Almost 30 years ago, Gabbe and associates,[72] working with fetal monkeys, noted that when AF was removed from the amniotic compartment, variable decelerations in the fetal heart rate developed. These decelerations resolved when the AF was replaced, suggesting that cord compression was the cause of the decelerations. Since that time, multiple investigators have studied amnioinfusion as a technique by which to treat variable decelerations in labor. Although most report a decrease in the frequency of variable decelerations, few have demonstrated any decrease in perinatal morbidity or mortality, or the cesarean delivery rate.[73-76] Amnioinfusion has been studied as a possible therapy in the case of thick meconium. In several small prospective studies, it has been shown to improve neonatal outcomes, including meconium visualized below the newborn vocal cords and meconium aspiration syndrome.[77-80] Sadovsky and associates[81] found that with the randomization of women with greater than light meconium to a control or amnioinfusion treatment group, 29% of control newborns had meconium below the umbilical cords, whereas none of the treated newborns did. Two meta-analyses of the therapeutic use of amnioinfusion for thick meconium demonstrated between a 75% and 84% reduction in meconium below the vocal cords at delivery.[82,83] A more recent, multicenter, randomized trial of 1998 women in labor at 36 weeks' gestation or later with thick meconium did not find that amnioinfusion reduced the risk for moderate or severe meconium aspiration syndrome or perinatal death.[84] **Based on this large multicenter trial the American Congress of Obstetricians and Gynecologists (ACOG) recommends against routine prophylactic amnioinfusion for the dilution of meconium-stained amniotic fluid (ACOG Committee Opinion, Number 346, October 2006).**

POLYHYDRAMNIOS

The incidence of polyhydramnios has been reported to be about 1% in large population-based studies.[85-88] The earlier in gestation polyhydramnios occurs and the greater the amount of fluid, the higher the perinatal morbidity and mortality.[4] Ultrasound assessment of the LVP or AFI is used to confirm the diagnosis of polyhydramnios.

Most authors report an LVP of greater than 8 cm to define polyhydramnios.[87] Hill and colleagues divided their patients with polyhydramnios into three groups: mild (LVP 8 to 11 cm, 79% of cases), moderate (LVP 12 to 15 cm, 16.5% cases), and severe (LVP ≥16 cm, 5% of cases). Overall, the PMR was 127.5 per 1000, which corrected to 58.8 per 1000 when lethal malformations were excluded.[87] This value is markedly increased over the background rate. A specific cause was identified in only 16% of the mild cases of polyhydramnios, 90% for moderate polyhydramnios, and 100% for severe polyhydramnios.[87] Fetal and maternal conditions associated with polyhydramnios are shown in Table 33-3. In a follow-up study, Many and associates[89] examined 275 women with polyhydramnios to determine if the degree of polyhydramnios had an impact on the rate of prematurity. Although excessive amniotic fluid did not have an impact on the rate of prematurity, the presence of anomalies or diabetes mellitus was associated with an increased risk for preterm delivery.[89] Severe polyhydramnios in the second trimester has a significant PMR, which is most commonly due to prematurity or aneuploidy.[90,91] Pregnancy complications associated with polyhydramnios have been reported to increase the risk for placental abruption and postpartum hemorrhage due to overdistention (or rapid deflation) of the uterus.

Table 33-3 Fetal and Maternal Causes of Polyhydramnios

Fetal Conditions
Congenital anomalies
Gastrointestinal obstruction
Central nervous system abnormalities
Cystic hygromas
Nonimmune hydrops
Sacrococcygeal teratoma
Cystic adenoid malformations of lung
Aneuploidy, genetic syndromes
Achondrogenesis type 1-B
Twin-to-twin transfusion syndrome
Muscular dystrophy syndromes
Infections—parvovirus B-19
Bartter syndrome
Placental abnormalities—chorioangioma
Maternal Conditions
Idiopathic
Poorly controlled diabetes mellitus
Fetal maternal hemorrhage

Using the four-quadrant AFI, Moore and Cayle[22] reported the AFI for varying gestational ages (see Figure 33-3) and concluded that one value for the AFI cannot be used throughout gestation but must be referenced to gestational age. The study found the 97.5 percentile at 35 weeks of gestation to be 27.9 cm, which represents the upper limits of normal for that gestational age. This value would clearly be abnormally increased for earlier and later measurements in gestation (see Figure 33-3).

Evaluation and Treatment of Polyhydramnios

The pregnant woman who presents with a rapidly enlarging uterus in midpregnancy, with or without preterm labor, needs to be evaluated by ultrasound examination to assess the AFV and look for a congenital malformation. Esophageal atresia with or without tracheoesophageal fistula can present with early-onset severe polyhydramnios due to an obstruction. The AFV may still be normal with some forms of tracheoesophageal fistula that allow for the movement of fluid into the stomach.[92] Other gastrointestinal obstructions, such as duodenal atresia, may result in polyhydramnios.[87] When a structural defect is seen in a fetus with polyhydramnios, consideration should be given to performing an amniocentesis (see Chapter 11).

Another common cause of acute, severe polyhydramnios in the second trimester is the condition associated with the twin-to-twin transfusion syndrome (TTTS) (see Chapter 30). The ultrasound findings associated with TTTS are marked polyhydramnios of the receiving twin and absent AFV or marked oligohydramnios of the donor twin.

When polyhydramnios occurs in the third trimester of pregnancy, it is usually mild and not associated with a structural defect.[87] Table 33-3 lists many of the causes of polyhydramnios. Although most cases in the third trimester are idiopathic, the other causes of polyhydramnios must be excluded.

In many cases, polyhydramnios may be transient. Golan and colleagues[88] examined 113 cases of polyhydramnios. On repeated examination, patients separated into two groups: cases in which the polyhydramnios worsened or the AFV remained markedly elevated, and those in which the AFV returned to normal or decreased to mild polyhydramnios. In the former group, all complications of pregnancy were greater, including preterm delivery (2.7-fold increase), preeclampsia (2.7-fold increase), IUFD (7.7-fold increase), and neonatal demise (7.7-fold increase). In the latter group, the most common diagnosis was idiopathic and showed a favorable outcome.[88] **This study suggests that if polyhydramnios is persistent, the fetus should be examined closely for congenital malformations and aneuploidy and monitored to prevent an IUFD.** In addition, the mother should be watched closely for other medical complications of pregnancy.[88]

Treatment options for patients with polyhydramnios are usually tailored to the underlying cause. With mild idiopathic polyhydramnios, in which the workup is negative and follow-up ultrasound demonstrates persistent polyhydramnios, the only possible intervention is antepartum testing with fetal kick counts, or nonstress tests. When poorly controlled diabetes mellitus is the cause of the polyhydramnios, proper glycemic control may be beneficial,[93,94] and antepartum surveillance is recommended. With the current aggressive management of diabetes in pregnancy, it is rare to see severe polyhydramnios associated with diabetes. Treatment options for TTTS are discussed in Chapter 30.

With severe polyhydramnios associated with preterm labor, one medical treatment option involves the administration of a prostaglandin inhibitor such as indomethacin, which works by decreasing fetal urine production.[95-97] This effect occurs within 5 hours of starting the medication and decreases the AFV within 24 hours.[95,96] Although indomethacin has been shown to be relatively safe when given over a short period, such as 72 hours, prolonged use may be associated with risks to the fetus such as premature closure, or narrowing, of the ductus venosus within the fetal heart and renal abnormalities in the newborn period.[96,97] Complications related to indomethacin use worsen with advancing gestational age, and such treatment beyond 31 to 32 weeks of gestation should be avoided.[98] Because of the adverse effects on the fetus associated with the long-term use of indomethacin, it probably has limited use in pregnancy for the treatment of severe polyhydramnios. The use of repetitive amino reductions, in which amniocentesis is performed and large volumes (1 to 5 L) of AF are removed through plastic tubing into a vacuum bottle, does prolong pregnancies in a number of cases but may need to be repeated on a regular basis.[5,98]

KEY POINTS

- Amniotic fluid is seldom considered important until polyhydramnios or oligohydramnios occurs, either of which may significantly impact perinatal survival.
- Amniotic fluid is dynamic, with large-volume flows into and out of the amniotic compartment each day.
- Clinical estimates of actual amniotic fluid volume through ultrasound measurements of the AFI or LVP are not very accurate at predicting true volume.
- Oligohydramnios, in the presence of IUGR or a prolonged gestation, is associated with significant increases in perinatal morbidity and mortality.
- Preterm or term isolated oligohydramnios, with an otherwise normal fetus, is not associated with an increase in perinatal morbidity or mortality.
- Early-onset or severe polyhydramnios is associated with a significant increase in aneuploidy, congenital malformations, preterm delivery, and perinatal mortality.
- The cause of mild polyhydramnios, especially in the latter part of the third trimester, is usually idiopathic, or related to diabetes mellitus, and has little positive or negative impact on perinatal survival.
- AFV, as estimated by the AFI, can be increased or decreased by the amount of water ingested orally.
- Short-term use of indomethacin decreases fetal urine production and can reduce AFV within 24 hours of administration.
- Absorption of amniotic fluid directly from the amniotic compartment into the blood vessels on the fetal surface of the placenta can explain the large differences between fetal swallowing and urine production.

Obstetricians have long recognized that there can be detrimental effects of preterm delivery, but for the last century there has also been concern for pregnancies that have gone beyond the normal period of gestation. Early descriptions from prolonged pregnancies described a large fetus, resulting in a difficult delivery, with an increased risk of stillbirth.[1] Later descriptions suggested that a postterm fetus not only could be large, but also small for gestational age.[2] These concerns led some to adopt a practice of inducing labor to avoid complications in prolonged pregnancies. This practice was variable, and somewhat controversial, because the upper limit of pregnancy was not well defined and the risks were inconsistent. More recent studies show a small but significantly increased risk in perinatal morbidity and mortality in postterm pregnancies, and hence, postterm pregnancy is one of the most common reasons for induction of labor in the United States.

DEFINITION

The American College of Obstetricians and Gynecologists (ACOG) and the World Health Organization (WHO) have defined a postterm pregnancy as a gestation that has completed or gone beyond 42 weeks or 294 days from the first day of the last menstrual period (LMP).[3-5] This gestational age cut-off has been used for several decades and was first suggested based on early studies that reported an increased risk of fetal death at 42 weeks and beyond.[6] However, in view of more recent perinatal mortality data that were derived from accurately dated pregnancies, it would be reasonable to conclude that the gestational age that warrants clinical concern should be 41 weeks.

There are many terms that have been used in the literature, including postmature, postdates, prolonged, and postterm. These terms have been used with varying definitions, which has led to some confusion regarding proper terminology. For the purposes of this chapter, we use the term *postterm* to describe a pregnancy than has gone beyond 42 weeks' gestation, and the term *prolonged* for a pregnancy between 41 and 42 weeks.

INCIDENCE

According to the vital statistics reported by the Centers for Disease Control and Prevention, the overall incidence of postterm pregnancies was 6% in 2006, compared to 7% in the previous year.[7] Other published studies have shown rates between 2% and 13% depending on the population studied.[8] The incidence of prolonged pregnancies in European countries also varies widely, with rates as low as 0.6% in Austria and as high as 7% in Denmark and Sweden.[9] These differences are most likely explained by (1) different approaches for managing pregnancies beyond the estimated date of delivery (EDD) and (2) different criteria for gestational age dating.

ETIOLOGY

The etiology of the majority of pregnancies that are prolonged or postterm is unknown, but some pregnancies may be defined as prolonged or postterm as the result of an error in dating. It is common practice to assign an EDD based on the date of the last menstrual period (LMP). This

practice has been proven by several studies to be unreliable and may have led to the incorrect classification of a pregnancy as prolonged or postterm.[10]

Understanding the events that lead to parturition in human gestation may help to provide clues to the pathophysiology in prolonged pregnancies. Parturition is the result of a complex interplay between the mother, fetus, and placenta.[11] The mechanism in human gestation is unknown but may be similar to that of other mammals. In sheep, the hypothalamic pituitary adrenal (HPA) axis is important in the timing of birth. The release of corticotrophin-releasing hormone from the fetal brain results in the secretion of adrenocorticotropic hormone from the pituitary gland and cortisol from the adrenal gland.[12] The increase in cortisol parallels an increase in the secretion of prostaglandin and estrogens and a fall in progesterone.[12] Decreases in progesterone and prostaglandins are known triggers uterine myometrium. Further support for the role of the HPA axis in the initiation of labor is seen in studies with hypophysectomized sheep; disruption of the HPA axis results in prolonged pregnancy.[13] More recent studies have proposed a similar involvement of the HPA axis in human gestation, and its dysregulation may play a role in prolonged pregnancies.

Early studies likened anencephaly to the hypophysectomized sheep. It is hypothesized that the absence of the fetal brain in the anencephalic fetus may result in a similar dysfunction of the HPA axis and lead to prolonged gestation. Epidemiologic studies of anencephalic pregnancies have observed prolongation of pregnancy.[14] This finding supports current thinking that the interaction between the fetal brain and placenta plays an important role in triggering labor.

Pregnancies complicated by placental sulfatase deficiency, an X-linked recessive disorder characterized by the absence of the enzyme steroid sulfatase, are marked by abnormally low estriol levels and, in general, fail to go into spontaneous labor.[15] This is an example of a genetic etiology for prolonged pregnancy and lends further support to the important role of the placenta in the initiation of labor.

A number of observational studies have identified risk factors for postterm pregnancy including primigravidity, prior postterm pregnancy, male fetus, obesity, and a genetic predisposition.[16-22] A 10-year cohort study of births in Norway failed to find a strong association of risk factors with postterm pregnancy but may have had a bias toward nondetection.[16] Intergenerational studies suggest a genetic predisposition for postterm pregnancy. Mothers who themselves were prolonged also have an increased risk of prolonged pregnancy. Twin studies have found higher rates of concordance for prolonged pregnancy among female twins as compared to male twins, implicating a maternal influence on the risk for prolonged pregnancy.[22]

DIAGNOSIS

The diagnosis of truly prolonged and postterm pregnancy is based on accurate gestational dating. The three most commonly used methods to determine the EDD are (1) knowledge of the date of the LMP, (2) timing of intercourse, and (3) early ultrasound assessment. Other methods have been described but are rarely used in contemporary practice, including the determination of uterine size, quickening, ability to detect fetal heart tones by Doptone, and fundal height measurement. In most cases, the date of conception is rarely known and therefore is infrequently used to determine gestational age. The EDD is most commonly assigned based on the first day of the LMP but this assumes that conception occurs on the fourteenth day of the menstrual cycle. This method can be very inaccurate because the timing of ovulation varies among an individual's menstrual cycles and between individuals.[23,24] Basing gestational age solely on the LMP generally results in an overestimation of gestational age, and may result in higher frequency of induction of labor for presumed postterm pregnancy.

The use of ultrasound to determine the accuracy of gestational dating based on the LMP is superior to the use of LMP alone. The EDD is most accurately determined if the crown rump length is measured in the first trimester with an error of plus or minus 5 to 7 days. Boyd and colleagues showed that the incidence of patients whose pregnancy exceeded 293 days was 7.5% based on menstrual dating and declined to 2.6% when dates were determined by early sonographic examination.[25] A similar conclusion was reached by Gardosi and colleagues, who evaluated 24,675 spontaneous, normal singleton deliveries and showed a decline in the postterm (>294 days) pregnancy rate from 7.5% when pregnancies were dated by LMP to 1.5% when ultrasound dating was used.[26] These authors also reported that about 72% of routine labor inductions at 42 weeks' gestation were not indicated because they were performed before the patients reached 42 weeks based on ultrasound assessment of gestational age. Similarly, Nguyen and colleagues evaluated 14,805 spontaneous deliveries with a reliable LMP and showed that ultrasound dating reduced the proportion of deliveries beyond 294 days of gestation by 39% (from 7.9% to 5.2%).[27] Bennett and colleagues confirmed these findings in a prospective, randomized study of 218 women and found fewer postterm inductions of labor in women dated by a first trimester sonogram when compared with women whose dates were established by second trimester sonography.[28]

PERINATAL MORBIDITY AND MORTALITY

Numerous studies have evaluated the risk to the fetus in prolonged and postterm pregnancies. Early descriptive studies found that pregnancies that continued past their EDD had an increased risk of fetal death. In 1963 McClure found a twofold increase in "fetal distress" at 42 weeks with an increase in operative deliveries and surmised that 42 weeks constituted a significant risk to the fetus, and proposed intervening with induction of labor or cesarean section to avoid the risk of fetal death.[6] Early studies were likely fraught with inaccurate dating and inconsistent definitions of postterm pregnancy. Lastly, it is important to note that these studies included pregnancies complicated by fetal anomalies, intrauterine growth restriction, and mothers with coexisting medical conditions, all of which increase the risk of fetal demise.

More recent observational studies that have evaluated the risk of perinatal mortality at each gestational week show

an increased risk as gestational age advances beyond the EDD.[29-31] Divon and colleagues evaluated fetal and neonatal mortality rates in 181,524 accurately dated term and prolonged pregnancies. A significant increase in fetal mortality was detected from 41 weeks' gestation onward (odds ratio [OR] of 1.5, 1.8, and 2.9 at 41, 42, and 43 weeks, respectively).[32] Campbell and colleagues performed a multivariate analysis of factors associated with perinatal death among 65,796 singleton postterm births (≥294 days).[16] Three variables were identified as independent predictors of perinatal mortality: (1) birthweight lower than the 10th percentile for gestational age had a relative risk (RR) of 5.7 and 95% confidence interval (CI), 4.4 to 7.4; (2) maternal age 35 years or greater had a RR of 1.88 and 95% CI, 1.2 to 2.9; (3) birthweight at the 90th percentile for gestational age or above was associated with a modest protective effect for perinatal death (RR of 0.51 with 95% CI, 0.26 to 1.0).

Many of these studies have used perinatal mortality rate, which has been suggested by Smith and others to be an inappropriate assessment of risk to the fetus.[33] The denominator in the calculation of the perinatal mortality rate is the number of deliveries.[33-36] As stated by Smith, "estimating the probability of an event requires that the number of events (numerator) be divided by the number of subjects at risk for that event (denominator)."[33] Therefore, it seems logical to calculate fetal mortality as fetal deaths per 1000 ongoing pregnancies (rather than per 1000 deliveries). When Hilder and colleagues used ongoing pregnancies in a large retrospective study that included 171,527 births, they found higher rates of stillbirth.[34] There was a nadir at 41 weeks but an eightfold increase in stillbirth at 43 weeks compared to 37 weeks' gestation (Figure 34-1).

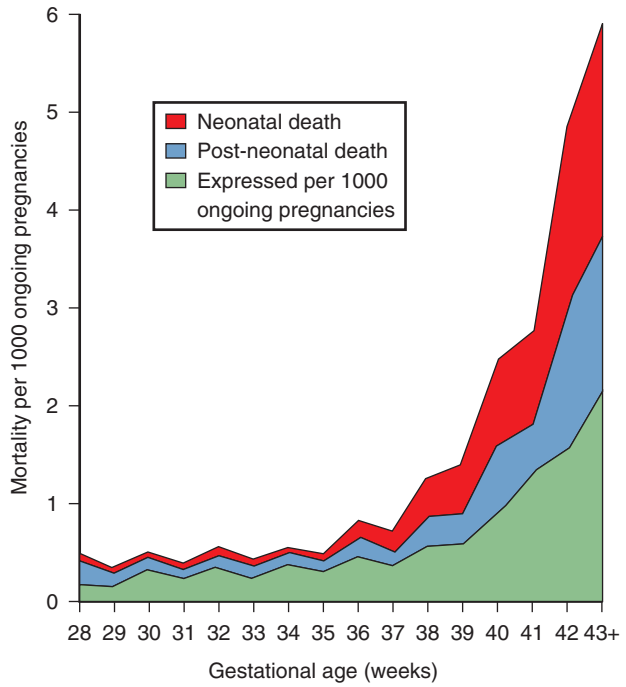

FIGURE 34-1. The summed mortality at each gestation for the rate of stillbirth (red), neonatal death (blue), and post-neonatal death (green) expressed per 1000 ongoing pregnancies. (Modified from Hilder L, Costeloe K, Thilaganathan B: Prolonged pregnancy: evaluating gestation specific risks of fetal and infant mortality. BJOG 105:169, 1998.)

Using the Scottish birth registry, Smith also found a significant increase in the risk of stillbirth from 37 weeks (0.4/1000) to 43 weeks (11.5/1000).

Several studies evaluated the association of perinatal morbidity with prolonged pregnancy. **Clausson and colleagues evaluated a large Swedish database of term and postterm (defined as ≥294 days) singleton, normal neonates, and showed that prolonged pregnancies were associated with an increased frequency of neonatal convulsions, meconium aspiration syndrome, and Apgar scores of less than 4 at 5 minutes (Table 34-1).**[37] Tunon and colleagues compared neonatal intensive care unit (NICU) admission rates among 10,048 term pregnancies and 246 prolonged pregnancies (≥296 days by both scan and LMP dates).[38] Prolonged pregnancy was associated with a significant increase in NICU admissions (OR of 2.05, 95% CI, 1.35 to 3.12).

Guidetti and colleagues reported an increased incidence of perinatal morbidity at 41 weeks' gestation or greater.[39] Maternal and fetal complications were evaluated in a large (n = 45,673) retrospective cohort study by Caughey and Musci.[40] These authors documented a significant increase in the rate of intrauterine fetal death beyond 41 weeks. They concluded that risks to both the mother and the infant increase as pregnancy progresses beyond 40 weeks' gestation.

Oligohydramnios

Oligohydramnios is a common finding in postterm pregnancies; it is presumably the result of fetal hypoxemia, which may result in altered renal perfusion and decreased urine production.[41] Doppler studies of renal blood flow are conflicting.[42,43] Thus, the etiology of oligohydramnios in postterm pregnancies is still debated.

Regardless of the pathophysiology of oligohydramnios in postterm pregnancies, there is an increased risk of perinatal morbidity and mortality in a setting of oligohydramnios.[44] The importance of oligohydramnios was identified by Leveno and colleagues, who used its presence to explain the increased incidence of abnormal antepartum

TABLE 34-1 NEONATAL MORBIDITY IN POSTTERM AGA AND SGA INFANTS

COMPLICATIONS	ODDS RATIOS AND 95% CI VERSUS TERM AGA NEONATES
Convulsions	
Term SGA	2.3 (1.6-3.4)
Postterm AGA	1.5 (1.2-2.0)
Postterm SGA	3.4 (1.5-7.6)
Meconium aspiration	
Term SGA	2.4 (1.6-3.4)
Postterm AGA	3.0 (2.6-3.7)
Postterm SGA	1.6 (0.5-5.0)
Apgar score <4 at 5 min	
Term SGA	2.2 (1.4-3.4)
Postterm AGA	2.0 (1.5-2.5)
Postterm SGA	3.6 (1.5-8.7)

AGA, Appropriate for gestational age; *CI*, confidence interval; *SGA*, small for gestational age.

and intrapartum fetal heart rate (FHR) abnormalities seen in prolonged pregnancies.[45] These authors suggested that prolonged FHR decelerations representing cord compression preceded 75% of cesarean deliveries for fetal jeopardy. The association between a reduced amniotic fluid index (AFI) and variable decelerations is well documented, and likely related to cord compression.[46,47] Meconium passage in amniotic fluid has also been associated with oligohydramnios and it is postulated that the hypoxemia may result in rectal sphincter relaxation. Some studies have shown meconium-stained fluid as high as 29% in postterm pregnancies complicated by oligohydramnios.[48] See Chapter 33 for further discussion of oligohydramnios.

A prospective, blinded observational study of 1584 pregnancies was performed by Morris and colleagues to assess the usefulness of ultrasound assessment of amniotic fluid in the prediction of adverse outcome in prolonged pregnancies.[49] The authors demonstrated that an AFI of less than 5 cm but not a single deepest vertical pocket less than 2 cm was significantly associated with birth asphyxia or meconium aspiration. In addition, there was a significant association between an AFI less than 5 cm and fetal distress in labor, cord arterial pH less than 7.0, and low Apgar scores.

The presence of oligohydramnios is often cited as an indication for delivery of pregnancies that reach term gestation or beyond. Importantly, there are no large, prospective, randomized studies documenting the benefits of delivery in this setting. **Still, given the well-described association between oligohydramnios and adverse pregnancy outcome, at or beyond term delivery is a reasonable choice for patients with oligohydramnios.**

Fetal Growth

The risk of macrosomia has been shown to increase with advancing gestational age. Although the majority of prolonged pregnancies are appropriately grown, there is an increased risk for macrosomia. Mclean and colleagues found in a sample of 7000 pregnancies between 39 and 42 weeks that there was an increase in both fetal weight and head circumference.[50] Eden and colleagues found that, compared to term pregnancies, postterm pregnancies have a twofold increase in the risk for macrosomia.[51] Macrosomia in these pregnancies was associated with an increased risk of operative delivery and shoulder dystocia leading to fetal injury.

Chervenak and colleagues investigated the use of ultrasound to evaluate the estimated fetal weight in pregnancies that were greater than 41 weeks and also found an increased incidence of fetal weight greater than 4000 grams.[52] They also showed there was an increase in the risk of cesarean delivery (22%) because of protracted and arrested labors when compared to nonmacrosomic infants (10%; $P < .01$). The positive and negative predictive values were 70% and 87%, respectively. However, a similar study of pregnancies at 41 weeks or greater found an absolute error of approximately 8% and a positive predictive value of 64% when ultrasound was used to estimate fetal weight within 1 week of delivery.[53] The ACOG has warned that the diagnosis of fetal macrosomia by ultrasound is not precise and early induction of labor or cesarean delivery has not been shown to reduce the morbidity associated with fetal macrosomia.[54]

Postmaturity

Postmaturity, another complication of prolonged pregnancies, occurs in approximately 10% to 20% of such pregnancies.[55-57] The "postmature" infant has decreased subcutaneous fat and lacks lanugo and vernix. The features are similar to intrauterine growth restriction and some authors believe that postmaturity is really another manifestation of intrauterine growth restriction. Postmaturity is also associated with an increased incidence of meconium-stained fluid.

Meconium

Meconium-stained fluid can be seen at any gestational age, although several studies have documented a significant increased risk of meconium-stained fluid in postterm pregnancies. Meconium aspiration is a serious neonatal condition resulting in decreased lung compliance, abnormal production of surfactant, and a chemical pneumonitis.

MATERNAL COMPLICATIONS

Prolonged pregnancies are also associated with significant risk to the mother. Not only is there significant anxiety as the pregnancy advances beyond the EDD but also an increased risk of maternal morbidity during the intrapartum period. Caughey and Musci studied 119,254 women who delivered at 37 weeks and beyond and found an increased risk in significant perineal laceration (OR 1.19, 95% CI, 1.09 to 1.22), chorioamnionitis (OR 1.32, 95% CI, 1.21 to 1.44), endomyometritis (OR 1.46, 95% CI, 1.14 to 1.87), postpartum hemorrhage (OR 1.21, 95% CI, 1.10 to 1.32), and cesarean section (1.28, 95% CI, 1.20 to 1.36).[40] The indications for cesarean section in this study were nonreassuring FHR and cephalopelvic disproportion.

MANAGEMENT

Accurate assessment of gestational age is paramount in the management of prolonged pregnancies. When ultrasound is used to confirm menstrual dating, the incidence of postterm pregnancies and unnecessary interventions are decreased.[58] Because prolonged and postterm pregnancies have an increased risk of fetal mortality, modern management includes the use of antenatal fetal surveillance and carefully timed intervention.

Antenatal Surveillance

Given the increased risk of stillbirth, antenatal surveillance is recommended in the management of prolonged and postterm pregnancies. Testing options for fetal surveillance include monitoring of fetal kick counts, nonstress test (NST), contraction stress test (CST), modified biophysical profile (NST and AFI), and biophysical profile (BPP). There are few data with adequate power to assess the timing of initiation or frequency of fetal testing in prolonged pregnancies. However, based on the studies on perinatal morbidity and mortality discussed above, it would seem prudent to initiate fetal testing no later than 41 weeks of gestation. There are a number of small studies that suggest that twice weekly antepartum testing is superior to once a week in prolonged pregnancies. John and Harman reported results on twice weekly testing with BPP

in 293 patients followed beyond 42 weeks. No stillbirths were observed in this small series.[59]

There are no large, randomized controlled trials comparing different modalities of fetal surveillance in prolonged pregnancies. One randomized controlled trial of 145 pregnancies beyond 42 weeks compared BPP with modified BPP.[60] This study found a significant increase in abnormal testing in the modified BPP group (42% vs. 20.5%, OR 3.5, 99% CI, 1.3 to 9.1), but no difference in cord blood gases and neonatal outcome between the two groups. Studies have not shown one modality of antepartum surveillance to be superior to another.[60]

ACOG proposed that amniotic fluid volume should be assessed when surveillance is initiated for prolonged pregnancies because oligohydramnios has been associated with abnormal fetal heart tracings, umbilical cord compression, and meconium-stained fluid. Chamberlain and colleagues studied 19,222 complicated pregnancies and found an increase in the risk of fetal demise with decreased amniotic fluid.[61]

There is a paucity of data demonstrating improved neonatal outcomes in postterm pregnancies when testing is used. Still, given the well-described increase in stillbirth in postterm pregnancies, ACOG currently recommends the initiation of fetal surveillance between 41 and 42 weeks with assessment of amniotic fluid volume.[3]

Umbilical artery Doppler measurements are sometimes used in cases of suspected placental insufficiency and hence one might imagine that this modality could be useful in postterm pregnancies. However, umbilical artery Doppler measurements have not been shown to be useful in the management of prolonged pregnancies.[62]

Expectant Management Versus Induction of Labor

Currently, ACOG does not define the gestational age at which expectant management is no longer recommended in prolonged pregnancies. Expectant management with fetal surveillance is typically advocated in pregnancies with an unfavorable cervix, whereas patients with a favorable cervix are induced presumably to decrease the risk of perinatal morbidity and mortality. There are several clinical trials that have compared induction of labor to expectant management in pregnancies that have progressed beyond their EDD. Hannah and colleagues performed one of the largest clinical trials; 3407 pregnant women were randomized at 41 weeks to induction or expectant management with fetal surveillance.[63] Delivery was indicated if the pregnancy reached 44 weeks or if there was evidence of fetal compromise. There was no difference in the perinatal mortality and neonatal morbidity, although there was an increased rate of cesarean deliveries in the expectantly managed group. There were no cases of fetal demise in the induction group and two in the expectantly managed group.

Another randomized controlled trial (RCT) of 440 uncomplicated pregnancies, performed by the National Institute of Child Health and Human Development Network of Maternal-Fetal Medicine Units, compared induction at 42 weeks versus expectant management until there was cervical effacement, dilation, or evidence of fetal compromise.[64] The primary outcome was perinatal or maternal death or a composite of variable for perinatal morbidity. Secondary outcomes for this trial included cesarean delivery, maternal infection, blood transfusion, severe variable or late deceleration, and 5-minute Apgar score less than 4. No differences were detected in primary outcome or rates of cesarean delivery. The study concluded that either induction or expectant management at 42 weeks was deemed acceptable practice.

More recently, Sanchez-Ramos published a meta-analysis that included 16 RCTs and 6588 patients, and found a 20% rate of cesarean delivery in uncomplicated pregnancies induced at 41 weeks compared to 22% in the expectantly managed group.[65] There was a nonsignificant but numerically lower perinatal mortality rate for the induction group (0.09% vs. 0.33%, OR 0.41, 95% CI, 0.14 to 1.18). They also found no differences in NICU admission and meconium aspiration.

The most recent Cochrane review, updated in 2011, is a meta-analysis of 19 RCTs.[66] The review included 7984 patients and looked at the potential benefits or harms of labor induction at or beyond 40 weeks' gestation versus expectant management. The primary outcome was perinatal mortality, which included intrauterine fetal demise and neonatal death in the first week of life. Labor induction was associated with a small but significant reduction in perinatal death (RR 0.30, 95% CI, 0.09 to 0.99), with no impact on the rate of cesarean delivery (RR 0.92, 95% CI, 0.76 to 1.12). This Cochrane meta-analysis suggests that induction may yield slightly improved perinatal outcomes, but based on the data, either approach seems reasonable.

Labor Induction

Induction of labor is discussed in Chapter 14. There are several studies that have addressed membrane sweeping as a method for labor induction in an attempt to reduce the occurrence of prolonged pregnancies. Membrane sweeping is the digital separation of the membranes from the lower uterine segment during a cervical examination. This practice is thought to increase the levels of endogenous prostaglandin, resulting in uterine contractions. A recent RCT by de Miranda and colleagues enrolled 742 patients at 41 weeks' gestation and randomized them to serial sweeping of membranes every 48 hours until 42 weeks or until labor was initiated, or to no intervention.[67] They found a decrease in the risk of postterm pregnancy in the first group; 23% were postterm (RR 0.57, 95% CI, 0.46 to 0.71) compared to 41% in the no-intervention group. The number needed to treat for this trial was six patients. Previously published trials have not shown a significant difference but these studies limited membrane sweeping to a single episode.[68,69] The most recent Cochrane review of trials that enrolled pregnant patients from 38 to 41 weeks to membrane sweeping found a reduced rate of pregnancies that continued past 41 weeks' gestation, with a number needed to treat of eight patients.[70] Although this practice may be effective in some pregnant patients, the procedure is known to cause maternal discomfort and bleeding. Thus, patients considering this option should be selected carefully and counseled appropriately.

Some have attempted to predict the likelihood of successful induction using transvaginal ultrasound of the cervix and fetal fibronectin. Pandis and colleagues

compared Bishop score to ultrasound cervical assessment and found cervical length to be more predictive of a successful labor induction than Bishop score (with a sensitivity and specificity of 87% and 71%, versus 58% and 27%, respectively).[71] Although promising, the use of transvaginal ultrasound assessment of the cervix to predict induction success is not commonly used. Attempts to evaluate the role of a fetal fibronectin in cervical secretions as a predictor of the onset of spontaneous labor have been inconclusive. In fact, Rozenberg and colleagues have recently shown that the spontaneous onset of labor within 7 days of evaluation is predicted by a Bishop score greater than 7 and a cervical length less than 25 mm but not with a positive fetal fibronectin.[72]

Prostaglandins are most commonly used for labor induction in patients with an unfavorable cervix or a Bishop score that is less than 6. Studies have shown both dinoprostone (PGE1) and misoprostol (PGE2) to be efficacious in prolonged pregnancy, and either preparation is acceptable.[63,64,73]

LONG-TERM NEONATAL OUTCOMES

There is a paucity of information on neonates who are born at 42 weeks and later. Ting and colleagues evaluated a population enrolled in the Collaborative Perinatal Study in Philadelphia and found the surviving children could not be differentiated from their matched controls either physically or mentally.[74] Shime and colleagues, who followed children at 1 and 2 years of age, found similar results.[75] They assessed intelligence by the Griffiths Mental Development Scale and found no difference when these children were compared to term births. Based on these small and old studies there does not appear to be any difference in long-term neonatal outcome.

MULTIPLE GESTATION

There is no defined gestational age cut-off to define a prolonged pregnancy in twin, triplet, or higher order multiples. The average gestation lengths for twin, triplet, and quadruplet pregnancies are 36, 33, and 29 weeks, respectively. The nadir of stillbirth occurs at 38 weeks for twins, 35 week for triplets, and is unknown for quadruplets and higher order multiples.[76] Intuitively, because we use rates of perinatal mortality to define these cut-offs for singletons, we should do the same for multiple gestations. There are no current strategies recommended as these pregnancies approach the above gestational ages, though it would seem reasonable to: (1) utilize antenatal testing as these gestational ages approach and (2) accomplish delivery at the nadir of stillbirth risk.

KEY POINTS

- Establish the estimated delivery date (EDD) by use of first or second trimester ultrasound, if possible.
- There is no gestational cut-off to define a prolonged pregnancy in multiple gestations. The nadir of stillbirth risk occurs at 38 weeks for twins and 35 weeks for triplets.
- Prolonged pregnancies are associated with an increased risk for perinatal morbidity and mortality, oligohydramnios, macrosomia, postmaturity, and maternal morbidity.
- It seems prudent to initiate antenatal fetal surveillance at 41 weeks in a normal, uncomplicated pregnancy in the absence of intrauterine growth restriction.
- Antenatal fetal surveillance at 41 weeks should include a modified biophysical profile (BPP) at least once a week.
- If the cervix is favorable at 41 weeks, it may be prudent to recommend induction of labor.
- Delivery by 42 completed weeks is reasonable based on the small but increased risk of perinatal morbidity and mortality.
- Either prostaglandin preparation (PGE1 or PGE2) can be used for the induction of the postterm pregnancy.

Hypertensive disorders are among the most common medical complications of pregnancy, with a reported incidence between 5% and 10%.[1] The incidence varies among different hospitals, regions, and countries. These disorders are a major cause of maternal and perinatal mortality and morbidity worldwide.[2] The term *hypertension in pregnancy* is commonly used to describe a wide spectrum of patients who may have only mild elevations in blood pressure (BP) or severe hypertension with various organ dysfunctions. The clinical manifestations in these patients may be similar (e.g., hypertension, proteinuria); however, they may result from different underlying causes, such as

TABLE 35-1 HYPERTENSIVE DISORDERS OF PREGNANCY

CLINICAL FINDINGS	CHRONIC HYPERTENSION	GESTATIONAL HYPERTENSION*	PREECLAMPSIA
Time of onset of hypertension	<20 wk	>20 wk	Usually in third trimester
Degree of hypertension	Mild or severe	Mild	Mild or severe
Proteinuria*	Absent	Absent	Usually present
Cerebral symptoms	May be present	Absent	Present in 30%
Serum urate >5.5 mg/dL (0.33 mmol/L)	Rare	Absent	Usually present
Hemoconcentration	Absent	Absent	Severe disease
Thrombocytopenia	Absent	Absent	Severe disease
Hepatic dysfunction	Absent	Absent	Severe disease

*Defined as ≥1++ by dipstick testing on two occasions or ≥300 mg in a 24-hour urine collection.

chronic hypertension, renal disease, or pure preeclampsia. The three most common forms of hypertension are acute gestational hypertension complicating pregnancy, preeclampsia, and chronic essential hypertension.

DEFINITIONS

Hypertension may be present before pregnancy, or it may be diagnosed for the first time during pregnancy. In addition, in some women, hypertension may become evident only intrapartum or during the postpartum period. For clinical purposes, women with hypertension may be classified into one of three categories (Table 35-1).[1-3]

Gestational Hypertension

Gestational hypertension is the development of an elevated BP during pregnancy or in the first 24 hours postpartum without other signs or symptoms of preeclampsia or preexisting hypertension. In these women, BP returns to normal within 12 weeks after delivery. Hypertension is defined as a BP greater than or equal to 140 mm Hg systolic **or** 90 mm Hg diastolic (Table 35-2). **The hypertension should be present on at least two occasions, at least 4 hours apart, but within a maximum of a 1-week period.**[4] **It is recognized that some women with gestational hypertension may have undiagnosed chronic hypertension, whereas others will subsequently progress to develop the clinical syndrome of preeclampsia.**[5] In general, the likelihood of progression to preeclampsia depends on gestational age at time of diagnosis, with higher rates if the onset of hypertension is before 35 weeks' gestation[5-8] (Figure 35-1).

Preeclampsia and Eclampsia

The classic triad of preeclampsia includes hypertension, proteinuria, and edema. However, there is now universal agreement that edema should not be considered as part of the diagnosis of preeclampsia.[1-3,9-11] Indeed, edema is neither sufficient nor necessary to confirm the diagnosis of preeclampsia because edema is a common finding in normal pregnancy and about one third of eclamptic women never demonstrate edema[12] **In general, preeclampsia is primarily defined as gestational hypertension plus proteinuria. Proteinuria is defined as a concentration of 0.1 g/L or more in at least two random urine specimens collected 4 hours or more apart or 0.3 g (300 mg) in a 24-hour period.** In the absence of proteinuria, the syndrome of preeclampsia should be considered when gestational hypertension is present in association with persistent cerebral symptoms, epigastric or right upper quadrant pain plus nausea or vomiting, fetal growth restriction (FGR), or abnormal laboratory tests such as thrombocytopenia and elevated liver enzymes.[2,9-11] In mild preeclampsia, the diastolic BP remains below 110 mm Hg and the systolic BP remains below 160 mm Hg (see box, Criteria for Severe Preeclampsia).[2,3] Eclampsia is the occurrence of seizures during the second half of pregnancy not attributable to other causes.[12]

TABLE 35-2 CRITERIA FOR MILD GESTATIONAL HYPERTENSION IN HEALTHY PREGNANT WOMEN

Systolic blood pressure <160 mm Hg and diastolic blood pressure <110 mm Hg
Proteinuria of <300 mg per 24-hr collection
Platelet count of >100,000/mm^3
Normal liver enzymes
Absent maternal symptoms
Absent intrauterine growth restriction and oligohydramnios by ultrasound

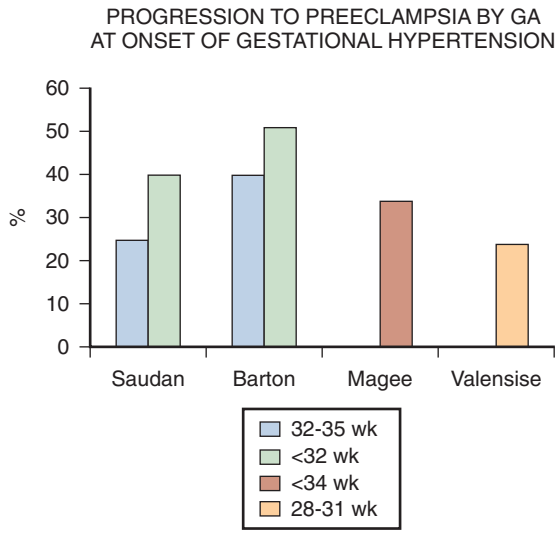

FIGURE 35-1. Rate of progression from gestational hypertension to preeclampsia by gestational age at diagnosis. *GA*, Gestational age. (Data from references 5, 6, 7, and 8.)

Criteria for Severe Preeclampsia

1. Blood pressure of ≥160 mm Hg systolic or ≥110 mm Hg diastolic, recorded on at least two occasions at least 6 hours apart with patient on bedrest
2. Proteinuria of ≥5 g in 24 hours
3. Oliguria (<500 mL in 24 hours)
4. Cerebral visual disturbances
5. Epigastric pain, nausea, and vomiting
6. Pulmonary edema
7. Impaired liver function of unclear etiology
8. Thrombocytopenia

Chronic Hypertension

Chronic hypertension is defined as hypertension present before the pregnancy or that is diagnosed before the 20th week of gestation. Hypertension that persists for more than 3 months postpartum is also classified as chronic hypertension.[2]

Chronic Hypertension with Superimposed Preeclampsia

Women with chronic hypertension may develop superimposed preeclampsia, which increases morbidity for both the mother and fetus. The diagnosis of superimposed preeclampsia is based on one or more of the following findings: development of new-onset proteinuria, defined as the urinary excretion of 0.5 g protein or greater in a 24-hour specimen in women with hypertension; no proteinuria before 20 weeks' gestation; or, in women with hypertension and proteinuria before 20 weeks, severe exacerbation in hypertension plus development of symptoms or thrombocytopenia and abnormal liver enzymes (Table 35-3).[13,14]

Gestational Hypertension

Gestational hypertension is the most frequent cause of hypertension during pregnancy. The incidence ranges between 6% and 29% in nulliparous women[2,4,15] and between 2% and 4% in multiparous women.[2] The incidence is markedly increased in patients with multiple gestation.[13,16-18] **In general, most cases of gestational hypertension develop at or beyond 37 weeks' gestation, and thus, the overall pregnancy outcome is usually similar to that seen in women with normotensive pregnancies (Table 35-4).**[4,5,15] Both gestational age at delivery and birthweight in these pregnancies are significantly higher than in normotensive pregnancies.[2,4] However, women with mild gestational hypertension have higher rates of induction of labor and thus higher rates of cesarean delivery.[4]

Maternal and perinatal morbidities are substantially increased in women with severe gestational hypertension.[2,4,19] **Indeed, these women have increased risk for morbidity compared with women with mild preeclampsia. The rates of abruptio placentae, preterm delivery (at less than 37 and 35 weeks), and small-for-gestational-age (SGA) infants in these women are similar to those seen in women with severe preeclampsia.**[2,19] Therefore, these women should be managed as if they had severe preeclampsia. It is unclear whether this increase in preterm delivery is secondary to scheduled early delivery according to physician preference or occurs because the disease process itself remains unknown.

PREECLAMPSIA

Preeclampsia is a form of hypertension that is unique to human pregnancy. The clinical findings of preeclampsia can manifest as either a maternal syndrome (hypertension and proteinuria with or without other multisystem dysfunction) or a fetal syndrome (FGR, reduced amniotic fluid, and abnormal oxygenation).[11-20] In practice, the maternal syndrome of preeclampsia represents a clinical spectrum with major differences between near-term preeclampsia without demonstrable fetal involvement and preeclampsia that is associated with low birthweight and

Table 35-3 Recommended Criteria to Diagnose Preeclampsia in Women with Preexisting Medical Conditions

CONDITION	CRITERIA NEEDED
Hypertension only	Proteinuria of ≥500 mg per 24 hr or thrombocytopenia
Proteinuria only	New-onset hypertension plus symptoms or thrombocytopenia or elevated liver enzymes
Hypertension plus proteinuria (renal disease or class F diabetes)	Worsening severe hypertension plus proteinuria either new onset of symptoms, thrombocytopenia, or elevated liver enzymes

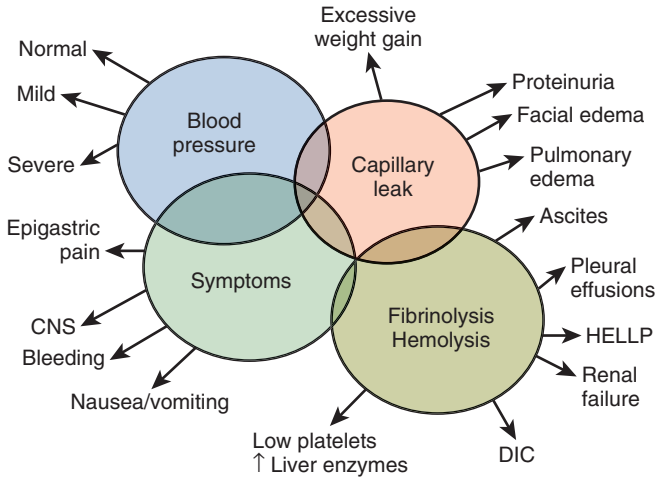

FIGURE 35-2. Various clinical and laboratory findings in women with preeclampsia or atypical preeclampsia. *CNS,* Central nervous system; *DIC,* disseminated intravascular coagulopathy; *HELLP,* hemolysis, elevated liver enzymes, and low platelets.

