Zidovudine (ZDV) (Retrovir) (AZT) • 300 mg BID	C	*Carcinogen:* Vaginal neoplasms in rodents. *Teratogen:* Increased resorption at extremely high dosage.	Not significantly altered in pregnancy; no change in dose indicated. High placental transfer to fetus.	No evidence of human teratogenicity (1.5-fold increase in birth defects ruled out). Well tolerated, short-term safety demonstrated for mother and infant. Associated with macrocytic anemia.	**Preferred** NRTI for use in combination ARV regimens in pregnancy based on efficacy studies and extensive experience; should be included in regimen unless significant toxicity, d4T use, resistance, or the women is already on a fully suppressive regimen.
Alternative Agents					
Abacavir (ABC) (Ziagen) • 300 mg BID or 600 mg once daily	C	*Carcinogen:* Thyroid tumors in female rats, and liver, preputial, and clitoral gland tumors of mice and rats. *Teratogen:* Developmental toxicity, anasarca and skeletal malformations at 35× human exposure during organogenesis.	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated. High placental transfer to fetus.	No evidence of human teratogenicity (2-fold increase in birth defects ruled out). Hypersensitivity reactions occur in ~5%-8% of nonpregnant persons; a much smaller percentage are fatal and are usually associated with rechallenge. Rate in pregnancy unknown. Patient should be educated regarding symptoms of hypersensitivity reaction; HLA-B*5701 testing identifies patients at risk.	Alternative NRTI for dual nucleoside backbone of combination regimens. Part of a triple NRTI regimen; however, this is less potent virologically and should only be used when NNRTI- or PI-based combination regimens cannot be used.
Didanosine (ddI) (Videx) • ≥60 kg: 400 mg once daily; *with TDF* 250 mg once daily • <60 kg: 250 mg daily; *with TDF* 200 mg once daily	B	*Carcinogen:* Negative *Teratogen:* Negative	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated. Moderate placental transfer to fetus.	Human birth defect rate was 4.7% (19 of 406), compared to 2.7% in the general population; no pattern of defects was discovered. Cases of lactic acidosis, some fatal, have been reported in pregnant women receiving ddI and d4T together.	Alternative NRTI for dual nucleoside backbone of combination regimens. ddI should be used with D4T only if no other alternatives are available.
Emtricitabine (FTC) (Emtriva) • Biologically active form of 3TC • 200 mg capsule once daily	B	*Carcinogen:* Negative *Teratogen:* Negative	Pharmacokinetic study shows slightly lower levels in third trimester compared to postpartum. No clear need to increase dose. High placental transfer to fetus.	No evidence of human teratogenicity (2-fold increase in birth defects ruled out). If HBV co-infected, possible HBV flare if drug is stopped postpartum.	Alternative NRTI for dual nucleoside backbone of combination regimens. Has antiviral activity against HBV.
Stavudine (d4T) (Zerit) • ≥60 kg: 40 mg BID • <60 kg: 30 mg BID	C	*Carcinogen:* Liver tumors in mice and bladder tumors in rats at very high doses. *Teratogen:* Negative, however incomplete ossification of sternebra at very high exposure.	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated. High placental transfer to fetus.	No evidence of human teratogenicity (2-fold increase in birth defects ruled out). Cases of lactic acidosis, some fatal, have been reported in pregnant women receiving ddI and d4T together.	Alternative NRTI for dual nucleoside backbone of combination regimens. d4T should not be used with ddI or AZT.

Tenofovir Disoproxil Fumarate (TDF) (Viread) • 300 mg once daily	B	*Carcinogen:* Liver adenomas in female mice at 16× human exposure. *Teratogen:* Negative, however primate exposure equivalent to 25× the human AUC show reduced fetal growth and bone porosity within 2 months of starting maternal therapy.	Limited studies in human pregnancy; data indicate AUC lower in third trimester than postpartum but trough levels adequate. High placental transfer to fetus.	No evidence of human teratogenicity (2-fold increase in birth defects ruled out). Clinical studies in humans (particularly children) show bone demineralization with chronic use; clinical significance unknown. If HBV co-infected, possible HBV flare is drug is stopped postpartum.	Alternative NRTI for dual-NRTI backbone of combination regimens. TDF would be a preferred NRTI in combination with 3TC or FTC in women with chronic HBV infection. Because of potential renal toxicity, renal function should be monitored.
NNRTIs					
Preferred Agent					
Nevirapine (NVP) (Viramune) • 200 mg once daily for 14 days, then 200 mg BID	C	*Carcinogen:* Hepatocellular adenomas and carcinomas in mice and rats. *Teratogen:* Negative	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated. High placental transfer to fetus.	No evidence of human teratogenicity (2-fold increase in birth defects ruled out). Increased risk of symptomatic, often rash-associated, and potentially fatal liver toxicity among women with $CD4^+$ counts >250/mm^3 when first initiating therapy, pregnancy not thus far found to increase risk.	NVP should be initiated in pregnant women with $CD4^+$ counts >250 cells/mm^3 only if benefit clearly outweighs risk due to the increased risk of potentially life-threatening hepatotoxicity in women with high $CD4^+$ counts. Women who become pregnant while taking NVP-containing regimens and are tolerating them well should continue therapy regardless of $CD4^+$ count.
Special Circumstances					
Efavirenz (EFV) (Sustiva) • 600 mg once daily at or before bedtime	D	*Carcinogen:* Hepatocellular adenomas and carcinomas, pulmonary alveolar/ bronchiolar adenomas in female mice at 1.7× human exposure. *Teratogen:* Increased fetal resorption, anencephaly, anophthalmia, microphthalmia, and cleft palate in cynomolgus monkey at exposures comparable to humans.	AUC decreased during third trimester, compared with postpartum, but nearly all third-trimester subjects exceeded target exposure and no change in dose is indicated. Moderate placental transfer to fetus.	Prospective data from the Antiretroviral Pregnancy Registry documents birth defects in 17 of 623 live births following first trimester EFV exposure, including a single case of neural tube defect with fetal alcohol syndrome and a single case of bilateral facial clefts, anopthalmia and amniotic band, (2.7%, 2-fold increase in overall birth defects ruled out). (REF) Risk of EFV is unclear, given the low prevalence of neural tube defects (0.1%-0.4%) in the general population. Retrospective data includes 6 case reports of central nervous system defects following EFV exposure. Meta-analysis of 1437 first trimester EFV-exposed live births showed no increase in overall birth defects (2.0%) and 1 neural tube defect overall incidence 0.07%).(Ford, 2011)	EFV should be avoided in the first trimester. After the first trimester, EFV can be considered if this is the best patient choice. If EFV is continued postpartum, adequate contraception must be ensured. Women of childbearing age must be counseled regarding the teratogenic potential of EFV and avoid pregnancy while using this drug. Because no contraceptive method is 100% effective, alternative ARV regimens should be strongly considered in women of childbearing potential.
Insufficient Data to Recommend Use					
Etravirine (ETR) (Intelence) • 200 mg BID	B	*Carcinogen:* Negative *Teratogen:* Negative	Limited PK data in human pregnancy, but is comparable to nonpregnant adults. Limited data suggests high placental transfer to fetus.	No experience in human pregnancy.	Safety and pharmacokinetic data are insufficient to recommend use during pregnancy.

TABLE 50-3 COMMONLY USED ANTIRETROVIRAL DRUGS IN PREGNANCY—cont'd

ARV DRUG DOSAGE RECOMMENDATIONS	FDA PREGNANCY CATEGORY	ANIMAL STUDIES CARCINOGEN/ TERATOGEN	PHARMACOKINETICS IN PREGNANCY	CONCERNS IN PREGNANCY	RECOMMENDED USE IN PREGNANCY
Rilpivirine (RPV) (Endurant) • 25 mg once daily		*Carcinogen:* Hepatocellular neoplasms at 21× human exposure. *Teratogen:* Negative	No pharmacokinetic studies in human pregnancy. Placental transfer unknown.	No experience in human pregnancy.	Safety and pharmacokinetic data are insufficient to recommend use during pregnancy.
Protease Inhibitors					
Recommended Agent					
Lopinavir/ Ritonavir (LPV/r) (Kaletra) • Built-in low-dose ritonavir boosting: 400/100 mg BID • In third (and second) trimester: 600/150 mg BID	C	*Carcinogen:* Hepatocellular adenomas and carcinomas in rodents at 1.6-2.2× (mice) and 0.5× (rats) human exposure. *Teratogen:* No teratogenicity, but fetal developmental toxicity observed at a maternally toxic dose.	AUC decreased in second and third trimester with standard dosing. LPV/r 600 mg/150 mg twice daily resulted in AUC similar to nonpregnant adults receiving LPV/r 400 mg/100 mg twice daily. Low placental transfer to fetus.	No evidence of human teratogenicity (2-fold increase in birth defect ruled out). Well-tolerated, short-term safety demonstrated in Phase I/II studies.	PK studies support increasing LPV/r to 600/150 mg BID in the third trimester, and considering this increased dose in the second trimester, especially in PI experienced patients. An alternative strategy is adding a pediatric LPV/r tablet (100/25 mg) to the standard adult dose. If standard dosing is used, monitor virologic response and LPV drug levels. Once-daily dosing is not recommended in pregnancy, as no data exist to evaluate the adequacy of drug levels with this administration.
Alternative Agents					
Atazanavir (ATV) (Reyataz) • Combined with low-dose ritonavir boosting (ATV 300 mg + RTV 100 mg once daily; adjust dose for TDV, EFV, or H_2 blocker)	B	*Carcinogen:* Benign hepatocellular adenomas in female mice at 2.8× human exposure. *Teratogen:* Negative	PK studies of ATV with RTV boosting during pregnancy suggests that standard dosing yields decreased AUC; however, for most pregnant women no dose adjustment was needed. TDF reduces ATV AUC in all patients 25%. Low placental transfer to fetus.	No evidence of human teratogenicity (2-fold increase in birth defects ruled out). Adults treated with ATV frequently have elevated indirect bilirubin levels; increased bilirubin has been reported in some infants born to mothers receiving ATV and is associated with uridine diphosphate glucuronosyltransferase 1 (UGT1A1) genotypes linked to decreased UGT function. Neonatal hypoglycemia has been reported in 3 of 38 ATV-exposed infants.	Alternative PI for use in combination regimens in pregnancy. Should give as low-dose RTV-boosted regimen, may use once-daily dosing. A study of 41 pregnant women concluded that no dose adjustment was needed for the majority of pregnant women infected with HIV strains susceptible to ATV. ART-experienced pregnant women on either TDV or an H_2 blocker (not both) should increase ATV dose to 400 mg (with RTV 100 mg).
Ritonavir (RTV) (Norvir) • 100-400 mg per day in 1-2 divided doses as booster	B	*Carcinogen:* Hepatocellular adenomas and carcinomas in male mice. *Teratogen:* No teratogenicity, but fetal developmental toxicity observed at maternally toxic dose.	RTV levels are reduced in pregnancy, including low-dose RTV regimens used to boost the concentrations of other PIs. Minimal placental transfer to fetus.	Limited experience at full dose in human pregnancy; is currently used as low-dose RTV boosting with other PIs. No evidence of human teratogenicity (2-fold increase in birth defects ruled out).	Given low levels in pregnant women when used alone, should only be used in combination with second PI (dual PI treatment) or as low-dose RTV "boost" to increase levels of another PI.
Saquinavir HGC (hard-gel capsule) (SQV) (Invirase) • Combined with low-dose ritonavir boosting (SQV 1000 mg + RTV 100 mg) BID	B	*Carcinogen:* Negative *Teratogen:* Negative	Limited PK data suggests that 1000 mg SQV HGC/100 mg RTV twice daily achieves adequate SQV drug levels in pregnant women. Minimal placental transfer to fetus.	Well-tolerated, short-term safety demonstrated for mother and infant for SQV in combination with low-dose RTV boosting. Baseline ECG recommended before starting because PR and/or QT interval prolongations have been observed.	PK data on SQV in pregnancy is limited; however the HGC and tablets both appear to achieve adequate drug levels. RTV-boosted SQV is an alternative PI for combination ARV regimens in pregnancy and are alternative, initial ARV recommendations for nonpregnant adults. Data are too limited to recommend once daily dosing within pregnancy at present.

Continued

Use in Special Circumstances					
Indinavir (IDV) (Crixivan) • Combined with low-dose ritonavir boosting (IDV 800 mg + RTV 100-200 mg) BID	C	*Carcinogen:* Thyroid adenomas in male rats at 1.3× human exposure. *Teratogen:* Negative	Limited studies using IDV showed markedly lower pregnancy levels, compared to postpartum, although HIV RNA suppression was seen. Minimal placental transfer to fetus.	No evidence of human teratogenicity (2-fold increase in birth defects ruled out). Pill burden and potential for renal stones are concerns. In rhesus monkeys neonatal IDV exacerbated transient physiologic hyperbilirubinemia; this was not seen following in utero exposure.	Given limited data regarding dosing, trough drug levels should be monitored during IDV use in pregnancy. IDV should only be used when preferred and alternative agents cannot be used, and this PI must be given as part of a low-dose RTV-boosted regimen. Furthermore, IDV as the sole "therapeutic" PI is not recommended in HIV-infected pregnant patients.
Nelfinavir (NFV) (Viracept) • 1250 mg BID	B	*Carcinogen:* Thyroid follicular adenomas and carcinomas in rats. *Teratogen:* Negative	Using the new 625-mg tablet formulation and 1250 mg BID dosing, lower AUC and peak levels were seen in the third trimester versus postpartum; however, viral load was suppressed in most women. Minimal to low placental transfer to the fetus.	No evidence of human teratogenicity (can rule out 2-fold increase in overall birth defects). Well-tolerated, short-term safety demonstrated for mother and infant.	Given extensive experience with use in pregnancy, NFV might be considered in special circumstances to reduce perinatal HIV transmission in women for whom therapy would not otherwise be indicated and/or when alternative agents are not tolerated. In clinical trials of initial therapy in nonpregnant adults, NFV based regimens had a lower rate of viral response compared with LPV/r or EFV-based regimens, but similar viral response to ATV or NVP-based regimens.
Insufficient Data to Recommend Use					
Darunavir (DRV) (Prezista) • Must be combined with low-dose RTV boosting • ARV-naïve (DRV 800 mg + RTV100 mg) once daily • ARV exp, with mutations: (DRV 600 mg + RTV 100 mg) BID	C	*Carcinogen:* Hepatic adenomas and carcinomas, thyroid neoplasms (male rats) at 0.4-0.7× (mice) and 0.7-1× (rats) human exposure. *Teratogen:* Negative	No PK studies in human pregnancy. Low to moderate placental transfer to fetus.	Very limited experience in human pregnancy.	Safety and PK data in pregnancy are insufficient to recommend use in ARV-naïve patients. Must give as low-dose RTV-boosted regimen.
Fosamprenavir (FPV) (Lexiva) • A prodrug of amprenavir, recommended to be combined with low-dose RTV boosting (FPV 1400 mg + RTV 100-200 mg) once daily or FPV 700 mg + RTV 100 mg BID)	C	*Carcinogen:* Interstitial cell hyperplasia and uterine endometrial adenocarcinoma in rats. In all rodents hepatic adenomas and carcinomas, thyroid adenomas, at 0.1-0.7× (mice) and 0.3-1.4× (rats) human exposure. *Teratogen:* Increased abortion in rabbits, decreased fertility and gestational body weights in rats.	With RTV boosting, AUC is reduced in the third trimester; however, levels appear adequate for patients without PI resistance mutations. Low placental transfer to fetus.	Limited experience in human pregnancy.	Safety and PK data in pregnancy are insufficient to recommend use in ARV-naïve patients. Recommended to be given as low-dose RTV-boosted regimen.
Tipranavir (TPV) (Aptivus) • Must be combined with low-dose RTV boosting • (TPV 500 mg + RTV 200 mg) BID	C	*Carcinogen:* Hepatic adenomas and carcinomas in mice below human exposure levels; benign thyroid adenomas in female rats at human exposure levels. *Teratogen:* Negative	Ongoing study in human pregnancy. Unknown rate of placental transfer to fetus.	Ongoing study in human pregnancy.	Safety and PK data in pregnancy are insufficient to recommend use in ARV-naïve patients. Must give as low-dose RTV-boosted regimen.

TABLE 50-4 PROPHYLACTIC ANTIBIOTIC REGIMENS FOR COMMON OPPORTUNISTIC INFECTIONS*

CONDITION	INDICATION FOR PROPHYLAXIS	ANTIBIOTIC REGIMEN
Pneumocystis jiroveci pneumonia	Prior infection or CD4 <200/mm^3	TMP-SMX 1 DS tablet qd indefinitely
Toxoplasmic encephalitis	CD4 <100/mm^3, serology	TMP-SMX 1 DS tablet qd indefinitely
Tuberculosis	+PPD >5 mm No active disease on chest radiograph	300 mg INH and 50 mg pyridoxine qd ×12 mo
Disseminated infection with *Mycobacterium avium* complex (MAC)	CD4 <50/mm^3	1200 mg azithromycin weekly
Cryptococcosis	CD4 <50/mm^3	Prophylaxis not recommended Patients treated for acute cryptococcal infection should receive 200 mg fluconazole qd indefinitely

*Recommendations in this table are based on guidelines from the CDC, NIH, and IDSA.[23]
INH, Isoniazid; TMP-SMX, trimethoprim-sulfamethoxazole.

preventing perinatal HIV transmission. Commonly encountered alternative agents include abacavir, which is associated with hypersensitivity reactions. HLA-B*5701 testing identifies patients at risk; testing should be performed and documented prior to initiating this therapy.[14] Tenofovir is a preferred NRTI for HIV-infected adults; however, it is an alternative agent in pregnancy secondary to concerns regarding fetal and postnatal growth and bone mineralization. All NRTIs bind to mitochondrial γ-DNA polymerase, potentially causing dysfunction manifesting as clinically significant myopathy, cardiomyopathy, neuropathy, lactic acidosis, or fatty liver, resembling HELLP syndrome. Lactic acidosis and hepatic failure have been noted with long-term, combined stavudine and didanosine use, linked to a genetic defect in mitochondrial fatty acid metabolism, so this regimen should not be used in pregnancy.[14] Mitochondrial toxicity has been observed in children born to HIV-infected mothers treated with NRTIs,[18,19] although no increase in mortality was observed[20]; long-term follow-up is ongoing.

NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

NNRTIs are typically used in combination regimens with two NRTI drugs. Nevirapine (NVP), the preferred agent in pregnancy, is associated with rash-associated hepatotoxicity. This drug should not be used for initial treatment in ART-naïve pregnant women with CD4$^+$ cell counts greater than 250 cells/mm^3; however it is safe to continue this drug in women becoming pregnant while taking NVP-containing regimens. Efavirenz (EFV), the preferred NNRTI for nonpregnant adults, is associated with central nervous system (CNS) defects. Although the relative risk is unclear, this drug should not be used in the first trimester of pregnancy.[21]

PROTEASE INHIBITORS

PIs are typically paired with two NRTI drugs and are characterized by minimal transplacental passage and few adverse side effects. Low-dose ritonavir boosting improves the pharmacokinetics of several of these drugs in all patients. PIs are associated with hyperglycemia in adults, but it is unclear if pregnancy increases the risk[22]; an early glucose challenge test followed by repeat testing after 28 weeks is reasonable in "high-risk" patients. Conflicting data exists regarding preterm delivery in women receiving PIs (discussed in counseling section). Lower serum concentrations of lopinovir/ritonavir, atazanavir, and nefinavir have been reported in pregnant women; adjusted dosage regimens are detailed in Table 50-3.[14]

OPPORTUNISTIC INFECTION PROPHYLAXIS

Patients with a CD4 count below 200 cells/mm^3 should also receive prophylaxis against opportunistic infections (OIs). Transient CD4 count decreases may occur secondary to pregnancy-associated hemodilution; in these cases the relative percentage of CD4$^+$ cells (Table 50-2) can be used to guide decisions regarding OI prophylaxis. Prophylaxis regimens for *Pneumocystis jiroveci* pneumonia, toxoplasmosis, tuberculosis (TB), *Mycobacterium avium* complex (MAC), and cryptococcosis are listed in Table 50-4. When HIV-untreated patients are diagnosed with a treatable OI, including TB, MAC, PCP, toxoplasmosis, histoplasmosis, HBV, CMV, VZV, or cryptococcal meningitis, consideration should be given to initiating OI treatment prior to starting ART to avoid immune reconstitution inflammatory syndromes (IRIS). At advanced gestational age or when diagnosed with an OI without specific treatment, ART may be started prior to or concurrent with treatment.[23]

SUMMARY

The preferred regimen for ART-naïve patients is AZT, 3TC, and lopinavir/ritonavir. Patients entering pregnancy on ART with complete viral suppression should continue their current therapy, unless a component of their regimen is contraindicated in pregnancy. Recommendations for ARV drug regimens during pregnancy should be individualized according to the woman's specific ARV history and the presence of comorbidities; incorporating the use of one or more NRTIs with good placental passage is recommended. The NRTIs lamivudine, emtricitabine, and tenofovir have antiviral activity against hepatitis B, therefore tenofovir in combination with emtricitabine or 3TC is the preferred NRTI backbone for HBV/HIV co-infected women. As needed, consultation with specialists in the treatment of HIV infection is advised for women with previous ARV use for maternal indications, who demonstrate significant ARV resistance upon testing, or when there is a suboptimal response to ART.[14] When a patient presents late in pregnancy, ARV therapy should be started immediately and not delayed for resistance testing results. Testing should still be performed because the information is important for ongoing patient care and can be used to modify treatment if needed.

Ongoing Management

In addition to routine prenatal care and evaluation, viral load and CD4 count assessment should be performed monthly when starting a new medication regimen or a change in viral load is detected. Patients on stable ART regimens and suppressed viremia can have viral loads and CD4 counts checked in each trimester. Vaccinations (as needed) should include the following: pneumococcus, influenza, hepatitis B (for women $HBsAg^-$, $HBcAb^-$, $HBsAb^-$), and hepatitis A (for women with chronic HBV infection). Women with HBV co-infection should have liver transaminase testing 1 month after initiating ARV and every 3 months thereafter. Coordination of services among prenatal care providers, primary care and HIV specialty care providers, mental health and drug abuse treatment services, and public assistance programs are essential to ensure that infected women remain active participants in their care and adhere to their ARV drug regimens.

Antenatal Karyotype Determination

In patients desiring fetal karyotype determination, the risks and benefits of amniocentesis or chorionic villous sampling (CVS) should be discussed and referral to a genetic counselor made. One study assessed vertical HIV transmission following amniocentesis; 1 of 61 infants was infected, which was not significantly different than the transmission rate in women deferring amniocentesis.[24] A second prospective cohort study reported no increase in mother-to child transmission rates in the 162 women undergoing amniocentesis (of 9302 HIV-infected pregnancies); moreover, no cases of MTCT were identified in 81 women receiving ART at the time of amniocentesis.[25] Larger studies are needed to better estimate the risk of HIV transmission following amniocentesis or CVS; however, published reports suggest that there is no increased risk of HIV transmission.[14]

Intrapartum Management of HIV

Every effort should be made to avoid instrumentation increasing the neonate's exposure to infected maternal blood and secretions. Recommendations include leaving the fetal membranes intact as long as possible, avoiding fetal scalp sampling and fetal scalp electrode placement, and reserving episiotomy and assisted vaginal delivery for select circumstances. If spontaneous rupture of membranes (SROM) has occurred, augmentation and/or induction of labor with pitocin should not be delayed for AZT administration. Intrapartum maternal IV AZT is given as a loading dose of 2 mg/kg administered over 1 hour and a maintenance dose of 1 mg/kg/hr.[15] Other ART should be taken with a sip of water, with the exception of stavudine, which is antagonistic to AZT and should be withheld. AZT is given intrapartum to all women, even those with AZT resistance, as wild type virus is most often transmitted. AZT is metabolized to its active form within the placenta and has good CNS penetration. If elective cesarean section is planned, patients should receive IV AZT for 3 hours prior to the procedure. However, if operative delivery is indicated for obstetric reasons, delivery must not be delayed for AZT administration. In cases of uterine atony, methergine should be avoided if possible in patients receiving a PI or efavirenz. These drugs are CYP3A4 inhibitors and concomitant ergotamine use is associated with exaggerated vasoconstrictive responses.

Intrapartum Testing

Rapid HIV testing should be performed for all women in labor without a documented HIV test during pregnancy unless the patient declines intrapartum testing, because 40% to 85% of HIV-infected infants in the United States are born to women whose HIV status is unknown prior to delivery.[26] Women who are found to be HIV seropositive upon rapid testing should be given intrapartum and postpartum ARV prophylaxis to limit perinatal HIV transmission without waiting for confirmatory testing.[14]

Spontaneous Rupture of Membranes (SROM)

Increasing duration of ruptured membranes is associated with perinatal HIV transmission; however, the incremental increased risk of transmission is not clinically significant. Meta-analysis of 4721 deliveries determined that the risk of HIV transmission increases by 2% over the baseline transmission risk (after adjusting for all other factors influencing transmission) for each hour increment following rupture of membranes.[27] Presuming a patient on ART with an undetectable viral load has a baseline perinatal HIV transmission rate of 2%, the risk of transmission after 1 hour of ruptured membranes would be 2.04%, and after 8 hours the risk of HIV transmission would be 2.32%. Given that prolonged SROM does not appreciably increase HIV transmission risk in term patients, we do not recommend elective cesarean delivery, as it is unlikely to reduce perinatal HIV transmission risk in patients being actively managed using oxytocin for augmentation or induction.

Untreated Women

For HIV-infected women who have not received ART before labor, IV AZT should be given during labor. Maternal single-dose NVP is not recommended; there is no added efficacy and a high likelihood of maternal harm, specifically the emergence of resistant virus. The safest, most effective option to reduce perinatal HIV transmission in this setting is expanded infant prophylaxis, consisting of AZT for 6 weeks with the addition of three doses of NVP in the first week of life (at birth, 48 hours post birth, and 96 hours after the second dose).[14] Providers should also evaluate whether the patient is a candidate for initiation of maternal therapy postpartum.

Elective Cesarean Delivery

Scheduled cesarean delivery at 38 weeks' gestation, documented by last menstrual period and ultrasonography, is recommended for women with HIV RNA levels >1000 copies/mL near the time of delivery, irrespective of ART, and for women with unknown HIV RNA levels near the time of delivery. These recommendations are based on studies conducted when the majority of HIV-infected women received AZT monotherapy or no ART, whereas a more recent study of 4864 European women showed that the perinatal HIV transmission rate in women receiving at least 14 days of ARV was 0.8%, regardless of the mode of delivery.[16] At this gestation the risk of any neonatal adverse event, including death, respiratory complications, hypoglycemia, sepsis, or NICU admission is 11%, as

compared to 8% at 39 weeks. HIV-infected women have increased morbidity and mortality following cesarean delivery, and the risk of complications is related to the degree of immunosuppression. Therefore, the patient's autonomy in decision-making regarding the route of delivery should be respected and prophylactic antibiotics should be administered.

Cesarean delivery after the onset of labor or SROM does not protect against HIV transmission, so in this setting we recommend delivery for obstetrical indications, irrespective of viral load. Scheduled cesarean delivery is not recommended for preventing perinatal HIV transmission in women receiving combination ART who have plasma HIV RNA levels <1000 copies/mL near the time of delivery. Data are insufficient to evaluate the potential benefit of cesarean delivery in this group, and given the low rate of transmission in these patients, it is unclear whether scheduled cesarean delivery would confer additional benefit in reducing HIV transmission. Delivery decisions should be individualized based on discussion between the obstetrician and the mother.

Postpartum Care of the HIV-Infected Woman

One of the primary issues following delivery is managing the woman's HIV infection outside of pregnancy. Women who have not received antepartum ART therapy can be started on ART postpartum, if indicated for their health as discussed later. For women receiving ART during pregnancy, they should establish a relationship with an HIV-medicine provider during the latter part of pregnancy, to transition into ongoing care. The guidelines for managing HIV infection in adults recommend treatment for individuals with a CD4 count below 350 cells/mm^3 or an HIV RNA level greater than 55,000 copies/mm^3, based on randomized, controlled clinical trial data demonstrating reduced morbidity and mortality.[12] The HIV treatment guidelines also make a moderate-to-strong recommendation for initiating lifelong ART in individuals with CD4 cell counts between 350 and 500 cells/mm^3, based on observational studies suggesting a relative decrease in mortality and possibly a decrease in complications such as cardiovascular events with initiation of ART in this setting compared with waiting until CD4 cell counts drop below 350 cells/mm^3. For individuals with CD4 counts >500 cells/mm^3, some experts would recommend initiating lifelong therapy, whereas other experts view this as optional, given that data are inconclusive on the clinical benefit of starting treatment at higher CD4 cell counts (>500 cells/mm^3). The adult HIV treatment guidelines discourage interruption of therapy; however, no increased risk of disease progression has been shown in studies of pregnant women with relatively high CD4 counts who stop ARV drugs after delivery. The potential benefits of early, continued therapy, including decreased HIV transmission risk to an uninfected partner, and consideration of future childbearing plans (to avoid episodic receipt of ART), must be weighed against possible drug toxicity, cost, and the risk of development of viral resistance with suboptimal adherence, which may be more likely during the postpartum period. Given the complexity of this decision, the risks and benefits of continuing or stopping ART postpartum should be discussed with women prior to delivery in consultation with the provider assuming responsibility for the woman's HIV care following the postpartum period.

If the patient continues ART postpartum, standard medication doses can be used immediately following delivery, predominantly affecting PIs. If ART is discontinued following delivery, all drugs should be stopped simultaneously, unless the patient is on an NNRTI-containing regimen. For women receiving NNRTI-based regimens, continuing the dual-NRTI backbone for at least 7 days after stopping the NNRTI is recommended to reduce the development of NNRTI resistance. An alternative, more conservative strategy is to replace the NNRTI with a PI while continuing the NRTIs, then to discontinue all the drugs at the same time. The optimal interval between stopping an NNRTI and stopping the other ARV drugs is unknown, but at least 7 days is recommended. Drug concentrations may be detectable for more than 3 weeks after EFV discontinuation; therefore some experts recommend continuing the other ARV agents, or substituting a PI for EFV in addition to the other agents for up to 30 days.[14]

Infant and maternal postpartum ARV prophylaxis significantly lowers, but does not completely eliminate, the risk of postnatal HIV transmission through breast milk. Studies showing this were performed in areas of the world where formula feeding is not a viable alternative. Because the benefits of breastfeeding in the United States do not outweigh the risk of HIV transmission, breastfeeding is not recommended for HIV-infected women in the United States. Women should also be counseled about the availability of highly effective contraceptives, including long-term reversible methods (implants, injectables, and IUDs) to be used in conjunction with condoms, to prevent unintended pregnancy. Finally, women should be counseled regarding the potential that the demands of caring for a new baby could make adherence to ART more difficult; nonetheless, maintaining adherence can prolong the effectiveness of ART.[14]

Infant Screening and Diagnosis

Because the fetus receives maternal immunoglobulin G (IgG) by transplacental passage, serologic tests of the HIV-exposed neonate will almost always be positive. In infants the diagnosis of HIV infection is made via PCR amplification of HIV DNA (more sensitive for the neonatal period) or RNA assays. Virologic tests to diagnose HIV infection should be performed within the first 14 to 21 days of life, at 1 to 2 months, and at 4 to 6 months of age. Two positive tests (on different specimens, excluding cord blood) are required to diagnose HIV infection; one positive test is a presumptive diagnosis. HIV is presumptively excluded with two or more negative tests, one at age 14 days or older and the second at age 1 month of older; definitive exclusion in a nonbreastfed infant is based on two negative tests at age 1 month or older and at age 4 months or older. Further details on case definitions for HIV infection are available from the CDC at www.cdc.gov.[9]

Factors Influencing Transmission

Perinatal HIV transmission risk is associated with cigarette smoking, illicit drug use, genital tract infections, and unprotected sexual intercourse with multiple partners

during pregnancy. Eliminating these modifiable risk factors not only reduces perinatal HIV transmission but improves maternal health. Other key factors influencing HIV transmission are listed in the box, Factors Increasing the Risk of Perinatal HIV Transmission. Most perinatal HIV transmission occurs within the intrapartum period and effective ART, or elective cesarean delivery in patients without viral suppression, substantially reduces transmission. A minority of infected infants acquire HIV in utero, as characterized by an infant who is PCR positive at birth. Most studies were not designed or powered to prevent in utero HIV transmission; however, newly reported data suggest that early, sustained control of viral replication may prevent in utero HIV transmission. The study evaluated perinatal transmission risk factors in women with HIV RNA <500 copies/mL at delivery; the overall HIV transmission rate was 0.5% in this population. HIV transmitters were less likely to have received ARV drugs at the time of conception than nontransmitters; moreover, HIV transmitters were less likely to have HIV RNA <500 copies/mL at 14, 28, and 32 weeks of gestation. Among women starting ARV during pregnancy, viral load decreased earlier in nontransmitting women, with both groups initiating therapy at the same gestational age (30 weeks). **This suggests that early and sustained control of viral replication is associated with decreased HIV transmission (including starting therapy prior to conception), and supports initiating ARV drugs as early in pregnancy as possible for all women.**[14,16]

Factors Increasing the Risk of Perinatal HIV Transmission

- History of previous child with HIV infection
- Mother with AIDS
- Preterm delivery
- Decreased maternal CD4 count
- High viral load
- Firstborn twin
- Chorioamnionitis
- Modifiable factors (cigarette smoking, illicit drug use, STDs, unprotected sexual intercourse with multiple partners during pregnancy)
- Intrapartum blood exposure (e.g., episiotomy, vaginal laceration, forceps delivery)
- Delivery following prolonged rupture of membranes
- Breastfeeding

ART and viral load at delivery are independent risk factors for HIV transmission; therefore ART is recommended for all women regardless of whether complete viral load suppression can be achieved. Moreover, this strategy protects neonates born following SROM or spontaneous labor occurring prior to a "planned elective cesarean delivery." Mechanisms of protection include the following: using ARVs with good placental transfer, and permitting adequate systemic drug levels in infants at birth. This is likely important when the fetus is exposed to virus within the birth canal, and when the fetus is the recipient of maternal-fetal blood transfusion during uterine contractions. ARVs can also decrease genital tract viral load and be excreted into genital tract secretions; AZT and 3TC are present at high concentrations within genital secretions, another potential mechanism of protection against HIV transmission. Most perinatal HIV transmission in the United States occurs in women who are not known to be HIV-infected prior to the birth of their child. Given this knowledge it is critical to emphasize the importance of prenatal care, universal HIV testing, and strategies to diagnose acute HIV infection in late pregnancy and during breastfeeding.

Preconception Counseling for HIV-Infected Women

Health care providers should discuss childbearing intentions, including preconception counseling and care, with all of their patients in a nonjudgmental manner as recommended by the ACOG and the CDC. Issues relevant to HIV-infected women include HIV disease status assessment, hepatitis B status assessment, the need for prophylaxis or treatment of opportunistic infections, and evaluating and potentially changing therapy based on the effectiveness and teratogenic potential of drugs within the ARV regimen. As approximately half of all pregnancies in the United States are unintended, avoiding drugs of teratogenic potential in women of reproductive age should be considered. It is also recommended that HIV-infected women attain a stable, maximally suppressed viral load prior to conception, because early and sustained control of HIV replication may be associated with maximally decreasing perinatal transmission. Counseling should also include discussing the influence of HIV on pregnancy, appropriate contraceptive choices to reduce the likelihood of unintended pregnancy and account for the fact that ART (predominantly NNRTIs and PIs) reduces hormonal contraceptive efficacy, and safe sexual practices to minimize the risk of acquiring sexually transmitted infections or acquiring more virulent or resistant HIV strains.[14]

HIV Discordant Couples

HIV-uninfected pregnant women with HIV-infected partners may seek consultation. Recommendations are to review and encourage safe sexual practices, including consistent use of barrier contraception, and establish a plan for HIV screening. As a high-risk patient, first and third trimester serum screening is appropriate; routine screening should not include viral load determination, because serology is sufficiently sensitive with a lower false-positive rate. If women present to labor and delivery without documented negative serology at 36 weeks, rapid intrapartum testing should be performed. Women should also be counseled to recognize the signs and symptoms of acute HIV infection and advised to seek immediate care if they experience these symptoms (diagnosis of acute HIV infection is discussed in the section on screening).

Consultation in the preconception period should include screening and treatment of genital tract infections in both partners, because inflammation is associated with viral shedding and increased HIV acquisition in both partners. This is also an opportunity to ensure that the HIV-infected partner is on an ARV regimen with maximal or complete suppression of viral load. Methods of safe conception depend on which partner is HIV infected. For the HIV-infected woman the safest method of conception is via artificial insemination. This can be accomplished by the

patient at home using a syringe. If the HIV-infected partner is male, the goal is to achieve pregnancy with as few sperm exposures as possible. The possibility of using donor sperm should be considered; if this is not an option sperm analysis should be performed because HIV and ARV may reduce sperm count and quality, raising the possibility that attempting conception is futile. Sperm preparation techniques coupled with intrauterine insemination (potentially with ovulation induction), in vitro fertilization, or intracytoplasmic sperm injection have been reported to be effective in avoiding seroconversion in uninfected women and offspring. The National Perinatal HIV Hotline (1-888-448-8765) is a resource for a list of institutions offering reproductive services for HIV-serodiscordant couples. In patients without resources enabling assisted reproductive technology, timed periovulatory unprotected intercourse (condoms all other times) with a maximally suppressed partner is probably the safest way to facilitate conception. Oral embtricitabine/tenofovir postexposure treatment prevented HIV transmission to males; however, this regimen did not protect women from HIV acquisition. Tenofovir gel prevented HIV acquisition in women, but it is not yet commercially available.[14]

Counseling

Ongoing care of the HIV-infected pregnant woman is enhanced by having a multidisciplinary team, which may include the physician(s), social workers, nutritionist, psychologists, and peer counselors. Management should include frequent visits and ongoing discussion regarding adherence to medication regimens to reduce perinatal HIV transmission and prevent the development of resistance to ART. Patients should be counseled about the impact of HIV infection on pregnancy, including the risk of perinatal transmission, side effects of medications, potential methods of delivery, and treatment options. Studies have shown that pregnancy does not affect the progression of HIV disease. It is unclear whether ART influences preterm delivery. Some studies have shown an increased risk; however, a recent prospective cohort study enrolling more than 800 patients between 2002 and 2008, in which all patients received combination ART, did not find an increased incidence of preterm birth in women receiving PIs.[28] Although a potential increased risk of preterm birth with ART cannot be fully ruled out, the clear maternal health benefits and reduced perinatal HIV transmission support the use of ART during pregnancy. Ascertaining whether the patient has disclosed her HIV serostatus to sex partners and needle sharing partners is appropriate. Addressing barriers preventing disclosure, including recommendations and/or referral for assistance regarding how to safely disclose HIV serostatus, is warranted. Some state and local governments require that clinicians report any known partners of HIV-infected patients to the local health department; thus providers should be aware of regulations that will influence their practice.

For both HIV-infected and exposed women, HIV prevention should be discussed using a straightforward, nonjudgmental approach. Identification of ongoing risks should be performed, including sexual behaviors, IV drug use, sexually transmitted diseases, and untreated psychiatric issues, which could increase a person's likelihood of engaging in risk behavior. Behavior interventions, treatment, and avoidance or risk factors should be discussed, emphasizing the importance of consistent condom use even though ART decreases the risk of HIV transmission. Although no reliable data on HIV serodiscordance rates in the United States exist, data on women from sub-Saharan Africa show that women in serodiscordant relationships may be particularly vulnerable to HIV infection; thus HIV testing of sexual partners should be encouraged.[14]

INFLUENZA

Virology/Epidemiology

Influenza is part of the Orthomyxoviridae family, containing the genera influenza A, B, and C. Influenza B is restricted to humans, whereas influenza A and C infect humans in addition to mammalian and avian species. Influenza virus has a negative-stranded, segmented RNA genome enabling reassortment, the rearrangement of viral gene segments in cells infected with two different influenza viruses. This results in the rapid generation of new influenza virus strains (recombinants), which have been responsible for pandemic outbreaks; this process is termed "antigenic shift." Point mutations within the viral genome result in minor, gradual antigenic changes defined as "antigenic drift." These genetic strategies, combined with a wide host range and our inability to generate a protective immune response against the entire genera, enable influenza virus to remain an important pathogen.

Influenza viruses are enveloped, hemagglutinin (H or HA) and neuraminidase (N or NA) viral glycoproteins are present on the surface, and the virus capsid proteins are M1 and M2. HA binds the cell surface receptor (neuraminic acid), is highly antigenic, and is the target of neutralizing antibodies protecting against infection. NA does not induce neutralizing antibodies; however, antibodies recognizing NA are disease suppressive while permitting infection. NA cleaves sialic acid from the infected cell surface, facilitating virus release (budding) from these cells, and may remove sialic acid from mucin, enabling cell-free virus to reach epithelial cells. Viral entry begins when HA binds the cell receptor, followed by endocytosis of the viral particle. Within the endocytic compartment, low pH triggers conformational changes in HA, which are required for fusion. Viral uncoating also requires M2, an ion channel protein permitting influx of H^+ ions into the virus particle, enabling the viral nucleoprotein to enter the cytoplasm.

Influenza strains are named according to their genus (type), the species from which the virus was isolated (omitted if human), and the H and N subtypes. H subtypes confer species specificity and there is only a single NA subtype for influenza B. Influenza is spread by respiratory droplets, is highly contagious, and occurs as an epidemic typically during the winter months. Approximately 50 million cases occur annually in the United States; children younger than 2 years old and the elderly have the highest hospitalization rates. In 2009 a novel influenza A, H1N1, emerged secondary to complex genetic reassortment. A unique pandemic ensued: 90% of hospitalizations and 87% of deaths occurred in people <65 years old, and 788 pregnant women with confirmed or probable H1N1,

resulting in 280 ICU admissions and 56 deaths, were documented. The documented case reports potentially underreport infection and overestimate the prevalence of severe illness; however, the influence of this pandemic can be extrapolated from the mortality rate. Five percent of H1N1-related deaths occurred in pregnant women (representing 1% of the population), suggesting that pregnant women infected with influenza had an elevated risk of serious illness and death, in accordance with previously published studies.[29]

Clinical Manifestations

Influenza virus causes acute upper respiratory tract illness, characterized by the abrupt onset of fever, chills, headache, myalgias, malaise, a dry cough, and nasal discharge. GI manifestations and conjunctivitis can also be present. The incubation period ranges from 1 to 5 days. Most cases of influenza are self-limited. Complications include pneumonia, occurring in up to 12% of influenza-infected pregnant women,[30] Reye's syndrome, and disseminated intravascular coagulation (DIC). Changes in the immune, cardiac, and respiratory systems likely increase the risk of severe illness in pregnant women infected with influenza.

Diagnosis

Rapid influenza diagnostic tests (RIDTs) are immunoassays identifying influenza A and B viral nucleoproteins in 15 minutes or less. RIDTs are very specific (90%-95%); however, sensitivity is limited (10%-70%), with the potential for false-negative results during periods of high influenza incidence. False-positive results occur when influenza is at low prevalence. Some RIDTs distinguish between influenza A and B, but they cannot determine viral subtype. The optimal time of specimen collection is within 48 to 72 hours of illness onset.[31] Confirmation is via RT-PCR, culture, ELISA, or immunofluorescence of respiratory secretions; immunofluorescence and RT-PCR have the most rapid turnaround.

Management of Influenza During Pregnancy

Pregnant women suspected to be infected with influenza should be treated immediately, without delay for diagnostic confirmation. The recommended treatment for both seasonal and pandemic influenza infection is osteltamivir (dosages are shown in Table 50-5); acetaminophen should be used as an antipyretic and additional recommendations regarding adjunctive therapy are presented in Chapter 37. The preterm birth rate following pandemic H1N1 infection was 30%, and increased preterm parturition also occurs following seasonal influenza infection; so appropriate monitoring should be undertaken, particularly in women with respiratory compromise.[29,32,33] Early antiviral treatment reduces illness duration, secondary complications, and hospitalizations; however, initiating treatment up to 5 days after symptom onset still confers benefit. The risk of severe illness and death is highest in the latter part of pregnancy, compared to the first trimester; other risk factors are described in the box, Risk Factors for Severe Illness and Death in Influenza Virus–Infected Pregnant Women.[29,32] The pregnancy-associated risk of illness persists for 2 weeks postpartum.

Risk Factors for Severe Illness and Death in Influenza Virus–Infected Pregnant Women

Asthma
Smoking
Obesity
Chronic hypertension
Delayed treatment

Chemoprophylaxis can be given to high risk, unvaccinated women exposed within 48 hours of presentation (see Table 50-5); alternative therapy for infection includes amantadine or rimantidine, which block M2 channel activity in influenza A. However, there is significant viral resistance to these drugs.[34] **ACOG and the CDC recommend vaccination of all pregnant women during influenza season (October-May) using the intramuscular, inactivated vaccine.**[35] The World Health Organization (WHO) and U.S. Public Health Service recommend the strains to be included in the annual vaccine based on recent prevalence; the vaccine is produced in eggs, which should be taken into account for patients with allergies. The optimal time to vaccinate patients is in October and November to minimize the risk of acquiring influenza; however, vaccination is safe and effective at any time of the year or gestational age. A study of 2000 pregnant women receiving the inactivated vaccine demonstrated no adverse fetal effects and safety in breastfeeding women; moreover, maternal vaccination also protects infants up to 6 months of age.[36] The intranasal vaccine contains live virus and should not be used during pregnancy.

PARVOVIRUS

Virology/Epidemiology

Parvoviruses are small, nonenveloped viruses containing negative-stranded DNA encoding two major genes: the REP or NS gene encoding functions required for transcription and DNA replication, and the CAP or S gene encoding the coat proteins VP1 and VP2. Parvovirus B19 was identified in the 1970s within blood bank specimens, and was first linked to sickle cell disease patients with transient aplastic crisis. Parvovirus B19 was then associated with

Table 50-5 Antiviral Medication Dosing Recommendations for Influenza

ANTIVIRAL AGENT	ACTIVITY	ACTION	USE	DOSAGE	DURATION	CONTRAINDICATIONS
Osteltamivir	Influenza A and B	NA inhibitor	Treatment	75 mg BID	5 days	None
			Prophylaxis	75 mg daily	7-10 days	
Zanamivir	Influenza A and B	NA inhibitor	Treatment	10 mg BID inhaled	5 days	Underlying respiratory disease
			prophylaxis	10 mg daily, inhaled	7-10 days	

Fifth's disease, or erythema infectiosum (EI), and later linked to hydrops fetalis.[37] Parvoviruses preferentially infect rapidly dividing cells, explaining the observed fetal and neonatal susceptibility. Parvovirus B19 infection is restricted to humans; the cellular receptor is erythrocyte P antigen, explaining the propensity of this virus to infect red blood cells and their precursors. P antigen is also expressed on megakaryocytes, endothelial cells, placenta, fetal liver, and fetal heart.[37] Parvovirus B19 is spread via respiratory droplets, infected blood products, perinatally, and with hand to mouth contact. The incubation period ranges from 4 to 20 days following exposure. Seroprevalence increases with age and 65% of pregnant women have evidence of prior infection and are immune. Conversely, susceptible women have approximately a 50% risk of seroconversion following exposure to parvovirus B19. Daycare workers, teachers, and parents have all been shown to be at increased risk of seroconversion.[38]

Clinical Manifestations

The most common presentation of B19 parvovirus infection is EI, which is characterized by a facial rash consistent with a slapped cheek appearance and a reticulated or lace-like rash on the trunk and extremities (Figure 50-1). The rash is immune-complex-mediated and may reappear secondary to temperature changes, sunlight exposure, and stress for several weeks. Infection can also be accompanied by fever, malaise, lymphadenopathy, and symmetrical peripheral arthropathy. The hands are most frequently affected followed by the knees and wrists. Symptoms are typically self-limiting, but may last for several months.[39] Asymptomatic infection occurs 20% of the time. Persistent parvovirus infection is rare and presents as pure red cell aplasia in patients failing to mount a neutralizing antibody response.[40] Fetal infection can be asymptomatic or characterized by aplastic anemia of varying severity. Severe anemia can lead to high-output congestive heart failure and non-immune hydrops. Direct infection of the myocardium may also contribute to fetal heart failure.

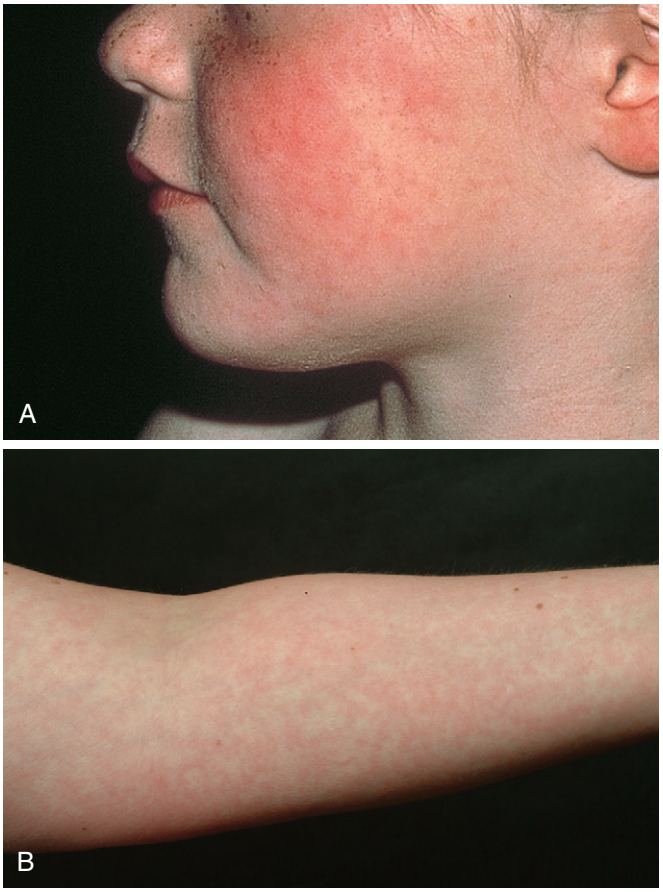

FIGURE 50-1. **A,** Characteristic "slapped cheek" rash of erythema infectiosum. (From Ferri F, et al: Ferri's Fast Facts in Dermatology. Philadelphia, Saunders, 2011.) **B,** Note lace-like rash on upper extremity.

Diagnosis

Serologic testing via ELISA detects IgG and IgM against B19 parvovirus. However, PCR amplification of viral DNA from maternal or fetal blood is a more sensitive method to confirm acute parvovirus infection, because viremia occurs prior to the development of specific antibodies and viral protein/antibody complexes can result in false-negative serology.[41] Maximum sensitivity is achieved with concurrent serologic and nucleic acid testing.[42]

Management of Parvovirus During Pregnancy

Following exposure to B19 parvovirus in a presumed seronegative woman, serologic and DNA testing should be performed. The presence of IgG antibody is consistent with prior exposure and/or infection, and no further workup is needed. Susceptible women should have repeat testing performed in about 3 weeks. Pregnant women with confirmed infection should be treated with supportive care because maternal B19 parvovirus infection is usually self-limited. The relationship between the gestational age at the time of exposure to B19 parvovirus and the risk of fetal parvovirus infection resulting in a severely affected fetus is shown in Table 50-6. Serial ultrasounds to evaluate the fetus for hydrops should be performed for 8 to 10 weeks after maternal illness. If no signs of hydrops are seen during this period, further evaluation is unnecessary. Recent studies have shown that measurement of the fetal middle cerebral artery peak systolic velocity can be useful in documenting fetal anemia prior to the development of hydrops in cases of congenital B19 parvovirus infection.[43]

Fetal infection occurs following approximately 33% of maternal infections.[44] However, the rate of fetal death secondary to intrauterine B19 parvovirus infection is dependent on when maternal infection occurs. Fetal death is rare when maternal infection occurs beyond 20 weeks of gestation, but fetal mortality associated with fetal hydrops is

TABLE 50-6 ASSOCIATION BETWEEN GESTATIONAL AGE AT TIME OF EXPOSURE AND RISK OF FETAL PARVOVIRUS INFECTION

TIME OF EXPOSURE (WEEKS' GESTATION)	FREQUENCY OF SEVERELY AFFECTED FETUSES (%)
1-12	19
13-20	15
>20	6

approximately 11% when maternal B19 infection occurs during the first 20 weeks of pregnancy.[45] Although 33% of fetal hydrops will resolve without treatment,[46] there are no reliable predictors for the resolution of hydrops versus fetal death. Thus, cordocentesis and intrauterine transfusion are recommended when fetal hydrops is present.[47] Recent studies have documented thrombocytopenia in parvovirus B19–infected fetuses at the time of cordocentesis;[48] however, it is unclear whether there is benefit to providing platelets at the time of RBC transfusion. The majority of fetuses infected with parvovirus B19 demonstrate normal long-term development.[49-51] Rare cases of neurologic morbidity, persistent infection with severe anemia, and other sequelae have been reported following fetal infection.

