Midvale, Utah). The mushroom-shaped cups are a hybrid of the stainless steel and plastic devices. Examples of these devices include the M-cup (Mityvac, Prism Enterprises, San Antonio, Texas), the Flex Cup (CMI,

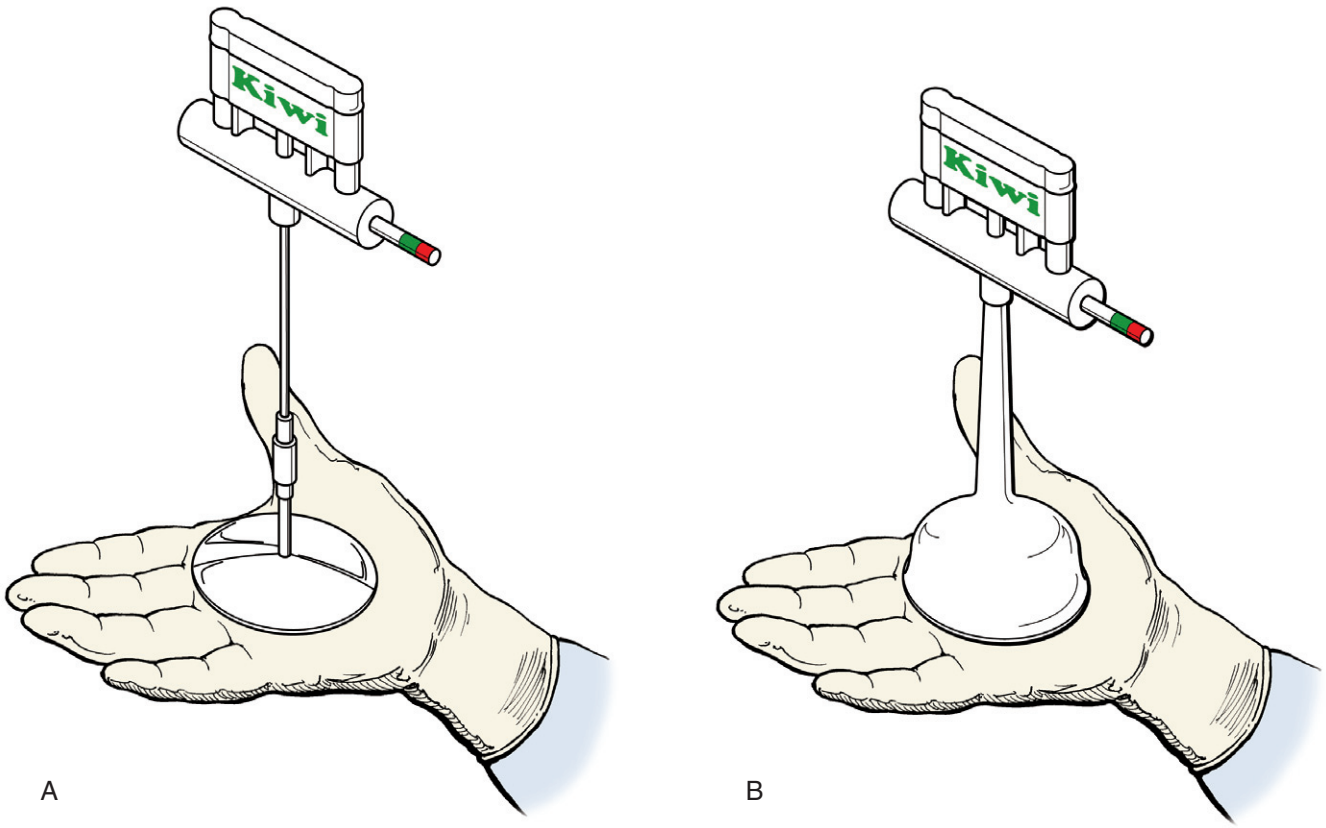

FIGURE 15-5. Depicted are two Kiwi vacuum devices demonstrating the hand-held pump and pressure gauge device. Unlike the cup in **B,** the stem on the cup in **A,** OmniCup is flexible and can be laid flat against the cup. (From Vacca A: Handbook of Vacuum Delivery in Obstetric Practice. Albion, Australia, Vacca Research Pty. Ltd., 2003.)

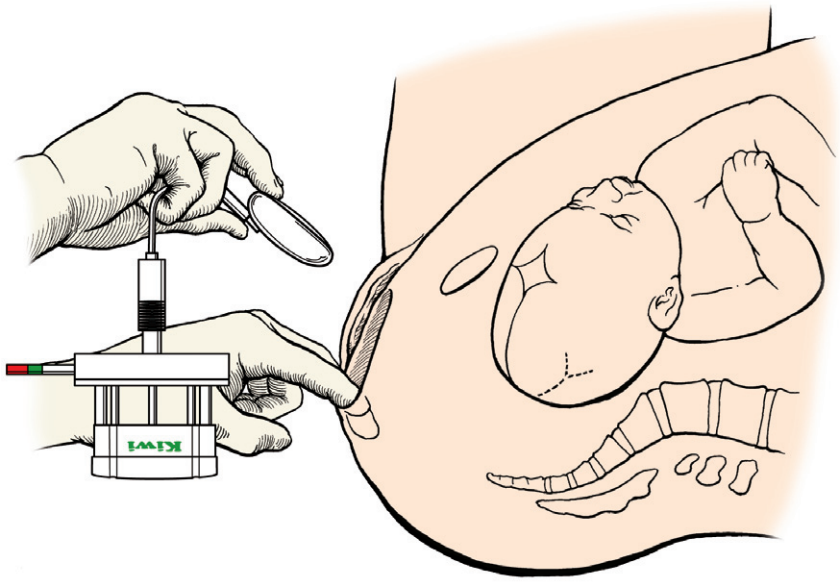

FIGURE 15-6. Placement of the OmniCup with flexible stem at the point of flexion of a fetal head in the occiput posterior position, which is otherwise difficult to accomplish with the traditional vacuum devices. (From Vacca A: Handbook of Vacuum Delivery in Obstetric Practice. Albion, Australia, Vacca Research Pty, Ltd., 2003.)

Utah Medical, Midvale, Utah) and the Omni-cup (Kiwi, Clinical Innovations, Murray, Utah). The maneuverability of these devices is superior to either the funnel-shaped or bell-shaped devices owing to their smaller size and increased flexibility of the traction stem relative to the cup. However, they (like other vacuum devices) are still limited in their use for either occiput posterior (OP) or occiput transverse (OT) positions owing to an inability to achieve the proper median flexing application. Advances to the Kiwi product have resulted in a style of cup in which the stem is completely collapsible against the cup (see Figure 15-5), thus allowing placement of the vacuum on the point of flexion of the head that is asynclitic or in the OP position.

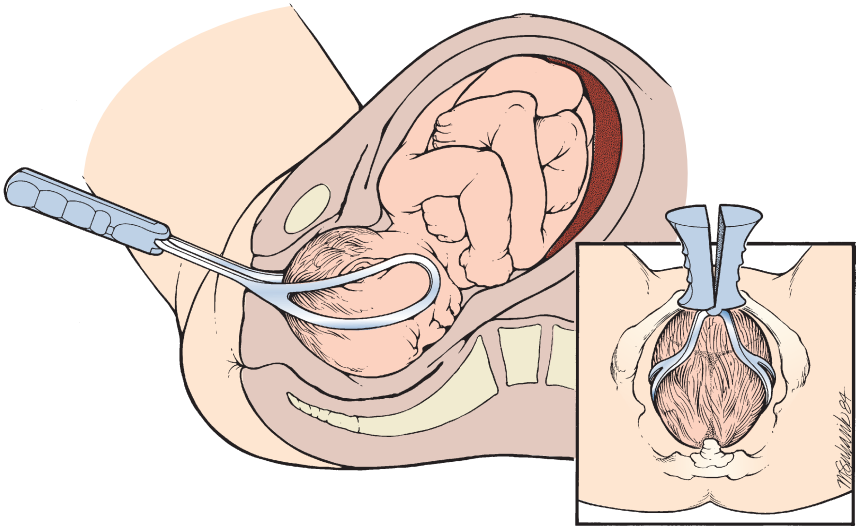

FIGURE 15-7. Proper application of obstetrical forceps. (From O'Brien WF, Cefalo RC: Labor and delivery. *In* Gabbe SG, Niebyl JR, Simpson JL [eds]: Obstetrics: Normal and Problem Pregnancies, ed 3. New York, Churchill Livingstone, 1996, p 377.)

OPERATIVE VAGINAL DELIVERY TECHNIQUES

Classic Forceps: Application for Occiput Anterior and Occiput Posterior Positions

Forcep blades are labeled left and right based on the maternal side into which they are placed. For example, the left blade refers to the maternal left side and its handle is held in the operator's left hand for placement (see Figure 15-3).[26] The posterior blade is conventionally placed first because it provides a splint for the fetal head to prevent rotation from the occiput anterior (OA) position to a more OP position when the second blade is applied. Therefore, when the fetus is OA to LOA, the left blade is placed first. The operator holds the handle of the left blade in his or her left hand, with the toe of the blade directed toward the floor. With the plane of the shank perpendicular to the floor, the cephalic curve of the blade is to be applied to the curve of the fetal head. To protect the vaginal sidewalls, the fingers of the right hand are placed within the left vagina with the palm of the hand facing the fetal skull. The cephalic curve of the blade should lie evenly against the fetal skull as the toe of the blade is placed at approximately 6 o'clock. The operator's right thumb guides the heel of the blade and the right index finger guides the toe of the blade gently over the left parietal bone. The handle of the blade should be held lightly with the left thumb and index finger. As the blade is inserted into the pelvis, its shank and handle are to be rotated counterclockwise toward the right maternal thigh and then inward toward the maternal midline. This movement will guide the toe of the blade over the left parietal bone and onto the left malar eminence. The force applied by the left thumb and index finger on the handle should be minimal as the blade enters the maternal pelvis. If there is anything more than very light or slight resistance to blade entry into the maternal pelvis, the blade should be removed and the application technique reevaluated. Once the blade has been applied, an assistant may hold it in place. To place the right blade, this process is repeated with opposite hands doing the maneuvers described earlier.

When the fetus is in a right occiput anterior (ROA) position, the right fetal parietal bone is located in the posterior maternal pelvis so the posterior blade will be the right blade, and this is placed first. Once both blades are in place, if the handles do not lock easily, the application is incorrect. The blades should have a bimalar, biparietal placement when applied properly (Figure 15-7). Once the handles are locked, proper blade location must be confirmed. Identification of the posterior fontanel, sagittal suture, lamdoid sutures, and blade fenestrations, if present, enable the operator to confirm proper forceps blade placement before their use. **The three criteria needed to confirm proper forceps application are (1) the posterior fontanel should be one finger breath above the plane of the shanks and midway between the blades or the lamdoid sutures (or anterior fontanelle for the OP fetus) should be equidistant from the upper edge of each blade; (2) the sagittal suture should be perpendicular to the plane of the shanks; and (3) if using fenestrated blades, the fenestrations should be barely palpable.[26] The operator should not be able to place more than one fingertip between the fenestration and the fetal head.**

The direction of traction on the fetal head is determined by the station of the BPD. For example, higher fetal stations require a steeper angle of traction below the horizontal. The shape of the maternal pelvis may be visualized as the terminal end of the letter "J." As the fetal head descends within the pelvis, the axis of traction follows a curved line upward from the floor. The axis of traction rises above the horizontal as the fetal head crowns and extends just as the head does in a spontaneous vaginal delivery. With the axis traction principle, force is directed in two vectors—downward and out. One hand holds the shanks and exerts downward traction while the operator's other hand holds the handles and exerts traction outward. An alternative method may be employed by the use of an axis traction instrument. This attachment may be joined to the handle to facilitate traction below the handles in the line of the pelvic axis (see Figure 15-2). Forceps traction should begin with the uterine contraction and coincide with

maternal pushing efforts until the contraction ends. Fetal heart tones should be monitored. Descent should occur with each pull, and if no descent occurs after two to three pulls, the operative delivery should be halted and measures should be taken to proceed with cesarean delivery. Switching to a vacuum should be done very cautiously (see Sequential Use of Vacuum and Forceps later in this chapter).

Forceps may also be appropriate for OP, left occiput posterior (LOP), or right occiput posterior (ROP) positions if the station of the bony part of the head is truly at least +2 station. Infants in persistent OP presentation present a unique challenge. With a deflexed or extended head, a wider diameter presents through the pelvic outlet. This requires more force for descent of the fetal head. Proper assessment of fetal station can be made complex by extension and molding of the fetal head.[26] With fetal molding, the widest diameter of the fetal head may be at a much higher station than the leading bony part, thus making traction within the proper pelvic axis difficult to ascertain. There is a tendency to overestimate station in OP presentations, so the operator must be confident in their station assessment.

Rotational Forceps: Application for Occiput Transverse Positions

Rotation must be accomplished from the OT position before delivery of the fetal head. This may happen spontaneously, with manual assistance, or with use of forceps, when appropriate. The reader is referred to *Dennen's Forceps Deliveries* for more extensive review of forceps rotation techniques.[26] Forcep rotations should be attempted only with an experienced operator.

Classic Forceps

For LOT presentations, the posterior left blade should be applied first. The toe of the blade is placed at 6 o'clock, and the cephalic curve is applied to the fetal head. The handle is lowered to facilitate blade entry into the posterior pelvis and rests below the horizontal, the degree of which will be determined by fetal station. The anterior right blade is labeled the wandering blade. The right blade is inserted with the right hand posteriorly at approximately 7 o'clock. Upward pressure on the blade is exerted with the fingers of the left hand as the right hand moves the handle in a clockwise arc across the left thigh toward the floor. The toe of the blade "wanders" from posterior to anterior, around the frontal bone, to rest anterior to the right ear. Elevation of the handle of the right blade permits movement of the blade further into the pelvis beyond the symphysis and articulation at the handles. The proper attitude of flexion is created by moving the handles toward the pelvic midline. Rotation of the fetal head is accomplished by counterclockwise rotation of the handles in a wide arc across the left thigh toward 12 o'clock. With classic forceps a wide rotational arc at the handles produces the desired smaller arc of rotation at the toe of the blades. Once the OA position is reached, the blades may be readjusted before the generation of traction. This same procedure may be employed for the right OT presentation with classic forceps. In this instance, however, the right blade is posterior and should be applied first.

Keilland's Forceps

Keilland's forceps were originally designed for delivery of the fetal head in deep transverse arrest.[20] They are now also used for rotation of the fetal head from OP or OT positions. The advantage of Keilland's forceps lies in the reverse pelvic curve, which permits placement of the blades in the direct OT position without elevation of the fetal head and loss of station. Unlike classic forceps, with Keilland's forceps the anterior blade is applied first. Three methods of Keilland's forceps application have been described: (1) the inversion method ("classic application"), (2) the wandering method, and (3) the direct method of application.[26]

The inversion method may be used in OT and LOP or ROP presentations. In left OT presentation, the right anterior blade is gently guided below the symphysis with assistance from the operator's left hand. With this application, the cephalic curve is facing up and beyond the symphysis, the handle is dropped below the horizontal, and the blade is rotated 180 degrees toward the midline until the cephalic curve rests on the parietal bone and malar eminence. If resistance is met with the inversion technique, the wandering technique may be used.

The wandering method for Keilland's forceps is similar to that used for classic forceps. The wandering method requires initial placement of the anterior blade onto the posterior parietal bone, with the cephalic curve directly applied to the fetus. The blade is then gently advanced around the face and frontal bone until it rests above the anterior fetal ear.

The direct method of application is preferred when the head is at low fetal station near the pelvic outlet. If the anterior ear is palpable beyond the symphysis, the forceps may be directly applied, often with less difficulty than the other two methods. With the cephalic curve facing the fetus, the blade is applied by lowering the handle toward the floor. The toe is then gently advanced with guidance from the operator's opposite hand. The posterior blade is then inserted at 6 o'clock, with the cephalic curve facing the fetal skull. The operator's free hand is inserted into posterior pelvis palm side up, and the blade is gently guided into position over the posterior ear. The sliding lock will permit closure of the blades and correction of asynclitism. Unlike rotation with classic forceps, the reverse pelvic curve of Keilland's forceps permits rotation directly on the axis of the shanks.[26] The shanks and handles are rotated around the midline point of application and should be held during rotation in a plane perpendicular to the plane of the fetal BPD. In some instances, the fetal head may need to be elevated and even disengaged to accomplish the rotation. This is performed by keeping the handles of the Keilland's forceps well below the horizontal plane pushing the forceps in an anterior-cephalad direction with respect to the maternal pelvis (e.g., toward the maternal umbilicus). Failure to angle in such a direction will result in the forceps making contact with the sacral promontory with an inability to achieve the room needed for rotation. During the rotation, one figure should follow the sutures to ensure that the forceps and fetal head move as a single unit. Generally speaking, use of one hand should provide sufficient force to complete the rotation and is a good guide for avoiding excess force. After successful

rotation, proper forceps placement should be confirmed before downward traction is applied. Alternatively, Keilland's forceps could be removed, and classic forceps placed before traction.

Forceps Rotation: Application for the Occiput Posterior Position

The fetal head may be rotated from OP to OA by use of the Scanzoni-Smellie technique using classic forceps.[27] The posterior blade should be applied first and then appropriate placement of forceps confirmed. Minimal elevation of the fetal head upward within the pelvis will facilitate rotation. Movement of the handles in a wide arc toward the fetal back will enable rotation from the LOP position to OA. After rotation of the handles in a wide arc, the toe of the blades will be upside down with respect to the fetal malar eminence. They must then be removed and replaced properly before traction on the fetal head. Rotation from OP may also be accomplished with Keilland's forceps. After successful rotation, traction can be applied for delivery of the fetal head.

Vacuum Extraction

As with forceps, successful use of the vacuum extractor is determined by (1) proper application on the fetal head and (2) traction within the pelvic axis.[28] **The leading point of the fetal head is the ideal position for vacuum cup placement**. It is labeled the flexion point or pivot point and is located on the sagittal suture 2 to 3 cm below the posterior fontanel for the OA presentation and 2 to 3 cm above the posterior fontanel for the OP presentation.[28] Placement of the vacuum cup over the pivot point maintains the attitude of flexion for a well-flexed head and creates flexion in a deflexed head if traction is applied correctly. Incorrect placement on an asynclitic head results in unequal distribution of force and increase the risk of neonatal intracranial injury and scalp lacerations.[28,29] Therefore, knowledge of exact fetal position is important for efficacious vacuum placement. The force generated by vacuum suction is substantial, with recommended pressures ranging from 550 to 600 mm Hg (11.6 psi).[30] After initial placement of the cup, correct application must be confirmed, including determining that there is no vaginal tissue caught underneath the vacuum cup, before the vacuum pressure is raised to the desired level. Just as with forceps, traction should begin with each contraction and coincide with maternal pushing efforts. Routine traction between contractions should be avoided. In the absence of maternal pushing, traction alone increases the force required for fetal descent and increases the risk of cup detachment.[28] Twisting or rocking of the vacuum cup to facilitate descent of the fetal head is not recommended because there is an increased risk of scalp laceration and intracranial hemorrhage (ICH).[28,31]

With correct application, however, traction in the pelvic axis often results in flexion and autorotation, depending on fetal station and the vacuum cup selected.[29]

Detachment of the vacuum cup during traction should be viewed as an indication for reevaluation of the site of application, direction of axis traction, and fetal maternal pelvic dimensions. The rapid decompression resulting from cup detachment for the soft and rigid vacuum cups has been associated with scalp injury, and it should not be viewed as a safety mechanism that is without potential for fetal risk.[29,32] There are limited data to provide evidence-based support for the maximum duration of safe vacuum application, maximum number of pulls required before delivery of the fetal head, and the maximum number of pop-offs or cup detachments before abandonment of the procedure.[28,29,33,34] There is a general consensus, however, that descent of the fetal bony vertex should occur with each pull, and if no descent occurs after three pulls, the operative attempt should be stopped. Most authorities have recommended that the maximum number of cup detachments (e.g., pop-offs) be limited to two or three and the duration of vacuum application before abandonment of the procedure a maximum of 20 to 30 minutes.[34,35] A randomized controlled trial (RCT) compared maintenance of suction of 600 mm Hg throughout the operative delivery to reduction of suction to 100 mm Hg between contractions and found no differences in duration of operative delivery or in neonatal outcome.[36] Finally, vacuum cup selection may play a role in the likelihood of successful vaginal delivery. The soft cup instruments used in modern practice are associated with less scalp trauma but have a higher failure rate than rigid metal vacuum cups.[35] A meta-analysis of nine RCTs of soft versus rigid vacuum extractor cups determined that the average failure rates were 16% and 9% for the soft and metal cups, respectively. The detachment rates were 22% and 10% for the soft and metal cups, respectively. Higher failure rates with the soft cup may be secondary to difficulties associated with proper placement and traction, particularly if the fetus is deflexed, malpositioned, or at higher station.[27,35]

RISKS AND BENEFITS OF OPERATIVE VAGINAL DELIVERY

Benefits of Operative Vaginal Delivery

Most women desire a vaginal delivery.[14] As such, the safe and effective application of instrumental delivery during the second stage of labor is crucial. In addition, acknowledging the benefits of operative vaginal delivery and the maternal views following these interventions is an important component to enhance counseling. In a cohort study of 393 women who had either a "difficult" operative vaginal delivery performed in the operating suite or a cesarean delivery for an arrest disorder in the second stage of labor, an equal proportion of patients in both groups desired future pregnancy (51% vs. 54%) when asked before hospital discharge. However, women who had an operative vaginal delivery were much more likely to desire a subsequent vaginal delivery compared with women delivered by cesarean section when asked immediately postpartum (79% vs. 39%)[11] and when asked again 3 years later (87% vs. 33%).[12] In addition, of those patients who achieved pregnancy within 3 years of the index delivery in this cohort, substantially more women who had an operative vaginal delivery achieved subsequent vaginal delivery compared with those who had a prior cesarean delivery (78% vs. 31%).[12] Johanson and colleagues followed patients 5 years after a randomized trial comparing forceps with vacuum extraction and demonstrated that more than 75% achieved a spontaneous vaginal delivery with a larger fetus in their second pregnancy.[37]

Because women report fear of childbirth as a common reason for avoiding future pregnancies,[12] patients who had an operative delivery were asked about their views on this procedure including preparation for this type of delivery. Most women felt that their birth plan or antenatal classes had not properly prepared them for the possibility of an operative delivery in the second stage of labor.[13] In addition, most had difficulty understanding the need for the intervention despite a review of the indications by the medical staff before discharge. These patients desired more focused antenatal information on operative delivery and a postdelivery debriefing by their delivering physician or midwife focusing on the reasons for the intervention and their future pregnancy and delivery implications.[13]

Maternal Risks

The focus of recent attention regarding operative vaginal delivery has been the risk of perineal trauma and subsequent pelvic floor dysfunction. The principle risks appear to be those of urinary and fecal incontinence. However, the difficulty in establishing the precise risks of this dysfunction in patients who have had an operative vaginal delivery compared with those who have not is confounded by many factors, including the indication for the operative delivery, number of deliveries, maternal weight, neonatal birth weight and head circumference, perineal body length, episiotomy, and the effects of maternal aging.[38] We will examine three aspects of maternal risk associated with operative vaginal delivery: significant perineal trauma (third- and fourth-degree laceration), urinary incontinence, and fecal incontinence.

Perineal Trauma

Significant perineal trauma is generally defined as a third-degree laceration, involving the anal sphincter, or fourth-degree laceration, involving the rectal mucosa. Estimated frequencies of these injuries vary based on multiple maternal factors, including parity, birth weight, type of delivery, and use of episiotomy. In a large, population-based retrospective study of more than 2 million vaginal deliveries, the frequency of severe perineal injury was noted to be 11.5% in nulliparous patients, 13.8% in patients with a successful vaginal birth after cesarean delivery, and 1.8% in multiparous patients.[39] Increased risks of anal sphincter injuries were found to be associated with primiparity, macrosomia, shoulder dystocia, maternal diabetes mellitus, prolonged pregnancy, nonreassuring fetal heart rate patterns, and operative vaginal delivery. In contrast to other studies demonstrating a much larger risk of severe perineal injury due to forceps and vacuum delivery (sevenfold to eightfold), the study by Handa and colleagues observed an odds ratio (OR) of only 1.4 for forceps delivery and 2.3 for vacuum delivery, suggesting that operative vaginal delivery may be associated with a much lower risk of third- and fourth-degree lacerations than was previously thought.[39] In addition, Handa and colleagues found that episiotomy was associated with a 10% decrease in anal sphincter laceration. Other studies have also observed that episiotomy associated with forceps use either did not increase the risk of third- or fourth-degree lacerations[40] or reduced their risk.[41] However, other investigations have noted an increased risk of severe perineal injury with episiotomy use.[42] Finally, in a retrospective review of more than 2000 consecutive deliveries, reduction in episiotomy use was found to be associated with an increased rate of vaginal lacerations, a decreased rate of fourth-degree lacerations, and no change in the rate of third-degree lacerations over a 10-year period from one institution.[43] Whether more liberal use of episiotomy affects the rate of severe perineal lacerations remains to be evaluated in a prospective randomized trial.

Urinary Incontinence

Stress urinary incontinence is defined as the involuntary leakage of urine during effort or exertion and occurs at least once weekly in one third of adult women.[44] **Both pregnancy and the interval time following pregnancy predispose women to urinary incontinence.** Viktrup and colleagues observed that 32% of nulliparous women developed urinary incontinence during pregnancy and 7% after delivery. One year following delivery, only 3% reported incontinence; however, 5 years later, 19% of women asymptomatic following delivery had incontinence.[45] The Norwegian EPINCONT study, with an 80% response rate to a survey of more than 11,000 nulliparous patients, observed a 24% prevalence of urinary incontinence and increased urinary incontinence symptoms with increasing age, body mass index (BMI), and number of years since their delivery.[46] In addition, incontinence was significantly associated with birthweight greater than 4000 g and fetal head circumference greater than 38 cm. Having at least one vacuum or forceps delivery in this cohort did not affect the risk of developing urinary incontinence. In a prospective study of the short- and long-term effects of forceps delivery compared with spontaneous vaginal delivery, which included both patient survey and clinical examination data, Meyer and colleagues observed a similar incidence of urinary incontinence at both 9 weeks (32% vs. 21%) and 10 months (20% vs. 15%).[47] In addition, bladder neck behavior, urethral sphincter function, and intravaginal pressures were similar between the groups. The only difference noted was an increased incidence of a weak pelvic floor in the forceps group (20% vs. 6%) at the 10-month examination. In a 5-year follow-up study of patients randomized to either forceps or vacuum delivery, Johanson and colleagues observed no difference in the incidence of urinary dysfunction between these groups.[48] However, Arya and colleagues in a prospective observational study using patient survey data reported that urinary incontinence after forceps delivery was more likely to persist at 1 year compared with spontaneous vaginal delivery or vacuum delivery (11% vs. 3%).[49] **The only prospective randomized trial to assess urinary incontinence symptoms after planned elective cesarean delivery compared with planned vaginal delivery is the Term Breech Trial.**[50] At 3 months postpartum, women randomized to cesarean delivery reported less urinary incontinence compared with those in the planned vaginal delivery group (4.5% vs. 7.3%; relative risk 0.62, 95% confidence interval [CI] 0.41 to 0.93). Finally, in a long-term (34-year) follow-up study of patients following either forceps, spontaneous vaginal delivery, or an elective cesarean delivery without labor, urinary incontinence was found more frequently in those women who had a spontaneous vaginal delivery compared with those who had a forceps delivery (19% vs. 7%). In addition, the total number of

vaginal deliveries was the only risk factor attributed to urinary incontinence in this cohort (OR 19.5; 95% CI, 4.01 to 34.8; $P = 0.001$).[51] **The precise association between mode of vaginal delivery (spontaneous, forceps, or vacuum) and urinary incontinence remains unclear at this time in light of the many other factors that appear to contribute to this condition. However, there appears to be little if any effect of forceps delivery on the subsequent development of urinary incontinence.** Therefore, it is reasonable to counsel patients that the use of forceps or vacuum for an appropriate obstetrical indication likely has no increased long-term affect on urinary incontinence compared with spontaneous vaginal delivery.

Fecal Incontinence

Overall rates of anal sphincter injury noted at the time of vaginal delivery in nulliparous patients are reported to be between 7% and 11.5%.[39,52,53] **Operative vaginal delivery has been associated with an increased risk of perineal injury, specifically third- and fourth-degree lacerations.**[39,40] However, what is not clear is the precise incidence of occult anal sphincter injury in patients delivering vaginally and the resulting effect on fecal incontinence. In the largest prospective study evaluating the prevalence of anal sphincter injury after forceps delivery in nulliparous women using endoanal ultrasound, de Parades and colleagues examined 93 patients 6 weeks after delivery and found a 13% prevalence of anal sphincter injury.[54] These findings are in contrast to other studies that have evaluated fewer patients each, but found a higher prevalence of anal sphincter injury shortly following forceps delivery[54-59] (Table 15-3).

The difficulty with many of the studies noted in Table 15-3 is the extremely low number of patients that return for the endoanal ultrasound following delivery. For example, even though Sultan recruited patients from a previous RCT of forceps and vacuum delivery, only 44 of the original 313 patients (14%) were assessed.[58] Because not all patients were evaluated, it is possible that significant selection bias occurred and that the actual prevalence of anal sphincter injury was lower because those patients most symptomatic would be likeliest to return for endoanal ultrasound. Indeed, in the largest randomized trial to date evaluating anal sphincter function following forceps or vacuum extraction, Fitzpatrick and colleagues was able to follow up on all 61 patients randomized to forceps delivery and demonstrated a much lower rate of anal sphincter injury than previously reported (56%). Even though more patients who delivered by forceps compared with vacuum delivery in this study described altered fecal continence (59% vs. 33%), there were no differences seen in endoanal ultrasound defects or in anal manometry results. In addition, there were no differences in symptom scores between the groups and the degree of disturbance to continence was low in both groups, with the most common symptom being occasional flatal incontinence.[59]

However, de Parades and colleagues found lower rates of anal sphincter injury (13%) and complaints of altered fecal continence (30%) following forceps delivery. Most symptomatic patients complained of persistence of incontinence of flatus (17/28), as noted in the study by Fitzpatrick. In addition, a significant increase in the daily number of stools was associated with anal sphincter defects visible on endoanal ultrasound, but the development of altered fecal continence symptoms was not.[54]

Even though it appears that immediate complaints of altered fecal continence and evidence of anal sphincter injury may be as high as 60% immediately following operative vaginal delivery, data from long-term follow-up does not bear this figure out. For example, Johanson and colleagues followed patients 5 years after randomization to either forceps or vacuum delivery and found no significant difference in complaints of altered fecal continence between the groups (15% vs. 26%).[48] In addition, most patients in the forceps and vacuum groups who noted altered fecal continence had occasional incontinence of flatus or diarrhea as their only symptom (70% and 68%, respectively). In addition, 34-year follow-up data on 42 patients delivered by forceps compared with 41 patients delivered by spontaneous vaginal delivery demonstrated a higher rate of anal sphincter injury on ultrasonography in the forceps group (44% vs. 22%), but no difference in the rate of altered fecal continence (14% vs. 10%).[51] **These data suggest that forceps delivery is a risk for sphincter injury but not for long-term fecal incontinence. In fact, logistic regression revealed that the largest neonatal birth weight, and not forceps delivery, was the contributing risk for significant fecal incontinence in this study.**[51] Therefore, based on these data, the anal sphincter injury rate in women who deliver by forceps may be higher; however, long-term rates of fecal incontinence appear to be no different than in women who deliver spontaneously. These findings could reflect the body's ability to heal and compensate for anal sphincter injury over time and may also be the basis for questioning the importance and validity of early outcome assessments of anal incontinence.

Fetal Risks

The focus of possible fetal injury associated with operative vaginal delivery includes craniofacial/intracranial injury and neurologic/cognitive effects. The risks of fetal injury

TABLE 15-3 PREVALENCE OF ANAL SPHINCTER INJURY FOLLOWING FORCEPS DELIVERY

STUDY SPHINCTER	FORCEPS DELIVERIES (*N*)	IAS INJURY (*N*)	EAS INJURY (*N*)	IAS AND EAS INJURY (*N*)	TOTAL ANAL INJURY (%)

EAS, External anal sphincter; *IAS*, internal anal sphincter; *MD*, missing data.

are generally instrument specific, with vacuum deliveries accounting for statistically significantly higher rates of cephalohematoma, and subgaleal and retinal hemorrhages, and forceps deliveries accounting for a nonsignificantly higher rate of scalp/facial injuries.[60] In addition, the sequential use of vacuum and forceps requires particular attention because use in this manner is associated with a maternal and neonatal risk, which is greater than the sum of the individual risks of these instruments.[53]

Craniofacial and Intracranial Injury

Cephalohematoma and Subgaleal Hemorrhage

Rates of subperiosteal cephalohematoma in vacuum-assisted vaginal deliveries are higher than rates for either forceps or spontaneous vaginal delivery (112/1000, 63/1000, and 17/1000, respectively).[61,62] However, the most clinically significant and potentially life-threatening injury in this category is a subgaleal hemorrhage (see Chapter 21). This "false cephalohematoma" was first described by Naegele in 1819 to differentiate it from a true subperiosteal cephalohematoma.[63] Subgaleal hemorrhage occurs when blood collects in the loose areolar tissue in the space between the galea aponeurotica and the periosteum. If the veins that connect the dural sinus and the scalp rupture in this layer due to shear forces, the potential space within this loosely applied connective tissue in the subgaleal space may expand with blood well beyond the limits of the suture lines (unlike a subperiosteal cephalohematoma, which is limited to blood and fluid collections within the margins of the suture lines). This space has the potential volume of several hundred milliliters of blood, which may produce profound neonatal hypovolemia, leading to hypoxia, disseminated intravascular coagulation (DIC), end-organ injury, and death.[64] Older literature cites several causes of subgaleal hemorrhage with the source as follows: vacuum extraction, 48%; spontaneous vaginal delivery, 28%; forceps, 14%; and cesarean delivery, 9%.[63] Although this is older literature reporting in an era when a "low-forceps" delivery was broadly defined by the 1965 ACOG Classification scheme, it is most important to note that these potentially life-threatening bleeds can also occur with spontaneous vaginal deliveries. **More recent data suggest that subgaleal hemorrhage occurs nearly exclusively with the vacuum device**[65-67] with an incidence of subgaleal bleeding of 26 to 45 per 1000.[68] Benaron[69] reported an incidence of 1 per 200 with soft silicone vacuum cups.

Subgaleal hemorrhage has an estimated incidence of approximately 4 per 10,000 spontaneous vaginal deliveries.[63] In a 30-month prospective study, Boo[70] evaluated more than 64,000 neonates and found that the incidence per live birth was much higher for vacuum extraction than other modes of delivery (41 per 1000 vs. 1 per 1000). Both the type of cup and the duration of its use are predictors of scalp injury. Soft cups are more likely to be associated with a decreased incidence of scalp injuries, but may not be less likely to result in a subgaleal hemorrhage.[4] In one study, vacuum application duration of more than 10 minutes was the best predictor of scalp injury.[71] **In May 1998, the Food and Drug Administration (FDA) issued a public health advisory regarding the use of vacuum-assisted delivery devices. The advisory cited a fivefold increase in the rate of deaths and serious morbidity during the previous 4 years compared with the past 11 years and recommended use of these devices only when a specific obstetrical indication is present.** Other recommendations included the following:

- Persons who use vacuum devices for assisted delivery are versed in their use, and that they are aware of the indications, contraindications, and precautions as supported in the accepted literature and current device labeling.
- The recommended use for all these products is to apply steady traction in the line of the birth canal. Rocking movements or applying torque to the device may be dangerous. Because the instructions may be different for each device type or style, it is important to use the instructions provided by the manufacturer of the particular product being used.
- Alert those who will be responsible for the infant's care that a vacuum-assisted delivery device has been used, so that they can monitor the infant for signs of complications.
- Educate the neonatal care staff about the complications of vacuum-assisted delivery devices that have been reported to the FDA and in the literature. They should watch for the signs of these complications in any infant in whom a vacuum-assisted delivery device was used.
- Report reactions associated with the use of vacuum-assisted delivery devices to the FDA.[31]

Despite the fact that many recommend allowing no more than three pop-offs before successful delivery, there is no clear evidence that three applications are safe because if the cup slips during traction without descent of the vertex, neonatal scalp injury may still occur.[71] For example, Benaron[69] demonstrated that the risk of injury and bleeding is increased in nulliparous patients and in those with severe dystocia, malposition, and forceful, prolonged vacuum extractor use. Therefore, caution must be taken with the use of vacuum extractor devices to avoid prolonged (greater than 30 minutes) or forceful use.