CRITERIA FOR ATYPICAL PREECLAMPSIA

- Gestational hypertension plus one or more of the following:
  - Symptoms of preeclampsia
  - Hemolysis
  - Thrombocytopenia (<100,000/mm^3)
  - Elevated liver enzymes: two times the upper limit of the normal value for aspartate transaminase (AST) and alanine transaminase (ALT)
- Gestational proteinuria plus one or more of the following:
  - Symptoms of preeclampsia
  - Hemolysis
  - Thrombocytopenia
  - Elevated liver enzymes
- Early signs and symptoms of preeclampsia-eclampsia at <20 weeks
- Late postpartum preeclampsia-eclampsia (>48 hours postpartum)

preterm delivery.[11,20] Preeclampsia is clearly a heterogeneous condition for which the pathogenesis could be different in women with various risk factors.[11,20,21] The pathogenesis of preeclampsia in nulliparous women may be different than that in women with preexisting vascular disease, multifetal gestation, diabetes mellitus, or previous preeclampsia. In addition, the pathophysiology of early-onset preeclampsia may be different than that of preeclampsia developing at term, during labor, or in the postpartum period.[11,20,21]

The incidence of preeclampsia ranges between 2% and 7% in healthy nulliparous women.[2,4,15] In these women, preeclampsia is generally mild, with the onset near term or intrapartum (75% of cases), and the condition conveys only a minimally increased risk for adverse fetal outcome.[2,4,15] In contrast, the incidence and severity of preeclampsia are substantially higher in women with multifetal gestation,[14,13,16,18,22] chronic hypertension,[13,14] previous preeclampsia,[23-28] pregestational diabetes mellitus,[13,29,30] or preexisting thrombophilias.[31]

Atypical Preeclampsia

The traditional criteria to confirm a diagnosis of preeclampsia include the presence of proteinuric hypertension (new onset of hypertension and new onset of proteinuria after 20 weeks' gestation). However, recent data suggest that in some women, preeclampsia and even eclampsia may develop in the absence of either hypertension or proteinuria.[10,11,32] In many of these women, there are usually other manifestations of preeclampsia, such as the presence of signs and symptoms or other laboratory abnormalities (Figure 35-2; see box, Criteria for Atypical Preeclampsia).

In the absence of proteinuria, the syndrome of preeclampsia should be considered when gestational hypertension is present in association with persistent symptoms, or with abnormal laboratory tests. It is also important to note that 25% to 50% of women with mild gestational hypertension progress to preeclampsia.[5-8] The rate of progression depends on gestational age at onset of hypertension and approaches 50% when gestational hypertension develops before 32 weeks' gestation.[5] Most of these cases result in preterm delivery or FGR, or both.[5,8] Therefore, such women require close observation for early detection of preeclampsia (frequent prenatal visits and serial evaluation of platelets and liver enzymes) and fetal growth (serial ultrasound).

Preeclampsia should also be considered when gestational hypertension is severe because of the associated adverse maternal-perinatal outcome reported in such women. In a secondary analysis of data from two multicenter trials, pregnancy outcomes in women with severe gestational hypertension were compared with those in women with mild or severe preeclampsia.[4,19] This analysis revealed that severe gestational hypertension is associated with higher maternal and perinatal morbidities than those found in mild preeclampsia. The results of these studies also revealed that women with severe gestational hypertension had adverse maternal or perinatal outcomes similar to those seen in women with severe preeclampsia.[4,19] **Therefore, women with severe gestational hypertension should be considered as having atypical preeclampsia and should be hospitalized.** For these patients, we recommend magnesium sulfate seizure prophylaxis, frequent laboratory follow-up, antihypertensive drugs, steroids for fetal lung maturity, and delivery beyond 34 weeks' gestation or earlier if indicated.[33]

Capillary Leak Syndrome: Facial Edema, Ascites and Pulmonary Edema, and Gestational Proteinuria

Hypertension is considered to be the hallmark for the diagnosis of preeclampsia; however, in some patients with preeclampsia, the disease may manifest as either a capillary leak (proteinuria, ascites, pulmonary edema), excessive weight gain, or a spectrum of abnormal hemostasis with multiple-organ dysfunction. These women usually present with clinical manifestations of atypical preeclampsia, such as proteinuria with or without facial edema, excessive weight gain (>5 pounds/week), ascites, or pulmonary edema, in association with abnormalities in laboratory values or presence of symptoms, but without

hypertension.[32] Therefore, we recommend that women with capillary leak syndrome with or without hypertension be evaluated for platelet, liver enzyme, and renal abnormalities. Those with symptoms such as significant headache or abnormal blood tests should be considered to have preeclampsia.[32]

Gestational Proteinuria

There is general agreement that urine dipstick protein measurements should be performed at each prenatal visit after 20 weeks' gestation. Gestational proteinuria is defined as urinary protein excretion of at least 300 mg per 24-hour timed collection or persistent proteinuria (≥1+ on dipstick on at least two occasions at least 4 hours apart, but no more than 1 week apart).[34] The exact incidence of gestational proteinuria before progression to preeclampsia is not known; however, isolated gestational proteinuria was reported in 4% of women enrolled in two multicenter trials.[34,35] In addition, these studies reported that 4.3% to 7% of patients had combined gestational hypertension and gestational proteinuria. Thus, it appears that at least one third of women with gestational proteinuria may progress to preeclampsia.[34,35] Indeed, some authors suggested that gestational proteinuria alone may herald the early manifestations of impending preeclampsia.[34,36]

Women with new-onset gestational proteinuria only should be monitored very closely, at least on a twice-weekly follow-up basis, for early detection of preeclampsia because the presence of gestational proteinuria alone may signify impending preeclampsia.[32]

Preeclampsia-Eclampsia at Less Than 20 Weeks' Gestation

Preeclampsia or eclampsia, or both, occurring before the 20th week of gestation has been reported with molar or hydropic degeneration of the placenta with or without a coexistent fetus. Additionally, although exceedingly rare, preeclampsia-eclampsia can occur during the first half of pregnancy without molar degeneration of the placenta.[32] On the other hand, the presence of hypertension, proteinuria, and abnormal laboratory tests before 20 weeks' gestation may be due to lupus nephritis, hemolytic uremic syndrome (HUS), antiphospholipid antibody syndrome, or thrombotic thrombocytopenic purpura (TTP).[32] Therefore, such women should be evaluated to rule out the presence of these disorders. In the absence of other pathology, the patient should be treated as for severe preeclampsia. **In addition, women in whom convulsions develop in association with hypertension and proteinuria during the first half of pregnancy should be considered to have eclampsia until proved otherwise. These women should have ultrasound examination of the uterus to rule out molar pregnancy and hydropic or cystic degeneration of the placenta.** A diagnostic modality that is also recommended is the measurement of uterine artery Doppler flow, which shows the classic "notching" characteristic of increased resistance in the placenta of patients with preeclampsia.[32]

Risk Factors for Preeclampsia

Several factors have been identified with increased risk for preeclampsia (see box, Risk Factors for Preeclampsia). Generally, preeclampsia is considered a disease of primigravid women. The risk increases in those who have limited sperm exposure with the same partner before conception.[11,20,37] The protective effects of long-term sperm exposure with the same partner might provide an explanation for the high risk for preeclampsia in women younger than 20 years old. A previous abortion (spontaneous or induced) or a previous normal pregnancy with the same partner is associated with a lower risk for preeclampsia. However, this protective effect is lost with a change of partner.[38] Both Scandinavian and U.S. studies have confirmed the importance of paternal factors, that is, the so-called dangerous father.[39,40] Using whole population data, Lie and colleagues[40] demonstrated that men who fathered one preeclamptic pregnancy were nearly twice as likely to father a preeclamptic pregnancy in a different woman (1.8; 95% confidence interval [CI] 1.2 to 2.6; after adjustment for parity), regardless of whether the new partner had a preeclamptic pregnancy in the past or not. Thus, mothers had a substantially increased risk in their second pregnancy (2.9%) if their partner had fathered a preeclamptic first pregnancy with another woman. This risk was nearly as high as the average risk among first pregnancies.[40]

Risk Factors for Preeclampsia

- Nulliparity
- Age >40 years
- Family history of preeclampsia
- Woman born small for gestational age
- Obesity/gestational diabetes
- Multifetal gestation
- Preeclampsia in previous pregnancy
- Poor outcome in previous pregnancy
  - Fetal growth restriction, abruptio, fetal death
- Preexisting medical-genetic conditions
  - Chronic hypertension
  - Renal disease
  - Type 1 (insulin-dependent) diabetes mellitus
  - Antiphospholipid antibody syndrome, factor V Leiden mutation

Recent advances in assisted reproductive technology have introduced several challenges for the maternal immune system that also increase the risk for preeclampsia.[17,18,41] These include a greater proportion of women older than 40 years, infertile women during their first gestation, obese women with polycystic ovary syndrome, and women who become pregnant with donated gametes or embryos.[41] The use of donated gametes can influence the maternal-fetal immune interaction. In addition, many of these women have multifetal gestations.[17,18,41] In addition, infertile women with recurrent miscarriage are also reported to be at increased risk for preeclampsia.[42]

Obesity increases the risk for preeclampsia, and this risk increases with increased body mass index.[43] The worldwide increase in obesity is thus likely to lead to a rise in the frequency of preeclampsia.[44,45] Obesity has a strong link to insulin resistance, which is also a risk factor for preeclampsia. The exact mechanism by which obesity or insulin resistance is associated with preeclampsia is not well understood.

Earlier studies found an overall higher rate of thrombophilia in women with preeclampsia compared with

controls.[31] Recently, a number of reports have failed to reproduce these findings.[46-48] The disparity in results can be seen to reflect the heterogeneity of the women being studied. In the largest series of preeclamptic women with thrombophilia, women had increasing risk for very-early-onset severe disease (delivery before 28 weeks) compared with those without thrombophilia.[31]

Pathophysiology

The etiology of preeclampsia remains unknown. Many theories have been suggested, but most of them have not withstood the test of time. Some of the theories still under consideration are listed in the box, Theories Associated with the Etiology of Preeclampsia.[11,21,49-51]

Theories Associated with the Etiology of Preeclampsia

- Abnormal trophoblast invasion or poor implantation
- Imbalance in angiogenesis
- Coagulation abnormalities
- Vascular endothelial damage
- Cardiovascular maladaptation
- Immunologic maladaptation
- Genetic predisposition
- Exaggerated inflammatory response
- Increased oxidative stress

During normal pregnancy, impressive physiologic changes occur in the uteroplacental vasculature in general and in the cardiovascular system in particular. These changes are most likely induced by the interaction of the fetal (parental) allograft with maternal tissue. The development of mutual immunologic tolerance in the first trimester is thought to lead to important morphologic and biochemical changes in the systemic and uteroplacental maternal circulation.

Uterine Vascular Changes

The human placenta receives its blood supply from numerous uteroplacental arteries that are developed by the action of migratory interstitial and endovascular trophoblast into the walls of the spiral arterioles. This transforms the uteroplacental arterial bed into a low-resistance, low-pressure, high-flow system. The conversion of the spiral arterioles of the nonpregnant uterus into the uteroplacental arteries has been termed *physiologic changes*.[52,53] In a normal pregnancy, these trophoblast-induced vascular changes extend all the way from the intervillous space to the origin of the spiral arterioles representing the radial arteries in the inner one third of the myometrium. It is suggested that these vascular changes are effected in two stages: "the conversion of the decidual segments of the spiral arterioles by a wave of endovascular trophoblast migration in the first trimester and the myometrial segments by a subsequent wave in the second trimester."[52,53] This process is reportedly associated with extensive fibrinoid formation and degeneration of the muscular layer in the arterial wall. These vascular changes result in the conversion of about 100 to 150 spiral arterioles into distended, tortuous, and funnel-shaped vessels that communicate through multiple openings into the intervillous space.

In contrast, pregnancies complicated by preeclampsia or by FGR demonstrate inadequate maternal vascular response to placentation. In these pregnancies, the previously mentioned vascular changes are usually found only in the decidual segments of the uteroplacental arteries. Hence, the myometrial segments of the spiral arterioles continue to exhibit their characteristic musculoelastic architecture, thereby leaving them responsive to hormonal influences.[52,53] Additionally, the number of well-developed arterioles is smaller than that found in normotensive pregnancies. It has been postulated that this defective vascular response to placentation is due to inhibition of the second wave of endovascular trophoblast migration that normally occurs from about 16 weeks' gestation onward. These pathologic changes may have the effect of curtailing the increased blood supply required by the fetoplacental unit in the later stages of pregnancy and correlate with decreased uteroplacental blood flow seen in most cases of preeclampsia.[52] Frusca and associates studied placental bed biopsy specimens obtained during cesarean delivery from normal pregnancies (n = 14), preeclamptic pregnancies (n = 24), and chronic hypertensive pregnancies only (n = 5).[54] Biopsy specimens from the preeclamptic group demonstrated abnormal vascular changes in every case, with 18 having acute atherosclerotic changes. In contrast, 13 of the 14 specimens from normotensive pregnancies had normal vascular physiologic changes, whereas specimens from hypertensive patients showed all three types of physiologic changes. In addition, they found that the mean birthweight was significantly lower in the group with atherosclerosis than it was in the other group without such findings. It is important to note that these vascular changes may also be demonstrated in a significant proportion of normotensive pregnancies complicated by FGR. Meekins and associates[55] have demonstrated that endovascular trophoblast invasion is not an all-or-none phenomenon in normal and preeclamptic pregnancies. These authors observed that morphologic features found in one spiral artery may not be representative of all vessels in a placental bed.

Vascular Endothelial Activation and Inflammation

The mechanism by which placental ischemia leads to the clinical syndrome of preeclampsia is thought to be related to the production of placental factors that enter the maternal circulation resulting in endothelial cell dysfunction.[49-51,56] **Soluble fms-like tyrosine kinase 1 (sFlt-1) is a protein that is produced by the placenta. It acts by binding to the receptor-binding domains of vascular endothelial growth factor (VEGF), and it also binds to placental like growth factor (PLGF). Increased levels of this protein in the maternal circulation results in reduced levels of free VEGF and free PLFG, with resultant endothelial cell dysfunction.**[56]

Maternal serum and placental levels of sFlt-1 are increased in pregnancies complicated by preeclampsia above values seen during normal pregnancies. Maynard and coworkers[57] demonstrated that soluble placenta-derived VEGF receptor (sFlt1), an antagonist of VEGF and PLGF, is unregulated in preeclampsia, leading to increased systemic levels of sFlt1 that fall after delivery.

Increased circulating sFlt1 in preeclampsia is associated with decreased circulating levels of free VEGF and PLGF, resulting in endothelial dysfunction. The magnitude of increase in sFlt levels correlates with disease severity,[58] lending further support to VEGF-soluble Flt balance representing one of the final common pathophysiologic pathways.

First-trimester PLGF levels are decreased in future preeclamptic pregnancies and in pregnancies complicated by FGR, whereas sFlt levels do not differ from controls.[59] Again, these data are compatible with decidual angiogenic growth factors, in particular PLGF, as being essential for early placental development (PLGF is low in both FGR and preeclampsia), with a later involvement of sFlt as a fetal rescue signal steering the maternal response, that is, the degree of maternal systemic hypertension. This hypothesis is supported by Levine and colleagues,[58] who demonstrated that during the last 2 months of pregnancy in normotensive controls, the level of sFlt-1 increased and the level of PLGF decreased.

Levine and associates[60] investigated urinary PLGF levels in pregnant women with and without preeclampsia and found that among normotensive pregnant women, urinary PLGF increased during the first two trimesters, peaked at 29 to 32 weeks, and decreased thereafter. Among women who ultimately developed preeclampsia, the pattern of urinary PLGF was similar, but levels were significantly reduced beginning at 25 to 28 weeks. There were particularly large differences among those who subsequently developed early-onset preeclampsia and in those delivering SGA infants.[60] A similar study suggested that urinary angiogenic factors can identify women with severe preeclampsia.[61]

During the past decade, our understanding of the molecular basis for the pathophysiologic abnormalities in preeclampsia has reached an unprecedented level. There is now clear appreciation for the role of cell adhesion molecules, angiogenic proteins, and activation of the inflammatory system in the pathogenesis of microvascular dysfunction in women with preeclampsia[49-52,58] There is clear evidence for an exaggerated inflammatory response (abnormal cytokine production and neutrophil activation) in women with the clinical findings of preeclampsia.[50,51] However, this enhanced inflammatory response is absent before the development of preeclampsia.[62]

Recent studies confirming increased levels of asymmetrical dimethylarginine at 23 to 25 weeks in pregnant women who develop preeclampsia have emphasized the importance of the nitric oxide–cyclic guanosine monophosphate pathway.[63,64] Endothelial dysfunction and inappropriate endothelial cell activation associated with alterations in nitric oxide levels in preeclampsia explain most typical clinical manifestations, including the increased endothelial cell permeability and increased platelet aggregation.[49,65]

Genetics and Genetic Imprinting

According to the genetic conflict theory,[11,20] fetal genes are selected to increase the transfer of nutrients to the fetus, whereas maternal genes are selected to limit transfer in excess of some optimal level. The phenomenon of genomic imprinting means that a similar conflict exists within fetal cells between genes that are maternally derived and genes that are paternally derived. The conflict hypothesis suggests that placental factors (fetal genes) act to increase maternal BP, whereas maternal factors act to reduce BP.[20] Endothelial cell dysfunction may have evolved as a fetal rescue strategy to increase nonplacental resistance when the uteroplacental blood supply is inadequate.

Nilsson and associates[66] published a model suggesting a heritability estimate of 31% for preeclampsia and 20% for gestational hypertension. It is unlikely that there will be one major preeclampsia gene because such a gene would be selected against through evolution, unless it also carried a major reproductive advantage. It is more likely that a rapidly growing number of susceptibility genes will be uncovered, many of these interacting with the maternal cardiovascular-hemostatic system or the regulation of maternal inflammatory responses.[67] These loci segregate with different populations.[68] It should be noted that these loci only explain a relatively small percentage of the overall cases of preeclampsia. In addition, although these linkage studies indicate maternal susceptibility, they do not exclude the additional involvement of fetal genes.[68] Another important consideration regarding the genetics of preeclampsia is the confounding effect of the so-called fetal origins of adult disease hypothesis suggesting that a hostile intrauterine environment for a female fetus would form the basis for the insulin resistance syndrome with its associated endothelial dysfunction and, as such, an increased risk for preeclampsia.[20]

Epigenetic features or imprinting is also involved in the pathogenesis of preeclampsia.[68,69] A direct proof of the role of imprinting was recently published by Oudejans and coworkers[68] and Nafee and associates.[69]

Changes in Prostanoids

Several investigators have described the various prostaglandins and their metabolites throughout pregnancy. They have measured the concentrations of these substances in plasma, serum, amniotic fluid, placental tissues, urine, or cord blood. The data have been inconsistent, reflecting differences in methodology.[70,71] During pregnancy, prostanoid production increases in both maternal and fetoplacental tissues. Prostacyclin is produced by the vascular endothelium as well as in the renal cortex. It is a potent vasodilator and inhibitor of platelet aggregation. Thromboxane A_2 (TXA_2) is produced by the platelets and trophoblasts. It is a potent vasoconstrictor and platelet aggregator. Hence, these eicosanoids have opposite effects and play a major role in regulating vascular tone and vascular blood flow (Figure 35-3). An imbalance in prostanoid production or catabolism has been suggested as being responsible for the pathophysiologic changes in preeclampsia. However, the precise role by which prostaglandins are involved in the etiology of preeclampsia remains unclear.[20]

Lipid Peroxide, Free Radicals, and Antioxidants

Evidence is accumulating that lipid peroxides and free radicals may be important in the pathogenesis of preeclampsia.[40,51] Superoxide ions may be cytotoxic to the cell by changing the characteristics of the cellular membrane and producing membrane lipid peroxidation. Elevated plasma concentrations of free radical oxidation products

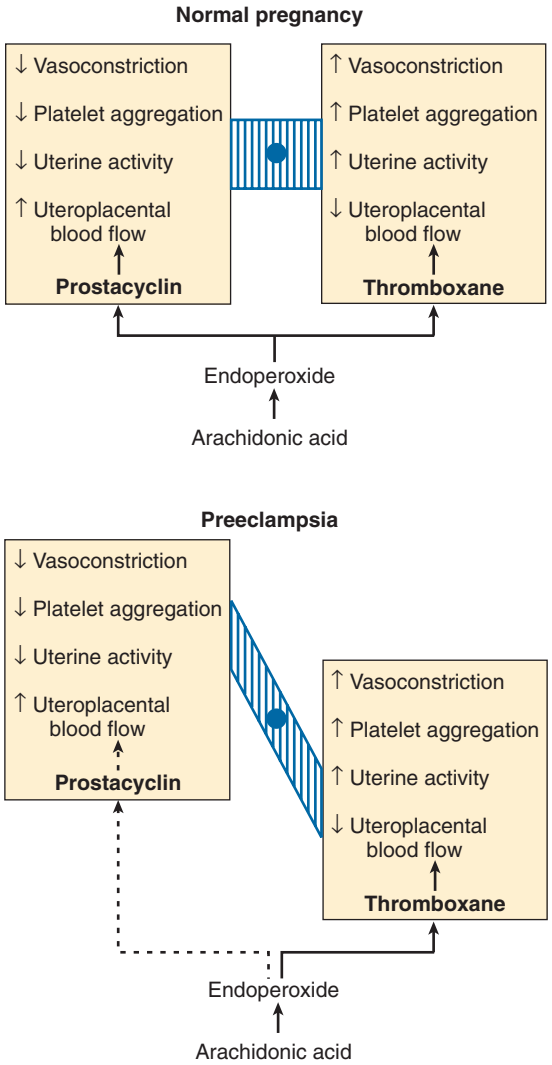

FIGURE 35-3. Comparison of the balance in the biologic actions of prostacyclin and thromboxane in normal pregnancy with the imbalance of increased thromboxane and decreased prostacyclin in pre-eclamptic pregnancy. The heavy type and box for thromboxane suggest an exacerbation of its actions in preeclampsia, whereas the lighter type and box for prostacyclin suggest a diminution of its actions. (From Walsh SW: Preeclampsia: an imbalance in placenta prostacyclin and thromboxane production. Am J Obstet Gynecol 152:335, 1985.)

precede the development of preeclampsia. In addition, some studies reported lower serum antioxidant activity in patients with preeclampsia than in normotensive pregnancies.[11,20]

Much of the controversy about oxidative stress is related to the nonspecificity of the markers. A recent study by Moretti and associates[72] measured oxidative stress "online" in exhaled breath (not subjective to in vitro artefacts) and confirmed greater oxidative stress in women with preeclampsia compared with uncomplicated pregnancies and nonpregnant controls.

Diagnosis of Preeclampsia

Preeclampsia is a clinical syndrome that embraces a wide spectrum of signs and symptoms that have been clinically observed to develop alone or in combination. Elevated BP is the traditional hallmark for diagnosis of the disease. The diagnosis of preeclampsia and the severity of the disease process are generally based on maternal BP. Many factors may influence the measurement of BP, including the accuracy of the equipment used, size of the sphygmomanometer cuff, duration of the rest period before recording, posture of the patient, and Korotkoff phase used (phase IV or phase V for diastolic BP measurement). **It is recommended that all BP values be recorded with the woman in a sitting position for ambulatory patients or in a semireclining position for hospitalized patients.**[2,3,9,10] The right arm should be used consistently, with the arm being in a roughly horizontal position at heart level. For diastolic BP measurements, both phases (muffling sound and disappearance sound) should be recorded. This is very important because the level measured at phase IV is about 5 to 10 mm Hg higher than that measured at phase V. A rise in BP has been used by several authors as a criterion for the diagnosis of hypertension in pregnancy. This definition is usually unreliable because a gradual increase in BP from second to third trimester is seen in most normotensive pregnancies. Villar and Sibai[74] prospectively studied BP changes during the course of pregnancy in 700 young primigravidas. One hundred thirty-seven patients (19.6%) had preeclampsia. The sensitivity and positive predictive values for preeclampsia of a threshold increase in diastolic BP of at least 15 mm Hg on two occasions were 39% and 32%, respectively. The respective values for a threshold increase in systolic pressures were 22% and 33%. Three recent studies from New Zealand,[75] the United States,[76] and Turkey[77] investigated pregnancy outcome in women with a rise in diastolic BP of more than 15 mm Hg but an absolute diastolic level below 90 mm Hg compared with gravidas who remained normotensive.[75-77] The New Zealand report[75] and Turkish study[77] included women with elevated BPs without proteinuria, whereas the American investigation[76] included women with an increased diastolic pressure by 15 mm Hg or more plus proteinuria (≥300 mg/24 hours). Overall, pregnancy outcomes were similar among women who remained normotensive and those who demonstrated a rise in diastolic pressure of 15 mm Hg or higher but did not reach 90 mm Hg. The use of an increase in BP as a diagnostic criterion is principally influenced by two factors: gestational age at time of first observation and frequency of BP measurements. Thus, these criteria are unreliable to diagnose preeclampsia as such.

The diagnosis of preeclampsia requires the presence of an elevated BP with proteinuria.[1-3] The presence of proteinuria is usually determined by the use of either dipstick or protein-to-creatinine ratio in random urine samples. The concentration of urinary protein is highly variable. It is influenced by several factors, including contamination, urine specific gravity, pH, exercise, and posture.[78] In addition, urinary protein-to-creatinine excretion is highly variable in patients with preeclampsia.[79] Moreover, urinary dipstick determinations as well as total protein-to-creatinine ratio correlate poorly with the amount of proteinuria found in 24-hour urine determinations in women with gestational hypertension.[79-82] Therefore, **the definitive test for diagnosing proteinuria should be quantitative measurement of total protein excretion over a 24-hour period.** However, the accuracy of 24-hour urine collection might

not be reliable.[83] The diagnosis of severe preeclampsia requires that proteinuria of more than 5 g per 24 hours be documented. Using urine dipstick measurements (≥3+) is not adequate.[83,84]

The traditional criteria to confirm a diagnosis of preeclampsia (new onset of hypertension and proteinuria after 20 weeks' gestation) are appropriate to use in most healthy nulliparous women. However, in some women, hypertension or proteinuria may be absent in 10% to 15% of women who develop the syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome)[85] and in 20% to 25% of those who develop eclampsia.[86]

Prediction of Preeclampsia

A review of the world literature reveals that more than 100 clinical, biophysical, and biochemical tests have been recommended to predict or identify the patient at risk for the future development of the disease.[87-92] The results of the pooled data for the various tests and the lack of agreement between serial tests suggest that none of these clinical tests is sufficiently reliable for use as a screening test in clinical practice.[28]

Numerous biochemical markers have been proposed to predict which women are destined to develop preeclampsia. These biochemical markers were generally chosen on the basis of specific pathophysiologic abnormalities that have been reported in association with preeclampsia. Thus, these markers have included markers of placental dysfunction, endothelial and coagulation activation, angiogenesis, and markers of systemic inflammation. However, the results of various studies evaluating the reliability of these markers in predicting preeclampsia have been inconsistent, and many of these markers suffer from poor specificity and predictive values for routine use in clinical practice[93-100]

Doppler ultrasound is a useful method to assess uterine artery blood flow velocity in the second trimester. An abnormal uterine artery velocity waveform is characterized by a high resistance index or by the presence of an early diastolic notch (unilateral or bilateral).[88,89,92] Pregnancies complicated by abnormal uterine artery Doppler findings in the second trimester are associated with more than a sixfold increase in rate of preeclampsia.[88] However, the sensitivity of an abnormal uterine artery Doppler for predicting preeclampsia ranges from 20% to 60%, with a positive predictive value of 6% to 40%.[88,92] **Current data do not support Doppler studies for routine screening of pregnant women for preeclampsia, but uterine artery Doppler could be beneficial as a screening test in women at very high risk for preeclampsia if an effective preventive treatment becomes available.**[20]

Prevention of Preeclampsia

There are numerous clinical trials describing the use of various methods to prevent or reduce the incidence of preeclampsia.[20,100] Because the etiology of the disease is unknown, these interventions have been used in an attempt to correct theoretical abnormalities in preeclampsia. A detailed review of these trials is beyond the scope of this chapter; however, the results of these studies have been the subject of several recent systemic reviews.[100] **In short, randomized trials have evaluated protein or salt restriction; zinc, magnesium, fish oil, or vitamins C and E supplementation; the use of diuretics and other antihypertensive agents; and the use of heparin to prevent preeclampsia in women with various risk factors. These trials have had limited sample size, and results have revealed *minimal to no benefit.*** Some of the methods studied are summarized in the box, Methods Used to Prevent Preeclampsia.

Methods Used to Prevent Preeclampsia

- High-protein and low-salt diet
- Nutritional supplementation (protein)
- Calcium
- Magnesium
- Zinc
- Fish and evening primrose oil
- Antihypertensive drugs including diuretics
- Antithrombotic agents
- Low-dose aspirin
- Dipyridamole
- Heparin
- Vitamins E and C

Calcium Supplementation

The relationship between dietary calcium intake and hypertension has been the subject of several experimental and observational studies. Epidemiologic studies have documented an inverse association between calcium intake and maternal BP, and the incidences of preeclampsia and eclampsia. The BP-lowering effect of calcium is thought to be mediated by alterations in plasma renin activity and parathyroid hormone.

There are 13 clinical studies (15,730 women) comparing the use of calcium with no treatment or a placebo in pregnancy. These trials differ in the populations studied (low risk or high risk for hypertensive disorders of pregnancy), study design (randomization, double-blind, or use of a placebo), gestational age at enrollment (20 to 32 weeks' gestation), sample size in each group (range, 22 to 588), dose of elemental calcium used (156 to 2000 mg/day), and the definition of hypertensive disorders of pregnancy used.

In the Cochrane review, calcium supplementation was associated with reduced hypertension (relative risk [RR], 0.65; 95% confidence interval [CI], 0.53 to 0.81) and reduced preeclampsia (RR, 0.45; 95% CI, 0.31 to 0.65), particularly for those at high risk and with low baseline dietary calcium intake (for those with adequate calcium intake, the difference was not statistically significant). No side effects of calcium supplementation have been recorded in the trials reviewed. In contrast, a recent evidence-based review by the U.S. Food and Drug Administration concluded that "the relationship between calcium and risk of hypertension in pregnancy is inconsistent and inconclusive, and the relationship between calcium and the risk of pregnancy induced hypertension and preeclampsia is highly unlikely." At present, the benefit of calcium supplementation for preeclampsia prevention in women with low dietary calcium intake remains unclear.[28] It is also important to note that none of the published randomized trials included women with high-risk factors such as previous preeclampsia, chronic hypertension, twins, or pregestational diabetes mellitus.[28]

Antithrombotic Agents

Preeclampsia is associated with vasospasm and activation of the coagulation-hemostasis systems. Enhanced platelet activation plays a central role in the previously mentioned process and reflects abnormalities in the thromboxane-prostacyclin balance. Hence, several authors have used pharmacologic manipulation to alter the previously mentioned ratio in an attempt to prevent or ameliorate the course of preeclampsia.

Aspirin inhibits the synthesis of prostaglandins by irreversibly acetylating and inactivating cyclooxygenase. In vitro, platelet cyclooxygenase is more sensitive to inhibition by low doses of aspirin (<80 mg) than vascular endothelial cyclooxygenase. This biochemical selectivity of low-dose aspirin appears to be related to its unusual kinetics that result in presystemic acetylation of platelets exposed to higher concentrations of aspirin in the portal circulation.

Most randomized trials for the prevention of preeclampsia have used low dose of aspirin (50 to 150 mg/dL). The rationale for recommending low-dose aspirin prophylaxis is the theory that the vasospasm and coagulation abnormalities in preeclampsia are caused partly by an imbalance in the TXA_2-to-prostacyclin ratio.[20]

Recently, the Perinatal Antiplatelet Review of International Studies (PARIS) Collaborate Group performed a meta-analysis of the effectiveness and safety of antiplatelet agents (predominantly aspirin) for the prevention of preeclampsia. Thirty-one trials involving 32,217 women are included in this review. There was a 10% reduction in the risk for preeclampsia associated with the use of antiplatelet agents (RR, 0.90; 95% CI 0.84 to 0.96). For women with a previous history of hypertension or preeclampsia ($n = 6107$) who were assigned to antiplatelet agents, the RR for developing preeclampsia was 0.86 (95% CI, 0.77 to 0.97). There were no significant differences between treatment and control groups in any other measures of outcome. The reviewers concluded that antiplatelet agents, largely low-dose aspirin, have small to moderate benefits when used for prevention of preeclampsia. Low-dose aspirin was also found to be safe. However, more information is clearly required to assess which women are most likely to benefit from this therapy as well as when treatment is optimally started and what dose to use.[28] Several studies evaluated the efficacy of aspirin in the prevention of preeclampsia in high-risk pregnancies as determined by Doppler ultrasound or other risk factors when aspirin was used early in pregnancy. A meta-analysis suggested that low-dose aspirin improves pregnancy outcome in these women when aspirin is started before 16 weeks' gestation. However, this review has numerous flaws in design and data analysis. **A large multicenter National Institute of Child Health and Human Development–sponsored study that included 2539 women with pregestational insulin-treated diabetes mellitus, chronic hypertension, multifetal gestation, or preeclampsia in a previous pregnancy showed no beneficial effect from low-dose aspirin in such high-risk women** (Table 35-5).[13] **Some authors recommend that aspirin use should be based on individualized risk assessment for preeclampsia. However, the available data do not support such a recommendation.**

Vitamins C and E

Reduced antioxidant capacity, increased oxidative stress, or both in the maternal circulation and in the placenta have been proposed to play a major role in the pathogenesis of preeclampsia. Consequently, several trials were designed using vitamins C and E for the prevention of preeclampsia. The first trial suggested a beneficial effect from pharmacologic doses of vitamins E and C in women identified as being at risk for preeclampsia by means of abnormal uterine Doppler flow velocimetry. However, the study had limited sample size and must be confirmed in other populations. **In contrast, several randomized trials with large sample size in women at low risk and very high risk for preeclampsia found no reduction in the rate of preeclampsia with vitamins C and E supplementation (Table 35-6).**[29]

Laboratory Abnormalities in Preeclampsia

Women with preeclampsia may exhibit a symptom complex ranging from minimal BP elevation to derangements of multiple-organ systems. The renal, hematologic, and hepatic systems are most likely to be involved.

Renal Function

Renal plasma flow and glomerular filtration rate (GFR) increase during normal pregnancy. These changes are responsible for a fall in serum creatinine, urea, and uric acid concentrations.[78] In preeclampsia, vasospasm and glomerular capillary endothelial swelling (glomerular endotheliosis) lead to an average reduction in GFR of 25%

TABLE 35-5 LOW-DOSE ASPIRIN IN HIGH-RISK WOMEN: NICHD TRIAL

ENTRY CRITERIA	NO. OF WOMEN	ASPIRIN*	PREECLAMPSIA (%) PLACEBO*
Normotensive and no proteinuria	1613	14.5	17.7
Proteinuria and hypertension	119	31.7	22.0
Proteinuria only	48	25.0	33.3
Hypertension only	723	24.8	25.0
Insulin-dependent diabetes	462	18.3	21.6
Chronic hypertension	763	26.0	24.6
Multifetal gestation	678	11.5	15.9
Previous preeclampsia	600	16.7	19.0

below the rate for normal pregnancy. Serum creatinine is rarely elevated in preeclampsia, but uric acid can be increased. In a study of 95 women with severe preeclampsia, Sibai and associates reported a mean serum creatinine of 0.91 mg/dL, a mean uric acid of 6.6 mg/dL, and a mean creatinine clearance of 100 mL/minute.

The clinical significance of elevated uric acid levels in preeclampsia-eclampsia has been confusing. Hyperuricemia is associated with renal dysfunction, especially decreased renal tubular secretion, and has been consistently associated with glomerular endotheliosis. In addition, it has been linked with increased oxidative stress in preeclampsia. **Despite the fact that uric acid levels are elevated in women with preeclampsia, this test is not sensitive or specific for the diagnosis of preeclampsia or for predicting adverse perinatal outcome.**

Elevated uric acid levels above 6 mg/dL are often found in women with normotensive multifetal pregnancies. As a result, some authors suggested that to secure a diagnosis of preeclampsia based on elevated uric acid values, the upper limit should be adjusted for those with multiple gestation. Elevated uric acid values are also found in women with acute fatty liver of pregnancy and underlying renal disease. It is suggested that uric acid values not be used as an indication for delivery in women with preeclampsia.

Hepatic Function

The liver is not primarily involved in preeclampsia, and hepatic involvement is observed in only 10% of women with severe preeclampsia. Fibrin deposition has been found along the walls of hepatic sinusoids in preeclamptic patients with no laboratory or histologic evidence of liver involvement. When liver dysfunction does occur in preeclampsia, mild elevation of serum transaminases is most common. Bilirubin is rarely increased in preeclampsia, but when elevated, the indirect fraction predominates. Elevated liver enzymes are part of the of HELLP syndrome, a variant of severe preeclampsia.

Hematologic Changes

Many studies have evaluated the hematologic abnormalities in women with preeclampsia. Plasma fibrinopeptide-A, D-dimer levels, and circulating thrombin-antithrombin complexes are higher in women with preeclampsia than in normotensive gravidas. In contrast, plasma antithrombin III activity is decreased. These findings indicate enhanced thrombin generation.

Plasma fibrinogen rises progressively during normal pregnancy. In general, plasma fibrinogen levels are rarely reduced in women with preeclampsia in the absence of abruptio placentae.

Thrombocytopenia is the most common hematologic abnormality in women with severe preeclampsia. It is correlated with the severity of the disease process and the presence or absence of abruptio placentae. In a study of 1414 women with hypertension during pregnancy, Burrows and Kelton found a platelet count of less than 150,000/mm^3 in 15% of cases.

Leduc and associates studied the coagulation profile (platelet count, fibrinogen, prothrombin time, and partial thromboplastin time) in 100 consecutive women with severe preeclampsia. A platelet count lower than 150,000/mm^3 was found in 50% and a count lower than 100,000/mm^3 in 36% of the women. Thirteen women had a fibrinogen level of less than 300 mg/dL, and two had prolonged prothrombin and partial thromboplastin times as well as thrombocytopenia on admission. They found the admission platelet count to be an excellent predictor of subsequent thrombocytopenia and concluded that fibrinogen levels, prothrombin time, and partial thromboplastin time should be obtained only in women with a platelet count of less than 100,000/mm^3. A recent study by Barron confirmed these observations in more than 800 women with hypertension in pregnancy.

HELLP Syndrome

There is considerable debate regarding the definition, diagnosis, incidence, etiology, and management of HELLP syndrome.[85] Patients with such findings were previously described by many investigators. Weinstein considered it a unique variant of preeclampsia and coined the term HELLP syndrome for this entity. Barton and associates performed liver biopsies in patients with preeclampsia and HELLP syndrome. Periportal necrosis and hemorrhage were the most common histopathologic findings. In addition, they found that the extent of the laboratory abnormalities in HELLP syndrome, including the platelet count and liver enzymes, did not correlate with hepatic histopathologic findings.

Laboratory Criteria for Diagnosis

Various diagnostic criteria have been used for HELLP. Hemolysis, defined as the presence of microangiopathic hemolytic anemia, is the hallmark of the triad of HELLP syndrome.[85] The classic findings of microangiopathic

hemolysis include abnormal peripheral smear (schistocytes, burr cells, echinocytes), elevated serum bilirubin (indirect form), low serum haptoglobin levels, elevated lactate dehydrogenase (LDH) levels, and significant drop in hemoglobin levels. A significant percentage of published reports included patients who had no evidence of hemolysis; hence, these patients will fit the criteria for HELLP syndrome.[85] In some studies in which hemolysis is described, the diagnosis is suspect because it has been based on the presence of an abnormal peripheral smear (no description of type or degree of abnormalities) or elevated LDH levels (threshold of 180 to 600 U/L).

There is no consensus in the literature regarding the liver function test to be used or the degree of elevation in these tests to diagnose elevated liver enzymes.[85] In his original report, Weinstein mentioned abnormal serum levels of aspartate transaminase (AST), abnormal alanine transaminase (ALT), and abnormal bilirubin values; however, specific levels were not suggested. In subsequent studies in which elevated liver enzymes were described (either AST or ALT), the values considered to be abnormal ranged from 17 to 72 U/L.[85] In clinical practice, many of these values are considered normal or slightly elevated.

Low platelet count is the third abnormality required to establish the diagnosis of HELLP syndrome. There is no consensus among various published reports regarding the diagnosis of thrombocytopenia. The reported cut-off values have ranged from 75,000/mm^3 to 279,000/mm^3, with a level of less than 100,000/mm^3 being most often cited.[85]

Many authors have used elevated total LDH (usually >600 U/L) as a diagnostic criteria for hemolysis. There are five different isoforms of LDH, and only two of them, LDH_1 and LDH_2, are released from ruptured red blood cells. In most women with severe preeclampsia-eclampsia, the elevation in total LDH is probably caused mostly by liver ischemia. Therefore, many authors advocate that elevated bilirubin values (indirect form), abnormal peripheral smear, or a low serum haptoglobin level should be part of the diagnostic criteria for hemolysis.

Based on a retrospective review of 302 cases of HELLP syndrome, Martin and colleagues devised the following classification based on the nadir of the platelet count. Class I HELLP syndrome was defined as a platelet nadir below 50,000/mm^3, class 2 as a platelet nadir between 50,000 and 100,000/mm^3, and class 3 as a platelet nadir between 100,000 and 150,000/mm^3. These classes have been used to predict the rapidity of recovery postpartum, maternal-perinatal outcome, and the need for plasmapheresis.

Hemolysis, defined as the presence of microangiopathic hemolytic anemia, is the hallmark of HELLP syndrome. The role of disseminated intravascular coagulation (DIC) in preeclampsia is controversial. **Most authors do not regard HELLP syndrome to be a variant of DIC because coagulation parameters such as prothrombin time, partial thromboplastin time, and serum fibrinogen are normal.**[85] However, the diagnosis of DIC can be difficult to establish in clinical practice. When sensitive determinants of this condition are used, such as antithrombin III, fibrinopeptide-A, fibrin monomer, D-dimer, α_2-antiplasmin, plasminogen, prekallikrein, and fibronectin, many patients have laboratory values consistent with DIC. Unfortunately, these tests are time consuming and not suitable for routine monitoring. Consequently, less sensitive parameters are often employed. Sibai and associates defined DIC as the presence of thrombocytopenia, low fibrinogen levels (plasma fibrinogen <300 mg/dL), and fibrin split products above 40 mg/mL. These authors noted the presence of DIC in 21% of 442 patients with HELLP syndrome. They also found that most cases occurred in women who had antecedent abruptio placentae or peripartum hemorrhage and in all four women who had subcapsular liver hematomas. In the absence of these complications, the frequency of DIC was only 5%.

In view of the previously mentioned diagnostic problems, we recommended that uniform and standardized laboratory values be used to diagnose HELLP syndrome.[85] Plasma haptoglobin and bilirubin values should be included in the diagnosis of hemolysis. In addition, the degree of abnormality of liver enzymes should be defined as a certain number of standard deviations from the normal value for each hospital population. Our laboratory criteria to establish the diagnosis are presented in the box, Criteria to Establish the Diagnosis of HELLP Syndrome.

Criteria to Establish the Diagnosis of HELLP Syndrome

- Hemolysis (as least two of these):
  - Peripheral smear (schistocytes, burr cells)
  - Serum bilirubin (≥1.2 mg/dL)
  - Low serum haptoglobin
- Severe anemia, unrelated to blood loss
- Elevated liver enzymes
  - Aspartate transaminase (AST) or alanine transaminase (ALT) ≥ twice upper level or normal
  - Lactate dehydrogenase ≥ twice upper level or normal
- Low platelets (<100,000/mm^3)
- HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome

Clinical Findings

The reported incidence of HELLP syndrome in preeclampsia has been variable, reflecting the differences in diagnostic criteria. The syndrome appears to be more common in white women and is also more common in preeclamptic women who have been managed conservatively.[85]

Early detection of HELLP syndrome can be a challenge in that many women present with nonspecific symptoms or subtle signs of preeclampsia. The various signs and symptoms reported are not diagnostic of preeclampsia and may also be found in women with severe preeclampsia-eclampsia without HELLP syndrome.[85] Right upper quadrant or epigastric pain and nausea or vomiting have been reported with a frequency ranging from 30% to 90% (Table 35-7). Most women gave a history of malaise typical of a nonspecific viral-like syndrome for several days before presentation, which led one investigator to suggest performing laboratory investigations (completed blood count and liver enzymes) in all pregnant women with suspected preeclampsia having these symptoms during the third trimester.[85] Headaches are reported by 33% to 61% of the patients, whereas visual changes are reported in about 17%. A small subset of patients with HELLP syndrome may present with symptoms related to thrombocytopenia, such as bleeding from mucosal surfaces, hematuria, petechial hemorrhages, or ecchymosis.

Modified from Sibai BM: Diagnosis, controversies, and management of HELLP syndrome. Obstet Gynecol 103:981, 2004.
HELLP, Hemolysis, elevated liver enzymes, and low platelets; *NR*, not reported.

Although most patients have hypertension (82% to 88%, see Table 35-7), it may be only mild in 15% to 50% of the cases and absent in 12% to 18%. Most of the patients (86 to 100%) have proteinuria by dipstick examination, although it has been reported to be absent in 13% of cases.

DIFFERENTIAL DIAGNOSIS

The presenting symptoms, clinical findings, and many of the laboratory findings in women with HELLP syndrome overlap with a number of medical syndromes, surgical conditions, and obstetrical complications. Therefore, the differential diagnosis of HELLP syndrome should include any of the conditions listed (see box, Medical and Surgical Disorders Often Confused with HELLP Syndrome). Because some women with HELLP syndrome may present with gastrointestinal, respiratory, or hematologic symptoms in association with elevated liver enzymes or low platelets in the absence of hypertension or proteinuria, many initially are misdiagnosed as having other conditions such as upper respiratory infection, hepatitis, cholecystitis, pancreatitis, acute fatty liver of pregnancy (AFLP), or immune thrombocytopenic purpura (ITP).[85] Conversely, some women with other conditions such as TTP, HUS, systemic lupus erythematosus, sepsis, or catastrophic antiphospholipid antibody syndrome may be erroneously diagnosed as having HELLP syndrome. In addition, preeclampsia may occasionally be superimposed on one of these disorders, further contributing to the diagnostic difficulty. Because of the remarkably similar clinical and laboratory findings of these disease processes, even the most experienced clinician can face a difficult diagnostic challenge. Therefore, efforts should be made to attempt to identify an accurate diagnosis, given that management strategies may be different among these conditions. It is important to emphasize that affected women may have a variety of unusual signs and symptoms, none of which are diagnostic of severe preeclampsia. Pregnant women with probable preeclampsia presenting with atypical symptoms should have a complete blood count, a platelet count, and liver enzyme determinations irrespective of maternal BP findings.

Occasionally, the presence of this syndrome is associated with hypoglycemia, leading to coma, severe hyponatremia, and cortical blindness. A rare but interesting complication of HELLP syndrome is transient nephrogenic diabetes insipidus. Unlike central diabetes insipidus, which results from the diminished or absent secretion of arginine vasopressin by the hypothalamus, transient nephrogenic diabetes insipidus is characterized by a resistance to arginine vasopressin mediated by excessive vasopressinase. It is postulated that elevated circulating vasopressinase may result from impaired hepatic metabolism of the enzyme.