MEASLES

Virology/Epidemiology

Measles, or rubeola, is an enveloped, negative-stranded RNA virus, part of the Paramyxoviridae family, which includes respiratory syncytial virus, canine distemper virus, mumps virus, and parainfluenza viruses. Measles host range is limited to humans. The envelope of this virus contains fusion and hemagglutinin (HA) proteins; HA binds the cellular receptor, which is a complement regulatory protein, and the fusion protein permits viral entry into the cell. **Rubeola (measles) is one of the most infectious viruses, spread primarily via respiratory droplets; with exposure 75% to 90% of susceptible contacts become infected.** A live, attenuated vaccine is readily available, resulting in three major patterns of measles outbreaks in the United States: unvaccinated preschoolers (including those <15 months of age), previously vaccinated school-age children and college students, **and persons originating from outside the United States.** The incidence of outbreaks in previously vaccinated individuals has been reduced since implementation of a two-dose vaccination strategy. Between 2001 and 2003, 44% of the measles cases reported in the United States occurred in an immigrant population.[52]

Clinical Manifestations

Rubeola has an incubation period of 10 to 14 days. Infected individuals first manifest prodromal symptoms, which may include fever, malaise, myalgias, and headache. These are followed by ocular symptoms including photophobia and a nonexudative conjunctivitis. Koplik spots, tiny white spots on a red base on the buccal mucosa lateral to the molar teeth, may appear during the prodrome and are pathognomonic for measles infection. If Koplik spots are visualized, they typically appear a day or so prior to the rash and disappear within 2 days of its appearance. The rash of measles appears between 2 and 7 days following the prodrome and is initially present behind the ears or on the face as a blotchy erythema. The rash then spreads to the trunk, followed by the extremities; the hands and feet may be spared. The rash is initially macular and blanches with pressure, but becomes papular and coalescent with a red, nonblanching component (Figure 50-2). The rash tends to fade after about 5 days. Fever can persist for up to 6 days and may reach 41° C; a productive cough may develop, which can persist after defervescence. Lymphadenopathy accompanies the fever and can persist for several weeks.

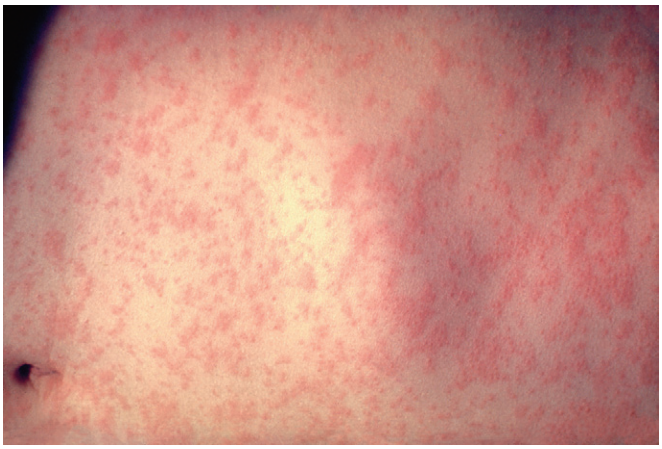

FIGURE 50-2. Maculopapapular rash of measles or rubeola showing coalescence of lesions. (Courtesy CDC/Dr. Heinz F. Eichenwald.)

Complications can include laryngitis, bronchiolitis, pneumonia, and otitis media due to secondary bacterial infections. Rare complications include hepatitis, encephalitis, atypical measles, and acute encephalitis. Encephalitis occurs in about 1 in 1000 cases of measles, resulting from either viral infection of the CNS or a hypersensitivity reaction to systemic viral infection. Symptoms include recurrence of fever and headache, vomiting, and a stiff neck followed by stupor and convulsions. The mortality is 10% and permanent neurologic sequelae, including mental retardation, develop in 50% of individuals. Atypical measles, which occurs in adults vaccinated with the formalin-inactivated measles vaccine, is characterized by high fever, pneumonia with pleural effusions, obtundation, and a hemorrhagic exanthema. These patients usually have high antibody titers to measles but lack antibodies to the fusion protein. Atypical measles is usually self-limiting, and patients are not contagious to others. A rare complication of measles infection is subacute sclerosing panencephalitis (SSPE), which occurs in 0.5 to 2 per 1000 cases of measles years after the acute infection. SSPE is most common in children who contracted measles prior to 2 years of age and is characterized by progressive neurologic debilitation and a virtually uniformly fatal outcome.

Diagnosis

Clinical features are usually used to diagnose infection; Koplik spots are pathognomonic for measles infection. In their absence diagnosis is based on a history of recent exposure and/or the presence of a rash. An increase in antibody titer may be detected as early as the first or second day of the rash; assays for detection of IgM and viral RNA are also available. Differential diagnoses include rubella, scarlet fever, infectious mononucleosis, secondary syphilis, toxic shock syndrome, Kawasaki's disease, erythema infectiosum, and drug rash. A guide to differentiating these illnesses is shown in Table 50-7.[53]

Management of Measles During Pregnancy

Pregnant women with rubeola infection should receive supportive care and undergo careful observation for

TABLE 50-7 A GUIDE TO THE DIFFERENTIAL DIAGNOSIS OF MEASLES

	CONJUNCTIVITIS	RHINITIS	SORE THROAT	EXANTHEM	LEUKOCYTOSIS	SPECIFIC LABORATORY TESTS
Measles	++	++	0	+	0	+
Rubella	0	±	±	0	0	+
Exanthem subitum	0	±	0	0	0	+
Enterovirus infection	0	±	±	0	0	+
Adenovirus infection	+	+	+	0	0	+
Scarlet fever	±	±	++	0	+	+
Infectious mononucleosis	0	0	++	±	±	
Drug rash	0	0	0	0	0	0

evidence of complications. The largest, most recently reported study of measles in pregnancy revealed that pregnant women with measles were twice as likely to require hospitalization (60%), three times as likely to acquire pneumonia (26%), and six times as likely to die from complications (3%) compared to nonpregnant adults.[54] Given the higher rate of maternal morbidity and mortality in the setting of measles infection, secondary bacterial infections should be treated promptly with antibiotics. Ribavirin can be considered for cases of viral pneumonia; however, it has not been conclusively shown to be of benefit.

There is a 20% to 60% risk of spontaneous abortion and preterm delivery following measles infection during pregnancy.[54] If miscarriage does not occur, patients should be counseled that measles does not appear to be associated with an increased risk of fetal malformations and that the risk of congenital measles infection appears to be well below 25%; two recent studies assessing a total of 98 maternal measles infections showed an absence of congenital measles infections.[54,55] Detailed serial ultrasounds may be performed. Evidence of in utero infection includes microcephaly, growth restriction, and oligohydramnios. There have been conflicting reports regarding whether an association exists between measles infection in pregnancy and Crohn's disease in offspring.[56,57] Others have reported an association between measles exposure at the time of birth and the development of Hodgkin's disease in children.[58]

The most effective way to prevent measles infection in pregnancy is to ensure vaccination prior to pregnancy using a two-dose series, which usually includes the trivalent MMR (measles, mumps, and rubella) vaccine. This live, attenuated vaccine should not be given to pregnant women, and patients are recommended to use effective contraception for 3 months postvaccination, although no cases of congenital measles infection have been reported secondary to the measles vaccine.[59] Although most pregnant women will have been previously vaccinated against measles, between 3.2% and 20.5% of pregnant women have either absent or low antibody titers, which would classify them as seronegative.[60] Any pregnant women exposed to measles should have an IgG titer drawn. Seronegative (susceptible) women should be treated with 0.25 mL/kg of immune globulin intramuscularly within 6 days of exposure (maximum dose of 15 mL).[59] Neonates delivered to a parturient who developed measles within 7 to 10 days of delivery should receive intramuscular immune globulin at a dose of 0.25 mg/kg. These children should also receive the MMR vaccine at 12 to 15 months of age.[59]

RUBELLA

Virology/Epidemiology

Rubella is a small, spherical, enveloped single-stranded RNA virus that is part of the Togavirus family. Transmission occurs via respiratory droplets and close personal contact. Following infection of respiratory mucosa, virus is found within cervical lymph nodes and disseminates hematogenously. Rubella outbreaks occur in school-aged children and in settings where crowded conditions exist, such as military bases, religious communities, college campuses, and prisons. No recent, major outbreaks have occurred in the United States secondary to routine vaccination. Elimination of endemic rubella is a national health objective; there were only seven reported rubella cases in the United States in 2009.[61] Most infections occur in foreign-born, unvaccinated individuals.

Clinical Manifestations

The incubation period following exposure is 12 to 19 days; however, acute rubella infection is not always diagnosed because 20% to 50% of infections are asymptomatic and there is no associated prodromal illness. Symptomatic, infected patients present with a rash, malaise, fever, conjunctivitis, and generalized lymphadenopathy. The rash is nonpruritic, begins on the face and neck as a faint macular erythema, and spreads rapidly to the trunk and extremities (Figure 50-3). The rash lasts approximately 3 days and blanches with pressure. Transient polyarthralgias and/or polyarthritis lasting 5 to 10 days may appear in adolescents and adults following the rash. Rare complications include thrombocytopenic purpura, encephalitis, neuritis, and orchitis.

Diagnosis

Serology is most commonly used to document exposure and/or infection with rubella. IgM specific for rubella is detectable prior to the onset of the rash.[62] Isolation and culture of the virus is possible as is detection of viral RNA by RT-PCR. In cases of suspected congenital rubella infection, RT-PCR can be used to detect viral RNA within chorionic villi, fetal blood, and amniotic fluid specimens.[63]

FIGURE 50-3. Photograph shows typical erythematous, maculopapular rash of rubella.

Management of Rubella Infection During Pregnancy

Maternal rubella infection is usually self-limited. However, congenital rubella infection is associated with miscarriage and/or stillbirth and can have significant deleterious effects on the fetus. IVIG administration does not prevent congenital rubella infection. The primary purpose of the rubella vaccine is to prevent congenital rubella infection; however, this live attenuated vaccine is contraindicated during pregnancy. Rubella vaccine is available as a monovalent form, a bivalent form (measles-rubella), or a trivalent form (MMR). The CDC has followed 500 cases of congenital rubella infection occurring from the vaccine strain, with no reported congenital malformations,[64] and smaller studies report similar findings. These observational studies demonstrate that rubella vaccination during pregnancy does not carry a significant risk of birth defects secondary to congenital rubella infection; therefore, therapeutic termination of pregnancy is not recommended in these cases.[64] Rubella serology is typically performed on obstetrical intake to identify women with inadequate levels of antibody. These women should receive rubella vaccine in the postpartum period.

Congenital Infection

There were 26 cases of congenital rubella infection documented in the United States from 1997 to 1999, and 92% of these infants were born to foreign-born mothers.[64] Because rubella cases have markedly declined in the past decade we have currently eliminated congenital rubella syndrome (CRS).[61] Several studies have established relationships between the frequency and severity of CRS and the timing of rubella infection in pregnancy. In general, infection in early pregnancy is associated with increased CRS severity. When maternal infection occurs within the first 12 weeks of pregnancy and is accompanied by a rash, more than 80% of fetuses become infected with rubella.[65] Of these infants, 67% will have findings consistent with CRS.[66] First-trimester infection with rubella is also associated with miscarriage, although some of the women in these studies terminated their pregnancy secondary to exposure. As the pregnancy progresses the risk of congenital rubella infection decreases; risk is 54% at 13 to 14 weeks, and 25% at the end of the second trimester.[65] The association of congenital rubella infection with CRS also decreases with increasing gestational age, with fetal defects being rare in fetuses infected beyond the 16th week of pregnancy.[65,66] Given that the association of congenital rubella infection and CRS is not absolute at any gestational age, ultrasound may be a useful adjunct in determining whether a fetus is affected, although this technique cannot detect many of the associated abnormalities.

The most common manifestation of congenital rubella infection is growth retardation. Sensorineural hearing loss is the most common single defect associated with CRS, affecting up to 90% of congenitally infected infants, and the rate of hearing loss is inversely related to the gestational age of congenital rubella infection.[64] When infection occurs prior to 12 weeks' gestation, other common defects include cardiac lesions (13%), most commonly patent ductus arteriosus, and eye defects (13%) such as cataracts, glaucoma, or retinitis.[66] Other findings consistent with CRS include micropthalmia, microcephaly, cerebral palsy, mental retardation, and intrauterine growth restriction (IUGR). Most of these findings are seen only in fetuses infected within the first 12 weeks of gestation; however, virtually all fetuses infected prior to the 11th week of gestation have CRS.[65] Severe disease can also include thrombocytopenic purpura or hepatosplenomegaly. Fetuses infected between 13 and 16 weeks of gestation have up to a 35% risk of being affected by CRS[65] and typically have hearing loss as their principal manifestation of CRS. Fetuses infected at more advanced gestational ages rarely have sequelae associated with CRS. Following congenital rubella infection, infants may shed virus for up to 1 year after birth. Even in neonates who are asymptomatic at birth, up to one third can manifest long-term complications, including type 1 diabetes mellitus and progressive panencephalitis in the second decade of life.[67,68]

CYTOMEGALOVIRUS INFECTION

Virology/Epidemiology

Cytomegalovirus (CMV) is a large, double-stranded DNA, enveloped virus that is a β-herpesvirus. Herpesviruses have large, complex genomes, replicating in the nucleus of infected cells, enabling these viruses to establish acute, persistent, and latent infection. Recurrent CMV infection occurs following reactivation from latently infected cells or by superinfection with a different strain or serotype of virus. CMV is not highly contagious; transmission primarily occurs by contact with infected saliva or urine, and CMV can also be transmitted via blood or by sexual contact. The incubation period is about 40 days following exposure. Within the United States, the rate of primary CMV infection in pregnant women ranges from 0.7% to 4%, and recurrent infection can be as high at 13.5%. Young infants

and children with subclinical infection are a major source of infectious CMV; approximately 50% of children attending day care actively shed CMV virus in their saliva and/or urine and fomites within day-care centers are potential sources of CMV infection. Thus day-care workers are at high risk for infection. Small children pose an infection risk to family members, with annual seroconversion rates of approximately 10% for parents and uninfected siblings.[69] CMV seropositivity correlates with lower socioeconomic status, birth outside North America, increasing parity and age, abnormal Pap smears, infection with *Trichomonas*, and the number of sex partners.[70] CMV infection is also increased in immunocompromised patients. Between 0.2% and 2.2% of infants born in the United States become infected with CMV in utero secondary to maternal infection, and congenital CMV is the leading cause of hearing loss in children. Another 6% to 60% of children become infected within the first 6 months of life secondary to intrapartum transmission, environmental exposure, and/or breastfeeding; however, peripartum-infected infants rarely demonstrate serious sequelae of CMV infection.[71]

Clinical Manifestations

Infected patients may be asymptomatic or have a mononucleosis-like syndrome with fever, malaise, myalgias, chills, and cervical lymphadenopathy. Infrequent complications include pneumonia, hepatitis, Guillain-Barré syndrome, and aseptic meningitis. Laboratory abnormalities include atypical lymphocytosis, elevated hepatic transaminases, and a negative heterophile antibody response (distinguishing CMV from Epstein-Barr virus infection).

Diagnosis

Active, maternal CMV infection is best diagnosed by culture, detection of CMV antigens, or DNA PCR of blood, urine, saliva, amniotic fluid, or cervical secretions. Serologic tests are available, but antibody levels may not be detectable for up to 4 weeks after primary infection and titers can remain elevated, making a serologic diagnosis of reinfection difficult. A fourfold increase in IgG titers within multiple specimens suggests active infection. IgM is used to diagnose recent or active infection, but both false-positive and false-negative results can occur. **Routine screening for CMV infection during pregnancy is not recommended given the prevalence of seropositivity.** Fetal infection is documented by culture or PCR of amniotic fluid; the sensitivity of PCR approaches 100% in gestations beyond 21 weeks.[72] Fetal serology and culture of fetal blood are much less sensitive. Fetal CMV infection can occur weeks to months following maternal infection; thus repeat testing may be warranted at 7-week intervals.[72] Antepartum CMV detection does not predict the severity of congenital CMV infection, and 80% to 90% of children with congenital CMV infection have no neurologic sequelae.

Management of Cytomegalovirus During Pregnancy

Pregnant women should be counseled regarding preventive measures: careful handling of potentially infected articles such as diapers, clothing, and toys; avoiding sharing food and utensils; and frequent handwashing. Antiviral therapy is not indicated in immunocompetent, infected individuals and ganciclovir is not effective for intrauterine treatment of congenital CMV infection. Passive maternal immunization of pregnant women with primary CMV infection with CMV-specific hyperimmune globulin was associated with a decreased incidence of congenital CMV infection and the number of infants born with symptomatic CMV disease[73]; however, as discussed in a recent Cochrane review no randomized controlled trials exist examining interventions for preventing antepartum CMV transmission and adverse outcomes in congenitally infected infants.[74] A recombinant protein vaccine against CMV glycoprotein B was recently shown to prevent maternal CMV infection; however, this vaccine is not yet commercially available.[75]

Congenital Infection

Congenital CMV infection is diagnosed by detection of virus or viral nucleic acid within the first 2 weeks of life. The risk of intrauterine **CMV transmission is highest in the third trimester and the overall risk of fetal transmission is 30% to 40%.**[76] **Serious sequelae occur most commonly after first-trimester infection; 24% of these infected fetuses have sensorineural hearing loss and 32% have other CNS sequelae.** For fetuses infected after the second trimester, 2.5% demonstrated sensorineural hearing loss and 15% had CNS sequelae.[77] Congenital CMV infection may occur following primary or recurrent CMV infection of pregnant women, but the incidence of serious sequelae is lower following recurrent infection.[78] Most infants with congenital CMV infection exhibit no obvious clinical findings at birth. However, subclinical, congenital CMV infection is associated with hearing loss in 15% of cases.[78]

After primary, maternal CMV infection, approximately 5% to 18% of infants exhibit serious sequelae, typically following infection during the first half of pregnancy. Clinical findings in these infected infants may include jaundice, petechiae, thrombocytopenia, hepatosplenomegaly, growth restriction, and nonimmune hydrops. Long-term neurologic sequelae include developmental delays, seizure activity, and gross neurologic impairment, including sensorineural hearing loss.[78] Ultrasound can be useful in identifying a congenitally infected infant with likely impairment. Findings consistent with fetal injury include microcephaly, ventriculomegaly, intracerebral calcifications, ascites, hydrops, echogenic bowel, IUGR, and oligohydramnios. Unusual findings include fetal heart block and meconium peritonitis.[79,80] In the setting of confirmed fetal infection with serial normal ultrasounds, the risk of clinical symptoms of congenital CMV infection following birth is approximately 10%. Thus, ultrasound findings (or a lack thereof) are an important part of counseling.

HERPESVIRUS

Virology/Epidemiology

Herpes simplex virus (HSV) is another large, enveloped, double-stranded DNA virus, replicating in the host cell nucleus. Epithelial cells are the primary targets; however, HSV can disseminate via hematogenous spread or its

capacity to form latent infections within dorsal root ganglia. Latent viral infection can be associated with integration of the viral genome into the host cell DNA. The HSV genome is complex, encoding more than 80 polypeptides, including several glycoproteins present on the envelope of the virus. Glycoprotein g permits differentiation of two well-defined antigenic and biologic viruses, HSV-1 and HSV-2. HSV-1 is typically associated with nongenital infection. The mouth and lips are the most common sites of viral replication; infection with this virus is most prevalent in lower socioeconomic populations, where 75% to 90% of individuals have antibodies against HSV-1 by 10 years of age. HSV-2 infection is usually acquired via sexual contact and is also related to socioeconomic factors. In the United States, 25% to 65% of individuals have antibodies to HSV-2, and seroprevalence risk correlates with the number of sexual partners. Some individuals have asymptomatic or subclinical primary HSV infections, accounting for seropositive patients in the absence of a clinical history of infection.

Clinical Manifestations

HSV-1 infection is normally evidenced by herpes simplex labialis (cold sores), whereas HSV-2 infection customarily involves the genital area and may affect the vulva, vagina, and/or cervix. Painful vesicles appear 2 to 14 days after viral exposure; the vesicles undergo spontaneous rupture, leaving lesions appearing as shallow eroded ulcers (Figure 50-4). Later in infection, a dry crust forms and lesions heal without scarring. Primary infection can be associated with fever, malaise, anorexia, bilateral inguinal lymphadenopathy, and is infrequently associated with aseptic meningitis. Women may also have dysuria and urinary retention secondary to urethral involvement. Rates of symptomatic and subclinical HSV shedding from the cervix and vulva during the first 3 months following primary infection are 1% to 3%.[81]

Healing of primary HSV-2 infection may take several weeks and primary symptoms are less severe in individuals with prior HSV-1 infection. Nonprimary, first episodes of genital HSV occur when a second HSV strain (either HSV-1 or HSV-2) establishes infection in the presence of preexisting antibodies from previous infection at a nongenital site (usually oral). Secondary or recurrent HSV infections usually represent viral reactivation and vary in frequency and intensity. Recurrent infections are usually less severe than primary infection, and associated with fewer lesions and a shorter period of viral shedding. One third of HSV-infected individuals have no recurrences, one third have approximately three recurrences per year, and another third have more than three recurrences per year. Table 50-8 compares clinical findings during primary and recurrent HSV infection. Disseminated HSV infection is rare, arising primarily in immunocompromised individuals, but it can also occur in pregnancy. Disseminated infection is characterized by skin, mucous membrane, and visceral organ involvement, and may include ocular involvement, meningitis, encephalitis, and ascending myelitis. Treatment with IV acyclovir should be initiated promptly in suspected cases of disseminated HSV.

FIGURE 50-4. Ulcerated lesions characteristic of herpes simplex infection. (From Ferri F, et al: Ferri's Fast Facts in Dermatology. Philadelphia, Saunders, 2011.)

Diagnosis

Definitive diagnosis of active HSV infection is made by viral culture or by nucleic acid detection of HSV DNA, which provides a more rapid and sensitive diagnosis. Both methods can differentiate between HSV-1 and HSV-2. Culture specimens should be collected from fresh vesicles or pustules, because viral recovery from crusted lesions is poor; this is not as critical for PCR-based assays. Serology can be useful to assess and differentiate primary infection from secondary infection, via IgM detection. Cytologic preparations (Tzanck test) show characteristic multinucleated giant cells and intranuclear inclusions; however, this is rarely performed given the enhanced sensitivity and specificity of the above methods.

Management of Herpesvirus During Pregnancy

Maternal primary infection with HSV prior to labor does not usually affect the fetus; increased rates of miscarriage following primary HSV infection have been reported, but a recent prospective study showed no increase in spontaneous pregnancy loss.[82] In addition, intrauterine HSV infection is rare, occurring in approximately 1 in 200,000 deliveries. Sequelae in such cases include skin vesicles and/or scarring, eye disease, microcephaly, or hydranencephaly.[83] An association between HSV infection in the

Famciclovir	250 mg TID for 7-10 days	500 mg followed by 250 g BID for 2 days or 1 g BID for 1 day	250 mg BID

third trimester of pregnancy and IUGR has also been reported. However, this observation was based on five patients.[84] Birthweight of infants born to asymptomatic HSV shedding mothers is lower than those of nonshedding mothers, but this small observed effect may be due to differences in gestational age at birth.[85] Treatment regimens are described in Table 50-9; women with more than two HSV recurrences per year are candidates for prophylaxis to decrease the frequency and severity of recurrences.

The greatest risk associated with intrapartum HSV exposure is that of developing neonatal herpes infection. Neonatal HSV infection complicates approximately 1 in 3500 deliveries in the United States; 70% of cases are caused by HSV-2, and significant neonatal morbidity and mortality follows neonatal infection. The estimated risk of neonatal HSV during primary maternal infection is 50%, whereas with recurrent HSV infection the neonatal HSV incidence ranges from 0% to 3%.[86] Thus, primary maternal HSV infection, rather than recurrent infection, accounts for the vast majority of neonatal HSV infections.[87] The ACOG recommends elective cesarean delivery for women with demonstrable genital herpes lesions or prodromal symptoms in labor to reduce the incidence of neonatal HSV infection.[86] Unfortunately, 60% to 80% of neonatal HSV infection cases occur following asymptomatic, primary maternal infection, limiting our ability to prevent neonatal HSV infection by performing cesarean delivery. A recent cost/benefit analysis of the current guidelines for the prevention of neonatal HSV infection found that given the low risk of neonatal HSV transmission with recurrent maternal infection, it takes 1580 elective cesarean sections to prevent one case of neonatal HSV.[88]

The risk of neonatal HSV infection in cases of active, nongenital maternal HSV lesions (i.e., thigh, buttock, mouth) is low. Therefore cesarean delivery is not recommended for these women. The duration of ruptured membranes prior to delivery increases the risk of neonatal HSV infection. However, there is no evidence that there is a period of time beyond which cesarean delivery is no longer beneficial. In the case of premature rupture of membranes, acyclovir or other antivirals should be considered in women with active HSV lesions being managed expectantly and given steroids to enhance fetal lung maturity.[86]

Various studies have investigated strategies to limit neonatal HSV transmission and reduce the number of cesarean deliveries performed prophylactically to limit neonatal HSV transmission.[89] Positive HSV cultures in the antepartum period are not associated with a positive culture at the time of delivery.[89] Prophylactic acyclovir or valacyclovir decreases the incidence of HSV shedding and reduces the number of cesarean deliveries performed to prevent neonatal HSV infection.[90] This strategy may be considered for women who have experienced a recurrence of HSV at some point during their pregnancy.

Neonatal Herpes Infection

Approximately 70% of neonatal HSV infections are caused by HSV-2. Factors predicting neonatal HSV transmission include cervical HSV shedding, invasive monitoring, preterm delivery, maternal age less than 21 years of age, and HSV viral load.[91] Neonatal HSV infection is treated with IV acyclovir. There are three patterns of neonatal HSV infections occurring with equal frequency: (1) Local or skin, eyes, and mouth (SEM) disease, limited to the skin, eyes, and mouth; this pattern has limited morbidity. (2) Disseminated infection involving multiple visceral organs including lungs, liver, adrenal glands, skin, eyes, and brain. Both SEM and disseminated disease present early, at 10 to 12 days of life. (3) CNS disease, occurring in the presence or absence of skin involvement, occurs later, during the second or third week of life. Using high-dose neonatal acyclovir, the 1-year mortality is 29% for disseminated disease and 4% for CNS disease; moreover, 83% of disseminated disease survivors have normal neurologic development and 31% of CNS disease survivors are neurologically intact.[92] Complications of neonatal HSV infection also include DIC and hemorrhagic pneumonitis.

VARICELLA

Virology/Epidemiology

Varicella, or chickenpox, is caused by the varicella zoster virus (VZV), a member of the α-herpesvirus subfamily. This enveloped virus contains double-stranded DNA and has at least 69 genes. Viral replication initially occurs within respiratory epithelial cells and is followed by systemic viremia. Long-term, latent infection occurs within the non-neuronal cells of the dorsal root ganglia. Humans are the only known host for varicella, a highly contagious disease transmitted by respiratory droplets or close contact. Approximately 95% of susceptible household contacts will become infected following exposure. The incubation period is about 14 days. Patients are infectious from 1 day prior to the rash until lesions are crusted. Immunity is usually lifelong. Prior to the advent of the VZV vaccine, most natural varicella infections occurred in early childhood, a time when VZV infection is usually self-limited. More than 50% of varicella-associated mortality occurs in adults, who represent less than 10% of all varicella infections.[93] Most adults (>90%) are immune to VZV, even in the absence of a clinical history of chickenpox.[94]

Clinical Manifestations

Infected patients classically present with a centripetal rash characterized by erythematous macules, papules, and vesicles that are highly pruritic, appearing in crops. The rash spreads to the extremities, and evidence of excoriation and scabbed lesions is typically seen. Fever is common and

infected adults frequently present with malaise, myalgias, arthralgias, and headache. Bacterial superinfection of skin lesions can occur. Patients should be carefully observed for the development of varicella pneumonia because the rate of this complication approaches 20% in pregnancy.[95,96] Cough and dyspnea usually occur about 3 days after the appearance of the first skin lesions. Cyanosis, hemoptysis, and pleuritic chest pain are common. Encephalitis is a rare complication of adult VZV infection. Reactivation of latent VZV infection causes herpes zoster or shingles, occurring primarily in the elderly and immunocompromised. Shingles is characterized by a rash within a segmental distribution correlating with specific dermatomes. Pain, itching, and/or paresthesias can occur as a prodrome or with the appearance of the rash. Although zoster is usually self-limited, patients are infectious and can transmit VZV to susceptible individuals.

Diagnosis

Diagnosis is usually made based on a history of exposure and the presence of a rash. Rapid diagnosis of acute infection can be obtained by PCR amplification of VZV-specific DNA from vesicular fluid, and/or throat swabs. Serologic confirmation of infection can be made by ELISA, which can quantitate VZV-specific IgG and IgM; this method is most useful to diagnose prior exposure. The Tzanck stain can also be used to identify multinucleated giant cells present within lesions, and varicella can be cultured.

Management of Varicella During Pregnancy

Pregnant women infected with VZV should be offered supportive care including calamine lotion, antipyretics, and if necessary, systemic antipruritics. Oral acyclovir (800 mg by mouth 5 times per day) or valacyclovir (1 g by mouth 3 times a day) are safe in pregnancy, decrease the duration of illness if instituted within 24 hours of the rash, and should be given to all infected women. Maternal varicella pneumonia usually presents 3 to 5 days following the rash and has a 5% mortality rate; patients should be treated with IV acyclovir upon diagnosis, 10 to 15 mg/kg every 8 hours. If maternal varicella occurs within 5 days before and 2 days following delivery, varicella zoster immune globulin (VZIG) should be given to the newborn to reduce the incidence of neonatal varicella. The infant should also be isolated from the mother until all vesicles have crusted over to prevent VZV transmission. If possible, delivery should be delayed 5 to 7 days following the onset of maternal illness to potentially prevent neonatal VZV, which has a 20% to 30% mortality rate.[96]

Prevention includes ascertaining VZV status prior to pregnancy in women without a clinical history of infection and offering the live, attenuated VZV vaccine (Varivax, Merck) to susceptible women. Adults should receive two subcutaneous doses of vaccine 4 to 8 weeks apart. The vaccine is 70% to 80% effective at preventing natural infection. This live vaccine is contraindicated during pregnancy, and pregnancy should be deferred for 3 months following vaccination, although there is no evidence of congenital VZV infection following vaccination during pregnancy.[97] If a pregnant woman without a clinical history of VZV infection or vaccination is exposed to varicella, serology should be performed within 96 hours of exposure. Most patients will be seropositive for varicella IgG, and not at risk for acute infection. If VZV susceptibility is confirmed or serology cannot be obtained in a timely fashion, the preferred prophylaxis is high-titer varicella zoster immune globulin (VZIG). VariZIG is given by intramuscular injections and can be obtained 24 hr a day from the sole authorized U.S. distributor (FFF Enterprises, Temecula, CA, tel. 1-800-843-7477; or online at www.fffenterprises.com); the recommended dose is 125 units/10 kg of body weight, up to a maximum of 625 units. In the absence of VariZIG, IV immune globulin (IVIG) can be substituted if necessary at a dose of 400 mg/kg.[98] Prophylactic acyclovir, 800 mg PO 5 times daily for 5 to 7 days, beginning within 9 days of exposure, is effective at preventing VZV infection in children, with an 85% reduction in infection.[99] These two therapies can be combined, potentially further reducing the risk of maternal varicella infection; a small study comparing varicella postexposure prophylaxis in children found that acyclovir and VZIG together are more efficacious than VZIG alone.[100] Given the time constraints for prophylactic treatment following exposure, consider varicella serologic assessment at the first prenatal visit for women denying a history of VZV infection/vaccination. Results can be useful during pregnancy, and can be used to plan vaccination of susceptible patients in the postpartum period.

Congenital Infection

Congenital varicella infection can lead to spontaneous abortion, intrauterine fetal demise, and varicella embryopathy. Congenital varicella syndrome (CVS) is characterized by cutaneous scars, limb hypoplasia, muscle atrophy, malformed digits, psychomotor retardation, microcephaly, cortical atrophy, cataracts, chorioretinitis, and microophthalmia. There is a low frequency of anomalies following exposure before 13 weeks; in a study of 472 women, only 0.4% of neonates were born with features of CVS. The highest risk occurs with maternal infection between 13 and 20 weeks' gestation; CVS incidence in this group is 2%.[101] No congenital malformations have been observed following maternal infection beyond 20 weeks' gestation, but neonatal skin lesions or scarring can be seen after birth. Ultrasound examination is the preferred assessment tool, because serology and the presence of VZV DNA do not predict fetal injury.[102] Ultrasound findings suggestive of CVS can include polyhydramnios, hydrops, echogenic foci within abdominal organs, cardiac malformations, limb deformities, microcephaly, and IUGR.[103]

HEPATITIS

Viral hepatitis comprises a spectrum of syndromes ranging from subclinical to fulminant disease, and is caused by several different viruses. Symptoms of acute viral hepatitis infection may include jaundice, malaise, fatigue, anorexia, nausea, vomiting, and right upper quadrant pain. Hepatic transaminases and bilirubin are moderately to markedly elevated and liver biopsy shows extensive hepatocellular injury with a prominent inflammatory infiltrate (Figure 50-5). Most cases of viral hepatitis are self-limited and resolve without treatment, but certain types of viruses can cause

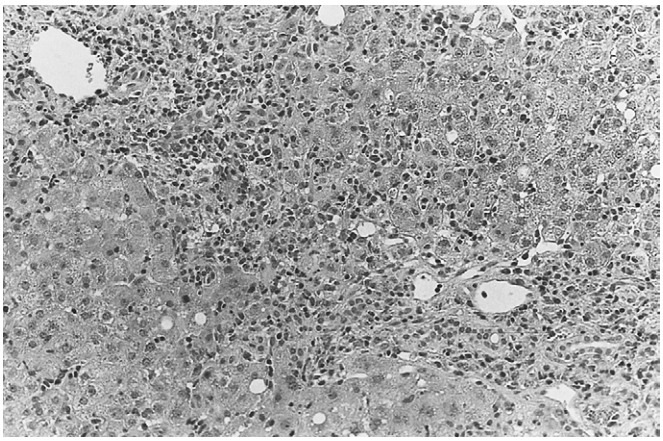

FIGURE 50-5. Photomicrograph of liver biopsy showing characteristic histologic changes of acute viral hepatitis. Note the intense inflammatory infiltrate.

persistent infection leading to chronic liver disease (see Chapter 45). The majority of hepatitis infections in the United States are caused by hepatitis viruses A, B, C, and D, whereas hepatitis E is endemic to Asia, Africa, and Mexico. Other viruses causing liver infection and inflammation (hepatitis) include cytomegalovirus, herpes simplex virus, Epstein-Barr virus, rubella, and yellow fever.[104]

Hepatitis A

Hepatitis A (HAV) is a small, single-stranded RNA virus that is part of the picornavirus family. HAV is transmitted primarily via oral-fecal contact and is responsible for approximately one third of acute hepatitis cases in the United States. The incidence of HAV in pregnancy is approximately 1 in 1000, and diagnosis is based on HAV IgM and IgG serology or detection of viral nucleic acid. The incubation period is approximately 28 to 30 days following exposure. Risk factors for HAV infection include exposure to contaminated food or water, recent travel outside the United States, illicit drug use, and having a child in day care. HAV infection is usually self-limited. Fewer than 0.5% of patients require hospitalization. HAV does not cause chronic infection. Physical activity should be limited to prevent hepatic trauma, and drugs with potential hepatotoxicity should be avoided. Sexual and household contacts of infected individuals should receive immunoprophylaxis with a single dose of HAV immune globulin and with HAV vaccine, an inactive vaccine that is safe for use in pregnancy.[105] Perinatal transmission has not been documented. However, infants delivered to an acutely infected mother should receive HAV immune globulin to prevent horizontal transmission following delivery.[106] HAV infection may be complicated by cholestatic hepatitis, characterized by pruritus, dark urine, direct hyperbilirubinemia, and elevated alkaline phosphatase. The duration of this syndrome can span several months, prognosis is good, and corticosteroid therapy is effective at alleviating symptoms.[104]

Hepatitis B

Virology/Epidemiology

Hepatitis B (HBV) is caused by a small, enveloped double-stranded DNA virus. The intact virus is called the Dane particle. There are three antigens of clinical importance associated with HBV. They are the surface antigen (HBsAg) or viral envelope glycoprotein, the core antigen (HBcAg), associated with viral nucleic acid, and HBeAg, a protein secreted from infected cells that is not a part of an infectious virus particle. HBV is transmitted primarily via parenteral routes, sexual transmission, and perinatal exposure. The incubation period is 4 weeks to 6 months following exposure, depending on viral inoculum; the clinical course is shown in Figure 50-6.[104] Eighty-five percent to 90% of patients acutely infected with HBV clear their infection. Fewer than 1% of infected patients develop fulminant hepatitis, characterized by massive hepatic necrosis and potentially accompanied by pancreatitis. Fifteen percent of patients become chronically infected with HBV, and 15% to 30% of these patients will develop liver cirrhosis and are at substantially increased risk for hepatocellular carcinoma.[104] HBV is the etiologic agent of 40% to 45% of all hepatitis infections and it is estimated that 1 million individuals in the United States are chronic viral carriers. The incidence of acute HBV infection in pregnancy is 1 to 2 per 1000, and 5 to 15 per 1000 pregnant women have chronic HBV infection.[107] Populations with increased HBV prevalence include Asians, Eskimos, drug addicts, dialysis patients, prisoners, and residents and employees of chronic care facilities.[104]

Diagnosis

Acute HBV infection is diagnosed by detection of HBsAg and IgM to the core antigen (HBc) or by viral load determination. Women with positive HBsAg serology greater than 6 months following acute HBV infection have chronic hepatitis; serologic findings are reviewed in Figure 50-6. Further testing is warranted to determine their level of viremia and assess ongoing liver injury manifested by elevated liver function tests. Chronic HBV infection has three forms. Typical chronic HBV (formerly described as chronic active) is characterized by positive HBsAg and HBeAg, an HBV DNA titer ranging from 10^7 to 10^{11}, and positive hepatic nuclear HBcAg. HBeAg-negative chronic HBV is characterized by positive HBsAg, negative HBeAg, an HBV DNA titer ranging from 10^5 to 10^9, and positive hepatic cytoplasmic HBcAg. Inactive HBV carrier state (formerly described as chronic persistent hepatitis) is characterized by positive HBsAg, negative HBeAg, an HBV DNA titer ranging from 10^1 to 10^5, and negative hepatic HBcAg.[108] In regard to other serologic markers, anti-HBs is present following hepatitis infection or vaccination, whereas antibody-recognizing core, or e antigen, is present only in patients who have been infected with hepatitis. Interpretation of serologic tests specific for hepatitis B are reviewed in Table 50-10.

Management of HBV Infection during Pregnancy

HBV infection is prevented by vaccination using a recombinant vaccine that is safe in pregnancy and should be offered to patients with significant risk factors, including a history of STDs, health care workers, and those with infected household or sexual contacts.[109] Lamivudine has been used to treat acute and chronic HBV infection in pregnancy and should be considered for maternal benefit in consultation with a hepatologist.[110] Pregnant women

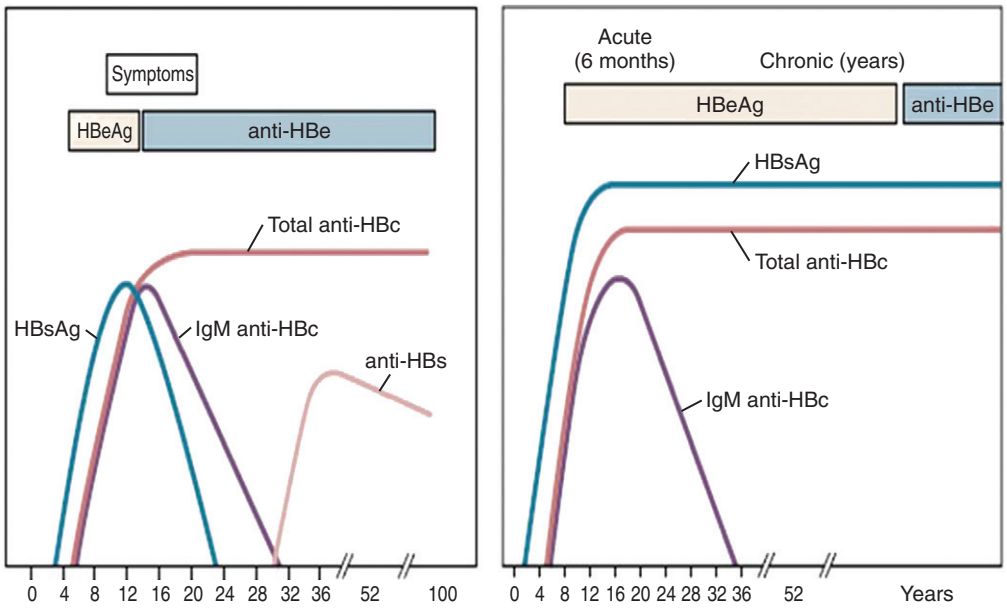

FIGURE 50-6. Typical course of hepatitis B. Timeline in weeks of acute hepatitis B infection is shown on the left and of chronic hepatitis B on the right. with known hepatitis B should be vaccinated against hepatitis A to prevent further liver injury. Amniocentesis is safe in chronically infected women.[111] There is no contraindication to HBV-infected women breastfeeding, because perinatal transmission is not increased in these patients.[112]

In the United States, all newborns receive HBV vaccine as part of the CDC's recommendations to decrease HBV prevalence.[113] Infants born to mothers who are HBsAg seropositive should receive the hepatitis B vaccine series and hepatitis B immune globulin (HBIg).[109] The combination of HBV vaccine and HBIg is 85% to 95% effective at preventing perinatal HBV transmission. Similar to HIV, the rate of perinatal HBV transmission correlates with maternal viral load.[114] It is reasonable to measure maternal viral load between 30 and 34 weeks, permitting counseling regarding the risk of perinatal transmission. Lamivudine and HBIg limit intrauterine HBV transmission in viremic pregnant women better than HBIg alone.[115] Lamivudine is administered orally at a dose of 150 mg daily starting at 34 weeks to reduce perinatal HBV transmission in high-risk patients (i.e., those with a viral load $>10^7$); consultation with a hepatologist is recommended. Up to 80% to 90% of the infants of women acutely infected with HBV in the third trimester of pregnancy will be HBsAg positive at birth[105]; however, it is not known whether antiviral treatment during acute HBV infection lowers this risk.

Hepatitis C

Virology/Epidemiology

Hepatitis C virus (HCV) is an enveloped, single-stranded RNA virus that is part of the Flaviviridae family. Prior to its identification in the 1980s it was known as non-A non-B

hepatitis. HCV is transmitted primarily parenterally and via vertical transmission. The risk of sexual transmission of HCV is substantially lower than that of HBV. Risk factors for HCV seropositivity include IV drug use, a history of transfusion of blood or blood products, obesity, and high gravidity.[116] More than 50% of individuals infected with HCV are chronic carriers, making HCV the most common chronic blood-borne pathogen in the United States.[117] The incubation period for HCV following exposure is 5 to 10 weeks, and 75% of acutely infected individuals are asymptomatic.

Diagnosis

The recommended initial screening test is ELISA for HCV-specific antibodies; for screen positive individuals the CDC recommends a more specific supplemental assay to verify serologic evidence of HCV infection, either the recombinant immunoblot assay (RIBA) or a nucleic acid test (NAT).[118] Universal screening is not recommended but individuals at risk should be tested (see box, Risk Factors for Hepatitis C). To assess chronic carrier status HCV viral loads are quantitated via PCR,[119] recognizing that there can be significant viral load and hepatic transaminase level variation over time. Thus, a single negative HCV viral load or normal hepatic transaminase level does not rule out chronic carrier status.[117]

Risk Factors for Hepatitis C

Definite Indications for Screening

- History of injection of illegal drugs (even once, many years prior)
- Known HIV positive
- Persistently abnormal liver function tests
- History of long-term hemodialysis
- History of blood transfusion or organ transplant prior to July 1992
- History of clotting factor concentrates before 1987
- History of exposure to blood from an individual known to have HCV
- History of incarceration

Consider Screening (Need Uncertain)

- In-vitro fertilization from anonymous donors
- History of intranasal cocaine or other non-injectable illegal drug use
- History of tattooing or body piercing
- Known sexually transmitted disease or multiple partners
- Steady sex-partner of known HCV-positive individual
- Steady sex-partner of individual with history of injection drug use

HCV in Pregnancy

There is no effective vaccine against HCV. Interferon and ribavirin therapy is used in adults, but these drugs are contraindicated in pregnancy,[117] resulting in expectant management of HCV-infected pregnant women. A ribavirin registry reported no increased incidence of birth defects in 49 direct exposures and 69 indirect exposures.[120] Perinatal HCV transmission correlates with maternal HCV viral load; detectable HCV viremia has a 4% to 7% perinatal HCV transmission rate, whereas perinatal HCV transmission in the absence of detectable HCV viremia is rare. Other risk factors for perinatal HCV transmission are maternal IV drug use and HIV co-infection. The HCV infection prevalence in children co-infected with HIV was 1.5%, and treatment of maternal HIV infection lowers both HIV and HCV transmission.[121] The strongest predictor of perinatal HCV transmission is maternal HCV viral load. HCV transmission risk is increased with invasive fetal monitoring and rupture of membranes greater than 6 hours[14]; however, elective cesarean delivery does not reduce perinatal HCV transmission.[122] Pregnant women with a history of hepatitis C infection should be immunized against hepatitis A and B if not immune, and there is no contraindication to breastfeeding in women chronically infected with HCV.

Hepatitis D

Hepatitis delta virus (HDV) is an incomplete RNA virus related to plant viruses. The hepatitis D genome encodes a single nucleocapsid protein, HDAg, which is present as two peptides. The short form is required for RNA replication and the long form is packaged with HDV RNA and the HBsAg envelope glycoprotein. Because hepatitis D virus utilizes HBV as a helper virus (providing envelope glycoprotein), simultaneous or chronic HBV infection is required for viral replication. HDV is present worldwide, with a high prevalence in the Mediterranean basin, Middle East, Central Asia, West Africa, and the Amazon basin. Risk factors include IV drug use and exposure to infected blood products. Chronic HDV infection occurs at a rate of 1% to 3% when acquired as an HBV co-infection; the chronic infection rate is 70% to 80% when HDV superinfection occurs in an individual chronically infected with HBV. Patients chronically co-infected with HBV and HDV have a 70% to 80% risk for developing cirrhosis and portal hypertension, and 25% die of hepatic failure. Acute infection with HDV is characterized by HDV antigen positivity in the absence of HDV antibody. Individuals chronically infected with HDV will have detectable HDV antigen and HDV antibody. Acute hepatitis D infection is associated with an increased incidence of fulminant hepatic failure, which has a mortality rate of 2% to 20%. HDV can be perinatally transmitted,[123] although perinatal HBV prophylaxis is also effective at preventing perinatal HDV transmission in patients co-infected with HBV.[105]

Hepatitis E

Hepatitis E virus is an enveloped, RNA virus that is most closely related to the togavirus family, which also includes rubella. Hepatitis E is transmitted by oral-fecal contact and is endemic outside of the United States in regions such as Africa, Asia, and Latin America. Similar to hepatitis A, hepatitis E infection causes only acute disease. Diagnosis can be made by the presence of a specific IgM or of viral nucleic acid (RT-PCR). There are 4 genotypes; genotypes 1 and 2 are non-zoonotic and present in developing countries, and genotypes 3 and 4 are zoonotic and present in industrialized countries. The mortality rate following acute hepatitis E infection in the general population is 1%. Significantly higher mortality (up to 20%) has been observed in pregnant women infected with hepatitis E. Most of

these women were infected with genotypes 1 and 2.[124] The preterm delivery rate in patients with hepatitis E is estimated as high as 66%,[125] and maternal morbidity and mortality escalates with increasing gestational age.[105,125] Hepatitis E virus can also be perinatally transmitted and it has been associated with significant perinatal morbidity and mortality.[126]

WEST NILE VIRUS

West Nile virus (WNV) is a flavivirus transmitted by mosquitoes that infects a variety of birds and mammals, including humans. Most infections are subclinical (80%) and most symptomatic infections present with "West Nile fever" consisting of fever, headache, fatigue, rash, lymphadenopathy, and eye pain. Much less common is severe disease, which includes gastrointestinal symptoms, ataxia, extrapyramidal signs, seizures, weakness, mental status changes, and other neurologic findings. Severe disease is associated with aseptic meningitis, encephalitis, and flaccid paralysis. No specific treatment is available for WNV infection; supportive care should be provided. Diagnosis of WNV infection is based on the presence of specific IgM antibody and by neutralization assays; PCR is of limited usefulness because of transient and low viremia. Overall outcome in pregnant women infected with WNV is good, although some infections result in severe disease or encephalitis.[127] Outcome is good for the majority of exposed infants; there have been rare cases of encephalitis, and no reports of congenital malformations.[128] There is one documented case of WNV transmission during breastfeeding; no adverse outcome was noted, leading the CDC to recommend that women infected with WNV continue breastfeeding.[127] Prevention of potential maternal WNV infection includes avoiding the outdoors during peak mosquito feeding times, wearing protective clothing, and using insect repellants containing DEET.

COXSACKIE VIRUS

Coxsackie virus is the causative agent of hand, foot, and mouth disease; it is an enterovirus transmitted through the fecal-oral route. Several serotypes exist, and adult infection typically results in a self-limited febrile illness requiring no treatment.[129] There is one reported case of coxsackie B virus infection in pregnancy leading to acute liver failure that resolved following expectant management.[130] Coxsackie virus infection during pregnancy has also been associated in several studies with an increased rate of miscarriage[129,131] and an increased rate of insulin-dependent diabetes in offspring,[129,132] although a causative relationship has not been established.

HUMAN PAPILLOMAVIRUS

Human papillomaviruses HPVs are a group of small DNA viruses. Some types cause warts (HPV types 6, 11), whereas other types do not cause warts and are instead highly associated with the development of cervical and oral cancer (HPV types 16, 18, 31, 33, 52b, 58). Infections are sexually and/or vertically transmitted and the incidence of infection in college-aged women is nearly 50%. Therefore, it is not uncommon for pregnant women to have evidence of HPV infection. A recent study found that 37% of pregnant women without evidence of infection had detectable HPV DNA in the cervix, demonstrating an unexpectedly high rate of HPV infection in asymptomatic women.[133] Anogenital warts, caused by non-oncogenic HPV types, are one presentation of HPV infection and may be managed expectantly. However, hormonal effects can cause rapid proliferation and growth of warts necessitating treatment. Trichloroacetic acid and/or cryotherapy are used to treat anogenital warts in pregnancy, as podophyllin is contraindicated and little is known regarding the safety of imiquimod in pregnancy. Vaginal delivery is not contraindicated, unless the wart burden and position would result in dystocia. Maternal HPV infection with HPV types 6 and 11 is associated with pediatric laryngeal papillomatosis. However, given the high prevalence of maternal HPV infection and the rarity of laryngeal papillomatosis, prophylactic cesarean delivery is not recommended.[133,134] Cervical dysplasia is another consequence of HPV infection; appropriate management of abnormal Pap smears should be undertaken independent of pregnancy.

EPSTEIN-BARR VIRUS

The causative agent of infectious mononucleosis is Epstein-Barr Virus (EBV), a member of the herpesvirus family. Clinical presentation includes malaise, headache, fever, pharyngitis, lymphadenopathy, atypical lymphocytosis, heterophile antibody, and transient mild hepatitis. Infection is typically self-limited. EBV establishes latent infection in B lymphocytes; EBV can be reactivated, and is associated with the development of Hodgkin's and non-Hodgkin's lymphoma. Most adults (>95%) are seropositive for EBV; thus primary EBV infection in pregnancy is rare. Primary infection and/or reactivation of EBV is not associated with significant adverse pregnancy outcome.[135] There is an association between EBV reactivation in pregnancy and the development of childhood acute lymphoblastic leukemia,[136] and in utero EBV transmission has been demonstrated by detection of EBV DNA in neonatal lymphocytes.[137] However, in utero infection has not been associated with adverse outcome. Routine testing is not indicated given the extremely high prevalence of seropositivity and the lack of impact on pregnancy.