Intracranial Hemorrhage

Rates of clinically significant ICH for vacuum, forceps and cesarean delivery during labor are similar (1/860, 1/664, and 1/907, respectively) but are higher than for cesarean delivery without labor (1/2750) or spontaneous vaginal delivery (1/1900).[72] Because cesarean delivery following abnormal labor was associated with the same rate of ICH as forceps and vacuum in this study, it is likely that the common risk factor for any increased risk of ICH is abnormal labor and not the type of operative vaginal delivery performed. In fact, because the prevalence of clinically silent subdural hemorrhages is approximately 6% following uncomplicated spontaneous vaginal delivery, the presence of this hemorrhage in an otherwise asymptomatic neonate does not necessarily indicate excessive birth trauma and again reflects the natural history of labor and delivery.[73] In these neonates with silent subdural hemorrhages, all resolved within 4 weeks of delivery.

Neurologic and Cognitive Effects

Vacuum-assisted vaginal deliveries increase the risk of neonatal retinal hemorrhages by approximately twofold

compared with forceps deliveries.[60] Despite this finding, data on the long-term consequences of these hemorrhages do not demonstrate any significant effect. Johanson and colleagues followed a cohort of children 5 years following an RCT of forceps versus vacuum extraction and found a 13% rate of visual problems in the group. However, there was no difference between those delivered by forceps compared with those delivered by vacuum extraction (12.8% vs. 12.5%).[48] Seidman and colleagues were also unable to detect any increased risk of vision abnormalities in a cohort of 1747 individuals delivered by vacuum extraction compared with more than 47,000 individuals delivered by spontaneous vaginal delivery and examined at age 17 years by the Israeli Defense Forces draft board.[74] There also does not appear to be any long-term effect of operative vaginal delivery on cognitive development. Seidman and colleagues demonstrated that mean intelligence scores at age 17 years were no different between those delivered by forceps or vacuum extraction compared to those delivered by spontaneous vaginal delivery. However, the mean intelligence scores for those delivered by cesarean delivery were significantly lower than those of the spontaneous delivery group.[74] Similarly, in a 1993 report from patients within the Kaiser system in Oakland, CA, Wesley and colleagues were unable to detect a difference in cognitive development by measuring intelligence quotient (IQ) in 1192 children delivered by forceps compared with 1499 who delivered spontaneously and were examined at age 5 years. Furthermore, of the 1192 forceps deliveries, there were 114 midforceps, and no differences in IQ were seen at age 5 compared with 1500 controls.[75] Finally, there also appears to be no association between forceps delivery and epilepsy in adulthood. Murphy and colleagues evaluated a cohort of more than 21,000 individuals and found forceps delivery was not associated with an increased risk of epilepsy or anticonvulsant therapy when compared with other methods of delivery.[76]

Dierker and colleagues[77] followed 110 infants for 5 years delivered by midforceps and matched with infants born by cesarean delivery for the same indications and found no differences in IQ or neurologic abnormalities.

Finally, in a similar 5-year follow-up of a prospective cohort of 264 women with term, singleton, cephalic pregnancies that required a second-stage operative delivery from 1999 to 2000, neonates delivered by forceps were found to have no significant differences in neurodevelopmental outcome compared to those delivered by cesarean section.[78]

Complex Operative Vaginal Delivery Procedures

Rotations Greater Than 45 Degrees

The correct application and delivery technique using forceps is critical to the safe performance of this procedure. The outcomes of forceps delivery are often directly compared to and contrasted with those of spontaneous vaginal delivery. When these comparisons are made, forceps deliveries are associated with a higher rate of maternal injury than spontaneous vaginal delivery. However, the comparison of these two modes of delivery is not appropriate because forceps applications require an indication for use that confounds the clinical outcome when compared with spontaneous vaginal delivery. A more appropriate comparison to forceps delivery (or operative vaginal delivery in general) is cesarean delivery for second-stage arrest disorder. Unfortunately, there are no prospective, randomized trials directly comparing these two modes of delivery. However, numerous retrospective studies comparing midcavity and rotational forceps delivery with cesarean delivery demonstrate no increased risk of fetal/neonatal adverse outcomes including Apgar score, umbilical cord blood gas values, birth trauma, and neonatal intensive care unit (NICU) admission.[79-82] Specifically, the rates of neonatal morbidity associated with Kielland's forceps rotation are similar to cesarean delivery, including rates of cephalohematoma (9% to 17%), facial bruising (13% to 18%), facial nerve injury (1% to 5%) and brachial plexus injury (less than 1%).[83,84] Interestingly, rates of maternal morbidity (intraoperative and postoperative complications, blood loss, and length of stay) have been found to be higher in patients delivered by cesarean delivery compared with those delivered by midcavity forceps delivery.[79,80]

The outcomes of rotational forceps deliveries have also been evaluated and compared with nonrotational forceps delivery. Healy and colleagues evaluated 552 Kielland's forceps rotations, 95 Scanzoni-Smellie maneuvers with classic instruments, and 160 manual rotations followed by delivery with a classic instrument and found no difference in neonatal outcomes between the groups.[85] Krivac and colleagues[86] compared 55 Kielland's forceps rotations with 213 nonrotational forceps deliveries. Fifteen of the rotations were greater than 90 degrees, and 40 were less than 90 degrees but greater than 45 degrees. They found that the Kielland's forceps rotation group had both a longer labor and longer second stage than the nonrotational group and a higher rate of 1-minute Apgar scores less than 6 and meconium at delivery. However, the nonrotational forceps group had a greater incidence of postpartum hemorrhage (14% vs. 7%) and a higher rate of third- and fourth-degree lacerations (24% vs. 14%). No other differences in maternal or neonatal morbidity were noted, including no difference in rates of nerve compromise (less than 1%), facial bruising (7%), shoulder dystocia (1%), or NICU admissions. Hankins and colleagues[87] performed a retrospective case-controlled study comparing 113 forceps deliveries greater than 90 degrees compared with 167 forceps deliveries less than 45 degrees. No differences in major fetal injury were demonstrated between these two groups. Major fetal injury was defined as skull fracture, subdural hematoma and brachial plexus or facial nerve injury, and fetal acidemia (pH less than 7.0). Finally, Feldman and colleagues compared 104 rotational forceps deliveries using Leff forceps for persistent OP position with 163 nonrotational forceps deliveries and found lower rates of episiotomy (66% vs. 82%) and perineal lacerations (16% vs. 23%) in the forceps rotation group and no differences in the rates of neonatal morbidity between the groups.[88] **These data suggest that when properly applied and used, forceps deliveries requiring greater than 45 degree rotation may be safely accomplished without increased risk of maternal or neonatal morbidity and, therefore, should remain a management option for women with second-stage labor abnormalities.**

Midpelvic Cavity Delivery

Like rotational forceps deliveries, delivery of the fetus from a 0 or +1 station (midpelvic or midforceps) requires a specific set of skills and precautions. In 1988, ACOG reported on required conditions for a midforceps delivery that included the following: (1) an experienced person performing or supervising the procedure, (2) adequate anesthesia, (3) assessment of maternal-fetal size, and (4) willingness to abandon the attempt at delivery. This information should be taken together with the prerequisites set forth by Richardson and colleagues[89]: the midforceps procedure (1) must rationally be needed as an alternative method of delivery to cesarean delivery, (2) must be associated with demonstrably less maternal morbidity than cesarean section, and (3) should not result in fetal harm. Several studies that compare cesarean delivery to midforceps procedures show that midforceps delivery is not associated with more adverse neonatal outcomes including cord blood gases, Apgar scores, NICU admissions, and birth trauma.[79,80,90] In 1997, Revah and colleagues[90] reported their findings of a retrospective chart review of 401 cesarean deliveries over a 7-year period in which a trial of operative delivery (forceps or vacuum) was conducted in 75 cases. There were no differences between cesarean delivery with a trial of operative delivery versus without an operative delivery attempt for any maternal or fetal outcome. **Although the outcomes of these studies are reassuring, because of the technical skills required, it is most reasonable to abide by the guidance set forth in the ACOG practice bulletin published in 2000, which states, "Unless the preoperative assessment is highly suggestive of successful outcome, trial of operative vaginal delivery is best avoided."**[68] In short, following the ACOG statement and the previously stated prerequisites provides the skilled practitioner with guidelines and support for attempting a safe midpelvic cavity delivery.

Sequential Use of Vacuum and Forceps

The sequential use of these instruments appears to increase the likelihood of adverse maternal and neonatal outcomes more than the sum of the relative risks of each instrument.[53,62] Compared with spontaneous vaginal delivery, deliveries by sequential use of vacuum and forceps are associated with significantly higher rates of ICH (RR, 3.9; 95% CI, 1.5 to 10.1), brachial plexus injury (RR, 3.2; 95% CI, 1.6 to 6.4), facial nerve injury (RR, 3.0; 95% CI, 4.7 to 37.7), neonatal seizures (RR, 13.7; 95% CI, 2.1 to 88.0), requirement for mechanical ventilation of the neonate (RR, 4.8; 95% CI, 2.1 to 11.0), severe perineal lacerations (RR, 6.2; 95% CI, 6.4 to 20.1), and postpartum hemorrhage (RR, 1.6; 95% CI, 1.3 to 2.0).[53] Therefore, care should be taken to avoid the sequential use of these instruments to reduce maternal and neonatal morbidity. Such switching of instruments should be limited to situations in which there is failure of application of one type of instrument and be performed by individuals skilled and experienced with operative vaginal delivery procedures.

Trial of Operative Vaginal Delivery

Historically, an unsuccessful operative vaginal delivery has been associated with a high maternal and neonatal morbidity and up to a 38% fetal mortality rate and 2% maternal mortality rate.[91] Reports of increased morbidity and mortality in these cases led to the development of the concept of a trial of forceps in which immediate cesarean delivery was performed if, following correction of malposition and gentle traction, further decent of the fetal vertex was not noted.[92] These attempts were often performed in the operating room instead of the delivery room, permitting rapid transition to cesarean delivery. Following implementation of this concept, rates of morbidity and mortality have fallen, documenting no difference in neonatal or maternal outcomes associated with a failed forceps or vacuum attempt in the absence of a nonreassuring fetal heart rate tracing.[93]

Vacuum Delivery and the Preterm Fetus

There are no quality data for firm recommendations regarding a gestational age limit below which the vacuum extractor should not be used. There are two studies reporting the use of soft cups without adverse outcomes in preterm fetuses. However, these studies were small and lacked power to demonstrate significance. There are no RCTs comparing forceps versus vacuums or comparing different vacuum types to pass judgment on a gestational age cut-off. **ACOG reports that most experts in operative vaginal delivery limit the vacuum procedure to fetuses greater than 34 weeks' gestation.**[68] This is a reasonable cut-off, given that the premature head is likely at greater risk for compression-decompression injuries simply due to the pliability of the preterm skull and the more fragile soft tissues of the scalp.

COUNSELING: FORCEPS, VACUUM, OR CESAREAN DELIVERY

The increasing use of vacuum extraction over forceps has resulted in numerous publications comparing efficacy and morbidity between methods. Table 15-4 provides a summary of the disadvantages associated with both methods. In a Cochrane meta-analysis including 10 RCTs of vacuum and forceps use, vacuum extraction had a greater failure rate than that of forceps.[94] Vacuum extraction was associated with less maternal trauma, including third- and fourth-degree extensions, and vaginal lacerations, than forceps use.[94] Less maternal regional and general anesthesia was used for vacuum extractions. There

Table 15-4 Comparative Morbidities Associated with Forceps Delivery and Vacuum Extraction

FORCEPS	VACUUM EXTRACTION
Greater third- and fourth-degree and vaginal lacerations	Higher failure rate than forceps
Greater maternal discomfort postpartum	Increased risk of neonatal injury:
Greater duration of training needed	Minor: cephalohematoma, retinal hemorrhage
Increased risk of neonatal facial nerve injury	Major: subarachnoid hemorrhage, subgaleal hemorrhage
	Less need for maternal anesthesia

Modified from Johanson RB, Menon BK: Vacuum extraction versus forceps for assisted vaginal delivery. Cochrane Database Syst Rev (2):CD000224, 2000.

were no differences in significant neonatal injury between the two groups. Despite small sample sizes, vacuum extraction was associated with an increased risk of cephalohematoma and retinal hemorrhage when compared with forceps use. Cephalohematoma formation with vacuum extraction was reported to have a mean incidence of 6%, with no difference between soft or rigid vacuum cups, and is considered to be a finding of little significance.[29,94]

Unless a patient is willing to undergo cesarean delivery before the onset of advanced labor, there does not appear to be any advantage to avoiding operative vaginal delivery in an attempt to reduce the long-term risks of incontinence. The effects of both forceps and vacuum delivery on the risk of developing urinary incontinence appear to be the same as those of spontaneous vaginal delivery with between 5% and 20% of women developing long-term persistent urinary incontinence regardless of vaginal delivery method. In addition, despite evidence that the anal sphincter injury rate in women who deliver by forceps is higher, it is not clear that the long-term rates of fecal incontinence in these women is any different than in those who deliver spontaneously. Approximately 10% to 30% of women develop some degree of altered fecal continence following vaginal delivery, with cesarean delivery before the onset of labor as the only reliable means of reducing this risk.

The greatest risk for urinary incontinence appears to be the total number of vaginal deliveries, and the greatest risk for subsequent development of fecal incontinence appears to be related to the effect of the largest neonate delivered vaginally, irrespective of mode of delivery. Regarding fetal risks, vacuum deliveries appear to increase the incidence of cephalohematoma, and subgaleal and retinal hemorrhages compared with forceps or spontaneous vaginal deliveries. Forceps deliveries increase the risk of facial bruising and transient facial nerve palsies compared with vacuum or spontaneous vaginal deliveries. However, there is no evidence that these immediate neonatal morbidities result in any long-term visual, neurologic, or cognitive developmental abnormalities. Finally, patients delivered by cesarean delivery in the second stage have a higher risk of intraoperative and postoperative complications, higher rates of blood loss, and longer hospital stays than those delivered by operative vaginal delivery.

Patients should also be informed that substantially more women who have an operative vaginal delivery achieve subsequent vaginal delivery in the next pregnancy compared with those who have a cesarean delivery (78% vs. 31%). Therefore, it is reasonable to counsel patients that the options for second-stage assisted delivery include both forceps and vacuum when appropriate, because the proper application of these instruments and execution of these deliveries can avoid the maternal morbidity associated with cesarean delivery and increase the likelihood of a subsequent vaginal delivery for the next pregnancy without additional long-term maternal or neonatal risk.

In a Cochrane review of 10 randomized studies comparing the use of forceps to vacuum extraction for assisted vaginal delivery, vacuum devices were found more likely to fail than forceps.[61] However, vacuum use was also more likely to result in vaginal delivery, probably because failed vacuum extraction led to the use of forceps and subsequent vaginal delivery due to a lower forceps failure rate. A lower failure rate is not the only reason to consider forceps. Forceps may be the only acceptable instrument to effect an operative vaginal delivery in some circumstances. Some examples of these clinical situations include delivery of the head at assisted breech delivery, assisted delivery of a preterm infant younger than 34 weeks' gestation, delivery with a face presentation, suspected coagulopathy or thrombocytopenia in the fetus, and instrumental delivery for maternal medical conditions that preclude pushing.[14] Because the specific clinical situation and operator experience are the key factors that contribute to the choice of instrument, it is critical that students of obstetrics be thoroughly familiar with the use of both instruments. Finally, an attempt at counseling patients on the risks, benefits, and alternatives of operative vaginal delivery should take place during prenatal visits. This is because it is not ideal to counsel patients in the second stage of labor when they are generally experiencing pain, exhaustion, and/or are under the influence of narcotics. This counseling should also be documented in the medical record.

SIMULATION AND RESIDENCY TRAINING IN OPERATIVE VAGINAL DELIVERY

The overall incidence of operative vaginal delivery has remained stable over the past 15 years. Interestingly, over this same time span, vacuum extraction procedures have overtaken forceps procedures as the instrument of choice (Figure 15-8). In a review of operative vaginal delivery, Yeomans strongly advocates that residency training programs incorporate detailed instructions in forceps techniques and that simulation training precede clinical work to enhance understanding of the mechanics.[95] Bahl and colleagues reviewed video recordings to establish critical components of nonrotational vacuum deliveries, defining key technical skills required for evaluating clinical competence of trainees in this technique.[96] Further detailed studies are needed to ensure that both vacuum and forceps techniques can be taught and evaluated first with the use of simulation and then in the clinical setting.

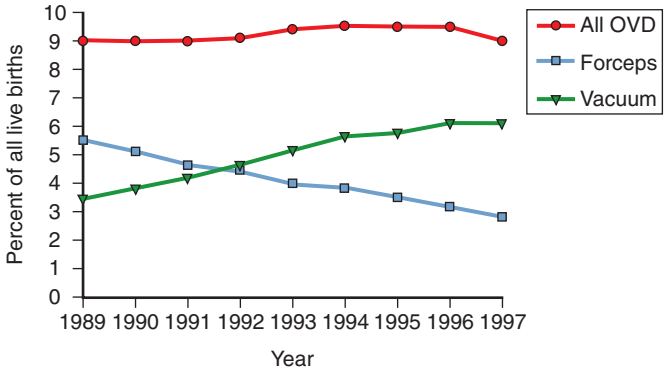

FIGURE 15-8. The overall incidence of operative vaginal delivery has remained stable over the last 15 years. Interestingly, over this same time span, vacuum extraction procedures have overtaken forceps procedures as the instrument of choice. (Modified from Miksovsky P, Watson WJ: Obstetric vacuum extraction: state of the art in the new millennium. Obstet Gynecol Surv 56:736, 2001.)

A 1992 report of a survey conducted by Ramin and colleagues of U.S. residency training programs reported that most programs use the 1988 classification scheme and that 86% taught midforceps.[97] It should be noted that even though a large percentage of programs teach the complex forceps procedures, the number of such procedures to reach proficiency has not been elucidated. In short, the overall decline in forceps procedures performed, the complexity of midpelvic cavity deliveries, and the shift from complex rotational deliveries to vacuum extraction and cesarean deliveries by younger faculty as shown by Tan and colleagues[83] and Jain and colleagues[98] may make the midforceps procedure obsolete in the near future.[97] In response to these types of concerns, Kim and colleagues[99] conducted a unique study to determine whether the rates of vacuum extraction and forceps procedures could be reversed without an increase in morbidity in a residency program. This retrospective study compared outcomes 2 years before and 2 years after an obstetrics faculty member was dedicated to the labor floor from Monday through Thursday, 7 AM to 5 PM **Table 15-5 depicts how such a dedicated instructor can increase the number of forceps relative to vacuum extractions without increasing third- or fourth-degree lacerations or adverse neonatal outcomes.**

Although the early 1990 report by Ramin and colleagues[97] provided encouraging information regarding the use of the 1988 classification scheme, a more recent study by Carollo and colleagues[100] is unsettling. In this 2004 study, Carollo conducted a survey of several teaching hospitals in the Denver area asking the following important questions: (1) How do you define fetal station? (2) How do you think a majority of your colleagues define fetal station? (3) How do you think the ACOG defines the classification of fetal station? and (4) How important do you think these distinctions are? What makes this study additionally unique is that these questions were asked of both attendings and residents in obstetrics and gynecology as well as nurses. Approximately 35% of attending physicians still defined station by dividing the pelvis into thirds rather than centimeters, as set forth in the old 1965 ACOG classification scheme. In addition, nearly 15% used the BPD rather than the presenting part as the landmark on the fetus to define station. These percentage numbers were higher for nurses and residents. The percent of correctly used techniques for defining station was highest at the university teaching hospital. These data suggest that, although we do fairly well at teaching proper technique for determining station, we are poor at disseminating the information into practice. Operative vaginal deliveries will be more difficult and dangerous if misunderstandings in defining fetal station persist.

TABLE 15-5 MODES OF DELIVERY AND BIRTH OUTCOMES BEFORE AND AFTER INITIATION OF DEDICATED OBSTETRICS STAFF LOCATED ON LABOR AND DELIVERY

	BEFORE	AFTER	P
Births	3481	4338	0.0001
Cesarean section	888 (26%)	1183 (27%)	NS
Operative vaginal delivery	394 (11%)	461 (11%)	NS
Forceps	172 (5%)	337 (8%)	0.00001
Vacuum	222 (6%)	124 (3%)	0.00001
Third- or fourth-degree lacerations	126 (4%)	134 (3%)	NS
Birth injury	8 (0.2%)	13 (0.3%)	NS
AS <7 at 5 minutes	67 (2%)	104 (2%)	NS

KEY POINTS

- Obstetrical forceps are the one instrument that makes the practice of obstetrical care unique to obstetricians. The proper use of these instruments has afforded safe and timely vaginal delivery to those whose abnormal labor course and urgent need for delivery require their use.
- Rates of cesarean delivery have risen in the United States, reaching a rate of approximately 25% of all deliveries in the United States, whereas rates of forceps deliveries have declined from 17.7% in 1980 to 4% in 2000.
- Resident work hour restrictions have resulted in a decline in resident experience with both primary cesarean delivery and vacuum-assisted vaginal delivery.
- Treat the vacuum extractor with the same respect as the forceps. The prerequisites for application of forceps or vacuum extractor are identical.
- When using vacuum extraction, descent of the fetal head should occur with each pull. If no descent occurs after three pulls, the operative attempt should be stopped.
- There appears to be little if any effect of forceps delivery on the subsequent development of urinary incontinence.
- The rate of anal sphincter injury in women who deliver by forceps may be higher; however, long-term rates of fetal incontinence appear to be no different than in women who deliver spontaneously.
- The risks of fetal injury associated with operative vaginal delivery are generally instrument specific, with vacuum deliveries accounting for higher rates of cephalohematoma and subgaleal and retinal hemorrhages, and forceps deliveries accounting for a nonsignificantly higher rate of scalp and facial injuries.
- Numerous retrospective studies comparing midcavity and rotation forceps delivery with cesarean delivery demonstrate no increased risk of fetal or neonatal adverse outcomes, including Apgar score, umbilical cord blood gas values, trauma, and neonatal intensive care unit admission.
- When properly applied and used, forceps deliveries requiring greater than 45 degrees may be safely accomplished without increased risk of maternal or neonatal morbidity and therefore should remain a management option for women with second-stage labor abnormalities.
- The sequential use of vacuum extraction and forceps increases the likelihood of adverse maternal and neonatal outcomes more than the sum of the relative risks of each instrument.

Summary 358

KEY TERMS

Acidemia	Increased hydrogen ion concentration in blood
Acidosis	Increased hydrogen ion concentration in tissue
Asphyxia	Hypoxia with metabolic acidosis
Base deficit	Buffer base content below normal (this is calculated from a normogram using pH and Pco_2)
Base excess	Buffer base content above normal
Hypoxemia	Decreased oxygen concentration in blood
Hypoxia	Decreased oxygen concentration in tissue
pH	The negative log of hydrogen ion concentration ($7.0 = 1 \times 10^{-7}$)

KEY ABBREVIATIONS

American Congress of Obstetricians and Gynecologists	ACOG
Association of Women's Health, Obstetric and Neonatal Nurses	AWHONN
Cardiotocography	CTG
Central Nervous System	CNS
Electrocardiogram	ECG
Electronic Fetal Heart Rate Monitoring	EFM
Federal Drug Administration	FDA
Fetal Heart Rate	FHR
Human Immunodeficiency Virus	HIV
Magnesium Sulfate	$MgSO_4$
Non-reassuring Fetal Status	NRFS
National Institute of Child Health and Human Development	NICHD
Premature Rupture of the Membranes	PROM

The question being asked by the clinician evaluating the fetus in labor is quite simple: What is the status of fetal oxygenation? If hypoxia is severe enough and lasts long enough, fetal tissue and organ damage will result, which may result in long-term injuries or death. Hypoxia severe enough to cause tissue damage virtually always occurs only in the face of a significant metabolic acidosis, and the term *asphyxia* is used in this situation (Figure 16-1). To clarify the terminology used in these situations, see the Key Terms.

Although there are other, less frequent causes of fetal injury and death in labor (e.g., infection, hemorrhage), hypoxia is by far the most common etiology and the one for which medical and surgical interventions have the potential for preventing injury and death. Before intensive intrapartum fetal heart rate (FHR) monitoring, relatively uniform intrapartum fetal death rates of 3 to 4 per 1000 were reported.[1] Thus, on an obstetrical service of 200 to 300 monthly deliveries, 1 intrapartum death would occur each month; but now such events are extremely rare in monitored fetuses. Fetal hypoxia that is severe and associated with metabolic acidosis, but not sufficient to result in death, may alternatively cause asphyxial injury to the fetus and newborn. The fetal central nervous system (CNS) is the organ system most vulnerable to long-term injury. **However, the fetus destined to have permanent neurologic damage will virtually always have multiorgan dysfunction**

in the newborn period. Usually, complications such as seizures, respiratory distress, pulmonary hypertension with persistent fetal circulation, renal failure, bowel dysfunction, and pulmonary hemorrhage are seen in the baby who will ultimately have permanent neurologic injury.[2] Babies who recover from these complications and survive may be normal or may develop cerebral palsy. Cerebral palsy is defined as a movement disorder, usually spastic in nature, that is present at birth, nonprogressive and often, but not always, associated with varying degrees of mental retardation.[3] Seizures are often seen in children with cerebral palsy. However, mental retardation or seizures, in the absence of spasticity, are rarely the result of peripartum asphyxia. It is still unclear whether other neurologic dysfunction in children, such as learning and behavioral disorders, can be the result of perinatal asphyxia. Cerebral palsy will develop in 0.5% of all births and is prevalent in about 0.1% of all school-aged children.[3,4] Prematurity remains the leading cause of cerebral palsy. It is estimated that peripartum events contribute to no more than 25% of the overall rate of this disease.[5]

Thus, the goal of intrapartum monitoring is to detect hypoxia in labor and allow the clinician to implement nonoperative interventions such as positioning and oxygen (O_2) administration to correct or ameliorate the oxygen deficiency. If this is unsuccessful, the monitor should help the clinician to determine the severity and duration of the hypoxia and whether there is a metabolic acidosis. And finally, if there is sufficient hypoxia and metabolic acidosis is present or developing, the monitor should give adequate warning and time to permit the clinician to deliver the baby expeditiously, whether by operative vaginal or cesarean delivery, to prevent damage or death from occurring. Unfortunately, the fetus is quite inaccessible, and until recently we have had crude and limited tools available to determine all the above information necessary to make correct and timely decisions to accomplish these goals.

HISTORY OF FETAL MONITORING

Because of the inaccessible location of the fetus, evaluating fetal well-being, or more specifically, fetal oxygen status, has been an ongoing and difficult challenge. In the 1600s, Kilian first proposed that the FHR might be used to diagnose fetal distress and to indicate when the clinician should intervene on behalf of the fetus. The sound of the fetal heart had first been detected by Marsac of France in the 1600s and described in a poem by his colleague, Phillipe LeGaust. This observation went unnoticed until 1818, when Mayor, and subsequently Kergaradec, described the fetal heart sounds by placing an ear on the maternal abdomen. Kergaradec suggested that auscultation of the fetal heart could be used to determine fetal viability and fetal lie. In 1893, Von Winckel described the criteria for fetal distress that were to remain essentially unchanged until the arrival of electronic FHR monitoring. These included tachycardia (FHR >160 beats/minute), bradycardia (FHR <100 beats/minute), irregular heart rate, passage of meconium, and gross alteration of fetal movement.[1]

These criteria went unquestioned until 1968, when Benson and colleagues published the results of the Collaborative Project.[6] These authors reviewed the benefits of auscultation in more than 24,000 deliveries and concluded, "there was no reliable indicator of fetal distress in terms of FHR save in extreme degree." Thus, it became apparent that other, more sophisticated means of intrapartum fetal evaluation were required. In 1906, Cremer described the use of the fetal electrocardiogram (ECG) using abdominal and intravaginal electrical leads.[7] Several investigators made attempts using ECG waveforms to detect fetal hypoxia, but ultimately concluded that there was no consistent fetal electrocardiographic changes with fetal distress.[8] The subsequent history of electronic FHR monitoring (EFM) is a story of technologic development and empirical observations of alterations in FHR associated with various causes of fetal hypoxia and acidosis.

In 1958, Edward Hon (the "father of EFM" in the United States) reported on the instantaneous recording of the fetal ECG from the maternal abdomen.[9] He and his colleagues manually measured R-R intervals from a continuous ECG tracing and mathematically converted these to rate, in beats per minute, and then hand-recorded each interval on graph paper. From these efforts Hon, Caldeyro-Barcia in Uruguay, and Hammacher in Germany began to describe various FHR patterns associated with fetal distress.[10-12] Despite attempts by these and subsequent

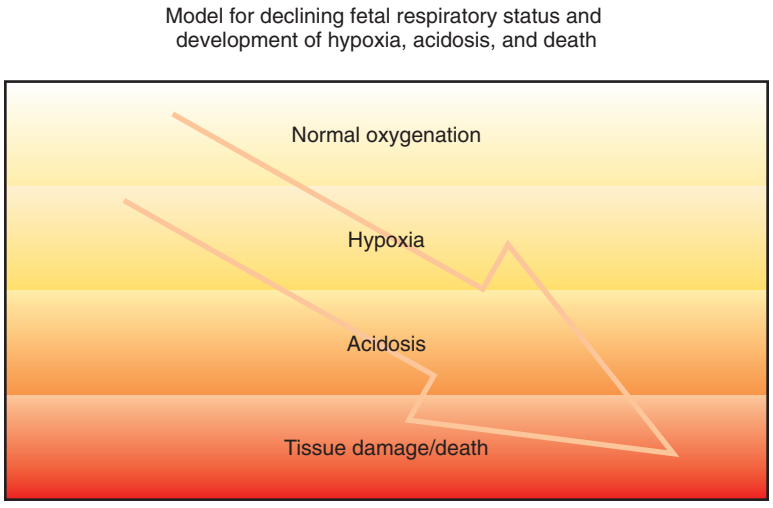

FIGURE 16-1. The purpose of fetal heart rate monitoring is to detect fetal hypoxia and metabolic acidosis. Many intrapartum fetuses develop hypoxia intermittently but never progress to metabolic acidosis. The idea is to avoid intervention for hypoxia, but to intervene in the presence of early metabolic acidosis before it can result in tissue damage or fetal death.

leaders in the field, universal standards for monitoring and terminology were never really established. For example, Europeans tend to refer to electronic fetal heart rate monitoring (EFM in the United States) as "cardiotocography" (CTG) and run their tracings at a paper speed of 1 cm/minute, compared with 3 cm/minute in the United States. **However, in recent years efforts by organizations such as the National Institute of Child Health and Human Development (NICHD) and American College of Obstetricians and Gynecologists (ACOG), *and similar societies in other countries,* have finally set standards for terminology that appear to be gaining widespread acceptance.** The first commercially available electronic fetal monitor was produced in the late 1960s, and by the mid-1970s, EFM was in use in most labor and delivery units in the United States. Today, most women giving birth in the United States have electronic FHR monitoring during labor.

INSTRUMENTATION FOR ELECTRONIC FETAL HEART RATE MONITORING

Many technologic advances have been made since the first monitors were produced. External FHR monitoring using electrocardiography did not work in labor, and phonocardiography was subject to fetal and maternal movement and other external noise. Doppler became the dominant modality for external monitoring. Initially, this modality was difficult to use because the complex Doppler signal made it difficult to determine which point within that signal the computer should use to measure the interval from beat to beat to convert to rate (Figure 16-2). Logic, or computer processing formulas, were used to get apparently good continuous signals, but this process introduced artifact, and the apparent variability and other aspects of the FHR were often inaccurate. Ultimately, better Doppler devices, coupled with autocorrelation formulas for processing the signal, have resulted in excellent external FHR signals that can be relied on clinically. **External monitoring is necessary at all times when the membranes are intact and cannot or should not be ruptured** (Figure 16-3). In addition, certain clinical situations make it unwise to puncture the skin with a fetal electrode for fear of vertical transmission of infection to the fetus. Such conditions include maternal infection with human immunodeficiency virus (HIV), hepatitis C, and herpes simplex.

It is often necessary to apply an internal electrode to obtain a high-quality, accurate, continuous FHR tracing. This is especially true in patients who are obese, in those with a premature fetus, or when the mother or fetus is moving too much to obtain an adequate signal. The original internal electrode was made from a modified skin clip that required a special instrument to place on the fetal scalp. In the mid-1970s, an easier to insert and less traumatic spiral electrode was introduced (Figure 16-4). This is applied to the fetal scalp manually without additional instruments and without the requirement for a speculum to visualize the scalp. The electrical circuit for this electrode includes the spiral electrode for one pole and a small

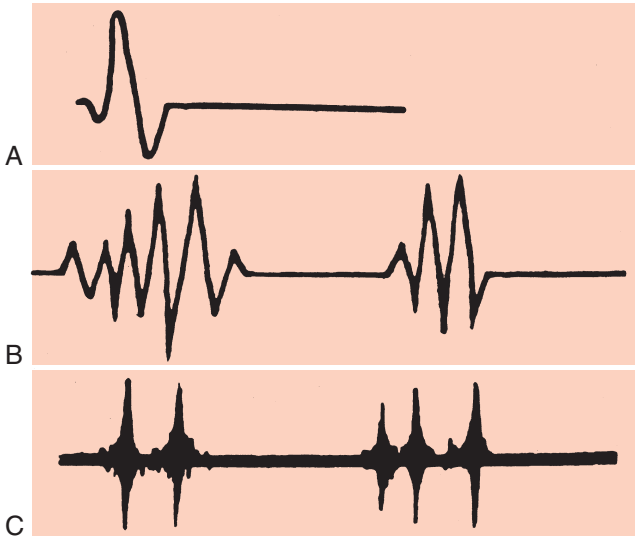

FIGURE 16-2. These complexes represent the types of signals that the fetal heart rate may be required to count. **A,** Electrocardiogram. **B,** Doppler. **C,** Phonocardiogram. Note the complexity of the Doppler signal. To consistently count the same place in the signal complex and avoid artifactually increasing variability, complex signal processing formulas are required.

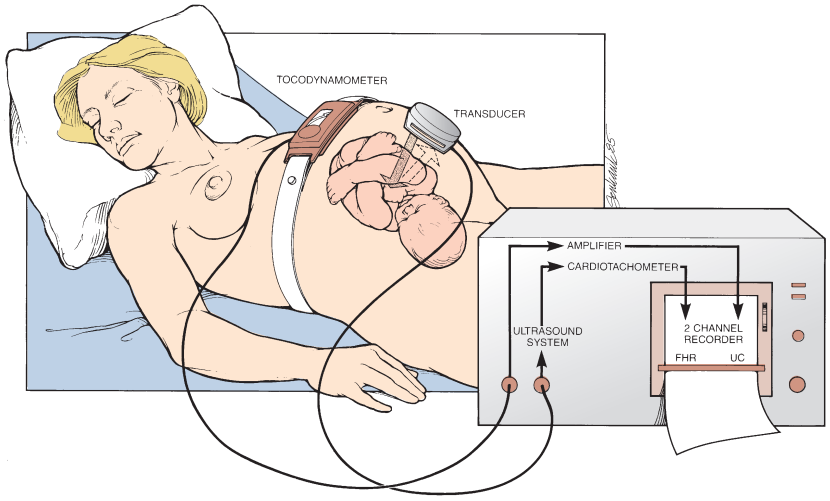

FIGURE 16-3. Instrumentation for external monitoring. Contractions are detected by the pressure-sensitive tocodynamometer, amplified, and then recorded. Fetal heart rate is monitored using the Doppler ultrasound transducer, which both emits and receives the reflected ultrasound signal that is then counted and recorded.

metal bar at the base of the plastic, which, bathed in vaginal secretions, completes the circuit through the mother's body. The spiral electrode has remained in use without substantial change since its introduction. **The FHR tracing results from the signal processor, which counts every R-R interval of the ECG from the scalp electrode, converts this interval to rate, and displays every interval (in rate as beats/minute) on the top channel of the two-channel fetal monitor recording paper.** The signal is amplified by an automatic gain amplifier, which increases the amplitude (gain) until an adequate signal is available to count (Figure 16-5). It must be remembered that when the fetus is dead, the amplifier may increase the gain of the small maternal ECG transmitted through the dead fetus, and this may be easily misinterpreted as a fetal bradycardia (Figure 16-6).