MEDICAL AND SURGICAL DISORDERS OFTEN CONFUSED WITH HELLP SYNDROME

- Acute fatty liver of pregnancy
- Appendicitis
- Gallbladder disease
- Glomerulonephritis
- Hemolytic uremic syndrome
- Hepatic encephalopathy
- Hyperemesis gravidarum
- Idiopathic thrombocytopenia
- Pyelonephritis
- Systemic lupus erythematosus
- Antiphospholipid antibody syndrome
- Thrombotic thrombocytopenic purpura
- Viral hepatitis
- HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome

MANAGEMENT OF HELLP SYNDROME

Management of preeclamptic women presenting with HELLP syndrome is highly controversial.[85] Consequently, there are several therapeutic modalities described in the literature to treat or reverse HELLP syndrome. Most of these modalities are similar to those used in the management of severe preeclampsia remote from term (see box, Therapeutic Modalities Used to Treat or Reverse HELLP Syndrome).

THERAPEUTIC MODALITIES USED TO TREAT OR REVERSE HELLP SYNDROME

- Plasma volume expansion
  - Bedrest
  - Crystalloids
  - Albumin 5% to 25%
- Antithrombotic agents
  - Low-dose aspirin
  - Dipyridamole
  - Heparin
  - Antithrombin III
- Immunosuppressive agents
  - Steroids
- Miscellaneous
  - Fresh-frozen plasma infusions
  - Exchange plasmapheresis
  - Dialysis
- HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome

Modified from Sibai BM: The HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets): much ado about nothing? Am J Obstet Gynecol 162:311, 1990.

The clinical course of women with true HELLP syndrome is usually characterized by progressive and sometimes sudden deterioration in the maternal condition.[85] Because the presence of this syndrome has been associated with increased rates of maternal morbidity and mortality, many authors consider its presence to be an indication for immediate delivery. **There is also a consensus of opinion that prompt delivery is indicated if the syndrome develops beyond 34 weeks' gestation or earlier if there is obvious multiorgan dysfunction, DIC, liver infarction or hemorrhage, renal failure, suspected abruptio placentae, or nonreassuring fetal status.**[85]

On the other hand, there is considerable disagreement about the management of women with HELLP syndrome at or before 34 weeks of gestation in whom maternal condition is stable, except for mild to moderate abnormalities in blood tests, and fetal condition is reassuring. In such patients, some authors recommend the administration of corticosteroids to accelerate fetal lung maturity followed by delivery after 24 hours,[85] whereas others recommend prolonging pregnancy until the development of maternal or fetal indications for delivery or until achievement of fetal lung maturity. Some of the measures used in these latter cases have included one or more of the following: bedrest, antihypertensive agents, antithrombotic agents (low-dose aspirin, dipyridamole), plasma volume expanders (crystalloids, albumin, fresh-frozen plasma), and steroids (prednisone, prednisolone, dexamethasone, or betamethasone).[85]

Expectant Management of HELLP Syndrome

There are few large case series describing expectant management of women with true HELLP, partial HELLP, or severe preeclampsia with isolated liver enzymes elevation. In general, these reports suggest that transient improvement in laboratory values or pregnancy prolongation from a few days to a few weeks is possible in a select group of women with HELLP syndrome. It is important to note that most of the patients included in these studies were ultimately delivered within 1 week of expectant management.[85]

Investigators from the Netherlands have reported their experience with expectant management in women with HELLP syndrome before 34 weeks' gestation. Visser and Wallenburg reported the use of plasma volume expansion using invasive hemodynamic monitoring and vasodilators in 128 women with HELLP syndrome before 34 weeks' gestation. Magnesium sulfate and steroids were not used in such women. Twenty-two of the 128 patients were delivered within 48 hours; the remaining 102 patients had pregnancy prolongation for a median of 15 days (range, 3 to 62 days). Fifty-five of these 102 women had antepartum resolution of HELLP syndrome, with a median pregnancy prolongation in these women of 21 days (range, 7 to 62 days). There were no maternal deaths or serious maternal morbidity. However, 11 (8.6%) resulted in fetal death at 25 to 34.4 weeks, and there were 7 (5.5%) neonatal deaths at 27 to 32 weeks' gestation.

Van Pampus and coworkers reported the use of bedrest, antihypertensive medication, and salt restriction in 41 women with HELLP syndrome before 35 weeks' gestation. Fourteen women (34%) were delivered within 24 hours; in the remaining 27 women, pregnancy was prolonged a median of 3 days (range, 0 to 59 days). Fifteen of these 27 women showed complete normalization of the laboratory abnormalities. There were no serious maternal morbidities; however, there were 10 fetal deaths at 27 to 35.7 weeks' gestation.

The study by Ganzevoort and colleagues included 54 women with HELLP syndrome at the time of enrollment. In a subsequent publication, the same authors compared maternal and perinatal complications in these women to the respective outcomes in women without HELLP. They found that the median days of pregnancy prolongation and maternal and perinatal complications were similar between the two groups.

There is one randomized, double-blind trial comparing prednisolone ($n = 15$) to a placebo ($n = 16$) in patients with HELLP syndrome before 30 weeks' gestation. Prednisolone was given intravenously twice a day. The primary outcome measures were the entry-to-delivery interval and the number of "recurrent HELLP" exacerbations in the antepartum period. The mean entry-to-delivery interval was similar between the two groups (6.9 days for prednisolone and 8 days for placebo). There were three cases of liver hematoma or rupture, with one maternal death in the placebo group. The perinatal mortality rate was similar between the two groups (20% in the prednisolone group and 25% in the placebo group).

The results of these studies suggest that expectant management is possible in a very select group of women with suspected HELLP syndrome before 34 weeks' gestation. However, despite pregnancy prolongation in some of these cases, the overall perinatal outcome was not improved compared with fetuses at a similar gestational age who were delivered within 48 hours after the diagnosis of HELLP syndrome.

Confounding variables make it difficult to evaluate any treatment modality proposed for this syndrome. Occasionally, some patients without true HELLP syndrome may demonstrate antepartum reversal of hematologic abnormalities following bedrest, the use of steroids, or plasma volume expansion. However, most of these patients experience deterioration in either maternal or fetal condition within 1 to 10 days after conservative management. It is doubtful that such limited pregnancy prolongation will result in improved perinatal outcome, and maternal and fetal risks are substantial.[85]

In summary, the results of these studies suggest that expectant treatment is possible in a select group of women with HELLP syndrome before 34 weeks' gestation. However, the number of women who were studied in these reports is inadequate to evaluate maternal safety. Therefore, such treatment should be considered experimental. In addition, most experts recommend delivery of such patients after completion of a course of corticosteroids for fetal lung maturity.[85]

Corticosteroids to Improve Pregnancy Outcome in Women with HELLP Syndrome

It is well established that antenatal glucocorticoid therapy reduces neonatal complications and neonatal mortality in women with severe preeclampsia at 34 weeks' gestation or less. The recommended regimens of corticosteroids for

Modified from Fonseca JE, Mendez F, Catano C, Arias F: Dexamethasone treatment does not improve the outcome of women with HELLP syndrome: a double-blind, placebo-controlled, randomized clinical trial. Am J Obstet Gynecol 193:1591-1598, 2005.
*Only included patients without the event before randomization.

the enhancement of fetal maturity are betamethasone (12 mg intramuscularly every 24 hours, two doses) or dexamethasone (6 mg intramuscularly every 12 hours, four doses). These regimens have been identified as the most appropriate for this purpose because they readily cross the placenta and have minimal mineralocorticoid activity. However, it is unclear whether the same or different regimens are beneficial in women with HELLP syndrome.

Corticosteroids have been suggested as safe and effective drugs for improving maternal and neonatal outcome in women with HELLP or partial HELLP syndrome. A review of the literature reveals substantial differences in methodology, time of administration, and drug selection among investigators who advocate the use of corticosteroids in women with HELLP syndrome. Different regimens of steroids have been suggested for preventing respiratory distress syndrome (RDS) as well as to accelerate maternal recovery in the postpartum period.[85] The regimens of steroids used included intramuscular betamethasone (12 mg/12 hours or 24 hours apart on two occasions) or intravenous dexamethasone (various doses at various time intervals) or a combination of the two. Some studies used steroids only in the antepartum period (for 24 hours, 48 hours, repeat regimens, or chronically for weeks until delivery). In other studies, steroids were given for 48 hours before delivery and then continued for 24 to 48 hours postpartum, whereas others recommend their administration only in the postpartum period.[85]

There are randomized trials comparing the use of high-dose dexamethasone to either no treatment or betamethasone in women with presumed HELLP syndrome. These studies were summarized in a recent review by Sibai.[85] The results of these studies demonstrated improved laboratory values and urine output in patients receiving dexamethasone but no differences in serious maternal morbidity. In addition, the number of patients studied was limited, and neither of these small studies used a placebo.[85]

More recently, three randomized, double-blind placebo trials were conducted evaluating dexamethasone versus placebo in women with antepartum and postpartum HELLP syndrome. Two of the trials were multicenter, and one was a single center. The results of the two large multicenter trials are summarized in Tables 35-8 and 35-9. Overall, these trials revealed no maternal benefit of using dexamethasone in women with HELLP syndrome.

*Each patient may have more than one complication.

MATERNAL AND PERINATAL OUTCOME

The presence of HELLP syndrome is associated with an increased risk for maternal death (1%)[85] and increased rates of maternal morbidities such as pulmonary edema (8%), acute renal failure (3%), DIC (15%), abruptio placentae (9%), liver hemorrhage or failure (1%), acute respiratory distress syndrome (ARDS), sepsis, and stroke (<1%).[85] Pregnancies complicated by HELLP syndrome are also associated with increased rates of wound hematomas and the need for transfusion of blood and blood products.[85] The rate of these complications depends on the population studied, the laboratory criteria used to establish the diagnosis, and the presence of associated preexisting medical conditions (chronic hypertension, lupus), or obstetrical complications (abruptio placentae, peripartum hemorrhage, fetal demise, eclampsia).[85] The development of HELLP syndrome in the postpartum period also increases the risk for renal failure and pulmonary edema. The presence of abruptio placentae increases the risk for DIC, need for blood transfusions, pulmonary edema, and renal failure. Patients who have a large volume of ascites appear to have a high rate of cardiopulmonary complications. Finally, women who meet all the criteria suggested for diagnosis will have higher rates of maternal complications than those who have partial HELLP or elevated liver enzymes only (Table 35-10).

From Sibai BM, Ramadan MK, Usta I, et al: Maternal morbidity and mortality in 442 pregnancies with hemolysis, elevated liver enzymes, and low platelets (HELLP syndrome). Am J Obstet Gynecol 169:1000, 1993.
HELLP, Hemolysis, elevated liver enzymes, and low platelets.

There is general agreement that perinatal mortality and morbidities are substantially increased in pregnancies complicated by the HELLP syndrome. The reported perinatal death rate in recent series ranged from 7.4% to 34%.[85] This high perinatal death rate is mainly experienced at very early gestational age (<28 weeks), in association with severe FGR or abruptio placentae.[85] It is important to emphasize that neonatal morbidities in these pregnancies are dependent on gestational age at time of delivery, and they are similar when corrected for gestational age to those in preeclamptic pregnancies without the HELLP syndrome. The rate of preterm delivery is about 70%, with 15% occurring before 28 weeks' gestation. As a result, these infants have a high rate of acute neonatal complications.

The HELLP syndrome may develop antepartum or postpartum. Analysis of 442 cases studied by Sibai and associates revealed that 309 (70%) had evidence of the syndrome antepartum, whereas 133 (30%) developed the condition postpartum. There were four maternal deaths, and morbidity was frequent (Table 35-11).

In the postpartum period, the time of onset of the manifestations may range from a few hours to 7 days, most developing within 48 hours postpartum. Thus, **laboratory assessment for potential HELLP syndrome should be considered during the first 48 hours postpartum in women with significant hypertension or symptoms of severe preeclampsia.** Eighty percent of the women who develop HELLP syndrome postpartum have had preeclampsia before delivery, whereas 20% had no evidence of preeclampsia either antepartum or intrapartum. It is the author's experience that patients in this group are at increased risk for the development of pulmonary edema and acute renal failure (Table 35-12). The differential diagnosis should include exacerbation of systemic lupus erythematosus, TTP, and HUS.

RECOMMENDED MANAGEMENT

The clinical course of women with HELLP syndrome is usually characterized by progressive and sometimes sudden deterioration in maternal and fetal condition. Therefore, **patients with a suspected diagnosis of HELLP syndrome should be hospitalized immediately and observed in a labor and delivery unit (Figure 35-4). Such patients should be managed as if they had severe preeclampsia and should initially receive intravenous magnesium sulfate as prophylaxis against convulsions and antihypertensive medications to maintain systolic BP below 160 mm Hg or diastolic BP below 105 mm Hg.**[85] This can be achieved with a 5-mg bolus dose of hydralazine, to be repeated as needed every 15 to 20 minutes for a maximal dose of 20 mg per hour. BP is recorded every 15 minutes during therapy and every hour once the desired values are achieved. If hydralazine does not lower BP adequately or if maternal side effects such as tachycardia or headaches develop, another agent such as labetalol or nifedipine can be used.

The recommended dose of labetalol is 20 to 40 mg given intravenously every 10 to 15 minutes for a maximum of 220 mg, and the dose of nifedipine is 10 to 20 mg orally every 30 minutes for a maximum dose of 50 mg. During the observation period, maternal and fetal conditions should be followed carefully.

The recommended regimen of magnesium sulfate is a loading dose of 6 g given over 20 minutes, followed by a maintenance dose of 2 g per hour as a continuous intravenous solution. Magnesium sulfate is initiated at the beginning of the observation period and then continued during labor and for at least 24 hours postpartum. In those with abnormal renal function (oliguria or serum creatinine ≥1.2 mg/dL), the dose of magnesium sulfate should be reduced and even discontinued.

Once the diagnosis of HELLP syndrome is confirmed, a decision must be made regarding the need for delivery (see Figure 35-4). Women with HELLP syndrome at less

than 35 weeks' gestation should be referred to a tertiary care facility if their condition is stable. The first priority is to assess and stabilize the maternal condition, particularly BP and coagulation abnormalities. The next step is to evaluate fetal status with the use of fetal heart rate monitoring, biophysical profile (BPP), or Doppler assessment of fetal vessels. Finally, a decision must be made as to whether delivery should be initiated or delivery could be delayed for 48 hours to allow the full benefit of corticosteroids. Thus, in practice, delivery is undertaken in all patients with true HELLP syndrome except in those with a gestational age between 24 to 34 weeks with stable maternal and fetal conditions. These latter patients are given betamethasone and are generally then delivered within 24 hours after the last dose of corticosteroids. Maternal and fetal conditions are assessed continuously during this time period. In some of these women, there may be transient improvement in maternal laboratory tests. However, delivery is still recommended despite such improvement.[85]

INTRAPARTUM MANAGEMENT

The presence of HELLP syndrome is not an indication for immediate cesarean delivery. Such an approach might prove detrimental for both mother and fetus. The decision to perform a cesarean delivery should be based on gestational age, fetal condition, the presence of labor, and the cervical Bishop score. Elective cesarean delivery is recommended for all women with HELLP syndrome before 30 weeks' gestation not in labor and with a Bishop score of less than 5. Elective cesarean delivery is also undertaken for those with HELLP syndrome complicated by FGR or oligohydramnios, particularly if the gestational age is less than 32 weeks in the presence of an unfavorable cervical Bishop score (Table 35-13).

Women having labor or rupture of membranes are allowed to deliver vaginally in the absence of obstetrical complications. When induction is indicated, it is initiated with either oxytocin infusion or prostaglandins in patients with a gestational age of more than 30 weeks, irrespective of the amount of cervical dilation or effacement. A similar approach is used for those at 30 weeks' gestation or less if the cervical Bishop score is at least 5.

Maternal pain relief during labor and delivery can be provided by intermittent use of small doses of systemic opioids. Local infiltration anesthesia can be used for all vaginal deliveries if an episiotomy or repair of a laceration is necessary. The use of a pudendal block is contraindicated in these patients because of the risk for bleeding and

  - Known subcapsular liver hematoma
  - Suspected abruptio placentae
- Management during cesarean delivery
  - General anesthesia for platelet count <75,000/mm^3
  - Transfuse 6 units of platelets if count <40,000/mm^3
  - Insert subfascial drain
  - Secondary skin closure or leave subcutaneous drain
- Observe for bleeding from upper abdomen before closure

HELLP, Hemolysis, elevated liver enzymes, and low platelets syndrome; IUGR, intrauterine growth restriction.

FIGURE 35-5. Subfascial drains used at time of cesarean section.

hematoma formation into this area. Epidural anesthesia is also contraindicated particularly if the platelet count is less than 75,000/mm^3. Therefore, general anesthesia is the method of choice for cesarean delivery in most thrombocytopenic women. O'Brien and coworkers assessed the impact of glucocorticoid administration on the use of epidural anesthesia in 37 women with partial HELLP syndrome who had a platelet count of less than 90,000/mm^3 before steroid administration. The authors found that administration of corticosteroids in these patients increased the use of epidural anesthesia, particularly in those who achieved a latency period of 24 hours before delivery (8 or 14 in steroid group vs. 0 or 10 in group without steroids; $P = .006$).

Platelet transfusions are indicated either before or after delivery in all patients with HELLP syndrome in the presence of significant bleeding (e.g., ecchymosis, bleeding from gums, oozing from puncture sites, wound, intraperitoneal) and in all those with a platelet count of less than 20,000/mm^3 (see Table 35-13). However, repeated platelet transfusions are not necessary because of the short half-life of the transfused platelets in such patients. Correction of thrombocytopenia is also important before any surgery. Administration of 6 units of platelets is recommended in all patients with a platelet count less than 40,000 to 50,000/mm^3 before intubation if cesarean delivery is needed. Generalized oozing from the incision site can occur during surgery or in the immediate postpartum period because of the continued drop in platelet count in some of these patients. The risk for hematoma formation at these sites is about 20%. Some individuals therefore prefer to use a vertical skin incision, whereas others employ a subfascial drain and keep the skin incision open for at least 48 hours in women requiring cesarean delivery (Figure 35-5).[85]

POSTPARTUM MANAGEMENT

After delivery, patients with HELLP syndrome should receive close monitoring of vital signs, fluid intake and output, laboratory values, and pulse oximetry for at least 48 hours. Intravenous magnesium sulfate prophylaxis is generally continued for 48 hours, and antihypertensive drugs are employed if the systolic BP is at least 155 mm Hg or if the diastolic BP is at least 105 mm Hg. In general, most women will show evidence of resolution of the disease process within 48 hours after delivery. However, some patients, especially those with abruptio placentae plus DIC, those with severe thrombocytopenia (platelet count <20,000/mm^3), and those with severe ascites or significant renal dysfunction may show delayed resolution or even deterioration in their clinical condition. Such patients are at risk for the development of pulmonary edema from transfusion of blood and blood products, fluid mobilization, and compromised renal function. These patients are also at risk for acute tubular necrosis and may require dialysis and intensive monitoring for several days. Some authors have suggested that such patients might benefit from plasmapheresis or plasma transfusions. In practice, most of these women will recover with supportive therapy only. **If the patient continues to deteriorate for more than 72 hours after delivery or shows improvement in laboratory values, and then starts to show thrombocytopenia and abnormal liver enzymes again, then a diagnosis of TTP/HUS should be considered. In such cases, plasmapheresis is indicated.**

The clinical and laboratory findings of HELLP syndrome may first appear during the postpartum period.[85] In these women, the time of onset of the manifestations ranges from a few hours to 7 days, with most developing within 48 hours postpartum.[85] Hence, all postpartum women and their health care providers should be educated and be aware of the signs and symptoms of HELLP syndrome. Management of patients with postpartum HELLP syndrome should be similar to that in the antepartum period, including the use of magnesium sulfate.

Hepatic Complications in HELLP Syndrome

Marked elevations in serum aminotransferases (>1000 to 2000 IU/L) are not typical of uncomplicated HELLP syndrome; however, when they occur, the possibility of hepatic infarction and subcapsular hematoma of the liver must be considered. The differential diagnosis should also include AFLP, abruptio placentae with DIC, acute cholecystitis with sepsis, viral hepatitis, and TTP. In addition to the signs and symptoms of preeclampsia, physical examination findings consistent with peritoneal irritation and hepatomegaly may be present.

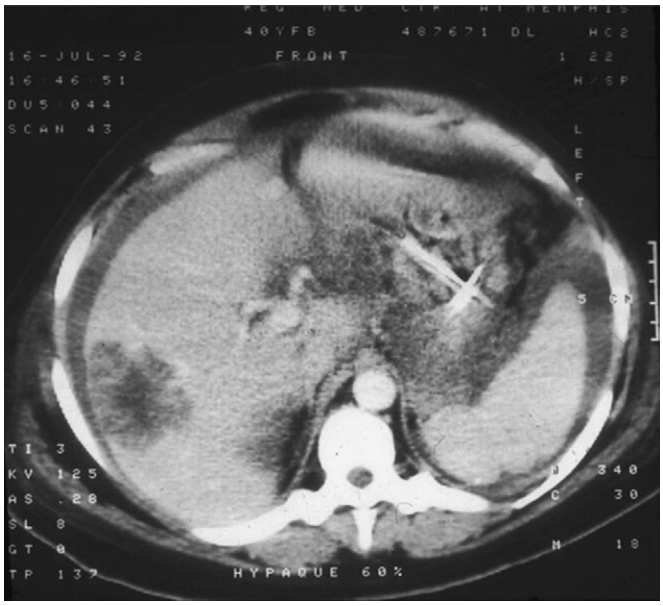

FIGURE 35-6. Computed tomography scan of the liver demonstrating hepatic infarct.

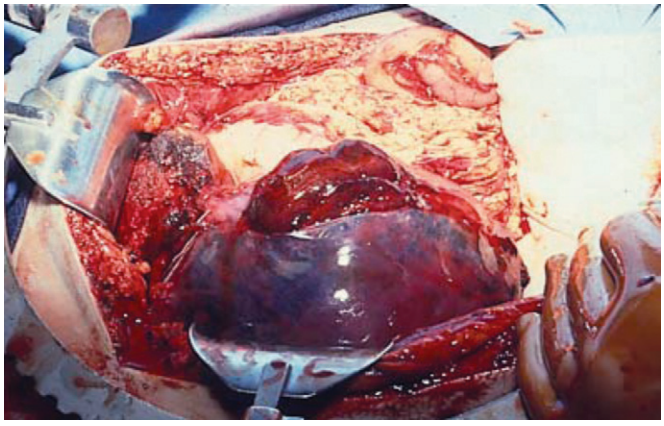

FIGURE 35-7. Subcapsular hematoma in patient with HELLP syndrome.

HEPATIC INFARCTION

Marked elevation in serum aminotransferases (usually 1000 to 2000 IU/L or higher) and LDH (usually 10,000 to 20,000 IU/L) associated with right upper quadrant pain and fever is characteristic of hepatic infarction; this diagnosis can be confirmed by hepatic imaging (Figure 35-6). Follow-up imaging after delivery typically demonstrates resolution of the infarcts. These women may have an underlying thrombophilia such as the antiphospholipid syndrome.[85]

HEPATIC HEMATOMA AND RUPTURE

HELLP syndrome may be complicated by hepatic rupture with the development of a hematoma beneath the Glisson capsule (Figure 35-7). Histology of the liver adjacent to the rupture shows periportal hemorrhage and fibrin deposition, along with a neutrophilic infiltrate suggestive of hepatic preeclampsia. The hematoma may remain contained, or rupture, with resulting hemorrhage into the peritoneal cavity. Women who develop a hepatic hematoma typically have abdominal pain and many have severe thrombocytopenia, shoulder pain, nausea, and vomiting. The aminotransferases are usually modestly elevated, but values of 4000 to 5000 IU/L can occasionally be seen. If hepatic rupture occurs, swelling of the abdomen from hemoperitoneum and shock rapidly ensue.

The management of a contained hematoma is to support the patient with volume replacement and blood transfusion, as needed, with consideration for percutaneous embolization of the hepatic arteries. If the size of the hematoma remains stable and the laboratory abnormalities are resolving, the patient may be discharged home with outpatient follow-up. It may take months for the hematoma to resolve completely.

Surgical repair has been recommended for hepatic hemorrhage without liver rupture. This complication, however, can be managed conservatively in patients who remain hemodynamically stable. Management should include close monitoring of hemodynamics and coagulation status. Serial assessment of the subcapsular hematoma with ultrasound or

Computed tomography (CT) is necessary, with immediate intervention for rupture or worsening of maternal status. It is important with conservative management to avoid exogenous sources of trauma to the liver, such as abdominal palpation, convulsions, or emesis, and to use care in transportation of the patient. Indeed, any sudden increase in intra-abdominal pressure could potentially lead to rupture of the subcapsular hematoma.

Rupture of a subcapsular hematoma of the liver is a life-threatening complication of HELLP syndrome. Profound hypovolemic shock in a previously hypertensive patient is the hallmark of rupture of hematoma. In most instances, rupture involves the right lobe and is preceded by the development of a parenchymal hematoma. Patients frequently present with shoulder pain, shock, or evidence of massive ascites, respiratory difficulty, or pleural effusions, and often with a dead fetus. Ultrasound or CT of the liver should be performed to rule out the presence of subcapsular hematoma of the liver and assess for the presence of intraperitoneal bleeding. Paracentesis can confirm intraperitoneal bleeding.

The presence of ruptured subcapsular liver hematoma resulting in shock is a surgical emergency requiring acute multidisciplinary treatment. Resuscitation should consist of massive transfusions of blood, correction of coagulopathy with fresh-frozen plasma and platelets, and immediate laparotomy.

A team experienced in liver trauma surgery should be consulted. If hepatic rupture is suspected, an incision in the upper abdomen is necessary for adequate surgical exposure. A lower abdominal midline incision can be extended superiorly. If a Pfannenstiel incision was used for operative delivery, a separate upper abdominal midline incision should be made to maximize visualization of the upper abdomen and liver. Options at laparotomy include packing and drainage, surgical ligation of the hemorrhaging hepatic segments, embolization of the hepatic artery to the involved liver segment, and loosely suturing omentum or surgical mesh to the liver to improve integrity.

Shrivastova and associates in a case report described the successful use of an argon-beam coagulator to obtain hemostasis from a ruptured liver hematoma in a patient with HELLP syndrome, although previous experience with this modality was unsuccessful. Even with appropriate treatment, maternal and fetal mortality is almost 50%. Mortality is most commonly associated with exsanguination with coagulopathy, and sepsis. Initial survivors are at increased risk for developing ARDS, pulmonary edema, liver failure, and acute renal failure in the postoperative period.

Reck and colleagues reviewed cases with HELLP syndrome–associated liver rupture (4 patients from their center in Germany and 49 identified from a MEDLINE literature search covering 1990 to 1999). Despite surgical interventions, HELLP syndrome–associated liver rupture carried a mortality rate of 39% (19 of 49) in their review. The main causes of death were hemorrhagic shock ($n = 11$) and multiorgan failure ($n = 7$). Based on their review, the authors suggested an interdisciplinary approach for patients with ruptured liver or hepatic failure, including the use of temporary packing of the liver to control bleeding. In those patients with hepatic failure or uncontrollable hepatic hemorrhage, they noted that a liver transplantation as a last resort measure must be considered.

Liver Transplantation for Intractable Hemorrhage

For women with intractable hemorrhage despite the previously described interventions and for those with necrosis with subsequent liver failure, liver transplantation has been successful in case reports and case series. Shames and colleagues queried the Organ Procurement and Transplantation Network database regarding liver transplantations performed for complications from HELLP syndrome. Eight deceased donor liver transplantations were identified in the United States with this indication between October 1987 and November 2003. At the time of their review, six of the eight patients were alive, whereas, two maternal deaths occurred within 1 month of transplantation. In addition, two patients required retransplantation. Based on the results of their review, these authors presented an algorithm in which liver transplantation is considered for patients with complicated HELLP syndrome, including ongoing, uncontrolled hemorrhage or liver necrosis and failure.

Zarrinpar and associates described eight women without a history of liver disease who underwent liver transplantation at their institution between February 1984 and December 2006 for complications of HELLP syndrome. All received cadaveric grafts with a mean interval from delivery to liver transplantation of 7 days. There were no deaths from intraoperative hematoma of the liver. There was one death from sepsis on postoperative day 19 and one death from cholangitis and sepsis more than 5 years after surgery. After liver transplantation, the Kaplan-Meier patient survival rates at 1, 5, and 10 years were 88%, 88%, and 65%, respectively; 1-, 5-, and 10-year graft survival rates were 64%, 64%, and 48%, respectively. Because of the very small number of available organs, death before transplantation is a concern. Marsh and associates suggest that potential candidates are only those in whom all other measures fail to control hemorrhage, or in whose liver has become devascularized such that there is no other alternative.

Table 35-14 Management of Patients with Documented Subcapsular Hematoma of the Liver

General Considerations

1. Inform the blood bank about the potential need for large amounts of packed red blood cells, fresh-frozen plasma, and platelet concentrate
2. Ensure consultation with a general or vascular surgeon
3. Avoid direct and indirect manipulation of the liver
4. Arrange for close monitoring of hemodynamic status
5. Intravenous magnesium sulfate to prevent seizures

Unruptured Hematoma

a. Conservative management
b. Correct coagulopathy
c. Serial computed tomography scans or ultrasound

Expanding or Ruptured Hematoma

a. Massive transfusions
b. Immediate laparotomy

Minimal Bleeding

a. Observation
b. Draining area with closed suction

Severe Bleeding

a. Application of laparotomy sponges as packs for pressure
b. Embolization of the hepatic artery to the involved liver segment
c. Surgical ligation of hemorrhaging hepatic segment
d. Loosely sutured omentum or surgical mesh to the liver to improve integrity
e. Argon beam coagulator to liver surface
f. Hepatic lobectomy
g. Hepatectomy and temporary portal caval shunt followed by liver transplantation

From our experience and review of the literature, we have developed a management plan of hepatic hematoma associated with HELLP syndrome. This plan emphasizes the potential for transfusion of large amounts of blood and blood products and the need for aggressive intervention if rupture of the hematoma is suspected (Table 35-14). We recommend 30 U of packed red blood cells, 20 U of fresh-frozen plasma, 30 to 50 U of platelets, and 20 to 30 U of cryoprecipitate be available if rupture of a subcapsular hematoma is suspected. **We agree with the observations of others that a stable patient with an unruptured subcapsular hematoma should be conservatively managed.** Constant monitoring must continue during this management, however, because patients can rapidly become unstable after rupture of the hematoma. Survival clearly is associated with rapid diagnosis and immediate medical or surgical stabilization so that these patients should be managed in an intensive care unit facility with close monitoring of hemodynamic parameters and fluid status to avoid the potential for pulmonary edema or respiratory compromise.

Postpartum follow-up for patients with subcapsular hematoma of the liver should include serial CT, magnetic resonance imaging (MRI), or ultrasonography until the defect resolves. Although the data on subsequent pregnancy outcome after a subcapsular hematoma of the liver in pregnancy are limited, we have managed three such patients who have had subsequent normal maternal and fetal outcomes, and Wust and coworkers reported the successful outcome of four subsequent pregnancies in three

women with a history of hepatic rupture and preeclampsia or HELLP syndrome.

Hemodynamic Monitoring in Preeclampsia

The cardiovascular hemodynamics of preeclampsia have been investigated over the years by many authors using various techniques for measurement of BP, cardiac output, pulmonary capillary wedge pressure (PCWP), and central venous pressure (CVP).

Hemodynamic findings in women with preeclampsia remain controversial. A review of the English literature demonstrates considerable disagreement regarding one or more of the hemodynamic parameters studied. This lack of agreement has been attributed to differences in the definition of preeclampsia, variable severity and duration of the disease process, presence of underlying cardiac or renal disease, techniques used to measure cardiac output and BP, and therapeutic interventions applied before obtaining the various measurements. In addition, the dynamic minute-to-minute fluctuation of the cardiovascular parameters studied makes it difficult to standardize the conditions under which these observations are made, limiting the value of a single measurement.

Invasive techniques have been used by many authors to study the hemodynamic findings in untreated women with severe preeclampsia. The reported cardiac index ranged from a low of 2.8 to a high of 4.8 L/m^2 per minute, and the reported PCWP from a low of 3.3 to a high of 12 mm Hg. The findings suggest that cardiac index and PCWP are either low or normal in severe preeclampsia. The reported CVP values also ranged from 2 to 6 mm Hg.

The findings demonstrate that treated patients with preeclampsia have normal to high cardiac index, normal to high systemic vascular resistance index, and normal to high PCWP.

In summary, variable hemodynamic findings accompany preeclampsia. Moreover, the clinical utility of invasive hemodynamic monitoring in preeclampsia is debatable. Most of the invasive monitoring data indicate that both cardiac output and systemic vascular resistance appear to be elevated in women with severe preeclampsia. This finding suggests that the problem in preeclampsia is a systemic vascular resistance that is inappropriately high for the level of cardiac output. Both the PCWP and the CVP appear to be in the low to normal range; however, there is no correlation between the two values.

Antepartum Management of Mild Hypertension-Preeclampsia

Gestational Hypertension

Women with gestational hypertension are at risk for progression to severe hypertension, preeclampsia, or eclampsia.[5-8] The risks are increased with a lower gestational age at the time of diagnosis.[5-8] Therefore, these patients require close observation of maternal and fetal conditions. Maternal evaluations require weekly prenatal visits, education about reporting preeclamptic symptoms, and evaluation of complete blood count, platelet count, and liver enzymes.[1-3] Fetal evaluation includes ultrasound examination of fluid and estimated fetal weight at the time of diagnosis and weekly nonstress testing.[1,2] Restriction of dietary salt as well as physical activity has not proved beneficial in the management of these patients.[1,2] Additionally, **the results of several randomized trials reveal that control of maternal BP with antihypertensive drugs does not improve pregnancy outcome in women with gestational hypertension.**

In the absence of progression to severe hypertension or preeclampsia, women with gestational hypertension can continue pregnancy until 37 weeks' gestation. During labor and immediately postpartum, they do not require seizure prophylaxis because the rate of eclampsia in these women is less than 1 in 500.[2]

The HYPITAT trial was a multicenter, open-label randomized controlled trial conducted at 6 academic and 32 nonacademic hospitals in the Netherlands. It included 756 women with singleton pregnancy at a gestational age between $36^{0/7}$ weeks and $41^{0/7}$ weeks who had mild gestational hypertension (n = 496) or mild preeclampsia (n = 246); 377 were randomized to induction and 379 to expectant monitoring. The primary outcome was a composite of adverse maternal outcomes: progression to severe disease or HELLP syndrome, eclampsia, pulmonary edema, abruption placentae, postpartum hemorrhage, thromboembolic disease, or death. Secondary outcomes were a composite of adverse neonatal outcomes and rate of cesarean delivery. There were no cases of maternal, fetal, or neonatal death and no cases of eclampsia or abruption in either group. However, women randomized to the induction group had a significant reduction in the primary outcome, (31% versus 44%; RR, 0.71; 95% CI, 0.59 to 0.86). This reduction was mainly due to differences in the rates of severe hypertension. There were no differences in the overall secondary outcomes; however, subgroup analysis revealed significant differences in the primary outcomes in the group enrolled with mild preeclampsia (33% vs. 54%; RR, 0.61; 95% CI, 0.45 to 0.8), but not in those with mild gestational hypertension (31% vs. 38%; RR, 0.81; 95% CI, 0.63 to 1.03). Unfortunately, the sample size was inadequate to answer the question in those with mild gestational hypertension only. Moreover, in the induction group, the rate of cesarean delivery was lower in nulliparous women and in those with cervical Bishop score of less than 2, refuting the belief that induction of labor in these women increases the rate of cesarean delivery. Results of this trial are summarized in Tables 35-15 and 35-16.

The optimal management of women with mild gestational hypertension or preeclampsia before 37 weeks' gestation is controversial. There is disagreement regarding the benefits of hospitalization, complete bedrest, and use of antihypertensive medications.

Hospitalization

In the past, management of these women has involved hospital bedrest for the duration of pregnancy with the belief that such management diminishes the frequency of progression to severe disease and allows rapid intervention in case of sudden disease progression, including the development of abruptio placentae, eclampsia, or hypertensive crisis. However, these complications are extremely rare among compliant women with mild hypertension or mild preeclampsia and absent symptoms. In addition, the results of two randomized trials in women with gestational

hypertension and several observational studies in women with mild hypertension and mild preeclampsia suggest that most of these women can be safely managed at home or in a day-care facility provided they undergo frequent maternal and fetal evaluation.[1,2] It must be emphasized that many women included in these studies had gestational hypertension only.[2]

BEDREST

Complete or partial bed rest for the duration of pregnancy is often recommended for women with mild hypertension-preeclampsia. There is no evidence to date suggesting that this practice improves pregnancy outcome. In addition, there are no published randomized trials comparing complete bedrest and restricted activity in the management of women with mild preeclampsia. On the other hand, prolonged bedrest for the duration of pregnancy increases the risk for thromboembolism.

BLOOD PRESSURE MEDICATIONS

There are several randomized trials describing the use of antihypertensive drugs compared with no treatment or a placebo in the management of women with mild hypertension or preeclampsia remote from term. Overall, these trials revealed lower rates of progression to severe disease with no improvement in perinatal outcome.[2] Of note, the sample size of these trials is inadequate to evaluate differences in FGR, abruptio placentae, perinatal death, or maternal outcome.

FETAL AND MATERNAL SURVEILLANCE

There is universal agreement that fetal testing is indicated during expectant management of women with gestational hypertension or preeclampsia.[1-10] Most authorities in the United States recommend daily fetal movement counts in association with either nonstress testing (NST) or BPP to be performed at the time of diagnosis and serially thereafter until delivery (1 to 2 times per week).[1-3] Because uteroplacental blood flow may be reduced in some of these women, ultrasound estimation of fetal weight as well as amniotic fluid status is also recommended at the time of diagnosis and serially thereafter, with the frequency depending on findings. Doppler flow velocimetry is recommended in the presence of suspected intrauterine growth restriction (IUGR).[9-11] The frequency of these tests is usually dependent on the severity of hypertension or preeclampsia, gestational age at the time of diagnosis, and fetal growth findings. Most clinical series suggest testing once weekly in women with mild gestational hypertension or preeclampsia, twice weekly if there is suspected fetal growth delay, and daily during expectant management of women with severe preeclampsia at less than 32 weeks' gestation.[32] However, there are no large prospective studies assessing outcomes of these monitoring techniques in women with gestational hypertension or preeclampsia.

Maternal surveillance is indicated in all women with gestational hypertension and preeclampsia. The goal of monitoring in women with mild gestational hypertension is to observe progression of the condition to severe hypertension or to preeclampsia.[1-8] In women with mild preeclampsia, the goal is early detection of severe preeclampsia. In those with severe preeclampsia, the goal is to detect the development of organ dysfunction. Therefore, all such women should be evaluated for symptoms of organ dysfunction, such as severe headaches, visual changes, altered mentation, right upper quadrant or epigastric pain, nausea or vomiting, shortness of breath, and decreased urine output.[1,2,9-11] In addition, they should undergo laboratory testing for 24-hour urine protein, serum creatinine, platelet count, and liver enzymes. Coagulation function tests are not necessary in the presence of a normal platelet count and liver

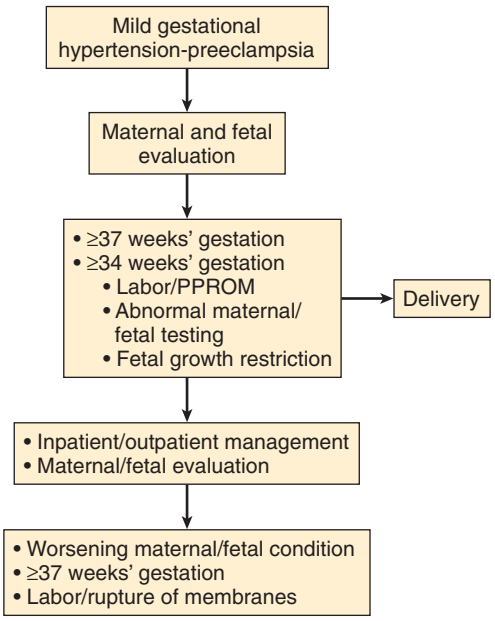

FIGURE 35-8. Management plan for patients with mild preeclampsia. *PPROM,* preterm premature rupture of the membranes.

enzymes. **The frequency of laboratory testing will depend on the initial findings, the severity of the maternal condition, and the ensuing clinical progression. Most authorities recommend evaluation and testing of platelet count, liver enzymes, and serum creatinine once weekly for women with mild gestational hypertension or mild preeclampsia, and performing these tests daily during expectant management of women with severe preeclampsia or HELLP syndrome remote from term.**[1,32]

RECOMMENDED MANAGEMENT

The primary objective of management in women with gestational hypertension-preeclampsia must always be safety of the mother and then delivery of a mature newborn that will not require intensive and prolonged neonatal care. This objective can be achieved by formulating a management plan that takes into consideration one or more of the following: the severity of the disease process, fetal gestational age, maternal and fetal status at time of initial evaluation, presence of labor, cervical Bishop score, and the wishes of the mother.

MILD HYPERTENSION OR PREECLAMPSIA

Once the diagnosis of mild gestational hypertension or mild preeclampsia is made, subsequent therapy will depend on the results of maternal and fetal evaluation (Figure 35-8). **In general, women with mild disease developing at 37 weeks' gestation or later should undergo induction of labor.**

In women who remain undelivered, close maternal and fetal evaluation are essential. These women are instructed to eat a regular diet with no salt restriction and to restrict their activity but not to complete bedrest. Diuretics and antihypertensive medications are not used because of the potential to mask the diagnosis of severe disease.[1] At the time of initial and subsequent visits, the women are educated and instructed about reporting symptoms of severe preeclampsia. Those managed as outpatients are also advised to come to the hospital or outpatient facility immediately if they develop abdominal pain, uterine contractions, vaginal spotting, or decreased fetal movement.

In women with mild gestational hypertension, fetal evaluation should include an NST and an ultrasound examination of estimated fetal weight and amniotic fluid index. If the results are normal, no repeat testing is undertaken, as previously described.

Maternal evaluation includes measurements of hematocrit, platelet count, and liver function tests, once weekly. The women are usually seen twice a week for evaluation of maternal BP, urine protein by dipstick, and symptoms of impending eclampsia. This evaluation is extremely important for early detection of progression to preeclampsia or severe hypertension. The onset of maternal symptoms, a sudden increase in BP to severe values, or development of persistent proteinuria (≥2+ on dipstick) requires prompt hospitalization for close evaluation.

In women with mild preeclampsia at less than 37 weeks' gestation but at more than 32 weeks, outpatient management can be considered for reliable patients with systolic BP of 150 mm Hg or less or diastolic BP of 100 mmHg or less and no increase in proteinuria if they have no symptoms and if they have normal liver enzymes and a normal platelet count (>100,000/mm^3). Women who do not satisfy these criteria are hospitalized, particularly those with mild preeclampsia before 32 weeks. During ambulatory management, women are instructed to rest at home and perform BP measurements and urine dipstick daily, and are given instructions about prompt reporting of symptoms of severe disease. These women are then seen twice weekly, at which time a platelet count and liver enzyme test are performed. Fetal evaluation includes daily fetal movement count, twice-weekly NST, and serial ultrasound evaluation of fetal growth and amniotic fluid. If there is evidence of disease progression (significant increase in BP or proteinuria to levels above the threshold mentioned previously, new onset of symptoms, or evidence of abnormal blood tests or abnormal fetal growth), these women are hospitalized for the duration of pregnancy. Women managed in the hospital receive similar maternal and fetal evaluation. Obstetrical management is summarized in Figure 35-8.

SEVERE HYPERTENSION IN PREECLAMPSIA

The incidence of severe preeclampsia ranges from 0.6% to 1%.[33] Pregnancies complicated by severe gestational hypertension or severe preeclampsia are associated with serous maternal and perinatal complications, particularly preterm delivery, fetal growth restriction, abruptio placentae, and perinatal death (Table 35-17). As a result, knowledge of the anticipated maternal, fetal, and neonatal risks is essential for appropriate counseling and management.

Expectant Management

The clinical course of severe preeclampsia may be characterized by progressive deterioration in both maternal and fetal conditions. **Because these pregnancies have been associated with increased rates of maternal morbidity and mortality and with significant risks for the fetus (growth restriction, hypoxemia, and death), there is general**

†These rates are for delivery at less than 34 weeks.

agreement that all such patients should be delivered if the disease develops after 34 weeks' gestation. Prompt delivery is also indicated when there is imminent eclampsia (persistent severe symptoms), multiorgan dysfunction, severe IUGR (<5th percentile), suspected abruptio placentae, or non-reassuring fetal testing.[33]

There is disagreement about management of patients with severe preeclampsia before 34 weeks' gestation when the maternal condition is stable and fetal condition is reassuring. Some authors consider delivery as the definitive treatment regardless of gestational age, whereas others recommend prolonging pregnancy unless maternal or fetal indications exist for delivery or fetal lung maturity is demonstrated before 34 weeks' gestation.[33]

Although delivery is beneficial to the mother, it must be weighed against the risk for prematurity. In the past, it was believed that infants born prematurely to severely preeclamptic women had lower rates of neonatal mortality and morbidity compared with infants of similar gestational age born to non-preeclamptic women. This belief was based on the clinical impression that fetuses of preeclamptic women have accelerated lung and neurologic maturation as a result of stress in utero. Reduced risk for prematurity-associated neonatal morbidity has never been documented in case-control studies. In contrast, **several recent case-control investigations have demonstrated that premature infants born after severe preeclampsia have similar neonatal complications and mortality and have higher rates of admission to neonatal intensive care units compared with other premature infants of similar gestational age. In addition, the results of case-controlled studies reveal that fetuses of preeclamptic women do not exhibit accelerated lung or neurologic maturation.**[33]

During expectant management, women should be aware that the decision to continue such management will be made on a daily basis and that the median time of pregnancy prolongation is 7 days (range, 2 to 35 days). There are only two randomized trials (133 women) that compared a policy of early elective delivery with a policy of delayed delivery.[33] Nevertheless, the results of retrospective and observational studies (more than 1000 women) suggest that expectant management is associated with reduced short-term neonatal morbidity in a select group of women with gestational age between 24 and 32 weeks.[33]

In the past, there was uncertainty regarding the efficacy and safety of corticosteroids administered to women with severe preeclampsia before 34 weeks' gestation. A prospective double-blind randomized trial of 218 women with severe preeclampsia with a gestational age between 26 and 34 weeks receiving either betamethasone ($n = 110$) or placebo ($n = 108$) reported a significant reduction in the rate of RDS (RR, 0.53; 95% CI, 0.35 to 0.82) in the steroid-treated group. Corticosteroid use also was associated with a reduction in the risks for neonatal intraventricular hemorrhage (RR, 0.35; 95% CI, 0.15 to 0.86), neonatal infection (RR, 0.39; 95% CI, 0.39 to 0.97), and neonatal death (RR, 0.5; 95% CI, 0.28 to 0.89). However, there were no differences in maternal complications between the two groups. Thus, **the data support the use of steroids to reduce neonatal complications in women with severe preeclampsia at 34 weeks' gestation or less.**

Recommended Management of Severe Hypertension-Preeclampsia

The presence of severe disease mandates immediate hospitalization in labor and delivery. Intravenous magnesium sulfate is begun to prevent convulsions, and antihypertensive medications are administered to lower severe levels of hypertension (systolic pressure ≥160 mm Hg *and/or* diastolic pressure ≥110 mm Hg). The aim of antihypertensive therapy is to keep systolic pressure between 140 and 155 mm Hg and diastolic pressure between 90 and 105 mm Hg. During the observation period, maternal and fetal conditions are assessed, and a decision is made regarding the need for delivery (Figure 35-9). Those with a gestational age of 24 to 34 weeks are given corticosteroids to accelerate fetal lung maturity. Maternal evaluation includes monitoring of BP, urine output, cerebral status, and the presence of epigastric pain, tenderness, labor, or vaginal bleeding. Laboratory evaluation includes a platelet count, liver enzymes, and serum creatinine. Fetal evaluation includes continuous fetal heart monitoring, a BPP, and ultrasonographic assessment of fetal growth and amniotic fluid. Patients with resistant severe hypertension despite maximal doses of intravenous labetalol (220 mg) plus oral nifedipine (50 mg) or persistent cerebral symptoms while on magnesium sulfate are delivered irrespective of fetal gestational age.