SMALLPOX

Variola virus is the causative agent of smallpox. Variola virus infection is restricted to humans and is highly transmissible via inhalation of airborne droplets or by direct contact with smallpox lesions on an infected individual.[138] Secondary to widespread vaccination, the last case of reported smallpox in the United States was in 1949; the World Health Organization declared smallpox's global eradication in 1980. Recent concerns regarding the potential use of variola virus as a bioterrorism agent has led to renewed interest in the clinical presentation and treatment of smallpox disease.

Patients with smallpox infection first experience high fever, chills, headache, backache, and vomiting; these

FIGURE 50-7. Smallpox vesicles, day 3 of clinical infection. (From Tyring S, et al: Tropical Dermatology. Edinburgh, Saunders, 2005.)

symptoms differentiate smallpox from chickenpox (varicella virus), which has a minimal prodrome.[138] Delirium is present in 15% of cases, and some infections progress to encephalitis. Skin lesions appear 2 to 3 days following the onset of symptoms, and progress from macula to papule to vesicle (Figure 50-7), vesicle to pustule to scabs, which then form pitted scars. Smallpox lesions appear in a centrifugal distribution and affect the soles and palms, in contrast to varicella infection, which exhibits a centripetal distribution of lesions and spares the palms and soles. Diagnosis should be confirmed by PCR reaction of pustular fluid and/or scabs in a biocontainment facility.

Maternal treatment is supportive; vaccination and containment are critical. The maternal mortality rate of unvaccinated women is more than 60%.[138] Death usually occurs secondary to viral pneumonitis, bacterial pneumonia, or cardiovascular collapse; moreover, pregnant women are at increased risk for hemorrhagic smallpox, a more severe and lethal manifestation of infection. When infection occurs prior to 24 weeks, 75% of pregnancies end in loss or premature delivery. During the latter half of pregnancy, smallpox infection is associated with a 55% rate of subsequent preterm delivery. Variola virus crosses the placenta, leading to intrauterine infection. During epidemics of the disease, the reported incidence of congenital variola (infection) ranges from 9% to 60%.

Vaccination within 2 to 3 days of initial exposure affords almost complete protection against disease.[138,139] The currently available vaccine, Dryvax, is composed of live, attenuated vaccinia virus. This vaccine has a higher risk of complications than other viral vaccines, including postvaccinal encephalitis (incidence 12 per million vaccines, 40% mortality rate), mild generalized vaccinia, and eczema vaccinatum. Smallpox vaccination is currently restricted to women in military service and researchers utilizing related viruses. Data on women vaccinated during pregnancy are being compiled in the National Smallpox Vaccine in Pregnancy Registry.[139] Fetal infection following maternal vaccination (fetal vaccinia) is rare, and is characterized by skin lesions and internal organ involvement but is not associated with fetal malformations. Therefore, vaccination is not considered an indication for pregnancy termination. The CDC recommends deferring elective smallpox vaccination while pregnant; however, immediate vaccination is indicated following smallpox exposure, independent of pregnancy, secondary to the risk of clinical smallpox infection to the mother and fetus.[139]

KEY POINTS

- All pregnant women should be offered HIV screening, using an "opt out" approach. In areas of high seroprevalence, repeat screening in the third trimester may be warranted.
- Rapid HIV testing should be offered in early labor to women without documented HIV status, because most perinatally infected infants are born to women who do not know their HIV status.
- Combination care with at least three drugs from at least two classes of ARV is the standard of care for HIV infection in the United States.
- Early and sustained control of viral replication is associated with decreased HIV transmission (including starting therapy prior to conception). ART should be started as early in pregnancy as possible for all women.
- Pregnant women suspected to be infected with influenza should be treated immediately, without delay for diagnostic confirmation.
- The ACOG and the CDC recommend vaccination of all pregnant women during the influenza season (October-May) using the intramuscular, inactivated vaccine.
- Fetal parvovirus infection may result in fetal anemia and hydrops. Women with documented infection should be screened serially with ultrasound and middle cerebral artery Doppler studies.
- Rubeola (measles) is one of the most infectious viruses; 75% to 90% of exposed, susceptible contacts become infected. Outbreaks often originate in individuals born outside the United States.
- Preconceptual vaccination with live attenuated viral vaccines can prevent antenatal rubeola, rubella, and varicella infection but should be avoided in pregnancy.
- Routine screening for CMV infection during pregnancy is not recommended given the prevalence of seropositivity.
- CMV transmission is highest in the third trimester and the overall risk of fetal transmission is 30% to 40%. Serious sequelae occur most commonly after first-trimester infection; 24% of these infected fetuses have sensorineural hearing loss and 32% have other CNS sequelae.
- Women without a history of varicella should be considered for serum testing. Susceptible women exposed to varicella should be treated with VZIG to reduce the risk of transmission.

- All pregnant women should be screened for hepatitis B infection. Infants delivered to seropositive mothers should receive both hepatitis B immune globulin (HBIg) and hepatitis B vaccine shortly after birth.
- Hepatitis A and B vaccination is safe in pregnancy and should be offered to susceptible women at risk.

Bacterial infections are the single most common complication encountered by the obstetrician. Some infections, such as puerperal endometritis and lower urinary tract infection, are of principal concern to the mother and pose little or no risk to the fetus or neonate. Others, such as listeriosis and toxoplasmosis, are of greatest threat to the fetus. Still others, such as group B streptococcal infection (GBS), pyelonephritis, and chorioamnionitis, may cause serious morbidity, even life-threatening complications, for both the mother and baby. The purpose of this chapter is to review in detail the major bacterial infections and the key protozoan infection (toxoplasmosis) that the obstetrician confronts in daily clinical practice.

GROUP B STREPTOCOCCAL INFECTION

Epidemiology

Streptococcus agalactiae is a gram-positive encapsulated coccus that produces β-hemolysis when grown on blood agar. **On average, about 20% to 25% of pregnant women harbor GBS in their lower genital tract and rectum.** The GBS is one of the most important causes of early-onset neonatal infection. The prevalence of neonatal GBS infection now is about 0.5 per 1000 live births, and about 10,000 cases of neonatal streptococcal septicemia occur each year in the United States.[1]

Neonatal GBS infection can be divided into early-onset and late-onset infection. **About 80% to 85% of cases of neonatal GBS infection are early in onset and result almost exclusively from vertical transmission from a colonized mother.** Early-onset infection presents primarily as a severe pneumonia and overwhelming septicemia. In preterm infants, the mortality rate from early-onset GBS infection may approach 25%. In term infants, the mortality rate is lower, averaging about 5%.[2] Late-onset neonatal GBS infection occurs as a result of both vertical and horizontal transmission. It is typically manifested by bacteremia, meningitis, and pneumonia. The mortality rate from late-onset infection is about 5% for both preterm and term infants.[1]

Unfortunately, obstetrical interventions have proved ineffective in preventing late-onset neonatal infection. Therefore, the remainder of this discussion focuses on early-onset infection.

Major risk factors for early-onset infection include preterm labor, especially when complicated by preterm premature rupture of the membranes (PROM); intrapartum maternal fever (chorioamnionitis); prolonged rupture of membranes, defined as greater than 18 hours; previous delivery of an infected infant; young age; and black and Hispanic ethnicity.[1] About 25% of pregnant women have at least one risk factor for GBS infection. The neonatal attack rate in colonized patients is 40% to 50% in the presence of a risk factor and less than 5% in the absence of a risk factor. In infected infants, neonatal mortality approaches 30% to 35% when a maternal risk factor is present but is less than 5% when a risk factor is absent.[2,3]

Maternal Complications

Several obstetrical complications occur with increased frequency in pregnant women who are colonized with GBS. The organism is one of the major causes of chorioamnionitis and postpartum endometritis. It may cause postcesarean delivery wound infection, usually in conjunction with other aerobic and anaerobic bacilli and staphylococci. The organism also is responsible for about 2% to 3% of lower urinary tract infections in pregnant women.[1] GBS urinary

*Sensitivities for identification of heavily colonized women ranged from 29% to 100%.
†Specimens were grown in culture for 3.5 hr before DNA probe was used.

tract infection, in turn, is a risk factor for preterm PROM and preterm labor. For example, Thomsen and colleagues[4] reported a study of 69 women at 27 to 31 weeks' gestation who had streptococcal urinary tract infections. Patients were assigned to treatment with either penicillin or placebo. Treated patients had a significant reduction in the frequency of both preterm PROM and preterm labor.

Other investigations have confirmed the association between GBS colonization and preterm labor and preterm PROM. Women with the latter complication who are colonized with GBS tend to have a shorter latent period and higher frequency of chorioamnionitis and puerperal endometritis compared with noncolonized women.[5]

Diagnosis

The gold standard for the diagnosis of GBS infection is bacteriologic culture. Todd-Hewitt broth or selective blood agar is the preferred medium. **Specimens for culture should be obtained from the lower vagina, perineum, and perianal area, using a simple cotton swab.** In recent years, considerable research has been devoted to assessment of rapid diagnostic tests for the identification of colonized women. Table 51-1 summarizes the results of several investigations of rapid diagnostic tests. The information in this table is based on the review by Yancey and associates.[6] These authors noted that, although the rapid diagnostic tests had reasonable sensitivity in identifying heavily colonized patients, they had poor sensitivity in identifying lightly and moderately colonized patients.

Although the first-generation rapid diagnostic tests were not as valuable as originally hoped, Bergeron and colleagues[7] recently reported exceptionally favorable results with a new polymerase chain reaction (PCR) assay for GBS. In a series of 112 patients, the authors documented a sensitivity of 97%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 99%. This PCR assay now is commercially available and offers clear promise as a rapid test for screening patients at the time of admission for labor.

Prevention of Group B Streptococcal Infection

In the past 20 years, several different strategies have been proposed for the prevention of neonatal GBS infection.[2,3,8-10] Each strategy has had major imperfections. In 1996, however, the Centers for Disease Control and Prevention (CDC) published a series of recommendations that incorporated the major advantages of previous protocols and minimized some of the more problematic aspects of selected strategies.[11] The initial CDC guidelines recommended either universal culturing of all patients at 35 to 37 weeks and intrapartum treatment of all colonized women or selective treatment on the basis of identified risk factors. Subsequently, in a large population-based survey, Rosenstein and Schuchat[12] assessed the theoretical impact of the CDC recommendations and showed that a strategy of universal culturing and treatment of all colonized patients would prevent 78% of cases of neonatal infection. In contrast, only 41% of cases were prevented when patients were targeted for prophylaxis just on the basis of risk factors. In addition, Locksmith and colleagues[13] confirmed that universal culturing also was of value in decreasing the rate of maternal infection compared with a strategy of only treating on the basis of risk factors.

In 2002, the CDC issued revised guidelines for prevention of early-onset GBS infection.[1] **The newest guidelines recommend universal cultures in all patients as the optimal method of prevention. Cultures should be performed at 35 to 37 weeks. All patients who test positive should receive intrapartum antibiotic prophylaxis with one of the regimens outlined in Table 51-2. Ideally, antibiotics should be administered at least 4 hours before delivery.** DeCueto and coworkers[14] demonstrated that the rate of neonatal GBS infection was reduced significantly when patients were treated for at least this period of time. In a subsequent investigation assessing timing of antibiotic prophylaxis, McNanley and associates[15] showed that mean vaginal GBS counts decreased 5-fold within 2 hours of antibiotic administration, 50-fold within 4 hours, and almost 1000-fold within 6 hours.

The new CDC guidelines also addressed issues that previously had been imprecisely defined.[1] Colonized patients scheduled for an elective cesarean delivery do not require intrapartum prophylaxis. Patients who tested positive for GBS in a previous pregnancy should not be assumed to be colonized and should be retested in the present pregnancy. This recommendation is supported by a later report from Edwards and coworkers.[16] These authors noted that only 59% of patients who were culture positive in a previous pregnancy were positive in the present pregnancy. Conversely, however, patients who have GBS bacteriuria in pregnancy, even if treated, should be considered heavily colonized and should be targeted for intrapartum prophylaxis. Moreover, patients who had a previous infant with GBS infection also should be considered colonized and treated during labor.

TABLE 51-2 ANTIBIOTICS WITH ACTIVITY AGAINST GROUP B STREPTOCOCCI

DRUG	DOSE FOR INTRAPARTUM PROPHYLAXIS
Ampicillin	2 g initially, then 1 g q4h
Penicillin	5 million units initially, then 2.5 to 3 million units q4h
Cefazolin*	1 g q8h
Clindamycin†	900 mg q8h
Vancomycin†	1000 mg q12h

Recommendations based on Prevention of perinatal group B streptococcal disease: revised guidelines from the CDC. MMWR Morb Mortal Wkly Rep 51(Suppl):1, 2002.
*Cefazolin should be used in patients who have a history of a non-life-threatening allergy to penicillin.
†Clindamycin or vancomycin should be used in patients who have a history of a life-threatening allergy to penicillin. Clindamycin should be used only if sensitivity testing confirms that the organism is sensitive (up to 10% of strains of GBS may be resistant). Vancomycin should be used if the organism is resistant to clindamycin or sensitivity tests are not available.

URINARY TRACT INFECTIONS

Acute Urethritis

Acute urethritis (acute urethral syndrome) is usually caused by one of three organisms: coliforms (principally *Escherichia coli*), *Neisseria gonorrhoeae*, and *Chlamydia trachomatis*. Coliform organisms are part of the normal vaginal and perineal flora and may be introduced into the urethra during intercourse or when wiping after defecation. *N. gonorrhoeae* and *C. trachomatis* are sexually transmitted pathogens.[17] Affected patients typically experience frequency, urgency, and dysuria. Hesitancy, dribbling, and a mucopurulent urethral discharge also may be present. On microscopic examination, the urine usually has white blood cells, but bacteria may not be consistently present. Urine cultures may have low colony counts of coliform organisms, and cultures of the urethral discharge may be positive for gonorrhea and chlamydia. A rapid diagnostic test, such as a nucleic acid probe, may be used in lieu of culture for gonorrhea and chlamydia.[17]

Most patients with acute urethritis warrant empirical treatment before the results of laboratory tests are available. Infections caused by coliforms usually respond to the antibiotics described later for treatment of asymptomatic bacteriuria and cystitis. **If gonococcal infection is suspected, the patient should be treated with intramuscular ceftriaxone (250 mg in a single dose).**[18] If the patient is allergic to β-lactam antibiotics, an effective alternative is azithromycin, 2000 mg orally in a single dose. This high dose of azithromycin is more likely to be associated with gastrointestinal side effects than more conventional lower doses. An alternative choice in the penicillin-allergic patient is ciprofloxacin 500 mg orally in a single dose. **If chlamydial infection is suspected or confirmed, the patient should be treated with azithromycin (1000 mg) in a single dose.**[18] The powder formulation of azithromycin is less expensive than the tablet formulation.

Asymptomatic Bacteriuria and Acute Cystitis

The prevalence of asymptomatic bacteriuria in pregnancy is 5% to 10%, and most cases antedate the onset of pregnancy. The frequency of acute cystitis in pregnancy is 1% to 3%. Some cases of cystitis arise de novo; others develop as a result of failure to identify and treat asymptomatic bacteriuria.[19]

***E. coli* is responsible for at least 80% of cases of initial infections and about 70% of recurrent cases. *Klebsiella pneumoniae* and *Proteus* species also are important pathogens, particularly in patients who have a history of recurrent infection. Up to 10% of infections are caused by gram-positive organisms such as GBS, enterococci, and staphylococci.**[17,19]

All pregnant women should have a urine culture at their first prenatal appointment to detect preexisting asymptomatic bacteriuria. If the culture is negative, the likelihood of the patient subsequently developing an asymptomatic infection is less than 5%. If the culture is positive (defined as greater than 10^5 colonies/mL urine from a midstream, clean-catch specimen), prompt treatment is necessary to prevent ascending infection. In the absence of effective treatment, about one third of pregnant women with asymptomatic bacteriuria will develop acute pyelonephritis.

Patients with acute cystitis usually have symptoms of frequency, dysuria, urgency, suprapubic pain, hesitancy, and dribbling. Gross hematuria may be present, but high fever and systemic symptoms are uncommon. In symptomatic patients, the leukocyte esterase and nitrate tests are usually positive. When a urine culture is obtained, a catheterized sample is preferred because it minimizes the probability that urine will be contaminated by vaginal flora. With a catheterized specimen, a colony count greater than 10^2/mL is considered indicative of infection.[20]

Asymptomatic bacteriuria and acute cystitis characteristically respond well to short courses of oral antibiotics. Single-dose therapy is not as effective in pregnant women as in nonpregnant patients. However, a 3-day course of treatment appears to be comparable to a 7- to 10-day regimen for an initial infection.[17] Longer courses of therapy are more appropriate for patients with recurrent infections. Table 51-3 lists several antibiotics of value for treatment of asymptomatic bacteriuria and cystitis.

When sensitivity tests are available, for example, for patients with asymptomatic bacteriuria, they may be used to guide antibiotic selection. When empirical treatment is indicated, the choice of antibiotics must be based on established patterns of susceptibility. In recent years, 20% to 30% of strains of *E. coli* have developed resistance to ampicillin. Thus, this drug should not be used when the results of sensitivity tests are unknown unless the suspected pathogen is enterococci.[18,21] When enterococcus is the offending pathogen, ampicillin or amoxicillin is the drug of choice.

When choosing among the drugs listed in Table 51-3, the clinician should consider the following factors. First, the sensitivity patterns of ampicillin, amoxicillin, and cephalexin are the most variable. Second, these drugs, along with amoxicillin-clavulanic acid, also have the most pronounced effect on normal bowel and vaginal flora and, thus, are the most likely to cause diarrhea or monilial vulvovaginitis. In contrast, nitrofurantoin monohydrate has only minimal effect on vaginal or bowel flora. Moreover, it is more uniformly effective against the common

TABLE 51-3 ANTIBIOTICS FOR TREATMENT OF ASYMPTOMATIC BACTERIURIA AND ACUTE CYSTITIS

DRUG (TRADE NAME)	STRENGTH OF ACTIVITY	ORAL DOSE	RELATIVE COST
Amoxicillin	Some *Escherichia coli*, most *Proteus* species, group B streptococci, enterococci, some staphylococci	500 mg tid or 875 mg bid	Low
Amoxicillin-clavulanic acid (Augmentin)	Most gram-negative aerobic bacilli and gram-positive cocci	875 mg bid	High
Ampicillin	Some *E. coli*, most *Proteus* species, group B streptococci, enterococci, some staphylococci	250 mg four times daily	Low
Cephalexin (Keflex)	Most *E. coli*, most *Klebsiella* and *Proteus* species, group B streptococci, staphylococci	250 mg four times daily	Low
Nitrofurantoin monohydrate macrocrystals—sustained-release preparation (Macrobid)	Most uropathogens except enterococci and *Proteus* species	100 mg bid	Moderate
Sulfisoxazole (Gantrisin)	Most gram-negative aerobic bacilli	2 g × 1 dose, then 1 g four times daily	Low
Trimethoprim-sulfamethoxazole double-strength (Bactrim-DS, or Septra-DS)	Most uropathogens except some strains of *E. coli*	800 mg/160 mg bid	Low

uropathogens, except for *Proteus* species, than trimethoprim-sulfamethoxazole. Third, amoxicillin-clavulanic acid and trimethoprim-sulfamethoxazole usually are the best empirical agents for treatment of patients with suspected drug-resistant pathogens.[22] In this situation, the latter drug offers a major cost advantage over the former. Finally, because of theoretical concerns about their effect on protein binding of bilirubin, sulfonamide drugs should be avoided near the time of delivery.

For patients who have an initial infection and experience a prompt response to treatment, a urine culture for test of cure may not be clinically necessary or cost-effective.[17,22] Cultures during, or immediately after, treatment are indicated for patients who have a poor response to therapy or who have a history of recurrent infection. During subsequent clinic appointments, the patient's urine should be screened for nitrites and leukocyte esterase. If either of these tests is positive, repeat urine culture and retreatment are indicated.

Acute Pyelonephritis

The incidence of pyelonephritis in pregnancy is 1% to 2%.[19] Most cases develop as a consequence of undiagnosed or inadequately treated lower urinary tract infection. Two major physiologic changes occur during pregnancy that predispose to ascending infection of the urinary tract. First, the high concentration of progesterone secreted by the placenta has an inhibitory effect on ureteral peristalsis. Second, the enlarging gravid uterus often compresses the ureters, particularly the right, at the pelvic brim, thus creating additional stasis. Stasis, in turn, facilitates migration of bacteria from the bladder into the ureters and renal parenchyma (Figure 51-1).

About 75% to 80% of cases of pyelonephritis occur on the right side. Ten to 15% are left sided, and a slightly smaller percentage are bilateral.[19] *E. coli* is again the principal pathogen.[19,21] *K. pneumoniae* and *Proteus* species also are important causes of infection, particularly in women with recurrent episodes of pyelonephritis. Highly virulent gram-negative bacilli, such as *Pseudomonas*, *Enterobacter*, and *Serratia*, are unusual isolates except in immunocompromised patients. Gram-positive cocci do not frequently cause upper tract infection. Anaerobes also are unlikely pathogens unless the patient is chronically obstructed or instrumented.

FIGURE 51-1. Intravenous pyelogram in a pregnant woman shows marked dilation of the right ureter and mild dilation of renal collecting system.

The usual clinical manifestations of acute pyelonephritis in pregnancy are fever, chills, flank pain and tenderness, frequency, urgency, hematuria, and dysuria. Patients also may have signs of preterm labor, septic shock, and acute respiratory distress syndrome (ARDS). Urinalysis is usually positive for white blood cell casts, red blood cells, and bacteria. Urine colony counts greater than 10^2 colonies/mL, in samples collected by catheterization, confirm the diagnosis of infection.

Pregnant patients with pyelonephritis may be considered for outpatient therapy if their disease manifestations are mild, they are hemodynamically stable, and they have no evidence of preterm labor.[23] If an outpatient approach is adopted, the patient should be treated with agents

that have a high level of activity against the common uropathogens. Acceptable oral agents include amoxicillin-clavulanic acid, 875 mg twice daily, or trimethoprim-sulfamethoxazole-DS, twice daily for 7 to 10 days. Alternatively, a visiting home nurse may be contracted to administer a parenteral agent, such as ceftriaxone, 2 g intramuscularly or intravenously (IV), once daily. Although an excellent drug for lower tract infections, nitrofurantoin monohydrate does not consistently achieve the serum and renal parenchymal concentrations necessary for successful treatment of more serious infections.

Pregnant patients who appear to be moderately to severely ill or who show any signs of preterm labor should be hospitalized for intravenous antibiotic therapy. They should receive appropriate supportive treatment and be monitored closely for complications such as sepsis, ARDS, and preterm labor. One reasonable choice for empirical intravenous antibiotic therapy is ceftriaxone, 2 g every 24 hours. Compared with a first-generation cephalosporin like cefazolin, ceftriaxone has expanded coverage against aerobic gram-negative bacilli and has the advantage of once-daily dosing.[18] If the patient is critically ill or is at high risk for a resistant organism, a second antibiotic, such as gentamicin (7 mg/kg/ideal body weight every 24 hours) or aztreonam (500 mg to 1 g every 8 to 12 hours) should be administered, along with ceftriaxone, until the results of susceptibility tests are available.

Once antibiotic therapy is initiated, about 75% of patients defervesce within 48 hours. By the end of 72 hours, almost 95% of patients are afebrile and asymptomatic.[19] The two most likely causes of treatment failure are a resistant microorganism and obstruction. The latter condition is best diagnosed with computed tomography (CT) scan or renal ultrasonography and typically results from a stone or physical compression of the ureter by the gravid uterus.

Once the patient has begun to defervesce and her clinical examination has improved, she may be discharged from the hospital. Oral antibiotics should be prescribed to complete a total of 7 to 10 days of therapy. Selection of a specific oral agent should be based on considerations of efficacy, toxicity, and expense. A repeat urine culture should be obtained after 5 to 7 days of therapy to ensure that the urine is sterile before antibiotics are discontinued.

About 20% to 30% of pregnant patients with acute pyelonephritis develop a recurrent urinary tract infection later in pregnancy. The most cost-effective way to reduce the frequency of recurrence is to administer a daily prophylactic dose of an antibiotic, such as sulfisoxazole, 1 g, or nitrofurantoin monohydrate, 100 mg. Patients receiving prophylaxis should have their urine screened for bacteria at each subsequent clinic appointment. They also should be questioned about recurrence of symptoms. If symptoms recur, or the dipstick test for nitrite or leukocyte esterase is positive, a urine culture should be obtained to determine whether retreatment is necessary.

UPPER GENITAL TRACT INFECTIONS

Chorioamnionitis

Epidemiology

Chorioamnionitis (amnionitis, intra-amniotic infection) occurs in about 1% to 5% of term pregnancies.[24] In patients with preterm delivery, the frequency of clinical or subclinical infection may approach 25%.[25] Although chorioamnionitis may result from hematogenous dissemination of microorganisms, it more commonly is an ascending infection caused by organisms that are part of the normal vaginal flora. **The principal pathogens are *Bacteroides* and *Prevotella* species, *E. coli*, anaerobic gram-positive cocci, GBS, and genital mycoplasmas.**

Several clinical risk factors for chorioamnionitis have been identified. The most important are young age, low socioeconomic status, nulliparity, extended duration of labor and ruptured membranes, multiple vaginal examinations, and preexisting infections of the lower genital tract (e.g., bacterial vaginosis).[24]

Diagnosis

In most situations, the diagnosis of chorioamnionitis can be established on the basis of the clinical findings of maternal fever and maternal and fetal tachycardia, in the absence of other localizing signs of infection. In more severely ill patients, uterine tenderness and purulent amniotic fluid may be identified. The disorders that should be considered in the differential diagnosis of chorioamnionitis include respiratory tract infection, pyelonephritis, viral syndrome, and appendicitis.[24]

Laboratory confirmation of the diagnosis of chorioamnionitis is not routinely necessary in term patients who are progressing to delivery. However, in preterm patients who are being evaluated for tocolysis or corticosteroids, laboratory assessment may be of value in establishing the diagnosis of intrauterine infection. In this clinical context, amniotic fluid should be obtained by transabdominal amniocentesis. Table 51-4 summarizes the abnormal laboratory findings that may be present in infected patients.[24-29]

Management

Both the mother and infant may experience serious complications when chorioamnionitis is present. Bacteremia occurs in 3% to 12% of infected women. When cesarean delivery is required, up to 8% of women develop a wound infection, and about 1% develop a pelvic abscess. Fortunately, maternal death due to infection is exceedingly rare.[24]

Five to 10% of neonates delivered to mothers with chorioamnionitis have pneumonia or bacteremia. The predominant organisms responsible for these infections are GBS and *E. coli*. Meningitis occurs in less than 1% of term infants and in a slightly higher percentage of preterm infants. Mortality due to infection ranges from 1% to 4% in term neonates but may approach 15% in preterm infants because of the confounding effects of other complications such as hyaline membrane disease and intraventricular hemorrhage.[24]

To prevent maternal and neonatal complications, parenteral antibiotic therapy should be initiated as soon as the diagnosis of chorioamnionitis is made, unless delivery is imminent. Three separate investigations have demonstrated that mother-infant pairs who receive prompt intrapartum treatment have better outcomes than patients treated after delivery.[30-32] The principal benefits of early treatment include decreased frequency of neonatal

TABLE 51-4 DIAGNOSTIC TESTS FOR CHORIOAMNIONITIS

TEST	ABNORMAL FINDING	COMMENT
Maternal white blood cell count (WBC)	≥15,000 cells/mm^3 with preponderance of leukocytes	Labor and/or corticosteroids also may result in elevation of WBC
Amniotic fluid glucose	≤10 to 15 mg%	Excellent correlation with positive amniotic fluid culture and clinical infection
Amniotic fluid interleukin-6	≥7.9 ng/mL	Excellent correlation with positive amniotic fluid culture and clinical infection
Amniotic fluid leukocyte esterase	≥1$^+$ reaction	Good correlation with positive amniotic fluid culture and clinical infection
Amniotic fluid gram stain	Any organism in an oil immersion field	Allows identification of particularly virulent organism such as group B streptococci. However, the test is very sensitive to inoculum effect. In addition, it cannot identify pathogens such as mycoplasmas.
Amniotic fluid culture	Growth of aerobic or anaerobic microorganism	Results are not immediately available for clinical management
Blood cultures	Growth of aerobic or anaerobic microorganism	Will be positive in 5% to 10% of patients; however, will usually not be of value in making clinical decisions unless patient is seriously ill or is at increased risk for bacterial endocarditis, is immunocompromised, or has a poor response to initial treatment

bacteremia and pneumonia and decreased duration of maternal fever and hospitalization.

The most extensively tested intravenous antibiotic regimen for treatment of chorioamnionitis is the combination of ampicillin (2 g every 6 hours) or penicillin (5 million units every 6 hours) plus gentamicin (1.5 mg/kg every 8 hours or 7 mg/kg/ideal body weight every 24 hours). The latter regimen of gentamicin is the most cost-effective.[18,24] These antibiotics specifically target the two organisms most likely to cause neonatal infection: GBS and *E. coli*. With rare exceptions, gentamicin is preferred to tobramycin or amikacin because it is available in an inexpensive generic formulation. Amikacin should be reserved for immunocompromised patients who are particularly likely to be infected by highly virulent, drug-resistant aerobic gram-negative bacilli. In patients who are allergic to β-lactam antibiotics, clindamycin (900 mg every 8 hours) should be substituted for ampicillin.

If a patient with chorioamnionitis requires cesarean delivery, a drug with activity against anaerobic organisms should be added to the antibiotic regimen. Either clindamycin (900 mg) or metronidazole (500 mg) is an excellent choice for this purpose. Failure to provide effective coverage of anaerobes may result in treatment failures in 20% to 30% of patients.[18]

Extended-spectrum cephalosporins, penicillins, and carbapenems also provide excellent coverage against the bacteria that cause chorioamnionitis. Dosages and dose intervals for several of these agents are listed in Table 51-5.[18] As a general rule, these drugs are more expensive than the generic combination regimens outlined earlier.

Antibiotics usually can be discontinued soon after delivery. Edwards and Duff[33] recently reported a randomized clinical trial in which patients were treated intrapartum with ampicillin plus gentamicin. In one group of patients, treatment was discontinued after the first postpartum dose of each antibiotic. In the second group, patients were treated until they had been afebrile and asymptomatic for 24 hours. Patients in both groups received at least one dose of clindamycin if they delivered by cesarean. There were no significant differences in treatment outcome in the two groups.

TABLE 51-5 SINGLE AGENTS OF VALUE IN TREATMENT OF CHORIOAMNIONITIS AND PUERPERAL ENDOMETRITIS

DRUG	DOSAGE AND DOSE INTERVAL	RELATIVE COST TO THE PHARMACY*
Extended-Spectrum Cephalosporins		
Cefepime	2 g q12h	Intermediate
Cefotaxime	2 g q8-12h	Intermediate
Cefotetan	2 g q12h	Low
Cefoxitin	2 g q6h	High
Ceftizoxime	2 g q12h	Intermediate
Extended-Spectrum Penicillins		
Ampicillin-sulbactam	3 g q6h	Low
Mezlocillin	3-4 g q6h	Intermediate
Piperacillin	3-4 g q6h	Intermediate
Piperacillin-tazobactam	3.375 g q6h	Intermediate
Ticarcillin-clavulanic acid	3.1 g q6h	Low
Carbapenem		
Ertapenem	1 g q24h	High
Imipenem-cilastatin	500 mg q6h	High
Meropenem	1 g q8h	High

*Cost estimates do not include dose preparation fees and administration charges.

Patients with chorioamnionitis are at increased risk for dysfunctional labor. About 75% require oxytocin for augmentation of labor, and up to 30% to 40% require cesarean delivery, usually for failure to progress in labor. Although chorioamnionitis by itself should not be considered an indication for cesarean delivery, affected patients need close monitoring during labor to ensure that uterine contractility is optimized. In addition, the fetus also needs close surveillance. Fetal heart rate abnormalities such as tachycardia and decreased variability (Figure 51-2) occur in more than three fourths of cases, and additional tests such as scalp stimulation may be necessary to evaluate fetal well-being.[34]

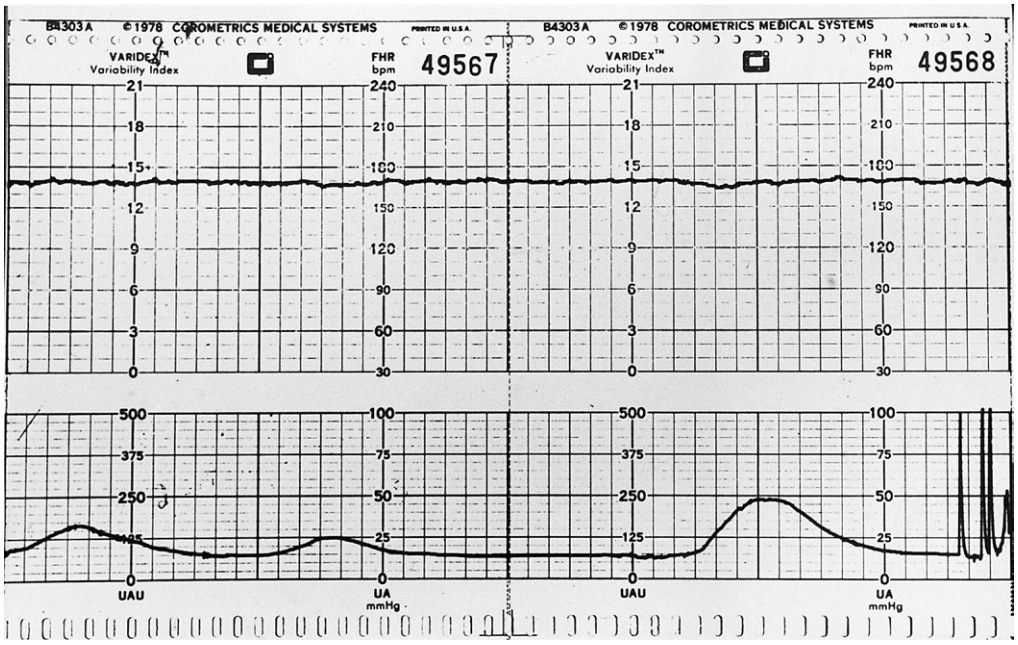

FIGURE 51-2. Fetal heart tracing from a patient with chorioamnionitis. Note the tachycardia of 170 beats/minute and the decrease in both short- and long-term variability.

Puerperal Endometritis

Epidemiology

The frequency of puerperal endometritis in women having vaginal delivery is about 1% to 3%. In women having a scheduled cesarean delivery before the onset of labor and rupture of membranes, the frequency of endometritis ranges from 5% to 15%. When cesarean delivery is performed after an extended period of labor and ruptured membranes, the incidence of infection is 30% to 35% without antibiotic prophylaxis and about 60% less with prophylaxis. In highly indigent patient populations, the frequency of infection may be even higher.[35]

Similarly to chorioamnionitis, endometritis is a polymicrobial infection caused by microorganisms that are part of the normal vaginal flora. These bacteria gain access to the upper genital tract, peritoneal cavity, and occasionally the bloodstream as a result of vaginal examinations during labor and manipulations during surgery. **The most common pathogens are GBS, anaerobic gram-positive cocci, aerobic gram-negative bacilli (predominantly *E. coli*, *K. pneumoniae*, and *Proteus* species), and anaerobic gram-negative bacilli (principally *Bacteroides* and *Prevotella* species).** *C. trachomatis* is not a common cause of early-onset puerperal endometritis but has been implicated in late-onset infection. The genital mycoplasmas may be pathogens in some patients, but they usually are present in association with more highly virulent bacteria.[35]

The principal risk factors for endometritis are cesarean delivery, young age, low socioeconomic status, extended duration of labor and ruptured membranes, and multiple vaginal examinations. In addition, preexisting infection or colonization of the lower genital tract (gonorrhea, GBS, bacterial vaginosis) also predisposes to ascending infection.

Clinical Presentation and Diagnosis

Affected patients typically have a fever of 38° C or higher within 36 hours of delivery. Associated findings include malaise, tachycardia, lower abdominal pain and tenderness, uterine tenderness, and discolored, malodorous lochia. A small number of patients also may have a tender, indurated inflammatory mass in the broad ligament, posterior cul de sac, or retrovesical space.

The initial differential diagnosis of puerperal fever should include endometritis, atelectasis, pneumonia, viral syndrome, pyelonephritis, and appendicitis. Distinction among these disorders usually can be made on the basis of physical examination and a limited number of laboratory tests such as white blood cell count, urinalysis and culture, and in select patients, chest radiograph. Blood cultures should not be done *routinely* because of their expense and their lack of impact on clinical decision making. However, they are indicated in patients who have a poor initial response to therapy and in those who seem seriously ill, are immunocompromised, or are at increased risk for bacterial endocarditis.

Management

Patients who have mild to moderately severe infections, particularly after vaginal delivery, can be treated with short intravenous courses of single agents such as the extended-spectrum cephalosporins and penicillins or carbapenem antibiotics such as imipenem-cilastatin, meropenem, and ertapenem. Table 51-5 lists several antibiotics that have acceptable breadth of coverage against the polymicrobial genital tract flora. Combination antibiotic regimens should be considered for more severely ill patients, particularly those who are indigent and in poor general health. Table 51-6 lists several antibiotic combinations of proven value in treatment of puerperal endometritis. As a general rule,

the combination generic drug regimens are less expensive than the single agents whose brand-name patents still are intact.

Once antibiotics are begun, about 90% of patients defervesce within 48 to 72 hours. When the patient has been afebrile and asymptomatic for about 24 hours, parenteral antibiotics should be discontinued, and the patient should be discharged. As a general rule, an extended course of oral antibiotics is not necessary after discharge.[18,36] There are at least two notable exceptions to this rule. First, patients who have had a vaginal delivery and who defervesce within 24 hours are candidates for early discharge. In these individuals, a short course of an oral antibiotic such as amoxicillin-clavulanate (875 mg every 12 hours) may be substituted for continued parenteral therapy. Second, patients who have had staphylococcal bacteremia may require a more extended period of administration of parenteral and oral antibiotics with specific antistaphylococcal activity.[37]

Table 51-6 Combination Antibiotic Regimens for Treatment of Puerperal Endometritis

ANTIBIOTICS	INTRAVENOUS DOSE	RELATIVE COST TO THE PHARMACY*
Regimen 1		
Clindamycin plus	900 mg q8h	Intermediate
Gentamicin	7 mg/kg ideal body weight q24h†	Low
Regimen 2		
Clindamycin plus	900 mg q8h	Intermediate
Aztreonam	1-2 g q8h	High
Regimen 3		
Metronidazole plus	500 mg q12h	Low
Penicillin or	5 million units q6h	Low
Ampicillin plus	2 g q6h	Low
Gentamicin	7 mg/kg ideal body weight q24h†	Low

*Cost estimate does not include dose preparation fees and administration charges.
†Single daily dosing of aminoglycoside antibiotics is more effective and less expensive than multidose treatment. In addition, it is less likely to cause toxicity.

Patients who fail to respond to the antibiotic therapy outlined earlier usually have one of two problems. The first is a resistant organism. Table 51-7 lists possible weaknesses in coverage of selected antibiotics and indicates the appropriate change in treatment. **The second major cause of treatment failure is a wound infection.** Wound infections may take the form of an incisional abscess or a cellulitis with no actual purulent collection. Incisional abscesses should be opened completely to provide drainage, and a specific antistaphylococcal antibiotic should be added to the treatment regimen. If extensive cellulitis at the margin of the incision is present, an antibiotic with specific coverage against staphylococci should be added, but the wound should not be opened. Vancomycin (1 g IV every 12 hours) is an excellent antistaphylococcal antibiotic, particularly against methicillin-resistant *Staphylococcus aureus* (MRSA).[18]

When changes in antibiotic therapy do not result in clinical improvement and no evidence of wound infection is present, several unusual disorders should be considered. The differential diagnosis of persistent puerperal fever is summarized in Table 51-8.[35]

Table 51-7 Treatment of Resistant Microorganisms in Patients with Puerperal Endometritis

INITIAL ANTIBIOTICS	PRINCIPAL WEAKNESS IN COVERAGE	MODIFICATION OF THERAPY
Extended-spectrum cephalosporins	Some aerobic and anaerobic gram-negative bacilli Enterococci	Change treatment to clindamycin or metronidazole plus penicillin or ampicillin plus gentamicin
Extended-spectrum penicillins	Some aerobic and anaerobic gram-negative bacilli	As above
Clindamycin plus gentamicin or aztreonam	Enterococci	Add ampicillin or penicillin*
	Some anaerobic gram-negative bacilli	Consider substitution of metronidazole for clindamycin

*Ampicillin alone is highly active against enterococci. Penicillin *plus* gentamicin works synergistically to provide excellent coverage against this organism.

Table 51-8 Differential Diagnosis of Persistent Puerperal Fever

CONDITION	DIAGNOSTIC TESTS	TREATMENT
Resistant microorganism	Blood culture	Combination antibiotics to cover all possible pelvic pathogens
Wound infection	Physical examination	Incision and drainage if abscess is present
	Needle aspiration	Add antibiotic to cover staphylococci
	Ultrasound	
Pelvic abscess	Physical examination	Drainage
	Ultrasound	Combination antibiotics to cover all possible pelvic pathogens
	Computed tomography	
	Magnetic resonance imaging	
Septic pelvic vein thrombophlebitis	Ultrasound	Heparin anticoagulation
	Computed tomography	Combination antibiotics to cover all possible pelvic pathogens
	Magnetic resonance imaging	
Recrudescence of connective tissue disease	Serology	Corticosteroids
Drug fever	Inspection of temperature graph	Discontinue antibiotics
	White blood cell count—identify eosinophilia	
Mastitis	Physical examination	Add antibiotic to cover staphylococci

Prevention of Puerperal Endometritis

Prophylactic antibiotics clearly are of value in reducing the frequency of postcesarean delivery endometritis, particularly in women having surgery after an extended period of labor and ruptured membranes.[38] For many years, the standard of care was to administer one dose of a relatively limited-spectrum antibiotic immediately after the baby's umbilical cord was clamped.[39] This practice was based primarily on two older studies, one prospective[40] and one retrospective,[41] that showed that delay in administration of antibiotics did not compromise the effectiveness of prophylaxis. Moreover, when compared with the effects of preoperative antibiotics, the delay in drug administration decreased the probability that neonates would require evaluations for sepsis.

Recently, however, several investigators have challenged the assumptions inherent in this standard. In 2007, Sullivan and colleagues[42] observed a significant reduction in the rate of endometritis and wound infection when intravenous cefazolin (1 g) was administered before surgery rather than after cord clamping. In patients who received antibiotics before the surgical incision, the relative risk for endometritis was 0.2; the 95% confidence interval [CI] was 0.15 to 0.94. The authors noted no increase in the rate of infection or the need for sepsis evaluations in the neonates exposed to preoperative antibiotics (level I evidence).

In a retrospective cohort study (level II evidence) using historical controls, Kaimal and coworkers[43] also noted a significant reduction in the overall rate of surgical site infection (adjusted odds ratio [AOR], 0.33) and endometritis (AOR, 0.34) when antibiotics were administered before surgery. Similarly, Owens and coworkers[44] conducted a retrospective study (level II evidence) comparing 4229 patients who received cefazolin after cord clamping with 4781 patients who received antibiotics before surgery. In patients who received antibiotics preoperatively, the authors noted a 50% reduction in the rate of endometritis and a 30% reduction in the rate of wound infection. There was no difference in the rate of culture-proven early-onset neonatal infection. In fact, there was actually a decreased rate of late-onset neonatal infection in the group that received antibiotics preoperatively. Finally, in a recent meta-analysis, Costantine and associates[45] reviewed five well-designed studies and concluded that administration of antibiotics before the skin incision, rather than after cord clamping, was more effective in reducing the frequency of endometritis (relative risk [RR], 0.47) and composite infection-related morbidity (RR, 0.50).

In another interesting departure from the previous standard of care, Tita and associates[46,47] showed that extending the spectrum of antibiotic activity by adding azithromycin (500 mg) to cefazolin (1 g) further reduced the risk for endometritis (RR, 0.41). The use of the broader-spectrum regimen also significantly decreased the rate of wound infection (1.3% vs. 3.1%; $P < .002$).

Dinsmoor and coworkers[48] recently reexamined the issue of whether the benefits of prophylaxis extended to seemingly low-risk women having cesarean delivery before the onset of labor. They conducted a secondary analysis of a previously reported observational study of cesarean delivery performed at 13 centers from 1999 to 2000 (level II evidence). The study included 9432 patients. Low-risk women who received antibiotic prophylaxis were less likely to develop postpartum endometritis (2% vs. 2.6%; AOR, 0.40; 95% CI, 0.28 to 0.59) and wound infection (0.52% vs. 0.96%; AOR, 0.49, 95% CI, 0.28 to 0.86).

Another important step in prevention of endometritis relates to the method of placental delivery. In 1997, Lasley and colleagues[49] conducted a prospective randomized trial (level I evidence) comparing manual removal of the placenta with removal by gentle traction on the umbilical cord. One hundred sixty-five women were randomized to the manual removal arm of the study, and 168 had spontaneous removal of the placenta. All patients in this study received prophylactic antibiotics, usually cefazolin, after the umbilical cord was clamped. In the patients whose placenta was removed by traction on the cord, the rate of endometritis was reduced from 27% to 15% (RR, 0.6; 95% CI, 0.4 to 0.9; $P = .01$).

Subsequently, the Cochrane database[50] evaluated 15 randomized trials ($N = 4694$ patients) comparing different methods of removing the placenta. A consistent finding in these trials was decreased blood loss, a decreased rate of endometritis, and, subsequently, a shorter duration of hospitalization in women whose placenta was removed by gentle traction on the umbilical cord.

A previous report by Yancey and associates[51] provides a logical explanation for why manual removal of the placenta is associated with an increased risk for infection. In that study, the authors specifically evaluated the contamination of the surgeon's dominant hand as a result of delivering the infant's head from the lower uterine segment. After this step of the operation, the bacterial contamination of the surgeon's glove was markedly increased. When the surgeon then places this hand behind the placenta and manually extracts the placenta, he or she inevitably introduces many microorganisms into the raw vascular bed beneath the placenta.

Based on the studies outlined earlier, I recommend that both low- and high-risk patients having cesarean delivery receive antibiotics 30 to 60 minutes before the start of surgery. I recommend use of cefazolin, 1 g, given as a rapid intravenous infusion, plus azithromycin, 500 mg administered IV over 1 hour. I also recommend that, whenever possible, the placenta be removed by traction on the umbilical cord, rather than by manual extraction.

Patients who have an immediate hypersensitivity to β-lactam antibiotics pose a special problem. The best alternative is to administer a single dose of clindamycin (900 mg) plus gentamicin (1.5 mg/kg) before surgery. Although these antibiotics commonly are used for treatment of overt infections, their administration still is warranted in penicillin-allergic patients who are at high risk for postoperative infection.[18]

Serious Sequelae of Puerperal Infection

Wound Infection

Wound infection after cesarean delivery may occur in association with endometritis or as an isolated infection. About 3% to 5% of patients who have a cesarean delivery develop a wound infection. The major risk factors for wound infection are listed in the box, Principal Risk Factors for Postcesarean Wound Infection. **The principal causative**

organisms are *S. aureus*, aerobic streptococci, and aerobic and anaerobic bacilli.[52]

Principal Risk Factors for Postcesarean Wound Infection

- Poor surgical technique—failure to close the bottom half of the subcutaneous layer, incorrect suture, or gauge of suture.
- Low socioeconomic status
- Extended duration of labor and ruptured membranes
- Preexisting infection, such as chorioamnionitis
- Obesity
- Insulin-dependent diabetes
- Immunodeficiency disorder
- Corticosteroid therapy
- Immunosuppressive therapy
- Connective tissue disorder
- Smoking

The diagnosis of wound infection always should be considered in patients who have a poor clinical response to antibiotic therapy for endometritis. Clinical examination characteristically shows erythema, induration, and tenderness at the margins of the abdominal incision. When the wound is probed with either a cotton-tipped applicator or fine needle, pus usually exudes. Some patients, however, may have an extensive cellulitis without harboring frank pus in the incision. Clinical examination should be sufficient to establish the correct diagnosis. Nevertheless, culture of the wound exudate is indicated to identify particularly virulent microorganisms such as MRSA.

When pus is present in the incision, the wound must be opened and drained completely. Antibiotic therapy should be modified to provide coverage against staphylococci because some regimens for endometritis may not specifically target this organism. Vancomycin, 1 g IV every 12 hours, is an excellent choice to cover MRSA.

Once the wound is opened, a careful inspection should be made to be certain that the fascial layer is intact. If it is disrupted, surgical intervention is necessary to reapproximate the fascia. Otherwise, the wound should be irrigated two to three times daily with a solution such as warm saline, a clean dressing should be applied, and the incision should be allowed to heal by secondary intention. Antibiotics should be continued until the base of the wound is clean and all signs of cellulitis have resolved. Patients usually can be treated at home once the acute signs of infection have subsided.

***Necrotizing fasciitis* is an uncommon but extremely serious complication of abdominal wound infection**. It also has been reported in association with infection of the episiotomy site.[53] This condition is most likely to occur in patients with type 1 diabetes mellitus, cancer, or an immunodeficiency disorder. Multiple bacterial pathogens, particularly anaerobes, have been isolated from patients with necrotizing fasciitis.

Necrotizing fasciitis should be suspected when the margins of the wound become discolored, cyanotic, and devoid of sensation. When the wound is opened, the subcutaneous tissue is easily dissected free of the underlying fascia, but muscle tissue is not affected. If the diagnosis is uncertain, a tissue biopsy should be performed and examined by frozen section.

Necrotizing fasciitis is a life-threatening condition and requires aggressive medical and surgical management. Broad-spectrum antibiotics with activity against all potential aerobic and anaerobic pathogens should be administered. Intravascular volume should be maintained with infusions of crystalloid, and electrolyte abnormalities should be corrected. Finally, and most importantly, the wound must be débrided and all necrotic tissue removed. In many instances, the required dissection is extensive and may best be managed in consultation with an experienced general or plastic surgeon.[54]

Pelvic Abscess

With the advent of modern antibiotics, pelvic abscesses after cesarean or vaginal delivery have become extremely rare. **Less than 1% of patients with puerperal endometritis develop a pelvic abscess.**[35] **When present, abscesses typically are located in the anterior or posterior cul de sac, most commonly the latter, or within the broad ligament.** The usual bacteria isolated from abscess cavities are coliforms and anaerobic gram-negative bacilli, particularly *Bacteroides* and *Prevotella* species.[55]

Patients with an abscess typically experience persistent fever despite initial therapy for endometritis. In addition, they usually have malaise, tachycardia, lower abdominal pain and tenderness, and a palpable pelvic mass anterior, posterior, or lateral to the uterus. The peripheral white blood cell count usually is elevated, and there is a shift toward neutrophils and bands. Ultrasound, CT scan, and magnetic resonance imaging (MRI) may be used to confirm the diagnosis of pelvic abscess.[56] Although CT and MRI may be slightly more sensitive, ultrasound offers the advantages of decreased expense and ready availability.

Patients with a pelvic abscess require surgical intervention to drain the purulent collection. When the abscess is in the posterior cul de sac, colpotomy drainage may be possible. For abscesses located anterior or lateral to the uterus, drainage may be accomplished by CT- or ultrasound-guided placement of a catheter drain.[57] When access is limited or the abscess is extensive, open laparotomy is indicated.

Patients with a pelvic abscess must receive antibiotics with excellent activity against coliform organisms and anaerobes.[18,55] One regimen that has been tested extensively in obstetrical patients with serious infections is the combination of penicillin (5 million units IV every 6 hours) or ampicillin (2 g IV every 6 hours) plus gentamicin (7 mg/kg of ideal body weight every 24 hours) plus clindamycin (900 mg IV every 8 hours) or metronidazole (500 mg IV every 12 hours). If a patient is allergic to β-lactam antibiotics, vancomycin (1 g IV every 12 hours) can be substituted for penicillin or ampicillin. Aztreonam (1 g IV every 8 hours) can be used instead of gentamicin when the patient is at risk for nephrotoxicity. Alternatively, the single agents imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g every 8 hours), and ertapenem (1 g every 24 hours) provide excellent coverage against the usual pathogens responsible for an abscess. Antibiotics should be discontinued until the patient has been afebrile and asymptomatic for a minimum of 24 to 48 hours.