It is clear that the term *electronic fetal monitoring*, unlike the European version *cardiotocography*, undervalues the lower channel of the fetal monitor tracing, which provides information about the uterine contractions in labor. Contractions can also be monitored externally or internally. The external monitoring device, or tocodynamometer, is basically a ring-style pressure transducer attached to the maternal abdomen by a belt that maintains tight continuous contact. When the uterus contracts, the change in shape and rigidity depresses the plunger of the sensor, which changes the voltage of the electrical current. The change in voltage is proportional to the strength of the uterine contractions. **The tocodynamometer depicts the frequency of the contractions accurately, but the strength of the contractions only relatively, because it cannot measure actual intrauterine pressure.** In addition, the apparent duration of the contraction varies with the sensitivity of the monitor, which is negatively affected by variables such as maternal obesity and premature gestational age (Figure 16-7). The advantage of the external monitor is that it can be used when membranes are intact, and it is noninvasive. Its disadvantages, in addition to its inherently limited accuracy, is that it is more uncomfortable for the mother and limits her mobility. Contractions can be more accurately monitored using an intrauterine pressure catheter. The catheters require that the membranes be ruptured and are inserted transcervically beyond and above the fetal presenting part to rest within the uterine cavity. The original pressure catheters were open water-filled systems attached to a pressure transducer adjacent to the fetal monitor. These systems, while accurate, required frequent adjustments and flushing. Newer catheters have closed systems with the strain gauges in the tips or with sensors that relay the signal to a strain gauge at the base of the catheter. Although more expensive, they are easier to use

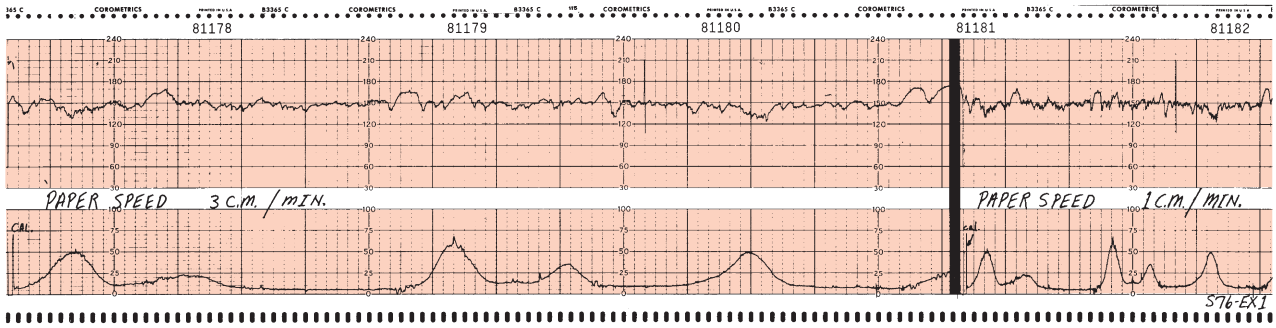

FIGURE 16-4. Internal fetal heart rate data gathered at the standard recording speed of 3 cm/minute for the first portion. The same data are being recorded at a speed of 1 cm/minute in the last segment. Normal long-term and short-term variabilities are present. Note that the uterine activity channel has been calibrated so that the intrauterine pressure readings can be measured correctly.

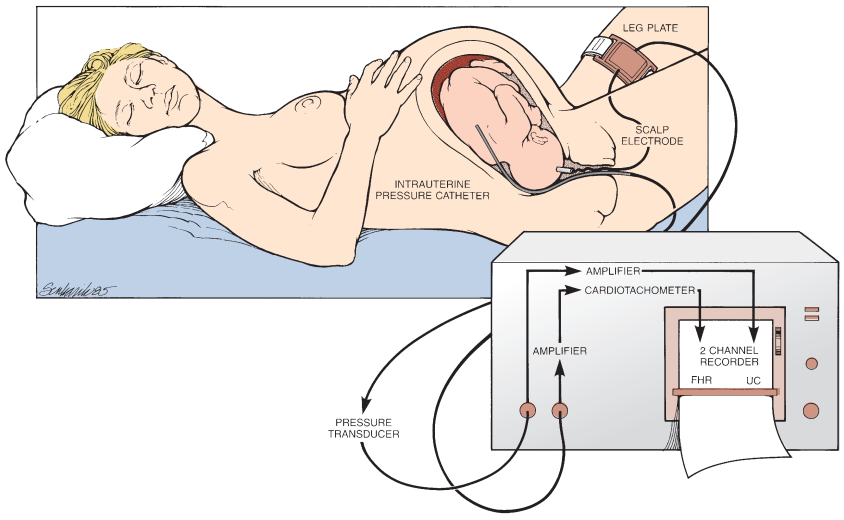

FIGURE 16-5. Techniques used for direct monitoring of fetal heart rate and uterine contractions. Uterine contractions are assessed with an intrauterine pressure catheter connected to a pressure transducer. This signal is then amplified and recorded. The fetal electrocardiogram is obtained by direct application of the scalp electrode, which is then attached to a leg plate on the mother's thigh. The signal is transmitted to the monitor, where it is amplified, counted by the cardiotachometer, and then recorded.

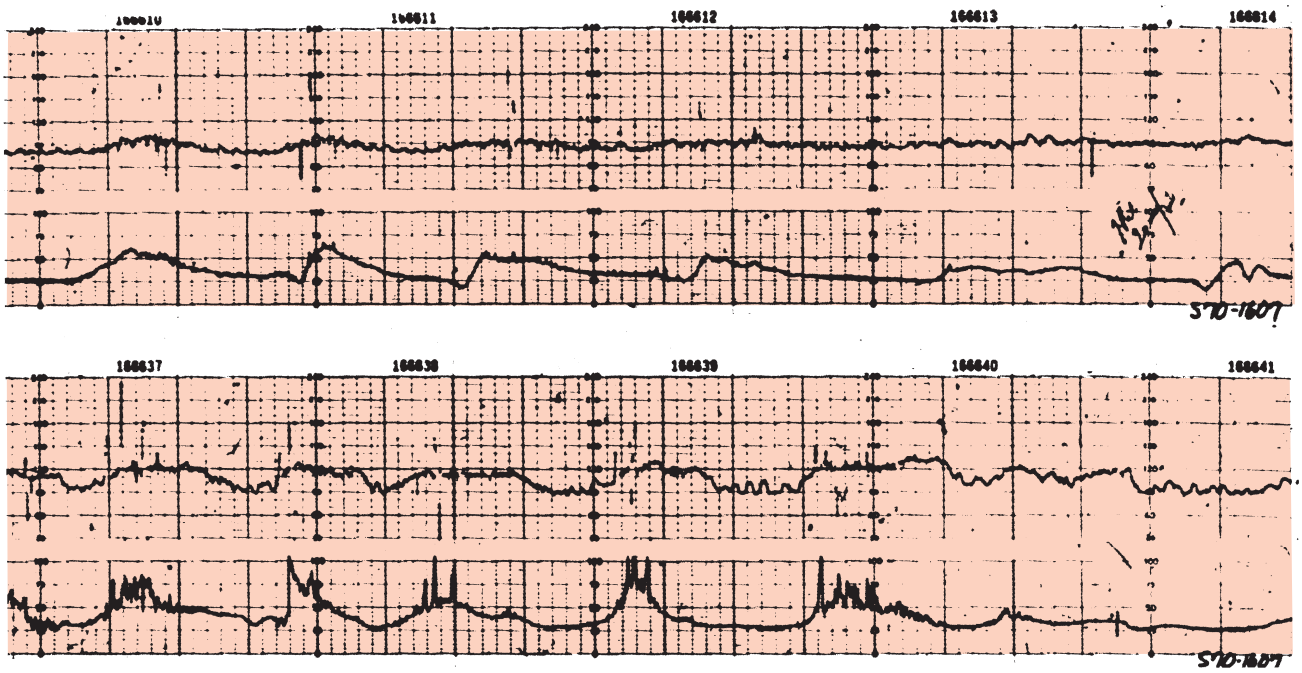

FIGURE 16-6. This is a tracing from an internal electrode demonstrating an apparent bradycardia with a rate of about 90 beats/minute. In actuality, this tracing is from a dead fetus, and the automatic gain amplifier increases the amplitude of the maternal electrocardiogram signal, allowing the monitor to count and display maternal heart rate. Note the accelerations of the maternal heart rate with contractions, typical of a heart rate response to the pain from contractions.

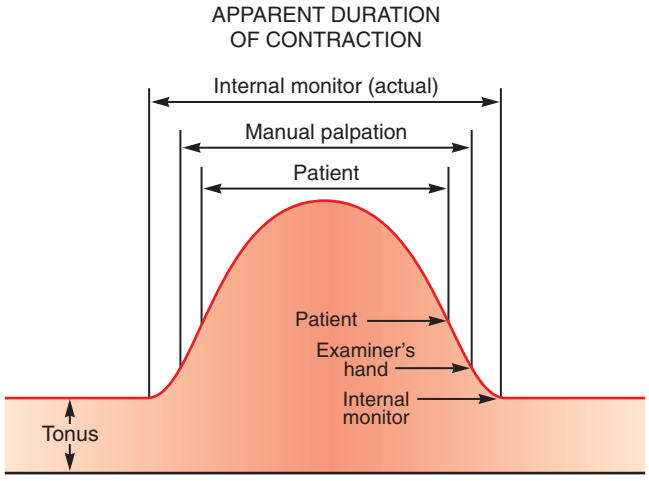

FIGURE 16-7. The sensitivity of the device used to monitor a uterine contraction can affect not only the apparent strength of the contraction but also the apparent duration of the contraction.

and require less nursing attention. Once the catheter is electronically "zeroed" (calibrated), the contractions are accurately recorded in terms of frequency, duration, and intensity on the lower channel of the two-channel recording paper or television monitor. This channel is conveniently calibrated at 0 to 100 mm Hg on its vertical scale, from which contraction amplitude can be read. These catheters also are often made with a second port through which saline can be infused for amnioinfusion (see later).

The goal of monitoring is to maintain adequate, high-quality, continuous FHR and contraction tracings while maintaining maximal maternal comfort and avoiding the risk for trauma and infection in the fetus and mother. External devices minimize risk but often give less accurate information and are more uncomfortable for the mother. In general, when the FHR is reassuring and there is an adequate tracing and when the progress of labor is adequate, the external devices are fine. When better-quality FHR monitoring is required or it becomes important to accurately assess uterine contraction duration and intensity, internal devices may be necessary.

PHYSIOLOGIC BASIS OF FETAL HEART RATE MONITORING

The basis of FHR monitoring is, in a real sense, fetal brain monitoring. The fetal brain is constantly responding to stimuli, both peripheral and central, with signals to the fetal heart that alter the heart rate on a moment-to-moment basis. Such stimuli to which the brain responds include chemoreceptors, baroreceptors, and direct effects of metabolic changes within the brain itself. The benefit for the brain to modulate the FHR is derived from its goal of maintaining optimal perfusion to the brain without compromising blood flow to other organs any more than is necessary. It should be intuitively obvious, therefore, that the use of FHR to monitor fetal oxygenation is inherently crude and nonspecific because many stimuli other than oxygen either cause the brain to alter the FHR or may have a direct effect on the fetal heart. **This really explains the most important basic premise of EFM: when the FHR is normal in appearance, one can be assured with high reliability that the fetus is well oxygenated, but when the FHR is not entirely normal, it may be the result of hypoxia or of other variables that may also affect FHR.** In the past when the FHR became abnormal and the clinician decided intervention was necessary because of concern over fetal

hypoxia, the term *fetal distress* was used. More often than not, however, such intervention results in the delivery of a well-oxygenated, nonacidotic, vigorous newborn. This understanding led to an attempt at more accurately reflecting the limitations of interpreting an abnormal FHR. **The term fetal distress was abandoned in favor of the more intellectually honest term, *non-reassuring fetal status* (NRFS).**[13] Even more recently, a further refinement has been recommended as a result of a second workshop sponsored by the NICHD and subsequently adopted by both ACOG and the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN), **which placed FHR patterns into three categories based on the likelihood of adequate or inadequate oxygenation and acidosis.**[14]

Fetal oxygenation is determined by many factors. **The placenta functions as the fetal lung.** Oxygen transfer across the placenta, as in the lung or any membrane, is proportional to the difference between partial pressures of oxygen between the mother and the fetus, the blood flow to the placenta, a coefficient of diffusion for the gas, and the surface area of the placenta. Transfer is inversely proportional to the thickness of the membrane (placenta). Thus, under normal circumstances during labor, the only variable that alters fetal oxygenation is the temporary interruption in blood flow to the placenta that occurs as a result of the compression of the spiral arteries by the wall of the uterus at the peak of the contraction. The duration that the spiral arteries will be compressed will thus depend on the duration and strength of the contraction (Figure 16-8). Under normal circumstances, the fetus tolerates these periods of stasis well without a significant change in its oxygen content. Contractions that are unusually long or unusually strong may, however, result in transient periods of fetal hypoxemia.

Other variables that have the potential for altering fetal oxygenation most commonly include those that affect uterine perfusion. A laboring woman in the supine position can develop hypotension as a result of vena caval compression from the uterus. Maternal hypotension with redistribution of blood flow away from the placenta occurs not infrequently with regional anesthesia. Maternal hemorrhage, such as in placenta previa or abruptio placentae, may have similar effects. There are several forms of microvascular disease that can impair fetal oxygenation from poor perfusion within the uteroplacental vascular bed. Examples include hypertension, preeclampsia or eclampsia, collagen vascular disease, diabetic vasculopathy, and postmaturity. Abruptio placentae may compromise fetal oxygenation in several ways. These include maternal hypotension, as previously mentioned; a decrease in the surface area of the placenta; and uterine hyperactivity.

Although the placenta functions as the fetal lung, the umbilical cord functions as its trachea, leading oxygen to the baby and carbon dioxide (CO_2) away. Alteration in umbilical cord blood flow is a very common occurrence during labor, either from direct compression or from stretch. Direct compression may occur when the cord becomes impinged between any part of the fetal body and the uterine wall, either with contractions or with fetal movement. This is especially more common when there is oligohydramnios because there is less amniotic fluid to provide a cushion for the cord.[15] Alternatively, cord stretch may occur as the fetus descends into the pelvis. Typically, this is seen just before complete dilation, when descent of the vertex normally occurs. There are three potent stimuli that produce spasm of the umbilical vessels that have evolved to allow cessation of fetal umbilical cord blood flow following birth. These include a lower ambient temperature, a higher oxygen tension as the baby begins breathing, and the stretch of the umbilical cord as the baby falls from the birth canal.[16] Thus, it should not be surprising that transient cessation of cord blood flow will occur with stretching of the cord during descent if the cord is looped around the baby's neck and descent of the vertex occurs.

It becomes important, therefore, to understand the physiologic mechanisms that control the FHR. This is so not only because the FHR may be used to determine the severity of the hypoxia and whether a metabolic acidosis is ensuing but also because the FHR pattern can elucidate the mechanism of the reduction in fetal oxygenation. Thus, by knowing the cause of any hypoxia, the treatment, when possible, can be more specifically directed at the cause. Finally, an understanding of the mechanism and progression of the FHR pattern can often also provide an opportunity to predict how fetal oxygenation will progress over time.

The FHR has many characteristics that we are able to use to accomplish this interpretation. These include the *baseline rate;* the *variability* of the FHR from beat to beat; transient alterations below the baseline, termed *decelerations;* and transient alterations above the baseline, termed *accelerations*. Rate and variability are generally included as *characteristics of the baseline* FHR, and decelerations and accelerations as *periodic changes*. In 1997, the NICHD convened a workshop to standardize terminology in FHR monitoring subsequently accepted and endorsed by most obstetrical organizations, and the subsequent descriptions and definitions in this chapter are consistent with those recommendations, except where explanations are provided to explain potential limitations of this newer system.[14]

Tachycardia

The baseline FHR is typically between 120 and 160 beats/minute. In very early gestation (15 to 20 weeks), the FHR is significantly higher than in the term fetus. The decline in FHR represents a maturation of fetal vagal tone with progressing gestation.[18] If atropine or other vagolytic drugs are administered, the FHR will regress to the higher baseline of 160 beats/minute. Thus, the baseline heart rate is largely a function of vagal activity. Many factors have the potential to alter the fetal baseline. For interpretation of the baseline rate, the minimal duration must be at least 2 minutes of adequate signal in a 10-minute window, or the baseline for that period is indeterminate. Rates above 160 beats/minute are called *tachycardia*. Tachycardia may have great clinical significance. **The two most common causes of tachycardia are maternal fever and drugs that directly raise the FHR.** Maternal fever raises the core temperature of the fetus, which is always about 1° F higher than the maternal temperature. With maternal fever, virtually all fetuses have tachycardia (Figure 16-9). The FHR rises approximately 10 beats/minute for each 1° F increase in

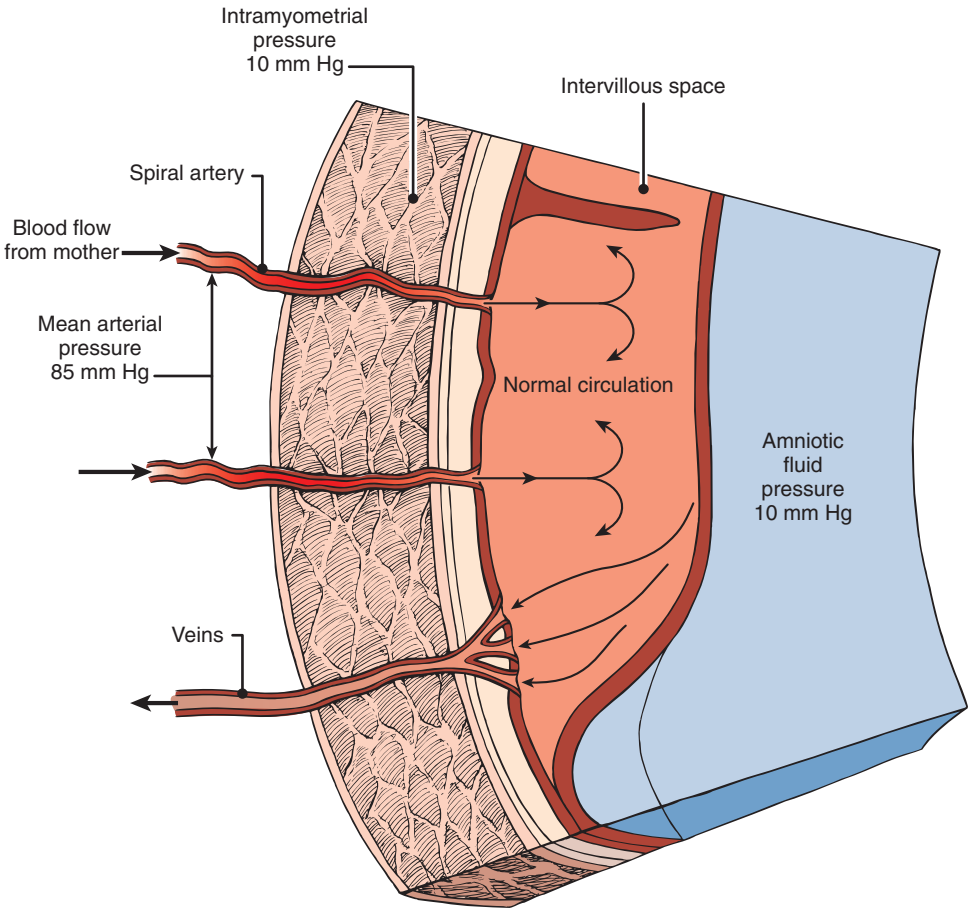

FIGURE 16-8. In the resting state between contractions **(A),** the intraluminal pressure within the spiral arteries exceeds the intramyometrial pressure. Thus, uteroplacental blood flow is sustained. However, at the peak of a uterine contraction **(B),** the myometrial pressure can exceed the arterial pressure, and uterine blood flow will be transiently interrupted, temporarily halting oxygen delivery to the placenta.

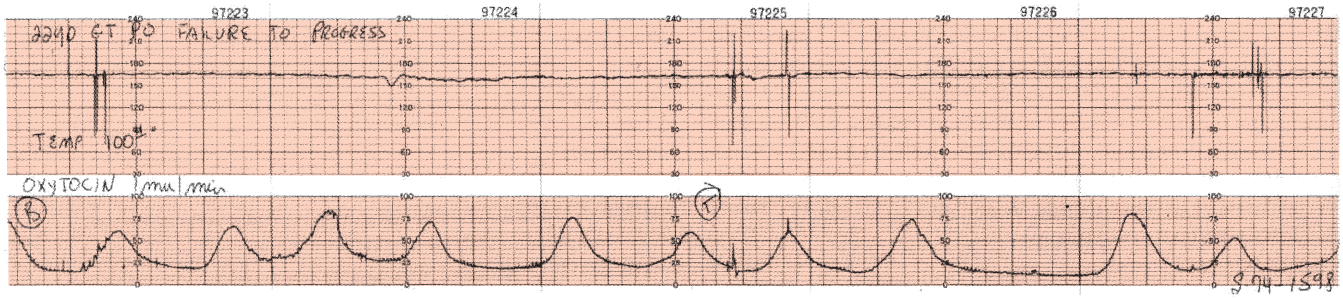

FIGURE 16-9. A tachycardia with a fetal heart rate of 170 beats/minute seen in association with a maternal fever of 38° C (100.4° F).

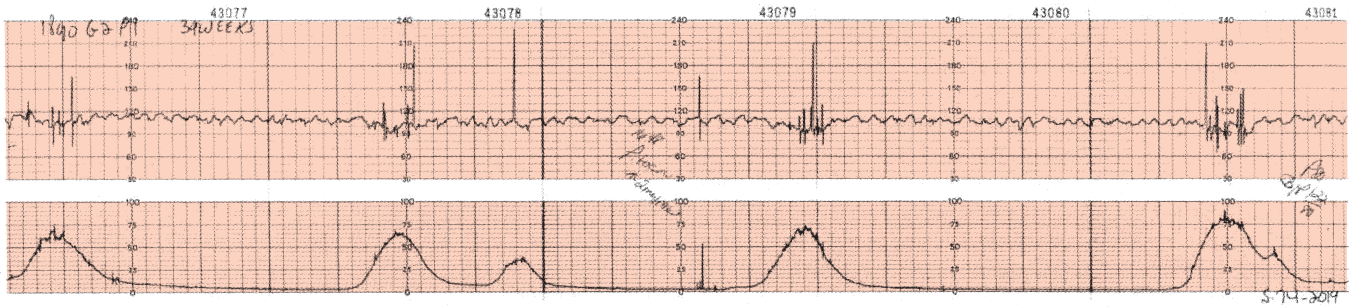

FIGURE 16-10. A bradycardia with a fetal heart rate of 110 beats/minute. This patient is in premature labor at 34 weeks' gestation and is being treated with magnesium sulfate. The fetal bradycardia is probably because of maternal hypothermia, which can be seen with vasodilation caused by the magnesium sulfate.

maternal temperature. Because at term with chorioamnionitis only 1% to 2% of fetuses are septic, the tachycardia is unlikely to indicate fetal sepsis, but rather is probably caused by an increase in fetal metabolic rate associated with the elevated temperature. Drugs that elevate the FHR fall into one of two categories: vagolytic and β-sympathomimetic. Commonly used drugs that are vagolytic include scopolamine, atropine and phenothiazines, and hydroxyzine. These drugs, however, rarely raise the FHR above 160 beats/minute. β-Sympathomimetics include terbutaline and ritodrine, used for preterm labor, and terbutaline and epinephrine, used for bronchospasm. Other, less common causes of fetal tachycardia include fetal hyperthyroidism, fetal anemia, fetal heart failure, and fetal tachyarrhythmias. As fetal hypoxia becomes progressively worse and persists over time, fetal tachycardia often develops. However, when contractions are present, tachycardia is not the first physiologic response to hypoxia and, in the absence of decelerations, in the laboring patient, is rarely if ever caused by hypoxia.[19]

Bradycardia

An FHR less than 110 beats/minute is termed a *bradycardia*. One must distinguish between a baseline FHR less than 110 beats/minute that is an established baseline and one that follows a prolonged deceleration. This is an important issue because an established baseline bradycardia is often innocuous (Figure 16-10), whereas a prolonged deceleration to less than 110 beats/minute lasting more than 60 to 90 seconds may often indicate significant fetal hypoxia (Figure 16-11). When a prolonged deceleration lasts more than 10 minutes it becomes a bradycardia according to the newer NICHD terminology.[17] True established fetal bradycardias occur infrequently and can be due to several possible causes. In the range of 90 to 110 beats/minute, a bradycardia may often be a normal variant, and these fetuses are usually bradycardic after birth, but are otherwise well oxygenated and normal. **As with tachycardia and fever, maternal hypothermia may cause fetal bradycardia.** This is commonly seen with patients on magnesium sulfate ($MgSO_4$) who are vasodilated and has also been described with maternal hypoglycemia and hypothermia.[20,21] Drugs, such as propranolol, may also result in fetal bradycardia. A fetal baseline heart rate in the range of 80 beats/minute or less, especially with minimal or absent variability, may be caused by a complete heart block. Complete heart block may be caused by antibodies associated with maternal lupus erythematosus, may be seen with congenital cardiac anomalies, or is idiopathic.[22] Whereas a heart block is not associated with hypoxia, it makes the FHR uninformative in monitoring fetal oxygenation because the fetal brain is no longer communicating with the ventricle of the heart that is being monitored. When a patient is admitted with a baseline bradycardia, one should also consider the possibility of maternal heart rate being recorded with a dead fetus (whether internal or external monitor) (see Figure 16-6). Real-time ultrasound is used to verify that the bradycardia is fetal in origin.

Variability

The fetal cardiotachometer is unique compared to adult monitors in that it records the interval-to-interval difference in rate for every heart beat. Thus, differences in heart rate from beat to beat are recorded as "variability" reflected visually as a line that fluctuates above and below the baseline. **This variability is a reflection of neuromodulation of the FHR by an intact and active CNS and also reflects normal cardiac responsiveness.** Generally, the variability of

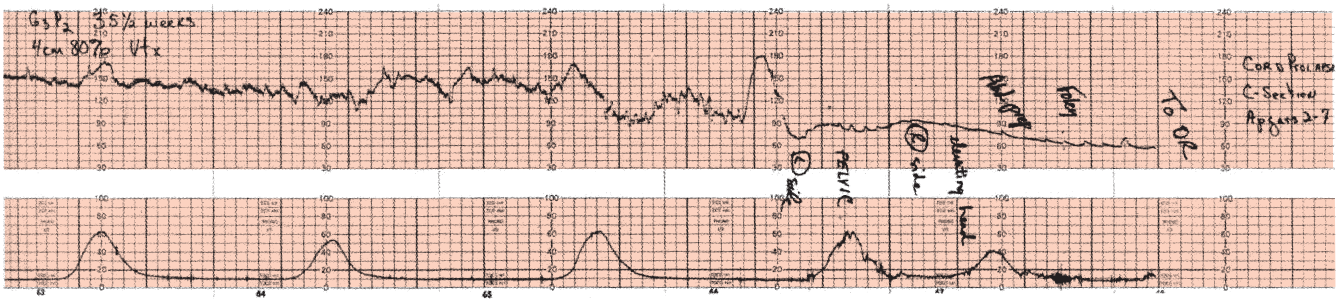

FIGURE 16-11. The prolonged deceleration to 60 beats/minute, in this case caused by umbilical cord prolapse, evolves following a prolonged deceleration from a normal baseline rate. When the prolonged deceleration lasts longer than 10 minutes, it then becomes a bradycardia according to the new NICHD terminology.[17]

the FHR is described as having two components: *short-term* and *long-term variability*. Short-term variability is the beat-to-beat irregularity in the FHR and is caused by the difference in rates between successive beats of the FHR. It is caused by the push-pull effect of sympathetic and parasympathetic nerve input, but the vagus nerve has the dominant role in affecting variability. Long-term variability is the waviness of the FHR tracing, and is generally seen in three to five cycles per minute. Previous texts spent considerable effort in distinguishing between the significance of short- and long-term variability, but in general they are reduced or increased together, and there is no clear evidence that distinguishing between the two is helpful clinically. **The NICHD Research Planning Workshop also concluded that no distinction should be made between short- and long-term variability.**[17]

This characteristic of the fetal baseline can be one of the most useful single parameters in determining the severity of fetal hypoxia if understood correctly. The simplest way to describe the causes of alterations, especially reductions, in FHR variability is to say that this parameter reflects the activity of the fetal brain. When the fetus is alert and active, the FHR variability is normal or increased. When the fetus is obtunded, by whatever cause, the variability is reduced. Because severe hypoxia, especially when it reaches the level of metabolic acidosis, will always depress the CNS, normal variability reliably indicates the absence of severe hypoxia and acidosis (Figure 16-12*A*). Unfortunately, the converse is not true because there are many things that cause the CNS to be depressed (see box, Potential Causes of Decreased Variability of the Fetal Heart Rate); thus, reduced (minimal or absent) variability is a very nonspecific finding and must be interpreted in the context of other indicators of hypoxia, and other causes of reduced variability must be considered (Figure 16-12*B*). **In general, anything that is associated with depressed or reduced brain function will diminish variability.** This includes fetal sleep cycles; drugs, especially CNS depressants; fetal anomalies, especially of the CNS; and previous insults that have damaged the fetal brain. FHR variability is also affected by gestational age, and very immature fetuses of less than 26 weeks' gestation often have reduced variability from an immature CNS, although this varies from fetus to fetus. In addition, as heart rate increases with fetal tachycardia, variability is often reduced from the rate alone because sympathetic dominance overrides the natural influence of the vagus. Increased FHR variability, original referred to as a "saltatory" FHR pattern, in nonlaboring animals has been shown to be associated with very early or minimal hypoxia.[23] This is a rare pattern and difficult to interpret. In labor, late, variable, or prolonged decelerations will virtually always be present with early hypoxia, and increased variability is not consistent with an acidotic fetus; therefore, this finding can be interpreted in context with the entire FHR pattern.

POTENTIAL CAUSES OF DECREASED VARIABILITY OF THE FETAL HEART RATE

- Depression due to hypoxia and acidosis
- Fetal anomalies, especially of the central nervous system
- Fetal sepsis
- Tumors of the central nervous system
- Fetal heart block
- Tachycardia
- Extreme prematurity
- Previous neurologic insult
- Fetal sleep cycles
- Drugs, medications
  - Narcotics
  - Barbiturates
  - Tranquilizers
  - Phenothiazines
  - Parasympatholytics
  - General anesthetics

Another problem with variability besides its nonspecificity is that the interpretation of variability is quite subjective. Variability is usually described quantitatively, The NICHD Research Planning Workshop[17] suggested that FHR variability be defined as follows:
Absent: amplitude undetectable
Minimal: amplitude > undetectable and ≤5 beats/minute
Moderate: amplitude 6 to 25 beats/minute
Marked: >25 beats/minute.

Experts given tracings to interpret often disagree on the quantification of variability even using just these four categories. Trying to categorize variability any further is fraught with even more potential for disagreement and does not appear to have predictive value.

PERIODIC CHANGES

Variability, tachycardia, and bradycardia are characteristic alterations of the baseline heart rate. Periodic changes of the FHR include decelerations and accelerations. These

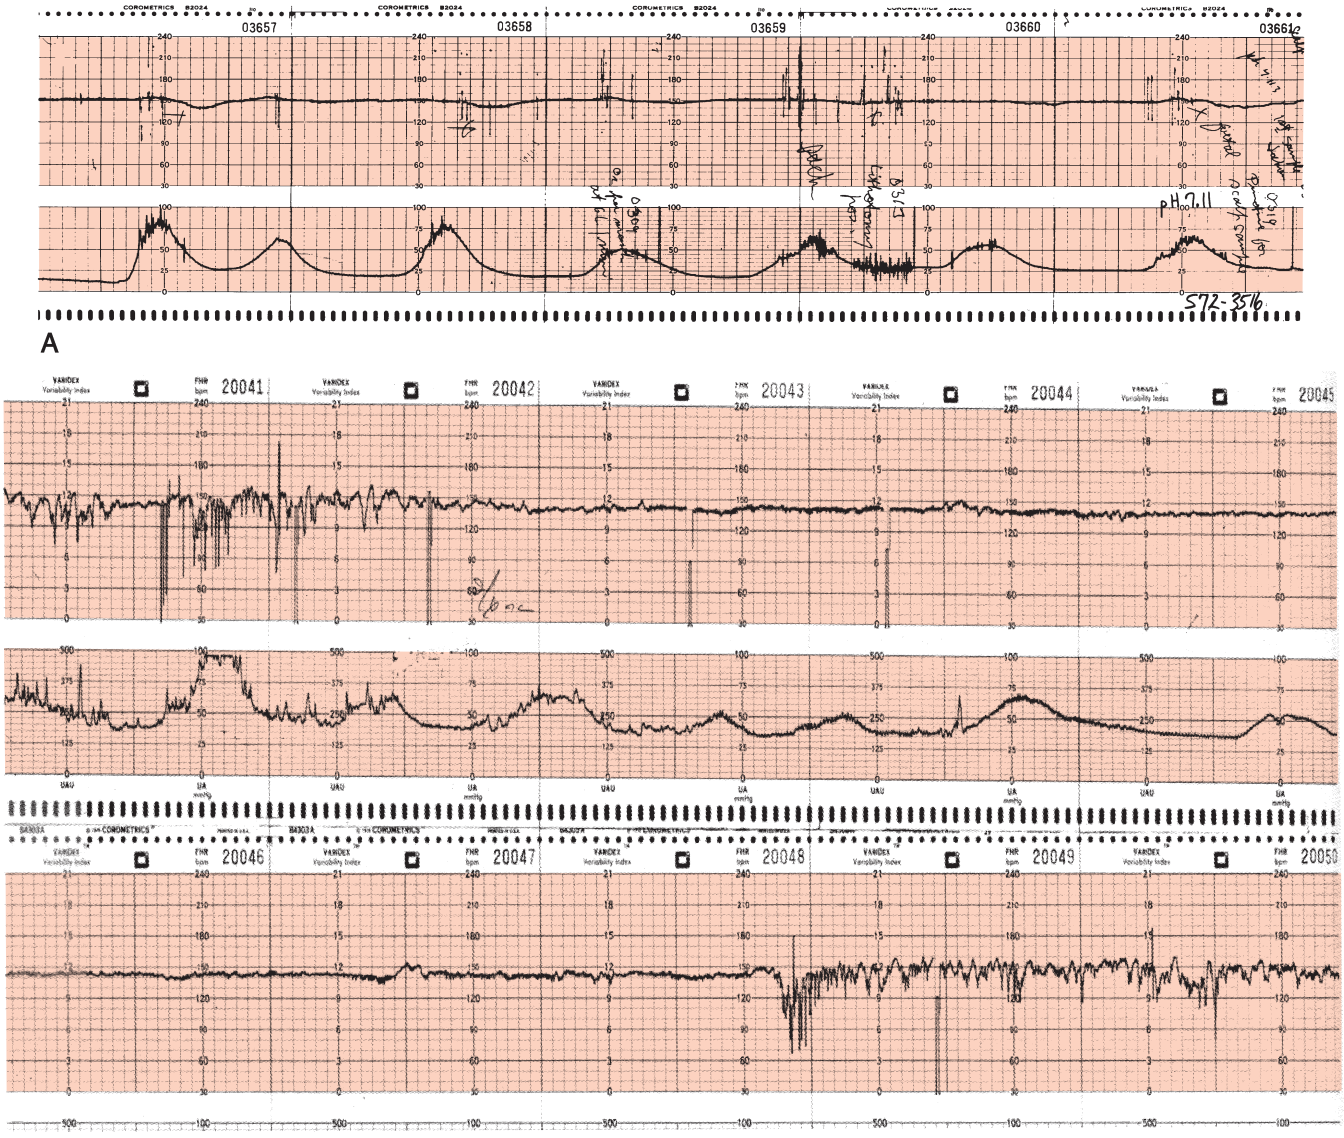

FIGURE 16-12. **A,** The markedly decreased variability seen in this case is in association with persistent late decelerations. A scalp pH of 7.11 confirms that the loss of variability is because of central nervous system depression caused by acidosis. **B,** The abrupt decrease in variability seen here, in contrast to **A,** is not seen in association with any decelerations that might suggest hypoxia. Thus, the decreased variability must be because of another reason, and in this case, given the equally abrupt return to normal variability in **B,** is probably caused by a fetal sleep cycle.

are transient changes in the FHR of relatively brief duration with return to the original baseline FHR. In labor, these usually occur in response to uterine contractions but may also occur with fetal movement.