After the initial evaluation, the need for immediate delivery versus the potential neonatal benefit and the relative maternal and fetal risks of expectant management should be determined.[33] Women who develop eclampsia, pulmonary edema, or documented or suspected abruption placentae; those with DIC or moderate to severe renal

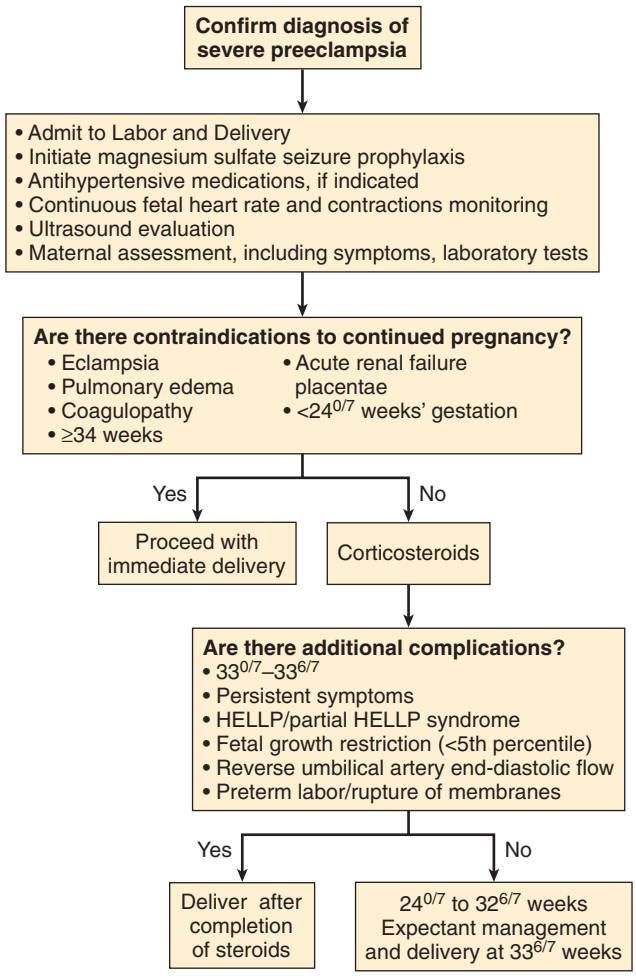

FIGURE 35-9. Management plan for patients with severe preeclampsia.

dysfunction (serum creatinine ≥1.5 mg/dL); and those with gestational age below $23^{0/7}$ weeks' gestation should be delivered after maternal stabilization. In addition, those with non-reassuring fetal heart rate tracing (repetitive variable or late decelerations) and those with persistent BPP of 4 or lower (on two occasions at least 4 hours apart) should be delivered promptly.[33] Women with gestational age between $23^{0/7}$ and $23^{6/7}$ weeks should receive extensive counseling about the minimal neonatal benefit and high maternal complications from expectant management and they should be offered the option of pregnancy termination.

For women with gestational age of $24^{0/7}$ weeks or greater without any indication for prompt delivery, corticosteroids are administered to accelerate fetal lung maturity.[33] Patients with gestational age between $33^{0/7}$ to $34^{0/7}$ weeks, severe FGR, preterm labor or premature rupture of the membranes (PROM), reverse umbilical artery diastolic flow, HELLP syndrome or partial HELLP, or persistent symptoms (headaches, visual changes, epigastric or right upper quadrant pain, nausea or vomiting) should be delivered no later than 24 hours after the last dose of corticosteroids. These patients should remain on magnesium sulfate with continuous monitoring of uterine contractions and fetal heart rate until delivery.

Women with pregnancy between $24^{0/7}$ and $32^{6/7}$ weeks' gestation with stable maternal and fetal conditions during the initial 24-hour observation period are considered candidates for expectant management (see Figure 35-9). In these women, magnesium sulfate is generally discontinued after 24 hours with transfer to a high-risk antepartum floor for close observation. Because of the potential for rapid deterioration in maternal and fetal conditions during expectant management, these women should be managed only in a tertiary care hospital with adequate maternal and neonatal intensive care facilities. They should be managed in consultation with a maternal-fetal medicine specialist and receive counseling by a neonatologist.[33]

Oral antihypertensive medications are used as needed to keep systolic BP between 140 and 155 mm Hg and diastolic BP between 90 and 105 mm Hg.[33] Oral labetalol and oral calcium channel blockers (nifedipine or nicardipine) have been commonly used in reported studies. The author's regimen consists of an initial dose of labetalol of 200 mg every 8 hours to be increased up to 800 mg every 8 hours (600 to 2400 mg/day) as needed. If the maximal dose is inadequate to achieve the desired BP goal, short-acting oral nifedipine is added with an initial dose of 10 mg every 6 hours and subsequently increased up to 20 mg every 4 hours (40 to 120 mg/day). An alternative regimen may include the long-acting (XL) version of nifedipine (30 to 60 mg) every 8 hours. During titration of oral antihypertensive agents, if the patient has persistent severe hypertensive episodes (systolic BP ≥160 mm Hg and/or diastolic BP ≥105 mm Hg), blood pressure should be assessed every 15 minutes. If the blood pressure remains in the severe range after 60 minutes, the patient should be transferred to the labor and delivery unit for more intensive monitoring and treatment with intravenous medications such as hydralazine or labetalol. Patients with resistant severe hypertension after maximal doses of intravenous hydralazine (25 mg) or labetalol (220 mg) should receive magnesium sulfate and be delivered. In addition, patients who develop persistent severe hypertension despite combined maximal doses of oral labetalol (2400 mg/day) plus short-acting nifedipine (120 mg/day) or nifedipine XL (180 mg/day) should also be considered for delivery.

Maternal assessment includes frequent evaluation of symptoms (headaches, blurred or double vision, confusion, nausea, vomiting, epigastric or right upper quadrant pain, shortness of breath, uterine activity, and vaginal bleeding) and intake and output.[33]

Laboratory assessment includes daily testing of complete blood count with platelet count, transaminases, LDH, and serum creatinine levels.[32] Coagulation studies are obtained only if there is thrombocytopenia or suspicion of abruption placentae.

Fetal assessment includes daily fetal kick counts, at least daily NST with uterine activity monitoring with a BPP if the NST is nonreactive, and twice weekly amniotic fluid assessment.[33] Ultrasonographic assessment of fetal growth is performed every 2 weeks.[33] Severe oligohydramnios is defined as an amniotic fluid index of 2 cm or less on at least two occasions that are at least 24 hours part.[33] Severe oligohydramnios is considered an indication for delivery in women with a gestational age of more than 30 weeks, irrespective of other fetal testing results. In those

at 30 weeks or less of gestation, pregnancy may be continued with a reassuring NST, BPP, and umbilical artery Doppler studies. Umbilical artery Doppler studies are performed weekly, or more often if FGR is suspected or testing reveals abnormal diastolic flow or severe oligohydramnios. If absent umbilical artery diastolic flow is present, the Doppler studies should be performed daily.

In general, most patients will require delivery within 2 weeks, but some patients may continue their pregnancies for several weeks. It is important to emphasize that this therapy is appropriate only in a select group of patients and should be practiced in a tertiary care center with adequate maternal and neonatal intensive care facilities. Once the decision is made for delivery, the patients should receive magnesium sulfate in labor and for at least 24 hours postpartum.[33]

Intrapartum Management

The goals of management of women with gestational hypertension-preeclampsia are early detection of fetal heart rate abnormalities and progression from mild to severe disease, and the prevention of maternal complications. Pregnancies complicated by preeclampsia, particularly those with severe disease or FGR, are at risk for reduced fetal reserve and abruptio placentae.[2] Therefore, women with preeclampsia should receive continuous monitoring of fetal heart rate and uterine activity. The presence of uterine tachysystole or recurrent fetal heart rate decelerations may be the first sign of abruptio placentae in these women.

Some women with mild hypertension-preeclampsia progress to severe disease as a result of changes in cardiac output and stress hormones during labor. Therefore, women with gestational hypertension-preeclampsia should have BP recordings every hour and should be assessed for symptoms suggestive of severe disease. Those who develop severe hypertension or symptoms should be managed as patients with severe preeclampsia.

Maternal pain relief during labor and delivery can be provided by either systemic opioids or segmental epidural anesthesia. Epidural analgesia is considered to be the preferred method of pain relief in women with mild gestational hypertension and mild preeclampsia. Although there is no unanimity of opinion regarding the use of epidural anesthesia in women with severe preeclampsia, evidence exists that epidural anesthesia is safe in these women. A randomized trial of 116 women with severe preeclampsia receiving either epidural analgesia or patient-controlled analgesia reported no differences in cesarean delivery rates, and the group receiving epidural had significantly better pain relief during labor.

The use of either epidural, spinal, or combined techniques of regional anesthesia is considered by most obstetrical anesthesiologists to be the method of choice during cesarean delivery. **In women with severe preeclampsia, general anesthesia carries the risk for aspiration and failed intubation owing to airway edema and is associated with marked increases in systemic and cerebral pressures during intubation and extubation.[1] Women with airway or laryngeal edema may require awake intubation under fiberoptic observation with the availability of immediate tracheostomy.** Changes in systemic and cerebral pressures may be attenuated by pretreatment with labetalol or nitroglycerine injections. It is important to recognize that regional anesthesia is contraindicated in the presence of coagulopathy or severe thrombocytopenia (platelet count, <50,000/mm^3).

Prevention of Eclamptic Seizures

Magnesium sulfate is the drug of choice to prevent convulsions in women with preeclampsia. The results of recent randomized trials revealed that magnesium sulfate is superior to placebo or no treatment for prevention of convulsions in women with severe preeclampsia. The overall results of the four trials demonstrate that magnesium sulfate prophylaxis, compared with placebo (two trials, 10,795 women), nimodipine (one trial, 1750 women), and no treatment (one trial, 228 women) in severe preeclampsia, is associated with a significantly lower rate of eclampsia (RR, 0.39; 95% CI, 0.28 to 0.55). Results from one of the largest randomized trials to date, that of 10,141 women with preeclampsia in 33 nations (largely in the Third World), has been recently reported. Almost all the enrolled patients had severe disease by U.S. standards: 50% received antihypertensives before randomization, 75% received antihypertensives after randomization, and the remainder had severe preeclampsia or imminent eclampsia. Among all enrolled women, the rate of eclampsia was significantly lower in those assigned to magnesium sulfate (0.8% versus 1.9%; RR, 0.42; 95% CI, 0.29 to 0.60). However, among the 1560 women enrolled in the Western world, the rates of eclampsia were 0.5% in the magnesium group versus 0.8% in the placebo, a difference that was not significant (RR, 0.67; 95% CI, 1.19 to 2.37).

Two randomized placebo-controlled trials evaluated the efficacy and safety of magnesium sulfate in women with mild preeclampsia. One of these trials included 135 women, and the other included only 222 women. There were no instances of eclampsia in either group in both of these trials. In addition, the findings of both studies revealed that magnesium sulfate does not affect either the duration of labor or the rate of cesarean delivery. However, neither of these studies had adequate sample size to address the efficacy of magnesium sulfate to prevent convulsions. Therefore, **whether there is a benefit of magnesium sulfate treatment in women with mild preeclampsia remains unclear.**

Control of Severe Hypertension

The objective of treating acute severe hypertension is to prevent cerebrovascular and cardiovascular complications such as encephalopathy, hemorrhage, and congestive heart failure.[1,2] For ethical reasons, there are no randomized trials to determine the level of hypertension to treat in order to prevent these complications. Antihypertensive therapy is recommended by some for sustained systolic BP values of 160 mm Hg or more and for sustained diastolic values of 110 mm Hg or more. Some experts recommend treating diastolic levels of 105 mm Hg, and still others use a mean arterial BP of 130 mm Hg or more.[1,2] The definition of sustained hypertension is not clear and ranges from 30 minutes to 2 hours.

Antihypertensive medications are indicated if there is sustained elevations in systolic BP to levels of 160 mm Hg or greater and/or if the diastolic BP is 105 mm Hg or

higher.[33] There are several antihypertensive medications that can be used to treat severe hypertension in severe preeclampsia. The most commonly recommended medications include intravenous bolus doses of hydralazine, bolus doses of labetalol, or oral nifedipine (rapid-acting tablets or long-acting capsules). Other antihypertensive medications recommended for treatment of severe hypertension have included intravenous ketanserin, intravenous nicardipine, and mini bolus diazoxide.

Despite the extensive literature on the subject, it remains unclear which is the ideal antihypertensive medication to use in the acute control of severe hypertension in women with severe preeclampsia. The results of a recent meta-analysis of relevant randomized trials found that parenteral hydralazine was associated with more adverse effects compared with other antihypertensives; however, such a finding was not confirmed in a recent large randomized trial. **Based on the available evidence, hydralazine, labetalol, or nifedipine can be used to treat severe hypertension in preeclampsia.**[2,3,33] **The provider should be familiar with the dosage to be used, expected response, and potential side effects of each of these drugs.** Both hydralazine and nifedipine are associated with tachycardia and headaches and thus should not be the first drug of choice in patients with heart rate above 100 beats/minute. In such case, labetalol is preferred. Labetalol, however, should be avoided in patients with moderate to severe asthma, bradycardia (heart rate <60 beats/minute) and in those with congestive heart failure. Compared with other antihypertensive medications, nifedipine has the advantage of increased renal blood flow with associated increase in urine output.[33] Thus, it may be the drug of choice in those with decreased urine output or oliguria, and for treatment of severe hypertension in the postpartum period.[33] In the past, there has been a theoretical concern that the combined use of magnesium sulfate and nifedipine in patients with severe preeclampsia can result in excessive hypotension and neuromuscular blockade. However, a recent review on this subject found that therapy with both magnesium sulfate and nifedipine does not increase the risk for the previously described complications in women with preeclampsia. Nevertheless, if neuromuscular blockage develops in these patients, this can be easily reversed by the administration of 1 g of intravenous calcium gluconate.

The recommended dose of hydralazine for the treatment of severe hypertension in pregnancy is intravenous hydralazine given as bolus injections of 5 to 10 mg every 15 to 20 minutes for a maximal dose of 20 mg. The recommended dose of labetalol is 20 to 40 mg intravenously every 10 to 15 minutes for a maximal of 220 mg, and the dose of nifedipine is 10 to 20 mg orally every 30 minutes for a maximal dose of 50 mg[33] Sustained BP values of 160 mm Hg systolic or more or 105 to 110 mm Hg diastolic or more require therapy intrapartum. For women with thrombocytopenia and those in the postpartum period, systolic values of 150 mm Hg or more or diastolic readings of 100 mm Hg or more are the recommended thresholds for therapy.[33] For this author, the first-line agent is intravenous labetalol, and if maximal doses are ineffective, oral nifedipine is added.

Mode of Delivery

There are no randomized trials comparing the optimal method of delivery in women with gestational hypertension-preeclampsia. A plan for vaginal delivery should be attempted in all women with mild disease without other indications for cesarean delivery and in most women with severe disease, particularly those beyond 30 weeks' gestation.[1,2,17] The decision to perform cesarean delivery should be based on gestational age, fetal condition, presence of labor, and cervical Bishop score. In general, the presence of severe preeclampsia is not per se an indication for cesarean delivery.

There are no randomized trials comparing the optimal methods of delivery in patients with severe hypertension or severe preeclampsia. The method for delivery will depend on gestational age, cervical Bishop score, and fetal condition. The cesarean delivery rate among reported studies in patients at before 34 weeks' gestation ranged from 66% to 96%[33] with the higher rates for patients with onset prior to 28 weeks' gestation. This high cesarean rate is expected considering that a deterioration in either fetal or maternal condition is the indication for delivery during expectant management (high rates of severe FGR, oligohydramnios, non-reassuring fetal status, abnormal presentation, high rates of maternal complications).[33] Thus, a very small percentage of these patients will be considered candidates for medical induction of labor.

There are several retrospective studies evaluating induction of labor in patients with preeclampsia before 34 weeks' gestation and absent contraindication for induction. However, most of the women included in these studies had gestational age beyond 32 weeks at the time of induction.[33] Only two of these studies included data on patients earlier than 28 weeks undergoing induction of labor.[33] Both of these studies reported a cesarean delivery rate above 95% and thus recommended elective cesarean delivery in such patients.

In general, the decision to perform cesarean delivery versus a trial of labor in such patients should be individualized and thus based on one or more of the following factors: fetal gestational age, fetal presentation, presence or absence of severe FGR, oligohydramnios, results of umbilical artery Doppler, BPP, fetal heart rate monitoring, presence of labor, and cervical Bishop score. On the basis of the available data, we recommend cesarean delivery for all women with gestational age below 28 weeks and for all those with severe FGR, severe oligohydramnios, BPP of 4 or less, or reverse umbilical artery Doppler flow at before 32 weeks of gestation.

Postpartum Management

During the immediate postpartum period, women with preeclampsia should receive close monitoring of BP and of symptoms consistent with severe disease and accurate measurements of fluid intake and urinary output.

These women often receive large amounts of intravenous fluids during labor as a result of prehydration before the administration of epidural analgesia, and intravenous fluids are given during the administration of oxytocin and magnesium sulfate in labor and postpartum. In addition, during the postpartum period, there is mobilization of extracellular fluid leading to increased intravascular

volume. As a result, **women with severe preeclampsia, particularly those with abnormal renal function, those with capillary leak, and those with early-onset disease, are at increased risk for pulmonary edema and exacerbation of severe hypertension postpartum. Careful evaluation of the amount of intravenous fluids, oral intake, blood products, and urine output, as well as monitoring by pulse oximetry and chest auscultation, are advised.**[2,33]

In general, most women with gestational hypertension become normotensive during the first week postpartum.[1,2] In contrast, in women with preeclampsia, hypertension often takes longer to resolve. In addition, in some of the women with preeclampsia, there is an initial decrease in BP immediately postpartum, followed by development of hypertension again between days 3 and 6. Moreover, a recent study found that resolution of hypertension and proteinuria may take up to 1 year postpartum. Antihypertensive drug treatment should be undertaken if the systolic BP is at least 150 mm Hg or if the diastolic BP is at least 100 mm Hg. Various agents may be employed. A common regimen is to prescribe oral nifedipine, 10 mg every 6 hours, or long-acting nifedipine.[33] If the BP is well controlled and maternal symptoms are absent, the woman is discharged home with instructions for daily BP measurements by a home visiting nurse for the first week postpartum or longer if necessary. Antihypertensive medications are discontinued if the BP remains below the hypertensive levels for at least 48 hours. Recently, some authors have suggested that 5 days of oral furosemide therapy (20 mg/dL) enhances recovery and reduces the need for antihypertensive therapy in women with severe preeclampsia.

Severe hypertension or severe preeclampsia may develop for the first time during the postpartum period. Hence, all postpartum women should be educated about the signs and symptoms of severe hypertension or preeclampsia. These women are at increased risk for eclampsia, pulmonary edema, stroke, and thromboembolism. Therefore, medical providers and personnel who respond to patient phone calls should be educated and instructed about symptoms of severe postpartum hypertension. Women who have persistent severe headaches, visual changes, and epigastric pain with nausea or vomiting and those with severe hypertension require immediate evaluation and potential hospitalization. These women often require magnesium sulfate for at least 24 hours and antihypertensive therapy. If neurologic symptoms exist, brain imaging is undertaken to rule out the presence of cerebral pathology.

Maternal and Perinatal Outcome with Preeclampsia

Maternal and perinatal morbidity is substantially increased in women with severe gestational hypertension. Indeed, these women have higher morbidity rates than women with mild preeclampsia.[19] In addition, the rates of abruptio placentae, preterm delivery (at less than 37 and 35 weeks), and rates of SGA infants in these women are similar to those seen in women with severe preeclampsia. However, whether this increase in rate of preterm delivery is a result of early delivery chosen by the physician or because of the disease process itself remains unknown. Therefore, these women should be managed as if they had severe preeclampsia.[33]

Maternal and perinatal outcomes in preeclampsia are usually dependent on one or more of the following: gestational age at onset of preeclampsia as well as at time of delivery, the severity of the disease process, the presence of multifetal gestation, and the presence of preexisting medical conditions such as pregestational diabetes, renal disease, or thrombophilias.

Severe preeclampsia is also associated with an increased risk for maternal mortality (0.2%) and increased rates of maternal morbidity (5%), such as convulsions, pulmonary edema, acute renal or liver failure, liver hemorrhage, DIC, and stroke. These complications are usually seen in women who develop preeclampsia before 32 weeks' gestation and in those with preexisting medical conditions.

Counseling Women Who Have Had Preeclampsia in Prior Pregnancies

We examined the pregnancy outcomes and incidences of preeclampsia in subsequent pregnancies, as well as the frequency of chronic hypertension and diabetes mellitus in women who had severe preeclampsia (287 women) or eclampsia (119 women) in their first pregnancies (aged 11 to 25 years) compared with 409 women (aged 12 to 25 years) who remained normotensive during their first pregnancies. Each woman had at least one subsequent pregnancy (range, 1 to 11) and was followed for a minimum of 2 years (range, 2 to 24). There was no significant difference in the incidences of diabetes mellitus in the two groups (1.3% versus 1.5%). The incidence of chronic hypertension was significantly higher in the preeclampsia patients (14.8% versus 5.6%; P <.001). This difference became even greater for those women followed more than 10 years (51% versus 14%; P <.001). The incidence of severe preeclampsia was also significantly higher in the second pregnancies (25.9% to 4.6%) and in the subsequent pregnancies (12.2% to 5.0%) of women with preeclampsia.

In a later report, subsequent pregnancy outcome and long-term prognosis were studied in 108 women who had severe preeclampsia in the second trimester. These women were followed for a minimum of 2 years (range, 2 to 12 years) and had a total of 169 subsequent pregnancies. Fifty-nine (35%) subsequent pregnancies were normotensive, and 110 (65%) were complicated by preeclampsia. Overall, 21% of all subsequent pregnancies were complicated by severe preeclampsia in the second trimester. In addition, these women had a higher risk for developing chronic hypertension, with the highest incidence being in those who had recurrent severe preeclampsia in the second trimester (55%).

Hnat and associates[23] reported subsequent pregnancy outcome in women with previous preeclampsia enrolled in a multicenter trial. The rate of recurrent preeclampsia was 17%. The authors also noted that these women had a high rate of severe preeclampsia and poor perinatal outcome. In addition, even in those who remained normotensive in their subsequent pregnancy, there was a greater likelihood of adverse pregnancy outcome (preterm delivery, SGA infants, and perinatal death).

Some women with preeclampsia remote from term may have abruptio placentae. The risk for this complication is

increased significantly in those with severe preeclampsia before 34 weeks' gestation and particularly in those who have severe preeclampsia in the second trimester. For women with preeclampsia complicated by abruptio placentae, the risk for abruptio in subsequent pregnancies ranges from 5% to 20%.

Pregnancy outcome and long-term prognosis were studied in 37 women with severe preeclampsia complicated by pulmonary edema, and 18 of these women had subsequent pregnancies. Ten of the 18 were normotensive, 4 were complicated by chronic hypertension, and 4 by preeclampsia; 1 of the latter women also had pulmonary edema.

Pregnancy outcome and remote prognosis were also studied in 18 women with severe preeclampsia complicated by acute renal failure. All 18 had acute tubular necrosis, 9 required dialysis, and 2 died within 8 weeks after birth. All women had serial evaluation of renal function, urine microscopic testing, and electrolyte studies at the onset of acute renal failure and during follow-up. All 16 surviving patients had normal renal function on long-term follow-up (average, 4 years). Four of the 16 women had seven subsequent pregnancies: one ended in miscarriage, one was complicated by preeclampsia at 35 weeks, and five were term pregnancies without complications.

Women with a history of HELLP syndrome are at increased risk for all forms of preeclampsia in subsequent pregnancies (Table 35-18). In general, the rate of preeclampsia in subsequent pregnancies is about 20%, with significantly higher rates if the onset of HELLP syndrome is during the second trimester. The rate of recurrent HELLP syndrome ranges from 2% to 19%, with the most reliable data suggesting a recurrence risk of less than 5%. Because of the previously mentioned risks, these women are informed that they are at increased risk for adverse pregnancy outcome (preterm delivery, FGR, abruptio placentae, and fetal death) in subsequent pregnancies. Therefore, they require close monitoring during subsequent gestations. At present, there is no preventive therapy for recurrent HELLP syndrome. There are case series describing subsequent pregnancy outcomes in women with previous ruptured liver hematomas. We have followed three women with previous ruptured liver hematomas through four subsequent pregnancies without complications. Other authors reviewed the literature and reported on several such women who had subsequent uneventful pregnancies under close maternal and fetal observation.

Liver function tests were studied in 54 women at a median of 31 months (range, 3 to 101 months) after pregnancies complicated by the HELLP syndrome. Serum levels of AST, LDH, and conjugated bilirubin were found to be normal. However, total bilirubin levels were elevated in 11 (20%) of the studied women. The authors of this report suggested the possibility that a dysfunction of the bilirubin-conjugating mechanism represents a risk factor for the development of this syndrome.

There are two reports describing long-term renal function after HELLP syndrome. One of the reports included 23 patients whose pregnancies were complicated by HELLP syndrome and acute renal failure: 8 of these women had 11 subsequent pregnancies, with 9 resulting in term gestation. All 23 women also had normal BP and renal function at an average follow-up of 4.6 years (range, 0.5 to 11 years). The other study compared renal function after at least 5 years after HELLP syndrome in 10 patients with the respective findings in 22 patients with previous normotensive gestation. There were no differences in renal function tests between the two groups. These findings suggest that the development of HELLP syndrome with or without renal failure does not affect long-term renal function.

Remote Prognosis

Women with preeclampsia should also be counseled regarding future cardiovascular risks and risks for underlying renal disease. **There is evidence that women with preeclampsia remote from term are at particular increased risk for chronic hypertension later in life.** In addition, these patients, particularly those with recurrent preeclampsia, are more likely to have underlying renal disease. In a recent report, 86 Japanese women who had severe hypertension, severe proteinuria, or both during pregnancy had a postpartum renal biopsy. The authors found that women who had gestational proteinuria or preeclampsia before 30 weeks' gestation were more likely to have had underlying renal disease.

Several recent studies suggested that women who develop preeclampsia may be at increased risk for coronary artery disease later in life. Indeed, many of the risk factors and pathophysiologic abnormalities of preeclampsia are similar to those of coronary artery disease. Ramsey and associates demonstrated for the first time, using laser Doppler imaging in vivo, impaired microvascular function in women 15 to 25 years of age following a pregnancy complicated by preeclampsia. Thus, microvascular dysfunction, which is associated with insulin resistance, may be a predisposing vascular mechanism for both coronary heart disease and preeclampsia. In addition, pregnancies complicated by preeclampsia are at increased risk for stroke later in life. Therefore, pregnancies complicated by preeclampsia may identify women at risk for vascular disease in later life and may provide the opportunity for

life style and risk factor modification to alter their risk for complications.

ECLAMPSIA

Eclampsia is the occurrence of convulsions or coma unrelated to other cerebral conditions with signs and symptoms of preeclampsia. Early writings of both the Egyptians and Chinese warned of the dangers of convulsions encountered during pregnancy. Hippocrates noted that headaches, convulsions, and drowsiness were ominous signs associated with pregnancy. The term *eclampsia* appeared in a treatise on gynecology written by Varandaeus in 1619. Clonic spasms in association with pregnancy were described by Pew in 1694. In 1772, De la Motte recognized that prompt delivery of pregnant women with convulsions favored their recovery.

Eclampsia is defined as the development of convulsions or unexplained coma during pregnancy or postpartum in patients with signs and symptoms of preeclampsia. In the Western world, the reported incidence of eclampsia ranges from 1 in 2000 to 1 in 3448 pregnancies. The reported incidence is usually higher in tertiary referral centers, in multifetal gestation, and in those without prenatal care.[12]

Pathophysiology

The pathogenesis of eclamptic convulsions continues to be the subject of extensive investigation and speculation. Several theories and pathologic mechanisms have been implicated as possible etiologic factors, but none of these has been proved conclusively. It is not clear whether the pathologic features in eclampsia are a cause or an effect of the convulsions.[86]

Diagnosis

The diagnosis of eclampsia is secure in the presence of generalized edema, hypertension, proteinuria, and convulsions. However, women in whom eclampsia develops exhibit a wide spectrum of signs, ranging from severe hypertension, severe proteinuria, and generalized edema to absent or minimal hypertension, no proteinuria, and no edema.[86] Hypertension is considered the hallmark for the diagnosis of eclampsia. The hypertension can be severe (≥160 mm Hg systolic or ≥110 mm Hg diastolic) in 20% to 54% of cases[16,86] or mild (systolic BP between 140 and 160 mm Hg or diastolic BP between 90 and 110 mm Hg) in 30% to 60% of cases.[12,86] However, in 16% of cases, hypertension may be absent.[16] In addition, severe hypertension is more common in patients who develop antepartum eclampsia (58%) and in those who develop eclampsia at 32 weeks' gestation or later (71%).[16] Moreover, hypertension is absent in only 10% of women who develop eclampsia at or before 32 weeks' gestation.[16]

The diagnosis of eclampsia is usually associated with proteinuria (at least 1+ on dipstick).[16,86] In a series of 399 women with eclampsia studied by the author, substantial proteinuria (≥3+ on dipstick) was present in only 48% of the cases, whereas proteinuria was absent in 14% of the cases.[16] Abnormal weight gain (with or without clinical edema) in excess of 2 pounds per week during the third trimester might be the first sign before the onset of eclampsia. However, edema was absent in 26% of 399 eclamptic women studied by the author.[16]

Several clinical symptoms are potentially helpful in establishing the diagnosis of eclampsia. These include persistent occipital or frontal headaches, blurred vision, photophobia, epigastric or right upper quadrant pain, and altered mental status. Women have at least one of these symptoms in 59% to 75% of the cases (Table 35-19). Headaches are reported by 50% to 75% of the patients, whereas visual changes are reported in 19% to 32% of the patients.[86] These symptoms may occur before or after the onset of convulsions.[86]

Time of Onset

The onset of eclamptic convulsions can be during the antepartum, intrapartum, or postpartum period. The reported frequency of antepartum convulsions among recent series has ranged from 38% to 53% (Table 35-20),[16] whereas the frequency of postpartum eclampsia has ranged

from 11% to 44%.[16] **Although most cases of postpartum eclampsia occur within the first 48 hours, some cases can develop beyond 48 hours postpartum and have been reported as late as 23 days postpartum.[16] In the latter cases, an extensive neurologic evaluation may be needed to rule out the presence of other cerebral pathology.[86]**

Almost all cases (91%) of eclampsia develop in the third trimester (≥28 weeks).[16] The remaining cases occur between 21 and 27 weeks' gestation (7.5%) or at or before 20 weeks' gestation (1.5%).[16] Eclampsia occurring before the 20th week of gestation is generally associated with molar or hydropic degeneration of the placenta with or without a coexistent fetus.[32,86] Although rare, eclampsia can occur during the first half of pregnancy without molar degeneration of the placenta.[32,86] These women may be misdiagnosed as having hypertensive encephalopathy, a seizure disorder, or TTP. Women in whom convulsions develop in association with hypertension and proteinuria during the first half of pregnancy should be considered to have eclampsia until proved otherwise.[32] These women should have an ultrasound examination to rule out molar pregnancy or hydropic degeneration of the placenta. They also should have an extensive neurologic and medical evaluation to rule out another pathologic process.

Late postpartum eclampsia is defined as eclampsia that occurs more than 48 hours but less than 4 weeks after delivery. Historically, eclampsia was believed not to occur more than 48 hours after delivery. However, several recent reports have confirmed the existence of late postpartum eclampsia.[86] These women have signs and symptoms consistent with preeclampsia in association with convulsions.[32,86] Some of these women demonstrate a clinical picture of preeclampsia during labor or immediately postpartum (56%), whereas others demonstrate these clinical findings for the first time more than 48 hours after delivery (44%). Of interest is the fact that late-postpartum eclampsia developed despite the use of prophylactic magnesium sulfate during labor and for at least 24 hours postpartum in previously diagnosed preeclamptic women.[86] Therefore, women in whom convulsions develop in association with hypertension or proteinuria or with headaches or blurred vision after 48 hours of delivery should be considered to have eclampsia and initially treated as such.[32]

Cerebral Pathology

Autoregulation of the cerebral circulation is a mechanism for the maintenance of constant cerebral blood flow during changes in BP and may be altered in eclampsia. Through active changes in cerebrovascular resistance at the arteriolar level, cerebral blood flow normally remains relatively constant when cerebral perfusion pressure ranges between 60 and 120 mm Hg. In this normal range, vasoconstriction of cerebral vessels occurs in response to elevations in BP, whereas vasodilation occurs as BP is lowered. Once cerebral perfusion pressure exceeds 130 to 150 mm Hg, however, the autoregulatory mechanism fails. In extreme hypertension, the normal compensatory vasoconstriction may become defective, and cerebral blood flow increases. As a result, segments of the vessels become dilated, ischemic, and increasingly permeable. Thus, exudation of plasma occurs, giving rise to focal cerebral edema and compression of vessels, resulting in a decreased cerebral blood flow.[86] Hypertensive encephalopathy, a possible model for eclampsia, is an acute clinical condition that results from abrupt severe hypertension and subsequent significant increases in intracranial pressure. Because this is an acute disturbance in the hemodynamics of cerebral arterioles, morphologic changes in anatomy may not be uniformly evident in pathologic material. Several autopsy findings that are relatively constant include cerebral swelling and fibrinoid necrosis of vessel walls.

The cause of eclampsia is unknown, and there are many unanswered questions regarding the pathogenesis of its cerebral manifestations. Cerebral pathology in cortical and subcortical white matter in the form of edema, infarction, and hemorrhage (microhemorrhage and intracerebral parenchymal hemorrhage) is a common autopsy finding in patients who die from eclampsia. However, although autopsy series provide information regarding the central nervous system abnormality in patients dying of eclampsia, this information is not necessarily indicative of the central nervous system abnormality present in most patients who survive this condition.[86] The diagnosis of eclampsia is not dependent on any single clinical or diagnostic neurologic findings. Focal neurologic signs such as hemiparesis or an unconscious state are rare in cases of eclampsia reported from countries in the developed world.[86] Although eclamptic patients may initially manifest a variety of neurologic abnormalities, including cortical blindness, focal motor deficits, and coma, most have no permanent neurologic deficits.[16,86] These neurologic abnormalities are probably due to a transient insult, such as hypoxia, ischemia, or edema.

Several neurodiagnostic tests, such as electroencephalography (EEG), CT, cerebral Doppler velocimetry, MRI, and cerebral angiography (both traditional and MRI angiography) have been studied in women with eclampsia. In general, the EEG is acutely abnormal in most eclamptic patients; however, these abnormalities are not pathognomonic of eclampsia. In addition, the abnormal EEG findings are not affected by the use of magnesium sulfate. Moreover, lumbar puncture is not helpful in the diagnosis and management of eclamptic women. The results of CT and MRI studies reveal the presence of edema and infarction within the subcortical white matter and adjacent gray matter mostly in the parieto-occipital lobes (see box, Reported Computed Tomography Scan and Magnetic Resonance Imaging Findings in Complicated Eclampsia). Cerebral angiography and Doppler velocimetry suggest the presence of vasospasm.

On the basis of cerebral imaging findings, attention has been directed to hypertensive encephalopathy as a model for the central nervous system abnormalities in eclampsia. The two conditions share many clinical, radiologic, and pathologic features. There is failure of normal cerebral blood flow autoregulation in patients with hypertensive encephalopathy and in some patients with eclampsia.[86] Two theories have been proposed to explain these cerebral abnormalities: forced dilation and vasospasm.[86] The forced dilation theory suggests that the lesions in eclampsia are caused by loss of cerebrovascular autoregulation.

Recently, MRI and apparent diffusion coefficient mapping were used to characterize the relative frequency

Reported Computed Tomography Scan and Magnetic Resonance Imaging Findings in Complicated Eclampsia

- Diffuse white matter low-density areas
- Patchy areas of low density
- Occipital white matter edema
- Loss of normal cortical sulci
- Reduced ventricular size
- Acute hydrocephalus
- Cerebral hemorrhage
  - Intraventricular hemorrhage
  - Parenchymal hemorrhage (high density)
- Cerebral infarction
  - Low-attenuation areas
  - Basal ganglia infarctions

of vasogenic and cytotoxic edema in two small series of eclamptic women. Cerebral edema (mostly vasogenic) was present in up to 93% to 100% of these women. However, concurrent foci of infarction evidenced by reduced apparent diffusion coefficient (restricted diffusion) were present in 6 of 27 eclamptic women studied by Zeeman and colleagues and in 3 of 17 eclamptic and preeclamptic women studied by Loureiro and associates. In addition, 5 of these 6 women reported by Zeeman and colleagues had persistent abnormalities on repeat MRI testing 6 to 8 weeks later, suggesting that these lesions might not be reversible. Moreover, 4 of the 17 women reported by Loureira and associates had persistent MRI abnormalities at a median of 8 weeks of follow-up.

In summary, cerebral imaging findings in eclampsia are similar to those found in patients with hypertensive encephalopathy. The classic findings are referred to as posterior reversible encephalopathy syndrome (PRES). Figure 35-10 demonstrates such a lesion. This syndrome is also seen in patients with reversible cerebral vasoconstriction syndrome. This syndrome is usually seen in patients who present in the postpartum period with signs and symptoms similar to eclampsia. The diagnosis is confirmed by angiogram (Figure 35-11). **Cerebral imaging is not necessary for the diagnosis and management of most women with eclampsia. Cerebral imaging is indicated for patients with focal neurologic deficits or prolonged coma. In these patients, hemorrhage and other serious abnormalities requiring specific pharmacologic therapy or surgery must be excluded. Cerebral imaging may also be helpful in patients who have an atypical presentation for eclampsia (onset before 20 weeks' gestation or more than 48 hours after delivery, and eclampsia refractory to adequate magnesium sulfate therapy).** Advances in MRI and magnetic resonance angiography, as well as in cerebral vascular Doppler velocimetry, may aid our understanding regarding the pathogenesis and improving long-term outcome of this condition.[86]

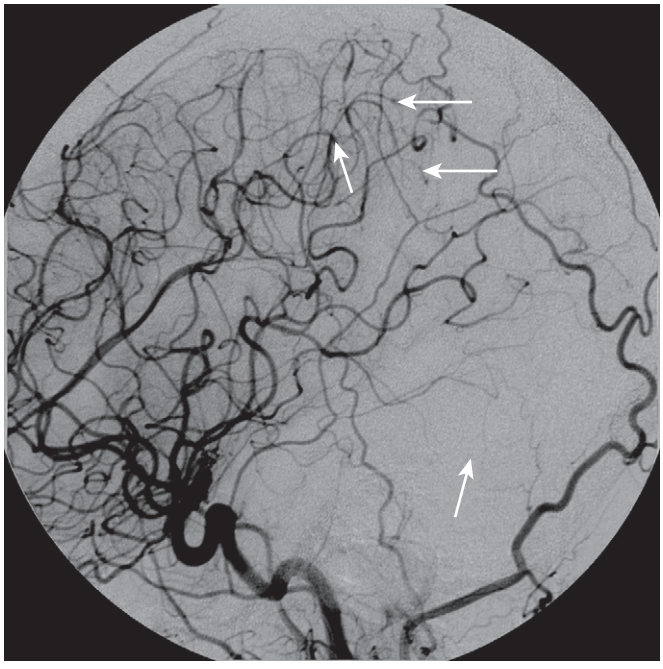

Figure 35-11. Cerebral arteriogram demonstrating cerebral vasoconstriction. *Arrows* show diffused vasoconstriction in small blood vessels.

Differential Diagnosis

The presenting symptoms, clinical findings, and many of the laboratory findings overlap with a number of medical and surgical conditions.[32] The most common cause of convulsions developing in association with hypertension or proteinuria during pregnancy or immediately postpartum is eclampsia. Rarely, other etiologies producing convulsions in pregnancy or postpartum may mimic eclampsia.[86]

These diagnoses are particularly important in the presence of focal neurologic deficits, prolonged coma, or atypical eclampsia. In addition, in some patients, gestational

hypertension or preeclampsia may develop in association with these disorders (connective tissue disease, thrombophilias, seizure disorder, hypertensive encephalopathy), further contributing to the diagnostic difficulty. Therefore, an effort should be made to identify an accurate diagnosis given that management strategies may differ among these conditions.

Differential Diagnosis of Eclampsia

- Hypertensive encephalopathy
- Seizure disorder
- Hypoglycemia, hyponatremia
- Posterior reversible vasoconstriction syndrome (Figure 35-11)
- Thrombotic thrombocytopenic purpura
- Postdural puncture syndrome
- Vasculitis, angiopathy
- Amniotic fluid embolism
- Cerebrovascular accidents
- Hemorrhage
- Ruptured aneurysm or malformation
- Arterial embolism, thrombosis
- Venous thrombosis
- Hypoxic ischemic encephalopathy
- Angiomas

Maternal and Perinatal Outcome

Eclampsia is associated with a slightly increased risk for maternal death in developed countries (0% to 1.8%),[86] but the maternal mortality rate may be as high as 14% in developing countries. The high maternal mortality reported from developing countries occurs primarily among patients who have had multiple seizures outside the hospital and those without prenatal care. In addition, this high mortality rate could be attributed to the lack of resources and intensive care facilities needed to manage maternal complications from eclampsia. Of 4024 pregnancy-related deaths reported from 1979 to 1992, a total of 790 (19.6%) were considered due to preeclampsia-eclampsia, with 49% of these 790 considered related to eclampsia. In this series, the risk for death from preeclampsia or eclampsia was higher for women older than 30 years, those without prenatal care, and black women; the greatest risk for death was found among women with pregnancies at or before 28 weeks' gestation.

Pregnancies complicated by eclampsia are also associated with increased rates of maternal morbidities such as abruptio placentae (7% to 10%),[86] DIC (7% to 11%),[86] pulmonary edema (3% to 5%), acute renal failure (5% to 9%), aspiration pneumonia (2% to 3%), and cardiopulmonary arrest (2% to 5%).[86] ARDS and intracerebral hemorrhage are rare complications in series of eclamptic patients reported from the developed world. It is important to note that maternal complications are greatest among women who develop antepartum eclampsia, particularly among those who develop eclampsia remote from term.[86]

Perinatal mortality and morbidities remain high in eclamptic pregnancies. The reported perinatal death rate in recent series ranged from 5.6% to 11.8%.[86] This high perinatal death rate is related to prematurity, abruptio placentae, and severe FGR.[86] The rate of preterm delivery is about 50%, with about 25% of cases occurring before 32 weeks' gestation.[86]

Is Eclampsia Preventable?

Prevention of eclampsia requires knowledge of its etiology and pathophysiology and of methods to predict patients at high risk for development of convulsions. However, as discussed earlier, the pathogenesis of eclampsia is largely unknown. Prevention of eclampsia can be primary by preventing the development of preeclampsia or secondary by employing pharmacologic agents that prevent convulsions in women with established preeclampsia. Prevention can also be tertiary by preventing subsequent convulsions in women with established eclampsia.

Current management schemes designed to prevent eclampsia are based on early detection of gestational hypertension or preeclampsia and subsequent use of preventive therapy in such women. Some of the recommended preventive therapies have included close monitoring (in-hospital or outpatient), use of antihypertensive therapy to keep maternal BP below a certain level (less than severe range or to normal values), timely delivery, and prophylactic use of magnesium sulfate during labor and immediately postpartum in those considered to have preeclampsia. These management schemes assume that the clinical course in the development of eclampsia is characterized by a gradual process that begins with progressive weight gain, followed by hypertension (mild to severe) and proteinuria, with the subsequent onset of premonitory symptoms, and ending with the onset of generalized convulsions or coma.[86] This clinical course may be present in some women who develop eclampsia in developed countries. However, recent data from large series of eclamptic women from the United States and Europe indicate that about 20% to 40% of eclamptic women do not have any premonitory signs or symptoms before the onset of convulsions.[16] In many of these cases, the onset of convulsions is abrupt and does not follow an indolent progression from mild to severe disease before the onset of eclampsia.[86]

It is also assumed that appropriate and timely standard preventive therapy will avoid eclampsia in virtually all patients with gestational hypertension-preeclampsia.[86] The efficacy of in-hospital management of patients with gestational hypertension or preeclampsia for the prevention of eclampsia has not been evaluated in randomized trials. Moreover, data from retrospective studies from the developed countries indicate that about 50% of eclamptic women develop their first convulsion while in the hospital under "close medical supervision."[86] Thus, early and prolonged hospitalization of women with mild hypertension or preeclampsia may not prevent most cases of eclampsia.

There are several randomized trials describing the use of antihypertensive drugs versus no treatment or a placebo in the treatment of women with mild hypertension or preeclampsia. Overall, these trials revealed lower rates of progression to severe disease. However, the study design and the sample size of these trials is inadequate to evaluate potential benefits regarding prevention of eclampsia.

Prophylactic magnesium sulfate is recommended only for women who are hospitalized with the established diagnosis of preeclampsia.[1-3] Its use is recommended only

during labor and for 12 to 24 hours' postpartum.[1-3] Therefore, it can be expected to have a potential effect in preventing eclampsia that develops only during this time period (40% of total).

There are several randomized trials comparing the efficacy of magnesium sulfate with other anticonvulsive agents for the prevention of recurrent seizures in women with eclampsia. In these trials, **magnesium sulfate has been compared with diazepam, phenytoin, and a lytic cocktail. Overall, these trials revealed that magnesium sulfate was associated with a significantly lower rate of recurrent seizures (9.4% versus 23.1%; RR, 0.41; 95% CI, 0.32 to 0.51) and a lower rate of maternal death (3% versus 4.8%; RR, 0.62; 95% CI, 0.39 to 0.99) than that observed with other agents.**

The low incidence of eclampsia in developed countries is probably related to prevention of cases of eclampsia in women with a classic presentation and with a classic progression from mild to severe preeclampsia.[86] As a result, most eclamptic cases described in reported series from the United States and Europe have an atypical presentation (abrupt onset, development of convulsions while receiving prophylactic magnesium sulfate, or onset of convulsions beyond 48 hours after delivery).[86] Indeed, most eclamptic convulsions in these series developed in hospitalized women, and in some of these women, the onset of convulsions was not preceded by warning signs or symptoms.[86] Overall, the percentage of eclampsia considered unpreventable in these series ranges from 31% to 87%.[86]

Maternal Transport of the Eclamptic Patient

During the past 20 years, there has been a marked reduction in the number of eclamptic patients. Consequently, most obstetricians have little or no experience in the management of eclampsia. A recent survey of a random sample of obstetricians from all 50 states indicated that about 50% of obstetricians in private practice had not seen an eclamptic patient during the past year.