Septic Pelvic Thrombophlebitis

Like pelvic abscess, septic pelvic thrombophlebitis is extremely rare, occurring in 1 in 2000 pregnancies overall and in less than 1% of patients who have puerperal endometritis.[58] Intrauterine infection may cause seeding of pathogenic microorganisms into the venous circulation; in turn, these organisms may damage the vascular endothelium and initiate thrombosis.

Septic pelvic thrombophlebitis occurs in two distinct forms.[58] **The most commonly described disorder is acute thrombosis of one (usually the right), or both, ovarian veins (ovarian vein syndrome).**[59] Affected patients typically develop a moderate temperature elevation in association with lower abdominal pain in the first 48 to 96 hours postpartum. Pain usually localizes to the side of the affected vein but may radiate into the groin, upper abdomen, or flank. Nausea, vomiting, and abdominal bloating may be present.

On physical examination, the patient's pulse usually is elevated. Tachypnea, stridor, and dyspnea may be evident in pulmonary embolization has occurred. The abdomen is tender, and bowel sounds often are decreased or absent. Most patients demonstrate voluntary and involuntary guarding, and 50% to 70% have a tender, ropelike mass originating near one cornua and extending laterally and cephalad toward the upper abdomen. The principal conditions that should be considered in the differential diagnosis of ovarian vein syndrome are pyelonephritis, nephrolithiasis, appendicitis, broad ligament hematoma, adnexal torsion, and pelvic abscess.

The second presentation of septic pelvic vein thrombophlebitis is termed *enigmatic fever*.[60] Initially, affected patients have clinical findings suggestive of endometritis and receive systemic antibiotics. Subsequently, they experience subjective improvement, with the exception of temperature instability. They do not appear to be seriously ill, and positive findings are limited to persistent fever and tachycardia. Disorders that should be considered in the differential diagnosis of enigmatic fever are drug fever, viral syndrome, collagen vascular disease, and pelvic abscess.

The diagnostic tests of greatest value in evaluating patient with suspected septic pelvic vein thrombophlebitis are CT scan and MRI (Figure 51-3).[61] These tests are most sensitive in detecting large thrombi in the major pelvic vessels. They are not as useful in identifying thrombi in smaller vessels. In such cases, the ultimate diagnosis may depend on the patient's response to an empirical trial of heparin.[58,62]

Patients with septic pelvic vein thrombophlebitis should be treated with therapeutic doses of either intravenous unfractionated heparin or low-molecular-weight heparin. Therapy should be continued for 7 to 10 days. Long-term anticoagulation with oral agents probably is unnecessary unless the patient has massive clotting throughout the pelvic venous plexus or has sustained a pulmonary embolism. Patients should be maintained on broad-spectrum antibiotics throughout the period of heparin administration.

Once medical therapy is initiated, the patient should have objective evidence of a response within 48 to 72 hours. If no improvement is noted, surgical intervention may be necessary.[58,62] The decision to perform surgery should be based on clinical assessment and the relative certainty of the diagnosis. The surgical approach, in turn, should be tailored to the specific intraoperative findings. In most instances, treatment requires only ligation of the affected vessels. Extension of the thrombosis along the vena cava to the point of origin of the renal veins may necessitate embolectomy or placement of an umbrella filter. Excision of the infected vessel and removal of the ipsilateral adnexa and uterus is indicated only in the presence of a well-defined abscess. Whenever any of the previously mentioned procedures are being considered, consultation with an experienced vascular surgeon or interventional radiologist is imperative.

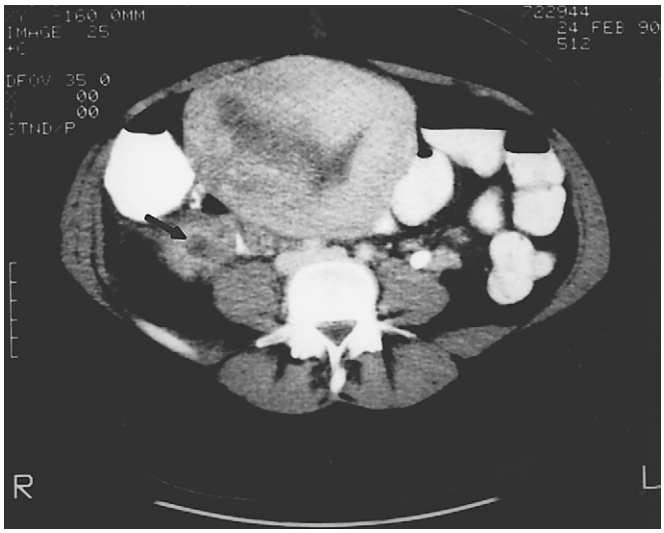

FIGURE 51-3. Computed tomography scan shows a thrombus *(arrow)* in the right ovarian vein.

Septic Shock

Septic shock in obstetrical patients usually is associated with four specific infections: septic abortion, acute pyelonephritis, chorioamnionitis, or endometritis. Fortunately, fewer than 5% of patients with any of these infections develop septic shock. **The most common organisms responsible for septic shock are the aerobic gram-negative bacilli, principally *E. coli*, *K. pneumoniae*, and *Proteus* species.** Highly virulent, drug-resistant coliforms such as *Pseudomonas*, *Enterobacter*, and *Serratia* species are uncommon except in immunosuppressed patients.[63]

Aerobic gram-negative bacilli have a complex lipopolysaccharide in their cell wall, which is termed *endotoxin*. When released into the systemic circulation, endotoxin is capable of causing a variety of immunologic, hematologic, neurohormonal, and hemodynamic derangements that ultimately result in multiorgan dysfunction.

In the early stages of septic shock, patients usually are restless, disoriented, tachycardic, and hypotensive. Although hypothermia is occasionally present, most patients have a relatively high fever (39° to 40° C). Their skin may be warm and flushed owing to an initial phase of vasodilation (warm shock). Subsequently, as extensive vasoconstriction occurs, the skin becomes cool and clammy.

Cardiac arrhythmias may be present, and signs of myocardial ischemia may occur. Jaundice, often due to hemolysis, may be evident. Urinary output typically decreases, and frank anuria may develop. Spontaneous bleeding from the genitourinary tract or venipuncture sites may occur as a result of disseminated intramuscular coagulation. ARDS is a common complication of severe sepsis and is associated with manifestations such as dyspnea, stridor, cough, tachypnea, and bilateral rales and wheezing.[64] In addition to these systemic signs and symptoms, affected patients also may have findings related to their primary site of infection such as purulent lochia, uterine tenderness, peritonitis, or flank tenderness.

The differential diagnosis of septic shock in obstetrical patients includes hypovolemic and cardiogenic shock, diabetic ketoacidosis, anaphylactic reaction, anesthetic reaction, and amniotic fluid or venous embolism. Distinction among these disorders usually can be made on the basis of a thorough history and physical examination and a limited number of laboratory studies. The white blood cell count initially may be decreased but, subsequently, is elevated in most patients. A large percentage of bands is usually evident. The hematocrit may be decreased if blood loss has occurred. Tests of coagulation such as platelet count, serum fibrinogen concentration, serum concentration of fibrin degradation products, prothrombin time, and activated partial thromboplastin time are frequently abnormal. Serum concentrations of the transaminase enzymes and bilirubin often are increased. Similarly, increased concentrations of blood urea nitrogen and creatinine reflect deterioration of renal function. Chest radiograph in patients with septic shock is indicated to determine whether pneumonia or ARDS is present. In addition, CT scan, MRI, and ultrasound may be of value in localizing an abscess.[57] Affected patients also require electrocardiographic monitoring to detect arrhythmias or signs of ischemic injury.

The first goal of treatment of septic shock is to correct the hemodynamic derangements precipitated by endotoxin. Two large-bore intravenous catheters and a urinary catheter should be inserted. Isotonic crystalloid such as Ringer lactate solution or normal saline should be administered and the infusion titrated in accordance with the patient's pulse, blood pressure, and urine output. If the patient is bleeding, packed red cells should be administered, and the goal is to maintain a hemoglobin concentration of 9 g/dL.

If the initial fluid infusion is not successful in restoring hemodynamic stability, a right-sided heart catheter should be inserted to monitor pulmonary artery wedge pressure. The "7-3" rule is helpful in gauging the volume of fluid replacement. An increment of 150 to 200 mL of isotonic crystalloid should be administered over 10 to 15 minutes. If the pulmonary capillary wedge pressure (PCWP) rises by more than 7 mm Hg, the fluid infusion shall be temporarily discontinued. If the PCWP increase is less than 3 mm Hg, additional increments of fluid should be given. The goals of fluid resuscitation are to achieve the following:

- Central venous pressure = 8 to 12 mm Hg
- Mean arterial pressure ≥65 mm Hg
- Urine output ≥0.5 mL/kg per hour
- Central venous oxygen or mixed venous oxygen saturation ≥70%

In addition, dopamine (starting dose, 1 to 3 mcg/kg per minute) should be administered. In low doses, this vasopressor stimulates myocardial contractility and improves perfusion of central organs. In higher doses, the drug has primarily vasoconstrictive effects and may actually compromise tissue perfusion. Norepinephrine (5 to 15 mcg/minute), vasopressin (0.01 to 0.03 U/minute), and dobutamine (0.5 to 1 mcg/kg per minute, maximum 40 mcg/kg per minute) also may be used as pressor agents.[65]

Hydrocortisone (200 to 300 mg/day for 7 days in three or four divided doses or by continuous infusion) should be administered early in the course of septic shock. Although ultimate mortality is not improved, patients who receive corticosteroids have a more rapid reversal of the shock state than those who are not treated.[66,67]

The second objective of treatment is to administer broad-spectrum antibiotics targeted against the most likely pathogens.[18] For genital tract infections, the combination of penicillin (5 million units IV every 6 hours) or ampicillin (2 g IV every 6 hours) plus clindamycin (900 mg IV every 8 hours) or metronidazole (500 mg IV every 8 hours) plus gentamicin (7 mg/kg ideal body weight IV every 24 hours) or aztreonam (1 to 2 g IV every 8 hours) is an appropriate regimen. Alternatively, imipenem-cilastatin (500 mg IV every 6 hours), meropenem (1 g every 8 hours), or ertapenem (1 g IV every 24 hours) can be administered as single agents. Patients also may require surgery, for example, to evacuate infected products of conception, drain a pelvic abscess, or remove badly infected pelvic organs. Indicated surgery never should be delayed because a patient is unstable; operative intervention may be precisely the step necessary to reverse the hemodynamic derangements of septic shock.

Patients with septic shock require meticulous supportive care. Core temperature should be maintained as close to normal as possible by use of antipyretics and a cooling blanket. Coagulation abnormalities should be identified promptly and treated by infusion of platelets and coagulation factors, as indicated. Finally, patients should be given oxygen supplementation and observed closely for evidence of ARDS, one of the major causes of mortality in cases of severe sepsis.[64] Oxygenation should be monitored by means of a pulse oximeter or radial artery catheter. If evidence of respiratory failure develops, the patient should be intubated and supported with mechanical ventilation.

The prognosis in patients with septic shock clearly depends on the severity of the patient's underlying illness. In previously healthy patients, mortality should not exceed 15%.[68] Fortunately, most obstetrical patients are in the latter category. Therefore, the prognosis for complete recovery is excellent provided that the patient receives competent, timely intervention.

Toxoplasmosis

Epidemiology

Toxoplasma gondii is a protozoan that has three distinct forms: trophozoite, cyst, and oocyst. The life cycle of *T. gondii* is dependent on wild and domestic cats, which are the only host for the oocyst. The oocyst is formed in the cat intestine and subsequently excreted in the feces. Mammals, such as cows, ingest the oocyst, which is

disrupted in the animal's intestine, releasing the invasive trophozoite. The trophozoite then is disseminated throughout the body, ultimately forming cysts in brain and muscle.[69]

Human infection occurs when infected meat is ingested or when food is contaminated by cat feces through flies, cockroaches, or fingers. Infection rates are highest in areas of poor sanitation and crowded living conditions. Stray cats and domestic cats that eat raw meat are most likely to carry the parasite. The cyst is destroyed by heat.[69]

About 40% to 50% of adults in the United States have antibody to this organism, and the prevalence of antibody is highest in lower socioeconomic populations. The frequency of seroconversion during pregnancy is 5%, and about 3 in 1000 infants show evidence of congenital infection. Clinically significant congenital toxoplasmosis occurs in about 1 in 8000 pregnancies. Toxoplasmosis is more common in western Europe, particularly France, most likely because of the practice in that country of eating rare or raw meat. More than 80% of women of childbearing age in Paris have antibody to *T. gondii*, and the incidence of congenital toxoplasmosis is about twice as frequent as that in the United States.[70]

Clinical Manifestations

The ingested organism invades across the intestinal epithelium and spreads hematogenously throughout the body. Intracellular replication leads to cell destruction. Clinical manifestations of infection are the result of direct organ damage and the subsequent immunologic response to parasitemia and cell death. Host immunity is mediated primarily through T lymphocytes.[69]

Most infections in humans are asymptomatic. Even in the absence of symptoms, however, patients may have evidence of multiorgan involvement, and clinical disease can follow a long period of asymptomatic infection. Symptomatic toxoplasmosis usually presents as an illness similar to mononucleosis.

In contrast to infection in the immunocompetent host, toxoplasmosis can be a devastating infection in the immunosuppressed patient. Because immunity to *T. gondii* is cell mediated, patients with human immunodeficiency virus infection and those treated with chronic immunosuppressive therapy after organ transplantation are particularly susceptible to new or reactivated infection. In these patients, dysfunction of the central nervous system is the most common manifestation of infection. Findings typically include encephalitis, meningoencephalitis and intracerebral mass lesions. Pneumonitis, myocarditis, and generalized lymphadenopathy also occur commonly.[69]

Diagnosis

The diagnosis of toxoplasmosis in the mother can be confirmed by serologic and histologic methods. Serologic tests that suggest an acute infection include detection of immunoglobulin M (IgM)-specific antibody, demonstration of an extremely high IgG antibody titer, and documentation of IgG seroconversion from negative to positive. Clinicians should be aware that serologic assays for toxoplasmosis are not well standardized. When initial laboratory tests appear to indicate that an acute infection has occurred, repeat serology should be performed in a well-respected reference laboratory. In addition, toxoplasmic DNA can be identified in the patient's serum using the PCR test.

T. gondii is most easily identified in lymphatic or brain tissues. Histologic preparations can be examined by light and electron microscopy. For light microscopy, specimens should be stained with either Giemsa or Wright stain.[70,71]

Congenital Toxoplasmosis

Congenital infection can occur if a woman develops acute primary toxoplasmosis during pregnancy. Chronic or latent infection is unlikely to cause fetal injury except perhaps in an immunosuppressed patient. **About 40% of neonates born to mothers with acute toxoplasmosis show evidence of infection**. Congenital infection is most likely to occur when maternal infection develops in the third trimester. However, fetal injury is most likely to be severe when maternal infection occurs in the first half of pregnancy. Less than half of affected infants are symptomatic at birth (see box, Clinical Manifestations of Congenital Toxoplasmosis).[70-72]

Clinical Manifestations of Congenital Toxoplasmosis

- Rash
- Hepatosplenomegaly
- Ascites
- Fever
- Chorioretinitis
- Periventricular calcifications
- Ventriculomegaly
- Seizures
- Mental retardation
- Uveitis

The most valuable tests for antenatal diagnosis of congenital toxoplasmosis are ultrasound, cordocentesis, and amniocentesis.[70-72] Ultrasound findings suggestive of infection include ventriculomegaly, intracranial calcifications, microcephaly, ascites, hepatosplenomegaly, and growth restriction. Fetal blood samples can be tested for IgM-specific antibody after 20 to 22 weeks' gestation. Fetal blood and amniotic fluid can be inoculated into mice, and the organism can subsequently be recovered from the blood of infected animals. In addition, Hohlfeld and coworkers[73] have now identified a specific gene of *T. gondii* in amniotic fluid using PCR. In this investigation, 34 of 339 infants had congenital toxoplasmosis confirmed by serologic testing or autopsy. All amniotic fluid specimens from affected pregnancies were positive by PCR, and test results were available within 1 day of specimen collection.

In a subsequent investigation, Romand and colleagues[74] reported that the PCR test had an overall sensitivity of 64% (95% CI, 53% to 75%) for diagnosing congenital toxoplasmosis. No false-positive results were noted, and the positive predictive value was 100%.

Management

Toxoplasmosis in the immunocompetent adult is usually an asymptomatic or self-limited illness and does not require treatment. Immunocompromised patients, however, should be treated, and the regimen of choice is a combination of

oral sulfadiazine (4 g loading dose, then 1 g four times daily) plus pyrimethamine (50 to 100 mg initially, then 25 mg daily). In such patients, extended courses of treatment may be necessary to cure the infection.[71]

Treatment also is indicated when acute toxoplasmosis occurs during pregnancy. **Treatment of the mother reduces the risk for congenital infection and decreases the late sequelae of infection.**[70,72,75] **Pyrimethamine is not recommended for use during the first trimester of pregnancy because of possible teratogenicity, although specific adverse fetal effects have not been documented to date. Sulfonamides can be used alone, but single-agent therapy appears to be less effective than combination therapy. In Europe, spiramycin has been used extensively in pregnancy with excellent success. It is available for treatment in the United States through the CDC.**

Aggressive early treatment of infants with congenital toxoplasmosis is indicated and consists of combination therapy with pyrimethamine, sulfadiazine, and leucovorin for 1 year. Early treatment reduces, but does not eliminate, the late sequelae of toxoplasmosis, such as chorioretinitis.[76]

In the management of the pregnant patient, prevention of acute toxoplasmosis is of paramount importance. Pregnant women should be advised to avoid contact with cat litter if at all possible. If they must change the litter, they should do so daily, wear gloves, and wash their hands afterward. They should always wash their hands after preparing meat for cooking and should never eat raw or rare meat. Meat should be cooked thoroughly until the juices are clear. Fruits and vegetables also should be washed carefully to remove possible contamination by oocysts.

Listeriosis

Listeria monocytogenes (LM) is a gram-positive bacillus responsible for severe infections in humans and a large variety of animal species. It is a facultative intracellular pathogen that invades macrophages and most tissue cells of infected hosts, where it can proliferate. **LM can cause meningitis, encephalitis, bacteremia, and febrile gastroenteritis**. In infected hosts, the bacteria cross the intestinal wall at Peyer patches to invade the mesenteric lymph nodes and blood. The main target organ is the liver, where the bacteria multiply inside hepatocytes. Most disease occurs in patients with impaired cell-mediated immunity, and, therefore, LM is an important cause of severe infections in neonates, pregnant women, elderly people, and transplant recipients. Although dramatic epidemics have received the most publicity, most cases of perinatal listeriosis are isolated.

LM is naturally widespread in nature and can be readily found in soil and vegetation. Recent seroepidemiologic studies show that the infection is foodborne. Heightened surveillance and quality control by the food industry have been instituted (see box, U.S. Department of Agriculture's Food Safety and Inspection Service and U.S. Food and Drug Administration's Advice for Pregnant Women to Prevent Listeriosis during Pregnancy), leading to a reduction in the number of cases and deaths from this infection in the past decade. However, most parents are still not aware of the risks of listeriosis and recommended practices for listeriosis prevention; thus, they are not taking precautions during their pregnancy to prevent listeriosis.[77] **Because LM can grow and multiply at temperatures as low as 0.5° C (or 32.9° F), refrigerating contaminated foods does not always prevent infection, but cooking contaminated foods at high temperatures consistently destroys the bacteria.** LM can also be contracted through the handling of the products of conception of animals, when the miscarriage is due to listeriosis. Therefore, it is important for pregnant women working with animals not to touch these tissues, if possible, or to wear gloves if contact cannot be avoided. Owing to the ubiquity of the organism in the environment, outbreaks and sporadic disease continue to occur.[78]

U.S. Department of Agriculture's Food Safety and Inspection Service and U.S. Food and Drug Administration's Advice for Pregnant Women to Prevent Listeriosis During Pregnancy

- Do not eat hot dogs, luncheon meats, or deli meats unless they are reheated until steaming hot.
- Do not eat soft cheeses such as feta, Brie, Camembert, blue-veined cheeses, or Mexican-style cheeses such as *queso blanco fresco*. Hard cheeses, semisoft cheeses such as mozzarella, pasteurized processed cheese slices and spreads, cream cheese, and cottage cheese can be safely consumed.
- Do not eat refrigerated paté or meat spreads. Canned or shelf-stable paté and meat spreads can be eaten.
- Do not eat refrigerated smoked seafood unless it is an ingredient in a cooked dish such as a casserole. Examples of refrigerated smoked seafood include salmon, trout, whitefish, cod, tuna, and mackerel, which are most often labeled as "nova style," "lox," "kippered," "smoked," or "jerky." This fish is found in the refrigerated section or sold at deli counters of grocery stores and delicatessens. Canned fish such as salmon and tuna or shelf-stable smoked seafood may be safely eaten.
- Do not drink raw (unpasteurized) milk or eat foods that contain unpasteurized milk.

The incubation period of LM ranges from as little as 1 day to as long as 90 days, making identification of the food or activity that caused the listeriosis extremely difficult. **Maternal symptoms can vary from "flu-like" or "food poisoning" to septicemia, meningitis, or pneumonia**. Because there is no reliable serologic evaluation, listeriosis is a difficult infection to test for outside the septic peak when it can be demonstrated in blood cultures. An overall perinatal mortality rate of 50% due to late miscarriage, premature delivery, and stillbirth was recorded before the use of modern therapies.[79] The clinical characteristics of neonatal listeriosis are similar to neonatal GBS sepsis, with early- and late-onset forms of disease. The mortality rate among liveborn infants is about 10%.[80]

The standard therapy for listeriosis is a combination of ampicillin and gentamicin or, for patients who are intolerant of β-lactam agents, trimethoprim-sulfamethoxazole. If LM chorioamnionitis is diagnosed preterm, in contrast to other types of chorioamnionitis, in utero therapy with high-dose penicillin or trimethoprim-sulfamethoxazole is possible, and preterm delivery may be avoided.

KEY POINTS

- Overall, 85% of neonatal GBS infections are early in onset and result from transmission from a colonized mother.
- All pregnant women should be cultured for GBS at 35 to 37 weeks. Culture-positive patients should receive intrapartum antibiotic prophylaxis to prevent early-onset neonatal infection.
- Patients with GBS bacteriuria should be considered heavily colonized and be targeted for intrapartum prophylaxis.
- All pregnant women should have a urine culture at their first prenatal appointment to detect asymptomatic bacteriuria.
- Most cases of pyelonephritis occur as a consequence of undiagnosed or inadequately treated lower urinary tract infections.
- The organisms most likely to cause chorioamnionitis and puerperal endometritis are GBS, *E. coli*, and gram-positive and gram-negative anaerobes.
- Prophylactic antibiotics are highly effective in preventing postcesarean endometritis. They should be administered before the surgical incision.
- Resistant organisms and wound infection are the most common causes of persistent fever in patients who are being treated for puerperal endometritis.
- Septic pelvic thrombophlebitis is another important cause of refractory postoperative fever. This condition is best diagnosed by CT or MRI and is treated with broad-spectrum antibiotics and intravenous heparin.
- The most common causes of septic shock in obstetrical patients are septic abortion, pyelonephritis, chorioamnionitis, and endometritis.
- The two most common methods of transmission of toxoplasmosis are consumption of undercooked beef and contact with cat litter.
- The best diagnostic tests for congenital toxoplasmosis are identification of toxoplasmic DNA in amniotic fluid by PCR and identification of specific fetal injury by ultrasound.
- Pregnant women and immunocompromised patients may reduce their risk for contracting listeriosis by avoiding unpasteurized dairy products.

Mental health is fundamental to health. This statement, made by Surgeon General David Satcher, emphasized the foundation that emotional well-being provides for health. In medical practice, we compartmentalize symptoms and diseases into manageable units; however, the patient comes as an integrated whole. The effect of pathology in any part of the body affects the entire patient. Psychiatric disorders are defined in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV),[1] a categorical classification that divides mental disorders into types based on criteria sets with defining features. This chapter covers the major

classifications of disorders that affect women of childbearing age as well as the tragedies of suicide and infanticide. For the pregnant woman and her family, the capacity to function optimally, enjoy relationships, manage the pregnancy, and prepare for the infant's birth is critical.

Perinatal health can be conceptualized within a model that integrates the complex social, psychological, behavioral, environmental, and biologic forces that shape pregnancy. Misra and colleagues[2] presented a comprehensive perinatal framework that integrates a life span approach with a multiple determinants model (Figure 52-1). The model contains four hierarchical levels that provide a paradigm for considering the determinants of perinatal health outcomes. The first level in the model is *Distal Determinants*, which brings focus to *distal* (in time) risk factors that place a woman at greater susceptibility to *proximal* (current) risk factors. Distal determinants derive from biologic, physical, and social domains. Although they have the potential to directly influence health status, distal factors typically increase or decrease a woman's likelihood of developing health problems, engaging in high-risk behaviors, or being exposed to potential toxins. Some of the most powerful influences on pregnancy outcome are related to these *distal* women's health factors that occur long before pregnancy. At the next level, *proximal determinants*, risk factors that have a direct impact on a woman's health status, are represented by biomedical and behavioral responses. The interaction between *distal* and *proximal* risk factors determines an individual's overall health status. The relationship between a woman's health status directly before conception and the demands of pregnancy affect perinatal health outcomes. For example, a woman who is told that her infant has spina bifida after an ultrasound examination (due to long-term low folate intake, a distal risk resulting in a negative outcome) develops a recurrence of a major depressive episode (proximal risk) that further affects maternal and fetal health. The third level, *processes*, is presented to emphasize the dynamic interaction of pre-, inter- and intraconceptional factors (as time variables in the women's health life course) on perinatal outcomes. At the fourth level, *outcomes*, the model includes constructs of disease, functioning, and well-being, which together

provide a comprehensive assessment of health status (both short and long term). Potential opportunities for interventions to affect perinatal health are included in this model. Childbearing is an opportune health promotion time because women have contact with professionals, access to health coverage, and are motivated toward positive behaviors to invest in the welfare of their offspring.

Each patient can be understood as coming to pregnancy with sets of malleable risks and assets that shape pregnancy outcome. To the extent that biopsychosocial exposures with negative impact upon pregnancy outcome can be diminished, eliminated, or replaced with positive factors, the risk of poor pregnancy outcome can be reduced. **The role of the health care professional is to have an impact on the patient's exposures and behaviors toward more positive comprehensive outcomes at various points depicted in Figure 52-1.**

This chapter focuses on the six major psychiatric disorders that occur commonly in women of childbearing age and their courses during pregnancy, postpartum, and breastfeeding. Within the life cycle context, the impact of childbearing on existing disorders or vulnerabilities in the female patient is of primary interest, as well as episodes that are etiologically related to childbearing. Treatment considerations for psychiatric disorders during childbearing invoke special modifications of the risk/benefit decision-making process.

MOOD DISORDERS

The mood disorders are characterized by a disturbance of affective state as the most prominent feature. Major depression and bipolar disorder (BD) are the exemplars of this category.

Major Depressive Episode

Diagnosis and Prevalence During Pregnancy and Postpartum

In the DSM-IV,[1] a major depressive episode (MDE) is defined as at least a 2-week period of either persistent depressed mood or loss of interest or pleasure in daily activities (the "gatekeeper" symptoms) plus four associated symptoms (or three if both gatekeeper symptoms are present) (see box, DSM-IV Criteria). *Persistent* is operationalized as meaning the symptom must be present for most of the day nearly every day. The patient also must have impairment of function in interpersonal relationships or work. Note that it is possible to have a *diagnosis* of MDE without the *symptom* of depression. A woman could have persistent loss of interest or pleasure but no depressed mood and four other symptoms from the following: appetite disturbance or significant weight change, sleep loss/excess, psychomotor agitation/retardation, fatigue or energy loss, feelings of worthlessness or guilt, impaired thinking or concentration, and suicidal ideation. Appetite, sleep, and motor activity can be either decreased or increased. For example, a fatigued woman who derives no pleasure from previously enjoyable activities, sleeps 15 hours per day, sits for long periods when awake, and is gaining weight has MDE. A guilt-ridden woman with depressed mood and 4 hours per day of sleep, weight loss of 15 pounds, and pacing at night also has MDE. Another mood disorder, dysthymia, is chronic depression (for at least 2 years) that does not meet full symptomatic criteria for an MDE.

DSM-IV Criteria

Over the last 2 weeks, most of the day nearly every day, five of the following (one symptom must be mood or interest), which must cause marked distress or impairment in important areas of functioning:

- Depressed mood
- Markedly diminished interest or pleasure
- Significant weight loss or gain unrelated to dieting
- Insomnia or hypersomnia
- Psychomotor agitation/retardation
- Fatigue or loss of energy
- Feelings of worthlessness/guilt
- Diminished ability to concentrate
- Recurrent thoughts of death

Nearly twice as many women (12%) as men (6.6%) suffer from a depressive disorder each year.[3] Women are at the greatest risk for MDE between 25 and 44 years. **The period prevalence of MDE is 12.7% during pregnancy (with 7.5% of women having a new episode) and 21.9% the year after parturition.**[4] Mothers at high risk are inner-city women, those with preterm infants, and adolescents. Depression persists from months to years after childbirth, with lingering limitations in physical and psychological functioning following recovery from depressive episodes. Twenty-five to 50% of women who experience depression in the postpartum period have episodes that last 7 months or longer.[5] The major factor contributing to the duration of the MDE is delay in identification and treatment.

Based on a prospective study of 680 female twins the strongest predictors for MDE were stressful life events, genetic factors, history of MDE, and excessive emotional sensitivity.[6] Other authors have identified stressful life events and history of MDE in the patient and her family[5] as predictors of MDE with postpartum onset. Women who have suffered one episode of postpartum onset MDE are at increased risk (25%-33%) for another episode after a subsequent birth, and more than 40% have later episodes of non-postpartum MDE.[7]

The most commonly used measure to screen for MDE is the Edinburgh Postnatal Depression Scale (EPDS; Figure 52-2), which has been validated for use both during and after pregnancy. This brief self-report instrument contains 10 items ranked from 0 to 3. The EPDS is scored by simple addition and is free to health care professionals. It is the most commonly used screening measure worldwide and is available in 23 languages. The recommended cut-off score is 15 or higher during pregnancy. Cox and Holden[8] suggested a cut-off score of 13 or higher (sensitivity for identifying MDE = 86%, specificity = 78%, positive predictive value = 73%) for postpartum depression (PPD) screening in clinical settings. As with any screening tool, positive scores on the EPDS must be followed with diagnostic assessment.

Natural History Across Childbearing

Consistently, specific female life-cycle periods of hormonal fluctuation (i.e., menstrual cycle, pregnancy, postpartum,

How are you feeling?
As you have recently had a baby, we would like to know how you are feeling now. Please check the answer which comes closest to how you have felt in the past 7 days, not just how you feel today.

1.	I have been able to laugh and see the funny side of things:	Score
	As much as I always could	0
	Not quite so much now	1
	Definitely not so much now	2
	Not at all	3
2.	I have looked forward with enjoyment to things:	
	As much as I ever did	0
	Rather less than I used to	1
	Definitely less than I used to	2
	Hardly at all	3
3.	I have blamed myself unnecessarily when things went wrong:	
	Yes, most of the time	3
	Yes, some of the time	2
	Not very often	1
	No, never	0
4.	I have been anxious or worried for no good reason:	
	No, not at all	0
	Hardly ever	1
	Yes, sometimes	2
	Yes, very often	3
5.	I have felt scared or panicky for no very good reason:	
	Yes, quite a lot	3
	Yes, sometimes	2
	No, not much	1
	No, not at all	0
6.	Things have been getting on top of me:	
	Yes, most of the time I haven't been able to cope at all	3
	Yes, sometimes I haven't been coping as well as usual	2
	No, most of the time I have coped quite well	1
	No, I have been coping as well as ever	0
7.	I have been so unhappy that I have had difficulty sleeping:	
	Yes, most of the time	3
	Yes, sometimes	2
	Not very often	1
	No, not at all	0
8.	I have felt sad or miserable:	
	Yes, most of the time	3
	Yes, quite often	2
	Not very often	1
	No, not at all	0
9.	I have been so unhappy that I have been crying:	
	Yes, most of the time	3
	Yes, quite often	2
	Only occasionally	1
	No, never	0
10.	The thought of harming myself has occurred to me:	
	Yes, quite often	3
	Sometimes	2
	Hardly ever	1
	Never	0

and perimenopause) are associated with MDE. During pregnancy, the brain is exposed to a 100-fold increase in estradiol levels, which abruptly decreases in the first postpartum week. Investigators have suggested that the rapid change in gonadal steroid levels is involved in the etiology of postpartum-onset MDE.[9] Although all women experience this phenomenon, the neurobiology of women who develop postpartum depression appears differentially sensitive to the mood-destabilizing effects of withdrawal from gonadal steroids.

Postpartum MDE does not differ from MDE at other periods during the childbearing years with respect to clinical presentation and duration of untreated episodes. However, aggressive obsessional thoughts (see Anxiety Disorders section) occur more commonly in women who have postpartum-onset MDE. **The differential diagnosis of depressed mood in the early postpartum period includes the maternity blues, a transient syndrome experienced by up to 80% of new mothers, which resolves by 10 days after birth. Usually a manifestation of BD, postpartum psychosis occurs in 1 to 2 per 1000 mothers within the first 8 weeks after delivery and represents a psychiatric emergency.**

The physiologic milieu created by MDE adversely affects maternal function and outcomes in offspring. Gestational MDE is associated with lack of prenatal care, poor nutrition, smoking, alcohol and drug use, and suicide. A recent meta-analysis affirmed that gestational MDE was associated with both low birthweight and preterm birth (PTB).[10] Offspring of women with MDE during pregnancy are at risk for insecure attachment, poor cognitive performance, sleep and eating disorders, and depression at age 16 years. Finally, gestational MDE is the strongest predictor of postpartum MDE.

Other serious sequelae of maternal mental illness are increased rates of accidental injury, child abuse, neglect, and infanticide. Early identification and intervention for postpartum MDE has the potential to prevent negative sequelae for women and families.

Treatment of MDE During Pregnancy

The emergence of an episode of mood disorder during childbearing compels a complete medical and family history, review of systems, and focused physical examination to assess for organic contributions to the mood disorder. The use of prescribed and over-the-counter medication as well as drugs and alcohol must be assessed. Thyroid abnormalities and anemia, which are common in childbearing women, should be ruled out; however, our experience is that the full depressive syndrome seldom remits with correction of hypothyroidism alone.[11]

Although MDE is a common condition, only 1 in 5 Americans receive any guideline-concordant intervention[12] and the rate is even lower in pregnant women.[13] In nearly 6500 Medicaid recipients with established MDE treatment, women who became pregnant had a significantly greater drop in both outpatient visits and antidepressant prescription claims compared with matched nonpregnant women, and did not resume care after birth.[14]

Evidence-based treatments for MDE are psychotherapy and antidepressant medications.[1] Interpersonal psychotherapy and pharmacotherapy during pregnancy both reduce depressive symptoms and improve maternal function. Psychotherapy is the preferred treatment[12]; however, it is not readily available in all practice settings nor is it feasible for many mothers. Barriers to clinic-based depression care include the physical demands of pregnancy, transportation, and childcare for other children. Adult mental health settings do not typically offer flexible appointment schedules or allow children on site. If psychotherapy is not feasible, or the woman prefers pharmacotherapy, decision making tends to focus on the potential adverse effects of medication rather than the adverse effects of the depressive disorder. Many physicians avoid drug treatment of pregnant women because of lack of expertise or medicolegal liability. The result is often the choice by the woman or her physician to avoid or stop drug treatment to obviate fetal exposure without equal consideration of the risks of MDE to both the mother and fetus. **For most pregnant women, the reality is that accessible and acceptable mental health treatment is very limited.** However, many federally funded programs provide home visitation to disadvantaged pregnant women, and program staff are potential partners for collaborative care with obstetricians and mental health professionals to improve rates of depression treatment.

Individually tailored interventions for the treatment of MDE are considered in view of their capacity to maximize maternal wellness while minimizing toxicity for the maternal-fetal pair. The patient and physician each contribute expertise to the process, because the patient's assignment of her own values dictates her choice. For example, some women will not consent to pharmacotherapy during pregnancy regardless of the degree of impairment related to the depressive episode. Others choose pharmacotherapy because they are not confident that other treatments will be efficacious, or because discontinuing medication invariably has been followed by recurrence with major psychosocial consequences. The verbal informed consent process promotes the treatment alliance, recognizes the patient's responsibility to make choices for herself and her baby, and provides an opportunity for ongoing assessment of the woman's competence to make decisions.

Although used commonly, the word *safe* has no operational definition in this context and its use implies a clear boundary between safe and unsafe. Confirming any exposure as harmless presents the impossible task of proving no effect on a number of reproductive and developmental outcomes such as intrauterine fetal demise, physical malformations, growth effects, neurobehavioral teratogenicity, and neonatal effects. What can be estimated from available studies is the magnitude of a subset of reproductive risks in women treated with selective-serotonin reuptake inhibitors (SSRI).[15] A prominent conclusion from published papers is the dearth of data to separate the impact of the drug exposure from the sequelae, both physiologic and psychosocial, of the underlying MDE.

Intrauterine Fetal Demise and Miscarriage. Studies to support an association between miscarriage rates and antidepressant use have inadequate control for confounding variables related to the depressive disorder.[16] There is no evidence that the rate of stillbirths is increased during antidepressant treatment.

Physical Malformations. The majority of studies do not demonstrate an association between tricyclic antidepressants (TCA) and birth defects. Similarly, studies of first-trimester SSRI exposure do not demonstrate consistent data to support a risk for structural malformations. **Two large-scale case-control studies revealed no increased risk for overall rates of malformations, including cardiac anomalies, for grouped SSRI exposure.** Louik and colleagues (2007)[17] compared the rates of malformation among 9849 case and 5860 control infants from the Slone Epidemiology Center Birth Defects Study. Analyses of the associations between individual SSRIs and specific defects showed significant associations between the use of sertraline and omphalocele (odds ratio 5.7, 95% CI, 1.6 to 20.7; 3 exposed subjects) and septal defects (odds ratio 2.0, 95% CI, 1.2 to 4.0; 13 exposed) and between the use of paroxetine and right ventricular outflow tract obstruction defects (odds ratio 3.3, 95% CI, 1.3 to 8.8; 6 exposed). Alwan et al[18] studied outcomes from 9622 infants with major birth defects and 4092 control infants from the National Birth Defects Prevention Study. Maternal SSRI use was associated with anencephaly (odds ratio 2.4, 95% CI, 1.1 to 5.1; 9 exposed); craniosynostosis (odds ratio 2.5, 95% CI, 1.5 to 4.0; 24 exposed), and omphalocele (odds ratio 2.8, 95% CI, 1.3 to 5.7; 11 exposed). In an editorial, Greene[19] observed that the malformations reported by each group were different, and that most had not been previously associated with SSRI exposure. These findings support associations by chance due to multiple comparisons. In individual drug analyses, both groups found a significant relationship between paroxetine and right ventricular outflow tract abnormalities; however, the specific defects were very rare and the absolute risks are small.

Agents released more recently, such as bupropion, venlafaxine, duloxetine, and mirtazepine, have been studied less rigorously. None of the investigations have demonstrated a significant difference in the rate of congenital anomalies compared to unexposed populations.[16]

Growth Effects. **In an elegant meta-analysis, Grote and colleagues found that maternal MDE or depressive symptoms during pregnancy increases the risk of PTB and low birthweight (LBW).**[10] Twenty studies assessed the association between antenatal depression and PTB (relative risk [RR] 1.13, 95% CI, 1.06 to 1.21). Eleven studies evaluated the association between antenatal depression and LBW (RR 1.18, 95% CI, 1.07 to 1.30). Twelve studies evaluated the association between antenatal depression and intrauterine growth restriction (IUGR), and with only 2 showing a significant association, the summary RR was not significant. In a prospective study (of 238 pregnant women with MDE, MDE with SSRI treatment, and controls with neither exposure), more than 20% of women who were either continuously treated with an SSRI (23%) or continuously exposed to MDE (21%) experienced PTB.[20] The rates of late and early PTB were similar. Therefore, avoiding SSRI treatment does not reduce the risk for PTB if the woman relapses.

Behavioral teratogenicity refers to long-term postnatal effects on offspring behavior due to prenatal exposure to agents that affect the central nervous system. Cognitive function, temperament, and general behavior were similar in children who were exposed prenatally to tricyclics or fluoxetine compared with controls. There are limited data about the postbirth development of individuals exposed to SSRI in utero; however, all converge on the finding that mental development as assessed by the Bayley Scales of Infant Development is similar in exposed compared to nonexposed children. Pedersen and colleagues reported a slight delay (within normal limits) to achievement of motor milestones in children exposed to SSRIs, but no differences were observed between the exposed and control groups at 19 months.[21]

Neonatal Effects. Both direct pharmacologic effects and withdrawal signs can occur in neonates after prenatal exposure to any antidepressant. Compared with early gestational SSRI exposure or no exposure, late SSRI exposure incurs an overall risk ratio of 3.0 (95% CI, 2.0 to 4.4) for a neonatal behavioral syndrome.[20] The most SSRI-related neonatal case reports specifically involved paroxetine and fluoxetine exposures.[20,23] Neonatal signs include central nervous system, motor, respiratory, and gastrointestinal signs that are usually mild and transient with resolution by 2 weeks of age. A severe syndrome that consists of seizures, dehydration, excessive weight loss, hyperpyrexia, or intubation is rare in full-term infants (1 in 313 quantifiable cases).[23] Based on the premise that neonatal signs are due to direct pharmacologic effects, tapering and discontinuation of the antidepressant over 10 to 14 days before the estimated delivery date, with reintroduction of the drug immediately after birth, has been suggested.[23] However, if a woman has a history of rapid decompensation during antidepressant taper or discontinuation, this strategy is likely to carry more risk to the maternal-fetal pair than continued treatment.

Antidepressant Treatment Modifications During Pregnancy. To review and guide the process of antidepressant treatment during pregnancy, members of the American College of Obstetricians and Gynecologists (ACOG) and the American Psychiatric Association (APA) developed a consensus document.[16] For mild cases of depression in pregnant women, psychotherapy is the treatment of choice as the initial intervention. Interpersonal psychotherapy (IPT) is a brief treatment to address relationship problems in the context of an MDE. It is delivered across 8 to 16 weekly sessions that focus on grief, interpersonal role disputes, role transitions, or interpersonal problems. Depressed pregnant women treated with IPT had a significant symptomatic improvement compared with a parenting education control group, and 60% of women who received IPT achieved recovery criteria.[24] However, IPT is not widely available outside academic settings. Other focused short-term therapies, such as cognitive behavioral therapy, are attractive options for MDE during childbearing and may be delivered by psychiatrists and nonphysician professionals such as psychologists, psychiatric nurse clinical specialists, or licensed clinical social workers.

For moderate to severe MDE with marked functional impairment, antidepressant pharmacotherapy should be considered. **Established efficacy and tolerability of any antidepressant for the individual woman is a strong consideration in drug choice during the risk/benefit decision-making process.** Women with chronic or highly recurrent MDE may already be taking maintenance antidepressant medication when pregnancy occurs. The risk of relapse in

pregnant women who discontinued medication proximate to conception was significantly greater compared to women who maintained antidepressant treatment.[25] Among 82 women who continued their medication, 26% relapsed compared with 68% of the 65 women who discontinued medication.

For pregnant women who have not been previously treated with an antidepressant, results from a large-scale meta-anlysis[26] are available to guide the selection of specific agents. Sertraline, escitalopram, venlafaxine, and mirtazepine were significantly more efficacious than duloxetine, fluoxetine, fluvoxamine, paroxetine, and reboxetine (not available in the United States). Sertraline and escitalopram had the most favorable profile of acceptability as assessed by significantly fewer discontinuations. The authors concluded that sertraline was the best choice when starting treatment for moderate to severe MDE in adults because it has the most favorable balance among efficacy, acceptability, and cost. This agent is a reasonable choice for pregnant women as well.

Dosage Changes Across Pregnancy. In a publication about the management of TCA dosage across pregnancy that included serum drug levels,[27] a strategy to determine the minimum *effective* dose of any antidepressant across gestation was presented. The mothers selected a target depressive symptom that was most disturbing (e.g., insomnia or irritability toward other children). Women were asked to contact the physician each time the symptom emerged, and a small incremental dose was added. The dosages increased during the second half of pregnancy and rapidly accelerated during the third trimester. The final dose achieved during gestation was an average of 1.6 times the nonpregnant dose for TCA.

Sit and colleagues examined the dose requirements and level-to-dose (L/D) ratios of citalopram, escitalopram, and sertraline during pregnancy and postpartum.[28] In the majority of women, the L/D ratios for the parent compound and primary metabolites decreased between 20 weeks' gestation and delivery, which reflects increased drug metabolism. By 12 weeks postpartum the L/D ratios were similar to those detected at 20 weeks' gestation. **These cases illustrate that dose requirements frequently increase during the second half of pregnancy to offset greater drug metabolism and maintain optimal pharmacotherapy.**

Integrative Treatments. Bright light therapy, delivered as an early morning bolus of 10,000 lux illuminance with commercially available boxes, is an efficacious treatment for MDE (Figure 52-3). Widely recognized as a treatment for seasonal (winter) MDE, light therapy is also efficacious for nonseasonal MDE. The responsivity of depressed pregnant women to bright light therapy was explored in three small studies, including a randomized controlled trial (RCT)[29] with 16 patients in the bright white (active) and 11 in the dim (placebo) arms. The response rates were significantly greater for bright white than dim light after 5 weeks of 1 hour early morning light therapy, and comparable to antidepressant drug treatment. An excellent clinician's guide is available.[30]

Manber and colleagues[31] performed a novel RCT (N = 150) of acupuncture treatment specific to MDE, acupuncture treatment targeted to a condition other than MDE, and a massage control group over 8 weeks (12 sessions). Women who received acupuncture specific for MDE had a significantly greater response rate than the control conditions, comparable to standard MDE treatments.

FIGURE 52-3. Light therapy. (From the Center for Environmental Therapeutics.)

Overall nutritional status plays an important role in mental health, and poor nutrition may contribute to the pathogenesis of MDE. Folate and vitamin B_{12} are needed for single-carbon metabolism involved in the synthesis of serotonin and other monoamine neurotransmitters and catecholamines. Deficiencies of folate, vitamin B_{12}, iron, zinc, and selenium are more common among depressed than nondepressed persons.[32] The depletion of nutrient reserves throughout pregnancy and lactation may increase a woman's risk for MDE. Marginal or low folate status also increases the likelihood of nonresponse to antidepressant medication as well as the probability of relapse in initial responders. Several RCTs have demonstrated that folic acid is an efficacious augmentation strategy for antidepressant medications.[32] Omega-3 fatty acid (O-3 FA) deficiency during pregnancy may potentially increase the risk of depression. In cross-national studies, an inverse relationship has been shown between per capita fish intake and prevalence rates of MDE, postpartum MDE, and BD.[33] O-3 FAs have received specific study in perinatal MDE in small RCTs; however, efficacy against placebo controls has not been convincingly demonstrated.[33]

Treatment of MDE in the Postpartum Period

Because of the dearth of treatment studies specifically in women with postpartum MDE, the assumption is that medications effective for MDE in women outside of childbearing are effective during childbearing. Evidence from

DOSES OF SUBJECTS WHO ACHIEVED REMISSION AT WEEK 8 IN AN RCT

SERTRALINE mg/day	<100	100	125 or 150	200
N (% remitted)	1 (4%)	12 (50%)	4 (17%)	7 (29%)

NORTRIPTYLINE mg/day	<100	100	125 or 150
N (% remitted)	15 (58%)	7 (27%)	4 (15%)

Start with half of the usual starting dose of any antidepressant (e.g., 25 mg of sertraline) for at least 2 days, then increase as tolerated to usual starting dose. Increase every 2 weeks as tolerated until full remission or the maximum recommended dose is achieved (e.g., 200 mg of sertraline or about 150 mg/day of nortriptyline (note: the dose is driven by serum levels for nortriptyline).

FIGURE 52-4. Treating postpartum depression: dose ranges for sertraline and nortripyline.

the few available RCTs support this contention.[34] Agents studied for postpartum MDE in RCTs include fluoxetine and paroxetine, both of which were efficacious compared to placebo. In a randomized comparative efficacy trial with no placebo, the TCA nortriptyline ($N = 54$) was compared to sertraline ($N = 55$).[35] The proportion of women who responded was equal; however, the majority of women required higher doses of sertraline than the usual starting dose and require dose adjustment approximately 2 weeks after treatment initiation (Figure 52-4). The total side effect burden for each drug was similar, although the side effect profiles differed for each drug.

In a novel study of the efficacy of estradiol treatment, Gregoire et al[36] randomized women with severe postpartum MDE to placebo ($N = 27$) or estradiol ($N = 34$) (200 mcg/day) delivered by transdermal patch for 6 months. By 3 months of treatment, 80% of the estradiol-treated and 31% of the placebo-treated group responded. Because assessments were done monthly, the time course of response in the early weeks of treatment is unknown. Estradiol treatment was well-tolerated as judged by low attrition. Endometrial changes were found in 3 participants at the study conclusion (6 months), despite co-administration of progesterone (10 mg/day, 12 days per month in the final 3 months of the trial); however, these changes resolved at follow-up. The inclusion of women who took concurrent antidepressant medications limits the ability to separate an estradiol-specific treatment effect. Further studies are needed to evaluate the potential of estradiol as a therapy for postpartum MDE. Little is known about estradiol secretion into breast milk; however, estradiol was not detected in the breast milk of 18 lactating women who used transdermal estradiol at doses of 50 to 100 mcg/day for 12 weeks.[37]

Prevention of Postpartum-Onset MDE. Studies of the efficacy of antidepressants or hormonal supplements for the *prevention* of postpartum MDE are limited to three RCTs.[34] The one positive placebo-controlled pharmacologic prevention study demonstrated the efficacy of sertraline.[38] Women with any history of MDE (not only postpartum) are candidates for the initiation of sertraline immediately following birth to prevent the emergence of episodes. The physician has the option of following the dosing protocol utilized in the original study as well as more flexible dosing for individual patients. For example, doses higher than the maximum used in that protocol (75 mg/day) could be prescribed for women who had previously responded to and tolerated higher doses. The duration of preventive treatment should be a minimum of 6 months. Although other serotonergic antidepressants have not been evaluated for preventive efficacy, the explanation for the efficacy of sertraline is based upon its serotonergic impact. Therefore, use of another serotonergic agent, particularly one to which the woman has responded in the past, is also a reasonable intervention.

Although open label studies supported that progesterone prevented recurrence, a placebo-controlled RCT of synthetic progesterone increased the risk of depressive symptoms at 6 weeks after birth. Estrogen was efficacious in preventing postpartum MDE recurrence in a small open study, which was not replicated in an RCT.

Treatment During Breastfeeding. The magnitude of antidepressant exposure through breast milk is substantially lower than during pregnancy. The approach to studying risk to infants when lactating mothers take antidepressants has been mother and nursing infant serum level monitoring. Comprehensive reviews of antidepressants in maternal serum, breast milk, and infant serum have been published.[34] SSRIs (sertraline or paroxetine) and TCAs (nortriptyline) are the drugs of first choice for the breastfeeding woman because they are the most evidence-based medications (similar findings across multiple laboratories, usually undetectable infant serum levels, and no reports of short-term adverse events). However, established efficacy of another drug for the individual woman must be considered strongly in the decision-making process (Table 52-1). Although TCAs are reasonable treatment options for PPD, they remain second-line drugs due to their toxicity in overdose. The more recently released antidepressants (escitalopram, duloxetine, bupropion) are second-line choices in breastfeeding women unless demonstrated efficacy in past episodes is clear and no new contraindications exist for their use in the individual woman.