Decelerations

There are four principal types of decelerations: *early*, *late*, *variable*, and *prolonged*. These are named for their timing, relationship to contractions, duration, and shape, but are important distinctions more because they describe the cause of the decelerations.

Early Decelerations

Early decelerations are shallow, symmetrical, uniform decelerations with onset and return that are gradual, resulting in a U-shaped deceleration (Figure 16-13). They begin early in the contraction, have their nadir coincident with the peak of the contraction, and return to the baseline by the time the contraction is over. Early decelerations are not associated with accelerations that precede or follow the deceleration. These decelerations typically do not descend more than 30 to 40 beats/minute below the baseline rate. **They are thought to be caused by compression of the fetal head by the uterine cervix as it overrides the anterior fontanel of the cranium.**[24] This results in altered cerebral blood flow, precipitating a vagal reflex with the resultant slowing of the FHR. More nonspecific head compression can result in decelerations that are indistinguishable from variable decelerations. Because of the similar cause, these latter decelerations have often been called *early decelerations*, but are by definition not so. Because the cervix creates the pressure, typically early decelerations are usually seen

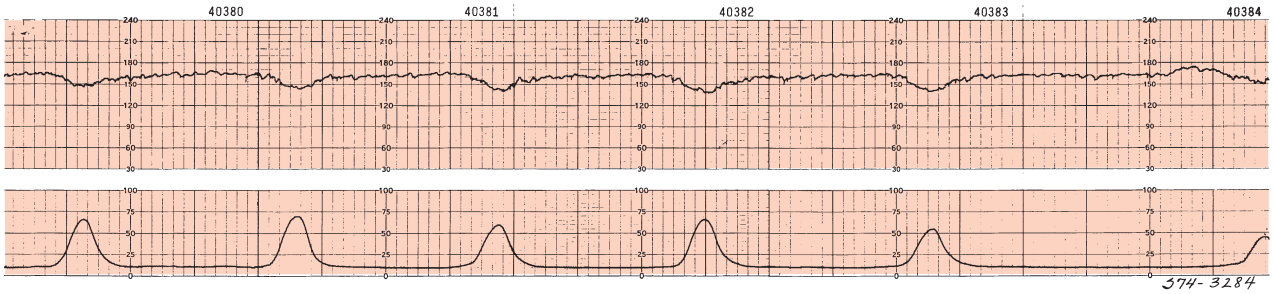

FIGURE 16-13. Early decelerations.

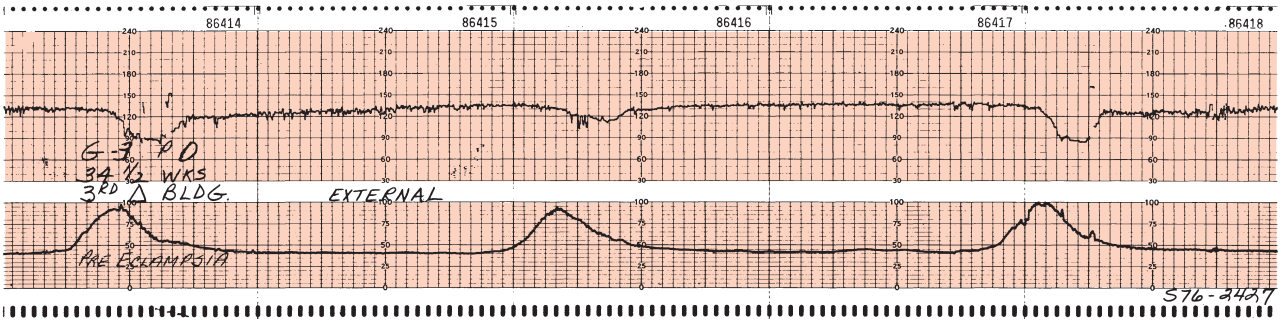

FIGURE 16-14. A case complicated by third-trimester bleeding in which the external heart rate and uterine activity data are collected. Note the presence of persistent late decelerations with only three contractions in 20 minutes as well as the apparent loss of variability of the fetal heart rate. The rise in baseline tone of the uterine activity channel cannot be evaluated with the external system.

between 4 and 6 cm of dilation (E.H. Hon, personal communication). They do not indicate fetal hypoxia and are only significant in that they may be easily confused with late decelerations because of their similar shape and depth. They are the most infrequent of decelerations, occurring in about 5% to 10% of all fetuses in labor.

Late Decelerations

Late decelerations are similar in appearance to early decelerations. They, too, are of gradual onset and return, are U-shaped, and generally descend below the baseline no more than 30 to 40 beats/minute, although there are exceptions. **However, in contrast to early decelerations, late decelerations are delayed in timing relative to the contraction.** They begin usually about 30 seconds after the onset of the contraction or even at or after its peak. Their nadir is after the peak of the contraction. In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and ending of the contraction, respectively. FHR variability may be unchanged or even increased during the decelerations. These decelerations are not associated with accelerations immediately preceding or following their onset and return (Figure 16-14).

The physiology of late decelerations is quite complex, but an understanding of the physiology pays dividends in terms of interpreting and managing these important FHR changes. **Late decelerations are generally said to be caused by "uteroplacental insufficiency."** This implies that uteroplacental perfusion is temporarily interrupted during the peak of strong contractions. The fetus that normally will not become hypoxic with this temporary halt in blood flow may do so if there is insufficient perfusion or oxygen exchange, as with, for example, hypotension or microvascular diseases within the uterus or placenta. Whereas this may be a correct idealized description, in reality any compromise of delivery, exchange, or uptake in fetal oxygen, other than by umbilical cord compression, can result in a late deceleration if the insult is sufficient. Physiologically, oxygen sensors within the fetal brain detect a relative drop in fetal oxygen tension in association with the uterine contraction. This change initially results in an increase in sympathetic neuronal response, causing an elevation in fetal blood pressure that, when detected by baroreceptors, produces a protective slowing in the FHR in response to the increase in peripheral vascular resistance. This has been referred to as the "reflex" type of late deceleration. This complex double reflex is probably the reason the deceleration is delayed.[25] During this type of reflex, the depth of the deceleration is proportional to the severity of the hypoxia, and the deceleration moves closer to the contraction as the hypoxia becomes more severe. However, there is also a second type of late deceleration, caused by "myocardial depression." As the hypoxia continues and becomes more severe, late decelerations are no longer vagally mediated and are seen even with interruption of the vagus nerve; thus, they are directly myocardial in origin. These decelerations are *not* proportional in their depth to the severity of the hypoxia and actually may become more shallow as the hypoxia becomes quite severe. Because of this latter type of deceleration, the depth of the late deceleration cannot always be used to judge the severity of the hypoxia. **Because of the mechanisms causing these changes, *late decelerations virtually always indicate fetal hypoxia.*** Only the severity of the hypoxia and the overall duration of the hypoxia will determine whether a metabolic acidosis will occur, and this is highly unpredictable.

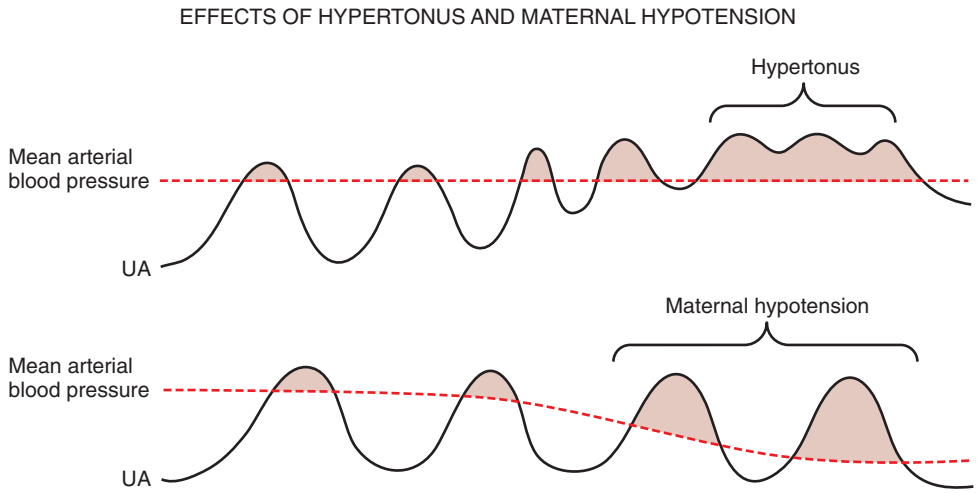

FIGURE 16-15. The two most common causes of late decelerations in labor are excessive uterine contractions (usually caused by oxytocin) and maternal hypotension. Both result in decrease in uteroplacental perfusion, hypertonus by interrupting the transmyometrial perfusion for a prolonged period, and hypotension by dropping the perfusion pressure, thus increasing the amount of time perfusion is interrupted even with a normal contraction. *UA,* Uterine artery.

One reason this may be so is found in recent data suggesting that the oxygen threshold that triggers the brain to slow the fetal heart in this characteristic way may be more related to the relative drop from baseline oxygenation rather than an absolute number.[26] Thus, the fetus accustomed to higher than average oxygen saturation may have a drop in oxygen at or only slightly below the normal range—a level deep enough to signal a late deceleration, but not low enough to require anaerobic metabolism. Another important point in understanding the results of hypoxia associated with late decelerations is that the placenta's capacity for exchanging oxygen is substantially less than its capacity for exchanging CO_2. In situations in which there are persistent late decelerations and the fetus becomes sufficiently hypoxic to develop a metabolic acidosis, there may be no retention of CO_2. This is quite analogous to the adult with lung but no airway disease in whom hypoxia is often seen without difficulty in eliminating CO_2. Thus, the metabolic acidosis is usually not mixed with a respiratory acidosis. The only common exception to this is with abruptio placentae, in which CO_2 retention is seen with late decelerations.[27]

Causes of late decelerations include any factor that can alter delivery, exchange, or uptake of oxygen at the fetal-maternal interface within the placenta. Most commonly, late decelerations are observed in patients without inherent pathology. Excessive uterine contractions, usually seen with oxytocin, are the single most common cause of late decelerations. In these situations, the duration of interruption of uterine blood flow is prolonged, the hypoxia is more than the normal fetus can endure, and late decelerations are expressed. Conduction anesthesia (spinal or epidural) can cause either systemic or local hypoperfusion or hypotension, and thus the level of contractions required to interrupt uterine blood flow is lower, and again the duration of interruption of uterine blood flow is prolonged (Figure 16-15). The most common pathologic conditions of the placenta associated with late decelerations are those characterized by either microvascular disease in the placenta or local vasospasm compromising blood flow and thus exchange. Common causes include postmaturity, maternal hypertension (chronic hypertension or preeclampsia), collagen vascular diseases, and diabetes mellitus in its more advanced stages. Besides altering perfusion, abruptio placentae is an example of altered placental exchange caused by a combination of reduced placental surface area and increased contractions that typically result in late decelerations when the separation is sufficient to cause fetal hypoxia. Severe maternal anemia or maternal hypoxemia may compromise oxygen delivery and result in late decelerations. Conversely, chronic fetal anemia may diminish fetal oxygen uptake and be associated with late decelerations.

Variable Decelerations

The most common type of decelerations seen in the laboring patient are variable decelerations. Variable decelerations are, in general, synonymous with umbilical cord compression, and anything that results in the interruption of blood flow within the umbilical cord will result in a variable deceleration. The variable deceleration is the most difficult pattern to describe, but the easiest to recognize visually. First and foremost, the term *variable* is by far the best single word to describe this type of deceleration. It is variable in all ways: size, shape, depth, duration, and timing relative to the contraction. The onset is usually abrupt and sharp. The return is similarly abrupt in most situations. The depth and duration are proportional to the severity and duration of interruption of cord blood flow. Variable decelerations are usually seen with accelerations immediately preceding the onset of the deceleration and immediately following the return to baseline. The definitions from the NICHD Research Planning Workshop also include that variable decelerations are those lasting a minimum of 15 seconds and descending 15 beats or more below the baseline and that the duration of a variable deceleration should be limited to 2 minutes, and that beyond 2 minutes, it should be called a prolonged

deceleration.[17] More than 50 years ago, Barcroft first described the variable deceleration when he ligated the umbilical cord of a fetal goat[28] (Figure 16-16). In 1975, Lee and Hon externalized the human umbilical cord before cesarean delivery and demonstrated that the reflex involved in the complex pattern of the variable deceleration is one that is caused primarily by changes in systemic blood pressure in the fetus and is mediated through baroreceptors (Figure 16-17).[29] When the umbilical cord is gradually compressed, the thinner-walled umbilical vein collapses first, and blood flow returning to the fetus is interrupted. This results in decreased cardiac return, fetal hypotension, and a baroreceptor reflex that leads the brain to accelerate the heart rate in order to maintain cardiac output. This increase in heart rate is the acceleration that precedes the variable deceleration. With continuing compression, the umbilical artery is compressed, and the fetus detects an increase in systemic vascular resistance because the previously low-resistance placental bed, to which 50% of fetal cardiac output normally flows, is occluded. The baroreceptors detect the increase in resistance, and the heart slows as a protective mechanism. As the cord vessels gradually open, the arteries open first, and the heart rate returns to baseline; but if the flow in the vein is still blocked, an acceleration of the same mechanism of the one that preceded the deceleration occurs. Although this model is idealized, one might surmise that the orderly occlusion of vein, vein and artery, vein does not always occur. This is probably the reason that, with variable decelerations, any combination of deceleration with acceleration preceding, preceding and following, following only, neither, or even acceleration alone may be seen with cord compression, as in Figure 16-18.

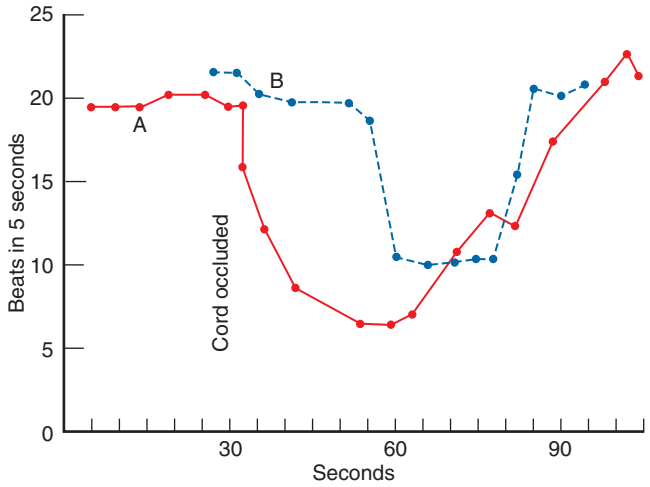

FIGURE 16-16. This is the original description of a variable deceleration in a fetal goat by Barcroft. The *solid line A* represents the fetal heart rate with temporary umbilical cord occlusion and the *dotted line B* is the fetal heart rate with temporary cord occlusion after the vagal nerve has been severed.

In reality, although we refer to umbilical cord compression as the single mechanism for interruption of cord blood flow, there are probably several different mechanisms that may have the same end result. Compression may be the mechanism that occurs when the cord is impinged between a fetal body part and the uterine wall during contractions or with fetal movement. As previously mentioned, cord stretch may be the reason the flow is compromised with

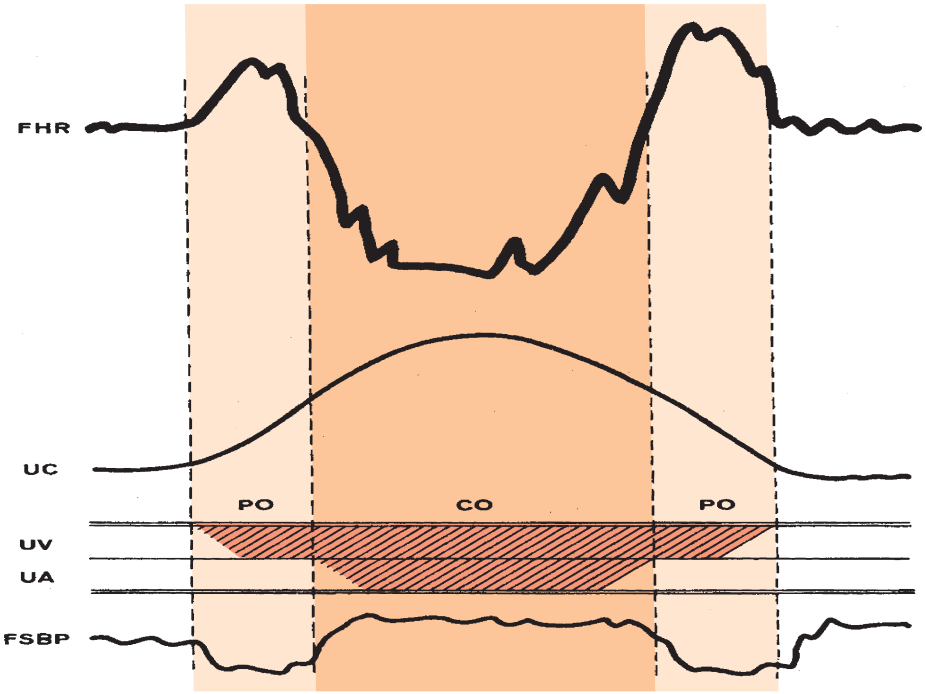

FIGURE 16-17. This figure represents fetal heart rate *(FHR)* and fetal systemic blood pressure *(FSBP)* occurring during compression of the umbilical vein *(UV)* and umbilical artery *(UA)*. Note the acceleration of the FHR as the FSBP is decreased, marking a baroreceptor response to decreased cardiac return, and the deceleration of the FHR when the FSBP is increased, the baroreceptor response to increased peripheral resistance. *UC,* Uterine contraction.

nuchal cords and seen as the baby descends through the pelvis. If cold saline is infused too rapidly with amnioinfusion, the FHR may slow, presumably as a result of cord spasm, the natural fetal reflex to cold stimulus. **Whatever the mechanism, it is most important to realize that variable decelerations are initially caused by a reflex in response to changes in pressure and not hypoxia.** Thus, variable decelerations (even deep and prolonged) can be seen in fetuses with no change in oxygen saturation (Figure 16-19).

Variable decelerations are seen in most labors, and most often these decelerations occur without fetal hypoxemia. It is apparent that additional criteria are needed to separate those benign variable decelerations not likely to be associated with hypoxia from those that are. Kubli and coworkers described a category of mild, moderate, and severe variable decelerations based on depth and duration (see box, Classifications of the Severity of Variable Decelerations).[30] Although there is indeed a correlation between the severity of these decelerations and the likelihood of hypoxia, one can see from Figure 16-19 that it is difficult to pick a specific depth and duration that always predicts oxygen compromise. Therefore, in addition, characteristics of the fetal baseline are also used, including the development of tachycardia and loss of variability (Figure 16-20). When cord compression occurs with each contraction and is sustained for a prolonged period of time, there can be a change from the usual abrupt return to baseline to a slow or delayed return to baseline (Figure 16-21). This is also often called a *late component*, although a combined pattern of late and variable decelerations (Figure 16-22) should be distinguished from progressive, severe variable decelerations that result in slow return to baseline because the etiologies and thus the potential treatments will differ. This particular discriminator of variable decelerations can be one of the most confusing aspects in all of fetal monitoring. Because a slow return to baseline can represent fetal hypoxia from either progressive cord compression or from a coincident late deceleration, the question is, Does this finding always represent hypoxia? Many times this sign appears without significant cord compression preceding its onset; therefore, it is unlikely that a substantial oxygen deficit has developed. Thus, many times these are benign findings and may represent more slow release of the cord or some other unexplained phenomenon. Finally, in extreme situations in which there is profound fetal hypoxia and acidosis, the variable decelerations will appear smoother and rounded or "blunted," rather than having the usual abrupt changes seen with the more common

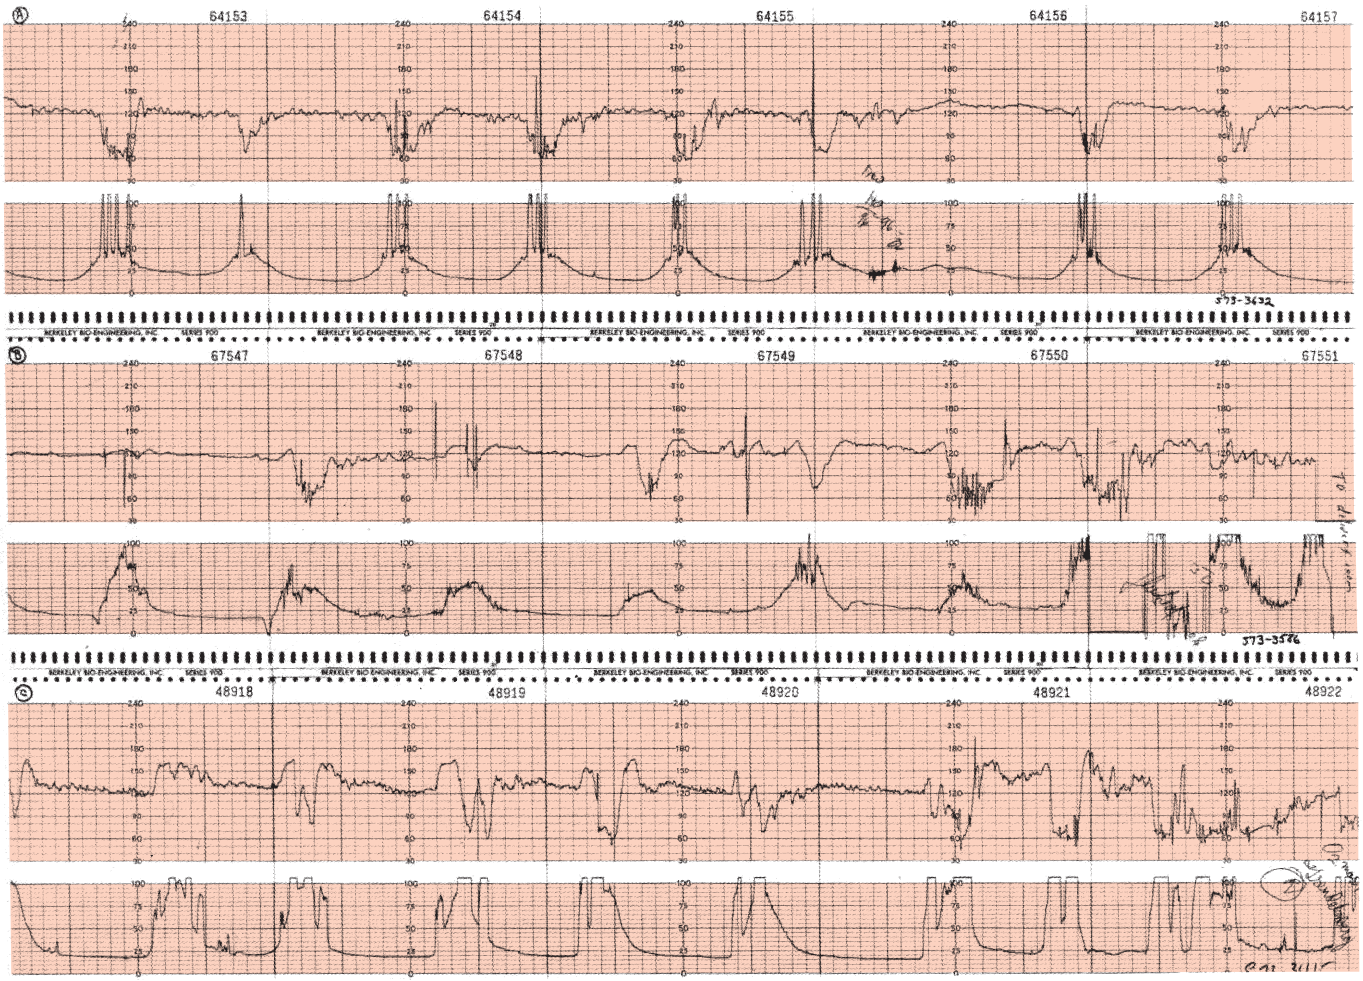

FIGURE 16-18. These are typical variable decelerations. Note that such decelerations are often recognized by the accelerations that precede and follow the decelerations.

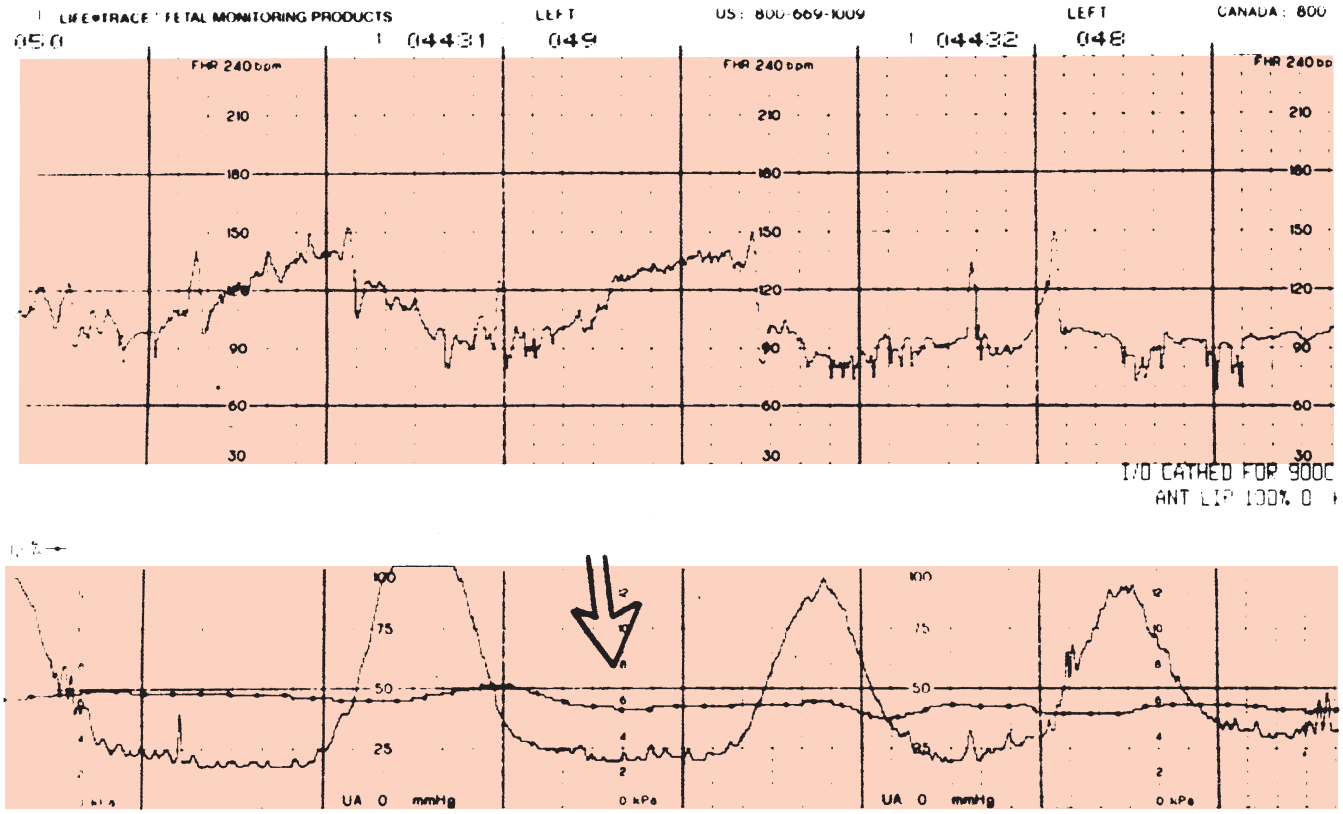

FIGURE 16-19. Superimposed on the contraction monitor tracing is a continuous tracing using a fetal pulse oximeter. The tracing shows an fetal oxygen saturation value ranging from 50% to 40% (normal, 35% to 60%). Note the consistently normal saturation values despite the prolonged fetal heart rate decelerations to 80 beats/minute.

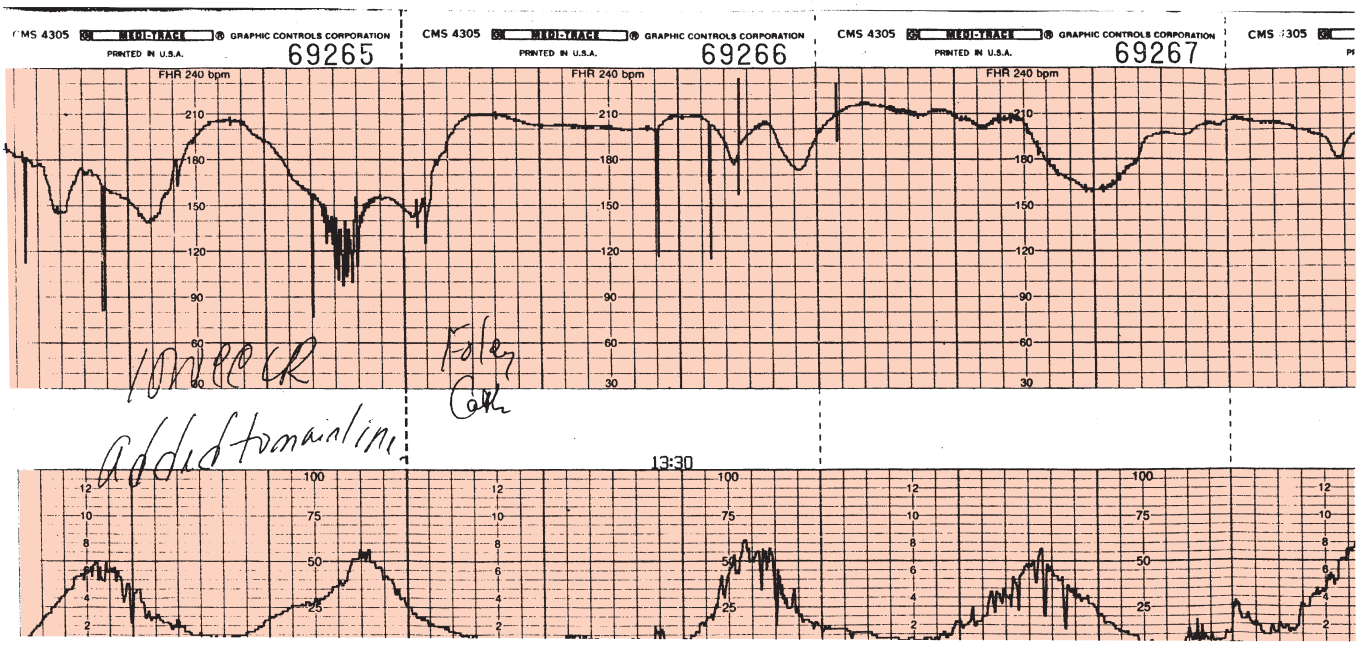

FIGURE 16-20. The loss of variability and tachycardia in association with these variable decelerations makes this a non-reassuring fetal heart rate pattern (NICHD Category III).[17]

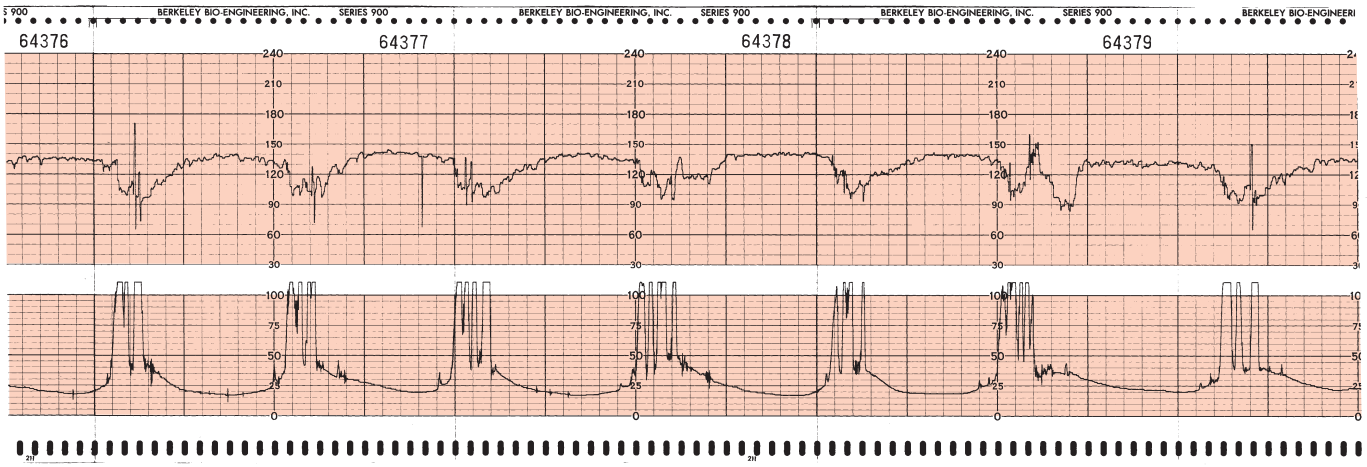

FIGURE 16-21. These variable decelerations, although mild in depth and duration, are associated with a slow, rather than abrupt, return to baseline. This may be a sign of developing hypoxia as a result of repetitive umbilical cord compression with inadequate opportunity to reoxygenate between events. Generally, this finding makes the variable decelerations non-reassuring.

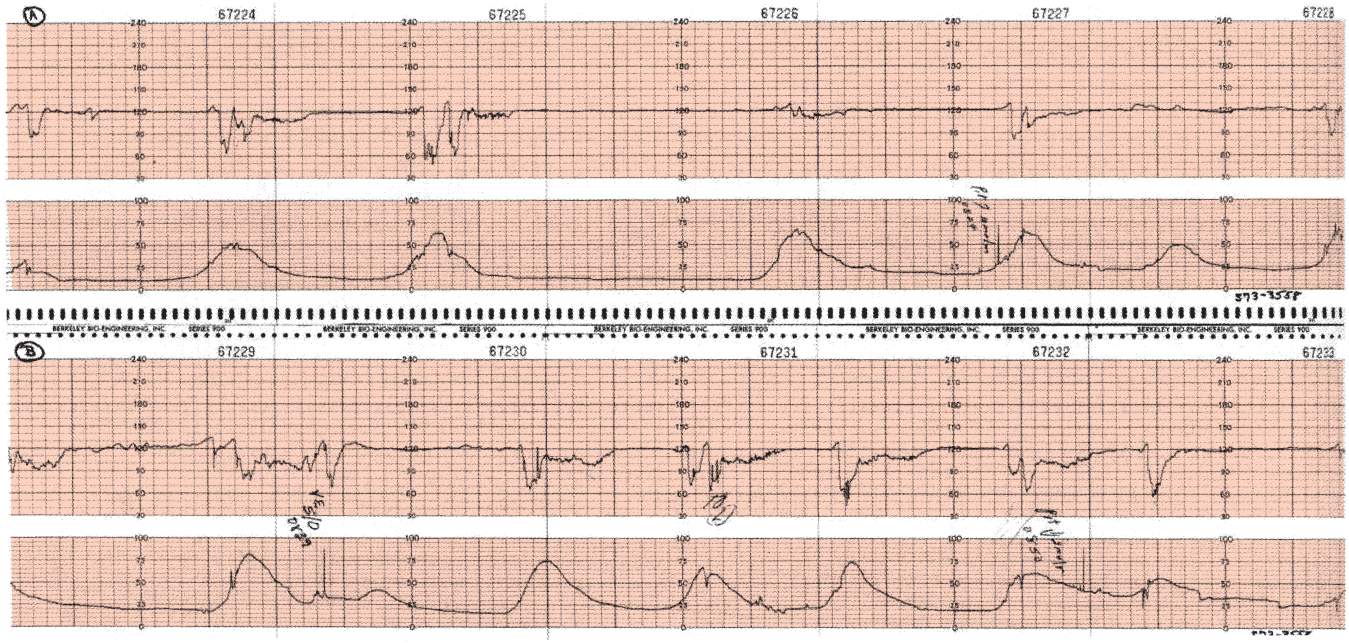

FIGURE 16-22. Here are repetitive variable decelerations with a slow return to baseline. However, the minimal depth and duration of the variable decelerations and the fact that one can see an independent late deceleration with the third contraction would suggest that this pattern is actually a combined one of mild variable and persistent late decelerations.