Because management of the eclamptic patient requires the availability of neonatal and obstetrical intensive care units and personnel with special expertise, it is recommended that eclamptic women at term be cared for only at level II or III hospitals with adequate facilities and with consultants from other specialties. For those eclamptic patients who are remote from term, referral should be made to a tertiary care center. The following steps should be taken before transfer of these critically ill patients:

1. The referring physician or nurse should consult with the physician at the perinatal center regarding the referral and appropriate treatment. All maternal records, including prenatal data and a detailed summary of the patient's condition, should be transmitted.
2. BP should be stabilized and convulsions controlled.
3. Adequate prophylactic anticonvulsive medications should be given. An accepted regimen is 4 g intravenous magnesium sulfate as a loading dose over 20 minutes
4. Maternal laboratory assessment (complete blood count with platelet count, liver enzymes) and fetal monitoring should be undertaken.
5. Such patients should be sent in an ambulance with medical personnel in attendance for proper management in case of subsequent convulsions.

Treatment of Eclamptic Convulsions

Eclamptic convulsions are a life-threatening emergency and require proper care to minimize morbidity and mortality. The development of an eclamptic convulsion is frightening to observe. Initially, the patient's face becomes distorted with protrusion of her eyes. This is followed by a congested facial expression. Foam often exudes from the mouth. The woman usually bites her tongue unless it is protected. Respirations are absent throughout the seizure. Typically, the convulsion, which can be divided into two phases, continues for 60 to 75 seconds. The first phase, which lasts 15 to 20 seconds, begins with facial twitching, proceeding to the body becoming rigid with generalized muscular contractions. The second phase lasts about 60 seconds and consists of the muscles of the body alternately contracting and relaxing in rapid succession. This phase begins with the muscles of the jaw and rapidly involves the eyelids, other facial muscles, and then all the muscles of the body. Coma follows the convulsion, and the woman usually remembers nothing of the recent events. If she has repeated convulsions, some degree of consciousness returns after each convulsion. She may enter a combative state and be agitated and difficult to control. Rapid and deep respirations usually begin as soon as the convulsions end. Maintenance of oxygenation is usually not a problem after a single convulsion; the risk for aspiration is low in the well-managed patient.

Because eclampsia is so frightening, the natural tendency is to attempt to abolish the convulsion. Drugs such as diazepam should not be given in an attempt to stop or shorten the convulsion, especially if the patient does not have an intravenous line in place and someone skilled in intubation is not immediately available. If diazepam is used, no more than 5 mg should be given over a 60-second period. Rapid administration of diazepam may lead to apnea or cardiac arrest, or both.

Prevention of Maternal Injury During the Convulsions

The first priority in the management of eclampsia is to prevent maternal injury and to support cardiovascular functions. During or immediately after the acute convulsive episode, supportive care should be given to prevent serious maternal injury and aspiration, assess and establish airway potency, and ensure maternal oxygenation. During this time, the bed's side rails should be elevated and padded, a padded tongue blade is inserted between the teeth (avoid inducing gag reflex), and physical restraints may be needed. To minimize the risk for aspiration, the patient should lie in the lateral decubitus position, and vomitus and oral secretions are suctioned as needed.[86] Aspiration may be caused by forcing the padded tongue blade to the back of the throat, stimulating the gag reflex with resultant vomiting.

Adequate oxygenation should be maintained during the convulsive episode because hypoventilation and respiratory acidosis often occur. Although the initial seizure lasts only a few minutes, it is important to maintain oxygenation

by supplemental oxygen administration through a face mask with or without an oxygen reservoir at 8 to 10 L/minute.[86] After the convulsion has ceased, the patient begins to breathe again, and oxygenation is rarely a problem. However, maternal hypoxemia and acidosis may develop in women who have had repetitive convulsions, in those with aspiration pneumonia, in those with pulmonary edema, or as a result of a combination of these factors. It is the author's policy to use transcutaneous pulse oximetry to monitor oxygenation in all eclamptic patients. Arterial blood gas analysis is required if the pulse oximetry results are abnormal (oxygen saturation ≤92%). Sodium bicarbonate is not given unless the pH is below 7.10.

Prevention of Recurrent Convulsions

The next step in the management of eclampsia is to prevent recurrent convulsions. **Magnesium sulfate is the drug of choice to treat and prevent subsequent convulsions in women with eclampsia.[86] A loading dose of 6 g over 15 to 20 minutes is recommended, followed by a maintenance dose of 2 g per hour as a continuous intravenous solution.** About 10% of eclamptic women have a second convulsion after receiving magnesium sulfate.[86] In these women, another bolus of 2 g magnesium sulfate can be given intravenously over 3 to 5 minutes. An occasional patient will have recurrent convulsions while receiving adequate and therapeutic doses of magnesium sulfate. In this patient, recurrent seizures can be treated with sodium amobarbital, 250 mg intravenously over 3 to 5 minutes.[86]

Rarely, a woman may experience an eclamptic seizure, lapse into a coma, and die. Magnesium toxicity should be considered in those women who do not regain consciousness. A case report of magnesium sulfate toxicity details the features of this serious complication. Within a few minutes of starting what was supposed to be a magnesium loading dose, 4 g magnesium sulfate in 250 mL saline, the patient went into cardiorespiratory arrest. Immediate resuscitation including intubation was performed. About half of the loading dose had been given. An intracerebral accident or eclampsia was thought to be the cause of the coma; the loading dose was continued and maintenance therapy started. Initial blood gases were normal, and the electrocardiogram (ECG) was normal 15 minutes after the arrest. Mechanical ventilatory support was required. The patient's vital signs were stable; however, her pupils were nonreactive. Serum electrolytes, glucose, blood urea nitrogen, and creatinine were normal. CT scan of the head and cerebral angiograms were normal. A magnesium level of 35 mg/dL was reported 3.5 hours later from a blood sample taken through femoral venipuncture at the time of arrest. The magnesium sulfate infusion was stopped immediately. During the first 5 hours after the cardiorespiratory arrest, 1344 mg of magnesium was excreted in the urine. Twelve hours after the arrest, an uncomplicated low vertical cesarean delivery was done for a breech presentation. The 3160-g male infant had Apgar scores of 8 and 9 at 1 and 5 minutes, respectively. Maternal and cord blood magnesium levels at delivery were 5.8 mg/dL. Both mother and baby were discharged from the hospital with no apparent sequelae. Of interest, the patient reported she could hear and see what was occurring around her, but she could not make any movements while she was intubated. Figure 35-12 presents the maternal magnesium levels in this case.

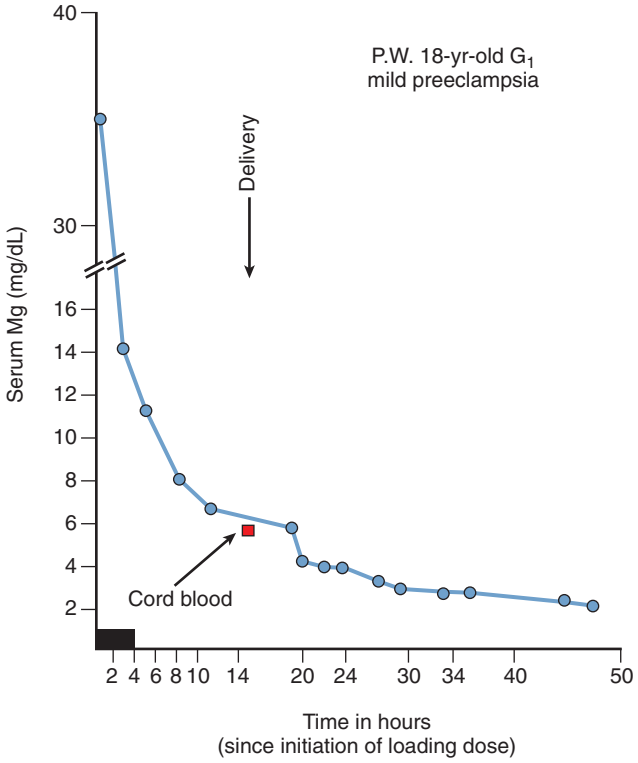

FIGURE 35-12. A patient with magnesium toxicity. (From McCubbin JH, Sibai BM, Abdella TN, et al: Cardiopulmonary arrest due to acute maternal hypermagnesemia [Letter]. Lancet 1:1058, 1981.)

Control of Severe Hypertension

The next step in the management of eclampsia is to reduce the BP to a safe range. The objectives of treating severe hypertension are to avoid loss of cerebral autoregulation and to prevent congestive heart failure without compromising cerebral perfusion or jeopardizing uteroplacental blood flow that is already reduced in many women with eclampsia.[86] Thus, **maintaining systolic BP between 140 and 160 mm Hg and diastolic BP between 90 and 105 mm Hg is a reasonable goal. This can be achieved with bolus 5 to 10 mg doses of hydralazine or labetalol (20 to 40 mg intravenously) every 15 minutes as needed.**[86] Other potent antihypertensive medications such as sodium nitroprusside or nitroglycerine are rarely needed in eclampsia. Diuretics are not used except in the presence of pulmonary edema.

Intrapartum Management

Maternal hypoxemia and hypercarbia cause fetal heart rate and uterine activity changes during and immediately after a convulsion. The fetal heart rate tracing may reveal bradycardia, transient late decelerations, decreased beat-to-beat variability, and compensatory tachycardia. Uterine contractions can increase in frequency and tone.[86] These changes usually resolve spontaneously within 3 to 10 minutes after the termination of convulsions and the correction of maternal hypoxemia. The patient should not be rushed to emergency cesarean delivery based on these

findings, especially if the maternal condition remains stable.

In a review of 10 women who had undergone electronic internal fetal monitoring during an eclamptic convulsion, 6 had fetal bradycardia (fetal heart rate <120 beats/minute) that varied in duration from 30 seconds to 9 minutes. The interval from onset of the seizure to the fall in fetal heart rate was 5 minutes. Transitory fetal tachycardia occurred frequently after the prolonged bradycardia. In addition, loss of beat-to-beat variability with transitory late decelerations occurred during the recovery phase. Uterine hyperactivity demonstrated by both increased uterine tone and increased frequency of uterine contractions occurs during an eclamptic seizure. The duration of the increased uterine activity varies from 2 to 14 minutes.

Fetal outcome is generally good after an eclamptic convulsion. The mechanism for the transitory fetal bradycardia may be a decrease in uterine blood flow caused by intense vasospasm and uterine hyperactivity. The absence of maternal respiration during the convulsion may also result in fetal hypoxia and heart rate changes. Because the fetal heart rate pattern usually returns to normal after a convulsion, other conditions should be considered if an abnormal pattern persists. It may take longer for the heart rate pattern to return to baseline in an eclamptic woman whose fetus is preterm with growth restriction. Placental abruption may occur after the convulsion and should be considered if uterine hyperactivity remains or the bradycardia persists.[86]

The presence of eclampsia is not an indication for cesarean delivery. The decision to perform a cesarean delivery should be based on gestational age, fetal condition, presence of labor, and cervical Bishop score.[86] Cesarean delivery is recommended for those with eclampsia before 30 weeks' gestation who are not in labor with an unfavorable cervix (Bishop score <5). Patients having labor or rupture of membranes are allowed to deliver vaginally in the absence of obstetrical complications. When labor is indicated, it is initiated with either oxytocin infusions or prostaglandins in all patients with a gestational age at or above 30 weeks, irrespective of the Bishop score. A similar approach is used for those before 30 weeks' gestation if the cervical Bishop score is at least 5.

Maternal pain relief during labor and delivery can be provided by either systemic opioids or epidural anesthesia as recommended for women with severe preeclampsia.[2] Either epidural, spinal, or combined techniques of regional anesthesia can be used for cesarean delivery. Regional anesthesia is contraindicated in the presence of coagulopathy or severe thrombocytopenia (platelet count <50,000/mm^3). In women with eclampsia, general anesthesia increases the risk for aspiration and failed intubation due to airway edema and is associated with marked increases in systemic and cerebral pressures during intubation and extubation.[86] Women with airway or laryngeal edema may require awake intubation under fiberoptic observation with the availability of immediate tracheostomy. Changes in systemic or cerebral pressures may be attenuated by pretreatment with labetalol or nitroglycerine injections.[86]

Postpartum Management of Eclampsia

After delivery, women with eclampsia should receive close monitoring of vital signs, fluid intake and output, and symptoms for at least 48 hours. These women usually receive large amounts of intravenous fluids during labor, delivery, and postpartum. In addition, during the postpartum period, there is mobilization of extracellular fluid leading to increased intravascular volume. As a result, women with eclampsia, particularly those with abnormal renal function, those with abruptio placentae, and those with preexisting chronic hypertension are at increased risk for pulmonary edema and exacerbation of severe hypertension postpartum.[86] Careful attention to fluid status is essential.

Parenteral magnesium sulfate should be continued for at least 24 hours after delivery or for at least 24 hours after the last convulsion. If oliguria is present (<100 mL/4 hours), both the rate of fluid administration and the dose of magnesium sulfate should be reduced. Once delivery has occurred, other oral antihypertensive agents such as labetalol or nifedipine can be used to keep systolic BP below 155 mm Hg and diastolic BP below 105 mm Hg. Nifedipine offers the benefit of improved diuresis in the postpartum period.

Subsequent Pregnancy Outcome and Remote Prognosis

Women with a history of eclampsia are at increased risk for all forms of preeclampsia in subsequent pregnancies (Table 35-21). In general, the rate of preeclampsia in subsequent pregnancies is about 25%, with substantially higher rates if the onset of eclampsia was in the second trimester. The rate of recurrent eclampsia is about 2%. Because of these risks, these women should be informed that they are at increased risk for adverse pregnancy outcome in subsequent pregnancies. At present, there is no preventive therapy for recurrent antepartum eclampsia.

The long-term effects of eclampsia on maternal BP and neurologic outcome have been the subject of few reports. The findings of these studies revealed that eclampsia did not cause hypertension in women who were normotensive before the eclamptic pregnancy. Two of these studies found that the rate of chronic hypertension on follow-up was significantly higher in those who had eclampsia remote from term compared with those who had eclampsia at or beyond 37 weeks of gestation. In addition, one of these

TABLE 35-21 RECURRENT PREECLAMPSIA-ECLAMPSIA IN WOMEN WITH ECLAMPSIA

	CHESLEY	LOPEZ-LLERA & HORTON	ADELUSI & OJENGBEDE	SIBAI ET AL.

Preeclampsia (%)	23	35	27	22

From Sibai BM: Diagnosis, differential diagnosis and management of eclampsia. Obstet Gynecol 105:402, 2005.

reports revealed that women who had eclampsia as multiparas were at increased risk for death from cardiovascular renal disease. Moreover, these investigations revealed no evidence of neurologic deficit during the follow-up period.

INCIDENCE OF CHRONIC HYPERTENSION

The frequency of chronic hypertension in pregnancy is estimated at 1% to 5%. It is more common in older obese women and in African American women. Because of the current trend of childbearing at an older age and the obesity epidemic, it is expected that the incidence of chronic hypertension in pregnancy will continue to rise. During the new millennium, and estimating a prevalence of chronic hypertension during pregnancy of 3%, at least 120,000 pregnant women (3% of 4 million pregnancies) with chronic hypertension per year will be seen in the United States.

Definition and Diagnosis

In pregnancy, chronic hypertension is defined as elevated BP that is present and documented before conception. **In women whose prepregnancy BP is unknown, the diagnosis is based on the presence of sustained hypertension before 20 weeks of gestation, defined as either systolic BP of at least 140 mm Hg or diastolic BP of at least 90 mm Hg on at least two occasions measured at least 4 hours apart.**

The diagnosis may be difficult to establish in women with previously undiagnosed chronic hypertension who begin prenatal care after 16 weeks' gestation because physiologic decline in BP occurs at that time. An analysis of pregnancy outcome in 211 patients with mild chronic hypertension suggests that the use of antihypertensive drugs is not necessary to achieve a good pregnancy outcome. The changes in average mean arterial pressure throughout the course of pregnancy are summarized in Figure 35-13. This decrease may result in normal BP findings in the second trimester that will eventually increase again during the third trimester. These women are more likely to be erroneously diagnosed as having gestational hypertension.

Women with chronic hypertension are at increased risk for superimposed preeclampsia. The development of superimposed preeclampsia is associated with high rates of adverse maternal and perinatal outcomes.[14] The diagnosis of superimposed preeclampsia should be made as described in Table 35-3.

Etiology and Classification

The etiology and severity of chronic hypertension are important considerations in the management of pregnancy. Chronic hypertension is subdivided into primary (essential) and secondary. Primary hypertension is by far the most common cause of chronic hypertension seen during pregnancy (90%). In 10% of cases, chronic hypertension is secondary to one or more underlying disorders such as renal disease (glomerulonephritis, interstitial nephritis, polycystic kidneys, renal artery stenosis), collagen vascular disease (lupus, scleroderma), endocrine disorders (diabetes mellitus with vascular involvement, pheochromocytoma, thyrotoxicosis, Cushing disease, hyperaldosteronism), or coarctation of the aorta.

Chronic hypertension during pregnancy can be subclassified as either mild or severe, depending on the systolic and diastolic BP readings. Systolic and diastolic (Korotkoff phase V) BPs of at least 160 mm Hg or 110 mm Hg, respectively, constitute severe hypertension.

For management and counseling purposes, chronic hypertension in pregnancy is also categorized as either low risk or high risk, as described in Figure 35-13. The patient is considered to be at low risk when she has mild essential hypertension without any organ involvement. The BP criteria are based on BP measurements at the initial visit irrespective of treatment with antihypertensive medications. For example, if the patient has a BP of 140/80 mm Hg on antihypertensive drugs, she is still classified as low risk. It is important to note that a patient initially classified as low risk early in pregnancy may become high risk if she later develops severe hypertension or preeclampsia.

Maternal-Perinatal Risks

Pregnancies complicated by chronic hypertension are at increased risk for the development of superimposed preeclampsia and abruptio placentae. The reported rates of preeclampsia in the literature in mild hypertension range from 14% to 28% (Table 35-22).[14] The rate of preeclampsia in women with severe chronic hypertension ranges from 50% to 79%. Sibai and associates[14] studied the rate of superimposed preeclampsia among 763 women with

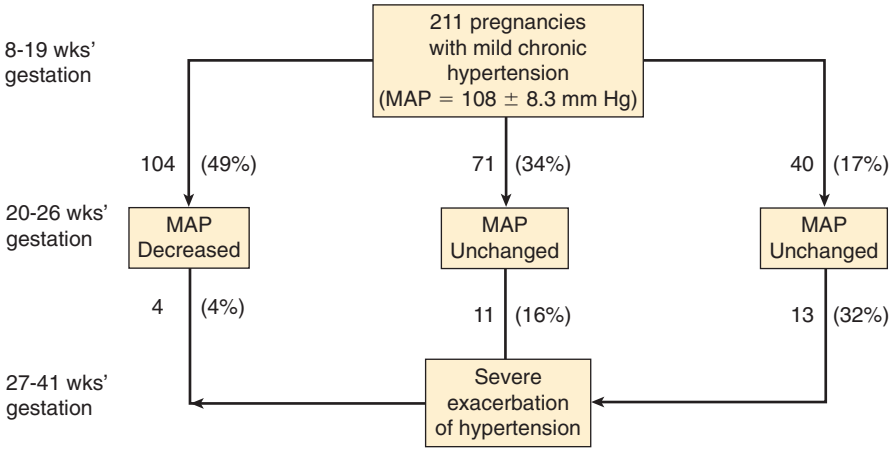

FIGURE 35-13. Mean arterial blood pressure (MAP) during pregnancy. (Modified from Sibai BM, Abdella TN, Anderson GD: Pregnancy outcome in 211 patients with mild chronic hypertension. Obstet Gynecol 61:571, 1983.)

NR, Not reported; SGA, small for gestational age.

chronic hypertension followed prospectively at several tertiary medical centers in the United States. The overall rate of superimposed preeclampsia was 25%. The rate was not affected by maternal age, race, or presence of proteinuria early in pregnancy. However, the rate was significantly greater in women who had hypertension for at least 4 years (31% versus 22%), in those who had preeclampsia during a previous pregnancy (32% versus 23%), and in those whose diastolic BP was 100 mm Hg or higher (42% versus 24%).[14]

The reported rate of abruptio placentae in women with mild chronic hypertension has ranged from 0.7% to 2.7% (see Table 35-22). The rate in those with severe or high-risk hypertension may be 5% to 10%. In a recent multicenter study that included 763 women with chronic hypertension, the overall rate of abruptio placentae was reported at 1.5%, and the rate was significantly higher in those who developed superimposed preeclampsia than in those without this complication (3% versus 1%, $P = .04$).[14] However, the rate was not influenced by maternal age, race, or duration of hypertension.[14] In addition, the results of a systematic review of nine observational studies revealed that the rate of abruptio placentae is doubled (odds ratio [OR], 2.1; 95% CI, 1.1 to 3.9) in women with chronic hypertension compared with either normotensive patients or the general obstetrical population.

In addition to preeclampsia and abruptio placentae, women with high-risk chronic hypertension are at increased risk for life-threatening maternal complications such as pulmonary edema, hypertensive encephalopathy, retinopathy, cerebral hemorrhage, and acute renal failure. These risks are particularly increased in women with uncontrolled severe hypertension, significant renal disease early in pregnancy, or left ventricular dysfunction before conception.

Fetal and neonatal complications are also increased in women with chronic hypertension. The risk for perinatal mortality is three to four times greater compared with the general obstetrical population (OR, 3.4; 95% CI, 3.0 to 3.7). The likelihood of premature delivery and an SGA infant is also increased in women with chronic hypertension (see Table 35-22). In women with severe chronic hypertension in the first trimester, the reported rates of preterm delivery were 62% to 70% and the rates of an SGA infant were 31% to 40%. Recently, Sibai and associates[14] reported risk factors for adverse perinatal outcome in a secondary analysis of 763 women with mild chronic hypertension who were enrolled in a multicenter trial comparing low-dose aspirin with a placebo for the prevention of preeclampsia. They found that the development of superimposed preeclampsia was associated with higher rates of preterm delivery (OR, 3.9; 95% CI, 2.7 to 5.4), neonatal intraventricular hemorrhage (OR, 4.5; 95% CI, 1.5 to 14.2), and perinatal death (OR, 2.3; 95% CI, 1.4 to 4.8). In addition, the presence of proteinuria early in pregnancy was an independent risk factor associated with higher rates of preterm delivery (OR, 3.1; 95% CI, 1.8 to 5.3), an SGA infant (OR, 2.8; 95% CI, 1.6 to 5.0), and neonatal intraventricular hemorrhage (OR, 3.9; 95% CI, 1.3 to 11.6).[14]

Goals of Antihypertensive Therapy in Pregnancy

In nonpregnant individuals, long-term BP control can lead to significant reductions in the rates of stroke and cardiovascular morbidity and mortality. The side effects of therapy are, of course, restricted to the treated individual. In contrast to hypertension in pregnancy, the duration of therapy is shorter, the benefits to the mother may not be obvious during the short time of treatment, and the exposure to medication will include both mother and fetus. In this respect, one must balance the potential short-term maternal benefits against possible short-term and long-term benefits and risks to the fetus and infant.

Most women with chronic hypertension during pregnancy have mild essential uncomplicated hypertension and are at minimal risk for cardiovascular complications within the short time frame of pregnancy. Several retrospective and prospective studies have been conducted to determine whether antihypertensive therapy in these women improves pregnancy outcome. An overall summary of these studies revealed that, regardless of the antihypertensive therapy used, maternal cardiovascular and renal complications were minimal or absent. **Based on the available data, there is no compelling evidence that short-term antihypertensive therapy is beneficial for the mother or the fetus in the setting of low-risk hypertension except for a reduction in the rate of exacerbation of hypertension. However, only two trials have had a sufficient sample size to evaluate the risks for superimposed preeclampsia and abruptio placentae.**

There are no placebo-controlled trials examining the benefits of antihypertensive therapy in women with severe hypertension in pregnancy, and none are likely to be performed. **Antihypertensive therapy is necessary in women with severe hypertension to reduce the acute risks for stroke, congestive heart failure, and renal failure. In addition, control of severe hypertension may permit pregnancy prolongation and thereby improve perinatal outcome. However, there is no available evidence that control of**

severe hypertension reduces the rate of either superimposed preeclampsia or abruptio placentae.

There are no trials examining the treatment of women with chronic hypertension and other risk factors, such as preexisting renal disease, diabetes mellitus, or cardiac disease. On the other hand, there is evidence from retrospective and observational studies that uncontrolled mild to moderate hypertension may exacerbate target organ damage during pregnancy in women with renal disease, diabetes mellitus with vascular disease, or left ventricular dysfunction. Therefore, some authors recommend aggressive treatment of mild hypertension in these women because of the belief that such management may reduce both short-term and long-term cardiovascular complications.

Safety of Antihypertensive Drugs in Pregnancy

The potential adverse effects of most commonly prescribed antihypertensive agents are either poorly established or unclearly quantified. Most of the evidence on harm associated with antihypertensives in pregnancy is limited to case reports. The interpretation of these reports is difficult because it is impossible to ascertain the exact number of women exposed to antihypertensive drugs during pregnancy. Also, it is likely that the number of published case reports is an underestimate of the actual number of women experiencing the reported adverse reaction. This limitation is amplified by the fact that information related to previous exposure during pregnancy is nonexistent. Furthermore, the condition for which pregnant women are treated with antihypertensive drugs can be partially responsible for the adverse fetal and neonatal outcomes.

In general, available information about teratogenicity, except in laboratory animals, is limited and selective. All available data have been obtained from registries such as state Medicaid registry data. Because of absent multicenter randomized trials in women with chronic hypertension, there are no placebo-controlled evaluations regarding the safety of these drugs when used at the time of conception and throughout pregnancy. At the present time, there are minimal data to help the clinician evaluate the benefits or risks of most antihypertensive drugs when used in pregnancy. **Nevertheless, the limited data in the literature suggest that there are potential adverse fetal effects, such as oligohydramnios and fetal-neonatal renal failure, when angiotensin-converting enzyme (ACE) inhibitors are used in the second or third trimester.** Similar effects are to be expected with the use of angiotensin II receptor blockers. Therefore, these agents should be avoided once pregnancy is established (see Chapter 8).

The use of atenolol during the first and second trimesters has been associated with significantly reduced fetal growth along with decreased placental growth and weight. On the other hand, no such effects on fetal or placental growth have been reported with other β-blockers, such as metoprolol, pindolol, and oxprenolol, but data on the use of these agents in early pregnancy are very limited.

Prospective trials examining the effect of either methyldopa or labetalol in women with mild chronic hypertension revealed no adverse maternal or fetal outcomes with the use of these medications. In a large and unique trial in which methyldopa or labetalol was started between 6 and 13 weeks' gestation in patients with chronic hypertension, none of the exposed newborns had major congenital anomalies.

There is a large clinical experience with the use of thiazide diuretics during pregnancy. The available data suggest that treatment with diuretics in the first trimester and throughout gestation is not associated with an increased risk for major fetal anomalies or adverse fetal-neonatal events. There is little information regarding the use of calcium channel blockers in women with mild chronic hypertension. **The available evidence suggests that the use of calcium channel blockers, particularly nifedipine, in the first trimester was not associated with increased rates of major birth defects.** The effects of nifedipine on fetal-neonatal outcome were evaluated in a prospective randomized trial of 283 women with mild to moderate hypertension in pregnancy in which 47% of the participants had chronic hypertension. Sixty-six of these women were enrolled between 12 and 20 weeks' gestation. In this study, the use of slow-release nifedipine was not associated with adverse fetal-neonatal outcomes.

The long-term effects on children of mothers exposed to antihypertensive drugs during pregnancy are lacking except for limited information concerning the use of methyldopa and nifedipine. A follow-up study of infants after 7.5 years showed no long-term adverse effects on development among those exposed to methyldopa in utero compared with infants not exposed to such treatment. A similar study examining the effects of slow-release nifedipine after 1.5 years of follow-up demonstrated no adverse effects on development.

Recommended Management of Chronic Hypertension in Pregnancy

The primary objective in the management of pregnancies complicated by chronic hypertension is to reduce maternal risks and achieve optimal perinatal survival. This objective can be achieved by formulating a rational approach that includes preconceptual evaluation and counseling, early antenatal care, frequent antepartum visits to monitor both maternal and fetal well-being, timely delivery with intensive intrapartum monitoring, and proper postpartum management.

Evaluation and Classification

Women with chronic hypertension should ideally be counseled before pregnancy, when extensive evaluation and complete workup can be undertaken. Assessment of the etiology and severity of hypertension, as well as the coexistence of other medical illnesses, and ruling out the presence of target organ damage resulting from long-standing hypertension can be accomplished. An in-depth history should delineate in particular the duration of hypertension, the use of antihypertensive medications, their type, and the response to these medications. Also, attention should be given to the presence of cardiac or renal disease, diabetes mellitus, thyroid disease, and a history of cerebrovascular accident or congestive heart failure. A detailed obstetrical history should include maternal and neonatal outcomes of previous pregnancies, stressing a history of

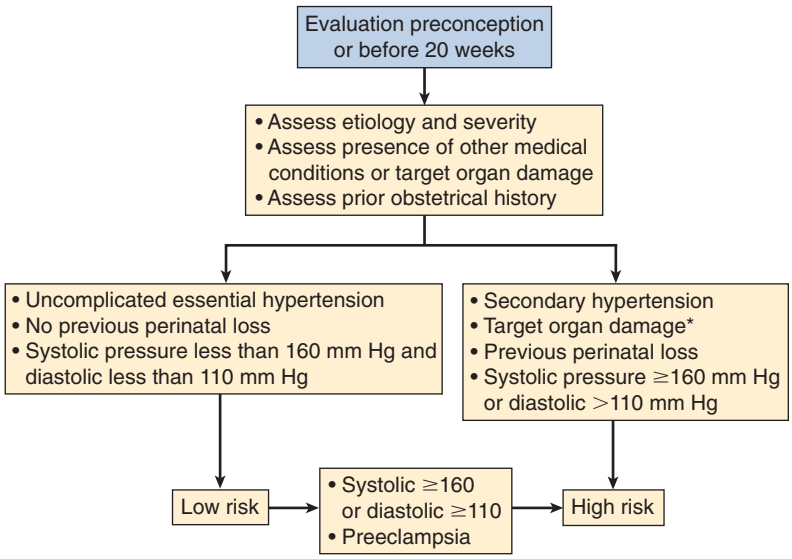

FIGURE 35-14. Initial evaluation of women with chronic hypertension. (From Sibai BM: Chronic hypertension in pregnancy. Obstet Gynecol 100:369, 2002.)

*Left ventricular dysfunction, retinopathy, dyslipidemia, maternal age above 40 years, microvascular disease, stroke.

the development of abruptio placentae, superimposed preeclampsia, preterm delivery, SGA infants, intrauterine fetal death, and neonatal morbidity and mortality.

Laboratory evaluation is obtained to assess the function of different organ systems that are likely to be affected by chronic hypertension and as a baseline for future assessments. These should include the following for all patients: urinalysis, urine culture and sensitivity, 24-hour urine evaluations for protein, electrolytes, complete blood count, and a glucose tolerance test.

Women with long-standing hypertension for several years, particularly those with a history of poor compliance or poor BP control, should be evaluated for target organ damage, including left ventricular hypertrophy, retinopathy, and renal injury. These women should undergo an ECG examination and echocardiography if the ECG is abnormal, ophthalmologic evaluation, and creatinine clearance.

Selectively, certain tests should be obtained to identify secondary causes of hypertension such as pheochromocytoma, primary hyperaldosteronism, or renal artery stenosis. These conditions require selective biochemical testing and are amenable to diagnosis with either CT or MRI. Pheochromocytoma should be suspected in women with paroxysmal severe hypertension, hyperglycemia, and sweating. Primary aldosteronism is extremely rare in pregnancy and should be considered in women with severe hypertension and marked hypokalemia. Based on this evaluation, the patient is then classified as having low-risk or high-risk chronic hypertension and managed accordingly (Figure 35-14).

Low-Risk Hypertension

Women with low-risk chronic hypertension without superimposed preeclampsia usually have a pregnancy outcome similar to that of the general obstetrical population. In addition, discontinuation of antihypertensive therapy early in pregnancy does not affect the rate of preeclampsia, abruptio placentae, or preterm delivery in these women. Many clinicians choose to discontinue antihypertensive treatment at the first prenatal visit because most of these women will experience a good pregnancy outcome without such therapy. Although many of these women will not require subsequent pharmacologic therapy, careful management is still essential (Figure 35-15). At the time of initial and subsequent visits, women are educated about nutritional requirements, weight gain, and sodium intake (maximum of 2.4 g of sodium per day). They are also counseled that consumption of alcohol and smoking during pregnancy can aggravate maternal hypertension and are associated with adverse effects on the fetus such as FGR and abruptio placentae. During each subsequent visit, they are observed closely for early signs of preeclampsia and FGR.

Fetal evaluation should include an ultrasound examination at 16 to 20 weeks' gestation, to be repeated at 30 to 32 weeks, and monthly thereafter until term. **Antihypertensive treatment with either nifedipine or labetalol is initiated if the patient develops severe hypertension before term. The development of either severe hypertension, preeclampsia, or abnormal fetal growth requires immediate fetal testing with NST or BPP. Women who develop severe hypertension and those with documented FGR by ultrasound examination require hospitalization and often delivery.** If superimposed preeclampsia is diagnosed at or beyond 37 weeks, delivery is undertaken as well. In the absence of these complications, the pregnancy may be continued until 40 weeks' gestation.

High-Risk Hypertension

Women with high-risk chronic hypertension are at increased risk for adverse maternal and perinatal complications. The likelihood and impact of these complications will depend on the etiology of the hypertension as well as the degree of target organ damage. Women with significant renal insufficiency (serum creatinine > 1.4 mg/dL), diabetes mellitus with vascular involvement (class R/F), severe collagen vascular disease, cardiomyopathy, or coarctation of the aorta should receive thorough counseling regarding the adverse effects of pregnancy before conception. These

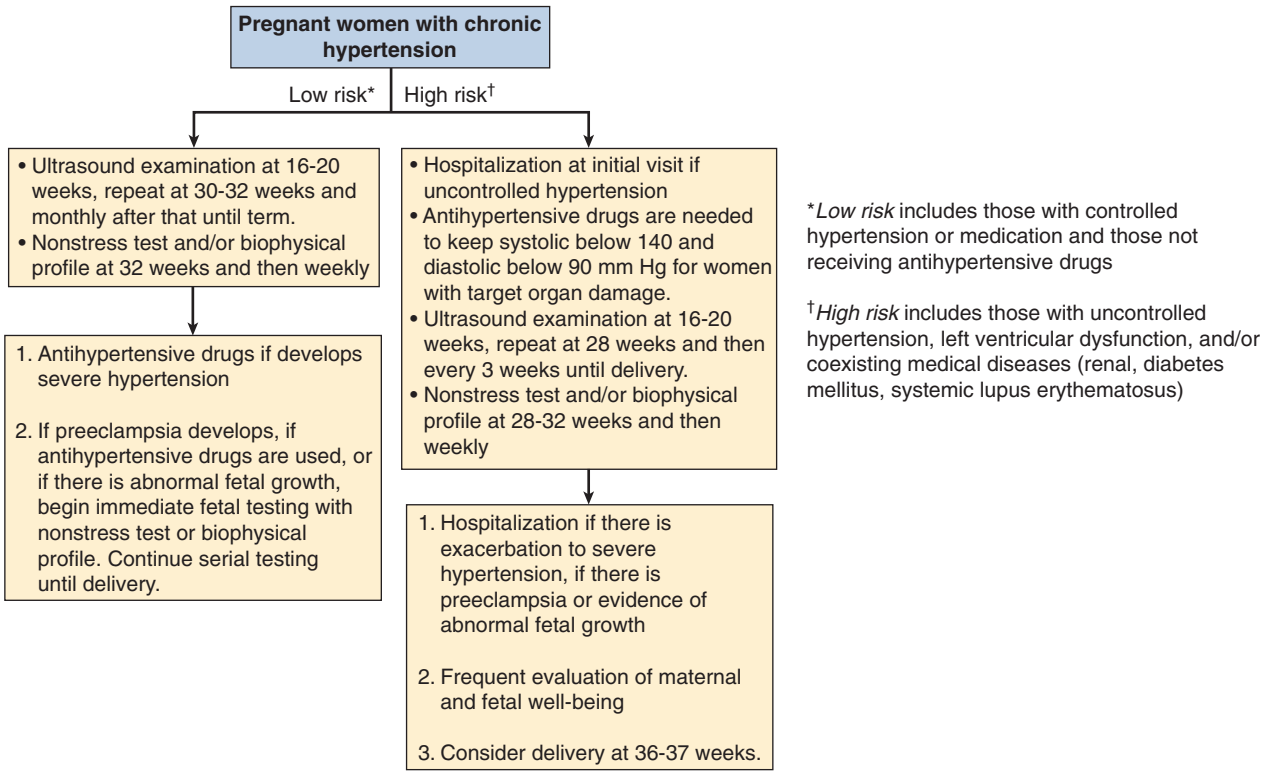

FIGURE 35-15. Antepartum management of chronic hypertension. (From Sibai BM: Chronic hypertension in pregnancy. Obstet Gynecol 100:369, 2002.)

women should be advised that pregnancy may exacerbate their condition, with the potential for congestive heart failure, acute renal failure requiring dialysis, and even death. In addition, perinatal loss and neonatal complications are markedly increased in these women. All such women should be managed by or in consultation with a subspecialist in maternal-fetal medicine as well as in association with other medical specialists as needed. In addition, these women must be observed and delivered at a tertiary care center with the appropriate resources for maternal and neonatal care.

Hospitalization of women with high-risk uncontrolled hypertension at the time of the first prenatal visit is recommended. This facilitates evaluation of cardiovascular and renal status and regulation of antihypertensive medications as well as other prescribed treatments (e.g., insulin, cardiac drugs, thyroid medications), if needed. Women receiving ACE inhibitors or angiotensin II receptor antagonists should have these medications discontinued under close observation. Antihypertensive therapy with one or more of the drugs listed in Table 35-23 is subsequently used in all women with systolic BP of 160 mm Hg or more, or diastolic BP of 110 mm Hg or more. In women without target organ damage, the aim of antihypertensive therapy is to keep systolic BP between 140 and 150 mm Hg and diastolic BP between 90 and 100 mm Hg. In addition, antihypertensive therapy is indicated in women with mild hypertension plus target organ damage because there are short-term maternal benefits from lowering BP in such women. In these women, maintaining systolic BP below 140 mm Hg and diastolic BP below 90 mm Hg is advised. In some women, BP may be difficult to control initially, demanding the use of intravenous therapy with hydralazine or labetalol or oral short-acting nifedipine with doses as described in Table 35-23. For maintenance therapy, one may choose either oral methyldopa, labetalol, slow-release nifedipine, or a diuretic. Methyldopa remains the drug most commonly recommended to treat hypertension during pregnancy; however, it is rarely used in nonpregnant hypertensive women. **The recommended first drug of choice for control of hypertension in pregnancy is labetalol starting at 100 mg twice daily, to be increased to a maximum of 2400 mg/day. If maternal BP is not controlled**

TABLE 35-23 DRUGS USED TO TREAT HYPERTENSION IN PREGNANCY

DRUG	STARTING DOSE	MAXIMUM DOSE	COMMENTS
Acute Treatment of Severe Hypertension			
Hydralazine	5-10 mg IV every 20 min	20 mg*	Avoid in cases of tachycardia and persistent headaches
Labetalol	20-40 mg IV every 10-15 min	220 mg*	Avoid in women with asthma or congestive heart failure
Nifedipine	10-20 mg oral every 30 min	50 mg*	Avoid in case of tachycardia and palpitations
Long-Term Treatment of Hypertension			
Methyldopa	250 mg bid	4 g/day	
Labetalol	100 mg bid	2400 mg/day	
Nifedipine	10 mg bid	120 mg/day	
Thiazide diuretic	12.5 mg bid	50 mg/day	

*If desired blood pressure levels are not achieved, switch to another drug.

with maximal doses of labetalol, a second drug such as a thiazide diuretic or nifedipine may be added. For women with diabetes mellitus and vascular disease, oral nifedipine is recommended. Oral nifedipine or a thiazide diuretic is the drug of choice for young black women with hypertension because these women often manifest a low-renin-type hypertension or salt-sensitive hypertension. If maternal BP is adequately controlled with these medications, the patient can continue with the same drug after delivery.

Diuretics are commonly prescribed in women with essential hypertension before conception. The use of diuretics throughout pregnancy is controversial. Of concern, women who use diuretics from early in pregnancy do not have an increase in plasma volume to the degree expected in normal pregnancy. However, this reduction in plasma volume has not been shown to be associated with an adverse effect on fetal outcome. Therefore, it is appropriate to start diuretics as a single agent during pregnancy or to use them in combination with other agents, particularly in women with excessive salt retention. However, diuretics should be discontinued immediately if superimposed preeclampsia develops or if there is evidence of suspected FGR because of the potential of reduced uteroplacental blood flow secondary to reduced plasma volume in women with these complications.

Early and frequent prenatal visits are the key for successful pregnancy outcome in women with high-risk chronic hypertension. These women need close observation throughout pregnancy and may require serial evaluation of 24-hour urine protein excretion and a complete blood count with a metabolic profile at least once every trimester. Further laboratory testing can be performed depending on the clinical progress of the pregnancy. During each visit, the woman should be advised about the adverse effects of smoking and alcohol abuse and should receive nutritional advice regarding diet and salt intake.

Fetal evaluation should include an ultrasound examination at 16 to 20 weeks' gestation, to be repeated at 28 weeks and subsequently every 3 weeks till delivery. NST or BPP testing is usually started at 28 to 32 weeks and then repeated weekly. **The development of uncontrolled severe hypertension, preeclampsia, or evidence of FGR requires maternal hospitalization for more frequent evaluation of maternal and fetal well-being. The development of any of these complications at or beyond 34 weeks' gestation should be considered an indication for delivery.** In all other women, delivery should be considered at 36 to 37 weeks' gestation after documentation of fetal lung maturity.

Postpartum Management

Women with high-risk chronic hypertension are at risk for postpartum complications such as pulmonary edema, hypertensive encephalopathy, and renal failure. These risks are particularly increased in women with target organ involvement, superimposed preeclampsia, or abruptio placentae. In these patients, BP must be closely controlled for at least 48 hours after delivery. Intravenous labetalol or hydralazine can be used as needed, and diuretics may be appropriate in women with circulatory congestion and pulmonary edema. This therapy is usually required in those who develop exaggerated and sustained severe hypertension in the first week postpartum.

Oral therapy may be needed to control BP after delivery. In some women, it is often necessary to switch to a new agent such as an ACE inhibitor, particularly in those with pregestational diabetes mellitus and those with cardiomyopathy. Some patients may wish to breastfeed their infant. All antihypertensive drugs are found in the breast milk, although differences are found in the milk-to-plasma ratio of these drugs. Additionally, the long-term effect of maternal antihypertensive drugs on breastfeeding infants has not been specifically studied. Milk concentrations of methyldopa appear to be low and are considered to be safe. The β-blocking agents (atenolol and metoprolol) are concentrated in breast milk, whereas labetalol and propranolol have low concentrations. Concentrations of diuretic agents in breast milk are low; however, they may induce a decrease in milk production.

There is little information about the transfer of calcium channel blockers to breast milk, but there are no apparent side effects. ACE inhibitors and angiotensin II receptor antagonists should be avoided because of their effects on neonatal renal function, even though their concentrations appear to be low in breast milk (see Chapter 8).

Finally, in breastfeeding women, the use of methyldopa as a first-line oral therapy is a reasonable choice. If methyldopa is contraindicated, labetalol may be used.

HYPERTENSIVE EMERGENCIES IN CHRONIC HYPERTENSION

On rare occasions, pregnant women may present with life-threatening clinical conditions that require immediate control of BP, such as hypertensive encephalopathy, acute left ventricular failure, acute aortic dissection, or increased circulating catecholamines (pheochromocytoma, clonidine withdrawal, cocaine ingestion). Patients at highest risk for these complications include those with underlying cardiac disease, chronic glomerular renal disease, multiple drugs to control their hypertension, superimposed preeclampsia in the second trimester, and abruptio placentae complicated by DIC. Although a diastolic BP of 115 mm Hg or greater is usually considered a hypertensive emergency, this level is actually arbitrary, and the rate of change of BP may be more important than its absolute level. The association of elevated BP with evidence of new or progressive end-organ damage determines the seriousness of the clinical situation.

Hypertensive Encephalopathy

Untreated essential hypertension progresses to a hypertensive crisis in up to 1% to 2% of cases for unknown reasons. Hypertensive encephalopathy is usually seen in patients with a systolic BP above 220 mm Hg or a diastolic BP above 130 mm Hg. Patients with the acute onset of hypertension may develop encephalopathy at pressure levels that are generally tolerated by those with chronic hypertension. Normally, cerebral blood flow is about 50 mL per 100 g tissue per minute. When the BP falls, cerebral arterioles normally dilate, whereas when BP increases, they constrict to maintain constant cerebral blood flow. This mechanism usually remains operative between 60 and 120 mm Hg diastolic BP. Hypertensive encephalopathy is currently considered to be a derangement of the

autoregulation of cerebral arterioles, which occurs when the upper limit of autoregulation is exceeded. With severe hypertension (130 to 150 mm Hg cerebral perfusion pressure), cerebral blood vessels constrict as much as possible and then reflex cerebral vasodilatation occurs. This results in overperfusion, damage to small blood vessels, cerebral edema, and increased intracranial pressure (breakthrough theory). Others believe that hypertensive encephalopathy results from an exaggerated vasoconstrictive response of the arterioles resulting in cerebral ischemia (overregulation theory). Patients who have impaired autoregulation involving the cerebral arterioles may experience necrotizing arteriolitis, microinfarcts, petechial hemorrhages, multiple small thrombi, or cerebral edema. Typically, hypertensive encephalopathy has a subacute onset over 24 to 72 hours.

During a hypertensive crisis, other evidence for end-organ damage may be present: cardiac, renal, or retinal dysfunction secondary to impaired organ perfusion and loss of autoregulation of blood flow. Ischemia of the retina (with flame-shaped retinal hemorrhages, retinal infarcts, or papilledema) may occur, causing decreased visual acuity. Impaired regulation of coronary blood flow and marked increase in ventricular wall stress may result in angina, myocardial infarction, congestive heart failure, malignant ventricular arrhythmia, pulmonary edema, or dissecting aortic aneurysm. Necrosis of the afferent arterioles of the glomerulus results in hemorrhages of the cortex and medulla, fibrinoid necrosis, and proliferative endarteritis resulting in elevated serum creatinine (>3 mg/dL), proteinuria, oliguria, hematuria, hyaline or red blood cell casts, and progressive azotemia. Severe hypertension may result in abruptio placentae with resultant DIC. In addition, high levels of angiotensin II, norepinephrine, and vasopressin accompany ongoing vascular damage. These circulating hormones increase relative efferent arteriolar tone, resulting in sodium diuresis and hypovolemia. Because levels of renin and angiotensin II are increased, the aldosterone level is also elevated. The impact of these endocrine changes may be important in maintaining the hypertensive crisis.