Nursing infants' clinical conditions, particularly for sick or low-birthweight infants, should be monitored to detect initial adverse effects that may be attributed to the maternal drug (behavioral activation or sedation; new-onset feeding or sleeping problems). Routine laboratory measurement of serum drug levels in healthy full-term infants is not warranted. Serum level monitoring in premature and sick infants has not been described in the literature.

Bipolar Disorder

Diagnosis and Prevalence

Bipolar disorder (BD) includes normal, depressed, and elevated mood states (mania or its less intense form, hypomania); depression is the predominant mood state in many bipolar patients and is mistaken for unipolar depression in 30% of cases. Mania is a persistent, abnormally elevated, expansive or irritable mood state with inflated self-esteem, excessive physical goal-directed activity, agitation, distractibility, and poor judgment, for a minimum of 1 week. Impairment in function at work or in relationships must be present. Hypomania is defined by a minimum of 4 continuous days of persistent increased creativity,

TABLE 52-1 SELECTED ANTIDEPRESSANT LEVELS IN BREASTFED INFANTS' SERA

ANTIDEPRESSANT DRUG	SERUM LEVEL RANGE IN BREASTFED INFANTS	TYPICAL MATERNAL DOSE RANGE, MG/DAY
Nortriptyline*	Nortriptyline, below limit of quantifiability to 10 ng/mL	50-150; maternal therapeutic serum levels = 50-150 ng/mL
Nortriptyline metabolites	E-10-OH- Nortriptyline = <4-16 ng/mL Z-10-OH- Nortriptyline = <4-17 ng/mL	
Sertraline	Sertraline, below limit of quantifiability to 8 ng/mL	50-200
Sertraline metabolites	Norsertraline, = below limit of quantifiability to 26 ng/mL	
Paroxetine	Paroxetine, below limit of quantifiability	10-60
No active metabolites		
Other Antidepressants†		
Fluoxetine	Fluoxetine, below quantifiability to 340 ng/mL	20-60
Fluoxetine metabolite‡	Norfluoxetine, below quantifiability to 265 ng/mL	
Citalopram	Citalopram, below quantifiability to 12.7 ng/mL	20-40
Citalopram metabolite	Desmethylcitalopram, below quantifiability to 3.1 ng/mL	
Venlafaxine	Venlafaxine, below quantifiability to 5	75-300
Venlafaxine metabolite	O-desmethylvenlafaxine, below quantifiability to 38 ng/mL	
Bupropion	Average infant exposure expected to be 2% of the standard maternal dose on a molar basis; infant serum levels not measured in largest series of $N = 10$§	300
Multiple metabolites		

*The most-studied tricyclic antidepressant during breastfeeding; minimal use of this drug class currently.
†Established efficacy of an antidepressant in a woman is a strong consideration in drug selection.

§Haas et al.[130]

productivity, and sociability, or increased irritability that family or coworkers notice. The woman's function may be enhanced by creativity and increased energy. Women also experience mixed states in which symptoms of depression and hypomania/mania occur within the same day. During a mixed episode, patients may experience bouts of low mood, loss of interest, tearfulness and hyperphagia (depressive symptoms) that are intermingled with periods of elation or intense irritability, decreased need for sleep, heightened energy, pressured speech, excessive spending, and risky behaviors (hypomanic symptoms).

BD is divided into two major types. BD I is characterized by the presence of depression and mania. This illness affects women and men equally, and the lifetime prevalence is estimated at 1.3%. Much higher prevalence rates (3.7%-6.4%) have been reported for BD II (depression plus hypomania rather than full-blown mania) and bipolar spectrum disorders. Several bipolar variants occur more commonly in women, such as BD II, mixed states, and rapid cycling BD (four or more episodes yearly).

Conditions that frequently co-occur with BD include panic disorder, agoraphobia, social phobia, marijuana use, and bulimia nervosa (BN). Women with BD more commonly have a history of past sexual abuse, alcohol abuse/dependence, migraines, drug-induced metabolic syndrome, pain disorders, and hypothyroidism compared to men. A seasonal pattern of mood episodes, with winter depression characterized by atypical symptoms like weight gain, hypersomnia, and extremely low energy, is also more common in women. In contrast, spring and summer are associated with hypomania or mania.

Inadequate screening for bipolarity contributes to the significant delay in diagnosis from illness onset to the confirmation of BD of about 11 years. In addition, antidepressant medication without an anti-manic agent increases the risk for cycle acceleration, mania, or a mixed state. The mood criterion symptoms for hypomania (high mood and/or irritability) can be used as a simple screen (because formal measures have low predictive value in general populations): "Have you ever had 4 continuous days in which you felt so good, high, excited, or "hyper" that other people thought you were not your usual self or you got into trouble? Have you ever had 4 continuous days when you were so irritable you found yourself shouting at people, or starting fights or arguments?"

Natural History Across Childbearing

The course of bipolar symptoms during pregnancy is unpredictable. Some researchers have described a benign course or mood stabilization for women with BD during gestation, whereas others have observed that patients are at high risk for another episode. Viguera and colleagues[39] reported that 71% of pregnant women with BD had at least one episode of major depression, mixed state, hypomania, or mania. Patients who discontinued mood stabilizer treatment proximal to conception had higher rates of recurrence (86%) compared to patients who continued treatment (37%).[39] **Because abrupt discontinuation of mood stabilizers increases the risk for a recurrent episode, drug tapering is advisable.** The overall risk of a new episode of mania was significantly greater after rapid (less than 2 weeks) than gradual (2 to 4 weeks) lithium discontinuation.

Women with BD have a high risk for both recurrence and first admission in the immediate period after birth (within 10 to 19 days).[40] Recent psychiatric hospitalization (in the past 3 years), hospitalization during the pregnancy, and frequent past hospitalizations (>4) are risk factors for severe postpartum episodes that require hospital care. Postpartum psychosis is typically a manifestation of BD,[41] which presents as a manic, depressive, or mixed state episode of BD with psychosis. It occurs in 1 to 2 per 1000 births within 2 weeks of delivery. Women develop mood lability, confusion, delusional thinking, hallucinations, poor concentration, and impaired judgment and insight. Acute-onset postpartum psychosis is an emergency, and

women must be screened for thoughts of harming themselves or others, especially the newborn.[41]

Women with mental illness have an overall higher risk for adverse pregnancy outcome than the general population. Jablensky and colleagues[42] determined the rate of complications during pregnancy in women with BD, schizophrenia, or MDE in a population-based cohort (N = 3174 children born from 1980 to 1992). A comparison sample of 3129 births to women without a psychiatric diagnosis was randomly selected from women who gave birth during the same time. Women with bipolar illness or MDE did not have elevated risk for placental complications; however, the rate of antepartum hemorrhage was significantly higher in mothers with bipolar illness (OR 1.66, 95 percent CI, 1.15 to 2.39). Separating adverse pregnancy outcomes related to the underlying disorder versus the medication treatments is an even greater challenge than for MDE.

Treatment of Bipolar Disorder During Childbearing

Although medication maintenance is the mainstay of treatment for BD, psychotherapy and educational interventions are critical adjuncts to pharmacotherapy. The physician has a major role in providing educational support and promoting treatment adherence. Early treatment for low-grade symptoms results in lower rates of relapse, increased time to recurrence, improved medication adherence, and better functioning.

Several classes of drugs are indicated for the treatment of mania. Lithium, some antiepileptic drugs (AEDs), and several newer atypical antipsychotic medications are efficacious; however, these agents result in a treatment response in only 36% to 50% of cases.[1] Therefore, patients often receive more than one drug to manage their mood symptoms. Strategies to minimize fetal exposure include the following: (1) use the lowest *effective* dose(s), (2) minimize the number of drugs to achieve response, and (3) divide daily doses to avoid high peak serum concentrations.

Lithium. Lithium is the standard drug for acute and maintenance therapy for BD. Before initiating lithium treatment, renal and thyroid function should be assessed, and gestational age considered. The starting dose is 300 mg twice daily. Serum drug levels and renal function tests should be repeated after 5 to 7 days of treatment. The target serum level is 0.4 to 1.0 mEq/L, measured at 12 hours post-dose. The dose can be increased by 300 mg every 5 to 7 days as tolerated with re-evaluation of the serum level. Treatment response is usually achieved at 900 to 1200 mg daily.

Patients are encouraged to have their lithium level monitored every 4 weeks throughout pregnancy to monitor for declining serum levels; the level should be checked weekly in the last month, and every few days shortly after delivery.[41] Typical side effects of lithium include sedation, tremor, renal dysfunction, weight gain, nausea, and vomiting. Lithium has a relatively narrow window between therapeutic and toxic serum levels. Toxicity is associated with excessive sedation, severe tremors, acute renal dysfunction, and intractable vomiting. Women who are dehydrated from hyperemesis are especially vulnerable. Lithium toxicity must be managed immediately with drug discontinuation, rehydration therapy, and monitoring of fluid and electrolyte balance and renal function. Diuretics and nonsteroidal anti-inflammatory drugs should be avoided in lithium-treated patients because these drugs may decrease the renal clearance of lithium and increase the risk for toxicity.

Lithium exposure during the first trimester was linked with Ebstein's anomaly in the past but subsequent prospective studies demonstrated that the risk was overestimated due to voluntary reporting to a registry, which inflates the number of cases (numerator) while underestimating the magnitude of population exposed (denominator).[41] **The absolute risk of Ebstein's anomaly after first-trimester exposure is 1 in 1000 to 2000** (20 to 40 times higher than the general population)**.**[41] Lithium-exposed neonates are at risk for large for gestational age, hypotonia, feeding difficulties, depressed reflexes, cyanosis, apnea, bradycardia, hypothyroidism, and diabetes insipidus.[41] The neonatal symptoms appear to be temporary and may be linked with higher maternal serum concentrations at delivery (>0.64 mEq/L).[43] The suspension of lithium 24 to 48 hours before a scheduled delivery or at the onset of labor reduces the likelihood for perinatal complications.[43] Developmental milestones are normal in infants exposed prenatally to lithium.[41]

Valproic Acid (VPA). VPA was the first FDA-indicated AED for the treatment of BD (specifically for mania). The starting dose is 500 to 750 mg daily in divided doses. Therapeutic levels range from 50 to 125 mcg/mL. Side effects include nausea, weight gain, fatigue, tremor, ataxia, diarrhea, abdominal pain, alopecia, hepatitis, thrombocytopenia, and rarely pancreatitis.

VPA increases the rates of birth defects including neural tube defects in offspring exposed during pregnancy. Because more than half of pregnancies in America are unplanned and the impact on neural tube development occurs 17 to 30 days postconception, **the use of valproate as a first-line treatment for BD in childbearing-aged women should be avoided.** VPA is associated with the highest rate of birth defects (10.7%; 95% CI, 8.2 to 13.3) compared to other anticonvulsants: lamotrigine 1%, carbamazepine 8.2%, phenytoin 10.7%, and VPA 20.3%.[44,45] Women treated with AED polytherapy have 2 to 5 times the risk for major malformations compared to monotherapy. The rates of malformations with polytherapy were 6% (N = 770) versus monotherapy 3.7% (N = 2598).[46] Although registry data suggest the hazard of AED polytherapy is from the exposure to valproate,[47] the American Academy of Neurology (AAN) consensus statement concluded that AED polytherapy probably contributes to the development of major malformations and impaired cognition compared to monotherapy. The relationship between the AED dose or serum level and risk for malformation needs to be clarified for all AEDs.

Complications associated with VPA use near delivery include fetal decelerations, and infant irritability, jitteriness, feeding difficulties, abnormal tone, hepatic toxicity, hypoglycemia, and reduction in neonatal fibrinogen levels. Because VPA is concentrated in the fetal compartment, the lowest effective dose in divided doses is recommended to avoid high single peak levels.[41] Postnatal studies suggest that VPA exposure is associated with slightly lower IQ scores at 3 years of age.[48]

Carbamazepine (CBZ) and Oxcarbazepine. CBZ is prescribed at doses between 400 and 1600 mg daily for BD to achieve a target range of 4 to 12 mcg/mL. Drug-induced toxicity is usually detectable from clinical symptoms, and the serum level provides objective evidence. During pregnancy, the total AED levels drop, but the amount of unbound bioavailable drug remains unchanged. Serum levels are useful in the assessment of patients with exacerbation of mood symptoms, serious side effects, and questionable treatment adherence. Hepatitis, leukopenia, thrombocytopenia, rash, sedation, and ataxia are CBZ side effects. Due to the potential for bone marrow suppression, combining CBZ and the antipsychotic clozapine is contraindicated.

The AAN committee found no increased risk of major malformations in the offspring of women who received CBZ for epilepsy. However, infants exposed to CBZ had twice the risk for being small for gestational age (SGA) and an increased risk for low Apgar scores (less than 7) but not for perinatal death. The exposed children do not have reduced cognitive function or developmental delays compared to children without AED exposure.

Fetal serum levels of CBZ are 50% to 80% of maternal levels.[49] Because adequate levels of vitamin K are necessary for normal midfacial growth and for the functioning of clotting factors, CBZ exposure in utero could increase the risk of neonatal bleeding.[41] Some experts recommend administering vitamin K 20 mg daily throughout pregnancy and 1 mg intramuscularly to neonates.[41]

Oxcarbazepine is a newer AED that has been used to treat mania despite minimal efficacy data and without an FDA indication. It is prescribed in divided doses (total dose, 600 to 1200 mg/day). The parent compound is rapidly and almost completely metabolized to an active hydroxy metabolite. The metabolite undergoes hepatic glucuronidation, and the conjugate product is excreted by the kidneys. Adverse effects include hyponatremia, hypersensitivity reactions, and decreased thyroxine levels (without altered triiodothyronine or TSH). Side effects include headaches, dizziness, gait disturbance, fatigue, and concentration and memory changes. In 55 babies exposed in utero to oxcarbazepine (20 combination therapy, 35 monotherapy), one cardiac malformation was reported in an infant also exposed to phenobarbital.[50]

Lamotrigine (LTG) is indicated for bipolar depression maintenance therapy at doses of 50 to 200 mg/day.[51] Higher doses (up to 500 mg/day) have been used for long-term treatment of patients with BD. Reported side effects include headaches, rash, dizziness, diarrhea, abnormal dreams, and pruritus, which did not differ from the rates of placebo-treated patients.[52] Aseptic meningitis is a rare but serious potential complication of treatment with LTG. A maculopapular or erythematous rash is most likely to occur with rapid dose escalation, when combined with VPA, and among adolescents.[53] In controlled studies, the rates of benign rash were 8.3% in LTG-treated and 6.4% in placebo-treated patients.[54] One case of Stevens-Johnson syndrome that did not require hospitalization occurred in a patient treated with LTG. Although the condition is potentially life-threatening, the very low risk of serious rash must be weighed against the much more common risks associated with BD.[54]

Continuing LTG may prevent recurrent illness in pregnant women with BD. Thirty percent of women who continued versus all who stopped LTG relapsed during pregnancy (P <0.0001; OR 23.2, 95% CI, 1.5 to 366).[55] Patients who stopped treatment suffered relapses rapidly (within 2 weeks) compared to patients who continued treatment. In the second and third trimesters LTG clearance increases by 65% to more than 90% compared to preconception; therefore, patients need higher doses to prevent recurrent symptoms.[56] After delivery, LTG metabolism reverts to the prepregnancy rate within 2 weeks.

The rate of congenital malformations is similar in infants exposed in utero to LTG monotherapy compared to the general population; however, the malformation rates may increase when LTG is combined with other AEDs.

Contrary to earlier reports of an increased risk for isolated clefts with LTG exposure, more recent findings indicate the odds for orofacial cleft malformations is not increased with LTG monotherapy compared to nonexposed controls.[57] No evidence of growth problems, postnatal occult malformations, neonatal seizures, or deviations in psychomotor development up to 1 year of age were observed in 62 infants exposed to LTG in utero.[58]

Atypical Antipsychotics. Antipsychotic medications are efficacious treatments for BD (and also schizophrenia). Antipsychotic medications are classified into first-generation (also called "typical," e.g., haloperidol) and second-generation ("atypical," e.g., olanzapine) agents. Antipsychotic drugs block dopamine-2 receptors and reduce symptoms such as hallucinations, but substantial variability in the response of individuals to antipsychotics is the rule. The atypical agents are associated with fewer extrapyramidal side effects such as tardive dyskinesia, tremor, rigidity, akathisia, bradykinesia, and dystonia compared to the older typical antipsychotic drugs. Other side effects include somnolence, dry mouth, akathisia (internal sense of restlessness), and increased hepatic transaminases. A marked and sustained hyperprolactinemia is frequently associated with risperidone (88% of patients), compared with conventional antipsychotics like haloperidol (48%) or olanzapine (minimal, if any).[59]

More recent indications for these medications include bipolar maintenance therapy, bipolar depression (quetiapine and olanzapine-fluoxetine combined therapy), and treatment-resistant depression. The usual daily maintenance dose ranges for these drugs are: olanzapine (5 to 20 mg), risperidone (1 to 6 mg), quetiapine (100 to 400 mg, maximum 800 mg), ziprasidone (80 to 160 mg), and aripiprazole (15 to 30 mg). The initial treatment is started at a lower dose and titrated against tolerance. Standard clinical practice does not include serum level monitoring of these drugs.

The metabolic side effects of atypical agents are a public health concern. Patients are at risk for significant weight gain, elevated triglycerides, and new-onset metabolic syndrome or insulin intolerance, particularly with olanzapine. Mothers treated with antipsychotics had increased risk for gestational diabetes and surgical delivery compared to all mothers who gave birth.[60] **Use of an atypical antipsychotic agent should prompt close monitoring of gestational weight gain and glucose tolerance throughout pregnancy.**

The reproductive risks of atypical antipsychotics have received minimal research attention. Pregnant women who received either typical or atypical drugs had increased risks for PTB, LBW, and major malformations compared to the general population. The malformations (mainly atrial and ventricular septal defects) affected only infants with exposure to first-generation (typical) antipsychotic agents.[60] The rates of PTB were similar among patients who received typical or atypical agents. Although genetic liability and gene-environment interactions contribute to these outcomes, maternal risk factors, substance abuse, nutritional status, and biological and behavioral concomitants of severe mental illness are likely to be the major determinants of increases in reproductive pathology in this cohort.

Infants of mothers who received typical antipsychotic drugs weighed less (3158 g ± 440) than infants of mothers who received atypical (3391 g ± 446) or non-antipsychotic (3382 g ± 384) drugs.[61] Significantly more large-for-gestational-age babies were born to mothers who received atypical agents (20%) compared to mothers who received typical agents (2%) or non-antipsychotic treated women (3%).[61]

Alternative or Supplemental Treatment Options. Some patients do not respond, have prohibitive side effects, or have medical disorders that complicate the use of lithium, anticonvulsants, and antipsychotics. Additional therapies are being evaluated to expand the therapeutic armamentarium during childbearing. An inverse correlation between O-3 FA dietary consumption and the population prevalence of BD has been demonstrated.[62] Increased duration of remission of episodes of BD occurred in subjects who were randomized to fish oil versus placebo supplementation.[33] Sporadic reports of the use of calcium channel blockers for BD have been published. Verapamil (VPM) possesses clinically relevant dopamine antagonist properties, as evidenced by its ability to increase prolactin release, as well as antiepileptic activity.[63] Although open case series data showed reduction of manic symptoms,[63] results of controlled studies have been less encouraging. The efficacy of VPM (or any other calcium channel blocker) has never been explored in randomized acute treatment trials with adequate power.

Electroconvulsive therapy (ECT) is highly effective for the management of treatment-resistant depression, acute mania, and severe mixed episodes.[41] ECT involves the delivery of an electrical stimulus with a brief pulse device to generate a brief grand mal seizure blocked from peripheral expression by succinylcholine. During ECT, the patient receives short-acting anesthetic agents, which are not likely to cause adverse impact on the mother-infant pair.[41]

Prevention of Bipolar Episode Recurrence After Delivery

The risk for recurrence of mania, depression, or mixed states after delivery is the highest at any point in a woman's life, and breakthrough episodes even with continued medication treatment are common. Viguera and colleagues[64] retrospectively compared recurrence rates in childbearing compared with non-childbearing women who discontinued lithium treatment. In the year before lithium discontinuation, the rate of recurrence was 21%. After lithium discontinuation, the rates of recurrence over the first 40 weeks were similar in pregnant (52%) and nonpregnant (58%) women. In the postpartum period, recurrences occurred at three times the rate observed in the nonpregnant women during the same time frame (70% vs. 24%). Nine women who continued lithium and remained well during pregnancy were also observed, and three suffered rapid postpartum recurrences despite continued lithium treatment. In a prospective trial, VPA did not reduce the number or time to episode recurrence in postpartum women with BD compared with nonmedicated women.[65]

In the clinical management of women with BD, educating partners to observe for manic and depressive symptoms and communicate with the treatment team is the most important strategy at this point in our knowledge of prophylactic approaches. The most prudent pharmacologic plan is to use the drug(s) to which the individual woman has responded and prepare a plan for rapid additional intervention if a breakthrough episode occurs.[41]

Breastfeeding for Women with Bipolar Disorder

The mother's commitment to breastfeeding is an important consideration in the postpartum management of women with BD. Sleep deprivation, which is often unavoidable in the postpartum period, is a major precipitant of mania and hypomania. If a partner can feed the baby at night, sleep can be preserved in vulnerable women; however, this level of support is not always available. Lactation success also may be compromised by not breastfeeding through the night early in the postbirth period.

Lithium is in the category of drugs that have been associated with significant effects in some nursing infants and should be given to nursing mothers with caution.[66] Viguera and colleagues examined 10 pairs of lithium-treated mothers and their breastfeeding babies 4 to 12 weeks after delivery.[66] They measured maternal and infant serum, breast milk lithium concentrations, and renal and thyroid function in the infants. One infant had an elevated thyroid-stimulating hormone (TSH) that resolved by 2 weeks after discontinuation of lithium exposure. Infant serum lithium levels were 25% of maternal levels. The investigators recommended clinical monitoring of breastfed infants for signs of toxicity or dehydration, such as poor feeding, lethargy, and hypotonia, and serum levels of lithium, TSH, blood urea nitrogen, and creatinine every 8 to 12 weeks while breastfeeding.[66] Mothers must be educated to observe for the evidence of dehydration in infants due to poor intake, excessive fluid loss, or fever, which increases the risk for lithium toxicity, and to seek pediatric evaluation for behavioral changes in their infants.[41] To avoid spuriously high levels of lithium, infant blood samples must be collected in tubes that do not contain lithium heparin as the stabilizing agent.

The American Academy of Pediatrics (AAP) Committee on Drugs and the AAN concluded that CBZ and VPA are compatible with breastfeeding because they are transferred into the breast milk in small amounts that are not likely to be clinically relevant. The outcomes of 25 breastfed infants whose mothers were treated with LTG revealed no adverse effects.[67] The ratio of infant to maternal concentrations was 18.3%; the ratio of free to maternal concentration was 1.7 times greater at 30.9%. LTG

undergoes glucuronidation and renal excretion, which is substantially lower in infants than adults. The risk for toxicity may be increased in the breastfeeding infants of women who receive additional similarly metabolized agents (e.g., lorazepam, aspirin, olanzapine, acetaminophen, VPA); however, we were unable to locate any published reports of LTG toxicity during breastfeeding.

ANXIETY DISORDERS

Diagnosis and Prevalence

Anxiety disorders are characterized by prominent symptoms of anxiety that impair functioning. Examples are obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), generalized anxiety disorder, panic disorder, agoraphobia, and other phobias. Each of these disorders is distinct and defined by specific diagnostic criteria according to DSM-IV.[1] In women, the lifetime prevalence of anxiety disorders is 5% for panic disorder, 5% for generalized anxiety disorder, 3% for OCD, 6% for social phobia, 13% for other specific phobias, and 10% for PTSD. However, the rule rather than the exception is for multiple anxiety disorders to occur in an individual. Without treatment, anxiety disorders usually have a chronic course. Although rates of OCD are similar in men and women, all other anxiety disorders are 1.5 to 2 times more common in women. In addition, women with anxiety disorders have an increased risk for development of comorbid MDE.

Panic attacks are characterized by brief (5 to 15 minutes), intense episodes of fear or discomfort. Panic attacks occur in a variety of anxiety disorders, as well as in healthy individuals exposed to acute stress. Symptoms include palpitations, sweating, shortness of breath, choking, nausea, abdominal discomfort, dizziness, unsteadiness, numbness or tingling, chills, hot flashes, or a fear of dying or losing control. Panic disorder is diagnosed if panic attacks are recurrent or associated with a continuing fear of future attacks, which result in anxiety between attacks. The most disabling consequence of panic disorder, agoraphobia, occurs in 30% to 40% of women with untreated panic disorder. Individuals with agoraphobia restrict their activities outside the home or insist on being accompanied by another individual due to fear of having a panic attack where help is unavailable.

Generalized anxiety disorder is characterized by excessive worrying about multiple problems. The issues of concern to persons with generalized anxiety disorder are realistic but the level of worry is much more intense than appropriate. For example, a woman might worry for hours about whether a friend received a thank-you note for a baby shower gift. Individuals with generalized anxiety disorder often have physical symptoms associated with worrying, such as muscle tension, fatigue, headache, nausea, diarrhea, or abdominal pain. To meet criteria for the disorder, individuals must have significant impairment of functioning and anxiety for at least 6 months.

In contrast to generalized anxiety disorder, women with OCD focus on more idiosyncratic and often unrealistic concerns. OCD is characterized by disturbing intrusive thoughts and performance of compulsions to temporarily relieve the distress generated by the intrusive thoughts. Intrusive thoughts usually center on a few key themes: contamination, causing harm, offensive violent or sexual images, religious preoccupations, and urges for symmetry or ordering. Compulsions performed to relieve these intrusive worries include cleaning or washing, checking, repeating, ordering, hoarding, and mental rituals like counting and praying. To meet criteria for the disorder, the symptoms must interfere with functioning and last at least 1 hour per day. During pregnancy and postpartum, contamination concerns are particularly common. **New mothers with OCD can experience repeated disturbing mental images of harming their infant, but, in contrast to women with acute psychosis, they are not at increased risk of actually causing any harm.**

Exposure to trauma in which a woman experienced or witnessed an event that involved actual or threatened death or serious injury (such as rape or military combat) is required for a diagnosis of posttraumatic stress disorder. The traumatic event is persistently re-experienced in one or more of the following ways: recurrent and intrusive distressing recollections of the event, recurrent distressing dreams, acting or feeling as if the event were recurring (flashbacks), intense distress at cues that remind her of the event, physiologic hyperarousal, and exaggerated startle responses. Symptoms usually begin within 3 months of the trauma and they must persist for at least 1 month to meet diagnostic criteria for posttraumatic stress disorder. There has been little study of whether birth trauma can result in new onset or a recurrence of PTSD. Preliminary estimates suggest an incidence of 1% to 2%.[68]

Finally, excessive fear of a discrete object or situation constitutes a phobia. Social phobia refers to fears of speaking or eating in public and fears of humiliation in social interactions. These fears must be excessive and significantly impair an individual's social or occupational functioning for the diagnosis to be made. Other common specific phobias are body injury phobia (blood drawing or medical procedures), acrophobia (heights), arachnophobia (spiders), and claustrophobia (enclosed spaces). Even the possibility of confronting the feared object or situation stimulates anxiety, which is described as anticipatory anxiety, which can be a feature of any anxiety disorder. Individuals with panic disorder often have fear of situations from which they could not escape if they had a panic attack, including airplanes, bridges, and subways. These fears are considered to be a feature of panic disorder and agoraphobia, and would not warrant an additional diagnosis of simple phobia.

Fear of Labor and Delivery. In modern obstetric practice, perinatal morbidity and mortality of mother and neonate are rare; however, some women have intense fear about childbearing. Approximately 5% to 10% of pregnant women develop extreme fear of delivery, which may be considered a type of phobia. These women often request a surgical delivery to avoid labor. Risk factors for intense fear of delivery and requesting cesarean section include prior emotional problems, abuse, less social support, unemployment, and prior complicated deliveries. Referral for focused, short-term psychotherapy can often enable these women to proceed with a vaginal delivery and can reduce the likelihood of having a subjectively negative birth experience.

Natural History Across Childbearing

Pregnancy, delivery, and lactation produce profound changes in physiology, including changes in multiple hormonal and neurotransmitter systems that modulate anxiety symptoms. Although pregnancy and the postpartum period have been identified as times of increased risk for relapse of depressive disorders, the course of anxiety disorders has not been as carefully studied. Most of the available data was collected retrospectively, which limits reliability of the information. In one large prospective study, more women scored above threshold on an anxiety scale during weeks 18 and 32 of pregnancy compared with 8 weeks and 8 months postpartum, suggesting that nonspecific anxiety symptoms worsen during pregnancy. Antenatal anxiety was associated with an increased risk of postpartum depression, even after controlling for antenatal depression.[69] Anxiety disorders seem to be as common as MDE in the postpartum period. With respect to specific anxiety disorders, there is preliminary evidence that panic disorder can improve during pregnancy, but recur postpartum. Weaning also may precipitate relapse of panic disorder.[70] Pregnancy and childbirth can trigger the onset of OCD and the exacerbation of preexisting OCD. In addition, obsessive-compulsive symptoms are very common in postpartum depression, and intrusive violent thoughts and contamination concerns are quite common in new mothers without psychiatric disorders. There is no information on the effects of pregnancy on the course of generalized anxiety disorder, phobias, or PTSD.

Beta-adrenergic agonists (e.g. terbutaline) may precipitate panic attacks and other anxiety symptoms during the treatment of premature labor. **Hyperthyroidism is associated with panic attacks and anxiety symptoms, and should be considered in the differential diagnosis of postpartum-onset anxiety episodes.**

Effects of Anxiety During Childbearing

Anxiety disorders are associated with an increased risk of preeclampsia, but less is known about any relationship with other delivery complications. Psychosocial stress has been linked to higher rates of PTB and several physiological pathways have been proposed to mediate the association. However, not all women who experience high levels of stress have anxiety disorders or symptoms.

In contrast, perinatal anxiety has been associated with adverse effects on offspring. The offspring of highly anxious women are exposed to an altered physiologic milieu during pregnancy and maternal anxiety-related behaviors postpartum. High levels of anxiety symptoms have been linked to increased uterine artery resistance, which potentially compromises blood supply to the fetus.[71] Fetuses of anxious women show increased heart rate reactivity to maternal stressors, and newborns of highly anxious mothers have reduced heart rate variability and poor autonomic regulation.[72,73] Poor autonomic regulation of heart rate has been linked to impaired emotional regulation in older children and adults. In utero and as newborns, offspring of anxious women spend more time in deep sleep.[72,73]

Maternal anxiety during pregnancy is associated with attention deficits, motor immaturity, and difficult temperament in offspring. In two large prospective, longitudinal studies, anxiety during pregnancy increased the risk for hyperactivity and anxiety in childhood, after controlling for obstetrical and sociodemographic risks as well as maternal depression. Further research is needed to determine whether developmental and psychiatric problems in offspring of anxious mothers are due to genetic risk factors or to an altered in utero environment.

Treatment of Anxiety Disorders

The boundary between normal and pathologic anxiety cannot be drawn with great precision. When anxiety substantially impairs work, family, or social adjustment, mental health evaluation is indicated and treatment is appropriate. Panic disorder responds to most antidepressant medications, which are first-line therapies for this disorder. Benzodiazepines are also effective but are associated with abuse and physical dependence in a subset of patients. Cognitive therapy, a time-limited, structured psychotherapy, also is efficacious for panic disorder. In contrast, OCD is effectively treated specifically with SSRIs. A specific behavioral therapy technique, exposure and response prevention, is also effective for OCD. Generalized anxiety disorder responds to a variety of antidepressant medications as well as cognitive therapy. Posttraumatic stress disorder is partially responsive to antidepressant medication, but cognitive therapy with exposure is more effective. The first-line medication treatment for social phobia is SSRIs, and cognitive therapy can also be very helpful. Specific phobias are most effectively treated with focused desensitization psychotherapy rather than medication.

A risk/benefit evaluation for treatments during pregnancy must be individualized for the pregnant woman with anxiety disorder, which, like MDE, can have a negative impact on pregnancy outcome. If psychotherapy treatment is refused, not available, or ineffective, pharmacologic treatment should be considered. The use of antidepressants in pregnancy and lactation has been reviewed in the section on major depression. Evidence from the available studies indicates that teratogenic risk from benzodiazepine exposure, if any, is very small. However, less is known about the effect of benzodiazepines on neurodevelopment. At delivery, neonates exposed to higher doses can have withdrawal seizures or "floppy baby" syndrome. There is also little known about the degree to which benzodiazepines are absorbed into the circulation of breastfed infants. Because alternative treatments are available for anxiety disorders, benzodiazepines often can be avoided or used to treat targeted symptoms for limited time periods during pregnancy and lactation. A useful handout for patients entitled "Benzodiazepines during Pregnancy" can be downloaded from the Organization of Teratology Information Specialists: www.otispregnancy.org/files/benzodiazepines.pdf. An excellent educational program and workbook on anxiety disorders is available (see Additional Resources list at the end of this chapter).

EATING DISORDERS

Eating disorders are characterized by serious disturbances in eating behavior and are 10 times more common in women. The most familiar and well described are anorexia nervosa (AN) and bulimia nervosa (BN). Binge-eating disorder and subclinical forms of AN and BN also occur.

Eating disorders are particularly relevant during pregnancy and lactation, when the increased requirement for nutritional intake is directly affected by disordered eating (see Chapter 7).

Diagnosis and Prevalence

AN is characterized by the woman's refusal to maintain a minimally normal body weight, defined as less than 85% of that expected for age and height. Amenorrhea (absence of at least three menstrual cycles) is required for the diagnosis of AN.[1] The prevalence of AN in adolescents and young women is 0.5% to 1%, and the mean age of onset is 17 years of age. The course of AN is highly variable, with a range of outcomes that include recovery, residual partial symptomatology, and a fluctuating or chronic course. Remission rates approximate 50% at 10 or more years after initial diagnosis. AN is associated with both elevated mortality rates and suicide rates.

BN occurs in 1% to 3% of young adult women. Women with BN maintain body weight at or above a minimally normal range but use binge eating plus compensatory methods to prevent weight gain. A binge is excess eating in a discrete period of time (within 2 hours) of an amount of food that is decisively larger than most people would eat during a similar period of time. The binge eating and inappropriate compensatory behaviors must occur at least twice a week for 3 months.[1] Inappropriate compensatory behaviors that occur in both AN and BN are self-induced vomiting; laxative, diuretic, or other medication (such as ipecac) abuse; fasting; and excessive exercise. A disturbance in the perception of body shape and weight that leads to negative self-evaluation is an essential feature of both disorders. Remission rates of BN are reported to be 75% at 10 or more years after intake, but the longitudinal course of BN may be chronic or intermittently recurrent. In women with BN, menstrual irregularities are common, but they have minimal impact on later ability to achieve pregnancy.[75] Follow-up of women 11.5 years after initial evaluation for BN revealed that 74.6% had been able to achieve pregnancy and only 1.7% reported an inability to conceive.

The etiology of eating disorders has contributions from multiple domains: the societal ideal of thinness and encouragement of women to define themselves by the way others perceive them; families that demand conformity and high achievement; genetic susceptibility (50% to 80% of the variance in liability to AN and BN is accounted for by genetic factors); personality traits that include low self-esteem, impulsivity, obsessionality, perfectionism, and affective dysregulation; and life events, such as chronic disease (e.g., diabetes mellitus). Dysregulation of neurotransmitters, neuropeptides, and endocrine factors also likely contribute to etiology. Dieting frequently triggers the onset of eating disorder in vulnerable individuals.

Women with eating disorders rarely voluntarily disclose their maladaptive eating behaviors, but they may present to their obstetrician-gynecologist with complaints of irregular menses or secondary amenorrhea, infertility, sexual dysfunction, unexplained vomiting, fatigue, or palpitations. However, fewer than half of obstetrician-gynecologists screen patients for eating disorders. The obstetrician-gynecologist or primary care clinician can screen for eating disorders with questions about restricted eating, binge eating, purging behavior, and compulsive exercise. Medical examination should include weight, loss of dental enamel, and abrasions on the hands from self-induced vomiting. Laboratory investigations may disclose abnormalities of electrolytes, blood urea nitrogen, creatinine, amylase, and thyroid indices. There are many medical consequences of AN and BN, and the medical complications of AN may be life threatening (see box, Physical and Laboratory Findings in Women with Eating Disorders).[76] Arrhythmias are common in AN and are typically reversible with improvement in nutritional status. Irreversible cardiomyopathy may occur due to chronic ipecac (emetine) abuse.[76] Osteopenia and osteoporosis of the lumbar spine occurs in women with active AN (54%) compared with recovered women (21%); in contrast, patients with BN typically have bone mineral densities within the normal range.[77] Weight restoration and nutritional replenishment are the ideal treatments for osteopenia and to prevent osteoporosis, whereas estrogen replacement and other medications demonstrate minimal benefit.[78]

Physical and Laboratory Findings in Women with Eating Disorders

Common in Women with Eating Disorders

Bradycardia
Hypotension and orthostasis
Hypothermia
Cardiac murmur (mitral valve prolapse)
Dry skin

More Common in Anorexia Nervosa Due to Severe Calorie Restriction

Emaciated, may wear oversized clothes
Sunken cheeks, sallow skin
Lanugo (fine downy body hair)
Atrophic breasts/atrophic vaginitis
Pitting edema of extremities
Dull, thinning scalp hair
Cold extremities, acrocyanosis
Fluid retention after laxative or diuretic withdrawal
Laboratory: Anemia, ↑BUN, ↑cholesterol, ↑liver function studies, ↑amylase; ↓platelets, ↓magnesium, ↓zinc, ↓phosphates, ↓thyroid. With laxative abuse: metabolic acidosis

More Common in Women Who Purge

Parotitis
Calluses on dorsal hand surface from self-induced emesis
Oral mucosal abrasions
Dental enamel erosion, tooth chipping, extensive cosmetic dental work
Cardiac and skeletal myopathies from ipecac abuse
Laboratory: metabolic alkalosis; ↓sodium, ↓chloride, ↓potassium, ↑bicarbonate from purging

Data from American Psychiatric Association: American Psychiatric Association: Diagnostic and Statistical Manual for Psychiatric Disorders, ed 4, Text Revision. Washington, DC, American Psychiatric Association, 2000; Mitchell-Gieleghem A, Mittelstaedt ME, and Bulik CM: Eating disorders and childbearing: concealment and consequences. Birth 29:182, 2002; Rome ES, et al: Children and adolescents with eating disorders: the state of the art. Pediatrics 111:e98, 2003.

Natural History Across Childbearing

Pregnancy can be a stimulus that moves a woman through the continuum from sub-threshold symptoms to frank eating disorder. Changing body shape and loss of control of weight gain may reactivate deviant eating patterns and concerns about body shape in women with a history of an eating disorder. Persistence of active eating disorder symptoms and the development of binge eating during pregnancy have been reported. However, several studies have suggested that many pregnant women with BN have a decrease in binge eating and purging. Some women with active eating disorders "allow" themselves to eat nutritiously and do not purge, with motivation derived from promoting the health of the growing baby. The optimal treatment of pregnant women with a prior or active eating disorder includes a multidisciplinary team of the obstetrician-gynecologist and/or primary care clinician, a nutritionist, and a mental health clinician. Frequent prenatal visits, regular weighing, and enhanced support are necessary to encourage recommended weight gain and nutrition to ensure fetal well-being. Women with past or current eating disorders have been reported to have a significantly higher risk of hyperemesis during pregnancy compared to controls, and women with hyperemesis gravidarum should be screened for BN.

Adverse birth outcomes in women with eating disorders include higher rates of miscarriage, low birthweight, PTB, congenital malformations, and cesarean sections. Sollid and colleagues[79] performed a follow-up study of 302 women who were hospitalized with an eating disorder before pregnancy and their 504 children. Outcomes were compared with 900 control subjects and their 1552 children. The risk of a low-birthweight infant was twice as high in women with a history of eating disorder. Weight-controlling behaviors (strict dieting, vomiting, and excessive physical exercise) that lead to undernutrition may contribute to impaired fetal growth. The undernutrition may also impact fetal brain development and fetal stress responses.

Maternal dieting behaviors are associated with an increased risk of neural tube defects (NTD).[80] In an analysis of 538 cases of NTD and 539 controls between 1989 and 1991, dieting to lose weight (OR 2.1, 95% CI, 1.1 to 4.1) and fasting diets (OR 5.8, 95% CI, 1.7 to 20.0) were associated with increased risk for NTD, presumably secondary to altered folate intake and absorption.

Mothers with a history of eating disorders are at equal or greater risk of developing postpartum MDE than women with a history of MDE. The risk of perinatal depression is three times higher in women with a history of BN or binge-eating disorder compared to women without an eating disorder.[81] Increased stress with a new infant, feelings of lack of control, and desire to lose pregnancy weight may precipitate recurrence of AN or BN even if the symptoms were in good control during pregnancy. The postpartum period is another critical time for a woman with an eating disorder to receive enhanced support and treatment from a multidisciplinary team.

Treatment of Eating Disorders

Treatment needs to address both the eating disorder symptoms and the underlying issues. Central to all eating disorders is that self-evaluation is unduly influenced by body shape and weight.[1] Specific treatment goals for patients with eating disorders include the following: (1) Address dysfunctional attitudes about self, weight and shape, and relationships with others. Alternatives to the patient's perfectionism, low self-esteem, pursuit of thinness, mood lability and poor coping skills must be developed through psychotherapy and experience to promote recovery. (2) Establish healthy eating behaviors. (3) Weight and nutritional stabilization are essential for recovery. Normalization of nutritional status improves physical and mental well-being. (4) Treat comorbid conditions such as depression and anxiety. Treatments targeted to these disorders may improve adherence to healthy behaviors. A nonconfrontational educational approach is used to engage the woman with an eating disorder.

Treatment of Anorexia Nervosa

Women with AN may require hospitalization because of emaciation, severe electrolyte disturbances, severe depression, suicidality, or failure of outpatient treatment. A structured behavioral inpatient program involves a multidisciplinary treatment that includes individual and group psychotherapy, meal planning and supervision, nutritionist consultation, psychiatric consultation, and medical monitoring. Caloric intake that increases too rapidly may lead to the re-feeding syndrome, a potentially serious condition characterized by electrolyte and mineral abnormalities and shifts in fluids. Length of inpatient hospitalization and weight achieved at discharge may be favorable prognostic predictors, yet 50% of weight-restored women with AN have a relapse in the first posthospitalization year.[82]

Psychotherapies that have been studied for anorexia nervosa include cognitive behavioral therapy (CBT), interpersonal psychotherapy (IPT), insight-oriented psychotherapy, supportive psychotherapy, and family therapy. Current research is evaluating the role of "enhanced" CBT in underweight women with AN, which involves the treatment of core eating disorder psychopathology in addition to eating disorder symptoms.[83] Following successful weight restoration, CBT may have a role in relapse prevention.[84]

No medications are approved by the FDA for the treatment of AN nor recommended by treatment guidelines. Although few randomized clinical trials are available to guide treatment, pharmacotherapy in AN is usually instituted to treat depression, obsessive perfectionism, and cognitive disturbances; to target potential neurotransmitter disturbances; or to treat psychiatric or medical comorbidities. The core symptoms of AN are relatively refractory to psychotropic agents. Older antipsychotics (haloperidol, chlorpromazine, amisulpride), TCAs (amitriptyline), SSRIs (fluoxetine, citalopram), and hormones have been studied. Recent studies have evaluated newer atypical antipsychotic medications such as olanzapine (OLZ), which may decrease anxiety with eating and increase weight.[85] Although initial studies were promising, there are concerns about the use of OLZ and other atypical antipsychotics during pregnancy, including weight gain, risk of metabolic syndrome, and insufficient data to inform use in pregnancy and lactation.

Relapse prevention is the most challenging clinical problem in the treatment of AN. Although initial reports

suggested that fluoxetine might be helpful after weight restoration, a controlled study reported that fluoxetine was not superior to placebo in weight-restored women also receiving CBT.[86] As mentioned earlier, CBT may help prevent a relapse in weight-restored women.

Treatment of Bulimia Nervosa

CBT is considered the first-line therapy for BN.[87] In CBT, the therapist identifies the stimuli to thought processes and emotions that maintain the binge-purge-starve cycle. The woman develops strategies to manage the disturbed eating, change the dysfunctional cognitions, and build alternative ways to manage distress. CBT is a time-limited individual or group psychotherapy. "Enhanced" CBT that also targets core psychopathology may be superior for marked mood intolerance, clinical perfectionism, low self-esteem, and interpersonal difficulties.[83] In locations where a CBT therapist is not available, self-help manuals and web-based programs utilizing the principles of CBT have wide appeal. *Overcoming Binge Eating*[88] is readable and provides a clear discussion of the implementation of self-help strategies. CBT appears to have both short- and long-term efficacy for BN.[87,88]

IPT has been less studied than CBT; it appears to have comparable recovery rates but may take longer to be effective. IPT involves evaluation of patient's significant life events, relationship between psychological symptoms and interpersonal processes, and the identification of areas of interpersonal difficulty such as role transitions, role disputes, grief, and interpersonal deficits. In IPT for eating disorders, the relationship between eating disorder symptoms and negative social evaluation and low self-esteem are explored.

Placebo-controlled studies with antidepressant medications have been far more promising for the acute treatment of BN than AN.[87] The first-line medication most commonly used is an SSRI, usually fluoxetine, which is FDA approved for BN at a dose of 60 mg/day. Efficacy has also been reported with TCA and monoamine oxidase inhibitors. Bupropion is contraindicated due to reduced seizure threshold in patients with eating disorders. Antidepressants reduce both binge eating and purging frequency, and the symptom relief is independent of comorbid depression. Many studies of antidepressants also demonstrate reduction of core eating disorder psychopathology such as weight and food preoccupation.[87] Although antidepressants may be as effective as CBT in the short-term, their long-term efficacy is less promising. Symptomatic improvement and sustained remission may be enhanced with combined CBT and antidepressant medication.[89] In general, a combination of CBT and an antidepressant drug is a prudent clinical strategy.

Other medications that hold promise for reducing binge eating and purging frequency include ondansetron and AED. Ondansetron is a 5-HT_3 antagonist that reduced symptoms compared to placebo, possibly due to regulation of vagal activity.[90] Topiramate has been reported to reduce the number of binge-purge days and improve self-esteem, eating attitudes, anxiety, and body image in short-term RCTs.[91] The dose may be limited by side effects (memory impairment, paresthesias, fatigue).[91] Medications reported to be helpful for reducing binge eating frequency in binge-eating disorder, such as lamotrigine, zonisamide, and sibutramine, may have a role in the treatment of BN and deserve further study, but there are limited data on reproductive side effects.[91]

SCHIZOPHRENIA

Diagnosis and Prevalence

Schizophrenia is a disabling disease that affects 1% of the population. The defining feature of schizophrenia is psychosis, which does not refer to the *severity* of the episode but to specific symptoms. Schizophrenia is characterized by the presence (for at least 6 months) of symptoms from three clusters[1]: (1) positive symptoms (delusions or fixed false beliefs; hallucinations or distortions of reality), (2) negative symptoms (decrease or loss of normal functions: lack of pleasure, social withdrawal, minimal speech production), and (3) cognitive impairment (inattention, poor working memory, and executive function deficits). The etiology of schizophrenia is unknown, but proposed mechanisms are: (1) excessive dopamine transmission, (2) in utero exposure to influenza or other viral agents, which results in neurobiologic disruptions, and (3) altered neuroplasticity or neurodevelopmental trajectories. Schizophrenia is distinguished from mood disorders, which may also present with psychosis, by the persistence of hallucinations or delusions even when mood symptoms have remitted. The mortality and morbidity of schizophrenia is high, and 10% of patients complete suicide.

Women are more likely to have a later onset, prominent mood symptoms, and a better prognosis than men. The median age of onset is in the late 20s for women. Women have lower symptom severity, fewer hospitalizations, a higher likelihood to return to work and more social support than males.[92] About 67% of women compared with 29% of men with schizophrenia are married, and women are twice as likely to have children.[92]

Natural History of Schizophrenia Across Childbearing

Women with schizophrenia have lower fertility rates compared with healthy women despite less frequent use of contraception and higher rates of irreversible causes of infertility (hysterectomy, menopause, sterilization).[93] Pregnant women are less likely to obtain prenatal care and have an increased risk for interventions during labor and delivery than unaffected women. They have a high frequency of recurrence of psychosis (27%) or depression (38%) in the first postpartum year.[94]

Children born to women with schizophrenia are susceptible to subtle problems in neurodevelopment but the origins (genetic, environment, psychosocial) are complex. Data on the mothers' nutritional status, exposures to psychotropic medications, other prescription or over-the-counter drugs that impact reproductive outcomes, violence, and comorbid medical disease are usually lacking.[42] Concurrent maternal smoking, substance use, and socioeconomic problems increase the risk for less optimal outcomes.

The data on relapse risk for schizophrenia in the general population must be extrapolated to pregnant patients because no specific data exist. A meta-analysis of 66 studies and more than 4000 patients indicated that individuals

with chronic schizophrenia who stop treatment have a cumulative relapse rate of 53%, compared with 16% among patients who remain on antipsychotic therapy over a 10-month period.[95] The highest rate of relapse occurred within the first 3 months of treatment discontinuation. Sudden cessation of antipsychotic medication, younger age, early age of illness onset, need for high doses of antipsychotic therapy, and recent psychiatric admission predicted recurrence. Patients with severe and persistent symptoms of schizophrenia, frequent relapses, dangerous behavior, poor self-care, and hospitalization often reasonably choose to remain on antipsychotic treatment throughout pregnancy. Very few women with schizophrenia achieve a sustained symptom-free period and good function without antipsychotic medications before pregnancy. If a woman elects to remain monitored without medication, a plan should be developed for reinstituting medication rapidly if prodromal symptoms occur. The antipsychotic agent that achieved the greatest symptom reduction and the least side effects for the individual patient balanced against its side effects is the preferred drug.

In a population-based cohort of more than 3000 children born from 1980 to 1992, Jablensky and colleagues[42] reported that women with schizophrenia had more than twice the risk for placental abruption compared to healthy controls (OR 2.75, 95% CI, 1.32 to 5.74). Rates of antepartum hemorrhage were significantly higher in mothers with schizophrenia (OR 1.65, 95% CI, 1.02 to 2.69) compared to women without psychiatric illness.

Treatment Interventions for Women with Schizophrenia

Mothers with schizophrenia often struggle with poverty, poor housing, social isolation, and difficulty obtaining basic services for their offspring. Comprehensive clinical services that offer case-integrated obstetrical and psychiatric management, consultation, pharmacotherapy, parent education groups, and family programs are optimal for promoting positive outcomes. Optimal maternal and infant outcomes are achieved through individualized treatment planning by a mental health team in collaboration with community programs. The antipsychotic agent associated with the greatest symptom reduction, balanced against its side effects, is the preferred drug for the individual pregnant woman. An additional consideration in risk/benefit discussions is whether that preferred drug could be replaced by one with a more favorable reproductive risk profile *without* compromising efficacy and tolerability, but no antipsychotic has emerged as definitively more efficacious or having less adverse reproductive effects than any other. Several factors affect the choice of a medication change, including patient and physician concern about the lack of data for the preferred drug, particularly for newer agents, and prior treatment experience with a drug that has less impact on a medical condition that existed before or developing during pregnancy. A factor in every risk benefit decision is the fact that pregnancy outcome data for drug exposure is inextricably tied to outcomes related to the underlying illness for which the drug is being prescribed.