CLASSIFICATIONS OF THE SEVERITY OF VARIABLE DECELERATIONS

Mild
- Deceleration of a duration of less than 30 seconds, regardless of depth
- Decelerations not below 80 beats/minute, regardless of duration

Moderate
- Deceleration with a level below 80 beats/minute

Severe
- Deceleration to a level below 70 beats/minute or more than 70 beats/minute below the baseline for more than 60 seconds

Data from Kubli FW, Hon EH, Khazin AE, et al: Observations on heart rate and pH in the human fetus during labor. Am J Obstet Gynecol 104:1190, 1969.

benign decelerations. Such cases are virtually always seen in association with absent FHR variability, and they can also be followed by a blunted acceleration following the return to baseline described by Goodlin and Lowe as "overshoot" (Figure 16-23).[31] This is a rare situation and is only seen when all criteria are met, including absent variability, blunted variable decelerations, no acceleration preceding the variable deceleration, and no other spontaneous accelerations of the FHR.

There are four categories of causes of cord compression patterns that are useful to consider from a management standpoint. Variable decelerations appearing early in labor are often caused by oligohydramnios. Other variable decelerations often first appear when the patient reaches 8 to 9 cm of dilation, the time in labor when the curve for descent of the presenting part becomes steep. This is

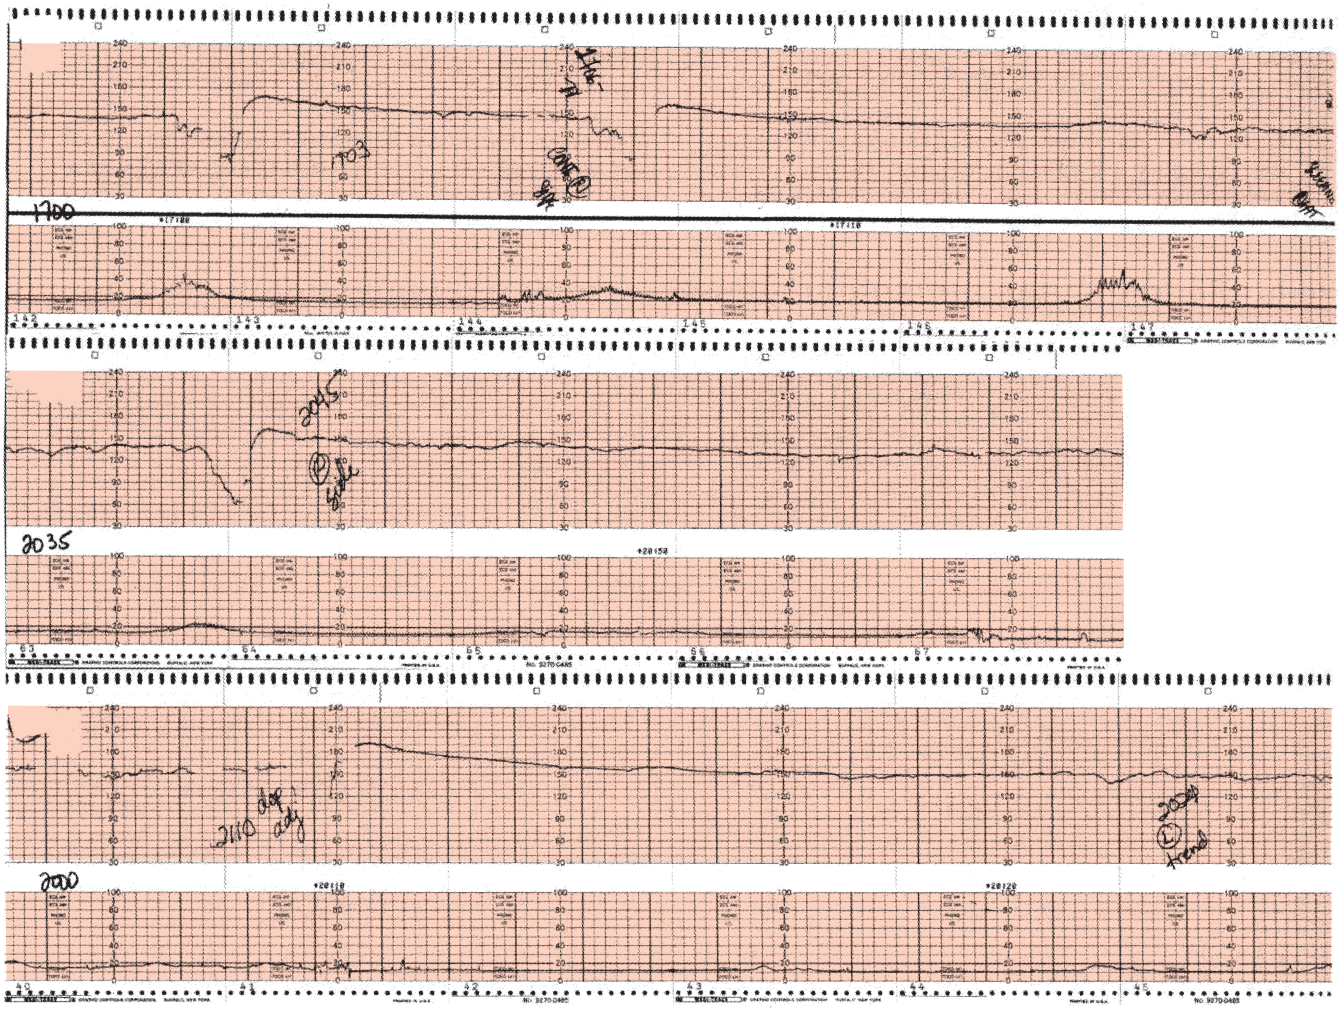

FIGURE 16-23. The accelerations following these variable decelerations, without any acceleration preceding, in association with absent variability fulfill the criteria to describe the accelerations as "overshoot." Such a finding can be ominous and is often associated with marked metabolic acidosis.

probably most often because of nuchal cords, wherein the cord becomes stretched with descent of the fetal head, and as previously described, cord stretch is a profound stimulus for vasospasm in the cord vessels.[16] Unusual types of abnormal umbilical cords, such as short cords, true knots, velamentous cord insertion, cord looped around the extremities, and occult cord prolapse, will produce variable decelerations. And finally, the rarest form of cord compression, and one that usually requires rapid cesarean delivery, is true umbilical cord prolapse.

Because the umbilical cord is most analogous to the adult trachea, interruption in cord flow results in both retention of CO_2 and cessation of O_2 delivery. When this becomes progressive, the intermittent compression often first leads to a progressive increase in fetal CO_2, which results in a respiratory acidosis. If the cord compression continues and also is sufficiently severe to cause insufficient delivery of oxygen, then a metabolic acidosis can also develop. Thus, in a fetal acidosis resulting from cord compression, the acidosis can be respiratory or combined respiratory and metabolic, but should not be metabolic alone.

Prolonged Decelerations

Prolonged decelerations are sporadically occurring decelerations lasting 90 to 120 seconds or more. The NICHD Research Planning Workshop proposed that prolonged decelerations be defined as those lasting 2 to 10 minutes and that beyond 10 minutes this is a baseline change.[17] In most cases, the sudden drop in FHR is the result of some adverse afferent stimulus caused by the brain detecting changes in oxygenation, blood pressure, or even intracranial pressure, as with sustained head compression. Unlike the other three decelerations, in which the type of deceleration defines the pathophysiologic mechanism, prolonged decelerations may be caused by virtually any of the mechanisms previously described, but usually are of a more profound and sustained nature. Prolonged umbilical cord compression, profound placental insufficiency, or even sustained head compression may lead to prolonged decelerations.

The presence of and severity of hypoxia are thought to correlate with the following variables with a prolonged deceleration: the depth and duration of the deceleration, how abruptly it returns to baseline, how much variability is

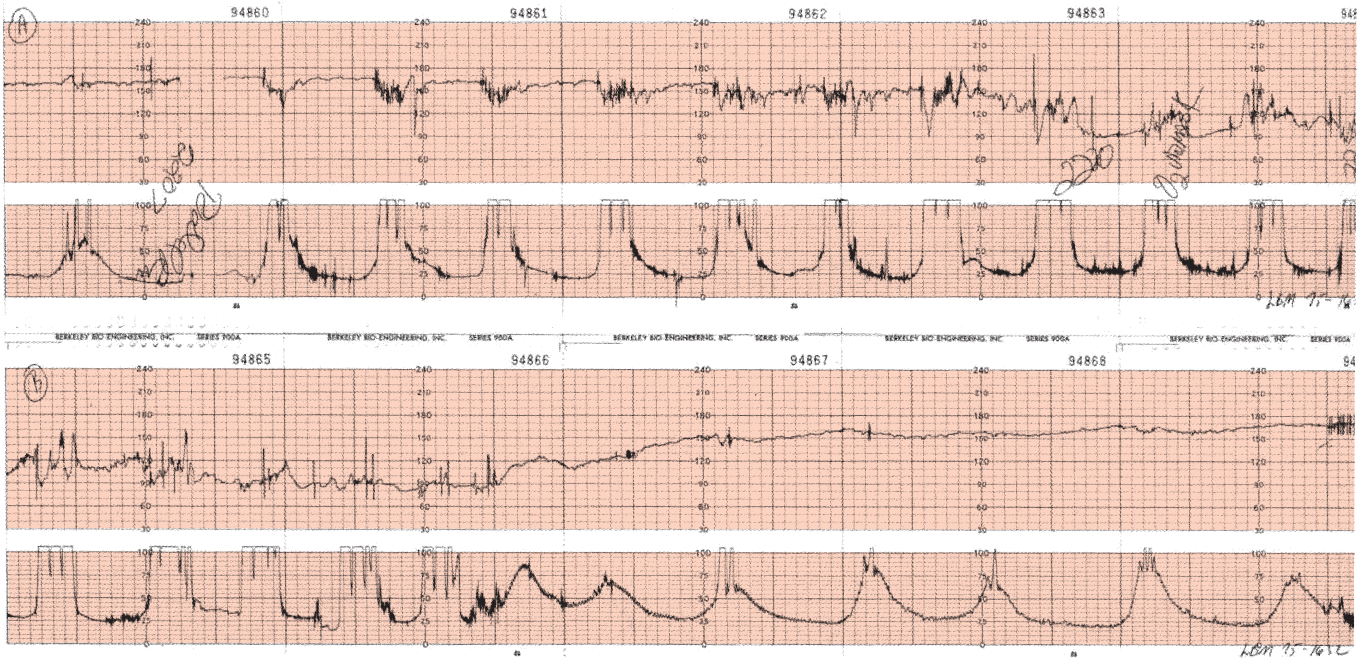

FIGURE 16-24. Often following a prolonged deceleration, as with the one shown in this figure, there is a temporary period of tachycardia and loss of variability. Such a response would suggest that this was a significant hypoxic event. The etiology of this deceleration is not clear but may have been a result of excessive uterine contractions compounded by maternal pushing.

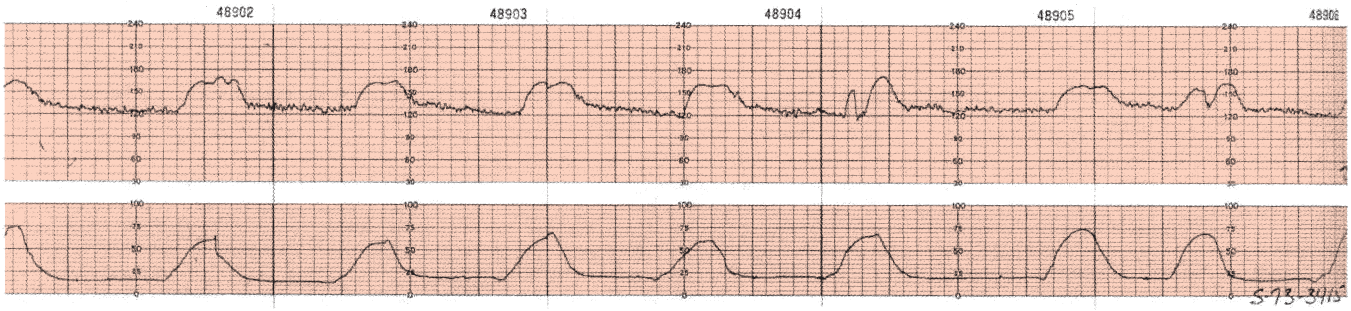

FIGURE 16-25. These are accelerations of the fetal heart. They are usually seen with fetal movement and are often coincident with uterine contractions as well, as in this patient.

lost during the deceleration, and whether there is a rebound tachycardia and loss of variability following the deceleration (Figure 16-24). Examples of the more profound stimuli that may result in this type of deceleration include prolapsed umbilical cord or other forms of prolonged cord compression, prolonged uterine hyperstimulation, hypotension following conduction anesthesia, severe degrees of abruptio placentae, uterine rupture, paracervical anesthesia, an eclamptic seizure, and rapid descent through the birth canal. Occasionally, less severe stimuli such as examination of the fetal head, Valsalva maneuvers, or application of a scalp electrode may cause milder forms of prolonged decelerations.

Accelerations

Accelerations are periodic changes of the FHR above the baseline (Figure 16-25) **defined as an transient increase of the FHR lasting at least 15 seconds and rising 15 beats or more above the baseline.** Because decelerations are of lower amplitude in more premature gestations, the definition of accelerations in the fetus before 32 weeks are those of an amplitude of 10 beats/minute or more lasting 10 or more seconds. They are not classified by type. Except for those accelerations previously described that are associated with variable decelerations, virtually all accelerations are a physiologic response to fetal movement.[32] Accelerations are usually short in duration, lasting no more than 30 to 90 seconds, but in an unusually active fetus, they can be sustained as long as 30 minutes or more. Again, the NICHD Research Planning Workshop disagrees somewhat on this definition, in that they propose that accelerations of more than 10 minutes be defined as a change in baseline.[17] This definition may not always be consistent with the actual fetal physiology because one can on occasion see sustained accelerations (Figure 16-26) that are associated with an actively moving fetus, and when the fetus becomes quiet, the FHR will return to baseline. It is important that this acceleration not be confused with a

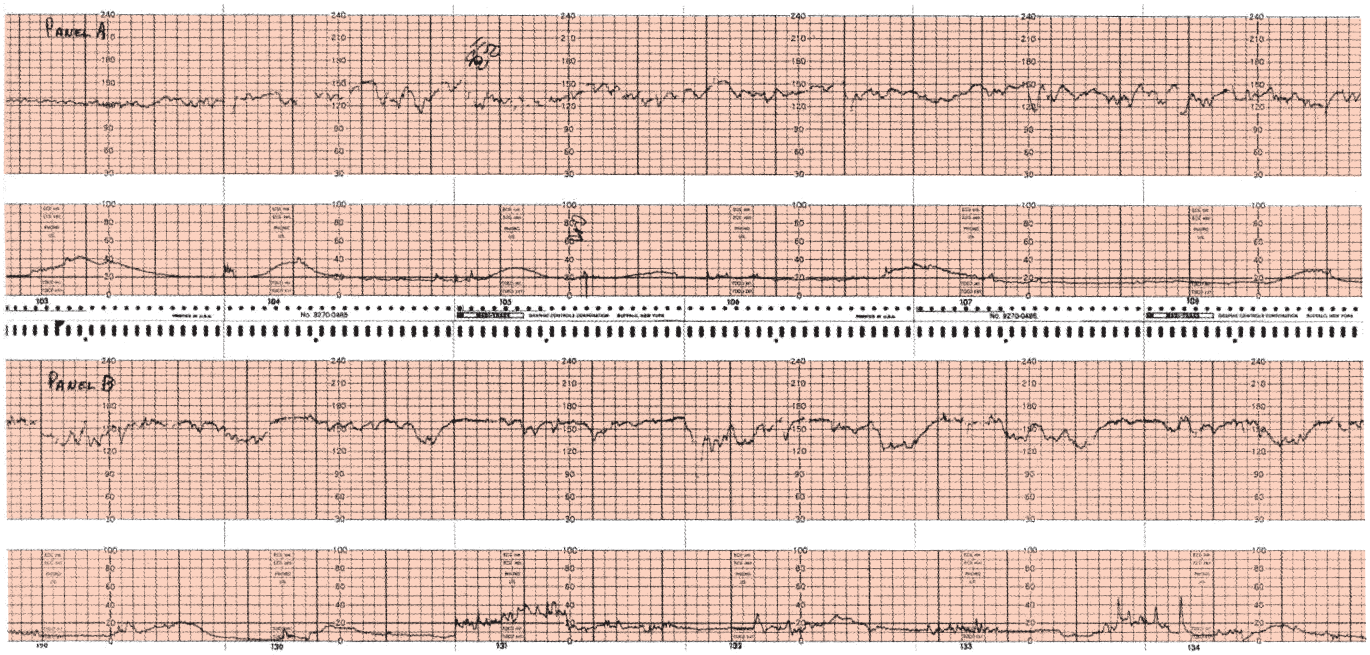

FIGURE 16-26. This figure shows prolonged and repetitive accelerations, especially in the lower panel. Accelerations that are sustained or confluent can be easily confused with a tachycardia, and the return to baseline can be confused with decelerations.

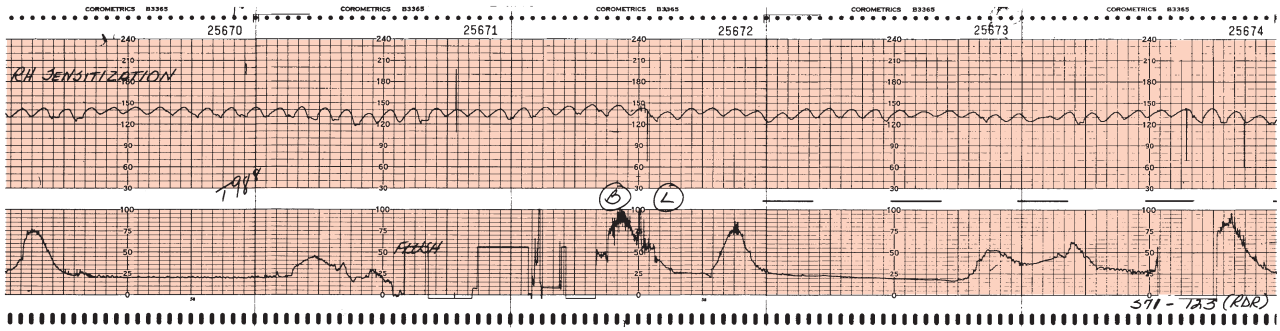

FIGURE 16-27. The sinusoidal heart rate pattern with its even undulations is demonstrated. Internal monitoring shows the absence of beat-to-beat variability characteristic of true sinusoidal patterns.

baseline change because sustained accelerations, which are consistent with a well-oxygenated, vigorous fetus, can be confused visually with fetal tachycardia, and the return of the FHR to the original baseline can be confused with decelerations.

The presence of accelerations has virtually the same meaning as normal FHR variability, but the absence of accelerations means only that the baby is not moving. Because accelerations can be quantified in beats per minute above the baseline and duration, their presence is less subjective than quantifying FHR variability. Clark and coworkers made the observation that in fetuses having otherwise non-reassuring FHR patterns, the presence of accelerations virtually always ruled out a pH less than 7.20 on scalp sampling.[33] Subsequently, these authors and others have confirmed that the presence of spontaneous accelerations or accelerations induced by stimulation of the fetal scalp or acoustic stimulation with a vibroacoustic stimulator has the same reliability.[34,35] If there is no acceleration in the face of an otherwise concerning (category II) FHR, most studies have shown that about 50% of these fetuses have an acidotic pH value on scalp sampling. However, the absence of accelerations in a fetus with a category I or otherwise reassuring pattern rarely indicates fetal acidosis.

Sinusoidal Patterns

This pattern was originally described by Kubli and colleagues in 1972[36] and Shenker in 1973[37] and is rare, but significant. This pattern is strongly associated with fetal hypoxia, most often seen in the presence of severe fetal anemia. Using strict criteria for this pattern, defined by Modanlou and associates, there will be a high correlation with significant fetal acidosis and/or severe anemia.[38] These criteria for identifying a sinusoidal FHR include (1) a stable baseline FHR of 120 to 160 beats/minute with regular sine wave–like oscillations, (2) an amplitude of 5 to 15 beats/minute, (3) a frequency of 2 to 5 cycles/minute, (4) fixed or absent short-term variability, (5) oscillation of the sine wave above and below the baseline, and (6) absence of accelerations (Figure 16-27). **The NICHD has defined the sinusoidal pattern more simply as one "having**

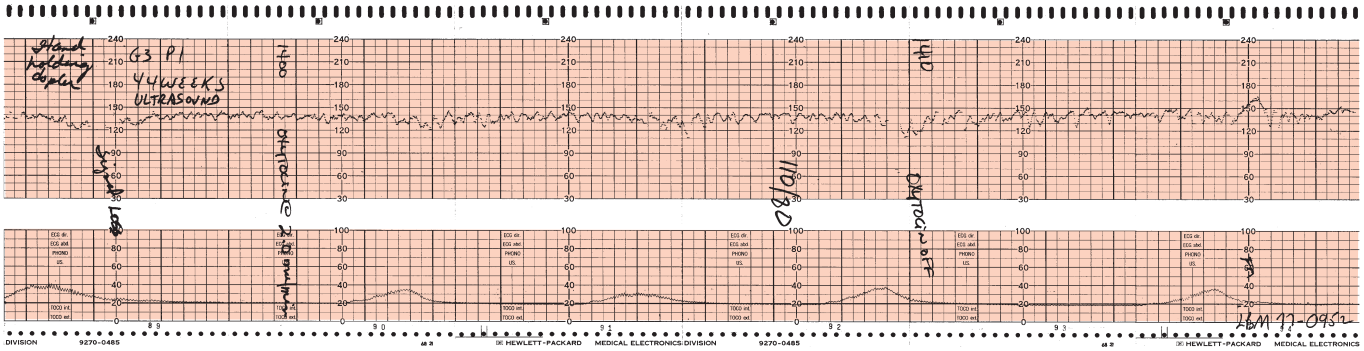

FIGURE 16-28. More common than sinusoidal tracings are those that are actually normal but can easily be confused with a sinusoidal pattern. There are often small accelerations or above-average variability that mimics the sine wave–like pattern. It is important to use the strict criteria defined in the text before interpreting a pattern as sinusoidal.

a visually apparent, smooth, sine wave-like undulating pattern in FHR baseline with a cycle frequency of 3-5 per minute lasting for 20 minutes or more." The pathophysiology of the sinusoidal pattern has been elucidated by Murata and colleagues, who correlated the pattern with levels of fetal arginine vasopressin and subsequently reproduced the pattern with vagotomy and injection of arginine vasopressin.[39] Arginine vasopressin is elevated with hemorrhage or acidosis, and it appears that in such situations with a severely compromised fetus and little vagal activity, the hormone directly affects the fetal heart, and this FHR pattern results. The sinusoidal pattern has also been described after injection of certain narcotics such as butorphanol (Stadol)[40] and meperidine (Demerol).[41] Unfortunately, there are relatively commonly seen FHR patterns that mimic sinusoidal patterns (pseudosinusoidal) and are associated with well-oxygenated and nonanemic fetuses.[38] These can easily be confused with sinusoidal FHR patterns (Figure 16-28); therefore, it is quite important to strictly apply all six criteria before calling a pattern sinusoidal.

Additional Terminology from the NICHD Workshop

In addition to those definitions provided previously, there are some additional points made in the accepted terminology for FHR patterns that are important to include.[17] When describing decelerations, they are termed *recurrent* if they occur with 50% or more of contractions and *intermittent* if they occur with less than 50% of contractions in any 20-minute segment of the tracing.

Uterine contractions are quantified as the number of contractions present in a 10-minute window averaged over 30 minutes. Normal contraction frequency is five or fewer per 10 minutes, and tachysystole is six or more. The Workshop advised abandonment of the terms *hyperstimulation* and *hypercontractility*.

TABLE 16-1 THREE-TIERED FETAL HEART RATE INTERPRETATION SYSTEM

Category I

Category I fetal heart rate (FHR) tracings include all the following:

- Baseline rate: 110-160 beats/min
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent

Category II

Category II FHR tracings include all FHR tracings not categorized as category I or category III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples of category II FHR tracings include any of the following:

Baseline Rate

- Bradycardia not accompanied by absent baseline variability
- Tachycardia

Baseline FHR Variability

- Minimal baseline variability
- Absent baseline variability not accompanied by recurrent decelerations
- Marked baseline variability

Accelerations

- Absence of induced accelerations after fetal stimulation

Periodic or Episodic Decelerations

- Recurrent variable decelerations accompanied by minimal or moderate baseline variability
- Prolonged deceleration: >2 minutes but <10 minutes
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics, such as slow return to baseline, "overshoots," or "shoulders"

Category III

Category III FHR tracings include either:

- Absent baseline FHR variability and any of the following:
  - Recurrent late decelerations
  - Recurrent variable decelerations
  - Bradycardia
  - Sinusoidal pattern

Evolution of Fetal Heart Rate Patterns

One of the sources of greatest confusion regarding FHR pattern interpretation and management is that the patterns have very poor specificity in terms of predicting fetal hypoxia and acidosis, newborn depression, or need for resuscitation (Table 16-1). **When patterns are normal or "reassuring"** (category I), there is almost always normal oxygenation, and the baby is born vigorous, with normal pH and Apgar scores. However, when the pattern is non-reassuring (category II), the baby is more often normal than depressed or acidotic.

In addition to the inherent problem we have in trying to use EFM, a nonspecific modality, to determine fetal oxygenation, there is another reason why many studies have demonstrated such poor correlation with adverse

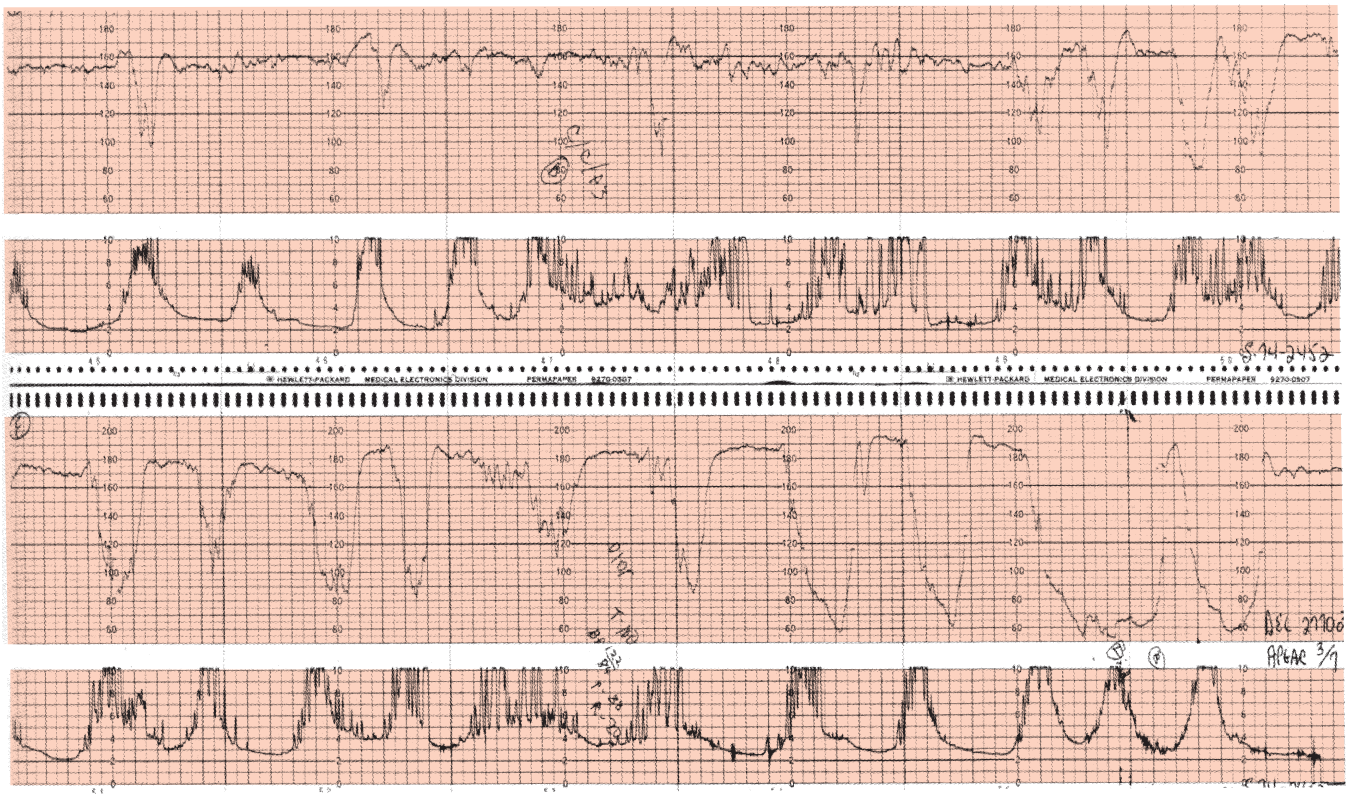

FIGURE 16-29. Loss of variability and tachycardia should only be interpreted as indicative of hypoxia and developing acidosis when they are associated with decelerations that suggest progressive hypoxia as with these variable decelerations, which are becoming deeper and more prolonged.

perinatal outcome. Investigators have tried to correlate specific FHR findings in isolation without taking into account the expected evolution of the FHR patterns.[19,30] For example, if one attempts to correlate FHR variability with acidosis or depression, normal variability will correlate well with a normal pH and normal Apgar scores, but reduced or absent variability will correlate poorly with acidosis or depression. This is partly because of the multiple causes of reduced variability. However, in the fetus with persistent late decelerations who then loses FHR variability, the correlation with acidosis and depression should improve substantially because there was evidence that *hypoxia led to the acidosis*. This is a critical concept in understanding FHR monitoring. Murata and coworkers demonstrated that, in the fetal monkey whose oxygenation was progressively reduced, late decelerations consistently *preceded* the loss of variability and accelerations.[42] **Decelerations are the indicators of hypoxia. If hypoxia is the cause of the reduced variability, then those decelerations indicative of hypoxia should *precede* the development of tachycardia, loss of variability, or disappearance of accelerations** (Figure 16-29). Furthermore, the duration and appearance of the decelerations should be of sufficient magnitude to suggest that CNS depression could have resulted.

Therefore, the fetus who develops one of the latter variables (e.g., loss of accelerations) in the absence of decelerations is not likely to have hypoxia and another cause should be considered (e.g., drugs, sleep cycle). It must be remembered that when the fetus demonstrates one of these baseline changes or absence of accelerations on admission, it is not possible to know whether evidence of hypoxia preceded these changes. In addition, this approach does not apply antepartum, when the nonstress test is used. Contractions are not present, and there will not be an opportunity to assess for the presence or absence of decelerations in response to contractions.

MANAGEMENT OF NON-REASSURING FETAL HEART RATE PATTERNS

Traditionally, a FHR pattern that suggested fetal hypoxia would be called fetal distress if it was sufficiently concerning to warrant immediate operative intervention. But, as previously mentioned, in most cases, when a cesarean or forceps delivery was done for "fetal distress," the fetus was delivered without evidence of significant hypoxia or acidosis. This has led to the recommendation from the ACOG to use the term *NRFS*[13] and subsequently to the *three-tiered system*. This is also descriptive of the approach to the management of the fetus with concerning FHR patterns. That is, when the FHR pattern is suggestive of hypoxia, and therefore non-reassuring, other means of reassurance should be used when possible.

Interventions for Non-reassuring Fetal Status

The ideal intervention for fetal hypoxia is a cause-specific, noninvasive one that permanently reverses the problem. Although not always possible, this should certainly be the goal. Obviously, the first step in achieving this goal is to

recognize the cause of the abnormal FHR pattern. A thorough knowledge of the pathophysiology of FHR changes, coupled with a careful clinical patient evaluation and a knowledge of common causes of specific FHR changes, will maximize the opportunity for this goal to succeed. In addition to cause-specific types of interventions, virtually all cases of hypoxia should theoretically also benefit by more generic interventions that have the potential to maximize oxygen delivery and placental exchange.

Nonsurgical Interventions

Oxygen Administration

One of the most obvious ways to maximize oxygen delivery to the fetus is to give additional oxygen to the mother. Whereas diffusion across a membrane is driven by P_{O_2} as opposed to oxygen content, and whereas maternal P_{O_2} can be raised substantially with mask O_2, it is not well established that fetal P_{O_2} is raised substantially by routine maternal oxygen administration. In the classic study by Khazin, Hon, and Hehre,[43] late decelerations were alleviated within a few minutes by administration of oxygen to the mother. Later studies showed beneficial effects with decreased FHR variability and tachycardia.[44,45] In 2003, Fawole and Hofmer[46] reviewed the available studies for the *Cochrane Database of Systematic Reviews* and concluded that there was not sufficient evidence that maternal oxygen administration improved fetal oxygenation and that maternal oxygen administration could not be supported at the time. Recent evidence, from fetuses being monitored with pulse oximetry, demonstrated that fetal oxygen did increase significantly in patients with both a regular face mask and even more so with a non-rebreathing face mask and that fetuses with the lower initial oxygen saturation increased the most.[47,48] Simpson and James[49] found similar results with oxygen administration, showing a 15% increase with normal baseline oxygen saturations and a 26% increase with a baseline oxygen saturation of less than 40%. These studies are physiologically plausible because the larger the difference in oxygen tension between the mother and the fetus, the larger the effect that would be expected to be seen in the fetal oxygen tension and saturation. **Routine oxygen administration by face mask has become such standard practice with non-reassuring FHR patterns that it is difficult to recommend otherwise until further studies are available to substantiate or refute current knowledge.**

Lateral Positioning

Ideally, all patients should labor in the lateral recumbent position, at least from the standpoint of maximizing uterine perfusion. The reasons for this are, at least theoretically, twofold: (1) in being inactive and recumbent, the body is required to deliver the least amount of blood flow to other muscles; and (2) in the lateral position, there is no compression by the uterus on the vena cava or aorta, thus maximizing cardiac return and cardiac output. Several studies have confirmed the beneficial effects of lateral maternal positioning.[50,51] In the study by Simpson and James,[49] patients were randomized to six positions, and fetal oxygen saturation was highest in both right and left lateral recumbent positions compared with the supine position by an average of 29%.

Hydration

Most patients in labor are either restricted or prohibited from taking oral fluids for fear of requiring an urgent operative delivery in the presence of a full stomach. If not fluid restricted, individuals involved in sustained exercise, and possibly by inference in active labor, do not voluntarily ingest adequate amounts of fluid because of a phenomenon called *autodehydration*.[52] In addition, recent evidence would suggest that the usual amount of intravenous fluid of 125 mL/hour is a gross underestimate of the replacement required in labor.[53] Thus, by increasing fluid administration, there is the potential to maximize intravascular volume and thus uterine perfusion.

Oxytocin

In a patient with a non-reassuring pattern, the more time there is between contractions, the more time there is to maximally perfuse the placenta and deliver oxygen. **In patients receiving oxytocin, there is potential to improve oxygenation by decreasing or discontinuing oxytocin.** Often, however, this becomes a difficult situation because many patients will stop progressing in labor in terms of continued dilation and descent if the oxytocin is discontinued. It is often necessary to restart the oxytocin, and this may be appropriate, especially if there are accelerations or other means to document the absence of acidosis. Written documentation explaining the necessity and appropriateness of continuing oxytocin in this situation is especially important. The situation with patients who develop persistently non-reassuring patterns, especially with loss of accelerations or absence of other reassurance, and who require discontinuation of oxytocin, but then fail to progress because adequate contractions cannot be sustained, is often referred to as *fetal intolerance to labor*; although this is not an endorsed term in the newer terminology.