Treatment of Hypertensive Encephalopathy

The ultimate goal of therapy is to prevent the occurrence of a hypertensive emergency. Patients at risk for a hypertensive crisis should receive intensive management during labor and for a minimum of 48 hours after delivery. Although pregnancy may complicate the diagnosis, once the life-threatening conditions are recognized, pregnancy should not in any way slow or alter the mode of therapy. **The only reliable clinical criterion to confirm the diagnosis of hypertensive encephalopathy is prompt response of the patient to antihypertensive therapy. The headache and sensorium often clear dramatically, sometimes within 1 to 2 hours after the treatment.** The overall recovery may be somewhat slower in patients with uremia and those in whom the symptoms have been present for a prolonged period before the therapy is given. Sustained cerebrovascular deficits should suggest other diagnoses.

Patients with hypertensive encephalopathy or other hypertensive crisis should be hospitalized for bedrest. Intravenous lines should be inserted for fluids and medications. Although there is a tendency to restrict sodium intake in patients with a hypertensive emergency, volume contraction from sodium diuresis may be present. A marked drop in diastolic BP with a rise in heart rate on standing from the supine position is evidence of volume contraction. Infusion of normal saline solution during the first 24 to 48 hours to achieve volume expansion should be considered. Saline infusion may help decrease the activity of the renin-angiotensin-aldosterone axis and result in better BP control. Simultaneous repletion of potassium losses and continuous monitoring of BP, volume status, urinary output, ECG readings, and mental status are mandatory. An intra-arterial line provides the most accurate BP information. Laboratory studies include a complete blood count with differential, reticulocyte count, platelets, and blood chemistries. A urinalysis should be obtained for protein, glucose, blood, cells, casts, and bacteria. Assessment for end-organ damage in the central nervous system, retina, kidneys, and cardiovascular system should be done periodically. Antepartum patients should have continuous fetal monitoring.

Lowering Blood Pressure in Hypertensive Encephalopathy

There are risks associated with too rapid or excessive reduction of elevated BP. The aim of therapy is to lower mean BP by no more than 15% to 25%. Small reductions in BP in the first 60 minutes, working toward a diastolic level of 100 to 110 mm Hg, have been recommended. Although cerebral blood flow is maintained constantly over a wide range of BPs, there is a lower and an upper limit to autoregulation. In chronic hypertensive women who have a rightward shift of the cerebral autoregulation curve secondary to medial hypertrophy of the cerebral vasculature, lowering BP too rapidly may produce cerebral ischemia, stroke, or coma. Coronary blood flow, renal perfusion, and uteroplacental blood flow also may deteriorate, resulting in acute renal failure, myocardial infarction, fetal distress, or death. Hypertension that proves increasingly difficult to control is an indication to terminate the pregnancy. If the patient's outcome appears to be grave, consideration of perimortem cesarean delivery should be made.

The drug of choice in a hypertensive crisis is sodium nitroprusside. Other agents such as nitroglycerin, nifedipine, trimetaphan, labetalol, and hydralazine can also be used.

Sodium Nitroprusside

Sodium nitroprusside causes arterial and venous relaxation by interfering with both influx and the intracellular activation of calcium. It is given as an intravenous infusion of 0.25 to 3 mcg/kg per minute. The onset of action is immediate, and its effect may last 3 to 5 minutes after discontinuing the infusion. Hypotension caused by nitroprusside should resolve within a few minutes of stopping the infusion because the drug's half life is so short. If it does not resolve, other causes for hypotension should be suspected. The effect of nitroprusside on uterine blood flow is controversial. Nitroprusside is metabolized into thiocyanate, which is excreted in the urine. Cyanide can accumulate if there is either increased production due to large doses (>10 mcg/kg per minute) or prolonged administration (>48 hours), or if there is renal insufficiency or decreased metabolism in the liver. Signs of toxicity include anorexia,

disorientation, headache, fatigue, restlessness, tinnitus, delirium, hallucinations, nausea, vomiting, and metabolic acidosis. When it is infused at less than 2 mcg/kg per minute, cyanide toxicity is unlikely. At a maximal dose rate of 10 mcg/kg per minute, infusion should never last more than 10 minutes. Animal experiments and the few reported cases of nitroprusside use in pregnancy have revealed that thiocyanate toxicity to mother and fetus rarely occur if it is used in a regular pharmacologic dose. Tachyphylaxis to nitroprusside usually develops before toxicity occurs. Whenever toxicity is suspected, therapy should be initiated with 3% sodium nitrite at a rate not exceeding 5 mL/minute, up to a total dose of 15 mL. Then, infusion of 12.5 g of sodium thiosulfate in 50 mL of 5% dextrose in water over a 10-minute period should be started.

Nitroglycerin

Nitroglycerin is an arterial but mostly venous dilator. It is given as an intravenous infusion of 5 mcg/minute that is gradually increased every 3 to 5 minutes to titrate BP up to a maximal dose of 100 mg/minute. It is the drug of choice in preeclampsia associated with pulmonary edema and for control of hypertension associated with tracheal manipulation. Side effects such as headache, tachycardia, and methemoglobinemia may develop. It is contraindicated in hypertensive encephalopathy because it increases cerebral blood flow and intracranial pressure.

KEY POINTS

- Hypertension is the most common medical complication during pregnancy.
- Preeclampsia is a leading cause of maternal mortality and morbidity worldwide.
- The pathophysiologic abnormalities of preeclampsia are numerous, but the etiology is unknown.
- At present, there is no proven method to prevent preeclampsia.
- The HELLP syndrome may develop in the absence of maternal hypertension.
- Expectant management improves perinatal outcome in a select group of women with severe preeclampsia before 32 weeks' gestation.
- Magnesium sulfate is the preferred agent to prevent or treat eclamptic convulsions.
- Rare cases of eclampsia can develop before 20 weeks' gestation and beyond 48 hours postpartum.
- Antihypertensive agents do not improve pregnancy outcome in women with mild uncomplicated chronic hypertension.
- Labetalol is the drug of choice for the treatment of chronic hypertension; angiotensin-converting enzyme inhibitors should be avoided in pregnancy.

Cardiovascular adaptations to pregnancy are well tolerated by healthy young women. However, these adaptations are of such magnitude that they can significantly compromise women with abnormal or damaged hearts. Without accurate diagnosis and appropriate care, heart disease in pregnancy can be a significant cause of maternal mortality and morbidity. Under more optimal conditions, many women with significant disease can experience good outcomes and should not necessarily be discouraged from becoming pregnant. This chapter develops an understanding of cardiovascular physiology as a basis for care of the pregnant woman with heart disease. Although published experience with more common conditions can be used to support these principles, information regarding many other conditions is limited to case reports. Data from case reports may, however, be biased toward more complicated cases with more adverse outcomes. The best care for women with heart disease is usually achieved from a thorough understanding of maternal cardiovascular physiology, knowledge of existing literature, and extensive clinical experience brought by a multidisciplinary team of clinicians.

MATERNAL HEMODYNAMICS

Hemodynamics refers to the relationship between blood pressure, cardiac output, and vascular resistance. Blood pressure is measured by auscultation, use of an automated cuff, or directly with an intra-arterial catheter. Cardiac output is measured by dilutional techniques requiring central venous access, by Doppler or two-dimensional echocardiographic techniques, or by electrical impedance. Peripheral resistance is calculated using Ohm's law:

$$TPR = MAP \times 80/CO$$

where TPR is total peripheral resistance (dyne · sec · cm^{-5}), MAP is mean arterial pressure (millimeters of mercury [mm Hg]), and CO is cardiac output (L/min).

Pregnancy and events unique to pregnancy, such as labor and delivery, are associated with significant and frequently predictable changes in these parameters. The hemodynamic changes of pregnancy, although well

tolerated by an otherwise healthy woman, may be tolerated poorly by a woman with significant cardiac disease. Therefore, the importance of understanding these changes and placing them in the context of a specific cardiac lesion cannot be overstated.

The maternal hemodynamics of 89 nulliparous women who remained normotensive throughout pregnancy are described in Figure 36-1.[1] MAP falls sharply in the first trimester, reaching a nadir by midpregnancy. Thereafter, blood pressure increases slowly, reaching near nonpregnant levels by term. CO rises throughout the first and second trimesters, reaching a maximum by the middle of the third trimester. In the supine position, a pregnant woman in the third trimester may experience significant hypotension due to venocaval occlusion by the gravid uterus. In normal pregnancy, venocaval occlusion may produce symptoms such as diaphoresis, tachycardia, or nausea but will rarely result in significant complications. Fetal heart rate decelerations may be observed but usually resolve when the mother, often spontaneously, shifts to a more comfortable position. Women with significant right or left ventricular outflow obstruction, such as aortic stenosis, may seriously decompensate in the supine position due to poor ventricular filling.

CO is the product of heart rate (HR) and stroke volume (SV):

$$CO = HR \times SV$$

HR and SV increase as pregnancy progresses to the third trimester. After 32 weeks, SV falls, with the maintenance of CO becoming more and more dependent on HR. Vascular resistance falls in the first and early second trimesters. The magnitude of the fall is sufficient to offset the rise in CO, resulting in a net decrease in blood pressure.

Labor, delivery, and the postpartum period are times of acute hemodynamic changes that may result in maternal decompensation. Labor itself is associated with pain and anxiety. Tachycardia is a normal response. Significant catecholamine release increases afterload. Each uterine contraction acutely redistributes 400 to 500 mL of blood from the uterus to the central circulation. In Figure 36-2, Robson and colleagues[2] describe the hemodynamic changes associated with unmedicated labor. HR, blood pressure, and CO all increase with uterine contractions, with the magnitude of the change increasing as labor advances. Obstructive cardiac lesions impede the flow of blood through the heart, blunting the expected rise in CO at the expense of increasing pulmonary pressures and pulmonary congestion. In Figure 36-3, intrapartum hemodynamic changes of a patient with aortic stenosis and a peak gradient of 160 mm Hg are shown.[3] In this individual, pulmonary pressures rise in parallel with uterine contractions.

Immediately after delivery, blood from the uterus is returned to the central circulation. In normal pregnancy, this compensatory mechanism protects against the hemodynamic effects that may accompany postpartum hemorrhage. **In the context of cardiac disease, this acute centralization of blood may increase pulmonary pressures and pulmonary congestion.**[4] During the first 2 postpartum weeks, extravascular fluid is mobilized, diuresis ensues, and vascular resistance increases, returning to nonpregnant norms. Decompensation during postpartum fluid mobilization is common in women with mitral stenosis. Volume loading coupled with vasoconstriction may also unmask maternal cardiomyopathy. Unsuspected cardiac disease may be diagnosed when a woman returns to the emergency room several days postpartum with dyspnea and

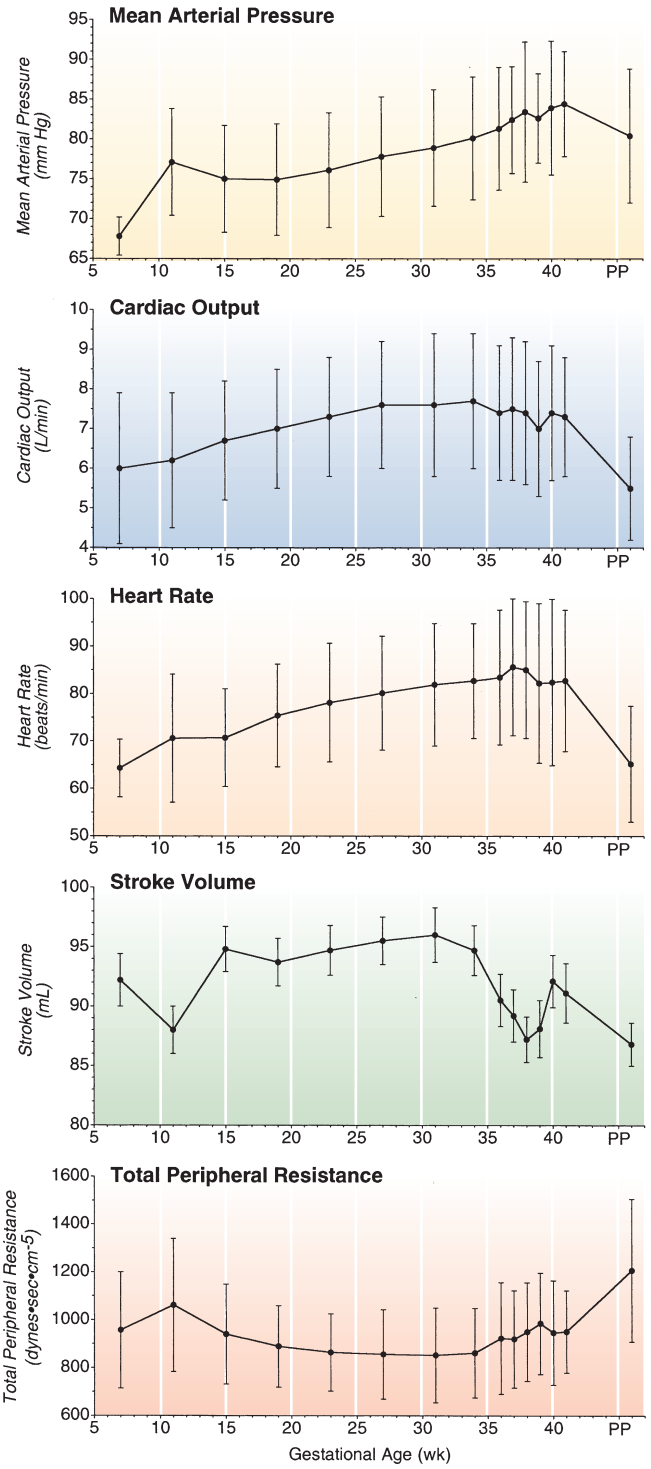

FIGURE 36-1. Changes in hemodynamic parameters throughout pregnancy (mean ± standard deviation).

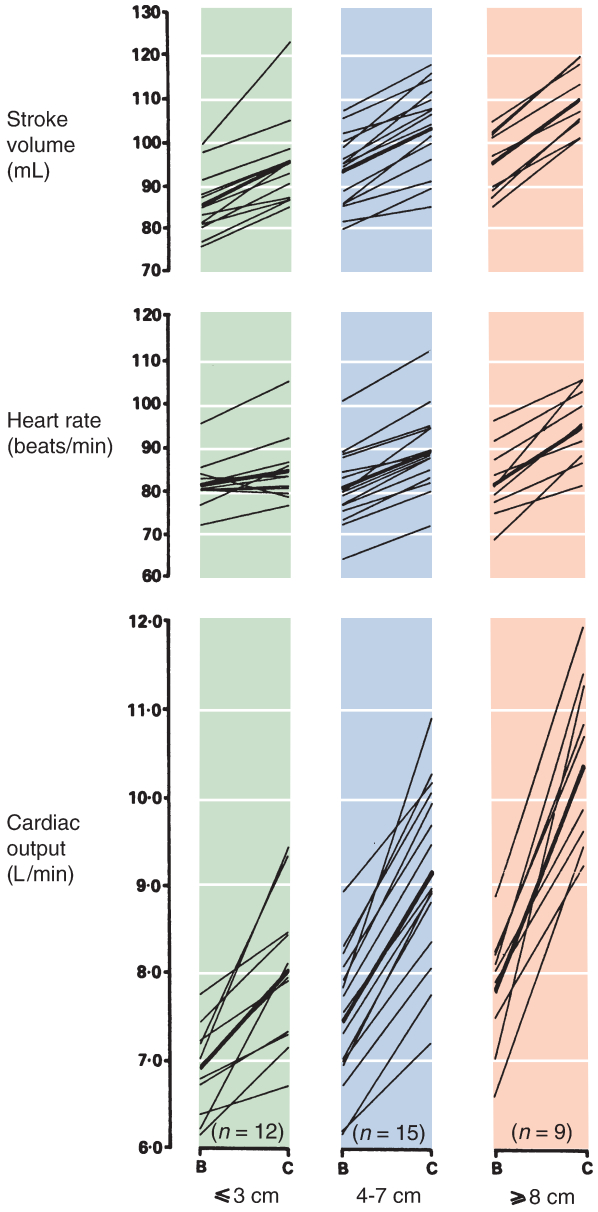

FIGURE 36-2. Changes in hemodynamic parameters at three different points during labor (≤3 cm, 4 to 7 cm, and ≥8 cm). Each line represents the change in an individual subject. *B,* Before contraction; *C,* during contraction. (From Robson S, Dunlop W, Boys R, Hunter S: Cardiac output during labour. BMJ 295:1169, 1987.)

oxygen desaturation. Maternal CO usually normalizes by 2 weeks postpartum.[5]

Three key features of the maternal hemodynamic changes in pregnancy are particularly relevant to the management of women with cardiac disease: (1) increased CO, (2) increased HR, and (3) reduced vascular resistance. In conditions such as mitral stenosis, in which CO is relatively fixed, the drive to achieve an elevated CO may result in pulmonary congestion. If a patient has an atrial septal defect, the incremental increase in systemic flow associated with pregnancy will be magnified in the pulmonary circulation to the extent that pulmonary flow exceeds systemic flow. If, for example, a shunt ratio of 3:1 is maintained in pregnancy, pulmonary flow may be as high as 20 L/min and may be associated with increasing dyspnea and potential desaturation.

Many cardiac conditions are HR dependent. Flow across a stenotic mitral valve is dependent on the proportion of time in diastole. Tachycardia reduces left ventricular filling and CO. Coronary blood flow is also dependent on the length of diastole. Patients with aortic stenosis have increased wall tension and, therefore, increased myocardial oxygen requirements. Tachycardia reduces coronary perfusion time in diastole while simultaneously further increasing myocardial oxygen requirements. The resulting imbalance between oxygen demand and supply may precipitate myocardial ischemia. Patients with complex congenital heart disease can experience significant tachyarrhythmias. The increasing HR in pregnancy may be associated with a worsening of tachyarrhythmias.

Reduction in vascular resistance may be beneficial to some patients; afterload reduction reduces cardiac work. Cardiomyopathy, aortic regurgitation, and mitral regurgitation all benefit from reduced afterload. Alternatively, patients with intracardiac shunts, in which right and left ventricular pressures are nearly equal when not pregnant, may reverse their shunt during pregnancy and desaturate because of to right to left shunting.

BLOOD VOLUME

Very early in the first trimester, pregnant women experience an expansion of renal blood flow and glomerular filtration rate. Filtered sodium increases by about 50%. Despite physiologic changes that would promote loss of salt and water and contraction of blood volume, **the pregnant woman will expand her blood volume by 40% to 50%.** In part, the stimulation to retain fluid may be a response to the fall in vascular resistance and reduction in blood pressure. The renin-angiotensin system is activated, and the plasma concentration of aldosterone is elevated. Although the simplicity of this explanation is attractive, the actual process is probably much more complicated.[6]

As plasma volume expands, the hematocrit falls, and hematopoiesis is stimulated. Red cell mass will expand from 18% to 25% depending on the status of individual iron stores. Physiologic anemia with a maternal hematocrit between 30% and 35% does not usually complicate pregnancy in the context of maternal heart disease. More significant anemia, however, may increase cardiac work and induce tachycardia. Microcytosis due to iron deficiency may impair perfusion of the microcirculation of patients who are polycythemic because of cyanotic heart disease because microcytic red blood cells are less deformable. Iron and folate supplementation may be appropriate.

In a similar fashion, serum albumin concentration falls by 22% despite an expansion of intravascular albumin mass by 20%. **As a result, serum oncotic pressure falls in parallel by 20% to about 19 mm Hg.**[7] In normal pregnancy, intravascular fluid balance is maintained by a fall in interstitial oncotic pressure. However, if left ventricular filling pressure becomes elevated or if pulmonary vascular integrity is disrupted, pulmonary edema will develop earlier in the disease process than in nonpregnant women.

DIAGNOSIS AND EVALUATION OF HEART DISEASE

Many women with heart disease have been diagnosed and treated before pregnancy. For example, in women with prior surgery for congenital heart disease, detailed historical information may be available. Others report only that they have a murmur or a "hole in my heart." Alternatively, heart disease may be diagnosed for the first time during pregnancy owing to symptoms precipitated by increased cardiac demands.

The classic symptoms of cardiac disease are palpitations, shortness of breath with exertion, and chest pain. Because these symptoms also may accompany normal pregnancy, a careful history is needed to determine whether the symptoms are out of proportion to the stage of pregnancy. Symptoms are of particular concern in a patient with other reasons to suspect underlying cardiac disease, such as being native to an area where rheumatic heart disease is prevalent.

A systolic flow murmur is present in 80% of pregnant women, most likely due to the increased flow volume in the aorta and pulmonary artery. Typically, a flow murmur is grade 1 or 2, midsystolic, loudest at the cardiac base, and not associated with any other abnormal physical examination findings. A normal physiologic split second heart sound is heard in patients with a flow murmur. Any diastolic murmur and any systolic murmur that is loud (grade 3/6 or higher) or radiates to the carotids should be considered pathologic. Careful evaluation for elevation of the jugular venous pulse, for peripheral cyanosis or clubbing, and for pulmonary crackles is needed in women with suspected cardiac disease.

Indications for further cardiac diagnostic testing in pregnant women include a history of known cardiac disease, symptoms in excess of those expected in a normal pregnancy, a pathologic murmur, evidence of heart failure on physical examination, or arterial oxygen desaturation in the absence of known pulmonary disease. The preferred next step in evaluation of pregnant women with suspected heart disease is transthoracic echocardiography. A chest radiograph is helpful only if congestive heart failure is suspected. An electrocardiogram (ECG) may be nonspecific but could have changes suggestive of the underlying heart disease, such as right ventricular hypertrophy and biatrial enlargement, seen in patients with significant mitral stenosis. If symptoms are consistent with a cardiac arrhythmia, an event monitor or 24-hour ECG monitor may be indicated. Rarely, cardiac catheterization is needed for full diagnosis of valvular or congenital heart disease. The exception is an acute coronary syndrome during pregnancy in which the risk for radiation exposure with cardiac catheterization is small compared with the benefit of early diagnosis and early revascularization to prevent myocardial infarction (MI).

Echocardiography provides detailed information on cardiac anatomy and physiology that allows optimal management of women with heart disease. Basic data obtained

on echocardiography include left ventricular ejection fraction, pulmonary artery systolic pressure, qualitative evaluation of right ventricular systolic function, and evaluation of valve anatomy and function. When valvular stenosis is present, the pressure gradient (ΔP) across the valve is calculated from the **Doppler-derived velocity (v) of flow across the valve: $\Delta P = 4v^2$.** Similarly, pulmonary artery systolic pressure can be calculated from the maximal Doppler velocity obtained across a tricuspid regurgitant jet.

Aortic valve area is calculated using the continuity equation. SV is calculated from the product of the cross-sectional area of the left ventricular outflow tract and the time-velocity integral derived from Doppler evaluation of the outflow tract. A time-velocity integral is then derived from the stenotic valve. Because the left ventricular outflow tract and the aortic valve are in continuity, SVs across each are equal. Therefore, valve area can be derived by dividing the stroke volume by the aortic valve time-velocity integral. Mitral valve area is measured directly by two-dimensional planimetry or by the Doppler pressure half-time method.[8] In patients with congenital disease, detailed evaluation of anatomy and previous surgical repair is possible. When complex congenital heart disease is present or when image quality is suboptimal, transesophageal imaging provides improved image quality. Cardiac magnetic resonance imaging may be used to define complex anatomy that is not well evaluated by echocardiography, but caution must be taken with magnetic resonance contrast agents such as gadolinium.

GENERAL CARE

Management of cardiac disease in pregnancy is frequently complicated by unique social and psychological concerns. Children with congenital heart disease may have experienced multiple hospitalizations and be fearful of the medical environment. Some have been cautioned against pregnancy and, therefore, have never expected to bear children. Women with rheumatic heart disease have frequently lived outside the traditional medical care system owing to conditions of poverty, immigration, and cultural differences. Care must be exercised to facilitate their access to care and their comfort with the environment of care. Their practitioner must be patient but persistent in the face of deviations from more traditional standards of compliance and medical care.

Deterioration in cardiac status during pregnancy is frequently insidious. Continuity of care with a single provider facilitates early intervention before overt decompensation. Regular visits should include particular attention to HR, weight gain, and oxygen saturation. An unexpected increase in weight may indicate the need for more aggressive outpatient therapy. A fall in oxygen saturation often precedes a clearly abnormal chest examination or radiograph. Regular use of a structured history of symptoms (see box, Structured Review of Cardiac Symptoms) alerts the physician to a change in condition. Regular review also educates the patients and reinforces their collaborative roles as "partners in care."

The physiologic changes of pregnancy are usually continuous and, therefore, offer adequate time for maternal compensation despite cardiac disease. **Intercurrent events superimposed on pregnancy in the context of maternal heart disease are usually responsible for acute decompensation.** The most common significant intercurrent events during the antepartum period are febrile episodes. Screening for bacteriuria and vaccination against influenza and pneumococcus are appropriate. Patients should be instructed to report symptoms of upper respiratory infection, particularly fever. Many women with heart disease (adolescents, recent immigrants, and those living in poverty) are also at risk for iron deficiency. Prophylaxis against anemia with iron and folate supplementation may decrease cardiac work.

A strategy of standard cardiac care for labor and delivery is described in the box. The general principles for care are similar for most cardiac diagnoses. **Physiologically, the ideal labor for a woman with heart disease is short and pain free.** Although induction of labor facilitates organization of care and early pain control, shortening the duration of pregnancy by 1 or 2 weeks at the cost of a 2- or 3-day induction of labor is not worthwhile. Induction of labor with a favorable cervix is therefore preferred. Some patients with severe cardiac disease benefit from invasive hemodynamic monitoring with an arterial catheter and a pulmonary artery catheter. These methods are discussed in detail later. Cesarean delivery is usually reserved for obstetrical indications. The American Heart Association (AHA) does not recommend routine antibiotic prophylaxis for the prevention of endocarditis, although it is optional in high-risk patients having a vaginal delivery (Table 36-1). Because bacteremia is common at the time of vaginal delivery and cesarean delivery,[9] many practitioners will provide antibiotic prophylaxis in all patients at risk. In contrast to AHA recommendations, compelling arguments supporting broad use of antibiotic prophylaxis have been

TABLE 36-1 PROPHYLACTIC REGIMENS FOR LABOR AND DELIVERY

PATIENTS	REGIMENS
High-risk patients • Prosthetic valves—both bioprosthetic and homografts • Complex cyanotic congenital heart disease (CHD) • Surgically constructed systemic pulmonic shunts or conduits • Previous bacterial endocarditis	**Ampicillin + gentamicin** In active labor: • Ampicillin 2 g IM or IV + Gentamicin 1.5 mg/kg (not to exceed 120 mg) 6 hr later: • Ampicillin 1 g IM/IV or amoxicillin 1 g PO
High-risk patients allergic to ampicillin/amoxicillin	**Vancomycin + gentamicin** • Vancomycin 1 g IV over 1-2 hr + gentamicin as above in active labor
Moderate-risk patients • Most other CHDs • Acquired valvular dysfunction (e.g., rheumatic heart disease) • Hypertrophic cardiac myopathy • Mitral valve prolapse with regurgitation	**Amoxicillin or ampicillin** In active labor • Amoxicillin 2 g PO or ampicillin 2 g IM/IV
Moderate-risk patients allergic to ampicillin/amoxicillin	**Vancomycin** In active labor • Vancomycin 1 g IV over 1-2 hr in active labor

made, citing limited large-scale studies supporting the recommendations and the high cost and risk associated with endocarditis.[10]

Structured Review of Cardiac Symptoms

"How many flights of stairs can you walk up with ease?"
"Two? One? None?"
"Can you walk a level block?"
"Can you sleep flat in bed?" "How many pillows?"
"Does your heart race?"
"Do you have chest pain?"
"With exercise?"
"When your heart races?"

Standard Cardiac Care for Labor and Delivery

1. Accurate diagnosis
2. Mode of delivery based on obstetrical indications
3. Medical management initiated early in labor
   - Prolonged labor avoided
   - Induction with a *favorable* cervix
4. Maintenance of hemodynamic stability
   - Invasive hemodynamic monitoring when required
   - Initial, compensated hemodynamic reference point
   - Specific emphasis based on particular cardiac condition
5. Avoidance of pain and hemodynamic responses
   - Epidural analgesia with narcotic/low-dose local technique
6. Prophylactic antibiotics when at risk for endocarditis
7. Avoidance of maternal pushing
   - Caudal for dense perineal anesthesia
   - Low forceps or vacuum delivery
8. Avoidance of maternal blood loss
   - Proactive management of the third stage
   - Early but appropriate fluid replacement
9. Early volume management postpartum
   - Often careful but aggressive diuresis

Women with significant heart disease should be counseled before pregnancy regarding the risk of pregnancy, interventions that may be required, and potential risks to the fetus. However, women with significant uncorrected disease often present with an ongoing established pregnancy. In this situation, the risks and benefits of termination of pregnancy versus those of continuing a pregnancy should be addressed. **The decision to become pregnant or carry a pregnancy in the context of maternal disease is a balance of two forces: (1) the objective medical risk, including the uncertainty of that estimate; and (2) the value of the birth of a child to an individual woman and her partner.** The first goal of counseling is to educate the patient. Only a few cardiac diseases represent an overwhelming risk for maternal mortality: Eisenmenger syndrome, pulmonary hypertension with right ventricular dysfunction, and Marfan syndrome with significant aortic dilation and severe left ventricular dysfunction. Most other conditions require aggressive management and significant disruption in lifestyle. Intercurrent events such as antepartum pneumonia or obstetrical hemorrhage pose the greatest risk for initiating life-threatening events. Fastidious care can reduce but not eliminate the risk for these events. Maternal congenital heart disease increases the risk for congenital heart disease in the fetus from 1% to about 4% to 6%.[11,12] Marfan syndrome and some forms of hypertrophic cardiomyopathy are inherited as autosomal dominant conditions; the offspring of these women carry a 50% chance of inheriting the disease. The second goal of counseling is to help each woman integrate the medical information into her individual value system and her individual desire to become a mother. Many women with significant but manageable heart disease choose to carry a pregnancy. The basis for their decisions should be individualized.

VALVULAR DISEASE

The American College of Cardiology (ACC) and the AHA have published guidelines for the management of valvular heart disease, including some guidelines for management during pregnancy.[13] These guidelines create a general framework for preconceptional care and care during pregnancy, realizing that treatment of a specific patient must be individualized.

Mitral Stenosis

Mitral stenosis is nearly always due to rheumatic heart disease. Valvular dysfunction progresses continuously throughout life. Deterioration may be accelerated by recurrent episodes of rheumatic fever. Rheumatic fever itself is an immunologic response to group A β-hemolytic streptococcus infections. The incidence of rheumatic fever in a population is heavily influenced by conditions of poverty and crowding. These same individuals are at risk for having reduced access and use of health care resources and may present undiagnosed or untreated.

Patients with asymptomatic mitral stenosis have a 10-year survival rate of greater than 80%. Once a patient is significantly symptomatic, the 10-year survival rate without treatment is less than 15%. In the presence of pulmonary hypertension, mean survival falls to less than 3 years. Death is due to progressive pulmonary edema, right-sided heart failure, systemic embolization, or pulmonary embolism.[13]

Stenosis of the mitral valve impedes the flow of blood from the left atrium to the left ventricle during diastole. The normal mitral valve area is 4 to 5 cm^2. Symptoms with exercise can be expected with valve areas less than or equal to 2.5 cm^2. Symptoms at rest are expected at less than or equal to 1.5 cm^2. The left ventricle responds with Starling mechanisms to increased venous return with increased performance, elevating CO in response to demand. The left atrium is limited in its capacity to respond. Therefore, **CO is limited by the relatively passive flow of blood through the valve during diastole; increased venous return results in pulmonary congestion rather than increased CO.** Thus, the drive for increased CO in pregnancy cannot be achieved, resulting in increased pulmonary congestion. The relative tachycardia experienced in pregnancy shortens diastole, decreases left ventricular filling, and therefore further compromises CO and increases pulmonary congestion.

The diagnosis of mitral stenosis in pregnancy before maternal decompensation is uncommon. Tiredness and dyspnea on exertion are characteristic symptoms of mitral stenosis but are also ubiquitous among pregnant women. Although the presence of a diastolic rumble or jugular venous distention may suggest mitral stenosis, these findings are subtle and may be overlooked or not appreciated. Not uncommonly, an intercurrent event such as a febrile episode will result in exaggerated symptoms and the diagnosis of pulmonary edema or oxygen desaturation. Under these circumstances, particularly in the context of a patient from an at-risk group, an echocardiogram should be performed to rule out mitral-valvular disease.

Echocardiographic diagnosis of mitral stenosis is based on the characteristic appearance of the stenotic, frequently calcified valve. Calculation of valve area from pressure half-time of the Doppler wave or by two-dimensional planimetry provides an objective measure of severity. Valve areas of 1 cm^2 or less usually require pharmacologic management during pregnancy and invasive hemodynamic monitoring during labor. Valve areas of 1.4 cm^2 or less usually require careful expectant management. Left atrial enlargement identifies a patient at risk for atrial fibrillation, subsequent atrial thrombus, and the potential for systemic embolization. Embolic complications have been reported in pregnant women with atrial enlargement without atrial fibrillation. Pulmonary hypertension, a complication of worsening mitral disease, can be diagnosed and quantified with Doppler evaluation of the regurgitant jet across the tricuspid valve. **Elevated pulmonary pressures may be due to hydrostatic forces associated with elevated left atrial pressures or, in more advanced disease, may result from pathologic elevations of pulmonary vascular resistance (PVR).** Hydrostatic pulmonary hypertension may respond to therapy that lowers left atrial pressure. Pulmonary hypertension due to elevated PVR is life threatening in pregnancy and may precipitate right-sided heart failure in the postpartum period.

Pregnancy itself does not negatively affect the natural history of mitral stenosis. Chesley[14] reviewed the medical histories of 134 women with functionally severe mitral stenosis who survived pregnancies between 1931 and 1943. These women lived before modern management of mitral stenosis and, therefore, represent the natural history of the disease. By 1974, only nine of the cohort remained alive. Their death rate was exponential; during each year of follow-up, the rate for the remaining cohort was 6.3%. Women with subsequent pregnancies had comparable survival to those who did not again become pregnant, allowing the authors to conclude that pregnancy itself did not negatively affect long-term outcome.

The goal of antepartum care in the context of mitral stenosis is to achieve a balance between the drive to increase CO and the limitations of flow across the stenotic valve. Most women with significant disease require diuresis with a drug such as furosemide. In addition, β-blockade reduces HR, improves diastolic flow across the valve, and relieves pulmonary congestion. Al Kasab and associates[15] evaluated the impact of β -blockade on 25 pregnant women with significant mitral stenosis. Figure 36-4 describes the functional status of women before pregnancy, during pregnancy before β-blockade, and after β-blockade. The deterioration associated with pregnancy and the improvement

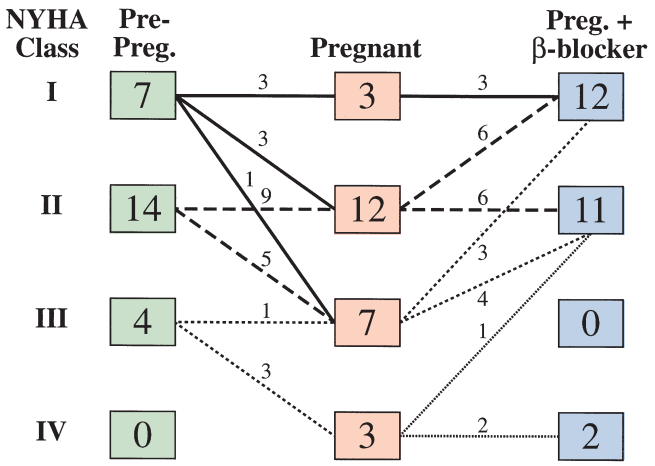

FIGURE 36-4. The effects of β-blockade on functional status of women with mitral stenosis. *NYHA*, New York Heart Association. (From Al Kasab S, Sabag T, Al Zaibag M, et al: Beta-adrenergic receptor blockade in the management of pregnant women with mitral stenosis. Am J Obstet Gynecol 163:37, 1990.)

with treatment are evident. Fastidious antepartum care as described earlier should supplement pharmacologic management.

Women with a history of rheumatic valvular disease who are at risk for contact with populations with a high prevalence of streptococcal infection should receive prophylaxis with daily oral penicillin G or monthly benzathine penicillin. Most pregnant women live in close contact with groups of children and usually are considered at risk. Atrial fibrillation is a complication associated with mitral stenosis due to left atrial enlargement. Rapid ventricular response to atrial fibrillation may result in sudden decompensation. Digoxin, β-blockers, or calcium channel blockers can be used to control ventricular response. In the context of hemodynamic decompensation, electrical cardioversion may be necessary. Anticoagulation with heparin should be used before and after cardioversion to prevent systemic embolization. Patients with chronic atrial fibrillation and a history of an embolic event should also undergo anticoagulation. Anticoagulation may be considered in women with a left atrial dimension of 55 mm Hg or greater.

Labor and delivery can frequently precipitate decompensation in patients with critical mitral stenosis. Pain induces tachycardia. Uterine contractions increase venous return and, therefore, pulmonary congestion. Women frequently cannot tolerate the work of pushing in the second stage. Clark and coworkers[4] described the abrupt elevation in pulmonary artery pressures in the immediate postpartum period associated with return of uterine blood to the general circulation (Figure 36-5). **Aggressive, anticipatory diuresis will reduce pulmonary congestion and the potential for oxygen desaturation.**

The hemodynamics of women with symptomatic stenosis or a valve area of 1 cm^2 or less may benefit from management with the aid of a pulmonary artery catheter. Ideally, hemodynamic parameters are assessed when the patient is well compensated, early in labor. These findings serve as a reference point to guide subsequent therapy. Pain control is best achieved with an epidural. HR control

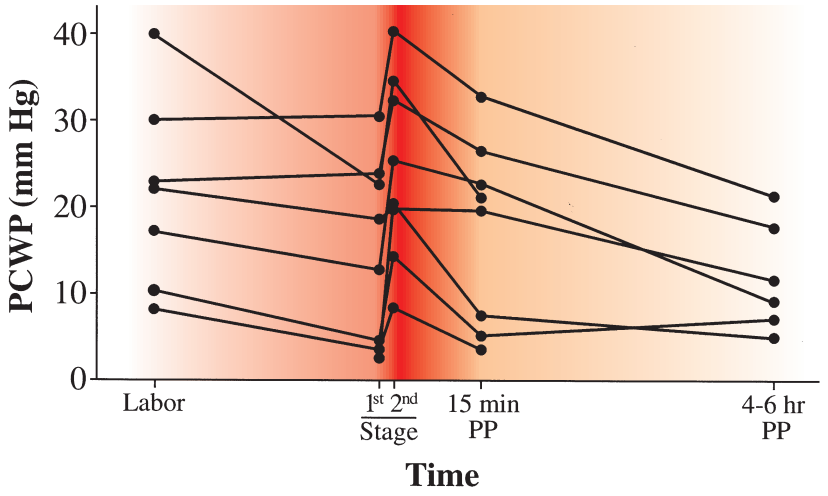

FIGURE 36-5. The changes in pulmonary capillary wedge pressure *(PCWP)* associated with delivery and subsequent diuresis in women with mitral stenosis. *PP,* postpartum. (From Clark S, Phelan J, Greenspoon J, et al: Labor and delivery in the presence of mitral stenosis: central hemodynamic observations. Am J Obstet Gynecol 152:384, 1985.)

is maintained through pain control and β-blockade. To avoid pushing, the second stage is shortened with low forceps or vacuum delivery. Aggressive diuresis is initiated immediately postpartum. Cesarean delivery is reserved for obstetrical indications. In a series of 80 pregnancies managed with a range of severity, the most common complications were pulmonary edema (31%) and arrhythmia (11%). When valve area was 1 cm^2 or less, the rate of pulmonary edema was higher (56%), as was the rate of arrhythmia (33%).[16] These rates will be dependent on the effectiveness of medical management and the timing of presentation and diagnosis.

Aggressive medical management, including hospital bedrest in selected cases, is sufficient to manage most women with mitral stenosis. The woman with uncommonly severe disease may require surgical intervention. Although successful valve replacement and open commissurotomy have been reported in pregnancy, they are now rarely needed. Two centers have reported successful balloon valvotomy in a series of 40 and 44 women with minimal complications.[17,18] Complications of balloon valvuloplasty outside of pregnancy occur at the following rates: mortality (0.5%), cerebrovascular accident (1%), and mitral regurgitation requiring surgery (2%). Mitral valvuloplasty in pregnancy has been reported with success rates between 89% and 100%. The incidence of severe mitral regurgitation requiring surgery is between 0% and 5%. The rate of fetal loss between 0% and 8%. **Medical management should be clearly exhausted before assuming these risks during pregnancy, when emergent intervention such as valve replacement is more complicated and carries a significant risk to the fetus.**

Rheumatic disease can also affect the aortic valve. Management of significant mitral stenosis, which limits ventricular filling, in the context of aortic stenosis that is critically dependent on ventricular filling, is particularly complicated.

Mitral Regurgitation

Mitral regurgitation may be due to a chronic progressive process such as rheumatic valve disease or myxomatous mitral valve disease, frequently associated with mitral valve prolapse. As regurgitation increases over time, forward flow is maintained at the expense of left ventricular dilation with eventual impaired contractility. Left atrial enlargement may be associated with atrial fibrillation that should be managed with ventricular rate control and anticoagulation. The patient with chronic mitral regurgitation may remain asymptomatic even with exercise. Preconceptional counseling should include consideration of valve replacement in consultation with a cardiologist. In general, valve replacement is recommended for (1) symptomatic patients, (2) atrial fibrillation, (3) ejection fraction less than 50% to 60%, (4) left ventricular end-diastolic dimension greater than 45 to 50 mm, or (5) pulmonary systolic pressure greater than 50 to 60 mm Hg.[13] As discussed later, the benefits of valve replacement before pregnancy must be balanced against the risks associated with a prosthetic valve in pregnancy and the potential for prosthetic valve deterioration in pregnancy. If surgery is required, valve repair rather than replacement is preferred when possible to avoid the need for anticoagulation.

Acute mitral regurgitation in young patients is uncommon and may be associated with ruptured chordae tendineae due to endocarditis or myxomatous valve disease. Without time for left ventricular compensation, forward flow may be severely compromised. Urgent valve surgery is usually required. Inotropic left ventricular support and systemic afterload reduction can be used to stabilize the patient.

The hemodynamic changes associated with pregnancy can be expected to have mixed effects. A reduction in systemic vascular resistance (SVR) tends to promote forward flow. The drive to increase CO will exacerbate left ventricular volume overload. Increased atrial dilation may initiate atrial fibrillation. Pulmonary congestion can be managed by careful diuresis with the knowledge that adequate forward flow is usually dependent on a high preload to achieve adequate left ventricular filling. Atrial fibrillation should be managed as in the nonpregnant state. An increase in SVR due to progressive hypertension secondary to advancing preeclampsia may significantly

impair forward flow and should be treated. Labor and delivery should be managed with standard cardiac care. Catecholamine release due to pain or stress impairs forward flow. Particular attention should be paid to left ventricular filling. **Excessive preload results in pulmonary congestion. Insufficient preload will not fill the enlarged left ventricle and will result in insufficient forward flow.** A pulmonary artery catheter can be used to determine appropriate filling pressure in early labor or before induction. Although a large v-wave may complicate the interpretation of pulmonary artery wedge pressure, the pulmonary artery diastolic pressure can be used as a reference point. Diuresis in the early postpartum period may be required.

Myxomatous mitral valve disease or mitral valve prolapse is a common condition, affecting as many as 12% of young women. **In the absence of conditions of abnormal connective tissue such as Marfan or Ehlers-Danlos syndrome and clinically significant mitral regurgitation, women with mitral prolapse can be expected to have uncomplicated pregnancies.** They may experience an increase in tachyarrhythmias that can be treated with β-blockers. Prophylactic antibiotics are usually used at the time of delivery.

Aortic Stenosis

Most patients who develop calcific stenotic tricuspid aortic valves do so outside their childbearing years (age 70 to 80 years). Patients with bicuspid valves develop significant stenosis after the age of 50 to 60 years. Rheumatic disease can also affect the aortic valve, usually after the development of significant mitral disease. Most pregnant women with significant aortic stenosis have congenitally stenotic valves: bicuspid valves with congenitally fused leaflets, unicuspid valves, or tricuspid valves with fused leaflets.[19]

The natural history of aortic stenosis is characterized by a long, asymptomatic period. With increasing outflow obstruction, patients develop angina, syncope, and left ventricular failure. Without valve replacement, only 50% of patients will survive 5 years after the development of angina; 3 years after the development of syncope; and 2 years after the development of left ventricular failure.[20] Although valve replacement is the only definitive treatment for calcific aortic stenosis, valvuloplasty may prove beneficial in some young adults whose valves are not calcified. Medical management of symptomatic patients is not generally efficacious. Mechanical valve replacement requires anticoagulation, complicating subsequent pregnancies.

Young women with aortic stenosis are usually asymptomatic. Although they may develop increasing exercise intolerance in pregnancy, the progression is insidious and not easily distinguished from the effects of normal pregnancy. The diagnosis is usually made by the auscultation of a harsh systolic murmur. **The murmur can easily be distinguished from a physiologic murmur of pregnancy by its harshness and radiation into the carotid arteries.** Diagnosis is confirmed by echocardiography whereby the gradient across the valve can be measured by Doppler, and the valve area can be calculated with the continuity equation. Many women with significant aortic stenosis experience the expected increase in CO associated with pregnancy.[3] Increased flow across the fixed, stenotic valve results in a proportionately increased gradient across the valve. Although the pressure gradient during pregnancy may be higher than that observed postpartum, these differences are not significant.

Four series of patients with aortic stenosis in pregnancy have been reported.[3,21-23] The reports summarize experiences with wide ranges in severity of disease and management ranging from the 1960s and 1970s to the present. Arias and Pineda[21] described a series of 23 cases managed before 1978 with a maternal mortality rate of 17%. More recent series, however, do not demonstrate this high level of maternal risk.[3,22,23] The potential for serious adverse outcomes reported by Arias should, however, serve as an indication for intensive management. The rate of mortality should not necessarily be used as an indication for termination or surgical intervention. Pregnant patients have been successfully managed with aortic gradients in excess of 160 mm Hg.[3] In general, patients with a peak aortic gradient of 60 mm Hg or less have had uncomplicated courses. Those with higher gradients require increasingly intensive management.

Aortic valve replacement and balloon valvotomy have been reported during pregnancy. Balloon valvotomy in a young patient without valve calcification can provide significant long-term palliation. Valvotomy before pregnancy may provide an interval of hemodynamic stability sufficient to complete a pregnancy without the complications associated with a mechanical prosthetic valve. **Consideration for valve replacement or valvotomy during pregnancy should be reserved for patients who remain clinically symptomatic despite hospital care.** In general, intervention should not be based solely on a pressure gradient or valve area.