In a double-blind controlled trial of 1500 nonpregnant patients with schizophrenia sponsored by the National Institute of Mental Health (NIMH), subjects were randomized to one of four atypical antipsychotics (OLZ, quetiapine, risperidone, ziprasidone) or an older typical antipsychotic (perphenazine) and followed for 18 months (Clinical Antipsychotic Trials of Intervention Effectiveness trial).[96] Few differences in outcome were observed among groups treated with the various medications. The typical antipsychotic perphenazine was as well tolerated as the newer compounds and as effective as three of the four newer agents. OLZ was slightly better than all the others in terms of lower drug discontinuation and hospitalization rates, but it was associated with higher rates of weight gain and metabolic side effects. Although this NIMH study excluded pregnant women, the results have implications for their treatment. Significantly more data about use during pregnancy are available for the older typical antipsychotics, and exposure for the period limited to pregnancy can be favorable in the risk/benefit analysis for some women, particularly women with insulin resistance, hypertension, and obesity. For the atypical antipsychotics, blood pressure, heart rate, and appropriate weight gain should be monitored. **Control of the disorder (which usually requires medication continuation) is paramount for maternal and fetal health.**

Antipsychotic Drugs During Pregnancy

Data on the use of atypical antipsychotics during gestation largely originate from case studies (which cannot establish etiological association), case series (which do not produce risk estimates), and rare controlled, prospective designs without long-term outcomes. However, data on the effects of these drugs during pregnancy are emerging as their duration of time on the market increases. Clozapine was the first atypical agent to be released; burdensome side effects (weight gain, lowered seizure threshold, tachycardia, dyslipidemia, sedation, drooling) and mandatory periodic monitoring for agranulocytosis create significant barriers to use. Clozapine is reserved for patients whose illness is nonresponsive to treatment with less toxic drugs. Clozapine use in pregnancy has been associated with normal deliveries as well as gestational diabetes, shoulder dystocia, hypotonia, and neonatal convulsions.[97]

The most reproductive data is available for OLZ. Goldstein and colleagues[98] prospectively identified 37 pregnancies with OLZ exposure at doses of 5 to 25 mg daily. One woman experienced an ectopic pregnancy, and 13 women underwent elective abortions unrelated to fetal anomalies. Of the remaining 23 pregnancies, 3 resulted in miscarriage. No major malformations were associated with the remaining 20 pregnancies, but 4 had adverse outcomes that included stillbirth, gestational diabetes, premature birth, and postdates birth.

Risperidone is an atypical agent with diverse receptor-blocking activities. At doses above 6 mg daily, hyperprolactinemia and motor side effects may emerge. A postmarketing survey provided 68 prospective and 197 retrospective reports of outcomes following treatment during pregnancy.[99] In the prospective group, tricuspid atresia occurred in one infant and multiple deformities in two infants; however, all infants were exposed to other drugs. From the retrospective group, 12 infants had malformations; 9 were exposed to multiple agents in the first trimester.

Quetiapine is an atypical antipsychotic with a wide dose range that allows for easy titration. Side effects include sedation, weight gain, and headache. The few published cases of in utero exposure to quetiapine resulted in normal intrauterine growth, full-term deliveries, and favorable Apgar scores.Yaeger and colleagues presented a sophisticated case discussion of quetiapine treatment of a pregnant woman[100] that provides an interesting clinical review.

Ziprasidone is a suitable choice for managing psychosis, with its neutral effects on weight and lipid and glucose metabolism[101]; however, its use may be associated with prolonged QTc syndrome. Limited information on perinatal exposures with ziprasidone is available. Among 57 in utero exposed cases with known outcomes, one malformation was observed.[102]

Aripiprazole has novel dopamine antagonist and partial agonist activity. It is indicated for schizophrenia, bipolar mania, mixed episodes, and severe MDE (combined with an antidepressant). One mother who received aripiprazole during the latter half of pregnancy required surgical delivery for fetal tachycardia.[103] Breastfeeding could not be established, which could be related to the partial dopamine-2 receptor agonist effect of this agent. At 6 months, the infant had normal developmental milestones.

Asenapine is a new atypical antipsychotic drug for the treatment of patients with acute schizophrenia and acute manic or mixed episodes of BD type I. Asenapine is contraindicated for patients with hepatic impairment. Common side effects include somnolence, extrapyramidal effects, akathisia, weight gain, dizziness, headache, and oral hypoesthesia after 6 weeks of treatment. As with newly released drugs, meaningful pregnancy exposure data is lacking.

Antipsychotic Drugs During Breastfeeding

Breast milk has a high concentration of clozapine attributed to its lipophilicity, and breastfed infants have developed sedation, agranulocytosis, and cardiovascular effects.[104] The excretion of OLZ, a highly protein-bound agent, in breast milk has been assessed in small case series. The median estimated dose in infants was 1.6% to 4.0% of the maternal dose.[105] Three breastfed infants of mothers who were treated with risperidone had undetectable serum drug metabolite levels and no adverse reactions.[106] A mother who was treated with risperidone (6 mg/day) provided serial samples of plasma and breast milk every 4 hours over a 24-hour period. The infant drug intake was estimated to be 0.84% of the maternal dose for risperidone, 3.5% for its metabolite, and 4.3% of the weight-adjusted maternal dose.[107] Six breastfeeding women who received treatment with quetiapine[108] provided breast milk; the total daily infant exposure was less than 0.01 mg/kg for five infants and less than 0.10 mg/kg for one infant. The only report on ziprasidone in human milk was obtained from a mother who began treatment 9 days after delivery; the investigators collected milk and maternal plasma samples daily from 9 to 25 days postpartum.[109] Breast milk drug levels were detectable only after 10 days of treatment; the milk (11 ng/mL) to plasma (170 ng/mL) ratio was 0.06; the estimated relative dose received by the infant was 1.2%. A woman who was treated with aripiprazole throughout pregnancy breastfed her full-term infant; at 27 days, no detectable levels of aripiprazole and its metabolite were found in milk samples.[110]

SUBSTANCE-RELATED DISORDERS

Diagnosis and Prevalence

Substance-related disorders among pregnant women comprise a public health problem associated with major individual and societal costs, yet women who abuse substances rarely are identified by health care professionals. The most objective picture of pregnant women who use drugs was derived from blinded urine toxicology screens conducted at representative hospitals nationally.[111] **The study revealed that the common perception of substance abuse as an affliction of poor, minority, and young women was erroneous. Similar rates of substance use during pregnancy occurred in women of different ages, races, and social classes.** The specific substances used differed by race and social class, with African American and poor women more likely to use illicit substances, particularly cocaine, and white and educated women more likely to use alcohol, although polysubstance use was common.

The National Pregnancy and Health Survey was the first national survey of drug use among pregnant women in the United States. A representative sample of the 4 million women who delivered during 1992 was obtained. Illicit drugs (marijuana, cocaine, methamphetamine, heroin, methadone, inhalants, hallucinogens, or nonmedical use of psychotropics during pregnancy) were used by 5.5% of pregnant women.[112] In a national survey done in 2002 to 2003 of pregnant women aged 15 to 44 years, 9.8% reported drinking alcohol during the past month, 4.1% reported binge alcohol use, and less than 1% reported heavy alcohol use.[113] In the year after pregnancy, women increased their substance use, although not to the level of nonpregnant women who were not recent mothers[113] (Figure 52-5).

Obstetricians are in a unique position to identify women with substance use disorders and to encourage treatment.

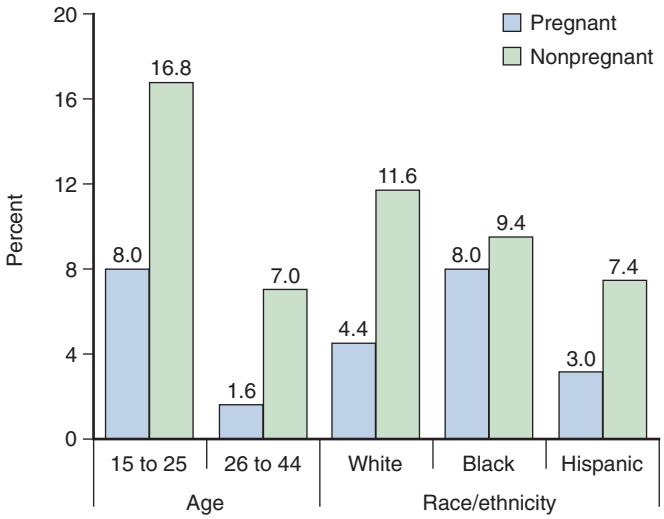

FIGURE 52-5. Drug and alcohol use during pregnancy. (From National Survey on Drug Abuse and Health: Substance Use During Pregnancy: 2002 and 2003 Update, http://oas.samhsa.gov/2k5/pregnancy/pregnancy.htm.)

Pregnancy is a strong motivator for change because most women want to protect their baby; however, women do not volunteer information about substance abuse unless asked. They fear stigma, being judged, or legal and custody concerns. For example, they worry that they will be reported to a child welfare agency or that their employer will learn about their drug use. Universal screening improves detection and has the potential to improve pregnancy and infant outcomes.

In the DSM-IV,[1] psychoactive substance use disorders are classified into two categories, abuse and dependence. The diagnosis of abuse is established if at least one of the following criteria is fulfilled in the past 12 months: (1) recurrent use resulted in failure to fulfill major role obligation at work, home, or school; (2) recurrent use in physically hazardous situations; (3) legal problems result from use; and (4) continued use despite persistent or recurrent social or interpersonal problems caused or exacerbated by substance use. Substance abuse is distinguished from dependence. At least three of the following criteria must be met in the past 12 months for substance dependence: (1) tolerance (marked increase in amount; marked decrease in effect); (2) characteristic withdrawal symptoms and substance is taken to relieve withdrawal; (3) substance is taken in larger amount and for longer period than intended; (4) persistent desire or repeated unsuccessful attempt to quit; (5) significant time and activity are spent to obtain, use, and recover from use; (6) given up or reduced important social, occupational, or recreational activities; and (7) use continues despite knowledge of adverse consequences. Although physiologic tolerance and withdrawal are not essential diagnostic criteria for dependence, they often occur. Abuse is often a precursor to dependence, or a category for those who do not fulfill the criteria for dependence but use substances in maladaptive ways that are harmful to themselves or others.

Comorbidity, or co-occurrence, of substance use with psychiatric illness is the rule rather than the exception. The neurobiologic sequelae of chronic stress may affect brain reward and other pathways to predispose or unmask vulnerability to psychiatric disorders, substance use disorders, or both. In a general population of women who were seeking treatment for cocaine and alcohol abuse, the co-occurring psychiatric disorders were: any mood or anxiety disorder, 70%; posttraumatic stress disorder, 46%; major depression, 40%; panic disorder, 18%; social phobia, 10%; and BD, 4%. For women, the co-occurring condition usually precedes the onset of substance use. One third to one half of substance-abusing women experienced sexual abuse during childhood,[111] and they are frequently involved with drug-using partners. Interpersonal violence is common in the lives of substance-abusing women.[111] Obstetricians provide potentially life-saving interventions for these women by monitoring for domestic violence, offering emergency resources to mothers, identifying children at risk, and reporting to child protective services as mandated by state law.

Obtaining a Substance Use History

Substance use information can be obtained by interview or with a screening tool. The overall approach and emotional tone of the clinician is more important than the specific wording or content. Women are more likely to divulge substance use when asked in a nonjudgmental manner by an empathetic interviewer and within the context of general health questions. Similar to obtaining a sexual history, the questions should be sequenced from least to most personal for the patient. In addition, questions should be open-ended.

Physicians and other health care providers, like all people, have developed personal beliefs and biases over their lifetime that can influence their approach to the issue of substance use. It is challenging but important for physicians to recognize and confront their personal biases in order to keep them from interfering with the care they provide. Helping women with substance use disorders challenges physicians to go beyond the traditional medical care paradigm to an expanded model of psychosocial care, which includes social services and establishing collaboration with addictions and psychiatric professionals (see section on Personality Disorders for other management strategies).

A general screening measure for substances in pregnancy is the *4 P's Plus* (Table 52-2), which was designed to identify obstetrical patients who need in-depth assessment. The *4 P's Plus* has been validated in multiple obstetric populations. This five-question screen is administered during a prenatal visit and takes less than 1 minute to complete.[114] The first *P* is for *Parents*, and the query is about family use of substances. A positive response does not predict the woman's substance use but allows the physician to introduce the issue in a nonthreatening manner. The second question, about the *Partner*, pertains to the partner's substance use. The partner's use does not predict the woman's substance use in pregnancy, but it is correlated with risk for domestic violence, a common psychosocial problem in women with substance use. The third *P*, for the woman's *Past* use of alcohol, places her at risk for use during pregnancy and can be coupled with prevention education as part of prenatal care. The fourth *P*, for *Pregnancy*, contains an open-ended question about cigarette use in the month before pregnancy. The fifth *P* is the amount of wine/beer/liquor consumed in the month before pregnancy. The authors observed that substance use *during* pregnancy was not as effective a screen as asking about a woman's use of substances *before* pregnancy. Women often use substances at prepregnancy levels until the pregnancy is confirmed after early first-trimester exposure has occurred. They often decrease, or report less use, of drugs during gestation. In administering the

TABLE 52-2 SCREENING WITH THE 4 P'S PLUS

- Parents Did either of your parents ever have a problem with alcohol or drugs?
- Partner Does your partner have a problem with alcohol or drugs?
- Past Have you ever had any beer or wine or liquor?
- Pregnancy
  - In the month before you knew you were pregnant, how many *cigarettes* did you smoke?
  - In the month before you knew you were pregnant, how much *beer/wine/liquor* did you drink?

Copyright NTI, 1998. Chasnoff IJ, Hung WC: The 4P's Plus. Chicago, NTI Publishing, 1999.

4Ps Plus, it is preferable to use the terms beer and wine (and liquor) because some women do not recognize beer to be alcohol.

Laboratory screening is another approach to substance use detection but it must be negotiated with the pregnant woman. In general, laboratory measures detect current exposure but do not reflect the historic pattern of use. Because pregnant women with substance use disorders are at increased risk for a variety of infections and medical conditions, a comprehensive medical history, examination, and laboratory studies are indicated. The studies should include a complete blood count, syphilis and hepatitis B and C serology, tuberculosis test, assessment of common sexually transmitted diseases, and confidential human immunodeficiency virus screening.

Specific Drugs of Abuse: Impact and Treatment Approaches

The impact of maternal substance use on pregnancy and infant outcomes is influenced by a variety of factors, such as the specific exposures, gestational timing, duration of exposure, and nutritional status. Disentangling the effects of substance use, co-occurring mental disorders, and the biopsychosocial milieu on pregnancy and infant outcomes is a challenging task (see Figure 52-1).[2] The following sections provide an overview of specific classes of drugs and their use during pregnancy.

Alcohol and Sedative Hypnotics

Most women who drink before becoming pregnant either reduce their intake or stop drinking during pregnancy. However, findings from the 2008-2009 National Survey on Drug Use and Health indicated that a minority of women continue alcohol use during pregnancy. Among pregnant women ages 15 to 44 years, 10% reported current alcohol use, 4.4% reported binge drinking in the past 30 days (5 or more drinks at least once in the past 30 days), and 0.8% reported heavy drinking.[115]

During pregnancy, the dose of alcohol at which no negative offspring outcomes occur has not been defined. Women who consumed more than three drinks per week had a significantly increased risk for miscarriage.[116] Women who consumed five or more drinks per week increased their risk for intrauterine fetal death by two to three times compared with nondrinkers.[117] Consumption of one or more drinks per day was associated with reduced birth weight and IUGR.[118]

Prenatal exposure to alcohol is probably the most common preventable cause of mental retardation in the United States. Children exposed to binge drinking are 1.7 times more likely to have mental retardation and 2.5 times more likely to demonstrate delinquent behavior than unexposed children.[119] Young adult offspring of binge drinkers also have increased odds of developing somatoform disorders, alcohol/drug abuse or dependence, and paranoid, antisocial, and passive aggressive personality disorder.[120] Neonatal effects of alcohol exposure can be subtle, such as slower habituation (attenuation of response to repetitive stimuli) and longer reaction times.[120] Moderate prenatal alcohol exposure is associated with learning problems, memory deficits, and mood disorders in school-aged children.[121]

Fetal alcohol spectrum disorders encompass the array of physical, cognitive, and behavioral deficits found in children born to mothers who consume alcohol during pregnancy. The incidence of fetal alcohol syndrome, the most severe manifestation of exposure, is approximately 1 in 100 births. The characteristic facial dysmorphology is midfacial hypoplasia, flat philtrum, low nasal bridge, epicanthal folds, shortened palpebral fissure, low-set ears, and microcephaly. Affected children may have visual, skeletal, and cardiac anomalies.

Detecting alcohol use among pregnant women is an important step toward preventing alcohol-related birth defects. Several short screening tools to detect pregnancy risk drinking are available. In a critical review, Chang[122] identified the T-ACE[123] (see Chapter 6) as a valuable and efficient tool for identifying alcohol use specifically in pregnant women. This brief tool was developed for detection of risk drinking (defined as 1 ounce or more of absolute alcohol per day). The four questions of the T-ACE reliably differentiated risk from nonrisk drinkers. The T-ACE questions take about 1 minute to ask. A positive screen indicates the need for education about the risks of alcohol use during pregnancy. Such brief interventions promote harm reduction, facilitate antenatal visit compliance, promote healthier choices during pregnancy, and support patients in making lifestyle changes. Screening is also useful to identify women who require referral to substance use treatment programs for alcohol intoxication and withdrawal during pregnancy.

Pregnant women requiring withdrawal from alcohol should be admitted for acute inpatient management. Clinical manifestations occur 6 to 24 hours after the last drink with early withdrawal signs including anxiety, sleep disturbance, vivid dreams, anorexia, nausea, and headache. Physical signs include tachycardia, elevation of blood pressure, hyperactive reflexes, diaphoresis, hyperthermia, and tremor in extended hands or tongue. Alcohol withdrawal seizures (generalized major motor seizures) peak 24 hours after the last drink and are preceded by hyperactive reflexes at biceps and knees. Alcohol withdrawal can progress within 72 to 96 hours to delirium tremens (DTs), characterized by extreme agitation, hallucinations, and autonomic hyperactivity that can be fatal to mother and infant. Benzodiazepines are effective for alcohol withdrawal symptoms and prevention of seizures. Treatment schedules may be "fixed dose" or "symptom based" using an alcohol withdrawal severity scale. The Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar) is a withdrawal severity scale, not copyright protected, available free online, and designed to be administered within 2 to 5 minutes. Symptom-guided withdrawal results in more rapid detoxification and lower total doses of benzodiazepine treatment but requires trained staff to implement. Chlordiazepoxide, diazepam, lorazepam, and oxazepam are common detoxification agents. These benzodiazepines have differing onset and duration of action, and are available in intravenous formulation. A typical fixed dose taper starts with chlordiazepoxide, 50 mg every 6 hours, or lorazepam, 2 mg every 6 hours, adjusting the dosing until symptoms are controlled. The dose is then tapered by 10% to 25% per day as tolerated. Acute management also requires thiamine replacement and

maintaining adequate hydration and electrolyte balance. A patient can be safely discharged to outpatient treatment when benzodiazepine treatment is no longer required to control symptoms for more than 24 hours.

Although, there are four FDA-approved medications for the treatment of alcohol dependence, there is little clinical data and experience with their use during pregnancy. Naltrexone is available in both oral and depot forms as an opioid antagonist that decreases the reinforcing effects of alcohol to prevent relapse to heavy drinking. Naltrexone's opioid antagonist activity blocks opioid analgesia with parturition and complicates pain control postoperatively. Naltrexone is not appropriate for use in patients on chronic opiate therapy. Acamprosate is a GABA receptor agonist and NMDA receptor modulator with more limited data showing modest improvement in maintaining abstinence and reducing drinking. These medications have modest efficacy and unknown reproductive risks, which must be weighed against the significant risk of continued alcohol consumption. Disulfram is an aversive medication to reduce alcohol intake. It has modest efficacy but potentiates the teratogenic effects of alcohol; therefore, it is contraindicated during pregnancy.

Long-term use of sedative-hypnotics, such as benzodiazepines, can result in dependence and addiction. **Withdrawal from benzodiazepines is similar to that with alcohol, with significant morbidity and potential mortality if untreated.** Women treated with benzodiazepine drugs that have a short half-life, such as alprazolam, will develop withdrawal symptoms upon discontinuation more rapidly than agents with longer half-lives. Clinically significant withdrawal symptoms occur with adherence to recommended dosing after 4 to 6 months of use and within 6 to 12 weeks for dosing above the recommended upper limits. Acute inpatient withdrawal is often accomplished by a fixed-dose drug taper with substitution of a long-acting benzodiazepine with provision of doses as needed to treat breakthrough symptoms. Once the patient has achieved a comfortable level of symptom control, the dose is tapered by 10% daily as tolerated. Close monitoring is needed for the patient tapering from benzodiazepines while on opioid medications because the risk of respiratory depression is additive. There is increasing evidence that adjunctive use of carbamazepine or valproate can be used in conjunction with a shorter inpatient benzodiazpine taper and be continued for up to 1 month to treat protracted sedative hypnotic withdrawal. However, polypharmacy in pregnant women, and particularly exposure to valproate, should be avoided.

Smoking

Women are more likely to attempt to stop smoking during pregnancy than at any other point in their lives, but only one third stop successfully and many relapse after birth. An office-based intervention for pregnant smokers called the 5 A's (*Ask* about tobacco use, *Advise* to quit, *Assess* willingness to make a quit attempt, *Assist* in quit attempt, and *Arrange* follow-up) was endorsed by the ACOG. The approach involves providing patients with a brief counseling session and pregnancy-specific self-help materials, and increases quit rates among pregnant smokers by a factor of 2 to 3. Web-based tools are also available for education and support for smoking cessation (www.cdc.gov/tobacco/how2quit.htm).

Carbon monoxide and nicotine from inhaled tobacco smoke interfere with oxygen supply to the fetus. Smoking is associated with increased risk for miscarriage, intrauterine and perinatal fetal death, PTB, and IUGR. Paradoxically, smoking appears to reduce the risk of preeclampsia, probably by inhibition of thromboxane A2 production or suppression of the immune system.[124] Newborns with in utero exposure to maternal smoking experienced poorer autonomic regulation and decreased auditory responsiveness compared to nonexposed infants.[125] **Infants of smokers have more than three times the risk of sudden infant death syndrome compared with infants of nonsmokers.**[126]

A negative dose-response relationship between maternal smoking and offspring intelligence was demonstrated across all social classes.[127] An analysis of nearly 3000 subjects who participated in an 11-year community cohort study in western Norway was performed to examine the impact of passive smoking exposure on risk of respiratory disease in adulthood.[128] After adjustment for multiple confounders, 17.3% of the adult incidence of asthma was attributable to maternal smoking, whereas 9.3% was due to exposure from other household smokers. Findings from the Maternal Lifestyles Study also found that maternal smoking during pregnancy is associated with sleep problems through age 12.[128]

Behavioral therapy is the first-line choice to support smoking cessation in pregnant women; however, pharmacologic approaches may be necessary, particularly in heavy smokers. Nicotine replacement therapy during pregnancy has been shown to improve smoking cessation in heavy smokers during pregnancy and 1-year postpartum.[129] Nicotine patch use in the second and third trimesters was not associated with maternal or fetal compromise.

The antidepressants bupropion and nortriptyline offer another pharmacologic approach to smoking cessation. Bupropion and nortriptyline double the likelihood of smoking cessation. A large retrospective epidemiologic study examined 1213 infants exposed to bupropion in the first trimester of pregnancy. The prevalence of congenital malformations was not increased in exposed infants.[129] Limited data show that bupropion doses up to 300 mg/day produce low levels in breast milk.[130] In a study of 10 healthy postpartum volunteers taking 150 mg of bupropion for 3 days and then 300 mg for 4 days, the mean infant exposure was 2% of the standard maternal dose, and no adverse effects in the infants were observed. Motivation to breastfeed is an opportunity to support continued cessation or reduction of smoking beyond that achieved during pregnancy. Breastfeeding is not contraindicated in mothers who smoke.[131] The most recent AAP Policy Statement from the Section on Breastfeeding concludes: "Tobacco smoking by mothers is not a contraindication to breastfeeding, but health care professionals should advise all tobacco-using mothers to avoid smoking within the home and to make every effort to wean themselves from tobacco as rapidly as possible."

Cannabis

During pregnancy, the most frequently used illicit drug was cannabis (2.9% of women).[112] Prenatal cannabis use is

not associated with increased rates of major birth defects, stillbirth, or spontaneous abortions.[132] Infants born to women who used cannabis during their pregnancies displayed altered responses to visual stimuli, increased tremulousness, exaggerated startle response, and high-pitched cries, which may indicate neurologic impairment. Deficits in sustained attention, memory, and cognitive function (e.g., problem-solving skills) in both preschool and school-aged children have been demonstrated in marijuana-exposed children.[124]

Continued exposure to cannabis through breastfeeding was associated with decreased motor capability in infants at 1 year of age.[133] The finding persisted after adjusting for the effects of prenatal and lactational exposure to nicotine, alcohol, and cocaine. However, none of the variance in infant mental scores was explained by maternal pre- or postpartum use of cannabis. Nonetheless, the AAP lists cannabis as contraindicated during breastfeeding.[131]

Certainly smoking, whether tobacco or cannabis, carries risks during pregnancy and should be discouraged to promote overall health. Numerous studies have associated regular cannabis use with psychotic symptoms in the cannabis user. Counseling and brief interventions that target lifestyle changes and provide support toward abstinence are primary goals of treatment.

Cocaine

About 1% of women used cocaine at some time during their pregnancy.[112] Cocaine can be snorted, injected, or smoked in the form of crack cocaine. Crack and injected cocaine reach the brain quickly and bring an intense and immediate high.

In a prospective, large, blinded, systematic investigation of prenatally cocaine-exposed children, no increase or consistent pattern of abnormalities was found, although significantly more cocaine-exposed infants were premature and had lower birthweight, length, and head circumference compared with unexposed matched for race, parity, level of pregnancy risk, and socioeconomic status.[134]

The risk of spontaneous abortion, abruptio placentae, premature rupture of membranes, and meconium-stained amniotic fluid are all associated with cocaine use. A pooled odds ratio of 33.92 was shown for abruptio placentae and cocaine use in a meta-analysis.[135]

Frank and colleagues[136] reviewed outcomes in early childhood after prenatal cocaine exposure. After controlling for confounders, there was no consistent association between prenatal cocaine exposure and physical growth, developmental test scores, or receptive or expressive language. Differences in neurophysiologic testing and short-term lag in motor scores were found. However, outcomes thought to be specific effects of in utero cocaine exposure were correlated with other factors, such as prenatal exposure to tobacco and other drugs, as well as the child's environment.

The pregnant woman using cocaine should be referred for psychosocial treatment. There are currently no effective medications for treatment of cocaine addiction. Acute cocaine intoxication and withdrawal can be treated with supportive measures. Women with a history of cocaine use should be counseled not to breastfeed their infants if they use cocaine due to the risk of tremulousness, hypertension, tachycardia, and lethargy.

Methamphetamine

Methamphetamine use has been called the twenty-first century's first drug "epidemic" but there are limited national data regarding prenatal methamphetamine prevalence. Data obtained from admissions to federally funded treatment centers in the United States showed that methamphetamine use accounted for 8% of pregnant women admitted in 1994 and 24% by 2006. The majority of methamphetamine admissions during pregnancy occurred in western states among white unemployed women.[137] As with cocaine dependence, lifestyle risk factors confound interpretation of studies of prenatal exposure to the fetus. Maternal adverse effects of methamphetamine include mood disturbance, psychotic symptoms, cardiovascular problems, hyperthermia, and convulsions. Long-term use is associated with exacerbation of psychiatric symptoms (especially psychotic disorders), cognitive deficits, dependent living, risky sexual behaviors, and criminal justice involvement.

For acute methamphetamine intoxication, judicious use of benzodiazepines and antipsychotic medications can be used to calm the agitated, combative, or psychotic patient. There is no effective treatment other than supportive care for methamphetamine withdrawal. As with cocaine, the AAP[131] lists amphetamines as contraindicated during breastfeeding.

Opioids

During pregnancy, 1% of women report opiate use and as many as 4% test positive for opiates.[138] Because there is no known teratogenic effect of maternal opiates on the fetus, the goals of treating opiate dependence during pregnancy are to minimize maternal and neonatal morbidity**. For women abusing heroin and prescription narcotics, therapy with methadone or buprenorphine decreases opioid and other drug abuse, reduces criminal activity, improves individual functioning, and decreases rates of infections such as hepatitis B and C, human immunodeficiency infection, sexually transmitted diseases, cellulitis, bacterial endocarditis, and tuberculosis.** Opioid replacement therapy is associated with superior relapse prevention, reduced fetal exposure to illicit drug use, improved adherence to obstetrical care, and enhanced neonatal outcomes.

Methadone has been the gold standard of treatment since the 1970s to treat opioid addiction during pregnancy. The methadone doses used to treat pregnant women have increased across time. Higher doses of methadone were not associated with an increased risk of neonatal withdrawal but did have a positive effect on decreasing maternal drug abuse. Methadone has direct effects upon fetal neurobehavioral functions. At peak methadone levels, the fetal heart rate was slower and less variable, and displayed fewer accelerations. Fetuses displayed less motor activity, and the integration between heart rate and motor activity was attenuated.[139] Between 34 and 37 weeks a slower rate of and fewer fetal breathing movements were observed on ultrasound for the methadone-treated group regardless of time since the mothers' daily dose compared to untreated women.[132]

Conversion to methadone during pregnancy has been outlined in the box entitled Initiation of Methadone Maintenance Treatment in Pregnancy. Between 30% and 80%[140] of infants exposed to opioids in utero require treatment for neonatal abstinence syndrome (NAS). NAS is characterized by irritability, tremulousness, sweating, nasal stuffiness, poor suckling, diarrhea, vomiting, and seizures. NAS can occur with any prolonged fetal opiate exposure, but the incidence of NAS is higher with methadone exposure than with shorter-acting opiates. NAS can begin as early as 24 hours and as late as 14 days, depending on the specific opioid. Short-acting opiates have earlier onset of NAS symptoms, whereas long-acting opiates, such as methadone, have later onset of NAS.

Initiation of Methadone Maintenance Treatment in Pregnancy

- Medical and substance abuse history.
- Physical examination to evaluate stigmata of IV opioid use (needle scars, phlebitis, and skin abscesses).
- Laboratory tests: Urine drug testing to document opioid and other drug use. Serum infection screening and baseline liver function if known hepatitis C infection.
- Quantify withdrawal symptoms with a standardized assessment such as Clinical Opioid Withdrawal Scale—COWS[165] (www.csam-asam.org/pdf/misc/COWS_induction_flow_sheet.doc).
- Initial dose of methadone 10-30 mg with additional dosing of 5-10 mg every 4 to 6 hours while patient is awake for breakthrough withdrawal symptoms.
- Titrate dose up to relieve withdrawal symptoms for 24 hours with minimal or no craving.
- Methadone has been associated with rate-corrected QTc prolongation and possible consequent cardiac arrhythmia. Review personal and family history for risk factors. Consider screening ECG and follow-up evaluation in collaboration with outpatient methadone clinic.
- Discharge, when stable, to methadone clinic to monitor subsequent dosing.
- Evaluate for methadone drug-drug interactions (tricyclic antidepressants, antipsychotic medications, and certain antiemetics and antibiotics are also associated with prolonged QT interval).
- As pregnancy progresses, the same methadone dosage produces lower blood methadone levels, so higher dosing may be required to control symptoms.
- After birth, monitor for signs of overmedication and adjust dosing as needed.

Neither the incidence nor severity of NAS correlate directly with maternal methadone dose at delivery, and NAS can occur in infants with maternal methadone doses as low as 10 mg per day. Babies born to mothers who reported smoking 20 or more cigarettes per day had significantly higher NAS peak scores and took longer to reach peak scores than lighter smokers. Methadone doses less than 90 mg were not significantly associated with PTB or low birthweight.[134] Arbitrarily limiting methadone dose as a way of minimizing the risk of NAS is not warranted. In an investigation of high-dose (>100 mg/day) and low-dose (<100 mg/day) administration, no difference in the rate of medication treatment for NAS or days of infant hospitalization between the high-dose (mean 132 mg) and low-dose (mean 62 mg) groups was observed. The group of mothers who received high-dose medication had less illicit drug use at delivery.[141] However, we do not yet have a method to determine which infants will develop NAS that requires treatment. Because methadone has a very long half-life in infants, methadone-exposed neonates should be observed for at least 7 days for onset of NAS.

To minimize the fetal load of methadone at birth, some investigators have suggested tapering the dose during pregnancy. Luty and colleagues[142] investigated the safety of methadone detoxification in pregnancy in a retrospective case series of 101 pregnant opiate-dependent women who underwent a 21-day methadone taper during hospitalization. One miscarriage occurred with detoxification in the first trimester. No miscarriages occurred in the second trimester, and no increase in PTB was observed. Dashe and colleagues[143] observed outcomes during tapering of methadone in 34 women at an average of 24 weeks' gestation. In opiate-using women not on methadone maintenance treatment (MMT), methadone was commenced at 20 mg daily and increased by 5 to 10 mg every 6 hours as needed to alleviate withdrawal symptoms. After reaching a stable dose, the methadone was tapered by 20% or less of the stable dose every 3 days. Each woman was observed in the hospital for several days after methadone was discontinued. Daily qualitative assessments of fetal activity were augmented with semiweekly fetal heart rate monitoring with gestations at or more than 24 weeks. Mild maternal symptoms of withdrawal that included cravings or restlessness were managed with supportive care, counseling, or both. Withdrawal signs that included nausea, vomiting, abdominal discomfort, or a concerning fetal heart rate tracing were managed with clonidine (38%) or methadone (62%). A 0.2-mg transdermal dose of clonidine was supplemented by 0.1 mg orally every 4 to 6 hours to decrease physiologic symptoms. Newborns were kept in the hospital nursery for 3 to 7 days to observe for NAS. The median time to detoxification in the mother was 12 days, and there were no observed fetal deaths, PTB, IUGR, or other perinatal complications. Fifteen percent of neonates needed treatment for NAS. Overall, 20 (59%) women successfully completed detoxification and did not relapse, whereas 10 (29%) resumed prenatal opioid use and 4 (12%) did not complete detoxification and elected methadone maintenance. The decision to opt for methadone detoxification compared with MMT during pregnancy involves consideration of the risks of obstetrical and neonatal complications produced by methadone dependence at delivery versus the risks of relapse and continued intravenous drug use after detoxification. If a woman declines MMT, plans to move to an area where MMT is unavailable, or plans to detoxify in a structured treatment program, a carefully individualized tapering regimen managed closely by a multidisciplinary team provides a viable treatment option.

Buprenorphine is a partial agonist-partial antagonist synthetic opioid with a long duration of action (72 hours). Buprenorphine has been used to treat opioid dependence both in Europe and in the United States. There is increasing evidence to support its use as an alternative to methadone. Because methadone is the standard of care, buprenorphine should be prescribed only if the woman does not tolerate methadone, if she is already on

buprenorphine therapy, or if she refuses methadone. Buprenorphine has more complex pharmacology and should be prescribed by an experienced physician with a special federal waiver to treat patients.

Buprenorphine is equally effective as moderate dosing of methadone and has the benefit of a "ceiling effect" as a partial opioid agonist that limits risk of respiratory depression at higher dosing and results in milder withdrawal symptoms upon discontinuation. Study findings to date suggest that infants exposed to buprenorphine compared to methadone have less severe NAS, lower medication doses, and shorter lengths of hospital stay.[144]

The AAP supports the use of methadone (without dose limitation) during breastfeeding. On average, infants receive 2% to 3% of the weight-adjusted maternal dose via breast milk. The doses of methadone received through milk are unlikely to fully prevent NAS but may be beneficial. Findings from four studies suggest that breastfeeding reduces the severity of NAS and shortens length of hospital stay. However, two infants who abruptly discontinued breastfeeding by mothers on methadone (70 mg and 130 mg/day) developed withdrawal symptoms.[145]

Infants of mothers on MMT are at risk for feeding problems, which may be due to altered sucking patterns. Opiate-exposed infants showed prolonged sucking, fewer pauses, more feeding problems, and increased arousal. Intrauterine drug exposure may adversely affect development of brainstem respiratory and swallow centers, which dysregulate the underlying biorhythms of feeding. Apnea and sudden infant death syndrome occur with increased incidence in infants born to opiate-addicted mothers, which may be due to respiratory abnormalities. In utero drug exposure may result in delayed maturation of the neurorespiratory axis.[146] Infants with NAS who experience excess weight loss (>8%-10%) or slow weight gain (not back to birth weight by 10 days) may benefit from caloric supplementation through the addition of breast milk fortifier or 24 kcal/oz infant formula.

Acute Pain Management for Women on Maintenance Opioids

Treatment of acute pain in labor and post-delivery is challenging in women on MMT. Common misconceptions about patients who receive maintenance treatment with methadone (or buprenorphine) include the following: (1) The maintenance opioid agonist provides analgesia; (2) the use of opioids for analgesia may result in addiction relapse; (3) the additive effects of opioid analgesics and maintenance therapy may cause respiratory and central nervous system depression; and (4) complaints of pain demonstrate drug seeking secondary to opioid addiction. Alford[147] also provided recommendations for acute pain management in patients who take maintenance opioids. Uninterrupted maintenance treatment (after verification of the daily dose) is imperative. Undertreating acute pain may lead to decreased responsiveness to opioid analgesics, which renders subsequent pain control more difficult. Multimodal analgesia (e.g., nonsteroidal anti-inflammatory drugs and acetaminophen) and adjuvant drugs that enhance opioid effects (e.g., TCAs) may be coadministered. Analgesic dosing should be continuous or scheduled rather than as needed. Mixed agonist and antagonist opioid analgesics, such as pentazocine, nalbuphine, and butorphanol, must be avoided because they may displace the maintenance opioid from receptors and precipitate acute opioid withdrawal.

PERSONALITY DISORDERS

Personality disorders (PDs) are a heterogeneous group of disorders that arise when an individual's personality traits are maladaptive and inflexible. The person's rigid belief systems and behaviors prevent adaptability of thinking, and limit use of problem-solving skills with effective coping strategies when confronted with new or stressful events. Coping with medical illness or a high-risk pregnancy creates a major challenge for these individuals. Most patients with PD have significant difficulty in interpersonal relationships[142] and are emotionally sensitive. They may react strongly to a long clinic wait or terse office staff.

Diagnosis and Prevalence

Unlike many of the disorders described in this chapter, there is no acute stressor or even a clear onset for PDs. Such traits develop gradually in adolescence or early adulthood and persist throughout life. Although the clinical features of a PD sound similar to characteristics that anyone could display occasionally, an actual PD is defined by exhibiting extremes on various traits and would not be diagnosed unless the patterns of behavior were chronic, pervasive, and dysfunctional.[1] The personality difficulty must lead to emotional distress and/or significantly impaired functioning across several domains. Within the health care system, women with a PD or PD-related traits (such as hostility or anxiety) often use medical resources extensively.

Although we were unable to locate any epidemiologic data on PDs specifically in obstetrical settings, information is available from primary care and internal medicine settings. Prevalence rates vary from 24% with interview-based diagnoses of PD[148] to 32% based on a questionnaire that indicated that the person was at high risk for PD.[149] Some investigators have suggested a much greater prevalence of PD among certain patient groups. Between 47% and 60% of chronic pain patients meet criteria for a PD,[150] and an association also has been found between PD and fibromyalgia.[151] The relationship of PD with medically unexplained symptoms is particularly strong,[147] and one investigator[152] demonstrated that an increasing number of medically unexplained symptoms among patients in primary care was positively correlated with PD-relevant traits (neuroticism, harm avoidance) and with the degree of functional impairment. Patients with an Axis I disorder, such as depression, also are more likely to have a comorbid PD, which typically interferes with their successful treatment. A common clinical perception is that dependent (anxious/fearful cluster), histrionic, and borderline PDs are more often diagnosed in women. Although there is some empirical support for borderline PD being more common in women, when population sex-ratios are controlled, these gender differences tend to attenuate or disappear.

Clinical Implications

Mental health treatments for patients with PD tend to be long-term with slow progress, particularly in severe forms

of the disorder. Available treatments include both psychotherapy and pharmacotherapy, although it is generally agreed that medication alone cannot fully treat the multidimensional problems associated with PD. Limited data have been published on the efficacy of different treatments; however, for severe PD, dialectical behavior therapy has the greatest amount of empirical support. Obstetricians generally do not have the time or training to provide formal psychotherapy to patients with PD. However, physicians can develop rapport, feel less frustrated, and develop better clinical recognition skills. This can help the physician make the decision to refer a patient to a mental health specialist for screening and treatment recommendations if PD is suspected. Physicians also will be in a better position to develop and coordinate effective treatment strategies for other disorders in the context of a PD. There are a number of strategies that can be used to interact with persons who have PDs.

Build a Working Alliance

One of the most important ways to begin to develop an alliance is to initiate eye contact with the patient, and maintain it while shaking her hand and introducing yourself. Second, use reflective listening in which you simply restate to the patient what she has said, perhaps by paraphrasing. This conveys that you listened and understood what she was telling you, which will facilitate the communication. For example, if a patient with gestational diabetes defensively explains that she did not check her glucose levels as prescribed because she kept forgetting to take her glucometer to work, a reflective statement such as "It sounds like you've had a hard time checking it four times daily" is neutral yet communicates interest and attentiveness.

Structure the Relationship

A common feature of many patients with PD is difficulty in conforming to the expectations or "script" of their current context. In the medical setting, they may make unreasonable demands for special treatment from the physician or clinic. They may become dependent and begin calling the physician excessively at the clinic or at home. Other patients with PD are mistrustful of authority figures, and may infer dishonesty or hostile intent on the part of the physician and clinic staff when there is any minor inconsistency in clinic procedure.

For these reasons, it is useful to make clear the procedures and respective roles of the doctor-patient relationship from the outset (e.g., appointments, emergencies, prescriptions, other aspects of clinic procedure). Doing so is to the benefit of the patient because it reduces the possibility of misunderstanding and promises that cannot be kept. The rules should be presented in a frank, nonjudgmental way, and it is useful to elicit some form of verbal agreement from the patient to these rules. The rules should be delivered in an emotionally neutral, matter-of-fact presentation as non-negotiable, with the option to seek another physician or clinic if she cannot agree to them. Allowing her to air concerns and discuss any pitfalls can both heighten adherence to the rules and reduce the likelihood of future problems. An important caveat is to keep the number of such rules to the minimum necessary and avoid listing numerous potential egregious behaviors and appearing as though you have negative expectations of the patient.

On the other hand, the moment it appears that a problem behavior is arising, swift and clear communication of the unacceptability of the behavior is needed. For example, the patient who becomes angry and begins shouting in the waiting area should be calmly told, "We don't tolerate shouting in the clinic; you'll have to calm down or leave immediately and reschedule your appointment." This conveys that the behavior (not the patient) is entirely unacceptable and yet the physician-patient relationship is reparable: the patient may reschedule her appointment. Finally, to reduce the frequency and disruptiveness of unscheduled phone contacts and requests for visits, it can be useful to schedule brief, frequent visits that follow a structured format.

Respect Patient Autonomy

Patients with PD may behave in a passive manner regarding their medical care and fail to adhere to the medical regimen, yet become angry when the physician cannot "fix" the problem for them. Other patients may feel very uncomfortable in a "one-down" role and may chafe at the notion that they are being "told what to do." To guard against these problems, it is advisable to encourage the most collaborative relationship possible. The most useful approach is: "How can we work this out together?" A physician's willingness to take this approach can be severely tested if the patient has serious medical problems or is engaging in egregious behaviors (drug abuse, consistent nonadherence with diabetes therapy) that could produce poor birth outcomes. A useful approach is to make statements that highlight the patient's freedom to choose, such as "I can't force you to do anything; I can only tell you the consequences of your behavior, but ultimately it's up to you to make the decision." Give these patients as much choice as possible; for example, ask them about their medication preferences and allow them to regulate medication within prescribed limits.

Find Something to Validate in the Patient's Response

Validation is a key technique to reduce conflict, strengthen the alliance, and promote change. Validation requires the physician to communicate to the patient, in word or action, that her response makes sense and is understandable within the current context. In the face of a great deal of problematic behavior, a physician may have to search for the "kernel of truth" and reflect this back to the patient. The physician may acknowledge, "I understand how hard it has been for you to get to your appointments." Or, "A lot of women would be very stressed by all the things you have going on in your home." Or "I know you are angry about this; you have a reason to be mad."

Physician Self-Regulation

When faced with a hostile, antagonistic patient, or one who is sobbing and demanding, it can be difficult for a physician to manage his or her own emotional reaction. Indeed, many physicians may disavow their strong feelings of irritation at a patient because they think they are

unprofessional or uncompassionate. Managing emotional reactions requires that they be recognized and discussed with a colleague on a regular basis. Peer support is vital for maintaining morale, warding off burnout, and providing an objective viewpoint. Physicians need not necessarily like the patient nor condone her behavior. Nonetheless, making a conscious effort to strive for empathy and a nonjudgmental stance toward the patient can greatly reduce physician frustration and increase effectiveness. Likewise, physicians must bear in mind that behavior change typically occurs slowly, and patience is required to develop some sense of acceptance of the patient-physician relationship.

SUICIDE

Suicide is a tragic outcome associated with psychiatric illness. Oates[153] performed an evaluation of the Confidential Enquiry into Maternal Deaths in the late 1990s from the United Kingdom. Psychiatric disorder, and suicide in particular, was the leading cause of mortality and accounted for 28% of maternal deaths. Women also died from other complications related to psychiatric disorder and a significant minority from problems related to substance abuse. The suicide rate following delivery was not significantly different to other times in women's lives and for the first 6 weeks following delivery may be elevated.[153] The overwhelming majority of the women died violently, which contrasts with the usual observation that women are more likely to die from an overdose of medication.

Suicide assessment requires direct questioning of the patient about her desire to live or die, specific thoughts about killing herself, plans for carrying out the act, and access to and lethality of means. The APA practice guidelines for the assessment of suicidal behaviors provide a comprehensive list of more than 40 questions that can help clinicians assess suicidal thoughts, plans, and behaviors.[153] Initial questions address patients' feelings about living ("Have you ever thought that life was not worth living?" "Did you ever wish you could go to sleep and just not wake up?"). These are followed by questions that address specific thoughts about death, self-harm, and suicide ("Have things ever reached the point that you've thought of harming yourself?"). If thoughts of self-harm are endorsed, physicians should evaluate the details of the thoughts including the nature, intensity, frequency, timing, persistence, and circumstances. Physicians must also ask whether the patient has made a specific plan. Routinely asking about pills, household poisons, firearms, or access to dangerous settings as part of the suicide assessment is critical. Has the patient made preparations for the plan or for after her death (i.e., purchasing the means, writing a will, arranging for childcare)? Answers to each of these questions inform evaluation of the immediate safety of the patient. If screening elucidates a significant potential risk, immediate emergency psychiatric consultation or involuntary commitment to a psychiatric facility is indicated.

The practice guidelines also identify situations in which a suicide assessment is clinically appropriate; these include emergency room evaluations, an abrupt change in clinical symptoms, lack of improvement or gradual worsening despite treatment, anticipation or experience of a significant interpersonal loss or stressor (divorce, loss of custody of children, financial loss, legal problems, personal humiliation), or onset of a physical illness associated with a threat to life, disfigurement, severe pain, or loss of function. Patients with increased risk are those with previous suicide attempts, major mood disorders (especially BD), schizophrenia, and substance use.

A potential association between antidepressant use and emergent suicidal behavior was the subject of an FDA black box warning for the use of antidepressants for children and adolescents, as well as considerable debate. Although 60% of suicides occur in persons with mood disorders (the majority untreated), little is known about the relationship between antidepressant drug use and the rate of suicide. Data from all Americans who committed suicide between 1996 and 1998 were analyzed for associations between prescriptions and suicide rate at the county level. The overall relationship between antidepressant prescription and suicide rate was not significant.[154]

INFANTICIDE AND NEONATICIDE

Resnick[155] differentiated filicide (murder of a child) from neonaticide (killing within 24 hours of birth) and infanticide (killing after the first day). In further elaboration of this conceptual framework, Oberman[156] defined four subtypes of infanticide that provide a model for a "differential diagnosis" of infanticide (Table 52-3). The total dependence of the newborn on the caretaker creates a number of risks. Direct killing of an infant by poisoning, traumatic injury, or starvation has been described. The serious cognitive disorganization in women with postpartum psychosis also can lead to failure to provide the vulnerable newborn with life-sustaining needs, such as adequate fluid and nutritional intake, appropriate environmental temperatures, safety, and emergency medical care. Environmental factors that are correlated with parental psychiatric illness, such as violence, hostility, irritability, and involvement in parental delusions, are also important predictors of poor infant outcomes.

TABLE 52-3 CATEGORIES OF INFANTICIDE

CATEGORY	DESCRIPTION
Neonaticide	Unaware of pregnancy, no prenatal care, unassisted birth (often into toilet), family/friends unaware of pregnancy, minimal physical signs of pregnancy
Assisted/Coerced	Killing is done in conjunction with violent, abusive, usually male partner
Neglect	Caretaker distraction results in accidental death, such as baby left in care of young siblings, limited resources, overwhelmed by economic obligations
Abuse	Chronic child abuse, marked irritability, poor caretaker impulse control, efforts to discipline result in unintentional death (most frequently at mealtime and bedtime)
Overt mental illness	Acute-onset postpartum psychosis with altruistic homicide delusions that involve the infant; chronic schizophrenia, social isolation, incapable of parenting without assistance

Postpartum Psychosis

The tragic case of Andrea Yates, who drowned her five children, resulted in discussions about the current conceptualization of postpartum psychosis juxtaposed against legal criteria that involve only tests of the cognitive capacity to acknowledge actions.[157] Women are more vulnerable to psychosis in the postbirth period than at any other time during their lives. In the first 30 days after birth, a woman is 21.7 times more likely to develop psychosis than in the 2-year period prior to childbirth. If she has not had a child before, she is 35 times more likely to suffer psychosis than women who have children.[158] **The magnitude of these relative risks demonstrates that postpartum psychiatric morbidity is a major public health problem.** The reasons for the vulnerability of postpartum women to psychosis and the high risk for postbirth decompensation in women with BD have not been elucidated. Sleep deprivation and marked interference with circadian rhythms related to labor are likely contributors to mood instability.[41] Hormone elevations near the end of gestation and massive postbirth withdrawal also contribute to the risk.[9]

Specific types of delusional thoughts are related to risk for infanticide. Delusional altruistic homicide (often associated with maternal suicide) to save them both "from a fate worse than death" was described in a review of filicides.[155] This type of delusion was present in the clinical symptoms of Andrea Yates. In his classic paper, Resnick[155] observed that 40% of the perpetrators of filicide had seen physicians shortly before the tragedy. Sensitive, direct questions about thoughts of harm to the infant, as well as harm to the self, are imperative in the examination. Nonjudgmental inquiry can be made as follows: "Some new mothers have thoughts such as wishing the baby were dead or about harming the baby; has this happened to you?"

The clinical picture of postpartum psychosis is characterized by rapid onset of hectic mood fluctuation, marked cognitive impairment suggestive of delirium, bizarre behavior, insomnia, visual and auditory hallucinations, and unusual hallucinations (tactile and olfactory). Women with acute-onset psychoses related to childbearing usually had recurrence of previously undiagnosed cyclic mood disorders rather than the triggering of a new disorder. **As discussed in the section on BD, postpartum psychosis is frequently a manifestation of bipolar illness: mania or depression with psychotic features.** In a historical cohort design, our group[159] studied mothers who presented to a psychiatric evaluation center. Half of the group with at least one child under the age of 3 years presented with episodes that began during pregnancy or postpartum. Women who presented with psychoses during childbearing had symptom patterns that differed from those of women who presented with non-childbearing related psychoses. **Particularly prominent was cognitive disorganization, which mimicked a delirium and often resulted in an extensive medical assessment**.

Delusions must be differentiated from the far more common occurrence of obsessional thoughts in the context of depression. Many depressed women have obsessional thoughts. Obsessions are recurrent and persistent thoughts, impulses, or images that are experienced as intrusive and inappropriate and cause marked anxiety or distress. For example, some mothers have obsessional thoughts about drowning their baby and refuse to bathe the child. Women often have "what if" questions such as: "What if I throw the baby over the banister?" Obsessions differ from psychotic symptoms because the patient recognizes that the thoughts, impulses, or images are a product of her own mind (not imposed by an external force as might occur in psychosis). Additionally, obsessional visual images also may occur but are brief and perceived as being in the "mind's eye" as opposed to an external hallucination. For example, a woman might have frightening images of her dead baby in a bathtub, but she is aware that the image was not actually present in the real world. The distinction is important clinically because women with obsessional thoughts are vigilant about preventing any action they might take in response to obsessional thoughts (such as asking that all knives be locked away), whereas women with psychosis are at risk for taking action. Although these symptom sets are not mutually exclusive, co-occurrence is very rare.