Tocolytics

There are numerous references in the obstetrical literature to the use of tocolytics to maximize oxygen delivery, by essentially the same mechanism described in the earlier paragraph on discontinuing oxytocin.[54-57] Tocolytics are appropriate when patients are having spontaneous excessive contractions leading to non-reassuring FHR patterns, especially prolonged decelerations (Figure 16-30). Different tocolytics have been described, but the most commonly used one, and perhaps the one that provides the most rapid response, is subcutaneous terbutaline, 0.25 mg. Tocolytics have also been used for intrauterine resuscitation after the decision is made to perform an operative delivery while waiting for preparations to be made. Subcutaneous terbutaline in this latter setting has been demonstrated to improve Apgar scores and cord pH values without apparent complications such as postpartum hemorrhage.[58]

Amnioinfusion

In situations in which variable decelerations appear to be caused by oligohydramnios, reestablishing intrauterine fluid volume by a process called *amnioinfusion* has been demonstrated in numerous randomized studies to ameliorate the variable decelerations, improve Apgar scores and

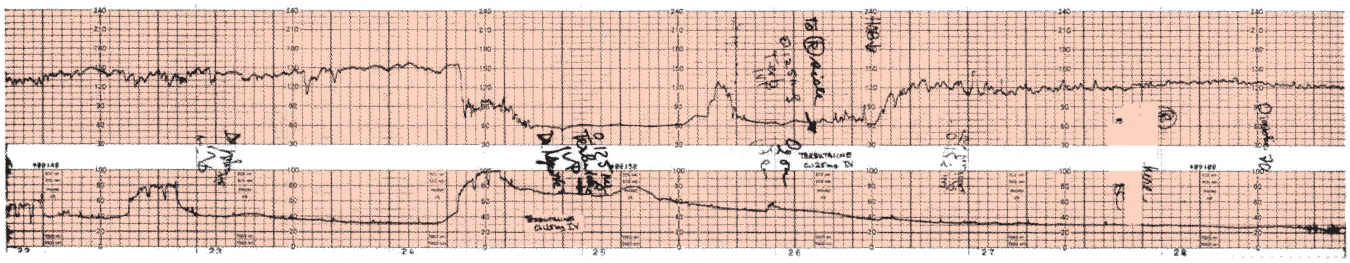

FIGURE 16-30. This prolonged deceleration in a patient with a spontaneous prolonged contraction is treated with subcutaneous terbutaline with apparent resolution of both the contraction and the deceleration.

cord pH values, and even reduce the need for cesarean delivery for NRFS.[59-61] Reference to this idea can be found as far back as 1925,[62] but it was rediscovered and proposed by Miyazaki and Taylor in 1983.[63] Intrauterine pressure catheters are now made with a port that allows the simultaneous administration of saline to accomplish this goal. Thus, in the patient with variable decelerations that suggest progression to more non-reassuring types, and in whom the likely cause is oligohydramnios, the implementation of amnioinfusion is warranted. What has not yet been established is whether in some situations amnioinfusion should be started prophylactically when there is an unusually high risk for the development of variable decelerations from oligohydramnios, such as preterm premature rupture of membranes (PROM).

Theoretically, using amnioinfusion before the onset of the decelerations in certain fetuses, such as very premature ones or those with intrauterine growth restriction that will progress to acidosis and depression much more rapidly with cord compression, will prevent the rapid evolution of hypoxia and acidosis. No studies are available as of yet to compare therapeutic and prophylactic amnioinfusion. Amnioinfusion also has been proposed, in several prospective randomized trials, to be used to avoid the fetal and neonatal pulmonary problems in the presence of meconium.[64] The theory behind this use of amnioinfusion is that (1) it dilutes the meconium by increasing fluid volume, and (2) by avoiding fetal gasping, which can occur with significant hypoxic episodes (i.e., sustained cord compression), the likelihood of meconium aspiration before delivery is reduced. Although initial studies of the benefits of amnioinfusion in the setting of meconium were promising and for a time its use for this indication gained widespread implementation,[65] recent studies have been less supportive. A review of this subject for the Cochrane database[66] including 13 studies of more than 4000 women concluded there was no reduction in meconium aspiration, perinatal death, or severe morbidity, except in an unexplained subgroup of studies done in populations in which "limited peripartum surveillance" was available.

MECONIUM

The presence of meconium is an extremely confusing issue when evaluating the fetus in labor. The quandary arises from the fact that although a hypoxic insult eliciting a significant vagal response from the fetus often results in the passage of meconium from the fetal gut, passage of meconium can also occur in the absence of any significant or sustained hypoxia. Meconium is not only a potential sign of fetal hypoxia but is also a potential toxin if the fetus aspirates this particulate matter with a gasping breath in utero or when it takes its first breaths following birth. **The thickness of the meconium is also a reflection of the amount of amniotic fluid, and thick meconium virtually always reflects some degree of oligohydramnios.** Thus, there may be a vicious cycle in such a situation. Oligohydramnios often leads to cord compression; the vagal response to cord compression may also lead to further passage of meconium, but also when sustained or prolonged, it may lead to fetal gasping, increasing the likelihood that meconium aspiration can occur before birth. Furthermore, because oligohydramnios may be an indicator of failing placental function, meconium may also indicate that the fetus is at risk for placental insufficiency. **In general, meconium should alert the clinician to the potential for oligohydramnios, umbilical cord compression, placental insufficiency, and meconium aspiration.** Fortunately, a reassuring FHR tracing is generally reliable, and patients with meconium can be managed expectantly. But in the presence of meconium, especially thick meconium, the risk factors associated with meconium should be entered in the equation when managing relatively non-reassuring patterns, as should all clinical variables.

Alternatives for Evaluating the Fetus with a Non-reassuring Fetal Heart Rate Pattern

In the fetus with a persistently non-reassuring FHR pattern, when nonsurgical efforts at reversing or improving the pattern fail, the next step is to attempt to find out whether the hypoxia has progressed to metabolic acidosis.

FETAL SCALP pH

Determination of fetal scalp pH is historically the oldest and most well-tested method for determining whether the fetus is acidotic. Technically, a plastic cone is inserted transvaginally against the fetal vertex. The cervix needs to be at least 4 to 5 cm dilated and the vertex at a –1 station or below to accomplish this. Mineral oil or another lubricant is applied to the scalp so that blood will bead, and then using a lancet, the scalp is pricked and blood is then collected in a long capillary tube (Figure 16-31). The tube will hold about 100 µL of blood, and about 30 µL is needed to perform a pH test alone and 70 µL to determine P_{CO_2} as well. To determine whether an acidosis is metabolic or respiratory, the P_{CO_2} is needed. This is an important distinction because the question being asked is whether there

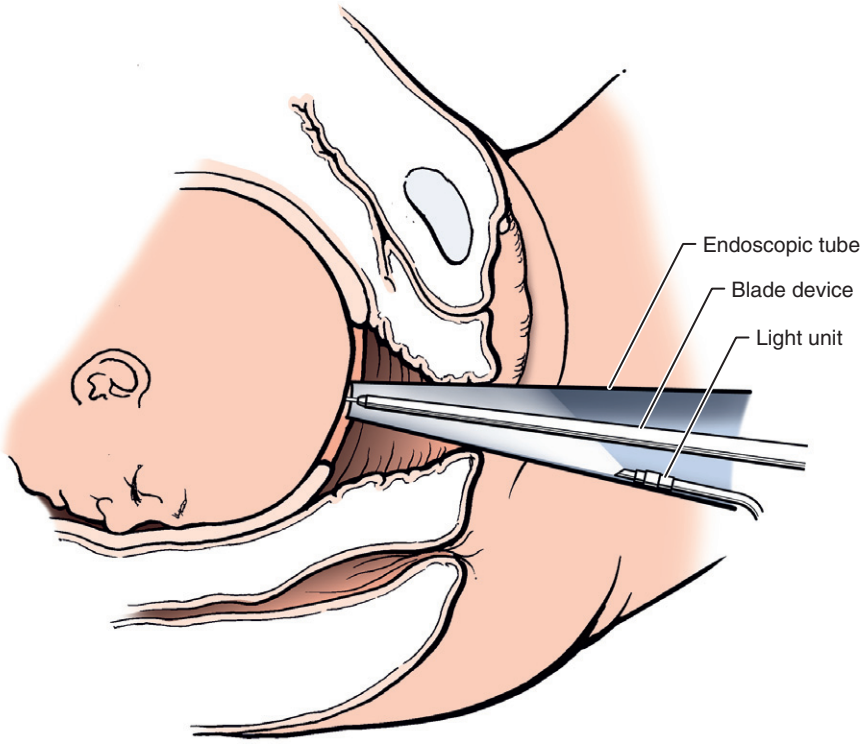

FIGURE 16-31. Technique of fetal scalp blood sampling.

has been sufficient hypoxia to lead to metabolic acidosis. Respiratory acidosis is far less concerning, but without determining PCO_2, this cannot be sorted out. Unfortunately, it is difficult to obtain enough blood for both pH and PCO_2 in most instances. PCO_2 determination is especially important when doing scalp pH for variable decelerations because most acidosis is respiratory in this situation. **A scalp pH less than 7.20 is consistent with fetal acidosis and a pH of 7.20 to 7.25 is borderline and should be repeated immediately.** A reassuring value higher than 7.25 must be repeated every 20 to 30 minutes as long as the pattern persists, and the fetus is not acidotic. In practice, because this technique is cumbersome, fraught with technical inaccuracy, uncomfortable for the patient, and with the requirement to perform repeated samples, scalp pH assessment is used very infrequently.[67] Even in large teaching services accustomed to using this technique, its abandonment, coupled with an appreciation for the utility of accelerations for predicting presence or absence of acidosis, does not appreciably increase the need for operative intervention.[68]

Accelerations and Variability

In the fetus with a non-reassuring pattern, spontaneous accelerations have the same significance as those elicited by scalp or acoustic stimulation. **Thus, any acceleration—spontaneous or induced—indicates the absence of acidosis.** It should be emphasized that the absence of accelerations as well when there is an absence of decelerations or other patterns suggesting hypoxia should not elicit concern. The fetus is often not moving in labor; and from a pathophysiologic perspective, without evidence of hypoxia, the fetus cannot develop a metabolic acidosis. Thus, the application of the interpretation of accelerations should generally be restricted to the fetus with an otherwise non-reassuring FHR pattern, when the question is being asked: Hypoxia is present. Is the fetus now developing a metabolic acidosis? Although moderate variability similarly can also be used to rule out the acidotic fetus, the problem with this choice is that interpretation of variability is not nearly as reliable as it is with accelerations. And although one can reliably wait on a pattern with non-reassuring decelerations such as recurrent late or recurrent severe variable decelerations based on moderate variability alone, one should be sure that there is no question that the FHR variability is at least moderate and that there is consistent agreement of this among the clinicians providing care to the patient.

Fetal Pulse Oximetry

One of the most potentially exciting yet currently disappointing developments in obstetrics was the introduction of fetal pulse oximetry. Because FHR monitoring is specifically intended to monitor fetal oxygenation and because this modality is so nonspecific, it stands to reason that what we should be using ideally is a device that directly monitors fetal oxygenation, pH, or both. Since the mid-1980s, the use of pulse oximetry has revolutionized monitoring of "air-breathing" adults, children, and neonates. Animal studies of this technology validated its accuracy.[69,70] Fetal pulse oximetry when first introduced was approved by the U.S. Food and Drug Administration (FDA) for clinical use. Its value for more accurately assessing fetal oxygenation in labor was promising in initial studies,[71] but not supported in later investigations[72] and ultimately not endorsed by ACOG. As a result, the manufacturer removed the product from the market, and it is no longer in use.

ST Analysis, the STAN Technology

One other promising new technology for improving interpretation of non-reassuring, especially category II, tracings is the introduction of fetal ECG waveform analysis using computerized algorithms detecting changes in the ST waveform which are indicative of fetal metabolic acidosis. Trials in Europe, including several randomized controlled trials usually coupled with scalp pH monitoring, have generally shown a reduction in operative deliveries for concerning FHR patterns and a reduction in the incidence of fetal acidosis.[73-75] An ongoing trial of this technology in the United States by the NICHD Maternal-Fetal Medicine Units Network is currently underway.

Computerized Interpretation of Fetal Heart Rate Patterns

One of the problems with FHR monitoring has been the dismal record of agreement on interpretation of FHR patterns. Intraobserver and interobserver comparisons of interpretation usually achieves only about 30% to 70% agreement.[76] The idea of computer interpretation of FHR patterns has been a goal attempted by many over the history of EFM. Recently, the first FDA-approved EFM computer-based interpretation system has come onto the market. Termed the *PeriCALM EFM system*, this product shows promise in accuracy of assessing which tracings are and are not associated with metabolic acidosis[77] and compares favorably with the agreement of interpretation of FHR patterns with expert interpreters.[78]

Operative Intervention for Non-reassuring Fetal Status

When the fetus is determined to have a persistently non-reassuring FHR pattern and backup methods (e.g., scalp pH, moderate variability, accelerations, ST waveform analysis) cannot provide reassurance that the fetus is not acidotic, operative intervention is indicated to expeditiously deliver the baby to avoid further deterioration. Because the interpretation of FHR patterns has been so inconsistent and the predictability of most non-reassuring patterns has been so poor, the NICHD convened a second Workshop on the Intrapartum Interpretation of EFM.[14] Their proposal, which has since been accepted by ACOG and AWHONN and many hospitals throughout the country, is that FHR patterns be divided into three categories (see Table 16-1). **Category I is strongly predictive of the absence of hypoxia and normal fetal acid-base status, and these patterns require no intervention. Category III patterns are predictive of a fetal metabolic acidosis and require "prompt evaluation."** Moreover, it can easily be stated that if measures at improving category III patterns, such as position change, oxygen administration, fluid boluses, and discontinuing oxytocin, do not improve the pattern, immediate operative delivery is warranted. **Category II includes more than 80% of FHR patterns seen in labor[79] and is said by the Workshop to "require evaluation and continued surveillance and reevaluation taking into account the entire clinical circumstances."** However, there are some substantial limitations of this new system for most patterns in category II. As Parer points out in his editorial on the limitations of this three-tiered system,[79] category II contains a mixture of patterns, some of which are well established to have no association with hypoxia or acidosis (e.g., mild or moderate variable decelerations with moderate variability) and others that have a high association with, or if left unchanged are likely to develop into, a fetus with hypoxia and acidosis (e.g., persistent late decelerations with minimal variability). Furthermore the Workshop recommendations and those adopted by ACOG give us little guidance on management of these FHR patterns in category II beyond "continued surveillance and reevaluation." Therefore, the following issues are raised and suggestions are made in an effort to provide more clearcut guidance on management of FHR patterns, acknowledging fully that the evidence to support these statements may be limited and that other experts may approach these situations differently.

Several questions arise when the decision has been made for intervention for delivery for a concerning FHR pattern. What is the best choice, operative vaginal or cesarean delivery? How much time do we have to perform the delivery? What anesthetic should be used? What is the prognosis of the baby? And, finally, are there situations in which the baby is already damaged or otherwise not likely to benefit from this intervention?

Choosing operative vaginal over cesarean delivery is not difficult if the patient is in early labor. For the patient near or at complete dilation, this becomes a question of judgment. Which route is more likely to create the more rapid delivery while at the same time result in the least complications for mother and baby? When the clinician is unsure whether an attempt at operative vaginal delivery will succeed, the question is even more difficult. This decision will depend not only on the variables that predict success for an operative vaginal delivery (e.g., station, clinical pelvimetry, size of the baby, skill of the clinician), but also on the severity of the FHR pattern and whether there is time to find out whether an operative delivery will succeed. The time for intervention also is a question of judgment. Except for the situation of a prolonged deceleration to less than 70 beats/minute with loss of variability that will not recover and requires the most rapid intervention safely possible, most other situations require judgment and integration of the entire clinical picture of mother and baby.

The question of how much time is available to perform an operative intervention in the face of a non-reassuring FHR pattern is a complex one, muddied not only by the unpredictability of the non-reassuring pattern but also by the medicolegal pressures that have arisen as a result of EFM. **The ACOG recommends that "all hospitals have the capability of performing a cesarean delivery within 30 minutes of the decision to operate,"[80] but that "not all indications for a cesarean delivery will require a 30-minute response time."** The examples given that mandate an expeditious delivery include hemorrhage from placenta previa, abruptio placentae, prolapse of the umbilical cord, and ruptured uterus. In some situations (e.g., sustained prolonged deceleration to <70 beats/minute with loss of variability), 30 minutes may be too long to avoid damage; in others, this may be too restrictive and may result in suboptimal anesthetic choices and compromised preoperative preparation. Thus, a judgment made on the basis of

the severity of the FHR pattern and the overall clinical status of mother and baby must be integrated into this difficult decision.

MANAGEMENT OF NON-REASSURING FETAL HEART RATE PATTERNS: A PROPOSED PROTOCOL

The following algorithm for management of non-reassuring (categories II and III) FHR patterns is proposed:

1. When the pattern suggests the beginning development of hypoxia or is already non-reassuring:
   a. Identify, when possible, the cause of the problem (e.g., hypotension from an epidural).
   b. Correct the cause when possible (e.g., fluids and ephedrine to correct the hypotension).
   c. Give measures to maximize placental oxygen delivery and exchange: oxygen by face mask, lateral positioning, hydration, consider decreasing or discontinuing oxytocin.
2. If the pattern becomes or remains non-reassuring and the above measures have been completed:
   a. Attempt to provide other measures to rule out metabolic acidosis.
      - Accelerations—spontaneous or elicited
      - Moderate variability
      - Scalp pH (if used)
   b. If reassurance using one of the above methods can be provided, and the pattern persists, continuous or intermittent (every 30 minutes) evidence of absence of acidosis must be ascertained.
   c. If reassurance of the absence of acidosis cannot be provided, deliver expeditiously by the safest and most reasonable means (operative vaginal or cesarean delivery).

Category II patterns that qualify as non-reassuring and cannot be corrected and therefore warrant evidence of the absence of metabolic acidosis include the following:

1. Recurrent late decelerations (≥50% of contractions)
2. Non-reassuring variable decelerations
   a. Progressively severe in depth and duration
   b. With developing tachycardia and loss of variability
3. Recurrent prolonged decelerations
4. The confusing pattern
   a. A pattern of absent variability but without explanatory decelerations at the time of initiating monitoring
   b. An unusual pattern that does not fit into one of the categories defined previously but does not have elements of a reassuring pattern.

Several of the previous presentations and others warrant additional discussion. Prolonged decelerations proceeding to bradycardia that will not return to baseline are a potentially ominous situation. Causes of these patterns include virtually any substantial insult that can cause severe hypoxia, especially when the FHR goes below 80 beats/minute. Examples include abruptio placentae, ruptured uterus, cord prolapse or sustained cord compression, profound hypotension, maternal seizure or respiratory arrest, and rapid descent and impending delivery of the fetus. Generally, the following approach to these bradycardias should be taken. First, be patient. Often these are noticed on the central monitor, and caregivers unnecessarily run to the room and frighten the patient and family. Because most of these decelerations will spontaneously resolve in 1 to 3 minutes, such action is usually unwarranted. If the deceleration does not resolve, the patient should be examined to rule out cord prolapse and sudden descent. If these are not present, determine whether there is an apparent cause that can be specifically corrected. If the cause cannot be found, the general explanation by process of elimination is sustained cord compression, and repositioning the patient, oxygen administration, and discontinuing oxytocin are done. Should none of these work, operative delivery will be required unless spontaneous delivery is imminent. How long one should wait for the corrective measures or spontaneous recovery to occur is somewhat variable. This will be determined by the depth of the deceleration, the loss of variability during the deceleration, whether evidence of hypoxia preceded the deceleration, and whether the heart rate is intermittently returning toward baseline or is just staying down. Evidence to recommend a precise amount of time wherein intervention must occur is difficult to integrate because the problem is usually relative hypoxia rather than complete anoxia. Complete anoxia in real life probably occurs only with severe degrees of uterine rupture and complete abruption. Even with cord prolapse there is usually some cord blood flow. Windle performed the classic experiment using complete anoxia in fetal monkeys.[81] Monkeys allowed to breathe in 6 minutes or less showed no clinical or pathologic ill effects. Asphyxiation for 7 to 12 minutes resulted in transient motor and behavioral changes, with some scarring in certain specific areas of the brain in some animals. Those anoxic for 12 to 17 minutes, if death did not occur, had the most severe neurologic and clinical effects. Therefore, in the worst case of all, if delivery occurs in less than 12 minutes from the onset of the deceleration, damage will be unlikely, unless there was some hypoxia before the deceleration.

The most difficult pattern to manage is recurrent prolonged decelerations with or without bradycardia that do recover (Figure 16-32). Generally, these can be managed using the same algorithm for non-reassuring patterns described previously. However, even if one can provide reassurance that acidosis does not exist following any of the decelerations, there is a concern that this pattern portends a deceleration that will recur and will not recover, and one will be placed in the situation described in the previous paragraph. Therefore, there will be occasions when the recurrent prolonged decelerations are concerning enough that operative intervention is warranted even if there is no concern about acidosis at the present moment. One must integrate the frequency, severity, and duration of the deceleration; the fetal response in terms of tachycardia and loss of variability; presence or absence of meconium, and how much time is expected before spontaneous delivery will occur to make this difficult decision. Therefore, for example, in the nulliparous patient at 4 cm, having decelerations lasting 4 minutes to 70 beats/minute every 10 minutes, operative delivery may be warranted. However, in the multipara at 8 cm making normal progress with similar or less frequent decelerations, it may be justified to manage these expectantly, but with all preparations

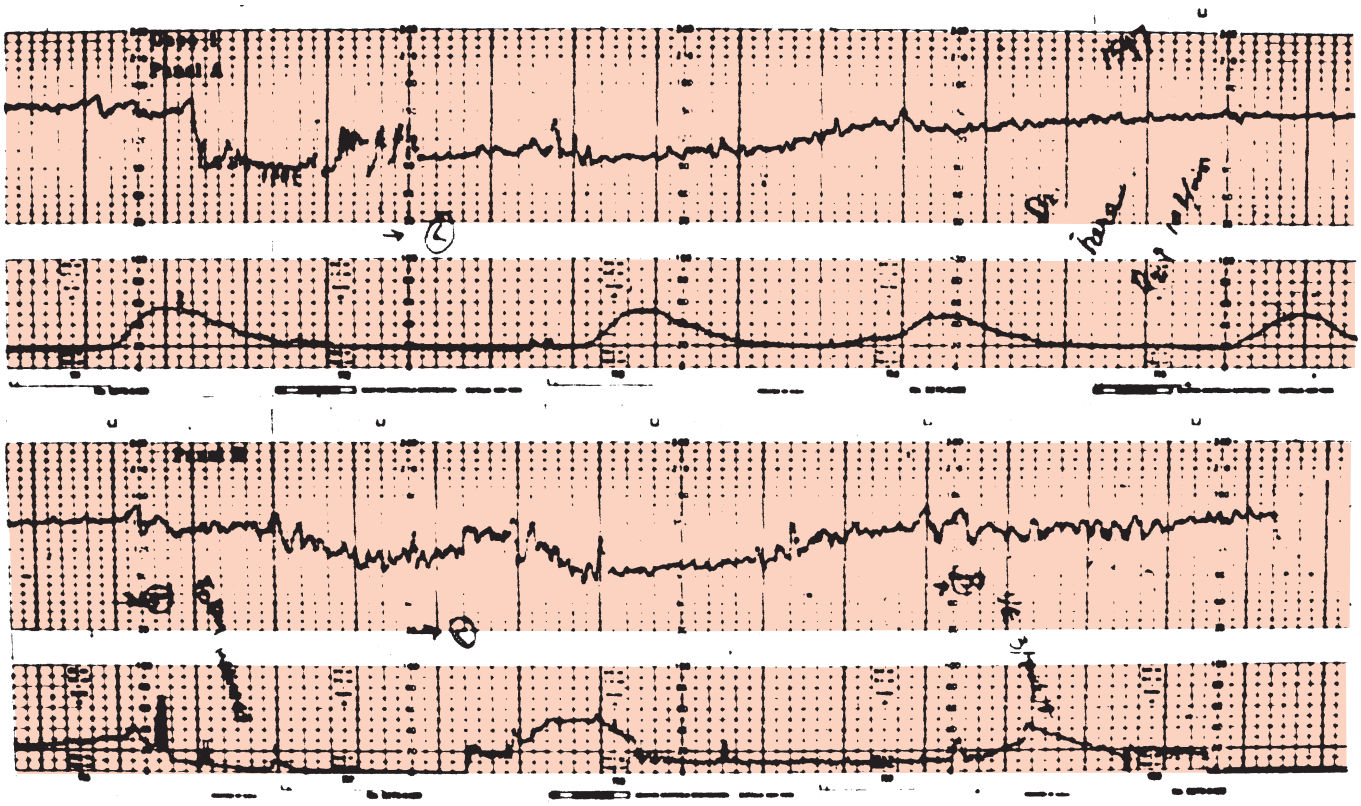

FIGURE 16-32. Recurrent unexplained prolonged decelerations.

made for immediate delivery should one of the decelerations not recover.

Auscultation as an Alternative

Almost all randomized controlled trials have demonstrated that intermittent auscultation is as effective as EFM in detecting fetal hypoxia in labor. There are some limitations to this statement, however. Virtually all these trials compared EFM to intermittent auscultation with one-on-one nursing, in which the auscultation was performed every 15 minutes in the first stage and every 5 minutes in the second stage, and the auscultation was performed for a period of 60 seconds through and following an entire uterine contraction. This is a situation that is difficult to duplicate in everyday practice because of lower nurse-to-patient ratios and because emergencies with other patients often take a nurse away from the bedside for long periods of time. Second, in most of the studies, fetuses who entered labor may have been monitored electronically before randomization, and often very-high-risk patients were excluded from study. Ingemarsson and associates have shown that 50% of patients who develop non-reassuring FHR patterns in labor had a non-reassuring FHR pattern on admission.[82] Finally, in virtually all the studies comparing EFM with auscultation, when the auscultated FHR was abnormal, the patient was then monitored electronically. Furthermore, there are non-reassuring FHR tracings that are quite indicative of hypoxia and acidosis and not likely to be detected with auscultation (Figure 16-33).

Therefore, it is reasonable to conclude that auscultation is an acceptable option for monitoring the fetus in labor when certain conditions are in place. The fetus should have a reassuring FHR on admission monitored electronically. The patient should have one-on-one nursing. The standards for frequency from the ACOG for auscultation are at least every 30 minutes in the first stage and every 15 minutes in the second stage for the low-risk patient and every 15 minutes in the first stage and every 5 minutes in the second stage for the high-risk patient.[83] Fetuses with abnormal FHR patterns on auscultation should have electronic monitoring to define the pattern and monitor for progression to worsening or non-reassuring patterns.

ASSESSMENT OF FETAL CONDITION AT BIRTH

The Apgar score was originally introduced as a tool to be used in guiding the need for neonatal resuscitation. Subsequently, this means of fetal assessment became used routinely for all births. However, the Apgar score has been expected to predict far more than was originally intended. Such expectations have included evaluating acid-base status at birth (i.e., the presence or absence of perinatal asphyxia) and even predicting long-term prognosis. **Unfortunately, the Apgar is a nonspecific measure of these parameters because many other causes of fetal depression may mimic that seen with asphyxia, such as drugs, anomalies, prematurity, suctioning for meconium, and so forth.** In situations in which FHR patterns have been concerning and other backup methods for evaluating fetal oxygenation or fetal acid-base status have been used, or in cases in which the baby is unexpectedly depressed, it is important to

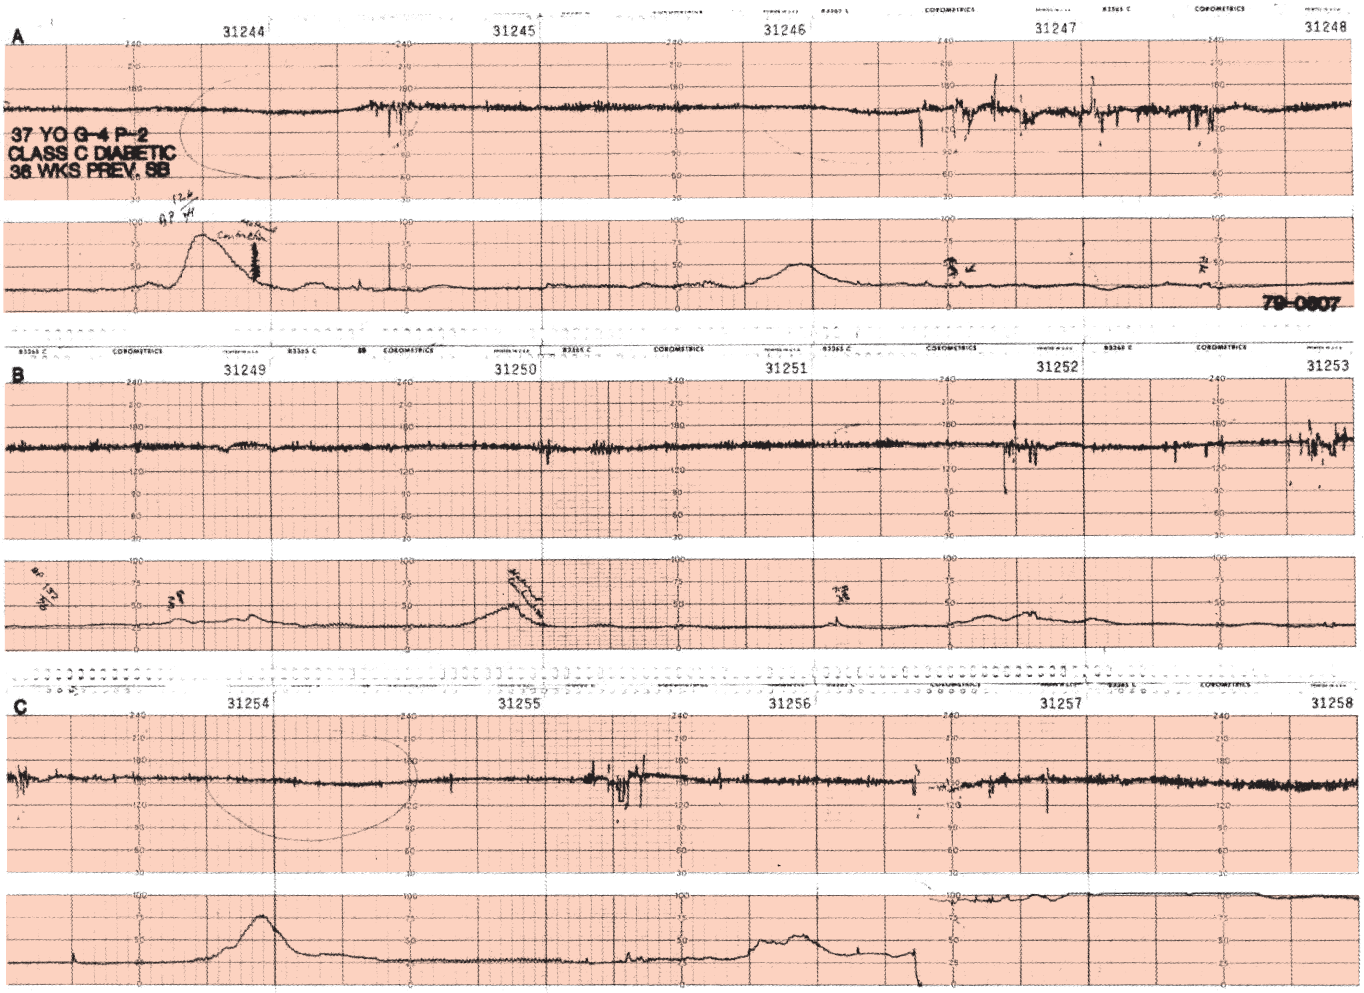

FIGURE 16-33. These persistent late decelerations associated with absent variability are difficult to recognize even with an internal electrode. This is a non-reassuring fetal heart rate pattern, which is often ominous. It is unlikely that such decelerations, associated with a normal baseline rate, would be recognized with intermittent auscultation.

specifically evaluate these parameters at birth, using umbilical cord blood gases. To accomplish this, a doubly clamped 10- to 30-cm section of umbilical cord is taken after the original cord clamping and separation of the baby from the cord. Using heparinized syringes, samples of umbilical artery and vein are separately obtained. These samples are evaluated for respiratory gases. Normal ranges for umbilical cord gases are shown in Table 16-2. Cord blood P_{O_2} or O_2 saturation is not useful because many normal newborns are initially hypoxemic until normal extrauterine respiration is established. Although cord pH, especially arterial, is the essential value, P_{CO_2} is also very important because if the pH is low, the P_{CO_2} is used to determine whether the acidosis is respiratory or metabolic. Respiratory acidosis is not predictive of newborn or long-term injury and should correlate with little or no need for resuscitation. In addition, the cord gases should be used to correlate interpretation of the FHR patterns, as previously described in the sections on their pathophysiology, and to determine the appropriateness of operative intervention or lack of it. These gases can help the pediatrician in determining the etiology of immediate complications and the need for more intense observation of the baby. In addition, these values are often

TABLE 16-2 NORMAL BLOOD GAS VALUES OF UMBILICAL ARTERY AND VEIN

	MEAN VALUE	NORMAL RANGE*
Artery		
pH	7.27	7.15 to 7.38
P_{CO_2}	50	–.35 to 70
Bicarbonate	–3.34	–.17 to 28
Base excess	–3.6	–2.0 to –9.0
Vein		
pH	7.34	7.20 to 7.41
P_{CO_2}	40	33 to 50
Bicarbonate	21	15 to 26
Base excess	–2.6	–1.0 to –8.0

Data from Nijland R, Jongsma HW, Nijhuis JG, et al: Arterial oxygen saturation in relation to metabolic acidosis in fetal lambs. Am J Obstet Gynecol 172:810-819, 1994.

*Values are ±2 SD and represent a composite of multiple studies.

useful if the baby develops any long-term neurologic injury in determining whether any such injury may have been related to peripartum asphyxia.[84] Studies have shown that if such asphyxia is present, in order for it to result in long-term injury, it must have been severe (metabolic acidosis

with a pH <7.00 to 7.05) and be associated with multiple organ dysfunction in the newborn period.[2]

RISKS AND BENEFITS OF ELECTRONIC FETAL HEART RATE MONITORING

Electronic FHR monitoring was introduced with the hope that this modality would reduce or eliminate the devastating consequences of asphyxia. Enthusiasm for this new technology established the role of continuous FHR monitoring in labor before studies demonstrated its accuracy. Initial retrospective studies evaluated more than 135,000 patients and showed more than a three-fold improvement in the intrapartum fetal death rate for patients monitored electronically.[1] However, most subsequent prospective, randomized, controlled trials have failed to demonstrate an improvement in the intrapartum fetal death rate using EFM.[85-91] In these studies, however, electronic FHR monitoring was compared with frequent intermittent auscultation with one-on-one nursing, a standard that is difficult to maintain. Many patients with abnormal FHR patterns on admission were not randomized, and virtually always, patients with an abnormal FHR on auscultation were ultimately monitored electronically. A randomized controlled trial of EFM versus intermittent auscultation conducted by Vintzileos and colleagues did demonstrate a significant improvement in perinatal mortality in the electronically monitored group.[92] The past three decades have not shown a change in the 2 per 1000 incidence of cerebral palsy, suggesting that the widespread use of EFM has not affected this problem. However, these data are somewhat difficult to analyze because of other changes occurring simultaneously. There has been a dramatic improvement in the survival of very-low-birthweight premature babies during this time period, and prematurity accounts for most cases of cerebral palsy. Second, term babies with asphyxia have had an increase in survival during this time period, allowing for a potential increase in surviving children with brain damage. Any of these factors may obscure an effect that FHR monitoring may have had in reducing the incidence of cerebral palsy. EFM has other potential benefits. These include an ability to understand the mechanism of developing hypoxia and to treat it more specifically. **It provides the ability to accurately monitor uterine contractions so that we can better understand progress or lack of progress in labor as well as monitor the effects of oxytocin-stimulated contractions on fetal oxygenation.** The monitor is ultimately, like all other monitors in intensive care situations, a labor-saving device that allows nurses to perform other tasks simultaneously.

EFM has several disadvantages, however. During the period in which FHR monitoring has risen in popularity, there was a parallel increase in the cesarean delivery rate. Certainly, this was not all caused by EFM because there were many other changes in obstetrical practice during this time period. In virtually all the randomized controlled trials, EFM resulted in an increase in the cesarean delivery rate over intermittent auscultation without a concomitant improvement in outcome.[85-89] There is also, however, a desire to deliver babies before significant hypoxia has any potential to damage the baby, and the nonspecific changes in FHR only fuel this concern, setting up the current environment of excessive intervention. **In reality, metabolic acidosis occurs in only about 2% of all labors, and even allowing for a reasonable amount of latitude in early intervention, cesarean delivery rates should not exceed 4% to 5% for this indication.** Unfortunately, rates of 10% for NRFS are common. Thus, the need for better, more specific modalities to allow us to evaluate hypoxia and acidosis in the fetus with a non-reassuring FHR pattern are still being sought. It was hoped that fetal pulse oximetry would meet this need, but that has not been realized.

The second major problem associated with EFM is the fear of a lawsuit should the child be compromised in any way. The monitor has created an expectation of perfect outcome. The interpretation of abnormal FHR tracings is highly subjective and variable, and "experts" often give diametrically opposite interpretations of the same tracing. The modality itself is nonspecific, and babies with anomalies or preexisting brain damage will often have abnormal FHR tracings easily confused with ongoing hypoxia. Finally, a jury cannot help but be sympathetic to a family and baby with disfiguring and debilitating cerebral palsy, and large financial awards seem to be the only way at present to compensate these unfortunate victims. However, these outcomes are not consistent with what we know about asphyxia. More than 75% of brain-damaged children have causes that are *not* related to perinatal asphyxia. Many cases of asphyxia occur *before* labor or early in labor before the patient arrives in the hospital. Few of these cases are truly preventable. One can only hope that once these pressures are removed from the labor and delivery suite by new technology or other solutions, the opportunity to do what is best for the fetus and mother will be enhanced, and this will be the only motivating force.