Aortic stenosis is a condition of excess left ventricular afterload. Ventricular hypertrophy increases cardiac oxygen requirement, whereas increased diastolic ventricular pressure impairs diastolic coronary perfusion. Each increases the potential for myocardial ischemia. The left ventricle requires adequate filling to generate sufficient systolic pressure to produce flow across the stenotic valve. **Given a hypertrophied ventricle and some degree of diastolic dysfunction, the volume-pressure relationship is very steep. A small loss of left ventricular filling results in a proportionately large fall in left ventricular pressure and, therefore, a large fall in forward flow, CO.** The pregnant patient with significant aortic stenosis is very sensitive to loss of preload associated with hemorrhage or epidural-induced hypotension. The window of appropriate filling pressure is narrow. Excess fluid may result in pulmonary edema; insufficient fluid may result in hypotension and coronary ischemia. In general, pulmonary edema associated with excess preload is much easier to manage than hypotension due to hypovolemia.

Appropriate antepartum care is described earlier. Given that most aortic stenosis in young women is congenital in origin, fetal echocardiography is indicated. Although some controversy persists, cesarean delivery is generally reserved for obstetrical indications. Pain during labor and delivery can be safely managed with regional analgesia using a low-dose bupivacaine and narcotic technique. Dense anesthesia during the second stage can be obtained with minimal

hemodynamic complications using a caudal catheter. Patients with gradients above 60 to 80 mm Hg may benefit from the use of a pulmonary artery and an arterial catheter during labor. Hospital admission 1 day before planned induction of labor with a favorable cervix is preferred. A prolonged induction should be avoided. Pulmonary artery and radial artery catheters, as well as epidural and caudal catheters are placed. The patient should be gently hydrated overnight to achieve a pulmonary artery wedge pressure (PAWP) of 12 to 15 mm Hg. Some patients with milder disease spontaneously diurese in the face of a volume load such that an elevation in PAWP cannot be achieved. An elevated PAWP serves as a buffer against a loss of preload. If with bleeding or the onset of anesthesia PAWP falls, volume can be administered before a reduction in forward flow. In general, pushing is minimized, and the second stage is shortened with operative vaginal delivery. Antibiotics may be administered for the prevention of endocarditis.

Postpartum, patients should be monitored hemodynamically for 24 to 48 hours. Diuresis is usually spontaneous; the patient can be allowed to find her predelivery compensated state. When diuresis must be induced to treat pulmonary edema, it should be done gently and carefully. Predelivery hemodynamic parameters should be used as an end point. Some have found that a significant delay in valve replacement in women with quite severe disease is associated with maternal complications.[3] In a larger cohort of women with less severe disease followed for 6 years and compared with a matched cohort who did not experience a pregnancy, women who experienced a pregnancy had a reduction in event-free survival.[24] These observations may be the result of accelerated valve deterioration due to pregnancy. For this reason, valve replacement within weeks of delivery may be indicated.

Aortic Regurgitation

Aortic regurgitation is most often due to a congenitally abnormal valve. Other causes include Marfan syndrome, endocarditis, and rheumatic disease. As with mitral regurgitation, the left ventricle compensates for a loss in forward flow with an increase in left ventricular end-diastolic volume. Afterload reduction prevents progressive left ventricular dilation and is recommended for patients with left ventricular dysfunction or dilation. Valve replacement is generally recommended for (1) New York Heart Association (NYHA) functional class III and class IV symptoms, (2) an ejection fraction less than 50%, or (3) left ventricular end-systolic dimension greater than 55 mm.[13] Acute regurgitation may be due to aortic root dissection or endocarditis and usually represents a medical emergency requiring urgent valve replacement.

The reduction in vascular resistance associated with pregnancy tends to improve cardiac performance. If afterload reduction has been achieved with an angiotensin-converting enzyme (ACE) inhibitor before pregnancy, hydralazine or a calcium channel blocker such as nifedipine should be substituted. Modest elevations of HR should be tolerated. Bradycardia may be associated with increased regurgitation due to prolongation of diastole. Labor and delivery are managed with standard cardiac care. Pulmonary artery catheterization is not usually required. As the hemodynamic changes associated with pregnancy resolve, a rise in vascular resistance should be anticipated and afterload reduction maintained.

TABLE 36-2 PREGNANCY OUTCOMES WITH PROSTHETIC VALVES

	MECHANICAL	PORCINE
Women	31	57
Pregnancies	56	95
Fetal loss	27.7%	12.3%
Premature birth	5.9%	7.7%
Valve deterioration	5.3%	7.0%
Thromboembolic event	5.3%	—

Prosthetic Valves

Definitive therapy for significant valvular disease requires surgical repair, or more commonly replacement. Mechanical valves are durable but require anticoagulation. Bioprosthetic valves, when used in a young woman, usually require replacement during her lifetime. Reports of pregnancies associated with prosthetic valves suggest significant variability in outcomes. Table 36-2 summarizes a review of 151 pregnancies complicated by a prosthetic valve.[25] Mechanical valves and anticoagulation were associated with a moderate increase in miscarriage and thromboembolic events. A report from France of 55 pregnancies suggests a less favorable prognosis.[26] Mechanical valves were associated with a maternal mortality rate of 3.7% and a thromboembolic rate of 14.8%. Thromboembolism was increased fourfold with heparin use rather than warfarin. Mitral valves accounted for 81% of thrombotic complications. The impact of pregnancy on the life of a bioprosthetic valve has been studied.[25] Ten-year graft survival following two pregnancies was 16.7% compared with 54.8% following a single pregnancy, suggesting that pregnancy may adversely affect the life of a porcine valve. Accelerated deterioration of bioprosthetic valves has been suggested by some studies but not confirmed by others.[27]

The management of care with prosthetic valves outside pregnancy has been extensively reviewed. Decisions surrounding the timing and choice of valve replacement for a woman of reproductive age are complex. Managing a pregnancy with moderate valve disease may be less complicated than managing a pregnancy with a prosthetic valve. The durability of a mechanical valve has considerable advantages for a young person, but it is associated with more adverse outcomes in pregnancy. Delay in valve replacement until childbearing is completed is appropriate when the severity of heart disease is believed to be manageable in pregnancy.

Anticoagulation is required with a mechanical valve. Management of anticoagulation in pregnant women with mechanical prosthetic valves remains very controversial. Many reported clinical series are confounded by adequacy of therapeutic monitoring and heparin dosing. Oral anticoagulation with warfarin in the first trimester is associated with congenital anomalies. **Potentially serious fetal bleeding may be encountered with use during the second and third trimesters. Warfarin is clearly associated with embryopathy and increased risk for stillbirth after 20 weeks'**

gestation.[28] Fetal risk appears to be dose dependent.[29] Nevertheless, less aggressive dosing will be associated with increased risk for valve thrombosis (see Chapter 43).

The ACC/AHA guidelines recommend consideration of heparin in the first trimester to avoid warfarin embryopathy, and the use of warfarin until 36 weeks, when subcutaneous heparin is substituted until after delivery.[13] These recommendations remain controversial in that they may underestimate the risk for fetal intracerebral bleeding in the absence of labor.[30] The fetus exposed to warfarin in the second and third trimesters is at risk for developmental toxicity.

The use of antithrombotic agents for prosthetic valves in pregnancy has been reviewed by the American College of Chest Surgeons (ACCS).[31] The review cites descriptive evidence regarding optimal treatment strategies in pregnancy, including no randomized trials. Cohort studies suggest an increased risk for valve thrombosis associated with use of unfractionated heparin (UFH) or low-molecular-weight heparin (LMWH). However, the cohort studies are confounded by treatment with low heparin dosing. Three possible regimens are considered:

1. Vitamin K antagonists (VKA) before 6 weeks of pregnancy; UFH or LMWH between 6 and 12 weeks of pregnancy; VKA from 12 weeks to near term; UFH or LMWH until postpartum; VKA postpartum
2. UFH throughout pregnancy
3. LMWH throughout pregnancy

If warfarin sodium (Coumadin) is used, the INR must be followed closely to maintain an INR of about 3. If UFH is used, the ACCS recommends dosing every 12 hours to achieve a therapeutic activated partial thromboplastin time (2.5 to 3 times normal) at mid-dosing interval. In our practice, we dose every 8 hours to maintain a higher trough effect. If LMWH is used, twice-daily dosing is recommended, with mid-dosing interval anti–factor Xa levels 1 to 1.2.

Before delivery, we stop heparin to permit use of regional analgesia. After delivery, we start intravenous heparin without a bolus to avoid bleeding at surgical sites and convert to oral therapy. We do not use LMWH to bridge to VKA because of excessive overlapping therapy and bleeding complications. Oral anticoagulation is consistent with breastfeeding. Individual patients should be counseled regarding the risks of either strategy and participate actively in a final choice of therapy.

Women treated for prolonged periods with heparin should be counseled regarding the risk for osteoporosis. Maternal platelet counts should be followed to screen for the development of heparin-induced thrombocytopenia (HIT). If HIT is diagnosed, heparin must be discontinued immediately and anticoagulation maintained with other agents.

When treatment with LMWH is chosen, fixed weight-based dosing is clearly inadequate and dangerous. To maintain anticoagulation in pregnancy with LMWH, anti–factor Xa levels must be monitored frequently with the expectation of increasing the dose as pregnancy advances.[32] Although monitoring of peak anti–factor Xa levels has been advocated, therapeutic trough levels are present only 15% of the time.[28] Successful treatment with LMWH has been reported when valve complications were associated uniformly with noncompliance or nontherapeutic anti–factor Xa levels.[33] Fetal survival rates were higher in women choosing LMWH (96%) than in those choosing warfarin (75%).[34] Nevertheless, lethal valve thrombosis has been reported in the face of therapeutic peak anti–factor Xa levels.

Continuous intravenous heparin infusion has been suggested. Although the incidence of line infection and subsequent endocarditis may be relatively low, the consequences are catastrophic. This choice should be made after careful counseling of the patient.

If valve thrombosis is encountered, thrombolysis can be considered. Successful thrombolytic therapy of a clotted valve in pregnancy has been reported. Although safe and effective for many patients, embolic complications, bleeding, and death have been reported in pregnancy. Surgery such as cesarean delivery cannot be performed in proximity to thrombolytic therapy.

Although clear strategies supported by randomized trials are not available and are not expected to be forthcoming, the following guidelines can be suggested:

1. Care by a team experienced with aggressive therapeutic monitoring and dose adjustment of anticoagulant medications
2. Emphasis of the need for patient compliance with frequent subcutaneous dosing
3. Monitoring of trough effect to ensure consistently adequate anticoagulation
4. Monitoring of peak dosing to assess potential for bleeding
5. Increasing dose frequency when safe peak dosing and therapeutic trough dosing cannot be achieved
6. Treatment with LMWH at a minimal dose interval of every 12 hours
7. Treatment with UFH at a minimal dose interval of every 8 hours.
8. Adjunctive treatment with aspirin
9. Avoidance of overlapping treatment with LMWH and VKA in the postpartum period

CONGENITAL HEART DISEASE

Congenital heart disease is present in 0.7% to 1% of live births, accounting for as many as 30% of infants with birth anomalies. Before the development of corrective surgery, many children died shortly after birth or in childhood. In 1939, the first patent ductus arteriosus (PDA) was ligated. In 1945, the first Blalock-Taussig shunt was performed for palliation of cyanotic heart disease. In 1953, cardiac bypass was introduced. Introduction of surgery under hypothermia in the late 1960s permitted longer and more complex repairs. Of children who survived surgery to correct tetralogy of Fallot between 1955 and 1960, the 23-year survival is 86%, approaching the expected survival rate of 96% for normal children. Before the 1960s, rheumatic heart disease was more common in pregnancy than congenital heart disease by a ratio of 4:1. By the 1980s, the ratio was 1:1. Currently, congenital disease is now estimated to exceed rheumatic disease by 4:1. Although most enter pregnancy with known heart disease, some women have their disease first recognized because of the hemodynamic demands of pregnancy.

Increased survival of children with congenital disease has created a population of young women with complex medical and psychosocial conditions entering their childbearing years. Those whose congenital heart disease was diagnosed in infancy have frequently experienced multiple cardiothoracic surgeries and extended hospitalizations. They have lived with continued concerns from parents and health care professionals regarding their ongoing health problem. Their childhood has been described as "growing up heart sick."[35] Some describe a lack of information regarding childbearing and contraception. They "seemed to believe that someone else could and would decide whether they should become pregnant." Kovacs and coworkers describe the contraception and pregnancy advice women with congenital heart disease recall receiving from their health care providers, and in many cases women received either no information or inaccurate information.[36] **Health care providers should strive to (1) objectively share information regarding reproductive health care, (2) direct decision making toward the patient rather than toward parents and health care professionals, and (3) improve self-esteem and body image.** When treating congenital heart disease during pregnancy, one must be willing to acknowledge and address the impact of the patient's disease on her life.

Table 36-3 summarizes the distribution of congenital heart disease in childhood and in pregnancy.[23,37] The spontaneous closure of lesions such as ventricular septal defect (VSD) and correction of patent ductus are reflected by reduced reporting in pregnancy. The increased reporting of aortic stenosis in pregnancy is probably due to a worsening of disease with age and the ease of recognition during pregnancy. The complexity and diversity of congenital heart disease confounds our ability to describe the prognosis or a management plan for the breadth of conditions. **Major risks in pregnancy include (1) cyanosis, (2) left (or systemic) ventricular dysfunction, and (3) pulmonary hypertension, particularly with right ventricular dysfunction.**

Outcomes have been most clearly described based on the presence or absence of maternal cyanosis. Table 36-4 is derived from a report of 482 pregnancies from 233 women with congenital heart disease who delivered between 1968 and 1982.[11] The rate of terminations was higher in the group of women with cyanotic heart disease and particularly high (42%) in those with uncorrected lesions. This reflects the anticipated poor neonatal outcome and maternal risks associated with uncorrected cyanotic disease. It is likely that patients with more severe disease are overly represented in the group of women who chose to terminate, which would bias the group who continued pregnancy toward a better outcome. Eighty-six to 90% of pregnancies without cyanosis ended in a live birth compared with 71% with an uncorrected lesion. Given an expected baseline rate of miscarriage, these outcomes are good. Corrected cyanotic disease was associated with outcomes comparable to noncyanotic disease. Table 36-5 is derived from a report of 144 pregnancies from women with congenital heart disease delivered between 1976 and 1986.[23] Adverse outcomes are again concentrated among women with uncorrected cyanotic heart disease.

Common maternal complications include congestive heart failure and pulmonary edema (4%), arrhythmia (4%), and hypertension (6%). Congestive heart failure and hypertension were commonly associated with uncorrected left ventricular outflow obstruction.[11,23] Arrhythmias were observed after surgery in and around atrial or ventricular septa. Maternal death was uncommon, 0 per 482 pregnancies in one series[11] and 1 per 144 pregnancies in a second.[23] Maternal deaths are most commonly reported in association with Eisenmenger syndrome, which is discussed more fully later.

A number of authors have recently developed criteria that predict complications in pregnancy. **A remarkable concordance in central findings are reported: impaired left ventricular function, cyanosis, impaired functional status, left ventricular outflow obstruction, and right heart dysfunction are associated with maternal complications.**[38-42]

TABLE 36-3 INCIDENCE OF CONGENITAL HEART DEFECTS IN CHILDHOOD AND IN PREGNANCY

DEFECT	CHILDHOOD (%)	PREGNANCY (%)
Ventricular septal defect	35	13
Atrial septal defect	9	9
Patent ductus arteriosus	8	2.7
Pulmonary stenosis	8	8
Aortic stenosis	6	20
Coarctation of the aorta	6	8
Tetralogy of Fallot	5	12
Transposition of the great vessels	4	5.4

TABLE 36-4 NEONATAL OUTCOME WITH CONGENITAL HEART DISEASE: LIVEBORN VERSUS TERMINATION

	LIVEBORN INFANT (%)	TERMINATION (%)
Noncyanotic	86	5
Cyanotic	85	26
Corrected	95	17
Palliative	87	17
Palliative	71	42

TABLE 36-5 NEONATAL OUTCOME WITH CONGENITAL HEART DISEASE BY SAB, SGA, PRETERM, AND BIRTHWEIGHT

	SAB (%)	SGA (%)	PRETERM (%)	BIRTH WEIGHT (g)
	(%)	(%)	(%)	
Noncyanotic	12	6	9	3,300 ± 600
Cyanotic	21	52	35	2,400 ± 800
Corrected	11	25	0	
Uncorrected/ palliative	25	67	53	

Preterm, Preterm birth; *SAB*, spontaneous abortion; *SGA*, small for gestational age.

Men and women with congenital heart disease are at increased risk for having children with congenital heart disease. In a prospective study with aggressive pediatric evaluation, Whittemore and associates[11] estimated the incidence to be as high as 14.2%. In a retrospective study, Rose and coworkers found the risk to be 8.8%.[43] The rate of congenital heart disease associated with an affected mother is 2 to 3.5 times that observed with an affected father. **Specific parental defects are not generally associated with the same defect in the child. The risk for cardiac maldevelopment is inherited rather than the risk for a specific defect.** The risk for congenital heart disease and the character of the risk should be discussed with an affected mother. In Whittemore's report, 58 of 60 affected infants were diagnosed with relatively benign correctable lesions (atrial septal defect, VSD, pulmonary stenosis, aortic stenosis, patent ductus arteriosus, or mitral valve prolapse). Only two infants from 372 pregnancies (0.5%) were diagnosed with complex congenital heart disease.[11] Gill and colleagues[12] examined the recurrence pattern of congenital heart disease in 6640 pregnancies for whom fetal echocardiography was obtained due to a family history of congenital heart disease. The recurrence rate was 2.9% (95% confidence interval [CI], 2% to 4%) for mothers with congenital heart disease, a rate lower than reported by others. However, the study is limited to diagnoses established by fetal echocardiography and, therefore, may under-represent the true incidence of abnormalities. The type and severity of cardiac defect seen in the mother did not predict the type or severity of cardiac defect in the offspring, with a few exceptions. Atrioventricular canal defects, especially those associated with situs abnormalities, had a highly concordant recurrence rate.[12] Congenital heart disease–associated 22q11.2 deletion (DiGeorge syndrome, velocardiofacial syndrome) will be inherited as an autosomal dominant condition. Many parents with congenital heart disease will not have been previously screened. Referral for genetic counseling and possible screening should be considered, particularly in the context of conotruncal abnormalities and other associated anomalies. All women who have congenital heart disease should undergo fetal echocardiographic examination at midpregnancy.

Contraceptive counseling should be offered to all women with congenital heart disease. **Given the problems experienced growing up with heart disease, contraceptive education should probably be initiated as part of general health care education, before the overt need for birth control.** In the context of congenital heart disease, complications associated with pregnancy are usually greater than those associated with any form of birth control. Cyanosis, pulmonary hypertension, low CO, dilated cardiac chambers, sluggish venous conduits (e.g., Fontan), and atrial fibrillation place patients at risk for thrombosis. This small group of women should probably avoid combined estrogen-progestin oral contraceptives. Progestin-only pills are not associated with risk for thrombosis but require regular dosing to achieve optimal efficacy. Parenteral progestins are safe for women with cardiac disease and are extremely effective. They do cause irregular bleeding, which may be significant if the patient is anticoagulated. The intrauterine device may be a suitable choice for women with congenital heart lesions.

Isolated Septal Defects

Ventricular and atrial septal defects represent greater than 40% of congenital heart disease identified in childhood. Many defects identified in children close with advancing age. In adulthood, 50% of large VSDs (>1.5 cm) lead to the development of Eisenmenger syndrome. Ten percent of patients with uncorrected atrial septal defects also develop pulmonary hypertension. The management of Eisenmenger syndrome in pregnancy is discussed later.

A harsh systolic murmur that radiates to the left sternal border but not to the carotids suggests the presence of a VSD. The diagnosis can be confirmed by color-flow Doppler echocardiography demonstrating a small, high-velocity lesion. The peak velocity of the jet across the septum can be used to assess the pressure gradient between the ventricles. A high velocity between ventricles indicates a large pressure gradient and low pressure in the right ventricle (RV) and the absence of pulmonary hypertension. In the absence of associated cardiac lesions and pulmonary hypertension, the presence of a VSD does not usually complicate pregnancy. Small defects create loud murmurs but are not usually hemodynamically significant. The high-velocity jet of a small lesion does create a risk for endocarditis.

Atrial septal defects are more difficult to diagnose by auscultation. The characteristic finding, a split S_2 that is fixed with respiration, is subtle and usually not appreciated without specific attention. Increased right-sided flow secondary to shunting across the defect may create a flow murmur that will be augmented in pregnancy. Other endocardial cushion defects may be associated with ostium primum defects. In the absence of other anomalies, the significance of the atrial septal defect is related to its size rather than its etiology. Hemodynamically significant defects result in significant shunting from the systemic circulation to the pulmonary circulation. As with the VSD, Eisenmenger syndrome may develop, but usually at an older age. Increased pulmonary blood flow may result in dyspnea on exertion and restriction of activity. Atrial arrhythmias are commonly associated with atrial enlargement or intrinsic conduction abnormalities in the case of ostium primum defects.

Piesiewicz and colleagues[44] reported 54 pregnancies in women with secundum atrial septal defects. **Impaired functional status (NHYA class III or IV) increased from 5.5% in the second trimester to 11.1% in the third trimester.** Although left-to-right shunting was present in all patients in the second trimester, three patients (5.5%) developed bidirectional shunting in the third trimester. One additional patient reversed her shunt. RV diameter and systolic pulmonary artery pressure increased from the second to third trimester (34.1 ± 8.4 mm Hg to 39.1 ± 12.2 mm Hg). Over the same time frame, the pulmonary flow (Q_p): systemic flow (Q_s) ratio decreased. Increased flow associated with pregnancy appears to adversely affect right ventricular function and pulmonary pressures. The fall in Q_p/Q_s suggests that the rise in pulmonary pressure is due to increased PVR. The authors also reported supraventricular arrhythmias in 50% of women in the third trimester.

The patient with a significant pulmonary-to-systemic shunt ratio can be expected to normally expand her CO during pregnancy. However, the price of a normal systemic CO is a high pulmonary flow. The pregnant patient may begin to experience symptoms at rest that she previously noted with exercise. She may also experience an increase in tachyarrhythmias. HR control with a β-blocker may provide symptomatic relief. Early diuresis may benefit the patient postpartum. Elevated pulmonary blood flow associated with pregnancy could accelerate the progression of pulmonary vascular disease. In the absence of associated anomalies, arrhythmias, and pulmonary hypertension, the presence of an atrial septal defect does not usually complicate pregnancy.

Patent Ductus Arteriosus

The diagnosis of a PDA is suggested by the characteristic continuous murmur at the upper left sternal border. Most cases are identified and ligated in childhood. Of patients with an uncorrected patent ductus, as many as 50% develop Eisenmenger syndrome, usually in childhood. In adults with a small patent ductus, the major risk is endocarditis. **In the absence of Eisenmenger syndrome, pregnancy is not usually complicated.** As with the atrial septal defect, the increase in pulmonary blood flow associated with the increase in CO in pregnancy may result in increased dyspnea with exertion and at rest. Early diuresis may benefit the patient postpartum.

Tetralogy of Fallot

Tetralogy of Fallot is a syndrome of abnormalities due to maldevelopment of the truncus arteriosus characterized by (1) right ventricular outflow tract obstruction, (2) VSD, (3) overriding aorta, and (4) right ventricular hypertrophy. Tetralogy of Fallot is the most common cyanotic congenital heart disease, and it was among the first to be successfully surgically palliated by Blalock and Taussig in 1945 and subsequently physiologically repaired. Therefore, a significant number of adults with congenital heart disease have repaired tetralogy of Fallot. The severity of the clinical presentation in infancy is dependent on the degree of outflow tract obstruction. More severe obstruction leads to more significant cyanosis and right-to-left shunting. Surgical repair generally includes closure of a VSD and relief of right ventricular outflow tract obstruction. Some patients with repaired tetralogy of Fallot have near-normal cardiac physiology, but many have residual lesions that may complicate pregnancy.

Patients with significant cyanosis at birth often had palliative Blalock-Taussig shunts in infancy using the subclavian artery to connect the systemic circulation with the pulmonary circulation, thus increasing pulmonary blood flow and reducing cyanosis. As a consequence, blood pressures in the arm supplied by the transected artery may not be reflective of aortic pressure. Patients should be asked if one arm is unreliable for blood pressure measurements, or examined to look for evidence of a thoracotomy scar resulting from the Blalock-Taussig shunt.

Efforts to correct the right ventricular outflow tract obstruction may result in incomplete relief and persistent pulmonary stenosis. More often, significant pulmonary insufficiency is a consequence of the transannular patch approach used to enlarge the outflow tract and valve. Several studies have demonstrated that women with severe pulmonary insufficiency and right ventricular dysfunction are more likely to have complications with pregnancy. Veldtman and colleagues[45] reported a series of 43 women with tetralogy of Fallot who had 112 pregnancies. Five percent experienced cardiac complications: supraventricular tachycardia (two), heart failure (two), pulmonary embolism associated with pulmonary hypertension (one), and progressive RV dilation (one).

Tetralogy of Fallot is often well tolerated during pregnancy. Preconceptual evaluation should include assessment of right and left ventricular function, severity of pulmonary insufficiency, and stenosis, with consideration for repair of severe pulmonary insufficiency before pregnancy, if appropriate.

Transposition of the Great Vessels

Transposition of the great vessels (TGV) is present in only 5% of pregnant women with congenital heart disease but is overrepresented in the publication of case reports and case series. In complete TGV, systemic venous blood returns to the right atrium and passes through the tricuspid valve, into the RV, and directly into the transposed aorta. Although an adequate circulation for fetal life, infants decompensate at birth owing to an inadequate pulmonary circulation. Some will have a sufficiently large VSD to achieve adequate pulmonary blood flow and oxygenation; others will require an immediate palliative procedure, an atrial septostomy.

TGV was first definitively corrected in 1964 with the Mustard operation. A baffle is constructed through the left and right atria so that systemic venous return is channeled through the mitral valve into the left ventricle, and pulmonary venous return is directed through the tricuspid valve into the RV. With a modest surgical intervention, the right and left pumps are placed in series with physiologic flow of systemic venous return through the pulmonary circulation. **The RV, as the systemic ventricle, must work against systemic resistance, and the tricuspid valve is exposed to systemic pressures. Long-term complications are associated with failure of the systemic ventricle and arrhythmia.** Of patients surviving the first 30 days after repair, 90% will be alive in 10 years and 87% will be alive in 20 years. After 13 years, only 5% suffer significant disability (NYHA classes II to IV).[46] A more physiologic repair can be achieved when transposition is accompanied by a VSD. The ventricular septum is reconstructed so that the aortic outflow tract lies within the left ventricle and a conduit is constructed to connect the RV to the pulmonary artery (Rastelli repair). The pulmonary conduit is prone to stenosis and deterioration of the transplanted valve. More recently, a direct surgical switch between the pulmonary artery and the aorta has been performed. Given the time when these operations were introduced, fewer young women entering pregnancy will have a Mustard repair. Increasing numbers will have an arterial switch.

The hemodynamic changes of pregnancy will have a mixed impact on a patient with a Mustard repair. Increased

CO increases the volume load on the right heart. Decreased vascular resistance reduces afterload on the right side of the heart. The box, Pregnancy Outcomes with Transposition of the Great Vessels, summarizes nine papers reporting a total of 49 pregnancies in 36 women.[23,46-53] No maternal mortality was reported. Neonatal outcomes were generally good. Two women entered pregnancy with disability due to their heart disease (NYHA classes III to IV). One delivered at 26 weeks due to preterm labor. The other developed severe congestive heart failure near term and died 19 months postpartum. Congestive heart failure was frequently associated with uncontrolled tachyarrhythmias.

Guedes and colleagues[54] have reported echocardiographic findings of 16 women with a Mustard repair completing 28 pregnancies. Mean gestational age at delivery was 38.1 ± 1.5 weeks, with a mean birthweight of 3040 ± 540 g. In four of 21 pregnancies, right ventricular function deteriorated. In three of the four patients, function did not return to baseline conditions. Although concerning, the authors noted that the rate of deterioration was not clearly different than that of a cohort who did not get pregnant.

Canobbiio and coworkers[55] reported a series derived from a registry. Of significance, this report is derived from a diversity of practices rather than from centers with considerable experience managing congenital heart disease. Forty women carried 54 pregnancies that resulted in live births. Thirty-six had Mustard repairs; 4 had Senning repairs. In 6 pregnancies, heart failure developed in the second or third trimesters. In 5, heart failure developed postpartum. One woman required transplantation postpartum; 1 died of heart failure 1 month after delivery; 1 died 4 years later. This report clearly documents the potential for adverse outcome.

Tobler and associates[56] reported on 17 pregnancies in 9 women with an arterial switch. One developed nonsustained ventricular tachycardia; 1 developed a valve thrombosis.

Congenitally corrected TGV (ventricular inversion) is characterized by the passage of systemic venous blood into the right atrium, directly into the morphologic left ventricle, and out through the transposed pulmonary artery. Pulmonary venous return passes directly from the left atrium into the morphologic RV and out through the aorta. The RV again serves as the systemic ventricle. Congenitally corrected TGV may be an isolated anomaly but may also be associated with other anomalies that result in cyanosis. See the box for a summary of two series of pregnancies with congenitally corrected TGV.[57,58] Again, maternal and neonatal outcomes are good. Consistent with outcomes associated with other cyanotic forms of congenital heart disease, miscarriage and premature birth are concentrated among those with cyanotic lesions.

Young women with surgically or congenitally corrected TGV successfully complete pregnancy. Nevertheless, they require aggressive management by an experienced team. Women who are functionally impaired or who are cyanotic before pregnancy can expect more adverse outcomes and may deteriorate postpartum. Evaluation before pregnancy should include assessment of functional status; evaluation of right systemic heart function; and confirmation of normal oxygenation. When the right side of the heart is the systemic heart, pharmacologic afterload reduction should be maintained until pregnancy is confirmed. ACE inhibitors should be discontinued early in the first trimester. Postpartum, the systemic RV should be considered "at risk" to fail and managed with rate control (ß-blocker), afterload reduction (ACE inhibitor), and appropriate management of preload (diuresis).

Pregnancy Outcomes with Transposition of the Great Vessels

Women	36
Pregnancies	49
Live births	41 (84%)
Miscarriages	5
Terminations	2
Fetal deaths	1
Premature birth (<35 weeks)	5 (12%)
Congenital heart disease	0 (0%)
Congestive heart failure	6 (15%)
Arrhythmia	8 (20%)

Pregnancy Outcomes with Congenitally Corrected Transposition of the Great Vessels

Women	41
Cyanotic	4 (10%)
Pregnancies	105
Cyanotic	13 (12%)
Live births	77 (73%)
Miscarriages*	22
Terminations	6
Fetal deaths	1
Premature birth (<35 weeks*)	6 (8%)
Congenital heart disease	1 (1%)
Congestive heart failure	5 (6%)
Cerebrovascular accident	1 (1%)

*Miscarriages and premature births were concentrated among cyanotic mothers.

The reported experience with TGV is to date the most extensive for any complex defect. The conclusions drawn from this experience are probably applicable to other, less common conditions. **Functional status and cyanosis are the most reliable predictors of complicated pregnancies.** Arrhythmia is common and is frequently the cause of cardiac decompensation.

Fontan Repair

The Fontan repair was initially performed to achieve a physiologic correction of tricuspid atresia by connecting the right atrium directly to the pulmonary artery. **The Fontan repair and subsequent modifications are currently used to correct a variety of complex congenital heart conditions characterized by a single functional ventricle.** The repair achieves a noncyanotic, functional flow of systemic venous return through the lungs and a functionally systemic ventricle. Without a pulmonary pump, the cardiac price for this result is intolerance of increased intrathoracic

pressure and elevated systemic and right atrial pressure if left ventricular end-diastolic or left atrial pressures increase. Experience with pregnancy in women with the Fontan repair is limited. In a survey of 76 women of reproductive age, Canobbio and associates[59] reported that 66% were counseled not to become pregnant despite a stable surgical outcome and a strong desire to have children. The remaining 34% were not counseled regarding pregnancy. Contraceptive use, despite counseling against pregnancy, was inconsistent. Although the miscarriage rate was higher than in the general population, the preterm birth rate was low. Maternal complications were limited to arrhythmia, usually atrial, and congestive heart failure in the postpartum period. Although not reported in these small series, sluggish flow through the right atrial and pulmonary circulation may increase the risk for thrombosis. The incidence of pulmonary emboli in nonpregnant patients with Fontan circulation may be as high as 17%. Another series reported 10 pregnancies in 6 women.[60] Of the 10 pregnancies, 5 ended in miscarriage before 12 weeks, and 1 was ectopic. Of the 4 completed pregnancies, 1 woman had a decline of NYHA class with both of her pregnancies, and the second pregnancy was complicated by atrial flutter. The other two women did not have maternal complications. These series remain small, and thus the ability to extrapolate to the individual with Fontan physiology is difficult, **but the uniqueness of the Fontan physiology warrants care in institutions with expertise in adult congenital heart disease.** The box, Pregnancy Outcomes with Fontan Repair, summarizes the outcomes of 43 pregnancies from 27 women reported by these groups.[59,60]

Pregnancy Outcomes with Fontan Repair

Women	27
Pregnancies	43
Live births	19 (44%)
Miscarriages	19
Terminations	6
Fetal deaths	0
Premature birth (<35 weeks)	3 (15%)
Congenital heart disease	1 (5%)
Congestive heart failure	3 (15%)
Arrhythmia	3 (16%)

Eisenmenger Syndrome

Eisenmenger syndrome describes pulmonary-to-systemic shunting associated with cyanosis and increased pulmonary pressures secondary to pulmonary vascular disease. **Eisenmenger syndrome may develop from any intracardiac shunt resulting in blood from the high-pressure systemic circulation being directed into the pulmonary circulation.** Systemic pressure and excessive flow lead to microvascular injury, obliteration of pulmonary arterioles and capillaries, and in the end, elevated PVR. The time to onset of shunt reversal is variable, but most patients who have a large VSD or large PDA develop shunt reversal in infancy. Those who have an atrial septal defect are delayed until early adulthood. Survival at 10 years from diagnosis is 80%; at 25 years, it is 42%.[61]

Patients with Eisenmenger syndrome are at risk for congestive heart failure, hemoptysis due to pulmonary hemorrhage, sudden death due to arrhythmia, a cerebrovascular accident, and hyperviscosity syndrome. The diagnosis should be considered in any cyanotic patient and is confirmed by echocardiography with the demonstration of increased pulmonary pressure and an intracardiac shunt. If the shunt is due to an atrial septal defect or a PDA, transesophageal examination may be necessary to establish the diagnosis. Treatment is nonspecific and includes supportive care and avoidance of destabilizing events such as surgery and unnecessary medications. Symptomatic hyperviscosity syndrome due to an elevated hematocrit can be treated with hydration and, if necessary, phlebotomy. Iron deficiency, preexisting or secondary to phlebotomy, can exacerbate hyperviscosity; microcytic cells are less deformable and therefore more prone to occlude the microcirculation. Definitive therapy can be achieved only with heart-lung or lung transplantation. However, the 4-year survival with lung transplantation is less than 50%, a less favorable prognosis than that for many patients with Eisenmenger syndrome.

VSD, atrial septal defect, and PDA are responsible for 89% of reported cases of Eisenmenger syndrome in pregnancy.[62] Each lesion is initially associated with shunting from the systemic, oxygenated circulation to the pulmonary circulation. As PVR and pulmonary pressures increase over time and approach systemic pressures, the characteristic murmurs of a VSD or PDA diminish. Reversal of flow from the right to the left, the development of hypoxemia, and increasing hematocrit herald the development of Eisenmenger syndrome. The fall in SVR associated with pregnancy may initiate shunt reversal in a patient not previously cyanotic.

In 1979, Gleicher reviewed published cases of Eisenmenger syndrome in pregnancy.[63] Seventy pregnancies from 44 women were evaluated. Fifty-two percent of the women died during pregnancy. Thirty percent of the pregnancies resulted in maternal death. The risks for death associated with first, second, and third pregnancies were 36%, 27%, and 33%, respectively. A first successful pregnancy did not confirm the safety of subsequent pregnancies. Most deaths (70%) occurred at the time of delivery or within 1 week postpartum. Excessive blood loss was associated with 35% of deaths, whereas thromboembolic conditions were responsible for 44%. Maternal mortality associated with cesarean delivery (80%) exceeded that associated with vaginal delivery (34%). Maternal death was not reported with first-trimester termination of pregnancy. Only 26% of pregnancies resulted in a term birth. Fifty-five percent of newborns were delivered preterm, and 32% were small for gestational age.

A more modern review of cases in the United Kingdom between 1991 and 1995 confirms the poor prognosis for pregnant women with Eisenmenger syndrome despite considerable advancement in the management of cardiac disease in pregnancy.[64] Mortality remains extremely high; 40% of the women died. Most deaths (96%) occurred within the first 35 days postpartum. Late diagnosis (relative risk [RR], 5.4) and delayed hospitalization significantly increased maternal mortality.

Although the risks associated with Eisenmenger syndrome in pregnancy are clear, appropriate management is controversial. Decreased activity, hospital observation, and oxygen supplementation are usually employed. Reduction of pulmonary pressures and improved systemic oxygen saturation after oxygen supplementation indicate that PVR is not fixed and suggest a better prognosis. Intercurrent antepartum events such as pneumonia or urinary tract infection are poorly tolerated. Preventing microcytosis with iron supplementation may decrease the risk for microvascular slugging.

Cesarean delivery is reserved for obstetrical indications and is avoided whenever possible. Hemodynamic stability must be maintained during labor and the postpartum period. When PVR is not fixed, oxygen supplementation may decrease pulmonary pressures. Systemic hypotension from hemorrhage or sympathectomy from epidural analgesia results in increased right-to-left shunting, increasing hypoxemia, increasing PVR, and worsening shunt. Volume overload or excessive systemic resistance, particularly postpartum, may further tax the failing right side of the heart. A pulmonary artery catheter and a peripheral arterial catheter are usually used to guide hemodynamic management. Narcotic-based regional analgesia provides adequate pain relief without excessive hemodynamic instability. Anticoagulation remains controversial. If patients are anticoagulated, caution should be exercised to avoid excessive treatment and associated hemorrhage.

Although use of a selective pulmonary vasodilator, inhaled nitric oxide, has been reported to reduce pulmonary pressures, increase CO, and improve systemic oxygenation, maternal death was not averted. Use of sildenafil and L-arginine has been reported with apparent hemodynamic benefit and the survival of a single patient. There are other case reports using pulmonary vasodilators with improved pregnancy outcomes, but nonetheless maternal risk remains high. **Unlike many cardiac conditions in pregnancy, meticulous care frequently fails to prevent maternal death.**

Coarctation of the Aorta

Coarctation of the aorta results from a constriction of the aorta at or about the level of the ductus arteriosus or left subclavian artery. Patients have a characteristic discrepancy in blood pressure between their right arm and lower extremities. Complications include dissection at the site of coarctation, rupture of associated berry aneurysms, and cerebrovascular accidents, heart failure, and ischemic heart disease associated with cephalic hypertension.

Modern reports of uncorrected coarctation in pregnancy are limited. Historically, pregnancy was associated with a maternal mortality rate of 9% owing to aortic rupture, congestive heart failure, cerebrovascular accidents, and endocarditis. β-Blockade may serve to protect against dissection and promote diastolic flow through the aortic narrowing.

Pediatric screening identifies most significant coarctations leading to repair. After repair, systemic hypertension may persist and require treatment. In two reports of 216 pregnancies in 104 women, 41 were complicated by hypertension and 1 by a lethal dissection at 36 weeks.[65,66]

Summary

An increasing cohort of young women with corrected congenital heart disease will be presenting to their obstetricians pregnant and desiring to bear children. Some basic conclusions can be drawn from our experience with congenital heart disease to date. **First, Eisenmenger syndrome and pregnancy remain a lethal combination. New, effective strategies for therapy are not anticipated. Second, cyanotic heart disease in the absence of pulmonary hypertension is associated with increased rates of miscarriage and preterm birth. Third, mothers with cardiac disability (NYHA classes III to IV) or with evidence of right heart dilation have a more complicated course in pregnancy. Fourth, arrhythmias may become worse in pregnancy and precipitate cardiac decompensation.** Aggressive pharmacologic treatment is appropriate. Finally, many young women who are initially well compensated and acyanotic can have successful pregnancies.

CARDIOMYOPATHY

Dilated cardiomyopathy is characterized by the development of pulmonary edema in the context of left ventricular dysfunction and dilation. Patients usually present with signs and symptoms of pulmonary edema: dyspnea, cough, orthopnea, tachycardia, and occasionally, hemoptysis. These symptoms of pulmonary edema, although characteristic of heart failure, may also be due to previously undiagnosed congenital or rheumatic heart disease, preeclampsia, embolic disease, intrinsic pulmonary disease, tocolytic use, or sepsis. The diagnosis of cardiomyopathy is made in the clinical circumstances of characteristic signs and symptoms and findings of left ventricular dysfunction and dilation on echocardiographic examination. The finding of an elevated B-type natriuretic peptide (BNP) can be used to help discriminate patients who need more definitive testing such as an echocardiogram. An elevated level may also be found with women with diastolic dysfunction or other conditions in which cardiac volume loading and stretch are increased. Ventricular dysfunction may be due to conditions extrinsic to the heart such as thyrotoxicosis or hypertension or to intrinsic myocardial dysfunction. Accurate diagnosis directs appropriate therapy and permits assessment of long-term prognosis.

Peripartum cardiomyopathy is a rare syndrome of heart failure presenting in late pregnancy or postpartum. The diagnosis is made after excluding other causes of pulmonary edema and heart failure. Failure to adhere to a rigorous definition of disease in the literature confounds conclusions regarding etiology and prognosis. A definition based on criteria for idiopathic dilated cardiomyopathy has been suggested (see box, Diagnostic Criteria for Peripartum Cardiomyopathy).[67] The incidence is estimated to be between 1 in 1300 and 1 in 15,000.[68] Although some of the variability in reported incidence is due to regional and ethnic differences, much is due to the imprecise definition of the disease. The cause of peripartum cardiomyopathy is unknown. Nutritional and immunologic mechanisms have been proposed. The prevalence of antibodies to echovirus and Coxsackie virus is not higher among women with cardiomyopathy compared with controls.[69]

Diagnostic Criteria for Peripartum Cardiomyopathy

1. Heart failure within the last month of pregnancy or 5 months postpartum
2. Absence of prior heart disease
3. No determinable cause
4. Echocardiographic indication of left ventricular dysfunction
   - Ejection fraction of <45% or fractional shortening of <30%
   - Left ventricular end-diastolic dimension of >2.7 cm/m^2

The mortality rate for peripartum cardiomyopathy (PPCM) is reported to be 25% to 50%. Death is usually due to progressive congestive heart failure, arrhythmia, or thromboembolism.[69] Within 6 months, half of patients demonstrate resolution of left ventricular dilation. Their prognosis is very good. Of those who do not, an 85% mortality rate can be expected within the next 4 to 5 years.[70] The magnitude of risk for subsequent pregnancies after peripartum cardiomyopathy is unclear. A recent survey of 67 pregnancies in 63 women suggests a mortality rate of 8% when left ventricular dysfunction has not resolved, and 2% in patients with normal function.[70]

Women with established dilated cardiomyopathy who enter pregnancy with known disease are reported to have less severe outcomes. As might be expected, moderate to severe left ventricular dysfunction and NYHA classes III and IV symptoms are associated with worse outcomes. In a series of 36 pregnancies in 32 women, no deaths were reported. Three women developed pulmonary edema. Arrhythmia complicated 6 pregnancies. Pregnant women were much less likely to be treated with diuretic and β-blocker than nonpregnant women.[71]

Women with a diagnosis of PPCM in a previous pregnancy are at risk for heart failure in a subsequent pregnancy. If left ventricular ejection fraction (LVEF) has not normalized, the mortality rate may be as high as 19%.[72] In those in whom LVEF has normalized, a worsening of function and an increased incidence of symptoms of heart failure can be expected. Aggressive, appropriate pharmacologic management is frequently required.

Acute treatment of cardiomyopathy is directed at improving cardiac function and, when present, treating the inciting event. Diuretics are used to decrease preload and relieve pulmonary congestion. Digoxin may improve myocardial contractility and facilitate rate control when atrial fibrillation is present. Afterload reduction is achieved with ACE inhibitors postpartum or hydralazine before delivery. β-Blockade in stable, euvolemic patients has been clearly demonstrated to improve cardiac function and survival outside of pregnancy and should not be withheld from pregnant women. Significantly dilated and hypokinetic cardiac chambers pose a risk for clot formation and systemic embolization. Anticoagulation with heparin antepartum or warfarin postpartum should be considered. Implanted defibrillators have been used in pregnancy without significant complications. Arrhythmia is a common cause of death associated with cardiomyopathy outside pregnancy. Hemodynamic management during labor and delivery is frequently directed by a pulmonary artery catheter. Pain control decreases cardiac work and reduces tachycardia. A carefully dosed epidural is appropriate. Cesarean delivery is reserved for obstetrical indications.

The postpartum period represents a time of particular risk. Women have received exogenous volume loading from intravenous fluid during labor; blood volume is centralized with uterine contractions; extravascular fluid is mobilized; tachycardia persists; and SVR increases. Each physiologic change will work toward left ventricular decompensation. Preemptive HR control, diuresis, and afterload reduction should be employed.

MYOCARDIAL INFARCTION

MI is a rare event among women of reproductive age. From a population base of 3.6 million women-years, Petitti and associates[73] identified 186 cases (5 per 100,000 women-years). More recent studies suggest a rate between 2.8 and 6.2 per 100,000 deliveries.[74,75] **An increased risk for MI in pregnancy is consistently associated with maternal age greater than 40 years, chronic hypertension, diabetes, smoking, migraine headache, transfusion, and postpartum infection.**[75]

Owing to the rarity of the event, information regarding MI in pregnancy is derived from case reports and, therefore, is subject to considerable reporting bias. Roth and Elkayam have summarized information from reports of 123 pregnancies between 1922 and 1995[76] and an additional 103 cases between 1995 and 2005.[77] (see box, Myocardial Infarction in Pregnancy).[76,77] **Coronary dissection and normal coronary arteries are observed in almost 50% of cases.** Delivery within 2 weeks of infarction may be associ-

*Sixty-two percent of infant deaths were associated with mother's death.

ated with a maternal mortality rate as high as 50%. MI has been reported in association with diabetes mellitus, pheochromocytoma, Ehlers-Danlos type IV, antiphospholipid syndrome, multiple gestation, and sickle cell anemia. Medications such as ergot alkaloids given for bleeding, bromocriptine for lactation suppression, ritodrine and nifedipine for tocolysis, and prostaglandin E_2 in conjunction with severe hypertension have also been associated with MI.