Prevention of infanticide involves increased *awareness* and a heightened index of suspicion by physicians, midwives, obstetric nurses, other health care professionals, patients, and families. Women with a previous episode of postpartum psychosis and women with BD are at high risk for the onset of postpartum psychosis. At a minimum, postpartum *monitoring* for the emergence of symptoms should be a collaborative plan between the physician and the patient's family. Because postpartum disorders are common in the general population of new mothers, *screening* (such as with the EPDS, see Figure 52-2), to identify cases for *early intervention* is an important public health goal. Aggressive *treatment* for women who develop the disorder with a thoughtful plan for family monitoring of the infant for safety or alternative care while the mother recovers is imperative.[41]

Neonaticide

Neonaticide refers to the death of a newborn within the first 24 hours of life. A striking consistency in the clinical presentations of neonaticides occurs. The adolescent or adult woman has minimal weight gain during pregnancy, perceives birth as the need to have a bowel movement, and secretly delivers into a toilet. She puts the baby in a bag, abandons or hides it, and continues her usual activities. If not rescued, the infant may suffocate or die from exposure. Affected women vary in terms of age, race, and demographics, and may have other children. Family members, friends, and boyfriends usually were not aware of their pregnancies, and the father is rarely identified. Childhood sexual trauma, physical abuse, and emotional abuse are common in women who commit neonaticide.

A common element in these cases is the psychophysiologic denial of pregnancy; that is, the conscious awareness of the pregnancy is suppressed. This is classic denial, in that the woman behaves in a way that demonstrates failure to accept either an obvious fact (pregnancy) or its significance. A fragmentation of perceptions (no pregnancy, delivery, or pain) and memory (no sexual encounter and continued menses) occurs to suppress painful emotional awareness. The woman denies somatic symptoms of pregnancy, perceives no fetal movements, claims to have menstrual cycles, and recognizes impending birth only as a

bowel movement. Essentially, the pregnancy is *not there*, *not real* for these patients in both mind and body. Most of these patients will not be seen by an obstetrician unless they present for another problem and the pregnancy is discovered, or if the baby is recovered and the mother is presented for pelvic examination, often due to legal intervention.

Neonaticide is the polar opposite of a desired but unachievable pregnancy, which in extreme cases results in pseudocyesis (see next section). Psychophysiologic mechanisms are common to both states, and both have neurohormonal underpinnings but opposite somatic manifestations.

PSEUDOCYESIS

Pseudocyesis is a condition in which the woman believes that she is pregnant but no conceptus exists. Pseudocyesis is characterized by an increase in body weight, enlargement of the mammary glands, and milk production. In animal models, it is associated with the abnormal persistence of the corpus luteum. Spontaneous cases of pseudocyesis have been reported in a number of mammalian species, including dogs, cats, bears, rodents, and humans; curiously, it occurs rarely in nonhuman primates.[160]

Women with pseudocyesis have amenorrhea, lactation, colostrum secretion, increased abdominal girth, and subjective experiences of fetal movement. Physical changes consistent with pregnancy have been detected upon examination, such as an enlarged uterus and softened, congested cervix. Women with pseudocyesis present with behaviors and somatic symptoms consistent with pregnancy, and they may be admitted to the delivery suite. Psychophysiologic mechanisms are common to both pseudocyesis and denial of pregnancy, which have neurohormonal underpinnings but opposite somatic manifestations. A psychiatric diagnostic assessment is crucial, because pseudocyesis must be differentiated from psychosis, in which a fixed conviction of pregnancy persists despite evidence to the contrary and other psychotic symptoms are present. Delusions of pregnancy also have been described in patients with schizophrenia.[161] Gentle and supportive provision of information to challenge the belief of pregnancy with referral for psychotherapy is an appropriate intervention strategy.[162]

FINAL COMMENT

We ended where we began; this is, with the powerful mind-body connections that impact the entire spectrum of outcomes for childbearing women. The biopsychosocial forces that affect women at the time of pregnancy create a plethora of childbearing experiences for our patients. **As health care professionals, we influence the trajectory of these forces to promote the well-being of the mother, her newborn, and her family, at a time when motivation for positive health behaviors to promote the offspring's well-being is maximal.**

KEY POINTS

- Mental health is fundamental to health. To the extent that maternal biopsychosocial exposures with negative impact on pregnancy outcomes can be diminished, eliminated, or replaced with positive factors, the risk of poor pregnancy outcome can be reduced.
- Major depression is a treatable illness that is the leading cause of disease burden among girls age 5 years and older worldwide. The period prevalence of depression during pregnancy is 12.7% during pregnancy, with 7.5% of women having a new (incident) episode.
- A brief and efficient 10-item self-report screening instrument, the Edinburgh Postnatal Depression Scale, is available to screen for perinatal depression. For clinical practice screening, the cutoff score for probable major depression in postpartum women is 13 or more and for pregnant women 15 or more.
- Women who present with depression should be evaluated for bipolar disorder, which is characterized by not only depression but also episodes of hypomania, mania, or mixed states, before prescribing antidepressant treatment because the pharmacologic intervention differs.
- The first-line medications for treatment of a breastfeeding woman are sertraline, paroxetine, and nortriptyline; however, established efficacy of another drug in the individual woman must be considered strongly in the decision-making process for drug choice.
- Abrupt discontinuation of any psychotropic medication creates a higher risk for recurrence than does gradual tapering and discontinuation (over at least 2 weeks).
- Cognitive behavioral psychotherapy or behavioral therapy and antidepressants are the first-line treatments for anxiety disorders and bulimia nervosa.
- Antipsychotic drug maintenance treatment and psychosocial support interventions aimed at maximizing function are the mainstays of treatment for schizophrenia. Concurrent maternal smoking, substance use, poor nutrition, and socioeconomic problems increase the risk for less optimal pregnancy outcomes.
- The perception of substance use disorders as afflictions solely of poor, minority, and young women is erroneous. Screening measures are available and easy to use, and multidisciplinary treatment intervention results in improved reproductive outcomes.
- Postpartum psychosis is characterized by rapid onset of hectic mood fluctuation, marked cognitive impairment suggestive of delirium, bizarre behavior, insomnia, visual and auditory hallucinations, and often, unusual hallucinations (tactile and olfactory). Women with acute onset postpartum psychosis usually have recurrences of previously undiagnosed bipolar disorder.

Health care quality has been defined by the Institute of Medicine (IOM) as "the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge."[1] Under the IOM framework, safety is part of the larger concept of health care quality.[1] The intent of this chapter is to describe methods to enhance patient safety and to measure and achieve high-quality care in obstetrics.

PATIENT SAFETY

Overview

Patient safety has become an increasing focus of the attention of the medical community. Although the reasons for the increased focus are multifactorial, one important contributor has been the recognition of significant numbers of preventable adverse events that commonly occur. The relatively high number of medical errors has been documented in the IOM report, *To Err is Human*. That report, published in 1998, suggested that between 44,000 and 98,000 mortalities occur in hospitals each year as the result of medical errors.[2] This report, correspondingly, noted the importance of error reduction as a means to improve health care and patient outcomes.

Because obstetrical admissions are the leading cause of hospitalization for women in the United States, accounting for more than 4 million hospital discharges each year,[3] pregnant women are at particular risk for encountering a medical error. Emphasizing the importance of obstetrical safety further is the fact that each obstetrical admission has the potential to affect the health not only of a single individual but of both a mother and her infant.

Frequency of Preventable Obstetrical Adverse Events

Many studies that have sought to determine the frequency of preventable obstetrical adverse events have used retrospective designs and studied in detail cases in which *adverse outcomes* have occurred. The overall frequency of preventable *adverse events* on a given obstetrical unit cannot be determined from these studies. This is particularly true given that adverse events may occur (e.g., administration of a medication to which the patient is stated to be allergic) that do not result in an actual adverse outcome (e.g., anaphylactic shock). However, these studies do give insight into the frequency with which, when an adverse outcome occurs, that adverse outcome may have been preventable.

Geller and colleagues analyzed cases of morbidity and mortality that occurred at their institution.[4] These cases included those with severe morbidity and with "near-miss" morbidity. It should be emphasized that their near-miss morbidity is not so named because a woman nearly misses having morbidity but because she nearly misses a mortal event.[5] Thus, in their framework, maternal morbidity has a spectrum of severity, and there is none that is more severe than near-miss morbidity. In their study, morbid and mortal events were often found to be preventable, with "preventable" being defined as an event that could have been avoided by any action or inaction on the part of the health care provider (e.g., clinical mismanagement, failure or delay in diagnosis), the system (e.g., failure

in communication), or the patient (e.g., noncompliance). Moreover, women who had the most adverse outcomes were more likely to have had preventable events: 16% of cases with severe morbidity were judged preventable compared with 46% of near-miss events and 41% of mortal events.

Berg and associates focused exclusively on maternal deaths that occurred in North Carolina.[6] They studied the circumstances surrounding the pregnancy-related deaths of 108 women between 1995 and 1999. Death were considered potentially preventable if (1) preconception care and counseling could have improved outcome; (2) the patient had not adhered to medical advice; (3) the structure and functioning of the health care system were suboptimal; or (4) clinical care was not satisfactory. In their study, 40% of deaths were considered preventable, although this frequency significantly differed on the basis of the primary underlying cause of death. For example, 93% of deaths related to hemorrhage but only 22% of deaths related to cardiomyopathy were thought to be preventable.

White and coworkers examined 90 cases that had resulted in litigation and in which the claims had been closed.[7] It should be noted that these cases included both gynecology and obstetrics cases, although most were related to obstetrics. In their study, 78% of these cases were thought to have had a contributing factor that was potentially avoidable. Clark and colleagues also analyzed claims data and focused only on those claims related to perinatal care.[8] Their findings were quite similar to those of White and coworkers; specifically, they noted that 70% of cases were potentially preventable and related to the care the patient received in the hospital.

Forster and associates did attempt to prospectively quantify the frequency of adverse events that occur on an obstetrical unit.[9] These investigators placed an observer in the labor and delivery unit during the weekday hours of a 6-week period. This observer was trained to ascertain poor patient outcomes, procedural errors, and unsafe working conditions. Cases of concern that were ascertained by the observer were then further evaluated by a multidisciplinary team. The primary outcome of the study was the occurrence of a "quality problem," defined as the occurrence of either an adverse event (i.e., "an adverse outcome due to health care management as opposed to progression of natural disease") or a potential adverse event (i.e., "defective processes that have a high likelihood of causing harm"). Of the more than 400 patients who were cared for during the study period, 5% had a quality problem occur (2% had an adverse event, and 3% had a potential adverse event). Sixty-six percent of the adverse events that occurred were judged to be due to errors in health care delivery.

Factors Contributing to Preventable Adverse Events

The literature that exists would suggest that there are multiple factors that contribute to the occurrence of adverse obstetrical events. Data from The Joint Commission illustrate how multiple factors can precipitate major adverse maternal and perinatal outcomes. For example, their analysis of major maternal adverse events revealed multiple root causes, including the lack of adequate communication, training, staffing, and patient assessment.[10] Other investigators similarly have found that preventable adverse events or potential events cannot be traced to one simple and easily remediable cause but rather are multifactorial and due to a complex interplay of factors. Geller, White, and Forster and their colleagues all have demonstrated the many different factors present at both the provider and systems level that have contributed to adverse events.[5,7,9]

Despite the many factors that have been implicated in the occurrence of preventable adverse events, it is worth noting that communication and systems issues that transcend simple individual error consistently have been found to be predominant etiologies in the occurrence of these events.[5,7,9-11] *Systems issues* is a term that refers to problems that stem not from an individual's actions but from the interconnected relationships of people, institutional policies, and the physical environment. **With regard to the sentinel events in maternal care that were analyzed by The Joint Commission, a communications issue was judged to be present in more than 80% of cases.**[10] This frequency far outstripped the next most frequent factors—competency and patient assessment—which were present in fewer than 40% of cases. In their review of closed claims, White and coworkers noted that inadequate communication among providers was the single most common preventable factor associated with the claim.[7] Similarly, in their prospective study, Foster and associates noted that systems issues were the most common reason that their trained observer was alerted to further assess the possibility of a quality problem.[9]

Approaches to Improve Obstetrical Safety

The previous discussion highlighting the different factors that contribute to patient safety suggests that efforts to improve safety may require multiple different approaches. The potential need for a multifaceted approach is further suggested by the different levels within an organization at which these factors can manifest. **Specifically, key components required for the prevention of adverse events occur at (1) the individual level (e.g., the level of education or training provided to workers); (2) the group level (e.g., team effectiveness and communication); and (3) the structural level (e.g., standardization of processes within an organization).**[11] Correspondingly, attempts to enhance patient safety within obstetrics have used several different types of modalities. The theoretical underpinning to believe that these modalities should be effective, as well as the evidence supporting their use, with a focus on obstetrics, is discussed in the following sections.

Checklists and Protocols

Because of the complexity of health care processes and the corresponding potential for errors in communication, one approach to improve patient safety has been the introduction of standardized approaches to patient care. These approaches have taken the form of protocols (i.e., mandatory items for completion to lead the user to a predetermined outcome) and checklists (i.e., a list of action items or criteria arranged in a systematic manner, allowing the user to record the presence or absence of the individual

items listed to ensure that all are considered or completed). Although both are concerned with standardization, checklists provide explicit lists of items, an action thought to be a cognitive aid because of grouping of relational items in an organized fashion in order to improve recall performance.[12]

Pronovost and coworkers have demonstrated the potential utility of checklists in their study regarding catheter-related bloodstream infections in the intensive care unit (ICU).[13] In this study, checklists detailing five key actions that were required during any central catheter placement were introduced in 108 ICUs throughout the state of Michigan. Of note, these key actions were evidence based. Also, the checklists were not merely posted, but were supported by local leaders versed in the supporting evidence who provided feedback with regard to optimal methods for implementation. Not only did the incidence of catheter-related bloodstream infections significantly decline by 3 months after implementation (incidence rate ratio [IRR], 0.62; 95% confidence interval [CI], 0.47 to 0.81), but this incidence also continued to decline until 18 months (IRR, 0.34; 95% CI, 0.23 to 0.50) after implementation, which was the end point of data collection.

A checklist to guide the administration of oxytocin was developed by Clark and colleagues, who then implemented this checklist in a private hospital setting.[14] The outcomes of the 100 women before checklist implementation were then compared with those of the 100 women receiving oxytocin after the implementation. After implementation, there was no difference in duration of labor, duration of oxytocin administration, or frequency of operative delivery, although the maximal dose of oxytocin used was significantly lower, as was the frequency of newborns with one or more complications ($P = .049$).

The potential benefits of a standardized approach to the evaluation and management of preeclampsia has been demonstrated by Menzies and associates.[15] After establishing a set of best practices, this group of investigators introduced these practices for preeclampsia management at British Columbia Women's Hospital. Among women with preeclampsia who were managed after the standardized approach was put into place, 0.7% experienced the composite end point of maternal adverse outcomes, which was an 86% reduction compared with the preintervention frequency of 5.1% ($P <.001$). Adverse perinatal outcomes also were reduced, although this finding did not reach statistical significance (odds ratio [OR], 0.65; 95% CI, 0.37 to 1.16).

Simulation

Simulation refers to the re-creation of an actual event that has previously occurred or could potentially occur.[16] **Simulation may be used to enhance patient safety in that an action or procedure can be repeated, thereby improving the execution of that action or procedure, without ever exposing providers or patients to harm.** Essentially, simulation of events is an opportunity for health care workers to prepare and train for interventions. Although simulation may have benefits for any type of obstetrical procedure (e.g., vaginal delivery), it has often been studied in the context of events such as shoulder dystocia and eclampsia. In these occurrences, simulation may be particularly helpful not only for the novice but also for experienced professionals, who can maintain skills in unpredictable and uncommon events.

Shoulder Dystocia

Data from multiple studies suggest that simulation may enhance several aspects of shoulder dystocia management, including performance of the maneuvers, communication among the team members, and documentation of the event. Moreover, these enhancements have been demonstrated for providers during both their residency training and postresidency experiences.

Deering and colleagues have demonstrated, in a randomized trial, that those residents who were assigned to train for a shoulder dystocia using an obstetrical birth simulator were significantly more likely to use maneuvers in a timely and correct fashion in a subsequent simulation when compared with those residents who did not undergo initial simulation training.[17] Furthermore, when judged by a blinded observer, those residents who had undergone simulation training scored higher on measures of overall performance and preparedness.

A study examining presimulation and postsimulation training outcomes among both residents and attending physicians was performed by Goffman and colleagues.[18] In this study, participants underwent a simulation of a shoulder dystocia event followed by a debriefing that included (1) a brief lecture about shoulder dystocia, (2) a review of the basic maneuvers and a basic algorithm for management of shoulder dystocia, (3) a discussion of optimizing team performance during an obstetrical emergency, (4) a review of the key components of documentation, and (5) a review of the digital recording of the simulations and discussion of provider performance. During a second, unanticipated, shoulder dystocia simulation, providers demonstrated significant improvements in use of maneuvers, communication, and overall performance.

Similar results were obtained by Crofts and coworkers in their multicenter comparison of presimulation and postsimulation outcomes.[19] This study additionally attempted to ascertain whether high-fidelity simulation (i.e., using a mannequin with a high degree of biofidelity) would enhance performance to a greater extent than low-fidelity simulation (e.g., using a simple doll-like mannequin) by randomizing participants to one of these options. Regardless of randomized group, performance during a simulated shoulder dystocia was improved subsequent to simulation training. Although some measures of performance (e.g., total applied force) were improved to a greater extent in those participants who had undergone high-fidelity training, many other measures (e.g., peak force, use of maneuvers) were no different between the high- and low-fidelity groups. Improvement in performance of simulated shoulder dystocia events has been demonstrated to persist up to12 months after training.[20]

The previous studies have examined outcomes during simulation events but have not demonstrated improvements in actual clinical outcomes related to simulation training. One observational study has assessed these clinical outcomes. In that study, investigators examined outcomes both before and after a shoulder dystocia training program was initiated at a single institution.[21] After the training program, there was a significant increase in the

frequency with which appropriate maneuvers were used during shoulder dystocias and a significant reduction in neonatal injury at birth after shoulder dystocia (9.3% to 2.3%; relative risk [RR], 0.25; 95% CI, 0.11 to 0.57).

Eclampsia

Studies that have evaluated simulation training for eclamptic seizure management have demonstrated improvements in response as measured during additional simulations. For example, after having staff in a single center participate in simulated eclamptic events with a debriefing session, Thompson and colleagues found that subsequent simulations of eclampsia were associated with patient resuscitations that were better managed.[22] Of note, these authors conducted their simulations on the actual delivery unit (as opposed to a separate simulation laboratory) and used their initial simulations not only for training but also for elucidating site-specific barriers (e.g., efficient paging system) to an optimal response. This ability of simulation to identify systems-level barriers to best practice has been noted by others as well.[23]

Ellis and associates also examined pretraining and posttraining outcomes during eclampsia simulations.[24] In their study, training was associated with an increase in the appropriate and timely completion of desired tasks (e.g., magnesium sulfate administration). Of note, although all participants underwent simulation training, they also were randomized to different training sites (i.e., simulation center vs. hospital unit) and to inclusion of teamwork training in their educational process. Neither site nor additional teamwork education was associated with additional improvement in performance.

Other Obstetrical Events

Other obstetrical events that have been examined in the context of simulation include breech delivery, postpartum hemorrhage, and cord prolapse. In one study that focused on breech delivery, residents, after undergoing a simulation of an imminent term vaginal breech, took part in a training session with the simulator on the proper techniques for vaginal breech delivery.[25] After this training, residents repeated the standardized simulation. Simulations both before and after training were videotaped and judged by an investigator who was blinded to whether the simulation occurred before or after training. Scores for skill and safety were significantly greater for residents participating in the simulated breech delivery after the training. With regard to postpartum hemorrhage, Toledo and colleagues used simulated examples of blood loss volumes to improve care providers' accuracy with regard to blood loss estimation.[26]

Siassakos and colleagues assessed whether clinical outcomes associated with cord prolapse improved after introduction of an obstetrical emergency training program that included cord prolapse drills.[27] They found that after these drills, there was a significant reduction in diagnosis to delivery interval (25 to 14.5 minutes; P <.001), although no significant difference in low Apgar scores or rate of admission to the neonatal ICU could be found.

Draycott and colleagues also examined clinical outcomes after introduction of a training session that included fetal heart tracing education and drills in shoulder dystocia, postpartum hemorrhage, eclampsia, twin deliveries, breech deliveries, adult resuscitation (including cardiopulmonary resuscitation), and neonatal resuscitation.[28] After this training, the frequency of hypoxic-ischemic encephalopathy (HIE) decreased by about half at their institution (27.3 to 13.6 per 10,000 births; P = .03). This decrease did not appear to be related to other preexisting trends in the frequency of HIE or changes in the population during the period of study.

Enhancement of Communication in General

Rather than focus on simulation of specific obstetrical events, some investigators have focused on improvement of communication processes and teamwork in general. One approach to this is through the establishment of a specific team that is trained to function and be engaged specifically at the time of obstetrical emergencies. **One institution, for example, created a "Condition O" team, according the precepts outlined for rapid-response systems.[29] These precepts include (1) case detection that triggers a medical crisis team response, (2) a medical crisis team response available at all times, (3) an evaluation and process improvement system, and (4) an administrative structure to support the system.** After implementation of this system, the investigators reported several quality improvement interventions that were able to be introduced because of case reviews associated with Condition O being invoked, although improvements in particular outcomes were not yet demonstrated.

A different approach is the training for and implementation of standardized communication processes throughout a unit or institution. **One often-cited approach to this type of intervention is Crew Resource Management (CRM). CRM training has been used extensively within the airline industry, where it was noted that accidents were primarily related to lack of coordination and poor teamwork.[30] CRM seeks to engender effective communication through standardized language, situational awareness, briefing and debriefing, and a leveling of hierarchy, allowing all team members to voice concerns about safety.** There is some evidence both from observational longitudinal studies and randomized trials that communication training can improve teamwork and communication among providers.[31,32]

In one longitudinal observational study, the introduction of a CRM course at a single institution was noted to be associated with a 62% reduction in "law suits, claims, and observation" of cases (i.e., those cases in which the insurance carrier reserves money) that were of high severity.[33] However, in the one randomized trial that was performed, and in which this CRM course (i.e., the MedTeams Labor and Delivery Team Coordination Course) was evaluated, investigators reported that institutions that were randomized to the intervention were no more likely to reduce the primary measure of obstetrical adverse outcomes (i.e., mean Adverse Outcome Index) than institutions that received no intervention at all.[34]

Multifaceted Approaches

Some have asserted that the complexity of obstetrical care is such that improvements in safety will come not through the use of one particular intervention but from a multifaceted approach that ultimately results in a fundamental

culture change within an institution. Correspondence with principles of high-reliability organizations have helped to guide some of these efforts. Longitudinal observational studies have suggested that the introduction of such programs is associated with outcome improvements. Examples of such programs have been reported by the following organizations:

- *Catholic Healthcare Partners* (CHP).[35] CHP instituted a program at 16 sites that included interdisciplinary education, routine medical record reviews to monitor ongoing adherence to appropriate practice, and standardization of forms to encourage adherence with best practices. After introduction of this program, birth trauma rates decreased from 5.0 to 0.17 per 1000 births, and the number of adverse obstetrical occurrences (specified as a birth-related event or injury that may lead to a claim) decreased by 65%, from 7.2 to 2.5 per 1000 births.
- *Seton Family Hospitals*.[36] At four sites, this organization began a program that included standardization of forms and care processes, introduction of routine communication processes such as SBAR (situation, background, assessment, recommendation), active surveillance of adverse outcomes with temporally proximate feedback, and interdisciplinary obstetrical crisis simulation with high-fidelity mannequins. Subsequent to the introduction of this program, birth injury rates declined from a 2-year average of 0.3% to 0.08%, and the average length of stay for infants admitted to the neonatal ICU for birth injury declined by 80%.
- *Yale–New Haven Hospital*.[37] This obstetrical department began a program of outside expert review of adverse events, anonymous event reporting, protocol standardization, the creation of a patient safety nurse position and patient safety committee, and training in team skills and fetal heart monitoring interpretation. Introduction of this program was associated with a significant reduction ($P = .01$) in their outcome of choice, the mean quarterly Adverse Outcome Index.
- *Hospital Corporation of America* (HCA).[38] HCA instituted a program including standardized processes, active peer review and feedback, and the empowerment of any member of the health care team to halt care considered possibly dangerous. Subsequent to this program's initiation, there was a significant reduction ($P < .001$) in the number of professional liability claims per 10,000 deliveries.

Summary

It seems clear that at least some of the adverse outcomes that occur in obstetrics are preventable and that the root causes of these preventable events, although many, often involve communication and teamwork. Theory supports several different approaches to error reduction, many of which have been used in obstetrics. **Although some studies have documented improvements in outcomes related to patient safety initiatives, these studies have been predominantly observational and have used different outcomes (e.g., provider satisfaction and perception, demonstration of skill acquisition in simulated scenarios, actual care processes, actual patient outcomes) to assess improvement.** Further work will be necessary to understand best the combination of practices and practice methodologies (e.g., simulation on site versus simulation in a laboratory) that most effectively improves care.

MEASUREMENT OF OBSTETRICAL QUALITY OF CARE

Understanding whether safe care is being provided and whether changes in approaches to patient safety are actually improving the quality of care requires measurement. Examples of patient safety measures include "retained surgical sponge" or "wrong site surgery" rates. In contrast, a quality measure assesses the degree to which maternal and neonatal care is optimized. This section details different approaches to measurement that have been used in an effort to optimize obstetrical care.

Overview

Many types of stakeholders have an interest in high-quality obstetrical care. Patients, physicians, and insurers desire high obstetrical quality at an affordable cost. However, each of these groups may perceive quality differently. Patients want to feel that their physicians are caring individuals and produce good outcomes. Physicians want to be sure that they have the best possible outcome for the patient but also, regardless of outcome, that they are employing best practices. Insurers are primarily concerned with whether the care given is cost effective. Each of these groups wants and needs access to quality measures that reflect their own interests. Thus, one of the first steps in measuring quality is to understand how and by whom the measure will be used.

Type of Quality Measures

There are three major categories of quality measures: structure, outcome, and process.[39] **Structural measures** assume that if the hospital contains high-quality components, the product (medical care) will be of high quality as well. Examples of structural measures include board certification, physician licensure, and hospital accreditation. Structural measures are appealing because they are easy to measure and reproduce. However, although structural measures may reflect that optimal structures are present, these measures do not guarantee that the different components of the hospital will work well together.

Outcome measures, as indicated by their name, reflect patient outcomes. Examples of outcome measures are "the frequency of maternal mortality" and "the frequency of neonatal hypoglycemia." **Because obstetricians generally treat healthy women, adverse outcomes in obstetrics are relatively uncommon. Consequently, the usefulness of many outcome measures (e.g., maternal mortality) may be limited because most hospitals may have none or few of these outcomes to measure.** Furthermore, if outcome measures are to be maximally useful and reflective of the actual care provided at a given institution, they need to reflect outcomes that the institution can actually affect and be **risk-adjusted** in order to account for differences in patient populations that may materially affect the outcome of interest. For example, although "preterm birth" is an adverse outcome, "frequency of preterm birth" may not

be a good measure to reflect a hospital's quality of care given the lack of useful interventions to prevent this adverse outcome. Also, a comparison of hospitals according to their frequency of peripartum hysterectomies may not reflect comparative quality of care if one hospital is much more likely to care for women with abnormal placentation. Finally, outcome measures may pose distinct challenges in obstetrics, when outcomes of two patients, the mother and the baby, occur. Thus, although a hospital may have comparatively good maternal outcomes, it also may have comparatively poor neonatal outcomes, and examination of only one of these sets of outcomes would not fully convey the care environment.

Process measures reflect practices that physicians or hospitals actually employ in their care of patients. An example of a process measure is "the frequency with which known GBS positive women receive appropriate antibiotics." **If a process measure were to conceivably be an adequate reflection of care quality, there should be evidence that the process is related to improved outcomes.** The most central advantage of a process measure is that it gives direct insight into desired actions within the health care system. Correspondingly, these measures give immediately insight into the processes that need to be attended to in order to enhance patient care. Conversely, one of the disadvantages of process measures is that outcomes are often due to the interplay of many different factors and processes, and improvements in these process measures may give false reassurance that improvements in quality of care have been fully realized.

With these considerations in mind, several criteria should be considered in whether a measure meets criteria for a good measure. **A good measures should (1) balance maternal and neonatal outcomes (e.g., not reflect improved care for one member of the mother-child dyad while embodying markedly worse care for the other), (2) have the potential to be altered by behaviors within the health care system of interest, (3) be affordable and applicable for use on a large scale, (4) be acceptable to stakeholders as a meaningful marker of quality, and (5) be reliable and reproducible.**[40]

Attempts to Establish Quality Measures

Because measuring the quality of care is a seminal step in improving patient safety and achieving enhanced quality care, there have been many attempts by a multitude of different organizations to determine quality measures in obstetrics. In lieu of reviewing all current quality measures, we have chosen to present some examples of measures to illustrate the strengths and weaknesses of different choices. The examples include traditional measures as well as those more recently suggested.

Traditional Measures

The more traditional measures often have been raw frequencies of selected adverse outcomes. One example of this type of measure is maternal mortality. It has been used because it is clearly a catastrophic bad outcome and there is little potential for misascertainment. However, in the modern era within developed countries, maternal mortality is so relatively uncommon that it is difficult to use within a hospital or health care system to reflect quality of health care. Many hospitals will have no maternal mortality even over a period of many years, and few hospitals will have a sufficient number of cases to enable them to use this measure to track their adequacy of care delivery. Furthermore, the absence of this outcome does not mandate that good-quality care is being provided; lack of quality care may still exist, and poor outcomes, short of death, may still be present. This does not suggest that any maternal mortality should not be fully investigated as a critical part of quality assurance and improvement efforts, but only that maternal mortality is unlikely to be useful as a quality marker for intrainstitutional quality tracking and interinstitutional comparisons.

Neonatal mortality has also been used as a marker of obstetrical quality. Neonatal mortality may be problematic as a marker for obstetrical quality for several reasons. First, when a neonate dies, it is unclear to what extent obstetrical care, pediatric care, or both may have contributed. Second, a large proportion of mortality is due to prematurity and lethal birth defects, neither of which can be materially affected by obstetrical care.[41] Thus, the residual fraction of obstetrics-related mortality is relatively small and once again may be so uncommon as to limit its use for evaluation of trends or institutional comparisons.

The cesarean delivery rate has been a common measure employed to reflect obstetrical quality of care. Although there is debate about whether cesarean delivery is a process measure or an outcome measure, it is regardless a flawed measure. First, because of perinatal regionalization, women with greater obstetrical complications are concentrated at particular hospitals best suited to providing specialized care. Thus, a comparison of cesarean rates among hospitals without accounting for the differences in patient populations among these hospitals may be misleading. Hospitals with the highest cesarean rates may be giving high-quality care but have high rates because of their patient population. Conversely, a hospital may be giving poor care and have an average rate of cesarean delivery when in fact the cesarean rate should be much lower for their low-risk population.

Newer Approaches to Measures

Although the use of "raw" cesarean rates to measure quality is not ideal, cesarean delivery rates are appealing as a measure because cesarean is an event that is easy to ascertain and is meaningful to multiple stakeholders. One approach to try and account for population differences among institutions is to calculate and use a "risk-adjusted" cesarean rate**. Many different techniques for risk adjustment for cesarean delivery, as well as other obstetrical outcomes, have been described.**[42-47] **Fundamentally, risk adjustment creates a model that predicts what the cesarean rate should be for the particular patient population and allows comparison with the actual rate.** By taking account of differences (such as parity, plurality, and comorbidities) among populations, risk-adjustment seeks to reflect differences in outcomes related to the health care system and not the patients contained within it.

Another approach to determining an outcome measure that is dependent on the health care system rather than the differences in patient populations is to determine an outcome frequency not for all women under care but for a more homogeneous group. Main and colleagues have

suggested, for example, the use of a cesarean rate only among nulliparous women who have a term singleton fetus in the vertex (NTSV) presentation.[48] Using data from the Sutter Health Care network of 20 birthing units, in which more than 40,000 women each year deliver, Main and colleagues determined age-adjusted NTSV cesarean rates. They found that 53% of the variation in NTSV cesarean rates was associated with differences in frequency of labor induction and early admission in labor. This finding suggests that some health care practices are associated with the NTSV cesarean rate. The disadvantage of the NTSV cesarean rate is that it excludes women having preterm deliveries and those who are multiparous, and thus gives no insight into their care.

One process measure that has recently gained attention is a "scheduled elective delivery prior to 39 weeks of gestation." This measure has gained popularity as the risks of early term birth have become better known.[49,50] This process measure has the advantage of being well supported by evidence, reflects a practice under the control of the health care system, and does not require risk adjustment. The difficulty with this measure is the lack of consensus for several indications as to whether or not they are indeed elective.

The frequency with which antenatal corticosteroids are administered to infants who are delivered at less than 34 weeks is another measure that has become widely used. This process measure is appealing because of the data showing that antenatal corticosteroids improve outcomes for premature infants. Nevertheless, this measure does have its disadvantages. Ascertainment of steroid administration, especially in a health care setting without electronic medical records, can be difficult. Steroids given during the pregnancy, but not during the delivery hospitalization, are time intensive to ascertain because inpatient and outpatient records may need to be reviewed. And, although 100% administration is the goal, it is not possible to administer corticosteroids to all women before premature delivery because of late patient arrival or emergent circumstances, such as a maternal trauma.

The frequency of neonates with a birthweight of less than 1500 g born outside of a tertiary care center is one recently suggested process measure that is appealing because it may reflect adequacy of coordination of an entire health care system. Although there are data that very-low-birthweight neonates have worse outcomes when delivered outside of a tertiary care center, many incentives may work against delivery at such a location.[51-53] This measure is easy to calculate from birth certificates, and the items from the birth certificate that are needed to calculate the measure are reliable.[43]

The quality measures discussed thus far have represented inpatient care. Outpatient quality measures do exist, although they are often process measures. An example of such a measure is the frequency with which pregnant women receive HIV screening early in their antepartum care.[54] One difficulty with these measures has to do with accurate ascertainment because prenatal care happens in many different settings and outpatient medical records data are often not in electronic form. Furthermore, although hospitals are required to generate administrative data that can be helpful for measuring inpatient quality, outpatient clinics are not required to generate the same kind of data.

Data Sources

Administrative data (i.e., data collected primarily for billing or nonmedical purposes) are a rich source of information. Administrative data have the advantages of being complete for the population and relatively cheap to use. **Unfortunately, administrative data often lack the clinical detail needed to make meaningful quality judgments.**[55] Paper-based medical records contain clinical detail but are hard to obtain in a uniform manner for a population and are expensive to collect.

Increasingly, electronic medical records have been used to provide the basis for quality measures. These data are easy to collect within an institution and have clinical detail. However, because there are many different types of electronic medical records systems, collating medical records information from many sources can be time intensive. **Electronic medical records also can have the advantage of linking outpatient and inpatient information, something that is very difficult to do with administrative data or paper-based medical records.** The types of information that are available from electronic medical records will increase and improve with time, and there is hope that eventually vital statistics records will be based on actual medical records rather than data extraction, thereby making birth certificate data a richer, more accurate source of medical data.

Quality Improvement

The main point of measuring quality of care is to use the measurements to improve care. Quality measurement tools allow stakeholders to assess the effects of changes in the system. **There are many ways to accomplish improved quality of care with measurement, but one of the most effective is benchmarking.**[56] **Benchmarking, also known as audit and feedback, is a technique whereby quality is measured, compared with like entities, and then shared back with the participants, often in a blinded manner.** For example, NTSV rates for all the hospitals in a city would be calculated. Each hospital would then receive a graph showing their rate (unblinded) compared with the rates of all the other hospitals (blinded) in the city.

One example in which this technique has been used and believed to be helpful was in the Ohio Perinatal Quality Collaborative.[57] This was a group of 20 hospitals in Ohio that came together to share data and compare techniques on how to lower the frequency of scheduled deliveries before 39 weeks' gestation without documentation of a medical indication. Each hospital collected data on the scheduled deliveries 36 0/7 to 38 6/7 weeks in their own institution and submitted the data to a central location for data collation. This data center then created reports that showed each hospital their own rate compared with the rates of all the other hospitals. Each hospital took that information and designed their own program to lower their frequency. There were monthly phone calls for hospitals to share their designs and progress. At the initiation of the project, 25% of scheduled deliveries between 36 and 38 6/7 weeks did not have a documented medical indications; this frequency was lowered to less than 5% ($P < .05$) after 1 year. It was estimated that approximately 1000 births

were moved from between 36 0/7 and 38 6/7 to over 39 weeks' gestation in the state of Ohio during the 12 months of this effort.

Summary

No one measure of quality is perfect, and a variety of quality measures will be needed to give a complete picture of the quality of obstetrical care.[58] Structure, process, and outcomes measures all have a role in measuring quality of care and moving toward optimal health care delivery. Hospitals, providers, patients, and insurers can use these different types of measures to help track the care being provided and better understand the areas that need to be targeted for improvement.

KEY POINTS

- A proportion of adverse obstetrical events have been shown to be preventable; this proportion varies with the clinical circumstances.
- Although multiple factors have been associated with the occurrence of adverse obstetrical events, issues with communication have been implicated as a frequent contributor.
- Because different factors contribute to patient safety, efforts to improve safety may require multiple different approaches.
- Specific approaches that have been considered to enhance obstetrical patient safety include checklists and protocols, simulation, and teamwork training.
- Further investigation is required to understand what approaches, and combinations of approaches, most improve clinical care and outcomes.
- Quality measure assesses the degree to which maternal and neonatal care is optimized.
- Major categories of quality measures include structural, process, and outcome measures.

Abortion Politics and National Health Insurance Reform 1204
Human Embryonic Stem Cell Research Funding 1205
Genetic Counseling, Screening, and Prenatal Diagnosis 1207
Genetic Screening 1207
Forced Cesarean Delivery 1209

Society has great expectations that modern medical technologies will improve longevity and quality of human life, and nowhere are these expectations higher than in the practice of obstetrics and the desire and expectation of having a healthy child. Along with the rapidly expanding capabilities in diagnosis and treatment, physicians find themselves facing numerous ethical dilemmas while practicing in a legal and social climate in which malpractice suits can threaten even the most competent and conscientious practitioner.

We cannot address in a single chapter the wide variety of ethical and legal controversies facing contemporary obstetrical practice and research. Instead, we focus on selected topics of particular relevance to the practicing obstetrician.

REPRODUCTIVE LIBERTY*

Although only about one in four pregnancies ends in elective abortion, abortion has been the most controversial and political medical procedure in the United States for the past four decades. The political debate over abortion has shifted among various dichotomous views of the world: life versus choice, fetus versus woman, fetus versus baby, constitutional rights versus states' rights, government versus physician, physician and patient versus state legislature. Most recently, in 2010, the abortion debate came close to derailing the Affordable Care Act, and was also the basis for an injunction temporarily halting National Institutes of Health (NIH) funding of human embryonic stem cell research. Because the 1973 U.S. Supreme Court opinion of *Roe v. Wade* remains so central to the law (and ethics) regarding the physician-patient relationship, as well as federal financing and regulation of clinical medicine and research, it is essential that obstetricians have a clear understanding of *Roe* and its enduring influence on patient rights—especially reproductive liberty, medical practice, and politics.[1]

Hundreds of statutes (including relatively new ones requiring ultrasound images of the fetus be made available to pregnant women before abortion, and suggesting that 20-week-old fetuses feel pain), and almost two dozen Supreme Court decisions on abortion later, the core legal aspects of *Roe v. Wade*,[2] the most controversial health-related decision by the Court ever, remain substantially the same as they were in 1973. Attempts to overturn *Roe* in both the courtroom and the legislature have failed, although they continue. **Pregnant women still have a constitutional right to abortion. The fetus is still not a person under the Constitution.** States still cannot make abortion a crime (either for the woman or the physician) before the fetus becomes viable (with the exception of the use of a specific procedure labeled "partial-birth abortion" by Congress). States still can outlaw abortion after the fetus becomes viable only if there is an exception that permits abortion to protect the life or health of the pregnant woman. And states still can impose restrictions on abortion before fetal viability only if those restrictions do not actually create a substantial obstacle to a pregnant woman's obtaining an abortion.

The first case to embrace the concept of reproductive liberty was *Griswold v. Connecticut*, in which the Court ruled in 1965 that a Connecticut statute criminalizing the use of contraceptives violated the constitutional right to privacy that married couples had in sexual relations.[3] Later, in 1972, the Court found that even outside marriage, a person had a "right to privacy…to be free from unwarranted governmental intrusion into matters so fundamentally affecting a person as the decision to bear or beget a child."[4] The following year, in *Roe*, the Court struck down a Texas law that made it a crime for physicians to perform an abortion unless it was necessary to save the life of the patient; there were no exceptions for the woman's health. The Court held that women have a constitutional right of privacy that is fundamental and "broad enough to encompass a woman's decision…to terminate her pregnancy."[2] Because the right is fundamental, states that wish to restrict abortion rights were required to demonstrate a compelling interest to restrict the exercise of this right. The Court ruled that the

*This section is adapted from Annas,[1] with permission.

state's interest in the life of the fetus became compelling only at the point of viability, defined as the point at which the fetus can survive independently of its mother. Even after the point of viability, the state cannot favor the life of the fetus over the life or health of the pregnant woman. Under the right of privacy, physicians must be free to use their "medical judgment for the preservation of the life or health of the mother."[2] On the same day that the Court decided *Roe*, it also decided *Doe v. Bolton*,[5] in which the Court defined health very broadly: "The medical judgment may be exercised in the light of all factors—physical, emotional, psychological, familial, and the woman's age—relevant to the well-being of the patient. All these factors may relate to health. This allows the attending physician the room he needs to make his best medical judgment."[5]

Roe and *Doe* together established that both physician and patient were protected by the constitutional right of privacy. In later cases, the Court continued to defer to the medical judgment of the attending physician. For example, in 1976 in *Planned Parenthood of Central Missouri v. Danforth*, the Court concluded that state legislatures could not determine when viability occurred; rather this "essentially medical concept…is, and must be, a matter for the judgment of the responsible attending physician."[6] This remains the case today; even as viability in general moves earlier in the pregnancy, it is not up to legislatures or courts to determine when an individual fetus is viable by drawing a line based on the age of the fetus—the viability of a specific fetus remains a matter of medical judgment to be determined by the attending physicians in a manner consistent with good and accepted obstetrical practice. **By the end of the 1980s, a pattern in Court decisions could be discerned in which abortion regulations that significantly burdened a woman's decision, treated abortion differently from other similar medical or surgical procedures, interfered with the exercise of professional judgment by the attending physician, or were stricter than accepted medical standards were struck down by the Court.**[7] Privacy as a constitutional right became a one-word description of liberty to make decisions regarding marriage, procreation, contraception, sterilization, abortion, family relationships, child rearing, and sexual relationships free of governmental interference.

One strategy to change *Roe* was to change the composition of the Supreme Court by appointing anti-*Roe* justices. Because of new justices on the Court in 1992, in *Casey*, the Court had its first real opportunity to overturn *Roe v. Wade*. Many Court observers thought it would. Instead, in an unusual procedure for the Court, three potentially anti-*Roe* justices, Justices Sandra Day O'Connor, David Souter, and Anthony Kennedy, joined together to write a joint opinion confirming the "core holding" of *Roe*. (They were joined in most of their opinion by two justices who would have simply upheld *Roe*, making this a 5-to-4 decision.) Most centrally, the authors of the joint opinion believed that although the pressure to overrule *Roe* had grown "more intense," doing so would severely and unnecessary damage the Court's legitimacy by undermining "the Nation's commitment to the rule of law."[8] Specifically, the three justices wrote that they were reaffirming "*Roe*'s essential holding" that before the point of viability a woman has a right to choose abortion without undue state interference, that after the point of viability the state can restrict abortion "if the law contains exceptions for pregnancies which endanger the woman's life or health," and that "the state has legitimate interests from the outset of the pregnancy in protecting the health of the woman and the life of the fetus that may become a child." The Court applied these principles to uphold laws mandating much more detailed requirements for abortion, as well as a mandatory 24-hour waiting period, but struck down a spousal-notification requirement as an "undue burden." Thus, **after *Casey, Roe* stood for the proposition that pregnant women have a "personal liberty" right ("privacy" went unmentioned) to choose to terminate their pregnancies before the point of viability and that the state cannot "unduly burden" such a right by erecting barriers that effectively prevent the exercise of that choice.**[9] Of course, a major problem was definitional: burdensome regulations were acceptable, "unduly burdensome" ones were not—but it was not clear what qualified as which. Put another way, the state could demonstrate its concern for fetal life by requiring that physicians make women seeking abortions jump through new and burdensome hoops (including offers of detailed and accurate information on abortion, the status of the fetus, adoption, sources of help for childbirth, and a 24-hour waiting period), as long as doing so did not "unduly burden" women by actually preventing them from being able to make a decision to have an abortion. With the loss of a realistic expectation in 1992 that the Court would overrule *Roe* wholesale without significant changes in the Court's membership, **anti-*Roe* advocates switched strategies dramatically, focusing on criminalizing a specific procedure that they believed would horrify most Americans and that they labeled "partial-birth abortion."** The first such bill passed Congress in 1996 and was vetoed by President Bill Clinton because the prohibition did not contain an exception for the health of the woman, as required by *Roe* and *Casey*. In 1997, this time with the support of the American Medical Association, the bill passed Congress again. President Clinton vetoed it, again for failure to contain a health exception.[10]

Proponents of the ban took their cause to the individual states, most of which enacted substantially identical laws. In 2000, Nebraska's partial-birth abortion law reached the Supreme Court. The Nebraska law carried a penalty of up to 20 years in prison for physicians who performed the procedure. The law reads in relevant part:

> No partial-birth abortion shall be performed in this state, unless such a procedure is necessary to save the life of the mother whose life is endangered by a physical disorder, physical illness, or physical injury, including a life-endangering physical condition caused by or arising from the pregnancy itself.
>
> [A "partial-birth abortion" is] an abortion procedure in which the person performing the abortion partially delivers vaginally a living unborn child before killing the unborn child and completing the delivery.…[The statute further defines the phrase "partially delivers vaginally a living unborn child before killing the unborn child" as] deliberately and intentionally delivering into the vagina a living unborn child, or a substantial portion thereof, for the purpose of performing a procedure that the person performing such procedure knows will kill the unborn child and does kill the unborn child.

This ban applies throughout pregnancy and has no exception to protect the woman's health, only to save her life. In a 5-to-4 opinion in *Stenberg v. Carhart*,[11] the Court found this law unconstitutional for two reasons. First, the description of the banned procedure was too close to dilation and evacuation (D&E), another procedure that was permitted by the law and widely used for second-trimester abortions. Therefore, this law would discourage physicians from using the lawful procedure, which would place an undue burden on their patients. Second, the law failed to provide an exception for instances in which the procedure was deemed necessary by the physician to protect the woman's health, as required by *Roe* and *Casey*. Justice John Paul Stevens, in his concurring opinion, noted that the extreme anti-*Roe* rhetoric as exemplified in the partial-birth abortion debate obscured the fact that during the 27-year period since *Roe* was decided, the core holding of *Roe* "has been endorsed by all but 4 of the 17 Justices who have addressed the issue."

A notable dissenting opinion was written by Justice Kennedy, who had specifically endorsed the core of *Roe* in *Casey*. Kennedy argued that the outlawing of "partial-birth abortion" was consistent with *Casey* because of the interest the state has throughout pregnancy in protecting the life of the fetus that may become a child. In his view, the banned procedure conflates abortion and childbirth in a way that "might cause the medical profession or society as a whole to become insensitive, even disdainful, to life, including life of the human fetus." He also argued that such a ban was not unduly burdensome to women because state legislatures can determine that specific medical procedures, like this one, are not medically necessary.[11]

Justice Stephen Breyer, the author of the *Stenberg* majority opinion, stated that a more precise law, with a health exception, could be constitutional.[11] In 2003, Congress passed a slightly revised law. It did not contain a health exception, but its preface did contain a declaration that the outlawed procedure was never medically necessary for the health of the woman. President Bush signed it into law on November 5, 2003. By the time the Court ruled on the constitutionality of this law in April 2007, in *Gonzales v. Carhart*,[12] there were two important changes in the composition of the Court: a new chief justice, John Roberts, who replaced the consistently anti-*Roe* Chief William Rehnquist, and Justice Samuel Alito, who replaced Justice Sandra Day O'Connor, who was consistently pro-*Roe* (as interpreted in *Casey*). The federal law provides that

> (a) Any physician who, in or affecting interstate or foreign commerce, knowingly performs a partial birth abortion and thereby kills a human fetus shall be fined under this title or imprisoned not more than 2 years, or both. This subsection does not apply to a partial birth abortion that is *necessary to save the life of a mother* whose life is endangered by a physical disorder, physical illness, or physical injury, including a life-endangering physical condition caused by or arising from the pregnancy itself.…
>
> (b) (1) The term "partial-birth" abortion means an abortion in which the person performing the abortion
>
> (A) *Deliberately and intentionally* vaginally delivers a living fetus until, in the case of a head-first presentation, the *entire fetal head is outside* the body of the mother, *or*; in the case of breech presentation, *any part of the fetal trunk past the navel is outside* the body of the mother, for the purpose of performing an overt act that the person knows will kill the partially delivered living fetus; and
>
> (B) Performs the overt act, other than completion of delivery, that kills the partially delivered living fetus [emphasis added].

The Court decided, 5 to 4, that this law was constitutional.[12] Justice Kennedy wrote the majority opinion for himself, Justices Antonin Scalia and Clarence Thomas, and the two new justices. In it he substantially adopts his dissenting opinion in *Stenberg* as the Court's new majority opinion. Although he concludes that his decision is consistent with *Stenberg*, all three U.S. District courts and all three Courts of Appeal that had examined this federal law found it unconstitutional under the principles in *Casey* and *Stenberg*, primarily because of the vagueness of the definition and the lack of a health exception. As to the vagueness argument, Kennedy writes that the new law is no longer vague because it clarifies the distinction between the prohibited procedure (which he calls "intact D&E") and standard D&E abortions because the former requires the delivery of an intact fetus, whereas the latter requires "the removal of fetal parts that are ripped from the fetus as they are pulled through the cervix." In addition, the new federal law specifies fetal landmarks (e.g., the "navel") instead of the vague description of a "substantial portion" of the "unborn child."

Because the law applies to fetuses both before and after the point of viability, Kennedy concedes that under *Casey* the law would be unconstitutional "if its purpose or effect is to place a substantial obstacle in the path of a woman seeking an abortion before the fetus attains viability." Kennedy finds Congress's purpose is twofold: first, lawmakers wanted to "express respect for the dignity of human life" by outlawing "a method of abortion in which a fetus is killed just inches before completion of the birth process," because use of this procedure "will further coarsen society to the humanity of not only newborns, but of all vulnerable and innocent human life.…" Second, Congress wanted to protect medical ethics, finding that this procedure "confuses the medical, legal and ethical duties of physicians to preserve and promote life.…"

The key to Kennedy's legal analysis is his conclusion that these reasons are constitutionally sufficient to justify the ban because under *Casey*, "the State, from the inception of pregnancy, maintains its own regulatory interest in protecting the life of the fetus that may become a child [and this interest] cannot be set at naught by interpreting *Casey's* requirement of a health exception so it becomes tantamount to allowing the doctor to choose the abortion method he or she might prefer." Kennedy then goes on to write that "respect for human life finds an ultimate expression in the bond of love the mother has for her child," and that "while no reliable data" exist on the subject, "it seems unexceptionable to conclude some women come to regret their choice to abort the infant life they once created and sustained.… Severe depression and loss of esteem can follow." Such regret, Justice Kennedy believes, can be caused or exacerbated if women later learn what the procedure entails, suggesting that physicians fail to describe it to patients because they "may prefer not to disclose

precise details of the means [of abortion] that will be used.…"

The final, critical issue is whether the prohibition would "ever impose significant health risks on women" and whether physicians or Congress should make this determination. Kennedy picks Congress: "The law need not give abortion doctors unfettered choice in the course of their medical practice, nor should it elevate their status above other physicians in the medical community.…Medical uncertainty does not foreclose the exercise of legislative power in the abortion context any more than it does in other contexts." Furthermore, Kennedy argues, the law does not impose an "undue burden" on women for another reason: alternative ways of killing a fetus have not been prohibited. In his words, "If the intact D&E procedure is truly necessary in some circumstances, it appears likely an injection that kills the fetus is an alternative under the Act that allows the doctor to perform the procedure."[12]

Writing for the four justices in the minority, Justice Ruth Bader Ginsburg observes, "Today's decision is alarming. It refuses to take *Casey* and *Stenberg* seriously. It tolerates, indeed applauds, federal intervention to ban nationwide a procedure found necessary and proper in certain cases by the American College of Obstetricians [and Gynecologists] (ACOG). It blurs the line, firmly drawn in *Casey*, between previability and postviability abortions. And, for the first time since *Roe*, the Court blesses a prohibition with no exception safeguarding a woman's health." Ginsburg argues that the majority of the Court has overruled the conclusion in *Stenberg* that a health exception is required when "substantial medical authority supports the proposition that banning a particular abortion procedure could endanger women's health.…" This conclusion, bolstered by evidence presented by nine professional organizations, including the ACOG, and conclusions by all three U.S. District Courts that heard evidence concerning the Act and its effects, directly contradicted the congressional declaration that "there is no credible medical evidence that partial-birth abortions are safe or are safer than other abortion procedures." Even Justice Kennedy agreed that Congress's finding was untenable.