SUMMARY

EFM has become the standard means for evaluating fetal oxygenation in labor. Because of fetal inaccessibility and the lack of alternatives to more specifically evaluate fetal oxygenation, this modality has been the only alternative. EFM is highly reliable when reassuring (category I) and most often unreliable with equivocal tracings (category II), except in the extreme (category III), when there is high likelihood of fetal acidosis. Despite or even because of these limitations, it is imperative that the clinician understand as much as possible about the underlying physiologic explanations of normal and abnormal FHR patterns because this allows the only reasonable opportunity to appropriately evaluate and manage these changes. The new terminology proposed by the NICHD Workshop and endorsed by ACOG and AWHONN should be used consistently. The goals of FHR monitoring should be to carefully and thoroughly monitor all patients in active labor; avoid unnecessary operative and nonoperative intervention for benign and innocuous FHR patterns; correct non-reassuring FHR patterns with noninvasive, etiology-specific therapies when possible, or if not possible use appropriate means such as scalp pH, accelerations, or moderate variability to rule out acidosis; and finally, if acidosis cannot be ruled out, operatively intervene in an expeditious manner appropriate for the entire clinical situation.

KEY POINTS

- The goals of intrapartum fetal evaluation by electronic FHR monitoring and available back-up methods are to detect fetal hypoxia, reverse the hypoxia with nonsurgical means, or if unsuccessful, determine whether the hypoxia has progressed to metabolic acidosis, and if so deliver the baby expeditiously to avoid the hypoxia and acidosis from resulting in any damage to the baby.
- New terminology has been proposed by the NICHD Workshop on intrapartum EFM and should be consistently employed in practice.
- EFM is an inherently suboptimal method of determining fetal hypoxia and acidosis because many factors besides these variables may alter the FHR and mimic changes caused by hypoxia and acidosis. When the FHR is normal, its reliability for predicting the absence of fetal compromise is high, but when the FHR is abnormal, its reliability for predicting the presence of asphyxia is poor.
- The three-tiered classification of FHR patterns proposed by the NICHD Workshop on EFM and endorsed by ACOG and AWHONN should be used as a template for evaluation and management of FHR patterns, but the limitations of the guidelines for the frequently occurring category II patterns should be realized and plans made to deal more specifically with different types of FHR patterns within this group.
- Late decelerations are always indicative of relative fetal hypoxia and are caused by inadequate oxygen delivery, exchange, or uptake that is aggravated by the additional hypoperfusion of the placenta caused by contractions. Variable decelerations are caused by a decrease in umbilical cord flow resulting from cord compression or cord stretch. Prolonged decelerations may be caused by any mechanism that decreases fetal oxygenation.
- In labor, loss of variability, loss of accelerations, and tachycardia should only be interpreted as indicative of fetal compromise in the presence of non-reassuring decelerations (late, non-reassuring variable or prolonged decelerations) because signs of hypoxia should always precede signs of neurologic depression secondary to hypoxia.
- In the presence of oligohydramnios and variable decelerations, intrapartum amnioinfusion has been shown to decrease rates of cesarean delivery for NRFS.
- In the presence of an otherwise non-reassuring FHR pattern, the presence of accelerations of the FHR, either spontaneous or elicited by scalp stimulation or vibroacoustic stimulation, indicates the absence of fetal acidosis. The absence of accelerations is associated with a 50% chance of fetal acidosis, but only in the setting of a non-reassuring FHR.
- Umbilical cord blood gases should be obtained and documented in situations in which there is a non-reassuring or confusing FHR pattern during labor, neonatal depression following birth, prematurity, or suctioning for meconium. These values will help clarify the reasons for abnormal FHR patterns or for neonatal depression.
- Although there is correlation between a non-reassuring FHR pattern and neonatal depression, the FHR is a poor predictor of long-term neurologic sequelae. Furthermore, fetuses with previous neurologic insults may have significantly abnormal FHR patterns even when they are well oxygenated in labor.

Obstetrical anesthesia encompasses all techniques used by anesthesiologists and obstetricians to alleviate the pain associated with labor and delivery: general anesthesia, neuraxial anesthesia (spinal or epidural), local anesthesia (local infiltration, paracervical block, pudendal block), and parenteral analgesia. **Pain relief during labor and delivery is an essential part of good obstetrical care.** Unique clinical considerations guide anesthesia provision for obstetrical patients; physiologic changes of pregnancy and increases in certain complications must be considered. This chapter reviews the various methods that can be used for obstetrical analgesia and anesthesia, as well as their indications and complications.

PERSONNEL

Anesthesiologists, working either independently or supervising a team of residents or certified nurse anesthetists, provide anesthesia for 98% of obstetrical procedures in larger hospitals in the United States.[1] Nurse anesthetists, independent of anesthesiologists, rarely provide anesthesia for obstetrical cases in larger hospitals but provide anesthesia for 34% of obstetrical procedures in hospitals with fewer than 500 births per year.[1] The American Society of Anesthesiologists (ASA) partnered with the American College of Obstetricians and Gynecologists (ACOG) to issue the Joint Statement on the Optimal Goals for Anesthesia Care in Obstetrics,[2] recommending that a qualified anesthesiologist assume responsibility for anesthetics in every hospital providing obstetrical care. The statement notes: "There are obstetric units where obstetricians or obstetrician-supervised nurse anesthetists administer anesthetics. **The administration of general or regional anesthesia requires both medical judgment and technical skills.** Thus, a physician with privileges in anesthesiology should be readily available."[2] To provide optimal care for the parturient, the ASA also states in their Practice Guidelines for Obstetric Anesthesia that, "**A communication system should be in place to encourage early and ongoing contact between obstetric providers, anesthesiologists, and other members of the multidisciplinary team.**"[3]

PAIN PATHWAYS

Pain during the first stage of labor results from a combination of uterine contractions and cervical dilation. Painful sensations travel from the uterus through visceral afferent (sympathetic) nerves that enter the spinal cord through the posterior segments of thoracic spinal nerves 10, 11, and 12 (Figure 17-1). During the second stage of labor, additional painful stimuli are added as the fetal head distends the pelvic floor, vagina, and perineum. The sensory fibers of sacral nerves 2, 3, and 4 (i.e., the pudendal nerve) transmit painful impulses from the perineum to the spinal cord during second stage and during any perineal repair (see Figure 17-1). **During cesarean delivery, although the incision is usually around thoracic spinal nerve 12 (T12) dermatome, anesthesia is required to a level of thoracic spinal nerve 4 (T4) to completely block peritoneal discomfort,**

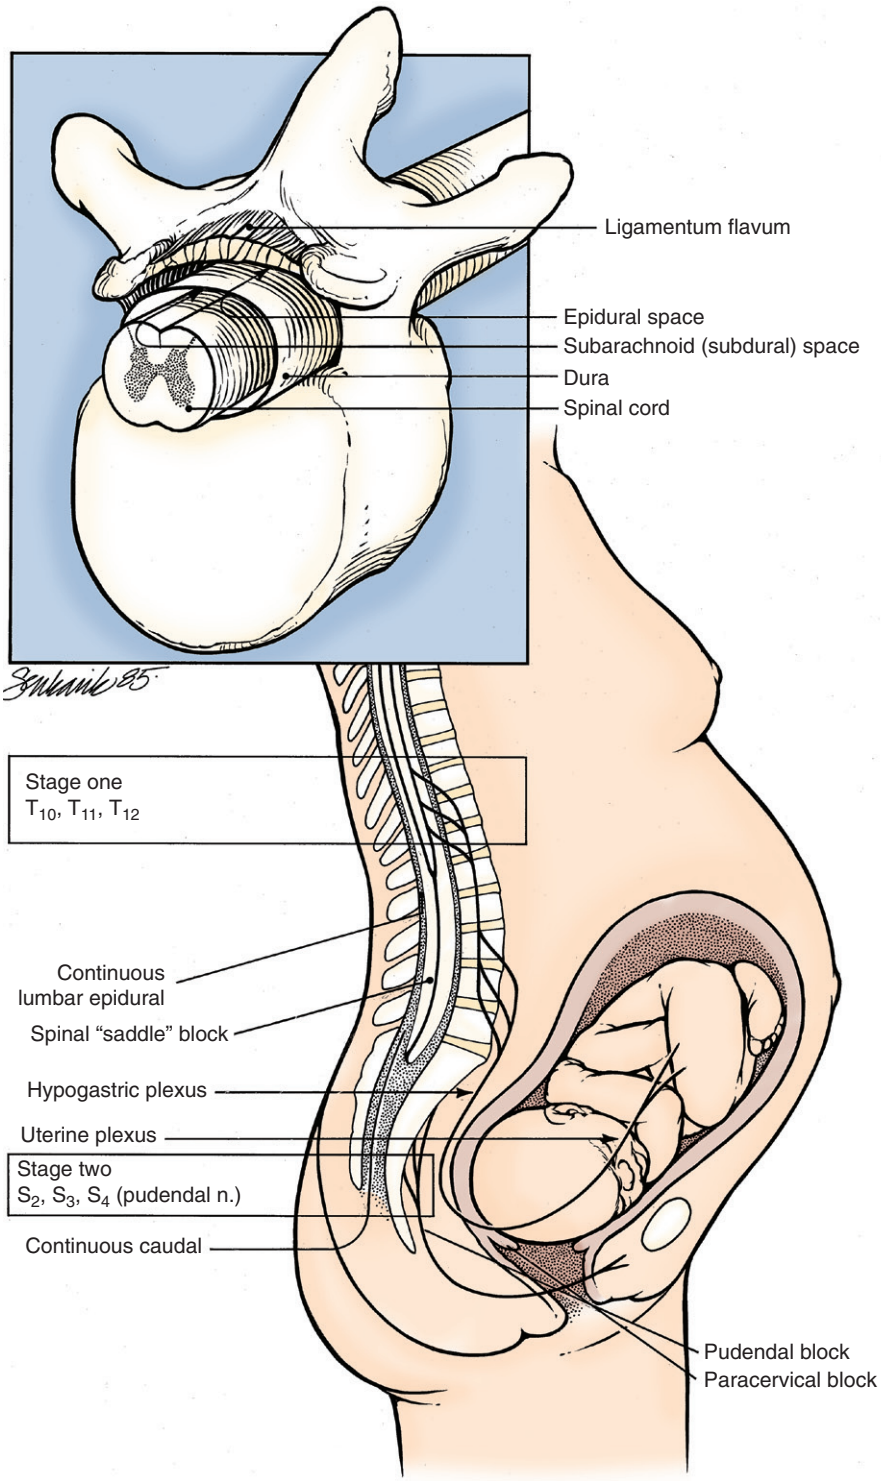

FIGURE 17-1. Pain pathways of labor and delivery and nerves blocked by various anesthetic techniques.

especially during uterine exteriorization. Pain after cesarean delivery is due to both incisional pain and uterine involution.

EFFECTS OF PAIN AND STRESS

The process of labor involves significant pain and stress for most women. Using the McGill Pain Questionnaire, which measures intensity and quality of pain, Melzack and colleagues[4] found that 59% of nulliparous and 43% of parous patients described their labor pain in terms more severe than did those suffering from cancer pain. **The most substantial predictors of pain intensity were ultimately socioeconomic status and prior menstrual difficulties.**

The maternal and fetal stress response to the pain of labor has been difficult to assess. Most investigators have

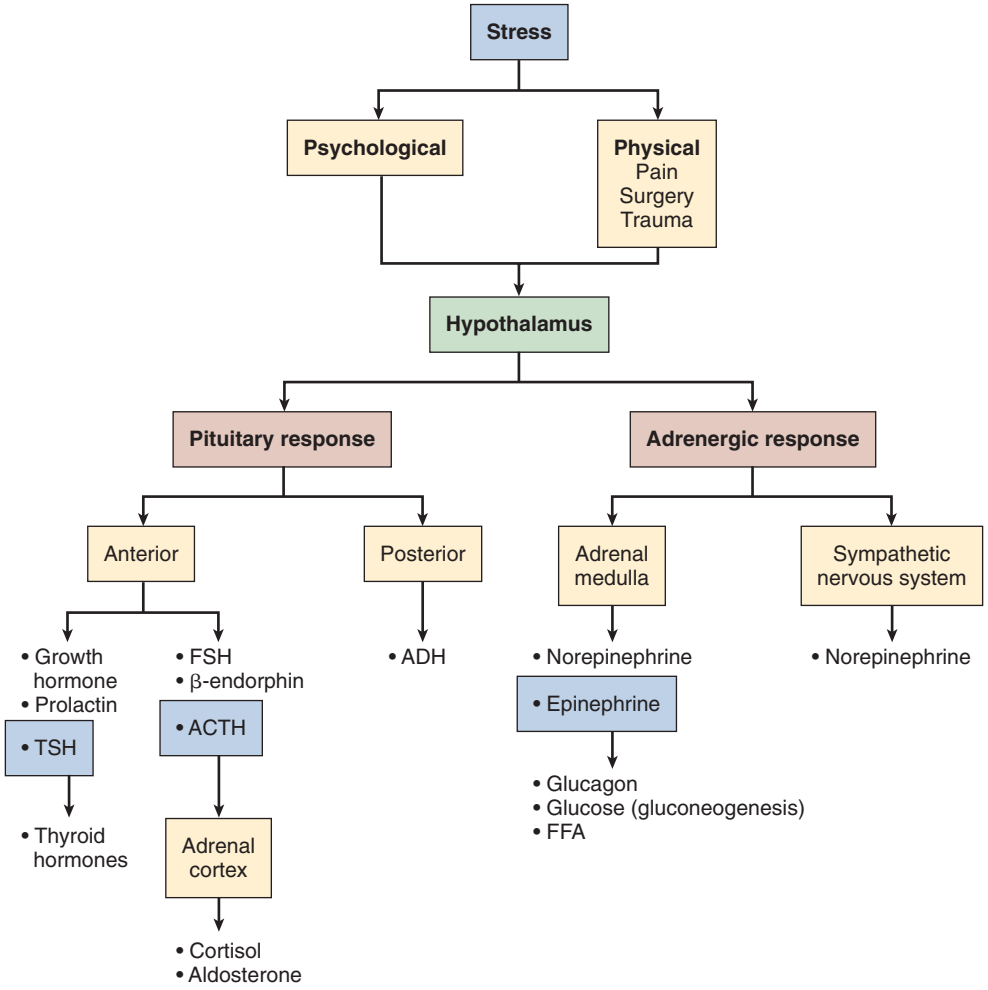

FIGURE 17-2. The stress response.

described and quantified stress in terms of the release of adrenocorticotropic hormone, cortisol, catecholamines, and β-endorphins (Figure 17-2). Furthermore, **animal studies indicate that both epinephrine and norepinephrine can decrease uterine blood flow in the absence of maternal heart rate and blood pressure changes, contributing to occult fetal asphyxia.** Maternal psychological stress (induced by bright lights or toe clamp) can detrimentally affect uterine blood flow and fetal acid-base status as demonstrated in baboons and monkeys.[5] In pregnant sheep, catecholamines increase and uterine blood flow decreases after painful stimuli and after nonpainful stimuli (such as loud noises) that induce fear and anxiety, as evidenced by struggling (Figure 17-3).

Although some of the physiologic stress of labor is unavoidable, analgesia and anesthesia may reduce stress responses that are secondary to pain. Postpartum women suffer objective deficits in cognitive and memory function compared with nonpregnant women.[6] Intrapartum analgesia does not exacerbate, but rather *lessens*, the cognitive defect compared with unmedicated parturients. Analgesia also reduces paternal anxiety and stress, increases the fathers' feelings of helpfulness, and enhances their involvement and satisfaction with the childbirth experience.[7]

TABLE 17-1 ANALGESIC PROCEDURES USED FOR LABOR PAIN RELIEF IN 2001 ACCORDING TO SIZE OF DELIVERY SERVICE

HOSPITAL SIZE (BIRTHS/YEAR)	NO ANESTHESIA (%)	NARCOTICS BARBITURATES TRANQUILIZERS (%)	PARACERVICAL BLOCK (%)	SPINAL OR EPIDURAL BLOCK (%)
<500	12	37	3	57
500-1499	10	42	3	59
>1500	6	34	2	77

Modified from Bucklin BA, Hawkins JL, Anderson JR, Ullrich FA: Obstetric anesthesia workforce survey. Anesthesiology 103:645, 2005.

Epidural analgesia prevents increases in both cortisol and 11-hydroxycorticosteroid levels during labor, but systemically administered opioids do not. Epidural analgesia also attenuates elevations of epinephrine, norepinephrine, and endorphin levels[8] (Figure 17-4). Assuming any hypotension is rapidly treated and perfusion is preserved by uterine displacement, fetal acid-base status (as measured by base deficit) of human infants whose mothers receive epidural anesthesia during the first stage of labor is altered less than that of infants of mothers who receive systemic opioid analgesia.

ANALGESIA FOR LABOR

Table 17-1 presents the frequency with which the various forms of analgesia are used during labor. The data are from a large survey of hospitals in the United States, stratified by the size of their delivery service.[1]

Psychoprophylaxis and Nonpharmacologic Analgesia Techniques

Psychoprophylaxis is any nonpharmacologic method that minimizes the perception of painful uterine contractions. Relaxation, concentration on breathing, gentle massage, and partner or doula participation contribute to effectiveness. One of the method's most valuable contributions is that it is often taught in prepared childbirth classes, where parents tour the labor and delivery suite and learn about the normal processes of labor and delivery, in many instances mitigating their fear of the unknown.

Although psychoprophylactic techniques can be empowering, most women will still ultimately blend them with pharmacologic methods.[1] Because most first-time mothers choose epidural analgesia, teaching that use of drug-induced pain relief represents failure or will harm the child is counterproductive and can heighten fear and anxiety during labor.

Nonpharmacologic techniques for labor analgesia may be used alone or in conjunction with parenteral or regional techniques. A systematic review of acupuncture concluded that the evidence for efficacy is promising but that there is a paucity of data.[9] From the three randomized clinical trials they reviewed, the authors suggest that acupuncture alleviates labor pain and reduces use of both epidural analgesia and parenteral opioids. Acupuncture may be helpful for patients who feel strongly about avoiding epidural analgesia in labor, although arranging to have a qualified and credentialed acupuncture provider available at the time of delivery may be challenging. A randomized controlled trial of laboring in water found no advantage in labor outcome or in reducing the need for analgesia, but the request for epidural analgesia was delayed by about 30 minutes.[10] The American Academy of Pediatrics Committee on Fetus and Newborn has expressed concerns about *delivering* in water because of the lack of trials demonstrating safety and the rare but reported unusual complications such as infection or asphyxia.[11] They state that, "underwater birth should

be considered an experimental procedure that should not be performed except within the context of an appropriately designed RCT after informed parental consent." Intracutaneous sterile water injections are simple to perform and have good evidence for efficacy, perhaps by a similar gating mechanism as acupuncture.[12] An intradermal injection of 0.1 mL of sterile water at four sites in the lower back significantly lowers visual analog pain scores during labor. A number of studies have examined transcutaneous electrical nerve stimulation during labor. Patients tend to rate the device as helpful, despite the fact it does not decrease pain scores or the use of additional analgesics. As one study noted, transcutaneous electrical nerve stimulation units do not appear to change the degree of pain, but somehow may have made the pain less disturbing.[13] **Although the efficacy of these techniques is largely unproved because of a lack of randomized clinical trials, there are no serious safety concerns with any of these techniques, which is attractive to patients and their caregivers.** Women expect to have choices and a degree of control during their childbirth, and their caregivers should provide analgesic options for them to choose from, including nonpharmacologic methods.

Systemic Opioid Analgesia

Opioids can be given in intermittent doses by intramuscular or intravenous routes at the patient's request, or through patient-controlled administration. All opioids provide sedation and a sense of euphoria, but their analgesic effect in labor is limited, and their primary mechanism of action is sedation.[14] Opioids can also produce nausea and respiratory depression in the mother, the degree of which is usually comparable for equipotent analgesic doses. Also, all opioids freely cross the placenta to the newborn, decreasing beat-to-beat variability, and can increase the likelihood of significant respiratory depression in the newborn at birth, with subsequent need for treatment. A meta-analysis that aggregates the results of several randomized trials reveals that opioid treatment is associated with an increased risk for an Apgar score of less than 7 at 5 minutes (odds ratio [OR], 2.6; 95% confidence interval [CI], 1.2 to 5.6) and increased need for neonatal naloxone (OR, 4.17; 95% CI, 1.3 to 14.3), although the overall incidence of both was low.[15]

An important and significant disadvantage of opioid analgesia is the prolonged effect of these agents on maternal gastric emptying. When parenteral or epidural opioids are used, gastric emptying is prolonged, and if general anesthesia becomes necessary, the risk for aspiration is increased.[16] The opioids in common use today are meperidine, nalbuphine, butorphanol, and fentanyl. Morphine fell out of favor in the 1960s to 1970s because of a single study reporting increased respiratory depression in the newborn compared with meperidine, but no recent study has compared their relative safety for the newborn in the setting of modern practice.

Patient-Controlled Analgesia

Intravenous patient-controlled analgesia (PCA) is often used for women with a contraindication to neuraxial analgesia (e.g., severe thrombocytopenia). The infusion pump is programmed to give a predetermined dose of drug on patient demand. The physician will program the pump to include a lockout interval to limit the total dose administered per hour. Advantages of this method include the sense of autonomy, which patients appreciate, and elimination of delays in treatment while the patient's nurse obtains and administers the dose. In general, PCA results in a decreased total dose of opioid during labor.[17] Fentanyl, remifentanil,[18] and meperidine are the opioids most commonly employed with this technique.

Meperidine (Demerol)

Meperidine is a synthetic opioid. Meperidine 100 mg is roughly equianalgesic to morphine 10 mg but has been reported to have a somewhat less depressive effect on respiration. Usually, a dose of 25 to 50 mg is administered intravenously; it may also be used intramuscularly or in a PCA pump delivering 15 mg of meperidine every 10 minutes as needed until delivery.[19] Intravenously, the onset of analgesia begins almost immediately and lasts approximately 1.5 to 2 hours. Side effects may include tachycardia, nausea and vomiting, and delayed gastric emptying.

Normeperidine is an active metabolite of meperidine, potentiating meperidine's depressant effects in the newborn. Normeperidine concentrations increase slowly, and therefore, it exerts its effect on the newborn during the second hour after administration. Multiple doses of meperidine result in greater accumulation of both meperidine and normeperidine in fetal tissues[20]; thus, administration of large doses of meperidine in the first stage of labor (rather than during the second stage of labor) leads to high doses accumulated in the fetus. A randomized controlled study using intravenous PCA meperidine for labor analgesia found 3.4% of infants required naloxone at delivery (versus 0.8% with epidural analgesia).[21] Normeperidine accumulation in the fetus can result in prolonged neonatal sedation and neurobehavioral changes.[22] These neurobehavioral changes are evident into day 2 and day 3 of life.

Nalbuphine (Nubain)

Nalbuphine is a synthetic agonist-antagonist opioid, meaning it has opioid blocking properties as well as analgesic properties. Its analgesic potency is similar to that of morphine when compared on a milligram-per-milligram basis, and usual doses are 5 to 10 mg intravenously every 3 hours. A reported advantage of nalbuphine is its ceiling effect for respiratory depression[23]; that is, respiratory depression from multiple doses appears to plateau. One limitation of nalbuphine is that its antagonist activity may also limit the analgesia it can produce, and it may interfere with spinal and epidural opioids given as part of a neuraxial technique. Nalbuphine causes less maternal nausea and vomiting than meperidine, but it tends to produce more maternal sedation, dizziness, and dysphoria, as well as the risk for opioid withdrawal in susceptible patients.

Butorphanol (Stadol)

Butorphanol is also a synthetic agonist-antagonist opioid analgesic drug. The dose of 1 to 2 mg is administered intravenously and compares favorably with 40 to 80 mg of meperidine or 5 to 10 mg morphine.[24] Nausea and vomiting appear to occur less often with butorphanol than with other opioids. Like nalbuphine, the major advantage is

a ceiling effect for respiratory depression, and the side effects of the two drugs are similar. Rarely, a pseudosinusoidal fetal heart rate pattern may occur after administration, but this is not unique to butorphanol.

Fentanyl

Fentanyl is a fast-onset, short-acting synthetic opioid with no active metabolites. In a randomized comparison with meperidine, fentanyl 50 to 100 mcg every hour provided equivalent analgesia, with fewer neonatal effects and less maternal sedation and nausea. The main drawback of fentanyl is its short duration of action requiring frequent redosing or the use of a patient-controlled intravenous infusion pump. A sample PCA setting for fentanyl is a 50-mcg incremental dose with a 10-minute lockout and no basal rate.[17]

Sedatives

Sedatives (barbiturates, phenothiazines, and benzodiazepines) do not possess analgesic qualities. All sedatives and hypnotics cross the placenta freely, and except for the benzodiazepines, they have no known antagonists. Sedation is rarely desirable during the childbirth experience.

Promethazine may actually impair the analgesic efficacy of opioids. In a randomized double-blind trial, women received placebo, metoclopramide, or promethazine as an antiemetic with meperidine analgesia.[25] Analgesia after placebo or metoclopramide was significantly better than that after promethazine as measured by pain scores and need for supplemental analgesics. Metoclopramide 10 mg has also been shown to improve PCA analgesia during second-trimester termination of pregnancy.[26] In two randomized double-blind studies, the group receiving metoclopramide (versus saline) used 54% and 66% less intravenous morphine.

Two major disadvantages of benzodiazepines are that they cause undesirable maternal amnesia[27] and may disrupt thermoregulation in newborns, which renders them less able to maintain body temperature.[28] Presumably this can occur with any of the benzodiazepines. As with many drugs, beat-to-beat variability of the fetal heart rate can be reduced even with a single intravenous dose, although these changes do not reflect alterations in the acid-base status of the newborn. Flumazenil, a specific benzodiazepine antagonist, can reliably reverse benzodiazepine-induced sedation and ventilatory depression.

Placental Transfer

Essentially, all analgesic and anesthetic agents except highly ionized muscle relaxants cross the placenta freely (see box, Factors Influencing Placental Transfer from Mother to Fetus).[29] The limited transfer of muscle relaxants such as succinylcholine enables anesthesiologists to use general anesthesia for cesarean delivery without causing fetal paralysis.

Because the placenta has the properties of a lipid membrane, most drugs and all anesthetic agents cross by simple diffusion. Thus, the amount of drug that crosses the placenta increases as concentrations in the maternal circulation and total area of the placenta increase. Diffusion is also affected by the properties of the drug itself, including molecular weight, spatial configuration, degree of ionization, lipid solubility, and protein binding. For example, bupivacaine is highly protein bound, a characteristic that some believe explains why fetal blood concentrations are so much lower than with other local anesthetics. On the other hand, bupivacaine is also highly lipid soluble. The more lipid soluble a drug is, the more freely it passes through a lipid membrane. Furthermore, once in the fetal system, lipid solubility enables the drug to be taken up by fetal tissues rapidly (i.e., redistribution), which again contributes to the lower blood concentration of the agent.

The degree of ionization of a drug is also important. Most drugs exist in both an ionized and nonionized state, with the nonionized form more freely crossing lipid membranes. The degree of ionization is influenced by the pH[30]; this may become relevant in situations in which there is a significant pH gradient between mother (normal pH 7.40) and an acidotic infant (pH <7.2) (Figure 17-5). For example, local anesthetics are more ionized at a lower pH, so the nonionized portion of the drug in the maternal circulation (normal pH) crosses to the acidotic fetus, becomes ionized, and thus remains in the fetus, potentially leading to higher local anesthetic concentrations in the fetus and newborn. Whether this has relevant adverse clinical effects on the fetus is unknown.

Factors Influencing Placental Transfer from Mother to Fetus

- Drug
  - Molecular weight
  - Lipid solubility
  - Ionization, pH of blood
  - Spatial configuration
- Maternal
  - Uptake into bloodstream
  - Distribution via circulation
  - Uterine blood flow: amount, distribution (myometrium versus placenta)
- Placental
  - Circulation: intermittent spurting arterioles
  - Lipid membrane: Fick's law of simple diffusion
- Fetal
  - Circulation: ductus venosus, foramen ovale, ductus arteriosus

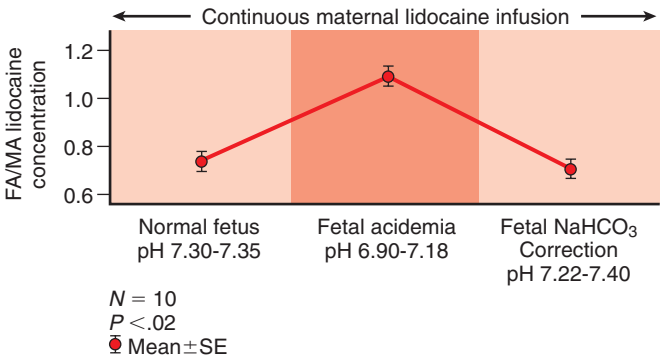

Figure 17-5. Fetal-maternal arterial (FA/MA) lidocaine ratios were significantly higher ($P < .02$) during fetal acidemia than during control or when pH was corrected with bicarbonate ($N = 10$; mean ± SE). (From Biehl D, Shnider SM, Levinson G, Callender K: Placental transfer of lidocaine: effects of fetal acidosis. Anesthesiology 48:409, 1978.)

Neuraxial Analgesic and Anesthetic Techniques

Neuraxial analgesic and anesthetic techniques (spinal, epidural, or a combination) use local anesthetics to provide sensory as well as various degrees of motor blockade over a specific region of the body. In obstetrics, neuraxial and other regional analgesic techniques include major blocks, such as lumbar epidural and spinal, and minor blocks, such as paracervical, pudendal, and local infiltration (see Figure 17-1).

Lumbar Epidural Analgesia and Anesthesia

Epidural blockade is a neuraxial anesthetic used to provide *analgesia* during labor, or surgical *anesthesia* for vaginal or cesarean delivery.[31] Epidural analgesia offers the most effective form of pain relief[32] and is used by most women in the United States.[1] In most obstetrical patients, the primary indication for epidural analgesia is the patient's desire for pain relief. Medical indications for epidural analgesia during labor may include anticipated difficult intubation due to morbid obesity or other causes, a history of malignant hyperthermia, selected forms of cardiovascular and respiratory disease, and prevention or treatment of autonomic hyper-reflexia in parturients with a high spinal cord lesion. The technique uses a large-bore (16-, 17-, or 18-gauge) needle to locate the epidural space. Next, a catheter is inserted through the needle, and the needle is removed over the catheter. After aspirating the catheter, a test dose of local anesthetic with a "marker" such as epinephrine may be given first to be certain the catheter has not been unintentionally placed in the subarachnoid (spinal) space or in a blood vessel. Intravascular placement will lead to maternal tachycardia due to the epinephrine, and rapid onset of sensory and motor block will occur if the local anesthetic is placed in the spinal fluid. Once intravascular and intrathecal placement have been ruled out, local anesthetic is injected through the catheter, which remains taped in place to the mother's back to enable subsequent injections throughout labor (Figure 17-6; see Figure 17-1). Thus, it is often called *continuous epidural analgesia*. Anesthesiologists use a technique described as *segmental epidural analgesia* (Figure 17-7). Low concentrations of local anesthetic[3] (<0.25% bupivacaine) are injected at L2 to L5, affecting the small, easily blocked sympathetic nerves that mediate early labor pain, but sparing the sensation of pressure and motor function of the perineum and lower extremities. The patient should be able to move about in bed and perceive the impact of the presenting part on the perineum. Patients vary in their responses to local anesthetics, and infusions may need to be adjusted to a lower rate or concentration if the patient develops excessive motor block. If perineal anesthesia is needed for delivery, a larger volume of local anesthetic can be administered at that time through the catheter (see Figure 17-7). Alternatively, for perineal anesthesia, the obstetrician can perform a pudendal block or local infiltration of the perineum.

A variant of the epidural technique involves passing a small-gauge pencil-point spinal needle through the epidural needle before catheter placement. This combined spinal-epidural (CSE) technique provides more rapid onset of analgesia using a very small dose of opioid or a local anesthetic and opioid combination. Some practitioners have used an opioid only or opioid plus local anesthetic technique to allow parturients to ambulate during labor (the "walking epidural") because there is little or no interference with motor function. Because the dose of drug used in the subarachnoid space is much smaller than that used for epidural analgesia, the risks for local anesthetic toxicity or high spinal block are avoided. Side effects of spinal opioids are usually mild and easily treated and include pruritus and nausea.