Justice Ginsburg concludes that this leaves only "flimsy and transparent justifications" for upholding the ban. She rejects those justifications, arguing that the state's interest in "preserving and promoting fetal life" cannot be furthered by a ban that targets only a method of abortion and that cannot save "a single fetus from destruction" by its own terms but may put women's health at risk. Ultimately, she believes that the decision rests entirely on the proposition, never before enshrined in a majority opinion and explicitly repudiated in *Casey*, that "ethical and moral concerns" unrelated to the government's interest in "preserving life" can overcome what had been considered fundamental rights of citizens. The majority seeks to bolster its conclusion by describing pregnant women as in a fragile emotional state that physicians may take advantage of by withholding information about abortion procedures. Justice Ginsburg concludes that the majority's solution to this hypothetical problem is to "deprive women of the right to make an autonomous choice, even at the expense of their safety." She continues, "This way of thinking [that men must protect women by restricting their choices] reflects ancient notions about women's place in the family and under the Constitution—ideas that have long since been discredited." Ginsburg further notes that the majority simply cannot contain its hostility to reproductive rights as articulated in *Roe* and *Casey*, calling physicians "abortion doctors," describing the fetus as an "unborn child" and as a "baby," labeling second-trimester abortions as "late term," and dismissing "the reasoned medical judgments of highly trained doctors…as 'preferences' motivated by 'mere convenience.'"[12]

Ginsburg makes two final points. First, although the Court invites a lawsuit to challenge the Act "as applied," it gives "no clue" as to how such a lawsuit should be brought. Surely, she asks, "the Court cannot mean that no suit to challenge the ban [based on how it affects an actual woman or her physician] may be brought until a woman's health is immediately jeopardized." Second, she argues that the opinion threatens to undercut the "rule of law" and the "principle of stare decisis," both of which the Court affirmed in *Casey*, concluding that, "A decision so at odds with our jurisprudence should not have staying power." As described in *Casey*, stare decisis is a doctrine that obligates courts to follow the principles set forth in prior cases, called precedents, to assure continuity in the law, and precedents should not be abandoned under "political pressure" or as an "unprincipled emotional reaction."

The major change in the law this opinion brings with it is the new willingness of Congress and the Court to discount the health of pregnant women and the medical judgment of their physicians.[13] This departure from precedent was made possible by categorizing physicians as unprincipled "abortion doctors" and infantilizing pregnant women as incapable of making serious decisions about their lives and health. The majority opinion ignores or marginalizes long-standing principles of constitutional law, substituting the personal morality of Justice Kennedy and four of his colleagues.

The majority asserts that giving Congress constitutional authority to regulate medical practice is not new but identifies no case in which Congress had ever outlawed a medical procedure. Its reliance on the more than 100-year-old case of *Jacobson v. Massachusetts* is especially inapt.[14] *Jacobson* was about mandatory smallpox vaccination during an epidemic. Refusal was punishable by a fine. The statute had an exception for "children who present a certificate, signed by a registered physician, that they are unfit subjects for vaccination," and the Court implied that a similar medical exception would be constitutionally required for adults. It is not just abortion regulations that have had a health exception for physicians and their patients—all health regulations have.[15]

On the other hand, **those who expect *Roe* to be overturned by this Court may be disappointed.** Although Justice Alito has replaced Justice O'Connor and is likely to vote in the opposite direction on *Roe*-related issues, Justice Kennedy is the new swing vote on the Court, and he insists that he is upholding the principles of *Roe v. Wade* as reaffirmed in *Casey*. Just as the question of whether a specific abortion regulation was an "undue burden" was once a determination Justice O'Connor could effectively make for the Court, the meaning of *Roe v. Wade* is, at least for

now, up to Justice Kennedy. The replacement of two Pro-*Roe* Justices (Souter and Stevens) with Sonia Sotomayor and Elena Kagan during the first 2 years of the Obama administration has made no change in this balance. On the other hand, the Court has become so political in the past decade that the replacement of any one of the five justices who currently support the "core" of *Roe* with an anti-*Roe* justice (which is very unlikely to happen during Obama's presidency) could result in *Roe* being overturned, and the contours of abortion law would then be returned to the individual states—some of which would outlaw abortion, but most of which would retain the law substantially as it now is.

ABORTION POLITICS AND NATIONAL HEALTH INSURANCE REFORM*

President Barack Obama made it clear during the great debate on health insurance reform that he did not want abortion politics to sabotage his legislation. In his September 10, 2009 speech about health insurance reform to a joint session of Congress, he said, "Under our plan, no federal dollars will be used to fund abortions." Nonetheless, the centrality of abortion in U.S. politics made it inevitable that abortion funding would play a major role in determining whether there was any health insurance reform law at all. The debate revolved around the Stupak amendment in the House of Representatives, which provided that "No funds authorized or appropriated by this Act…may be used *to pay for any abortion or to cover any part of the costs of any health plan that includes coverage of abortion*, except in the case where a woman suffers from a physical disorder, physical injury, or physical illness that would, as certified by a physician, place the woman in danger of death unless an abortion is performed, including a life-endangering physical condition caused by or arising from the pregnancy itself, or unless the pregnancy is the result of rape or incest" (italics added). The House passed this amendment by a vote of 240 to 194, with 64 Democrats voting in favor (the House health care bill itself passed 220 to 215). Many thought that the Catholic bishops who lobbied fervently for passage of the Stupak amendment were the most influential in supporting it. More influential, however, were the previously secret fundamentalist Christian political leadership group known variously as the Family or the Fellowship, which includes among its members both of the amendment's main sponsors, Bart Stupak (D-MI) and Joe Pitts (R-PA).[16]

The Stupak amendment was defended as merely continuing the practice created by the Hyde amendment. That amendment, named after the late Congressman Henry Hyde (R-IL), which has been attached to every Health and Human Services Appropriations Act passed since 1976 (and has also been added to appropriations legislation for the Defense Department, the Indian Health Service, and federal employees' health insurance plans) prohibits the use of federal funding for "any abortion" or for any "health benefits coverage that includes abortion," unless the pregnancy is the result of "rape or incest" or "would, as certified by a physician, place the woman in danger of death unless an abortion is performed." Under the Hyde amendment, states may use their own funds to finance abortion services through their Medicaid programs, and 17 states currently do so.

The U.S. Supreme Court has ruled on the constitutionality of limiting government funding for abortion twice. The first case, in 1977, involved a Connecticut regulation that limited state Medicaid funding to "medically necessary" abortions, thus excluding those not necessary to preserve a woman's life or health. The Court ruled that women have a constitutional right to choose to have an abortion, but the state has no obligation to pay for the exercise of this right and may constitutionally encourage women to continue their pregnancies to term by providing funding for childbirth and not abortion. The state may not constitutionally create obstacles to abortion, but it has no obligation to remove obstacles, such as poverty, that are not of its own making.[17]

Three years after the Connecticut decision, **the Court upheld the Hyde amendment, which prohibited federal funding for medically necessary abortions.[18] Under this ruling, even low-income women who would have devastating health outcomes if they continued a pregnancy could not have an abortion paid for by Medicaid.** In both cases, the Court ruled that the government could make "a value judgment favoring childbirth over abortion and [implement] that judgment by the allocation of public funds." There is no constitutional requirement for the federal government to fund any abortion. Federal funding is a political question to be decided by Congress.

The U.S. Senate bill on health insurance reform, which Majority Leader Harry Reid (D-NV) created by blending bills from two committees, did not contain the Stupak amendment but specifically excluded federal funding for abortions as prohibited by any federal law (including the Hyde amendment) that was in effect "6 months before the beginning of the plan year involved." States must also ensure that "no federal funds pay or defray the cost" of abortion services in new health plans that cover abortion. Moreover, states are required to offer at least two plans in the proposed health insurance exchanges (where most people who currently lack coverage will purchase insurance): one that covers abortion services and one that does not. Nonfederal funds for abortion coverage in any plan must be segregated, and payment must be made separately, in an amount estimated by the secretary of health and human services, to cover this benefit.

Three major questions were raised about the differences between the House and Senate approaches: Did they fulfill Obama's no-federal-funding promise? Did they follow the Hyde amendment "tradition"? And did they represent good health insurance policy? As for the first question, the Senate version fulfilled the President's promise by requiring abortion funding to come from sources other than federal tax dollars. This aspect of the provision was denigrated as a "bookkeeping trick," but all payments involve bookkeeping. Even federal employees who pay for abortions with their government salaries are using funds that came from federal tax dollars. As for the second question, the Stupak amendment goes far beyond the Hyde amendment by prohibiting the use of federal tax

*This section is adapted from Annas,[16] with permission.

dollars not only for abortion itself but also for any health plan available on the proposed exchanges that covers abortion. The goal is to limit access to abortion, even when no federal funds are being used for it. The third question relates to public health policy. The Hyde amendment institutionalizes the moral view of some members of Congress that even medically necessary abortions should not be considered health care. This view, for example, led Congress to criminalize an abortion procedure (designated "partial-birth abortion," discussed previously) without an exception for the health of the pregnant woman. These are the types of federal government intrusions into health care that opponents of public insurance plans usually decry.

After the Democrats lost Ted Kennedy's Senate seat in a special election in Massachusetts (and with it the 60 votes needed to end a filibuster), the bill previously passed by the Senate became the vehicle for health insurance reform, and a budget "reconciliation" measure (requiring only 51 votes for Senate passage), negotiated by Democratic House and Senate leaders, was used to make modifications to the Senate bill to make it acceptable to the House.

Because the Stupak-Pitts abortion language was not in the Senate bill, it was uncertain whether the 216 House votes needed for passage could be found. **Stupak himself ultimately agreed to vote for the Senate bill as long as President Obama signed an executive order agreeing not to use any aspect of the legislation to fund abortions.** The bill ultimately passed 219 to 212, which suggests that the votes of Stupak and his colleagues were essential. President Barack Obama signed the order on March 24, at a private White House event.

The order aims to "establish an adequate enforcement mechanism to ensure that Federal funds are not used for abortion services (except in cases of rape or incest, or when the life of the woman would be endangered), consistent with a longstanding Federal statutory restriction that is commonly known as the Hyde Amendment." In addition to this general language, the order contains specific language on the two areas of the health care bill that have continued to foster controversy: abortion coverage by insurance policies to be offered on the future health insurance exchanges, and the possibility that community health centers will use new funds provided under the act to offer abortion services. As to the former, the order requires, as in the Senate bill, that any payment for abortion coverage not consistent with the Hyde Amendment be made with private segregated funds. To clarify how that can be done, the executive order requires the director of the Office of Management and Budget and the secretary of health and human services "to develop, within 180 days…a model set of segregation guidelines for State health insurance commissioners to use" to determine whether exchange plans are in compliance with the act. These guidelines will then go through the process of becoming federal regulations with the force of law.

Conservative critics of the executive order argued that to be upheld in the courts it must be consistent with current law. It is, so that's not an issue. They also argued that the President could rescind it at any time. Although this is true as a matter of law, it is not as a matter of politics. If Obama did not intend to follow the law, he would have issued a "signing statement" (as president George W. Bush did for almost every portion of every bill he signed into law to which he objected), not a pledge to enforce it. The executive order will be in place as long as President Obama is in office, and no Republican president is likely to change it. Barring some extraordinary event, the order and its resulting regulations will be the rule for federal funding of abortion services for the foreseeable future. The National Organization for Women has indicated that it will campaign for the repeal of the Hyde Amendment. It seems unlikely that such a campaign could succeed, although a more modest one, aimed at expanding the exceptions permitted to include, for example, serious fetal disorders, might. Soon after the passage of the Affordable Care Act, abortion politics shifted to stem cell research and a "companion" funding restriction amendment to the Hyde Amendment: the Dicky-Wicker Amendment.

HUMAN EMBRYONIC STEM CELL RESEARCH FUNDING*

Embryo research was born political. Expressions of shock and surprise at the August 23, 2010 ruling of federal district court judge Royce Lamberth enjoining federal funding of stem cell research—which was based largely on his reading of an amendment to an appropriations bill—were thus not terribly persuasive.[19,20] The amendment, known as the **Dickey-Wicker amendment, provides that no federal funds can be expended by the NIH for "(1) the creation of a human embryo or embryos for research purposes; or (2) research in which a human embryo or embryos are destroyed, discarded, or knowingly subjected to risks of injury or death."** The creation and destruction of human embryos for research are deeply tied not only to political and religious debates concerning abortion but also to in vitro fertilization (IVF). In 1979, during the Carter administration, the Ethics Advisory Board of the Department of Health, Education, and Welfare (forerunner of the Department of Health and Human Services) recommended that the government support research on embryos in order to study and improve IVF. Federal research funding was never authorized, and IVF was introduced to clinical medicine without a research phase. The Reagan administration dissolved the ethics board and ignored its recommendations. The issue was next taken up during the Clinton administration by an NIH Human Embryo Research Panel, which voted on 27 goals of embryo research and recommended 7 as "acceptable for federal funding" —but failed to produce a credible ethical justification for its recommendations, which were widely ignored.[21] Congress, however, responded to the report, and in 1996 President Clinton signed the first appropriations bill containing the Dickey-Wicker amendment, named for its sponsors, Representatives Jay Dickey (R-AR) and Roger Wicker (R-MS). It has been added to NIH appropriations bills every subsequent year, just as the Hyde Amendment restricting abortion funding is added.

*This section is adapted from Annas,[20] with permission.

The derivation of stem cells from embryos involves destroying the embryo. In 2001, President George W. Bush authorized federal funding for human embryonic stem cell (ESC) research but limited it to cell lines that had been derived before his August 9, 2001 speech—and specifically to cell lines from surplus IVF embryos used with the consent of the couple whose egg and sperm were used to create them. No one challenged this policy as a violation of Dickey-Wicker, perhaps because, as Bush said, the "life and death decision" for these embryos had already been made.

President Barack Obama was well aware that federal funding of ESC research represents a political flash point, but he had promised to rescind the Bush policy, and there is wide support for expanded federal funding of ESC research. When Obama announced his new policy authorizing funding for cell lines derived after August 2001 (if derived from surplus IVF embryos, without the use of federal funds), he knew he could be reawakening the funding debate. He expressed his hope that "Congress will act on a bipartisan basis to provide further support for this research."

Congress did not act. Instead, the debate shifted to the courts, where the core question is whether the new Obama guidelines are consistent with Dickey-Wicker. Although he has not (as of this writing) decided this question, Lamberth has said he believes Dickey-Wicker is "unambiguous" and does not permit the NIH "to separate the derivation of ESCs from research on the ESCs," because "derivation of ESCs from an embryo is an integral step in conducting ESC research."[19] Whether he will change his mind after briefing, argument, and perhaps testimony—or whether the Court of Appeals will rule otherwise—remains to be seen. **The Obama administration's new guidelines are based on the political compromise of deriving ESCs only from surplus IVF embryos, and as part of this compromise, the NIH seemed to have conceded that derivation is an integral part of stem cell research, which is why it sets strict limits on the source of the embryos used and the quality of consent obtained.** The political argument for permitting the use of surplus IVF embryos is that these embryos were created for a legitimate reproductive purpose, and when they're no longer wanted for that purpose, their donation for research is ethically preferable to their destruction without any potential societal benefit.[21] Of course, anyone who objects to the creation of embryos for IVF would also object to this compromise. Does Dickey-Wicker permit this political compromise as a matter of law?

President Clinton's National Bioethics Advisory Commission argued in 1999 that it was not ethically reasonable to separate the derivation of stem cells for research from their use in research. The commission believed that the federal government should fund both, for at least as long as the embryos used were those "remaining after infertility treatments."[21] Their reasons were "the close connection in practical and ethical terms between derivation and use of the cells" and the hope that permitting funding for cell derivation could advance science in this area. Lawyers asked by the commission to examine the meaning of Dickey-Wicker concluded that the NIH's distinction between derivation and use of human ESCs was a "reasonable" interpretation of the amendment—but that "there is no indication that either proponents or opponents [of ESC research] contemplated the situation…in which research that destroyed the embryo was separately conducted from research using the cells derived from the embryo."[22]

The Clinton panel's report got less attention than it deserved because at that time the national debate was focused on creating research embryos through cloning (somatic cell nuclear transfer). Bush's Council on Bioethics concentrated on cloning, but it was also the only national ethics panel ever to discuss federal funding as an ethical (rather than political) issue. It concluded that "the decision to fund an activity is…a declaration of official national support and endorsement, a positive assertion that the activity in question is deemed by the nation as a whole…to be good and worthy." Such rhetoric seems disconnected from special-interest legislation[23]; a more honest statement regarding federal funding is that since *Roe v. Wade,* funding for anything remotely related to abortion (and since no one is pregnant, embryo research is only remotely related) has become a potent political liability in Congress. Obama's own ethics panel has sensibly stayed out of this political funding debate.

Three paths are open to proponents of federal funding for human ESC research. The first is to mount a vigorous defense in the ongoing lawsuit, aiming to persuade the courts that the Obama administration's interpretation of Dickey-Wicker is correct. As of July 2011 this strategy is succeeding, with the federal Court of Appeals ruling 2 to 1 in 2011 that Dickey-Wicker permitted the funding of research on human ESCs that had been derived from leftover IVF embryos by nonfederal employees who did not use federal money. I think this opinion is solid and will prevail. But because ultimate court victory remains at least somewhat uncertain, the Obama administration could also seek congressional authorization for its current regulations. The vehicle could be a bill proposed by Representative Diana DeGette (D-CO), which authorizes research on stem cells derived from surplus IVF embryos; it has been passed twice (and vetoed by Bush) and would certainly be signed by Obama. Because this approach would retain Dickey-Wicker, however, and could thus lead to more legal challenges, it would be preferable (and probably more politically feasible) to amend Dickey-Wicker by adding language such as the following: "Nothing in part (2) prohibits the NIH from funding research using embryos created for procreation, including the derivation of stem cells, when the couple no longer wants to use them for procreation and has provided their informed authorization for them to be used in NIH-funded research." Doing so would legislatively adopt the ethics position of the Clinton bioethics commission. The third path is continued reliance on private and state funding until sufficient scientific progress is made that the public demands federal funding for this research.

NIH Director Francis Collins has said that this issue "goes beyond politics…to patients and their families who are counting on us to do everything in our power, ethically and responsibly, to learn how to transform these cells into entirely new therapies." This argument, of course, is itself political, and if Collins is right, **the only place to ultimately resolve the funding issue is in Congress.**

GENETIC COUNSELING, SCREENING, AND PRENATAL DIAGNOSIS

All women who rely on a physician for prenatal care should have the right to have the physician fully inform her of any reason the physician has to believe that her fetus might have a disability and to inform her further of the existence of diagnostic tests that might identify the precise condition. The physician incurs this duty to disclose because it is this type of information that the pregnant woman seeks prenatal care to discover (i.e., to learn all she can to help her have a healthy child). It is therefore entirely reasonable for the pregnant woman to expect her physician to apprise her of any relevant information regarding her fetus and options she might have so that she and the child's father can determine what action to take.[24]

If relevant information is not provided to the pregnant woman, and if a child with a serious disability is born, there are two potential types of lawsuits that could be brought against the physician. A wrongful birth suit must allege and prove not only that the physician was negligent in the care of the pregnant woman, but also that had the negligent act not been done the child would not have been born (e.g., had the woman been properly informed that she was at risk to have a child with Down syndrome, she could have sought amniocentesis or chorionic villus sampling and had an abortion if her fetus were so affected). A related but far more controversial lawsuit is brought by the child (through its parents or guardian) against the physician because it was born, a so-called wrongful life suit. Most courts have rejected lawsuits by the child because they thought it was impossible to put a monetary value on life in an impaired condition compared with nonexistence. The choice for these children is *never* to be born healthy, but only to be born with a handicap (such as Down syndrome or Tay-Sachs disease) or not to be born at all. We think that future courts are likely to limit such actions to *serious* handicaps, those in which fetuses, if they could speak to us (which, of course, they can only do through their parents), would agree with an "objective societal consensus" that their own best interest would be served if they were aborted. Put another way, they would be better off *from their own perspective* if they never existed. Conditions like deafness and Down syndrome would not qualify, whereas conditions like Tay-Sachs would. Measuring damages *is* problematic, but courts are likely to award at least the added medical costs caused by the handicap itself. However, because medical costs can be recovered in a wrongful birth case directly, wrongful life cases are only likely to be brought in those rare instances in which for some reason (e.g., the child has been given up for adoption) the parents have lost the right to sue on their own behalf.[25]

The following conclusions may be drawn regarding the legal and ethical obligations of the obstetrician in relationship to genetic counseling and prenatal diagnosis:

- **First, the law requires physicians to give accurate information to the parents and forbids the withholding of vital information from them.** These principles are consistent with the doctrine of informed consent and the reasonable expectations of pregnant women under a physician's care. The physician does not guarantee a healthy child, but the reasonable expectation of the patient is that she will be apprised of any information the physician has that the child might be seriously disabled and of the alternative ways to proceed so that the patient can determine what action to take.[26]
- Second, no obstetrician can be required to perform chorionic villus sampling, genetic amniocentesis, or fetal DNA analysis. Indeed, many are not qualified to perform these procedures and for them to do so may itself be malpractice.
- Third, genetic counseling should be morally nondirective (to the extent possible); that is, the counselor should remain impartial and objective in providing information that will allow competent counselees to make their own informed decision. The Judicial Council of the American Medical Association[27] has given the following opinion:

> Physicians, whether they oppose or do not oppose contraception, sterilization, or abortion, may decide that they can engage in genetic counseling and screening, but should avoid the imposition of their personal moral values and the substitution of their own moral judgment for that of the prospective parents. The ethical and moral decisions have to be made by the family and should not be imposed by the physician.

- **Fourth, to ensure the patient's interest in both autonomy and privacy, no information obtained in genetic counseling or screening should be disclosed to any third party, including insurers and employers (now prohibited by federal law), without the patient's informed consent.**[28,29] Such strict nondisclosure policies should be maintained unless and until specific state legislation is enacted that would clearly delineate the circumstance in which confidentiality must be breached, analogous to certain contagious diseases, gunshot wounds, and child abuse. On the other hand, counselors should be permitted to attempt to persuade patients to make disclosures of important information to potentially affected relatives if there is a high probability of serious harm and if the disclosure is limited to pertinent genetic information. We recommend that the genetic counselor make clear, both verbally and in writing, the policy that he or she follows so that the patient can refuse to be screened or counseled if he or she is not in agreement with the disclosure policy. Such agreements will serve to heighten the public's confidence in genetic counseling and will encourage people to participate voluntarily in both screening and counseling.

Genetic Screening*

Our ability to translate our expanding genetic knowledge into usable information for individual patients is at best uncertain, as is the future of "personalized medicine." Taking a family history and, when indicated, recommending certain tests to identify carriers of genetic diseases are standard in obstetrical care. Today's screening tests usually focus on conditions that occur either in the family or in the racial or ethnic group of one or both prospective

*This section has been adapted from Elias and Annas,[30] with permission.

parents. As our ability to identify genes associated with particular diseases increases, a panel of screening tests to identify carriers of numerous genes will be offered more routinely. It will then become increasingly difficult, if not impossible, to inform those offered screening or testing for reproductive purposes about all the genetic information that can be obtained and the implications of that information.

Our current model for screening and testing requires pretest counseling.[30] Such counseling is a method of obtaining informed consent, and the obligation to counsel can be seen as inherent in the fiduciary nature of the doctor-patient relationship.[31] For ordinary medical procedures, the physical risks and treatment alternatives are the chief items of information that must be disclosed. There are few physical risks in genetic screening. What must be conveyed in counseling regarding genetic screening is that the tests may yield new information that may ultimately force some unwelcome choices (such as whether to marry, abort, or adopt). **Self-determination and rational decision making are the central values protected by informed consent.**[32] In the setting of reproductive genetics, what is at stake is the right to decide whether or not to have a genetic test, with emphasis on the right to refuse if the potential harm (in terms of stigma or unacceptable choices) outweighs, for the individual person or family, the potential benefit.

As the Human Genome Project bears fruit, hundreds of new genetic screening tests, and even full genome screening, will compete for introduction into routine clinical practice. Already some researchers have suggested population-based screening to identify carriers of the genes for such conditions as the fragile X syndrome and myotonic dystrophy. Each new screening test presents the same questions: What information should be given to which patients, when should it be presented, who should present it, and how and by whom should the results be conveyed? It will soon be impossible to do meaningful prescreening counseling about all available carrier tests. Giving too much information ("information overload") can amount to misinformation and make the entire counseling process either misleading or meaningless. **To prevent disclosure from being pointless or counterproductive, we believe that strategies based on general or "generic" consent should be developed for genetic screening. Their aim would be to provide sufficient information to permit patients to make informed decisions about carrier screening, yet avoid the information overload that could lead to "misinformed" consent.**

Traditionally, goals of reproductive genetic counseling, including counseling about screening carrier status, involve helping the person or family to (1) comprehend the medical fact, including the diagnosis, the probable course of the disorder, and the available management; (2) appreciate the way heredity contributes to the disorder, and the risk for recurrence in specified relatives; (3) understand the options for dealing with the risk for recurrence; (4) choose the course of action that seems appropriate to them in view of their risk and their family goals and act in accordance with that decision; and (5) make the best possible adjustment to the disorder in an affected family member or to the risk for recurrence of that disorder.

For example, in the current context of counseling a couple at least one of whom is of Italian ancestry, each of these issues would be discussed as it relates specifically to α-thalassemia, with explanation of the use of hemoglobin electrophoresis as a screening test to determine carrier status. If consideration of another prenatal test were appropriate—as in the case of screening of maternal serum for α-fetoprotein, human chorionic gonadotropin, and unconjugated estriol to detect fetal aneuploidy, open neural tube defects, and other abnormalities—a separate discussion about these tests, including information on their sensitivity and specificity, and of each of the possible associated fetal disorders would also be required. Even knowledgeable couples could become confused, frustrated, and anxious if faced with scores of such options for genetic screening.

By contrast, **an approach based on generic consent would emphasize broader concepts and common denominator issues in genetic screening.** We envision a situation in which patients would be told of the availability of a panel of screening tests that can be performed on a single blood sample. They would be told that these tests could determine whether they carry genes that put them at increased risk for having a child with a birth defect that could involve serious physical abnormalities, mental disabilities, or both. Several common examples could be given to indicate the frequency and spectrum of severity of each type or category of condition for which screening was being offered. For example, prenatal screening could include tests for fetal conditions such as neural tube defects and chromosome abnormalities such as cystic fibrosis and fragile X syndrome. In the near future, a sample of fetal blood cells may be retrievable from maternal blood to be used not only for estimation of risks but also perhaps for definitive diagnosis.

In the course of such counseling, **important factors common to all genetic screening tests would be highlighted.** Among these are the limitations of screening tests, especially the fact that negative results cannot guarantee a healthy infant; the possible need for additional, invasive tests, such as chorionic villus sampling or amniocentesis, to establish a definitive diagnosis; the reproductive options that might have to be considered, such as prenatal diagnosis, adoption, gamete donation, abortion, or acceptance of risks; the costs of screening; issues of confidentiality, including potential disclosure to other family members; and the possibility of social stigmatization, including discrimination in health insurance and employment. If carrier status is detected in the woman, it must be emphasized that the partner should also be screened. Before prenatal testing was agreed to in such cases, the woman would need to be told that she would be advised to consider abortion if the fetus was found to be affected with a nontreatable condition.

This type of generic consent to genetic screening can be compared with obtaining consent to perform a physical examination. Patients know that the purpose of the examination is to locate potential problems that are likely to require additional follow-up and that could present them with choices they would rather not have to make. The patient is not generally told, however, about all the possible abnormalities that can be detected by a routine physical examination or routine blood work, but only the general

purpose of each. On the other hand, tests that may produce especially sensitive and stigmatizing information, such as screening of blood for the human immunodeficiency virus, should not be performed without specific consent. Similarly, because of its reproductive implications, genetic testing has not traditionally been carried out without specific consent. Even in a generic model, **tests for untreatable fatal diseases such as Huntington disease should not be combined with other tests or performed without specific consent.**[33]

What is central in the concept of generic consent for genetic screening is not a waiver of the individual patient's right to information. Rather, it would reflect a decision by the genetics community **that the most reasonable way to conduct a panel of screening tests to identify carriers of serious conditions is to provide basic, general information to obtain consent for the screening and much more detailed information on specific conditions only after they have been detected.** Since, in most cases, no such conditions will in fact be found, this method is also the most efficient and cost-effective. Some patients require more specific and in-depth information on which to base their decision regarding screening. It is therefore essential to build into the screening program ample opportunity for patients to obtain all the additional information they need to help them make decisions. Clinicians, of course, must be open and responsive to the concerns and questions of patients. Counseling could be provided in person by a physician or other health professional. Alternatively, audiovisual aids could be used, which would help ensure consistency in the information provided, be more efficient, and respond to the shortage of genetic counselors.

Generic consent for genetic screening should help prevent information overload and wasting time on useless information. It would not, however, solve what is likely to be an even more central problem in genetic screening: are there genetic conditions for which screening should not be offered to prospective parents? Examples might include genes that predispose a person to a particular disease late in life (such as Alzheimer disease, Parkinson disease, or breast cancer). From the perspective of the fetus, life with the possibility—or even the high probability—of developing these diseases in late adulthood is much to be preferred to no life at all. Thus, in this case, unlike that of the fetus with anencephaly, for example, no reasonable argument could be made that precluding abortion by denying this information could amount to forcing a "wrongful life" on the child.[31] Because of a personal experience with a friend or family member who suffered from one of these diseases, however, the couple might see abortion as a reasonable choice under such circumstances.

We must address this question directly and publicly. Are there genetic diseases and predispositions for which screening of prospective parents and testing of fetuses should not be offered as a matter of good medical practice and public policy, regardless of the technical ability to screen and the wishes of the couple? Offering carrier screening to assist couples in making reproductive decisions is not a neutral activity but, rather, implies that some action should be taken on the basis of the results of the test. Thus, for example, merely offering screening for a breast cancer or colon cancer gene suggests to couples that artificial insemination, adoption, and abortion are all reasonable choices if they are found to be carriers of such a gene.[34] In general, we do not believe that pregnancies in women who want to have a child should be terminated for this reason, and thus we believe carrier screening for the breast cancer gene should not be offered in the context of reproductive planning, at least outside of preimplantation genetic diagnosis in cases in which a woman is a known carrier and has had personal experience with a strong family history of breast or ovarian cancer. In the absence of an effective way to set the standard of care for carrier screening, however, we recognize that prenatal screening tests for these and similar genes will inevitably be offered by at least some commercial companies and private physicians.

A standard of care for genetic screening and consent in the face of hundreds or thousands of available genetic tests will inevitably be set. We believe the medical profession should take the lead in setting such standards and that, with public input, the model of generic consent for genetic screening will ultimately be accepted.

FORCED CESAREAN DELIVERY

Almost 25 years ago, Kolder and colleagues[35] reported a U.S. national survey revealing that court orders had been obtained for cesarean deliveries in 11 states, for hospital detentions in 2 states, and for intrauterine transfusions in 1 state. Among 21 cases in which court orders were sought, the orders were obtained in 86%; in 88% of those cases, the orders were received within 6 hours. Most of the women involved were black, Asian, or Hispanic, and all were poor. Nearly half were unmarried, and one fourth did not speak English as their primary language. In the survey, they also found that 46% of the heads of fellowship programs in fetomaternal medicine thought that women who refused medical advice and thereby endangered the life of the fetus should be detained. Forty-seven percent supported court orders for procedures such as intrauterine transfusions. Until 1990, with the exception of one case in the Georgia State Supreme Court, all cases had been decided by lower courts and therefore had little precedential importance.[36] In most cases, judges were called on an emergency basis and ordered interventions within hours. The judge usually went to the hospital. Physicians should know what most lawyers and almost all judges know: when a judge arrives at the hospital in response to an emergency call, he or she is acting much more like a lay person than a jurist. Without time to analyze the issues, without representation for the pregnant woman, without briefing or thoughtful reflection on the situation, in almost total ignorance of the relevant law, and in an unfamiliar setting faced by a relatively calm physician and a woman who can easily be labeled "hysterical," the judge will almost always order whatever the doctor advises.

There is nothing in *Roe v. Wade*,[2] or any other appellate decision, that gives either physicians or judges the right to favor the life or well-being of the fetus over that of the pregnant woman. Nor is there legal precedent for a mother being ordered to undergo surgery (e.g., kidney or partial liver transplantation) to save the life of her dying child. It would be ironic and inconsistent if a woman could be forced to submit to more invasive surgical procedures for

the sake of a fetus than a child. Forcing pregnant women to follow medical advice also places unwarranted faith in that advice. Physicians often disagree about the appropriateness of obstetrical interventions, and they can be mistaken.[37] In three of the first five cases in which court-ordered cesarean delivery was sought, the women ultimately delivered vaginally and uneventfully. In the face of such uncertainty—uncertainty compounded by decades of changing and conflicting expert opinion on the management of pregnancy and childbirth—the moral and legal primacy of the competent, informed pregnant woman in decision making is overwhelming.[38]

Physicians may feel better after being "blessed" by the judge, but they should not. First, the appearance of legitimacy is deceptive; the judge has acted injudiciously, and there is no opportunity for meaningful appeal. Second, the medical situation has not changed, except that more time has been lost that should have been used to continue discussion with the woman directly. And, finally, the physician has now helped to transform himself or herself into an agent of the state's authority.[38]

The question of how to deal with a woman who continues to refuse intervention in the face of a court order remains. Do we really want to attempt to restrain and forcibly medicate and operate on a competent, refusing adult? Although such a procedure may be "legal," it is hardly humane. It is not what one generally associates with modern obstetrical care and may cause harm. It also encourages an adversarial relationship between the obstetrician and the patient. Moreover, even from a strictly utilitarian perspective, this marriage of the state and medicine is likely to harm more fetuses than it helps because many women will quite reasonably avoid physicians altogether during pregnancy if failure to follow medical advice can result in forced treatment, involuntary confinement, or criminal charges.

Extending notions of child abuse to "fetal abuse" simply brings government into pregnancy with few, if any, benefits and with great potential for invasions of privacy and deprivations of liberty. It is not helpful to use the law to convert a woman's and society's moral responsibility to her fetus into the woman's legal responsibility alone.[35] After birth, the fetus becomes a child and can and should thereafter be treated in its own right. Before birth, however, we can obtain access to the fetus only through its mother and, in the absence of her informed consent, can do so only by treating her as a fetal container, a nonperson without rights to bodily integrity.

In 2005, the ACOG revised and updated its 1987 Ethics Committee report on "Patient Choice: Maternal Fetal Conflict," now titled "Maternal Decision Making, Ethics, and the Law"[39] that we believe provides thoughtful and useful guidance for the medical practitioner. The statement highlighted six considerations, which we combine into three:

1. Coercive and punitive legal approaches to pregnant women who refuse medical advice fail to recognize that all competent adults are entitled to informed consent and bodily integrity.
2. Court-ordered interventions in cases of informed refusal, as well as punishment of pregnant women for their behavior that may put a fetus at risk, neglect the fact that medical knowledge and predictions of outcomes in obstetrics have limitations…[and treat medical problems] as if they were moral failings.
3. Coercive and punitive policies are potentially counterproductive in that they are likely to discourage prenatal care and successful treatment, adversely affect infant mortality rates, and undermine the physician-patient relationship…[and] unjustly single out the most vulnerable women…and create the potential for criminalization of many types of otherwise legal maternal behavior.

Based on these, the Committee on Ethics made four recommendations, the most central of which are:

1. Pregnant women's autonomous decisions should be respected.…In the absence of extraordinary circumstances, circumstances that, in fact, the Committee cannot currently imagine, judicial authority should not be used to implement treatment regimens aimed at protecting the fetus, for such actions violate the pregnant woman's autonomy.
2. Pregnant women should not be punished for adverse perinatal outcomes.
3. Policy makers, legislators, and physicians should work together to find constructive and evidence-based ways to address the needs of women with alcohol and other substance abuse problems.

This 2005 statement is even stronger than a 1990 opinion by the District of Columbia Court of Appeals, which ruled that the decision of the pregnant woman must be honored in all but "extremely rare and truly exceptional" cases.[40] ACOG's Ethics Committee "cannot currently imagine" what that "rare and truly exceptional" case might look like,

KEY POINTS

- In *Roe v. Wade* (1973), the U.S. Supreme Court determined that a fundamental "right to privacy existed in the Fourteenth Amendment's concept of personal liberty" that is "broad enough to encompass a woman's decision whether or not to terminate a pregnancy" before fetal viability without state interference.
- In *Planned Parenthood of Southeastern Pennsylvania v. Casey* (1992), the U.S. Supreme Court reaffirmed the "core" of *Roe v. Wade* and ruled that, before fetal viability, states cannot "unduly burden" a woman's decision to terminate a pregnancy (i.e., although consent and waiting periods may be constitutionally acceptable, states cannot regulate abortion in ways that will actually prevent women from obtaining them).
- *Roe* and *Casey* are critical to understanding the rights of obstetricians (which are derived from the rights of their patients) because they are the major sources of law regarding how far states can go to regulate decisions made in the obstetrician-patient relationship.
- With the exception of a procedure Congress has labeled "partial birth abortions," unless they contain an exception for the health of the pregnant

woman, laws that criminalize abortions are unconstitutional because they are inconsistent with *Roe* and *Casey*.

- *Roe* has been the source of political controversy since it was decided in 1973. Congress has enacted the "Hyde Amendment" every year since the mid-1970s, prohibiting the use of federal funds for almost all abortions, and its constitutionality has been upheld by the U.S. Supreme Court.
- The Hyde Amendment was the basis for another similar amendment, the Dickey-Wicker Amendment, which prohibited the use of federal funds for human embryonic stem cell research, and was the basis for a temporary injunction prohibiting the NIH from funding such research in 2010 (overturned in 2011) under the Obama administration's changed rules.
- The legal and ethical obligations of an obstetrician in relationship to genetic counseling and prenatal diagnosis can be summarized as follows: (1) the physician must give accurate information to the parents and cannot withhold vital information from them; (2) no obstetrician can be required to perform prenatal diagnostic procedures; (3) prenatal genetic counseling should be morally nondirective; and (4) to protect patient privacy and autonomy, no information obtained in genetic counseling or screening should be disclosed to any third party without the patient's authorization.
- "Generic" consent for genetic *screening* that emphasizes broad concepts and common denominator issues should help maximize rational decision making by preventing information overload and wasting time on useless information.
- Self-determination and rational decision making are the central purposes of informed consent, and information on recommended procedures, risks, benefits, and alternatives should be presented in a way that furthers these purposes.
- Consent of the pregnant woman is a mandatory prerequisite for both investigative procedures and therapy. Her consent must be informed, and she should be told as clearly as possible about the proposed experimental procedures or therapy, its risks to herself and her fetus, and alternatives, success rates, and the likely problems of recuperation.
- The fetomaternal relationship is a unique one that requires physicians to promote a balance of maternal health and fetal welfare while respecting maternal autonomy. Obstetricians should not perform procedures that are refused by pregnant women, although reasonable steps to persuade a woman to change her mind are appropriate.

APPENDIX I
Normal Values in Pregnancy

Henry L. Galan and Laura Goetzl

Invasive Cardiac Monitoring 1212
Noninvasive Cardiac Monitoring 1212
Arterial Blood Gas Values (Third Trimester) 1212
Pulmonary Function Tests 1213
Mean Values 1213
Peak Flows (5th% Shown as Lower Limit of Normal) Stable Over Gestation 1213
Liver/Pancreatic Function Tests 1213
Electrolytes, Osmolality, and Renal Function 1213
Cholesterol and Lipids 1214
Hematologic Indices, Iron and B12 1214
Homocysteine, Vitamin, and Mineral Levels 1214
Calcium Metabolism 1215
Coagulation 1215
Inflammation and Immune Function 1215
Endocrine Tests 1216
Umbilical Cord Blood Gas Values and Hematologic Parameters 1216
Crown-Rump Length (6-18 Weeks) 1216
Head Circumference (percentile values) 1217
Abdominal Circumference (percentile values) 1217
Femur Length (percentile values) 1217
Humerus Length (percentile values) 1217
Tibia Length (percentile values) 1218
Fibula Length (percentile values) 1218
Radius Length (percentile values) 1218
Ulna Length (percentile values) 1218
Foot Length (mm; mean and SD) 1219
Transcerebellar Diameter (percentile values and mean ± SD) 1219
Amniotic Fluid Index (percentile values) 1220
Small Head Circumference Measurements (SD) 1220
Umbilical Artery Resistance Index (RI) and Systolic-to-Diastolic (S/D) Ratio 1220
Middle Cerebral Artery Pulsatility Index (percentile values) 1220

Invasive Cardiac Monitoring

MEASURE	VALUE (36-38 WEEKS)	UNITS
Cardiac output	6.2 ± 1.0	liters/minute
Systemic vascular resistance	1210 ± 266	dyne cm second^{-5}
Heart rate	83 ± 10	beats/minute
Pulmonary vascular resistance	78 ± 22	dyne cm second^{-5}
Colloid oncotic pressure	18.0 ± 1.5	mm Hg
Mean arterial pressure (MAP)	90.3 ± 5.8	mm Hg
Pulmonary capillary wedge pressure (PCWP)	7.5 ± 1.8	mm Hg
Central venous pressure (CVP)	3.6 ± 2.5	mm Hg
Left ventricular stroke work index	48 ± 6	g mm^{-2}

Modified from Clark SL, Cotton DB, Lee W, et al: Central hemodynamic assessment of normal term pregnancy. Am J Obstet Gynecol 161:1439, 1989; Spatling L, Fallenstein F, Huch A, et al: The variability of cardiopulmonary adaptation to pregnancy at rest and during exercise. Br J Obstet Gynaecol 99(Suppl 8):1, 1992.

Cardiac output is increased in pregnancy but is essentially unchanged over the course of pregnancy.

Heart rate gradually rises 5 to 10 bpm over the course of pregnancy.

Noninvasive Cardiac Monitoring

MEASURE	10-18 WEEKS	18-26 WEEKS	26-34 WEEKS	34-42 WEEKS
Cardiac output (L/min)	7.26 ± 1.56	7.60 ± 1.63	7.38 ± 1.63	6.37 ± 1.48
Stroke volume (mL)	85 ± 21	85 ± 21	82 ± 21	70 ± 14
SVR (dyne cm second^{-5})	966 ± 226	901 ± 224	932 ± 240	1118 ± 325
Heart rate (beats/min)	87 ± 14	90 ± 14	92 ± 14	92 ± 7
Mean arterial pressure (mm Hg)	87 ± 7	84 ± 7	84 ± 7	86 ± 7

Modified from Van Oppen CA, Van Der Tweel I, Alsbach JGP, et al: A longitudinal study of maternal hemodynamics during normal pregnancy. Obstet Gynecol 88:40, 1996.

SVR, Systemic vascular resistance.

Arterial Blood Gas Values (Third Trimester)

	NORMAL ALTITUDE	MODERATE ALTITUDE (1388 M, PROVO, UT)
Arterial pH	7.40-7.48	7.44-7.48
Arterial P_{O_2} (mm Hg)	80-90	78.9-93.5
Arterial P_{CO_2} (mm Hg)	26.9-32.5	23.9-29.3
Sodium bicarbonate (mEq/L)	19.9-24.1	16.7-20.5

Modified from Hankins GD, Clark SL, Harvey CJ, et al: Third trimester arterial blood gas and acid base values in normal pregnancy at moderate altitude. Obstet Gynecol 88:347, 1996; Eng M, Butler J, Bonica JJ: Respiratory function in pregnant obese women. Am J Obstet Gynecol 123:241, 1975.

Pulmonary Function Tests

	8-11 WEEKS	20-23 WEEKS	28-31 WEEKS	36-40 WEEKS
Respiratory Rate (br/min)	15 (14-20)	16 (15-18)	18 (15-20)	17 (16-18)
Tidal Volume (mL)	640 (550-710)	650 (625-725)	650 (575-720)	700 (660-755)

(Median, 25th-75th Percentile)

Modified from Spatling L, Fallenstein F, Huch A, et al: The variability of cardiopulmonary adaptation to pregnancy at rest and during exercise. Br J Obstet Gynaecol 99:1, 1992.

Mean Values

	FIRST TRI	SEC TRI	THIRD TRI
Mean Vital Capacity (L)	3.8	3.9	4.1
Mean Inspiratory Capacity (L)	2.6	2.7	2.9
Mean Expiratory Reserve Volume (L)	1.2	1.2	1.2
Mean Residual Volume (L)	1.2	1.1	1.0

Modified from Gazioglu K, Kaltreider NL, Rosen M, Yu PN: Pulmonary function during pregnancy in normal women and in patients with cardiopulmonary disease. Thorax 25:445, 1920; Puranik BM, Kaore SB, Kurhade GA, et al: A longitudinal study of pulmonary function tests during pregnancy. Indian J Physiol Pharmacol 38:129, 1994.

Peak Flows (5th% Shown as Lower Limit of Normal) Stable Over Gestation

	PEAK FLOW (L/min)
Standing	>320
Sitting	>310
Supine	>300

Modified from Harirah HM, Donia SE, Nasrallah FK, et al: Effect of gestational age and position on peak expiratory flow rate: a longitudinal study. Obstet Gynecol 105:372, 2005.

Liver/Pancreatic Function Tests

	FIRST TRIMESTER	SEC TRIMESTER	THIRD TRIMESTER	TERM
Total alkaline phosphatase (IU/L)	17-88	39-105	46-228	48-249
Gamma glutamyl transferase (IU/L)	2-34	2-31	4-32	5-79
Aspartate transaminase (AST, IU/L)	4-40	10-33	4-32	5-103
Alanine transaminase (ALT, IU/L)	1-30	2-34	2-26	5-115
Total bilirubin (mg/dL)	0.05-1.3	0.1-1.0	0.1-1.2	0.1-1.1
Unconjugated bilirubin (mg/dL)	0.1-0.5	0.1-0.4	0.1-0.5	0.2-0.6
Conjugated bilirubin (mg/dL)	0-0.1	0-0.1	0-0.1	—
Lactate dehydrogenase (U/L)	78-433	80-447	82-524	—
Amylase (IU/L)	11-97	14-92	14-97	10-82
Lipase (IU/L)	5-109	8-157	21-169	—

Modified from Bacq Y, Zarka O, Brechot JF, Mariotte N, Vol S, Tichet J, Weill J: Liver function tests in normal pregnancy: a prospective study of 103 pregnant women and 103 matched controls. Hepatol 23:1030, 1996; Karensenti D, Bacq Y, Brechot JF, Mariotte N, Vol S, Tichet J: Serum Amylase and lipase activities in normal pregnancy: a prospective case-control study. Neth J Med 46:73, 1995.

Electrolytes, Osmolality, and Renal Function

	FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER	TERM
Total osmolality (mOsm/kg)	267-280	269-289	273-283	271-289
Sodium (mEq/L)	131-139	129-142	127-143	124-141
Potassium (mEq/L)	3.2-4.9	3.3-4.9	3.3-5.2	3.4-5.5
Chloride (mEq/L)	99-108	97-111	97-112	95-111
Bicarbonate (meq/L)	18-26	18-26	17-27	17-25
Urea nitrogen (BUN, mg/dL)	5-14	4-13	3-13	4-15
Creatinine (mg/dL)	0.33-0.80	0.33-0.97	0.3-0.9	0.85-1.1
Serum albumin (g/dL)	3.2-4.7	2.7-4.2	2.3-4.2	2.4-3.9
Uric Acid (mg/dL)	1.3-4.2	1.6-5.4	2.0-6.3	2.4-7.2
Urine volume (mL/24 hours)	750-2500	850-2,400	750-2700	550-3900
Creatinine clearance (mL/min)	69-188	55-168	40-192	52-208
Urine protein (mg/24 hours)	19-141	47-186	46-185	—

Modified from Ezimokhai M, Davison JM, Philips PR, Dunlop W: Non-postural serial changes in renal function during the third trimester of normal human pregnancy. Br J Obstet Gynaecol 88:465, 1981; Higby K, Suiter J, Phelps JY, et al: Normal values of urinary albumin and total protein excretion during pregnancy. APPENDIX II
Anatomy of the Pelvis

Steven G. Gabbe

A-1 Major components of the bony pelvis, frontal superior view
A-2 Major ligaments and notches of the female pelvis, posterior view
A-3 Muscles of the pelvic diaphragm, oblique view
A-4 Muscles of the pelvic diaphragm, superior view
A-5 Muscles of the pelvic diaphragm, inferior view
A-6 Fascial and peritoneal relationships of the pelvic diaphragm
A-7 Muscles of the deep perineal space, inferior view
A-8 Muscles of the superficial perineal space, from below
A-9 Ischiorectal fossa, frontal section
A-10 Ischiorectal fossa and urogenital diaphragm, sagittal section
A-11 External anal sphincter as viewed in dorsal lithotomy position
A-12 Cutaneous nerve supply to the perineum
A-13 Superficial perineal blood supply and nerves
A-14 Vessels and nerves of the deep perineal space
A-15 Major organs of the pelvis, sagittal section
A-16 Anatomy of the fallopian tube and ovary, posterior view
A-17 Anatomic regions of the uterus, lateral view
A-18 Anatomic relationships of the uterus, lateral view
A-19 Broad ligament and contained organs, frontal view
A-20 Organs of the pelvis, posterior view
A-21 Major vessels of the pelvis, frontal view
A-22 Major vessels of the pelvis, lateral view
A-23 Blood supply to the uterus, tube, and ovary
A-24 Blood supply to the vagina
A-25 Major lymphatics of the pelvis
A-26 Major nerves of the pelvis, lateral view
A-27 Afferent innervation of the female genital tract
A-28 Changes in the uterus with age and parity
A-29 Changes in the uterus caused by pregnancy and parturition

***The illustrations for the Anatomy of the Pelvis Appendix can be found online at *www.expertconsult.com*.**

KEY POINTS

- To facilitate childbearing, the female pelvis—as opposed to the male pelvis—is characterized by a wider subpubic angle, increased width of the sciatic notch, and greater distance from the symphysis pubis to the anterior edge of the acetabulum.
- The levator ani, the major supporting structure for the pelvic viscera, is a tripartite muscle mass composed of the iliococcygeus, pubococcygeus, and puborectalis; the iliococcygeus is the broadest and most posterior portion.
- Innervation of the levator ani is through the third and fourth sacral nerves.
- The major nerve supply of the perineum is derived from the pudendal. However, the ilioinguinal, genitofemoral, perineal branch of the posterior femoral cutaneous, coccygeal, and last sacral nerve also contribute; thus, a pudendal nerve block anesthetizes only a portion of the perineum.
- The internal iliac (hypogastric) artery arises at the level of lumbosacral articulation. It can be distinguished from the external iliac by its smaller size and by its more medial and more posterior position.
- The ureter lies more superficially and is either medial or slightly anterior to the internal iliac artery.
- The cardinal ligaments are located at the base of the broad ligament, are continuous with the connective tissue of the parametrium, and are attached to the pelvic diaphragm through continuity with the superficial superior fascia of the levator ani.

- Because the origin of the uterine artery is variable, its isolation and ligation for control of postpartum bleeding are often fruitless. The uterine artery usually arises as an independent vessel from the internal iliac artery, but it may also arise from the inferior gluteal, internal pudendal, umbilical, or obturator arteries.
- Afferent pain fibers for the uterus, tubes, and ovary enter the cord at T10, T11, T12; thus, spinal or epidural anesthesia must extend to these levels. Fortunately, efferent fibers to the uterus enter above these levels, thus not interfering with contractions.
- The body of the nonpregnant uterus weighs approximately 70 g, whereas at term it weighs approximately 1100 g.