Non-reassuring fetal heart rate changes may occur more often in patients receiving combined spinal-epidural analgesia than epidural analgesia alone.[33] Although the incidence of hypotension is similar between the two techniques, the etiology of fetal bradycardia after spinal analgesia may relate more to uterine hypertonus than hypotension. Rapid onset of spinal analgesia decreases maternal catecholamines, specifically epinephrine, which may cause uterine relaxation through its β-agonist activity. Fortunately, these non-reassuring fetal heart rate changes do not seem to affect labor outcome. In a review of 2380 deliveries in a community hospital, there was no increase in emergency cesarean delivery in the 1240 patients who received regional analgesia for labor (98% of which were CSE) compared with the 1140 patients who received systemic or no medication.[34] A systematic review of randomized comparisons of intrathecal opioid analgesia versus epidural or parenteral opioids in labor found that the use of intrathecal opioids significantly increased the risk for fetal bradycardia (OR, 1.8; 95% CI, 1 to 3.1).[35] However, the risk for cesarean delivery for fetal heart rate abnormalities was similar in the two groups (6% versus 7.8%). Fetal heart rate should be monitored during and after the administration of either epidural or intrathecal medications to allow for timely intrauterine resuscitation.[3]

Complications of Neuraxial Blocks

Side effects of epidural or CSE analgesia include hypotension, local anesthetic toxicity, allergic reaction, high or total spinal anesthesia, neurologic injury, and postdural puncture headache. In addition, epidural analgesia use may increase the rate of intrapartum fever and possibly operative vaginal delivery. The effect of epidural analgesia on labor progression, fetal position, and risk for cesarean delivery is discussed in detail later. Because epidural anesthesia is associated with side effects and complications, some of which are dangerous, those who administer it must be thoroughly familiar not only with the technical aspects of its administration but also with the signs and symptoms of complications and their treatment. Specifically, the ASA and ACOG have stated: "Persons administering or supervising obstetric anesthesia should be qualified to manage the infrequent but occasionally life-threatening complications of major regional anesthesia such as respiratory and cardiovascular failure, convulsions due to toxic levels of local anesthetic, or vomiting and aspiration. Mastering and retaining the skills and knowledge necessary to manage these complications require adequate training and frequent application."[2] The ASA Practice Guidelines also state: "When a neuraxial technique is chosen, appropriate resources for the treatment of complications (e.g., hypotension, systemic toxicity, high spinal anesthesia) should be available."[3]

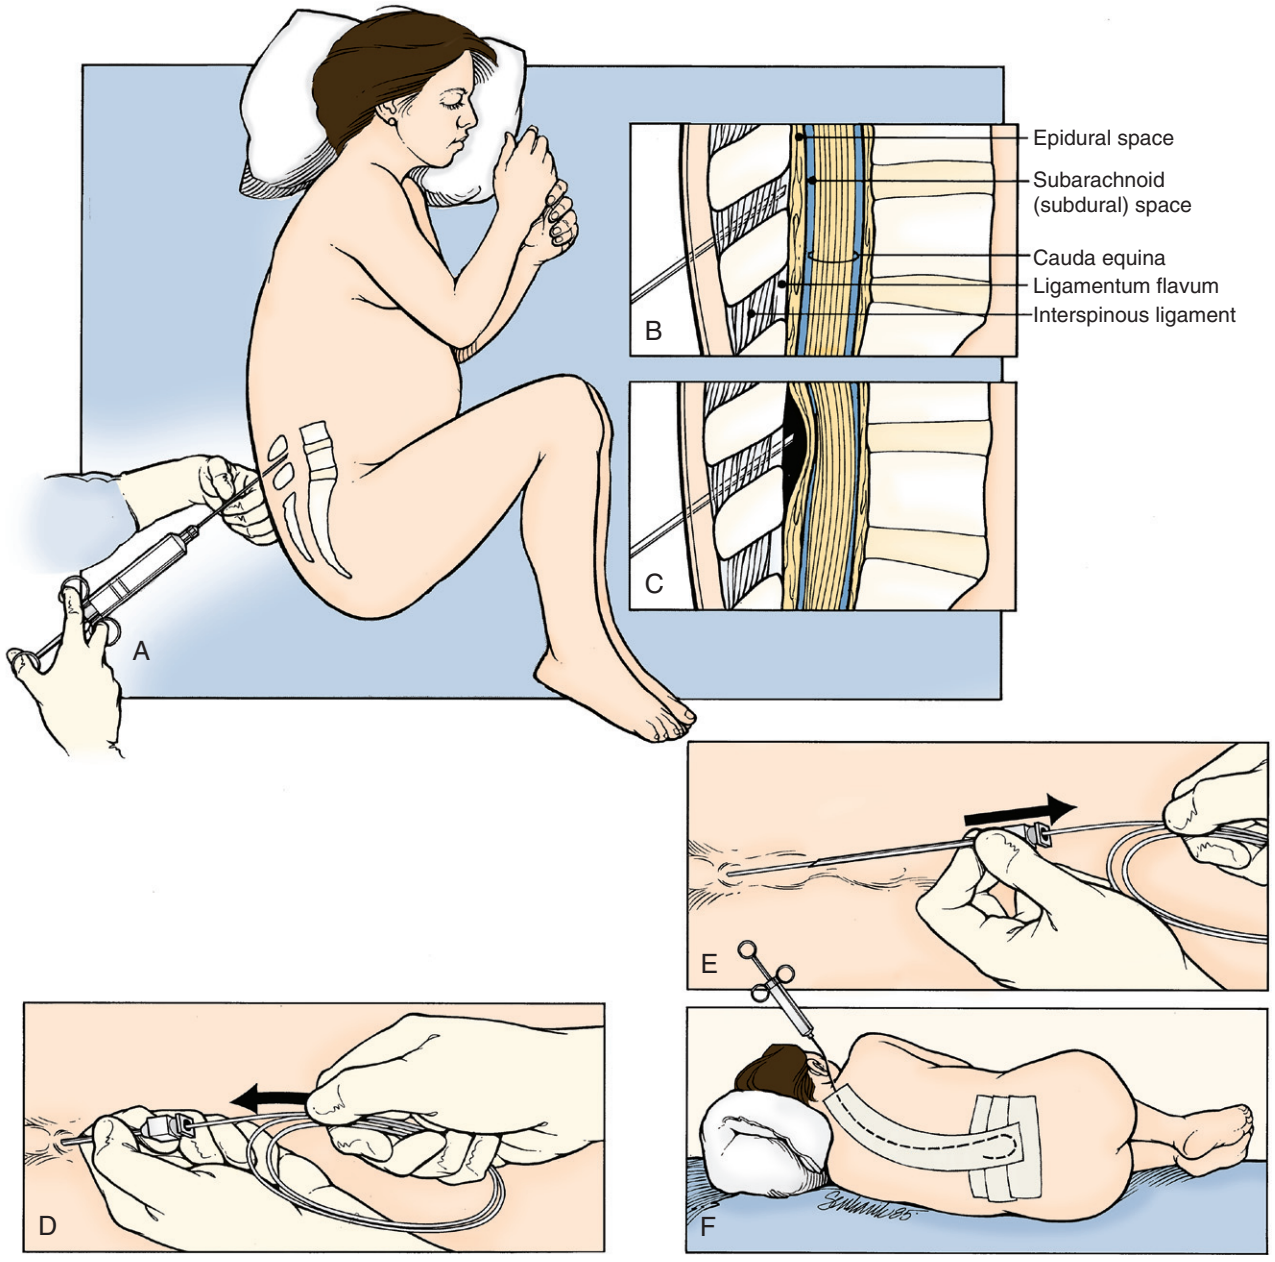

FIGURE 17-6. Technique of lumbar epidural puncture by the midline approach. **A,** This side view shows left hand held against patient's back, with thumb and index finger grasping hub. Attempts to inject solution while point of needle is in the interspinous ligament meet resistance. **B,** Point of needle is in the ligamentum flavum, which offers marked resistance and makes it almost impossible to inject solution. **C,** Entrance of the needle's point into epidural space is discerned by sudden lack of resistance to injection of saline. Force of injected solution pushes dura-arachnoid away from point of needle. **D,** Catheter is introduced through needle. Note that hub of needle is pulled caudad toward the patient, increasing the angle between the shaft of the needle and the epidural space. Also note technique of holding the tubing: It is wound around the right hand. **E,** Needle is withdrawn over tubing and held steady with the right hand. **F,** Catheter is immobilized with adhesive tape. Note the large loop made by the catheter to decrease risk for kinking at the point where the tube exits from the skin. (From Bonica JJ: Obstetric Analgesia and Anesthesia. Amsterdam, World Federation of Societies of Anesthesiologists, 1980.)

HYPOTENSION

Hypotension is defined variably, but most often as a systolic blood pressure of less than 100 mm Hg or a 20% decrease from baseline. It occurs after about 10% of spinal or epidural blocks given during labor.[36] Hypotension occurs primarily as a result of the effects of local anesthetic agents on sympathetic fibers, which normally maintain blood vessel tone. Vasodilation results in decreased venous return of blood to the right side of the heart, with subsequent decreased cardiac output and hypotension. A secondary mechanism may be decreased maternal endogenous catecholamines following pain relief. Hypotension threatens the fetus by decreasing uterine blood flow. However, when recognized promptly and treated effectively, few, if any, untoward effects accrue to either mother or fetus (Table 17-2). Special care should be taken to avoid or promptly

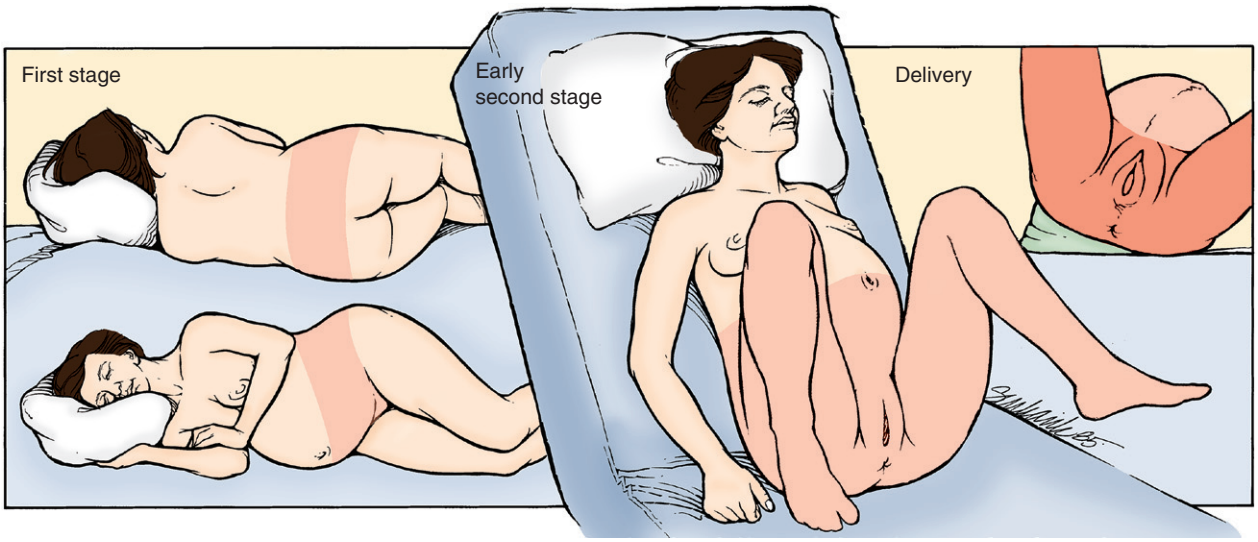

FIGURE 17-7. Segmental epidural analgesia for labor and delivery. A single catheter is introduced into the epidural space and advanced so that its tip is at L2. Initially, small volumes of low concentrations of local anesthetic are used to produce segmental analgesia. For the second stage, the analgesia is extended to the sacral segments by injecting a larger amount of the same concentration of local anesthetic, with the patient in the semirecumbent position. After internal rotation, a higher concentration of local anesthetic is injected to produce motor block of the sacral segments and thus achieve perineal relaxation and anesthesia. The wedge under the right buttock causes the uterus to displace to the left. (From Bonica JJ: Obstetric Analgesia and Anesthesia. Amsterdam, World Federation of Societies of Anesthesiologists, 1980.)

*Values are means; they indicate that properly treated hypotension need not result in a compromised fetus.

†Hypotension was severe enough to be treated with the vasopressor ephedrine.

treat hypotension, especially in situations in which acute or chronic fetal compromise is suspected.

Treatment of hypotension begins with prophylaxis, which includes (1) intravenous access for volume expansion and administration of pressors and (2) left uterine displacement to maintain cardiac preload. Isotonic crystalloid infusion may mitigate the effects of vasodilation. Rapid boluses should not contain dextrose because of the association with subsequent neonatal hypoglycemia. Proper treatment of hypotension depends on immediate diagnosis. Therefore, the individual administering the anesthesia must be present and attentive. **Once diagnosed, hypotension is corrected by increasing the rate of intravenous fluid infusion and exaggerating left uterine displacement. If these simple measures do not suffice, a vasopressor is indicated.**

The vasopressor of choice has evolved from ephedrine, given in 5- to 10-mg doses, to phenylephrine, in 50- to 100-mcg increments. Ephedrine is a mixed α- and β-agonist, and was thought to be less likely to compromise uteroplacental perfusion than the pure α-agonists. Of concern, ephedrine is associated with fetal tachycardia. **Recent clinical studies have suggested that phenylephrine may be given safely to treat hypotension during neuraxial anesthesia for cesarean delivery, and the drug indeed may lead to higher umbilical artery pH values in the fetus and less maternal nausea and vomiting.** When compared with phenylephrine for treatment of hypotension following neuraxial analgesia in a randomized trial, ephedrine was associated with higher degrees of fetal acidosis.[37] The β-agonist action of ephedrine may increase fetal oxygen requirements, leading to hypoxia in cases of uteroplacental insufficiency.[38] Phenylephrine corrects maternal hypotension, apparently without causing clinically significant uterine artery vasoconstriction or decreased placental perfusion, even in extremely high doses. Rather than causing abnormal increases in systemic vascular resistance, these doses may simply return vascular tone to normal after spinal anesthesia. It is also possible that constricting peripheral arteries may preferentially shunt blood to the uterine arteries. The parturient has decreased sensitivity to all vasopressors, and that may also protect the fetus from excessive vasoconstriction. α-Adrenergic agents such as methoxamine and phenylephrine cause reflex bradycardia that may be useful when a parturient is excessively tachycardic in association with hypotension, or if tachycardia associated with ephedrine would be detrimental.

LOCAL ANESTHETIC TOXICITY

The incidence of systemic local anesthetic toxicity (high blood concentrations of local anesthetic) after obstetrical lumbar epidural analgesia is 1 in 5000, or 0.02%.[39] However,

TABLE 17-3 MAXIMAL RECOMMENDED DOSES OF COMMON LOCAL ANESTHETICS

	WITH EPINEPHRINE*		WITHOUT EPINEPHRINE	
Local Anesthetic	**mg/kg**	**Dose (mg/70 kg)**	**mg/kg**	**Dose (mg/70 kg)**

Chloroprocaine	14.0	980	11.0	770
Etidocaine	5.5	385	4.0	280
Lidocaine	7.0	490	4.0	280
Mepivacaine	—	—	5.0	350

*All epinephrine concentrations 1:200,000.

cases of local anesthetic toxicity were absent from most recent review of the ASA Closed Claims Project database.[40] In contrast, the Confidential Enquiries into Maternal Deaths in Great Britain reported a maternal death during labor when a bupivacaine epidural infusion was connected to an intravenous line instead of the epidural catheter.[41] Most often, toxicity occurs when the local anesthetic is injected into a blood vessel rather than into the epidural space or when too much is administered even though injected properly. **These reactions can also occur during placement of pudendal or paracervical blocks. All local anesthetics have maximal recommended doses, and these should not be exceeded.** For example, the maximal recommended dose of lidocaine is 4 mg/kg when used without epinephrine and 7 mg/kg when used with epinephrine. Epinephrine delays and decreases the uptake of local anesthetic into the blood stream. Package inserts for all local anesthetics contain appropriate dosing information (Table 17-3).

Local anesthetic reactions have two components: central nervous system (CNS) and cardiovascular. Usually, the CNS component precedes the cardiovascular component. Prodromal symptoms of the CNS reaction include excitation, bizarre behavior, ringing in the ears, and disorientation. These symptoms may culminate in convulsions, which are usually brief. After the convulsions, cognitive depression follows, manifested by the postictal state. The cardiovascular component of the local anesthetic reaction usually begins with hypertension and tachycardia but is soon followed by hypotension, arrhythmias, and in some instances, cardiac arrest. Thus, the cardiovascular component also has excitant and depressant characteristics. One frequently sees the CNS component without the more serious cardiovascular component. Bupivacaine may represent an exception to this principle. **Resuscitation of patients who receive an intravascular injection of bupivacaine is extremely challenging, likely owing to the prolonged blocking effect on sodium channels.**[42] Laboratory evidence supports bupivacaine's increased cardiotoxicity over equianalgesic doses of other amide local anesthetics such as ropivacaine and lidocaine.[43] The manufacturers of bupivacaine have recommended that the 0.75% concentration not be used in obstetrical patients or for paracervical block. However, use of a more dilute concentration does not guarantee safety; bupivacaine and all local anesthetics should be administered by slow, incremental injection.

Adverse events due to local anesthetic toxicity have decreased because of greater emphasis on incremental dosing and use of a test dose, typically containing 15 mcg of epinephrine to exclude unintentional intravenous or subarachnoid catheter placement. Others have questioned the lack of specificity of test doses during labor and the potential harm to the fetus or hypertensive mother.[44] Intravascular injection of 15 mcg of epinephrine produces maternal tachycardia, which may be difficult to differentiate from that seen during a contraction. Non-reassuring fetal heart tones due to decreased uterine blood flow may also occur after intravascular epinephrine, especially when there is fetal compromise.

Treatment of a local anesthetic reaction depends on recognizing the signs and symptoms.[45] Prodromal symptoms should trigger the immediate cessation of the injection of local anesthetic. If convulsions have already occurred, treatment is aimed at maintaining proper oxygenation and preventing the patient from harming herself. Convulsions use considerable amounts of oxygen, which results in hypoxia and acidosis (Table 17-4). Should the convulsions continue for more than a brief period, small intravenous doses of propofol (30 to 50 mg) or a benzodiazepine (2 to 5 mg midazolam) are useful. The depressant effects of these agents add to the depressant phase of the local anesthetic reaction; therefore, appropriate equipment and personnel must be available to maintain oxygenation and a patent airway and to provide cardiovascular support. Rarely, succinylcholine is needed for paralysis to prevent the muscular activity and to facilitate ventilation and perhaps intubation. In cases of complete cardiac collapse, delivery of the infant may facilitate maternal resuscitation. The American Heart Association has stated: "Several authors now recommend that the decision to perform a perimortem cesarean section should be made rapidly, with delivery effected within 4 to 5 minutes of the arrest."[3] **Intravenous lipid emulsion may be an effective therapy for cardiotoxic effects of lipid-soluble local anesthetics such as bupivacaine or ropivacaine.**[46] **Intralipid should be available wherever regional anesthesia is provided.**

ALLERGY TO LOCAL ANESTHETICS

There are two classes of local anesthetics: amides and esters. **A true allergic reaction to an amide-type local anesthetic (e.g., lidocaine, bupivacaine, ropivacaine) is extremely rare. Allergic reactions to the esters (2-chloroprocaine, procaine, tetracaine) are also uncommon but can occur.** They are often associated with a reaction to para-aminobenzoic acid (PABA) in skin creams or suntan lotions. When a patient reports that she is "allergic" to local anesthetics, she is frequently referring to a normal reaction to the epinephrine that is occasionally added to local anesthetics,

TABLE 17-4 BLOOD GAS DETERMINATIONS DURING AND AFTER LOCAL ANESTHETIC–INDUCED CONVULSIONS

particularly by dentists. Epinephrine can cause increased heart rate, pounding in the ears, and nausea, symptoms that may be interpreted as an allergy. Therefore, it is important to document the situation in which the reaction occurred.

HIGH SPINAL OR "TOTAL SPINAL" ANESTHESIA

This complication occurs when the level of anesthesia rises dangerously high, resulting in paralysis of the respiratory muscles, including the diaphragm (C3 to C5). The incidence of total spinal anesthesia after epidural anesthesia is 1 in 16,200 or 0.006%.[39] Total spinal anesthesia can result from a miscalculated dose of drug or unintentional subarachnoid injection during an epidural block. The ASA Closed Claims Project analysis of obstetrical anesthesia liability claims found that the most common cause of maternal death or brain damage in neuraxial anesthesia claims was high block; 80% were associated with dosing epidural anesthesia, and 20% involved spinal anesthesia.[40] The accessory muscles of respiration are paralyzed earlier, and their paralysis may result in apprehension and anxiety and a feeling of dyspnea. The patient usually can breathe adequately as long as the diaphragm is not paralyzed, but treatment must be individualized. Dyspnea, real or imagined, should always be considered an effect of paralysis until proved otherwise. Cardiovascular effects, including hypotension and even cardiovascular collapse, may accompany total spinal anesthesia.

Treatment of total spinal anesthesia includes rapidly assessing the true level of anesthesia. Therefore, individuals who administer major regional anesthesia should be thoroughly familiar with dermatome charts (Figure 17-8) and should also be able to recognize what a certain sensory level of anesthesia means with regard to innervation of other organs or systems. For example, a T4 sensory level may represent total sympathetic nervous system blockade. **Numbness and weakness of the fingers and hands indicates that the level of anesthesia has reached the cervical level (C6 to C8), which is dangerously close to the innervation of the diaphragm.** If the diaphragm is not paralyzed, the patient is breathing adequately, and cardiovascular stability is maintained, administration of oxygen and reassurance may suffice. If the patient remains anxious or if the level of anesthesia seems to be involving the diaphragm, then assisted ventilation is indicated, and endotracheal intubation will be necessary to protect the airway. In addition, cardiovascular support is provided as necessary. Delay in treatment due to inadequate monitoring, absence of the anesthesia provider, lack of airway equipment or emergency drugs in the labor room, or delay in resuscitation during transfer of the patient to the operating room for delivery will worsen outcome.[47] With prompt and adequate treatment, serious sequelae should be extremely rare.

NERVE INJURY

Paralysis after either epidural or spinal anesthesia is extremely rare; even minor injuries such as footdrop and segmental loss of sensation are uncommon. **However, the ASA Closed Claim Project analysis of liability claims notes that the incidence of claims for nerve injury has increased in their most recent review and is now the most common cause of liability in obstetrical anesthesia.**[40] Nerve injury occurs in 0.06% of spinal anesthetics and 0.02% of epidural anesthetics.[48] With commercially prepared drugs, ampules, and disposable needles, infection and caustic injury rarely occur. When nerve damage follows regional analgesia during obstetrical or surgical procedures, the anesthetic technique must be suspected, although causation is rare. Other potential etiologies include incorrectly positioned stirrups, difficult forceps applications, or abnormal fetal presentations. During abdominal procedures, overzealous or prolonged application of pressure with retractors on sensitive nerve tissues may also result in injury. Fortunately, most neurologic deficits after labor and delivery are minor and transient; however, consultation with a neurologist or neurosurgeon should be considered.

A systematic review of serious adverse events among 1.37 million women receiving epidural analgesia during labor

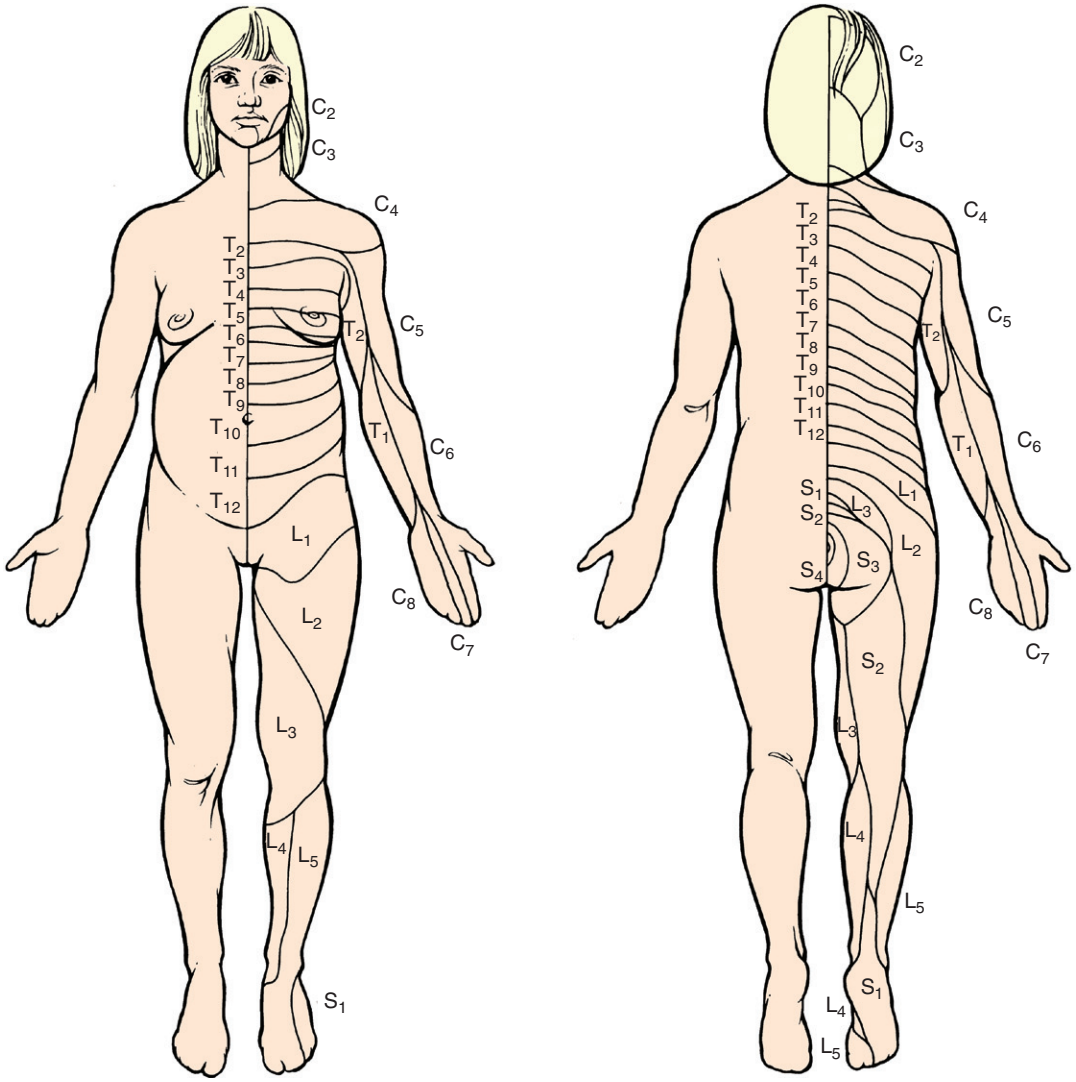

FIGURE 17-8. Dermatome chart. (Modified from Haymaker L, Woodhall B: Peripheral Nerve Injuries. Philadelphia, WB Saunders, 1945.)

found the risks for epidural hematoma and epidural abscess were 1 case per 168,000 women and 1 per 145,000, respectively.[49] The risk for persistent neurologic injury was 1 case per 240,000 women, and the risk for transient neurologic injury was 1 per 6700. One of the more dramatic and correctable forms of nerve damage follows compression of the spinal cord by a hematoma that has formed during the administration of spinal or epidural anesthesia, presumably from accidental puncture of an epidural vessel. If the condition is diagnosed early, usually with the aid of a neurologist or neurosurgeon, the hematoma can be removed by laminectomy and the problem resolved without permanent damage. Fortunately, this is a rare complication. Nonetheless, spinal and epidural blocks are contraindicated if the patient has a coagulopathy or if the patient is pharmacologically anticoagulated. Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome may be a particularly strong risk factor because of multifactorial sources for coagulation defects.[50] Any significant motor or sensory deficit after regional anesthesia should be investigated immediately and thoroughly (Figure 17-8).

Although the incidence of neuraxial infection such as spinal meningitis or epidural abscess is rare, it is an important cause of significant maternal morbidity and mortality. Recently, the Centers for Disease Control and Prevention reviewed five cases of bacterial meningitis linked to intrapartum spinal anesthesia in which one woman died.[51] A common denominator in these cases was that either the anesthesiologist performing the block or visitors in the room were not wearing masks. **Both the American Society of Regional Anesthesia (ASRA) and the ASA have published guidelines on prevention of infection during regional anesthesia that include recommendations to remove jewelry, wash hands, wear a fresh face mask, and disinfect the patient's back using 2% chlorhexidine in alcohol.**[52,53]

Spinal Headache

Spinal headache may follow uncomplicated spinal anesthesia, but it is far more common when, during the process of administering an epidural block, the dura is punctured and spinal fluid leaks out (i.e., "wet tap"). The incidence of this complication varies between 1% and 3%, and its

occurrence depends on the experience of the person performing the epidural block.[54] The risk for postdural puncture headache following CSE is no different than that with epidural analgesia alone, approximately 1.5%.

Once a wet tap occurs, a spinal headache results in as many as 70% of patients. The incidence is much less following spinal anesthesia because smaller, atraumatic (pencil-point) needles are used. **Characteristically, a spinal headache is more severe in the upright position and is relieved by the supine position. A differential diagnosis should include migraine, pneumocephalus from the loss of resistance to air technique, infection, cortical vein thrombosis, preeclampsia, and intracerebral or subarachnoid hemorrhage.**[55] A spinal headache is thought to be caused by loss of cerebrospinal fluid, which allows the brain to settle and thus meninges and vessels to stretch. Hydration, bedrest, abdominal binders, and the prone position have all been advocated as prophylactic measures after known dural puncture. However, most anesthesiologists now agree that these actions are of little value.[55]

When a patient develops a postdural puncture headache (PDPH), she should be counseled about the cause and potential treatment options, which range from conservative to aggressive. Close follow-up, reassurance, and treatment if required are important because headache is the third most common cause of a lawsuit in obstetrical anesthesia.[40] If the headache is mild and interferes minimally with activity, treatment may be initiated with oral analgesics and caffeine or theophylline, which are cerebral vasoconstrictors that may provide symptomatic relief.[56] If simple measures prove ineffective, an epidural blood patch should be considered. About 20 mL of the patient's own blood is placed aseptically into the epidural space, providing a tamponade effect that may result in immediate relief. It may also coagulate over the hole and prevent further cerebrospinal fluid leakage. Patients can be released within 1 to 2 hours. Patients should be instructed to avoid coughing or straining for the first day after insertion of the blood patch. **The epidural blood patch has been found to be remarkably effective and nearly complication free, despite the fact that it is an iatrogenic epidural hematoma.** Prophylactic epidural blood patches inserted through the epidural catheter immediately after delivery are not effective in preventing headaches. A preventive measure that may be effective is passing the epidural catheter through the dural hole at the time of wet tap to provide continuous spinal anesthesia, with removal of the catheter 24 hours after delivery.[57] Injecting preservative-free saline through the catheter before removing the spinal catheter may also decrease the incidence of headache, although these data are preliminary.

Back Pain

Back pain is a common peripartum complaint, and a common concern for women considering regional anesthesia for their delivery. An antepartum survey of pregnant patients, before their delivery or any use of regional anesthesia, found that 69% of patients reported back pain, 58% reported sleep disturbances due to back pain, 57% said it impaired activities of daily living, and 30% had stopped at least one daily activity because of pain.[58] Only 32% informed their obstetrical providers they had back pain, and only 25% of those providers recommended treatment. **Despite concerns that using regional anesthesia contributes to back pain, postpartum surveys indicate that the incidence of back pain after childbirth is the same whether women had regional analgesia for their delivery or not—about 40% to 50% at 2 and 6 months postpartum.**[59,60] Despite these reassuring findings, liability for back pain claims is increasing for obstetrical anesthesiologists.[40]

Breastfeeding Issues

Some patients and providers are concerned that regional analgesia may hinder the newborn's ability to breastfeed effectively.[61] Observational studies showing an association between difficult breastfeeding and anesthetic use during labor do not account for obstetrical events such as prolonged labor or operative delivery, factors that can cause difficulty with early breastfeeding. **Factors contributing to successful breastfeeding include lactation consultation services, maternal motivation, and support from obstetricians and pediatricians.**

There are no randomized trials comparing breastfeeding outcomes in patients who received epidural analgesia or no medication. However, a prospective cohort study found no difference in the number of women successfully breastfeeding 1, 4, and 6 weeks after delivery, whether or not they used epidural analgesia during labor.[62] Large doses of epidural fentanyl (>150 mcg) given during the course of labor may interfere with early breastfeeding success; thus, high concentrations and boluses should be avoided.[63] Not surprisingly, women treated with epidural analgesia for postoperative pain control after cesarean delivery are more successful at breastfeeding than those treated with systemic opioids.[64] Infants of women treated with intravenous PCA after cesarean delivery were less alert and had more neonatal neurobehavioral depression after meperidine than after morphine, probably due to meperidine's active metabolites, and presumably intravenous opioids administered during labor would have the same effect.

Effects on Labor and Method of Delivery

In the past there was significant controversy about how to appropriately counsel patients regarding the effect of regional analgesia on their labor course and risk for cesarean delivery. **The most recent opinion on this subject from the ACOG states: "Neuraxial techniques are the most effective and least depressant treatments for labor pain. The ACOG previously recommended that practitioners delay initiating epidural analgesia in nulliparous women until the cervical dilation reached 4 to 5 cm. However, more recent studies have shown that epidural analgesia does not increase the risks for cesarean delivery. The fear of unnecessary cesarean delivery should not influence the method of pain relief that women can choose during labor."**[65] More recent studies,[66,67] as well as a meta-analysis[68] of eight randomized controlled trials and cohort studies (N = 3320), of early labor versus late initiation of neuraxial analgesia further support the most recent ACOG Committee Opinion that there is no increase in cesarean delivery rate when epidural analgesia is initiated early in labor (<4 cm dilated).

Study Design

Multiple prospective randomized studies of epidural analgesia have been performed both in nulliparous populations

and in mixed populations. However, the poor quality of analgesia provided by systemic opioids typically leads to high rates of crossover of control patients into the epidural analgesia arm. Neither intent-to-treat analysis nor actual-use analysis are entirely satisfactory in this situation. Studies with the lowest crossover rates have accomplished their goal through the use of substantial doses of parenteral opioids, resulting in higher than expected rates of neonatal resuscitation in the opioid groups.[20,22] Nonrandomized studies provide interesting observational data; however, careful analysis of potential confounders is critical because patients who self-select epidural analgesia are clearly different from patients who avoid it. Furthermore, with declining rates of operative vaginal delivery and increasing rates of cesarean delivery, up-to-date studies are needed to examine these outcomes. Of concern, randomized studies are often conducted in academic centers where operative delivery rates in low-risk patients may be significantly lower than in community hospitals. Finally, regional analgesia techniques vary, and modifications in technique occur continuously. More modern techniques use lower concentrations of local anesthetic and titrate the dose to the specific needs of the patient, potentially lowering the risk for operative delivery. Despite these limitations, the published literature offers considerable insight regarding the effects of regional analgesia on the progress of labor and method of delivery.

Progress of Labor and Cesarean Delivery Rate

Management of epidural analgesia and timing of administration should be individualized to the patient's needs and level of pain. Attention should be focused on minimizing local anesthetic concentrations while still providing adequate pain control, and on avoiding routine administration of epidural analgesia in latent labor.

The impact of neuraxial analgesia on cesarean delivery rates has been one of the most important labor and delivery outcomes studied over the past several decades. Multiple studies have evaluated this outcome in an attempt to identify factors associated with cesarean delivery. **Although older observational studies suggested an increased risk for cesarean delivery associated with neuraxial analgesia, the preponderance of recent evidence now supports the use of neuraxial analgesia without a significant increase in cesarean delivery rates.** A recent Cochrane Review assessed the effects of all modalities of neuraxial analgesia (including CSE) on obstetrical outcome when compared with nonepidural or no pain relief during labor.[69] Twenty-one randomized controlled trials involving 6664 women were included. All studies except one compared epidural analgesia with opiates. The authors concluded that epidural analgesia was effective in reducing pain during labor without evidence of a significant difference in the risk for caesarean delivery (relative risk [RR], 1.07; 95% CI, 0.93 to 1.23; 20 trials, 6534 women). Another concern has been a possible dose-response effect; that is, more dense analgesia could result in an increased cesarean delivery rate. Several randomized controlled trials evaluated traditional epidural analgesia with 0.25% bupivacaine compared with low-dose bupivacaine or fentanyl epidural techniques and found no differences in the rate of cesarean delivery.[70] **Although epidural analgesia itself does not increase the risk for cesarean delivery, management of neuraxial analgesia should be individualized to the patient's needs and level of pain, with a focus on minimizing local anesthetic concentrations and motor block while still providing adequate pain control.**

Potential for prolonged labor, increased oxytocin use, and increased risk for instrumental delivery have been additional considerations for clinicians and their patients who receive neuraxial analgesia. Although the relative risk of oxytocin treatment after initiation of epidural analgesia varies considerably depending on obstetrical practice (i.e., rates of induction and active management of labor), systematic reviews[70] evaluating this outcome demonstrate that **epidural analgesia is associated with a significant increase in the use of oxytocin after initiation of epidural analgesia**. Despite aggressive use of oxytocin, there are some effects of epidural analgesia on the length of active labor. **Although neuraxial analgesia may shorten first-stage labor in some women and lengthen it in others, there is little doubt that effective neuraxial analgesia prolongs the second stage of labor by 15 to 30 minutes.** Although few obstetricians in the past would allow the second stage to continue for more than 2 hours, most agree that a delay in the second stage does not adversely affect maternal or neonatal outcome, provided that (1) electronic fetal monitoring confirms reassuring fetal status; (2) maternal hydration and analgesia are adequate; and (3) there is ongoing progress in the descent of the fetal head. ACOG has stated that if progress is being made, the duration of the second stage alone does not mandate intervention. In such cases, **potential strategies for decreasing the risk for instrument-assisted delivery include reducing the density of neuraxial analgesia during the second stage, delaying pushing, and avoiding arbitrary definitions of a prolonged second stage.**

Any analysis of the relationship between neuraxial analgesia and instrument-assisted vaginal delivery is complicated by the strong influence of obstetrical practice and the obstetrician's attitude toward operative vaginal delivery. Also, obstetricians may be more likely to perform elective instrument-assisted delivery in patients with effective analgesia. Three systematic reviews have evaluated the effect of neuraxial analgesia on mode of vaginal delivery.[70-72] These trials included nearly 10,000 patients, and the results suggested that epidural analgesia was associated with an increased risk for instrumental vaginal delivery. However, operator bias is an important consideration. In clinical practice, indications vary widely among obstetricians, and it is often difficult to distinguish between "indicated" and elective instrumental deliveries. Although most obstetricians are more likely to perform such deliveries in women with adequate pain relief, another factor affecting the rate of instrumental vaginal deliveries is whether these deliveries are conducted in teaching institutions. Such deliveries are more likely to be performed in patients with adequate analgesia for the purposes of teaching. Minimizing the risk for instrumental vaginal delivery while maximizing analgesia in such cases requires attention by the anesthesiologist to the individual needs of the patient. Modern neuraxial techniques use lower concentrations of local anesthetic and a titrated dose. These factors likely contribute to lowering the risk for operative delivery in such patients.

In a given population, the risk for cesarean delivery may vary depending on the patient population, obstetrical management, protocols for oxytocin augmentation, obstetrical provider, patient attitudes toward cesarean delivery, and provider comfort with instrument-assisted vaginal delivery, as well as other risk factors. Neuraxial analgesia alone does not increase the risk for cesarean delivery.

Fever

Epidural analgesia during labor is associated with an increase in maternal temperature compared with women receiving no analgesia or systemic opioids alone.[73] In a well-designed study with a low crossover rate (6%), Sharma and colleagues[72] reported a 33% rate of intrapartum fever greater than 37.5° C in nulliparous patients randomized to epidural analgesia, compared with 7% in those receiving parenteral opioids. The more than fourfold increased risk for fever occurred despite relatively minor prolongations in the mean duration of labor (50 minutes). Similarly, Yancey and associates[74] also described an 18-fold increase in the rate of intrapartum fever in nulliparous patients (from 0.6% to 11%) in a single year following the introduction of an epidural analgesia service in their hospital.