The diagnosis of MI in pregnancy is often delayed because of the rarity of the event and common symptoms of pregnancy. During normal pregnancy, most women experience some increase in exercise intolerance and dyspnea. Chest pain due to reflux is common. ECG changes that suggest ischemia have been reported in as many as 37% of women having a repeat cesarean delivery.[76] **However, ST-segment elevation is not a normal finding and, in the context of ongoing chest pain, should markedly increase the suspicion of acute MI.** The MB fraction of creatinine kinase isoenzymes may be elevated at cesarean delivery as well. Troponin I levels are not elevated during labor and delivery. If confusion regarding the appropriate diagnosis exists in the context of a constellation of findings suggestive of MI, an echocardiogram can be used to confirm abnormal wall motion in the ischemic region.

Acute therapy is based on rapid coronary reperfusion. Coronary angioplasty and stenting have been reported in pregnancy and should not be withheld when appropriate for the mother's condition. Thrombolytic therapy has also been used in pregnancy.[76] Although effective, there may be a small but real incidence of associated maternal bleeding, preterm delivery, or fetal loss. Surgery after thrombolytic therapy is associated with significant risk for hemorrhage.

Medications commonly used in the management of MI such as morphine, organic nitrates, lidocaine, β-blockers, aspirin, magnesium sulfate, and calcium antagonists may be used in appropriate doses in pregnancy. Care should be taken to avoid the supine position and maternal hypotension during procedures. The fetus, if viable, should be monitored.

Elective delivery within 2 weeks of infarction should be avoided because it is associated with an increased risk for maternal death. Cesarean delivery is reserved for obstetrical indications. Labor and delivery are managed with standard cardiac care. Pain is controlled, usually with carefully administered regional analgesia. Tachycardia is prevented with pain control and treated with β-blockers as needed. Hemodynamic stability is maintained, frequently using information from pulmonary and peripheral arterial catheters. Maternal pushing is avoided, and the second stage of labor is shortened with low forceps or vacuum. Diuresis is gently initiated postpartum with diuretics.

The experience with pregnancy after a remote MI is limited. Of 33 reported cases, recurrent infarction and significant complications have not been reported.[78]

MARFAN SYNDROME

Marfan syndrome is an autosomal dominant genetic disorder caused by an abnormal gene for fibrillin on chromosome 15. Disease prevalence is estimated to be four to six per 10,000. Sporadic cases represent 15% of those diagnosed. The production of abnormal connective tissue results in the characteristic feature of the disease: aortic root dilation, dislocation of the optic lens, deformity of the anterior thorax, scoliosis, long limbs, joint laxity, and arachnodactyly. Diagnosis is usually based on family history and physical examination, including ocular, cardiovascular, and skeletal features.

Untreated, life expectancy is reduced by one third, with most deaths due to aortic dissection and rupture. Elective aortic repair is associated with a low mortality rate (1.5%), whereas emergent repair results in a much higher mortality rate (11.7%). Therefore, elective repair has been recommended when the aortic root diameter measures 5.5 to 6 cm. Using an absolute aortic diameter (AD) as an indication for surgery ignores relevant differences in aortic size associated with patients of different stature. These considerations are particularly important when caring for young women. An aortic ratio between measured and predicted AD can be calculated. The predicted diameter for young adults can be calculated: $AD_{predicted} = 1.02 + (0.98 \times \text{body surface area [BSA]})$. A ratio of less than 1.3 with a dilation rate of less than 5% per year suggests a low risk for a cardiovascular event.

The risk for aortic dissection is associated with the rate of change of blood pressure in the aorta over time in systole. Although simple reduction in blood pressure does not reduce the risk for dissection, β-blockade lowers the risk for reaching a clinical cardiac end point at 10 years from about 20% to 10%.

MARFAN SYNDROME IN PREGNANCY

Women	84
Pregnancies	241
Live births	181 (75%)
Miscarriages	38 (16%)
Terminations	17 (7%)
Fetal deaths	2 (0.8%)
Aortic events	8 (4.3%)
Dissection	6 (3.3%)*
Rapid dilation	2 (1.1%)*
Death	2 (1.1%)*

*Observed in patients with an aortic root diameter of less than 4 cm.

Literature surveys of case reports suggest a maternal mortality rate associated with Marfan syndrome in pregnancy in excess of 50%.[79] These case reports likely represent bias of reporting more severely affected pregnancies. Three population-based studies are summarized in the box, Marfan Syndrome in Pregnancy.[80-82] Aortic events, dissection or rapid dilation, occurred in 8% of cases. In seven of nine patients, the AD was known to be greater than 4 cm. Of the remaining two, one died due to aortic dissection and rupture without a diagnosis and without a measurement of AD; the other had a prior graft replacement. A second death was due to endocarditis associated with mitral valve prolapse.

These studies suggest that women with mild disease, an AD less than 4 cm, can attempt pregnancy with only

modest risk. The risk associated with more advanced disease is certainly greater. **Given the data available, a precise risk for death from aortic dissection or rupture cannot be quantified. Women with ADs greater than 5.5 cm should certainly be counseled to have graft and valve replacement before pregnancy.** They will then assume the risk associated with an artificial valve and the risk associated with the remaining aorta. These risks may be significant; however, adequate data do not exist to quantify the risks. Women with aortic roots greater than 4 cm but less than or equal to 5.5 cm are at significant risk, but aortic replacement may be premature. Fifty percent of the offspring of women with Marfan syndrome should be expected to have the disease.

Management of pregnancies affected by Marfan syndrome should begin with an accurate assessment of the aortic root. An absolute diameter or preferably an aortic ratio can be used to assess specific risk. The aortic root should be protected from hemodynamic forces with β-blockade. A resting HR of about 70 beats/minute can usually be achieved. Although β-blockade may potentially contribute to impaired fetal growth, this risk is outweighed by the maternal risk without such treatment.

Labor and delivery are managed with standard cardiac care, with particular emphasis on the prevention of tachycardia. Patients with aortic roots less than 4 cm can be delivered vaginally, reserving cesarean delivery for obstetrical indications. Some authors have recommended cesarean delivery for women with larger roots based on concerns about increased pressure in the aorta during labor. Data do not exist to make this a firm recommendation.

PULMONARY HYPERTENSION

Although pulmonary hypertension is fundamentally a pulmonary disease, the major pathologic impact is on the right side of the heart. The incidence of primary pulmonary hypertension is 1 to 2 per 1 million, with women affected more commonly than men. Secondary pulmonary hypertension may develop as a complication of cardiac disease such as mitral stenosis or secondary to intrinsic pulmonary disease. Drugs such as cocaine or appetite suppressants may also be associated with pulmonary hypertension. If left untreated, the median survival after diagnosis is 2.5 years.[83] More recently, survival has been reported to be 68% to 77% at 1 year, 40% to 56% at 3 years, and 22% to 38% at 5 years[84] As might be expected, right heart failure and NYHA class III/IV symptoms predict adverse outcome. General therapy may include limitation of extreme exercise, supplemental oxygen, diuresis, and in some cases anticoagulation.

Pulmonary vasodilator therapy generally improves symptoms, and lifestyle changes may improve survival. About 10% of patients will respond to high-dose calcium channel blockers. Of those who initially respond to nifedipine, the 5-year survival rate is 95%. Intravenous prostacyclin is associated with a larger response rate but also is associated with side effects such as headache, jaw pain, diarrhea, flushing, and leg pain. A chronic intravenous line is required, and the dose must be increased on a regular basis. The 5-year survival rate for those who require treatment with prostacyclin is 54%. Subcutaneous and oral and inhaled prostacyclin are also available, each having limitations because of the route or timing of delivery.

Sildenafil, a cyclic guanosine monophosphate phosphodiesterase inhibitor, increases the endogenous production of nitric oxide and therefore operates as a potent vasodilator. Treatment with sildenafil improves functional status and hemodynamic profile. Ease of administration is a significant advantage. Pharmacologic management of pulmonary hypertension requires a team with considerable experience.

The maternal mortality with severe pulmonary hypertension is reported to be as high as 50%.[85] Although a review of reported cases suggests an improvement in mortality from 30% between 1978 and 1996 to 17% between 1997 and 2007, the risk remains high. The improvement may be associated with the advent of vasodilator therapy. **Sudden, irreversible deterioration in the postpartum period is common. As many as 75% of deaths will occur postpartum.**[86]

The symptoms of pulmonary hypertension are nonspecific. Increasing fatigue and shortness of breath are associated with progressive right-sided heart failure but are also ubiquitous in pregnancy. They can easily be attributed to a presumed upper respiratory infection. Hoarseness may be a result of impingement on the laryngeal nerve by an enlarged pulmonary artery. Patients may exhibit disproportionate lower extremity edema or oxygen desaturation out of proportion for a presumed illness. The diagnosis can be confirmed with echocardiography, in which the velocity of the regurgitant jet across the tricuspid valve can estimate pulmonary systolic pressure. A dilated, hypokinetic RV with displacement of the intraventricular septum into the left ventricle suggests right-sided heart failure.

Pulmonary hypertension with right ventricular dysfunction is poorly tolerated in pregnancy. A mortality rate between 17% and 30% should be expected. Antepartum management often requires hospitalization. Oxygen therapy may reduce PVR and improve right ventricular performance. Pharmacologic treatment with pulmonary vasodilators may also be effective.[84,87] Anticoagulation with heparin should be considered. Worsening disease will usually be manifest by falling CO rather than rising right ventricular pressure. Labor and delivery should be managed with standard cardiac care, with particular attention to right ventricular filling as assessed by measurement of central venous pressure (CVP). **Although the RV requires adequate filling to generate forward flow against an elevated PVR modest elevations in CVP may precipitate increasing right ventricular dysfunction.** Given fluid mobilization postpartum and the potential need to treat volume loss associated with delivery, appropriate filling may be difficult to achieve. Aggressive diuresis may be required. Modest underloading or overloading of the RV can result in rapid decompensation and death.

Women with pulmonary hypertension and right ventricular dysfunction should be strongly discouraged from becoming pregnant. Because pulmonary artery pressures fall as the RV fails, the condition of the RV may be a more important consideration than an absolute systolic pulmonary pressure. Some women may consider pregnancy after a favorable response to treatment with pulmonary

vasodilators. In a small series, two women whose pulmonary pressures and right ventricular function had normalized carried three pregnancies successfully while being treated with nifedipine or prostacyclin. Neither experienced deterioration in their condition during the first year postpartum.

OTHER CONDITIONS

Young women may experience malignant ventricular arrhythmias due to idiopathic ventricular fibrillation, cardiomyopathy, long-QT syndrome, congenital heart disease, or hypertrophic cardiomyopathy. Implantable cardioverter-defibrillators (ICDs) can effectively protect them from sudden death. In a report of 44 pregnancies, no women experienced generator erosion or lead fractures due to the expanding pregnancy. Twenty-five percent experienced electrical discharges during pregnancy without complication.

Hypertrophic cardiomyopathy is a genetic condition usually inherited in an autosomal dominant pattern with variable penetrance. Although the condition can be subclassified, the physiologic impact of different forms is similar. Patients are at risk for malignant arrhythmia, diastolic dysfunction, and outflow tract obstruction. A risk for sudden death is suggested by a family history of sudden death, extreme hypertrophy (left ventricular wall ≥ 30 mm), a history of syncope, nonsustained ventricular tachycardia, and hypotension with exercise. Arrhythmia risk is managed with an ICD and β-blockade. Volume loading during pregnancy in the face of diastolic dysfunction may result in pulmonary edema. Serum BNP can be used to direct volume management with diuretics. Left ventricular outflow tract obstruction is uncommon in young women. Reduced ventricular filling associated with blood loss, dehydration, or tachycardia will increase the functional obstruction. Management of hypertrophic cardiomyopathy has been recently reviewed.[88]

Reviews of case reports suggest a maternal mortality rate of 1% to 2% in these cases.[89-91] Given the biases associated with case report–derived data, this estimate probably sets an upper limit of expected mortality. Thaman and colleagues[91] reported 271 pregnancies in 127 women with hypertrophic cardiomyopathy, which were only complicated by two cases of pulmonary edema postpartum that resolved with appropriate therapy. In pregnancy, increased blood volume and left ventricular dimension will tend to benefit the patient. Increased HR will not. β-Blockers are generally used to manage tachycardia and some arrhythmias. Implantable ICDs may also be used. Labor and delivery are managed with standard cardiac care, with particular emphasis to ensure generous left ventricular filling. **Excessive volume loading may reveal a stiff ventricle and diastolic dysfunction. In some patients, a relatively small increase in vascular volume results in a substantial increase in pulmonary pressure, pulmonary congestion, and desaturation.** Although diastolic dysfunction may be difficult to diagnose by echocardiography, careful attention to an O_2 saturation monitor during labor and postpartum can reveal the need for augmented diuresis. Supine hypotension must be carefully avoided, and obstetrical bleeding should be treated early and aggressively with volume replacement.

CRITICAL CARE: HEMODYNAMIC MONITORING AND MANAGEMENT

Diseases unique to pregnancy, the physiologic stresses of pregnancy, and the special conditions surrounding labor and delivery operate to create circumstances in which intensive care may be necessary more frequently than would be required among young nonpregnant individuals. Specialists in intensive care may not be familiar with the physiology of pregnancy and associated unique conditions such as preeclampsia or amniotic fluid embolus. They may also be unfamiliar with maternal-fetal physiologic relationships and decision making that must balance the needs of the mother and the fetus. **Therefore, obstetricians must be familiar with basic principles and techniques of critical care medicine in order to primarily manage critically ill pregnant women or to serve as valuable consultants to a critical care team.**

Acute indications for invasive hemodynamic monitoring can be broadly categorized based on questions of physiology (see box, Indications for Hemodynamic Monitoring). Severe preeclampsia, sepsis, acute respiratory distress syndrome (ARDS), pneumonia, previously undiagnosed heart disease, and fluid management after resuscitation from obstetrical hemorrhage are the most common conditions that require hemodynamic monitoring. Certain conditions, particularly maternal heart disease as discussed earlier, require a planned, prospective decision for invasive monitoring. In these cases, the therapeutic window for hemodynamic management is narrow, and knowledge of the patient's baseline, compensated hemodynamic status can serve as a goal for intrapartum management.

Indications for Hemodynamic Monitoring

1. Why is the patient hypoxic?
   - Are pulmonary capillary pressures high because of relative volume overload (e.g., mitral stenosis postpartum)?
   - Are pulmonary capillary pressures high because of depressed cardiac function (e.g., cardiomyopathy)?
   - Is capillary membrane integrity intact (e.g., ARDS, pneumonia)?
2. Why is the patient persistently hypertensive?
   - Is vascular resistance elevated?
   - Is cardiac output elevated?
3. Why is the patient hypotensive?
   - Is left ventricular filling pressure low (e.g., after hemorrhage)?
   - Is vascular resistance low (e.g., septic shock)?
4. Why is the patient's urine output low?
   - Is left ventricular filling pressure low, resulting in low cardiac output?
5. Is the patient expected to be unstable in labor?
   - Is the window of left ventricular filling narrow (e.g., aortic stenosis)?
   - Will normal physiologic changes associated with delivery be tolerated poorly (e.g., volume loading postpartum, mitral stenosis, pulmonary hypertension)?

In many cases, initial therapy can and should be based empirically on an understanding of the patient's pathophysiology. If subsequent interventions are needed, specific data obtained from hemodynamic monitoring may be required. Physicians with abundant experience treating a particular disease may rely less on invasive monitoring because an improved understanding makes the clinical course more predictable. In contrast, physicians with less experience may have a lower threshold for using invasive hemodynamic monitoring. Therefore, understanding principles of management is particularly important for obstetricians who do not necessarily anticipate critically ill patients in their practice.

Hemodynamic Monitoring

The objective of hemodynamic monitoring is to provide continuous assessment of systemic and intracardiac pressures and to provide the means to determine CO and, therefore, to calculate systemic and pulmonary resistances. An arterial catheter is usually placed in the radial artery to measure systemic pressure. The diastolic pressure obtained usually correlates well with noninvasive measurements. Systolic pressure may be significantly higher than noninvasive measurements because of a very brief peak in pressure in early systole. (The spike in pressure contributes little to MAP. The noninvasive measurement is usually more clinically relevant to the patient's condition. The arterial catheter permits easy access to arterial blood sampling and relieves the patient from the discomfort of frequent blood draws.

Measurement of intracardiac pressures and CO are obtained through the insertion of a catheter into the central venous circulation and advancement into and through the right side of the heart. Venous access is most commonly obtained through the right internal jugular vein; a subclavian approach may also be employed. Traditionally, insertion is guided by using the sternocleidomastoid muscle and the clavicle as landmarks. The higher-frequency ultrasound transducer found on a vaginal probe can also be used to facilitate insertion under direct visualization. Once central venous access has been obtained and confirmed, a pulmonary artery catheter can be "floated" into the right side of the heart and pulmonary artery. Figure 36-6 demonstrates the waveforms and normal pressure values found as the catheter passes through the heart. Success in floating the catheter is initially confirmed by observation of characteristic waveforms in the RV, pulmonary artery, and wedged position, and subsequently with a radiograph. In experienced hands, complications from pulmonary artery catheterization are uncommon and include pneumothorax (<0.1%), pulmonary infarction (0 to 1.3%), pulmonary artery rupture (<0.1%), and septicemia (0.5% to 2.0%). Arrhythmias are usually transient and associated with passage of the catheter through the RV. If the patient has significant pulmonary hypertension, difficulty may be encountered maintaining placement in the pulmonary artery.

Once the catheter has been successfully placed, continuous readings of CVP and pulmonary artery pressures can be obtained. By inflating the balloon at the catheter

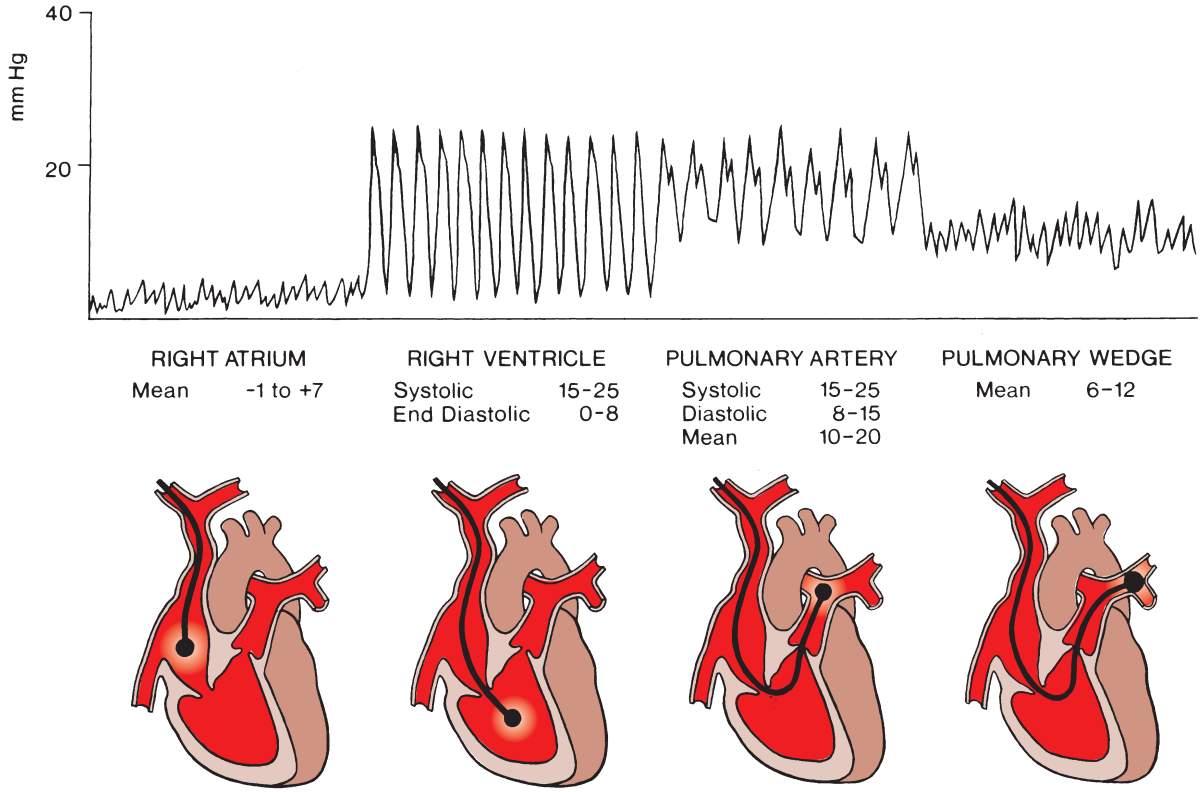

FIGURE 36-6. Hemodynamic waveforms and normal pressure values associated with catheter positions during advancement of a pulmonary artery catheter.

tip, the catheter can be wedged in the pulmonary artery to obtain a PAWP. PAWP reflects the filling pressure, preload, in the left ventricle. CVP measured in the right atrium is a measure of right ventricular filling pressure. In pregnant women, CVP cannot be assumed to accurately reflect left ventricular filling. Right atrial pressures and systolic pulmonary pressures can be measured noninvasively by echocardiography.

CO is measured by thermodilution. A bolus of cold fluid is injected into the right atrium, and a curve of temperature change over time is recorded as the bolus passes through the pulmonary artery. From the shape of the curve, CO can be calculated; when the CO is higher, the dilutional curve is shorter in time and greater in maximal temperature change. More recently, catheters have been equipped with a heating element in the right atrial segment so that continuous measurement of CO can be performed. CO can be measured noninvasively with Doppler and impedance techniques. Doppler technique has been validated under a wide range of clinical circumstances.[92-95] The impedance technique tends to underestimate CO in pregnancy but accurately reflects changes in hemodynamics in many conditions. In conditions of pathologically high flow, impedance may significantly underestimate CO.[96-98] CI can be derived from CO in order to adjust for maternal size: CI = CO/BSA. However, BSA does not seem to be related to CO in pregnancy; therefore, CO is usually preferred.[95] When CO is measured noninvasively and CVP is not available, resistance is expressed as TPR rather than SVR. In most clinical conditions, the differences between the two are not important.

Table 36-6 summarizes formulas used to calculate hemodynamic parameters not directly measured. Normal values for CO, MAP, HR, SV, and TPR are summarized in Figure 36-1. In a study of 10 normal pregnant women at term, Clark and coworkers determined that CVP, pulmonary artery pressure, PAWP, and left ventricular work index were not different from nonpregnant measurements made about 3 months postpartum.[99] The relationship between PAWP and left ventricular work index fell within the normal range for nonpregnant individuals, suggesting normal contractility in pregnancy. PVR was 34% lower, and colloid osmotic pressure was reduced by 14%.

TABLE 36-6 CALCULATED HEMODYNAMIC VARIABLES

		CALCULATION	UNITS
Mean arterial pressure	MAP	$\frac{sBP + 2(dBP)}{3}$	mm Hg
Stroke volume	SV	$\frac{CO \cdot 1000}{HR}$	mL
Systemic vascular resistance	SVR	$\frac{(MAP - CVP) \cdot 80}{CO}$	dyne · sec · cm^{-5}
Total peripheral resistance	TPR	$\frac{MAP \cdot 80}{CO}$	dyne · sec · cm^{-5}
Pulmonary vascular resistance	PVR	$\frac{80\,(mPAP - PAWP)}{CO}$	dyne · sec · cm^{-5}

CO, Cardiac output; *CVP*, central venous pressure; *dBP*, diastolic blood pressure; *mPAP*, mean pulmonary artery pressure; *PAWP*, pulmonary artery wedge pressure; *sBP*, systolic blood pressure.

Hemodynamic Management

Strategies of hemodynamic therapy that may be applicable to a variety of clinical circumstances are discussed in this section. As outlined earlier, the use of hemodynamic monitoring should be directed at answering specific questions of maternal pathophysiology. To achieve a particular goal, a number of physiologic interventions are possible. Each of these interventions will precipitate a secondary or compensatory response. The secondary response, if excessive, may adversely affect the patient. The choice of intervention from available options will often be determined by the potential for and magnitude of adverse effect. Hemodynamic monitoring permits the physician to choose an intervention and subsequently assess the positive and negative effects.

Disruption of alveolar capillary fluid dynamics is frequently associated with acute oxygen desaturation due to excess alveolar fluid. Pulmonary edema is usually due to excess hydrostatic capillary pressure (e.g., cardiomyopathy, mitral stenosis) or to a disruption of alveolar capillary membrane integrity (e.g., pneumonia, ARDS). Although a reduction in serum oncotic pressure is rarely a primary cause of pulmonary edema, the reduced serum albumin level in normal pregnancy can act in synergy with other forces, resulting in earlier or more severe pulmonary edema than would normally occur.

The use of pulse oximetry facilitates the early detection of maternal desaturation. Oxygen supplementation improves maternal saturation but does not correct the underlying cause. If desaturation is progressive, further intervention will be required. In the normal heart, diuresis to reduce preload works to decrease alveolar water in patients with elevated PAWP and in patients with capillary leak. A reduction in capillary pressure from high normal to low normal will reduce the egress of water across damaged membranes. In many circumstances, these interventions are made empirically based on a diagnosis and an understanding of maternal physiology. For example, tocolysis with β-mimetic agents can induce pulmonary edema. Timely diagnosis, discontinuation of the offending agent, oxygen supplementation, and a single diuretic dose will usually be sufficient therapy. When initial interventions do not achieve an adequate effect, invasive monitoring may be required to direct subsequent care. Maternal diuresis to improve oxygen saturation, when excessive, may lead to a reduction in CO. Fetal decompensation is usually encountered before a significant reduction in maternal perfusion and hypotension. The maternal PAWP and CO can be used to direct maternal diuresis. If desaturation continues despite hemodynamic management, intubation may be required. Positive end-expiratory pressure (PEEP) can be used to increase intra-alveolar pressure to impede the forces driving water into alveolar spaces. PEEP may impede venous return and decrease CO as a result of the effects of the associated increase in extracardiac intrathoracic pressure. A PAWP in excess of PEEP is required for adequate ventricular filling. Only in the sickest of pregnant women will PEEP have a clinically significant impact on CO.

Disorders of blood pressure and perfusion can be managed with the knowledge of maternal hemodynamics. Figure 36-7 describes the relationships between MAP, CO,

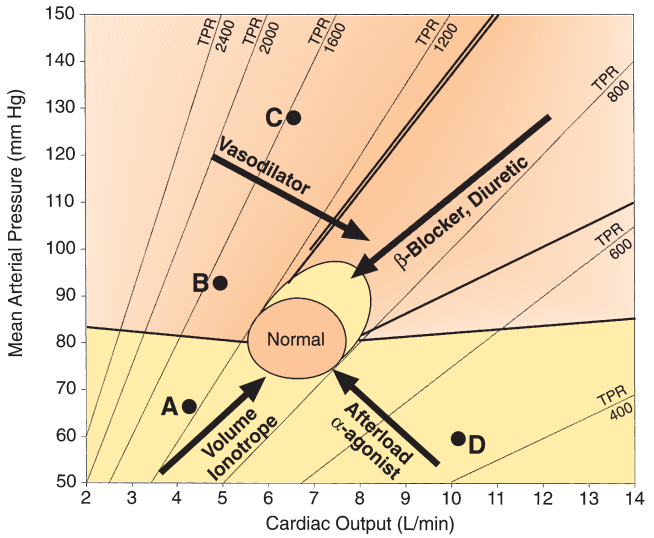

FIGURE 36-7. Hemodynamic flow chart. Cardiac output and mean arterial pressure are plotted on the *x*-axis and *y*-axis, respectively. *Diagonal lines* are isometric lines of vascular resistance. Anticipated vectors of change can be used to predict patient response to intervention. *TPR,* Total peripheral resistance.

and vascular resistance. CO and MAP are represented on the *x*-axis and *y*-axis, respectively. Resistance is represented by diagonal isometric lines. Vasodilators or vasopressors that act on resistance produce vectors of change that run perpendicular to lines of resistance. Interventions that decrease CO (β-blockers, diuresis) or increase CO (dopamine, volume) produce vectors of change that run roughly parallel to lines of resistance. The region labeled "normal" represents the goal of therapy. Plotting patient data on the chart allows one to visually determine the vector or combination of vectors that could return hemodynamics to normal.

Patient A represents a patient who is hypotensive with a low CO, as might be expected after hemorrhage or in heart failure. Given a low PAWP associated with hemorrhage, volume administration would be expected to create a vector that would return hemodynamics to normal. Alternatively, the patient could have a normal or high PAWP associated with heart failure and would need an inotropic agent such as dopamine. Patient B has a normal blood pressure but a high vascular resistance and low CO such as might be expected with a cardiomyopathy. Afterload reduction with a medication such as hydralazine will produce a vector of vasodilation and return hemodynamics to normal. Patient C is hypertensive with a mixed hemodynamic pattern. She will need a combination of vectors to approach normal hemodynamics (e.g., hydralazine and β-blocker). Patient D is hypotensive and hyperdynamic with a low vascular resistance. The hemodynamics might be found in a patient with early sepsis. Treatment with volume could increase pressure but at the expense of high filling pressures and a potentially negative impact on developing ARDS. Alternatively, a small dose of an α-adrenergic agent such as phenylephrine (Neo-Synephrine) would create a vector perpendicular to lines of resistance that return hemodynamics to normal.

KEY POINTS

- Hemodynamic changes in pregnancy may adversely affect maternal cardiac performance.
- Intercurrent events such as infection during pregnancy are usually the cause of decompensation.
- Women with heart disease in pregnancy frequently have unique psychosocial needs.
- Labor, delivery, and postpartum are periods of hemodynamic instability.
- The postpartum period can be characterized as a "perfect storm" of volume loading, tachycardia, and increased afterload—each of which may contribute to the destabilization of a pregnant woman with heart disease.
- Invasive hemodynamic monitoring should be used to address specific clinical questions.
- Many maternal heart conditions can be medically managed during pregnancy.
- Management of anticoagulation in women with mechanical valves requires an experienced team and careful consideration of the balance between maternal and fetal risk followed by appropriate counseling. Very aggressive therapeutic monitoring is required.
- Mothers with cyanotic heart disease are at particular risk for adverse fetal and neonatal outcomes.
- Eisenmenger syndrome, Marfan syndrome with a dilated aorta, and pulmonary hypertension with right heart dysfunction are associated with a very high risk for maternal mortality.
- Many women with congenital heart disease can successfully complete a pregnancy.
- Preconceptual counseling is based on achieving a balance between medical information and the patient's value system.

Pulmonary diseases are among the most common medical complications of pregnancy. The occurrence of pulmonary disease during gestation may result in increased morbidity or mortality for both the mother and her fetus. Pregnancy may have an adverse or positive impact on the pulmonary function of the gravida depending on the particular complication that is being encountered. The cardiorespiratory changes that occur in pregnancy are reviewed in Chapter 3, and the obstetrician and medical consultants should have a thorough understanding of these changes and their potential effects on the respiratory disease in question. It is also extremely important to realize that most diagnostic tests used to evaluate pulmonary function are not harmful to the fetus and, if indicated, should be performed during gestation. In this section, we discuss some of the respiratory complications that may be encountered during gestation, the impact of pregnancy on the disease, and the potential impact of the disease on pregnancy.

PNEUMONIA IN PREGNANCY

Pneumonia is an uncommon complication of pregnancy, observed in 0.78 to 2.7 per 1000 deliveries.[1,2] However,

pneumonia contributes to considerable maternal mortality and is reportedly the most common nonobstetrical infection to cause maternal mortality in the peripartum period.[3] Before the introduction of antibiotic therapy, maternal mortality was as high as 24%.[2] However, **with modern management and antibiotic therapy, the maternal mortality rate ranges from 0% to 4%.**[1,3,4] **Preterm delivery is a significant complication of pneumonia and, even with antibiotic therapy and modern management, continues to occur in 4% to 43% of affected pregnancies.**[1,3,4]

The incidence of pneumonia in pregnancy may be increasing primarily as a reflection of the declining health status of certain segments of the childbearing population.[1] In addition, the epidemic of human immunodeficiency virus (HIV) infection has increased the number of potential mothers who are at risk for opportunistic lung infections. HIV infection further predisposes the pregnant woman to the infectious complications of the acquired immunodeficiency syndrome (AIDS).[5] Reported incidence rates range from 97 to 290 cases per 1000 HIV-infected persons per year.[6] **HIV-infected persons are 7.8 times more likely to develop pneumonia** than non-HIV-infected individuals with similar risk factors.[6] Women with medical conditions that increase the risk for pulmonary infection, such as cystic fibrosis, are now living to childbearing age more frequently than in the past. This disorder also contributes to the increased incidence of pneumonia in pregnancy.

Pneumonia can complicate pregnancy at any time during gestation and may be associated with preterm birth, poor fetal growth, and perinatal loss. Benedetti and colleagues[3] described 39 cases of pneumonia in pregnancy. Sixteen gravidas presented before 24 weeks' gestation, 15 between 25 and 36 weeks' gestation, and 8 after 36 weeks' gestation. Twenty-seven patients in this series were followed to completion of pregnancy; only 2 required delivery during the acute phase of pneumonia. Of these 27 patients, 3 suffered a fetal loss, and 24 delivered live fetuses. There was one neonatal death due to prematurity.[1] Madinger and associates[4] reported 25 cases of pneumonia occurring among 32,179 deliveries and observed that fetal and obstetrical complications were much more common than in earlier studies. **Preterm labor occurred in 11 of 21 patients who had complete follow-up data. Pneumonia was present at the time of delivery in 11 patients. Preterm labor was more likely in those women who experienced bacteremia, required mechanical ventilation, or had a serious underlying maternal disease.** In addition to the complication of preterm labor, there were three perinatal deaths in this series. In Berkowitz and La Sala's report[1] of 25 patients with pneumonia complicating pregnancy, full-term delivery of normally grown infants occurred in 14 women, 1 delivered preterm, 3 had a voluntary termination of pregnancy, 3 had term deliveries of growth-restricted babies, and 4 were lost to follow-up. Birthweight was significantly lower in the study group (2770 ± 224 g versus 3173 ± 99 g in the control group; P <.01). In this series, pneumonia complicated 1 in 367 deliveries, and the authors attributed the increase in the incidence of pneumonia in this population to a decline in general health status, including anemia and a significant incidence of cocaine use in the study group (52 versus 10% in the general population) as well as HIV positivity in the study group (24 versus 2% in controls). **Madinger[4] reported preterm labor in 44% of cases with antepartum pneumonia, with a preterm birth rate of 36%. Maternal complications of pneumonia include respiratory failure and mechanical ventilation in 10% to 20%, bacteremia in 16%, and empyema in 8%.**[1,4] Respiratory failure due to pneumonia accounts for 12% of intubations during pregnancy.[7]

BACTERIOLOGY

Most series describing pneumonia complicating pregnancy have used incomplete methodologies to diagnose the etiologic pathogens involved, relying primarily on cultures of blood and sputum. In most cases, no identifiable pathogen is reported; however, ***Streptococcus pneumoniae*** **and** ***Haemophilus influenzae*** **remain the most common identifiable causes of pneumonia in pregnancy.**[1,3] Because comprehensive serologic testing has rarely been undertaken, the true incidence of viral pneumonia, *Legionella*, and *Mycoplasma* pneumonia in pregnancy is difficult to estimate. In Berkowitz and La Sala's series, one patient had *Legionella* species.[1] **Several unusual pathogens have been reported to cause pneumonia in pregnancy, including mumps, infectious mononucleosis, swine influenza, influenza A, varicella, coccidioidomycosis, and other fungi.**[8] **Varicella pneumonia complicates primary varicella infections in 9% of infections in pregnancy, compared with 0.3% to 1.8% in the nonpregnant population.**[9] Influenza A has a higher mortality in pregnant than in nonpregnant patients.[10] **The increase in virulence of viral infections reported in pregnancy may be secondary to the alterations in maternal immune status that characterize pregnancy, including reduced lymphocyte proliferative response, reduced cell-mediated cytotoxicity, and a decrease in the number of helper T lymphocytes** (see Chapter 4).[11,12] Viral pneumonias can also be complicated by superimposed bacterial infection, particularly with pneumococcus. **There are recent reports of community-acquired methicillin-resistant** ***Staphylococcus aureus*** **(CA-MRSA) causing necrotizing pneumonia in pregnancy and the postpartum period.**[11-13]

Chemical pneumonitis results after the aspiration of gastric contents. Chemical pneumonitis can be superinfected with pathogens present in the oropharynx and gastric juices, primarily anaerobes and gram-negative bacteria.[8]

Heterosexual transmission of HIV has become an increasingly important mode of transmission. Many of these women are of childbearing age. They are at risk for developing *Pneumocystis jiroveci* pneumonia (PJP) during pregnancy. The reported maternal mortality rate from PJP is as high as 50%.[14] Although the risk for maternal mortality is high with PJP infection, most HIV-infected pregnant women in the United States today are receiving prophylaxis. This practice may actually lead to a decrease in the incidence and mortality from PJP pneumonia in pregnancy.

BACTERIAL PNEUMONIA

S. pneumoniae **(pneumococcus) is the most common bacterial pathogen to cause pneumonia in pregnancy, with**

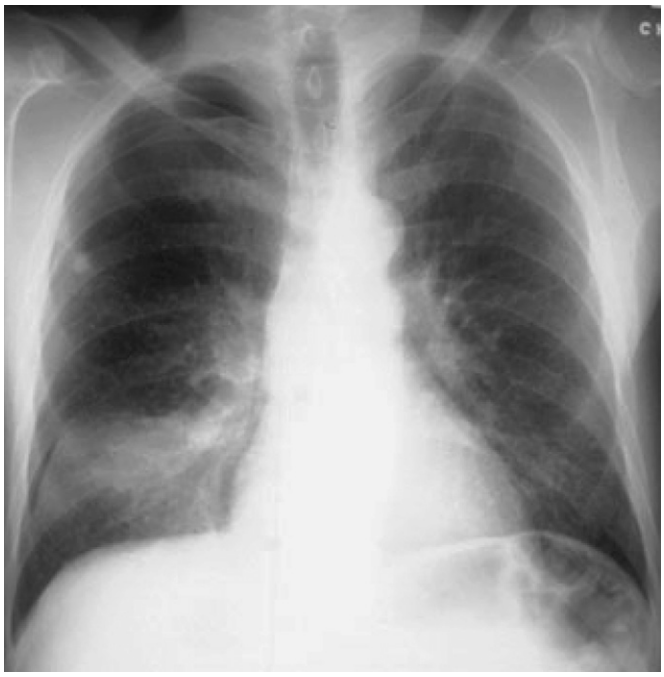

FIGURE 37-1. Right lower lobe pneumonia.

***H. influenzae* being the next most common.** These pneumonias typically present as an acute illness accompanied by fever, chills, purulent productive cough, and a lobar pattern on chest radiograph (Figure 37-1). **Streptococcal pneumonia produces a "rusty" sputum, with gram-positive diplococci on Gram stain and asymmetrical consolidation with air bronchograms on chest radiograph. *H. influenzae* is a gram-negative coccobacillus that produces consolidation with air bronchograms, often in the upper lobes. Less frequent bacterial pathogens include *Klebsiella pneumoniae,* which is a gram-negative rod that causes extensive tissue destruction, with air bronchograms, pleural effusion, and cavitation noted on chest radiograph. Patients with *S. aureus* pneumonia present with pleuritis, chest pain, purulent sputum, and consolidation without air bronchograms noted on chest radiograph. CA-MRSA can present with a viral-like prodrome that progresses to severe pneumonia with high fever, hypotension, and hemoptysis followed by septic shock and need for ventilator support.[11] Severe cases of CA-MRSA have been reported during influenza seasons or associated with a preceding influenza illness in 33% to 71% patients.[11] Leukopenia can be observed and has been found to be a predictor of poor outcome.[11] Patients can present with multilobar infiltrates and cavitation. Mortality from CA-MRSA pneumonia in the United States and Europe is reportedly greater than 50%.**

Patients with atypical pneumonia pathogens, such as ***Mycoplasma pneumoniae, Legionella pneumophila,* and *Chlamydia pneumoniae* (TWAR agent), present with gradual onset and a lower fever, appear less ill, and have a mucoid sputum and a patchy or interstitial infiltrate on chest radiograph.** The severity of the findings on chest radiograph is usually out of proportion to the mild clinical symptoms. ***M. pneumoniae* is the most common organism responsible for atypical pneumonia and is best detected by the presence of cold agglutinins, which are present in 70% of cases.**

The normal physiologic changes in the respiratory system associated with pregnancy result in a loss of ventilatory reserve. This, coupled with the relative immunosuppression that accompanies pregnancy, puts the mother and fetus at great risk from respiratory infection. **Therefore, any gravida suspected of having pneumonia should be managed aggressively. Hospital admission is generally recommended**, and an investigation should be undertaken to determine the pathologic etiology. A recent study examined 133 women admitted with pneumonia during pregnancy using protocols based on the British and American Thoracic Societies' admission guidelines for management in nonpregnant individuals.[15] The authors reported that if the American Thoracic Society guidelines were used, 25% of the pregnant women with pneumonia could have avoided admission.[16] Using the American criteria, none of the gravidas who would have been managed as an outpatient had any complications.[17] If the British Thoracic Society guidelines had been used, 66% of the pregnant women in this group would have been assigned to outpatient therapy. However, of those, 14% would have required readmission for complications. Of note, most of the 133 women who were hospitalized with pneumonia in this study did not receive a chest radiograph for confirmation of diagnosis. This limits the value of the study for use in guiding admission criteria for pneumonia in pregnancy. **Therefore, until additional information is available, admission for all pregnant women with pneumonia is prudent.**

Workup should include physical examination, arterial blood gases, chest radiograph, sputum for Gram stain and culture, as well as blood cultures. Several recently published studies have called into question the use of cultures to identify the microbiology of community-acquired pneumonia. **The successful identification of the bacterial etiology with cultures ranges from 2.1% to about 50%.[18,19] Review of available clinical data reflects an overall reliance on clinical judgment and the patient response to treatment to guide therapy.** There are other tests available to identify the etiology of pneumonia that do not require culture and are more sensitive and specific. **An assay approved by the U.S. Food and Drug Administration (FDA) for pneumococcal urinary antigen has been assessed in several studies.[20] The sensitivity for identifying pneumococcal disease in adults is reportedly 60% to 90%, with specificity close to 100%.**[20] In one study, the pneumococcal antigen was detected in 26% of patients in whom no pathogens had been identified.[21] This suggests that cases that are undiagnosed by standard testing can be identified with the assay. In this study, **10% of samples from patients with pneumonia caused by other agents were positive for the pneumococcal assay, indicating a potential problem with specificity.[21] Therefore, if the response to therapy directed at pneumococcus is inadequate, coverage for other potential pathogens should be added. There is a test for *Legionella* urinary antigen as well, with a sensitivity of 70% and specificity of 90% for serogroup 1.**[22] This is especially useful in the United States and Europe because about 85% of *Legionella* isolates are serogroup 1.[22] Legionella is a common cause of severe community-acquired pneumonia. Therefore, the urinary antigen for serogroup 1 should be considered for any patient requiring admission into an intensive care unit (ICU) for pneumonia.[22]

Percutaneous transthoracic needle aspiration (PTNA) has been advocated as a valuable and safe method to increase the chance of establishing a causative agent in pneumonia.[23] This test should be reserved for use in compromised individuals, suspected tuberculosis (TB) in the absence of a productive cough, selected cases of chronic pneumonia, pneumonia associated with neoplasm or foreign body, suspected PJP pneumonia, and suspected conditions that necessitate lung biopsy.[17]

When admission for pneumonia is required, there is evidence that inpatient and 30-day mortality has been reduced when antibiotics are administered in less than 8 hours. **Therefore, current U.S. federal standards require that the first dose of antibiotics be administered within 4 hours of arrival to the hospital.**[24] **Empirical antibiotic coverage should be started, usually with a macrolide for mild illness with addition of a β-lactam for severe illness.** Yost and colleagues demonstrated that monotherapy with erythromycin was adequate in 118 of 119 women with pneumonia in pregnancy.[15] **A macrolide combined with a β-lactam is safe and will provide adequate coverage for most community-acquired bacterial pneumonias, including *Legionella*.** Dual coverage has been demonstrated to improve response to therapy even for abbreviated macrolide regimens.[17] This is theoretically because of an added anti-inflammatory effect of the macrolides.[19] Azithromycin administration has been shown to be an independent predictor of positive outcome and reduced length of hospital stay in mild to moderate community-acquired pneumonia.[17] However, **the use of macrolides to treat community-acquired pneumonia should be limited when possible because their use has also been associated with increased penicillin resistance among patients with *S. pneumoniae*.**[25]

Once the results of the antigen, sputum culture, blood cultures, Gram stain, and serum studies are obtained and a pathogen has been identified, antibiotic therapy should be directed toward the identifiable pathogen. **The quinolones as a class should be avoided in pregnancy because they may damage developing fetal cartilage. However, with the emergence of highly resistant bacterial pneumonia, their use may be life-saving and therefore justified in specific circumstances.** The respiratory quinolones are not only effective against highly penicillin-resistant *S. pneumoniae* strains, but their use reportedly does not increase resistance.[25-27] **The respiratory quinolones include levofloxacin, gatifloxacin, and moxifloxacin. These are ideal agents for community-acquired pneumonia because they are highly active against penicillin-resistant strains of *S. pneumoniae*. They are also active against *Legionella* and the other atypical pulmonary pathogens.** Another advantage is a favorable pharmacokinetic profile, such that blood/lung levels are the same whether the drug is administered orally or intravenously.[28] Arguments against more extensive respiratory quinolone use are based on concerns about the potential for developing resistance, the variable incidence of *Legionella*, and cost. An additional caveat is that the respiratory quinolones are partially effective against mycobacterial TB. Therefore, evaluation for this infection should be done when considering the use of quinolones for pneumonia. **If CA-MRSA pneumonia is suspected, vancomycin or linezolid should be added to empirical therapy.**[11] Additional therapy with clindamycin can be considered in difficult-to-treat cases because it has been shown to reduce production of staphylococcal exotoxins.[26] **CA-MRSA is susceptible to fluoroquinolones and trimethoprim-sulfamethoxazole and often are only resistant to β-lactams.**[11]

In addition to antibiotic therapy, oxygen supplementation should be given. Frequent arterial blood gas measurements should be obtained. **Arterial saturation should be monitored with pulse oximetry, with a goal of maintaining the Po_2 at 70 mm Hg, a level necessary to ensure adequate fetal oxygenation. When the gravida is afebrile for 48 hours and has signs of clinical improvement, an oral cephalosporin or macrolide, or both, can be initiated and intravenous therapy discontinued. A total of 10 to 14 days of treatment should be completed.**

Pneumococcal polysaccharide vaccination prevents pneumococcal pneumonia in otherwise healthy populations, with an efficacy of 65% to 84%.[17] **The vaccine is safe in pregnancy** and should be administered to high-risk gravidas. Those at high risk include individuals with sickle cell disease secondary to autosplenectomy, patients who have had a surgical splenectomy, and individuals who are immunosuppressed. **An additional advantage to maternal immunization with the pneumococcal vaccine is that several studies have demonstrated a significant transplacental transmission of vaccine-specific antibodies.**[27] **After in utero exposure to the vaccine, there are significantly high concentrations of pneumococcal antibodies in infants at birth and at 2 months of age.**[27] **In addition, colostrum and breast milk antibodies are significantly increased in women who have received the pneumococcal vaccine.**[28]

Pneumonia in pregnancy can be complicated by respiratory failure requiring mechanical ventilation. In such cases, team management should include the obstetrician, maternal-fetal medicine specialist, and intensivist. In addition to meticulous management of the gravida's respiratory status, maintenance of the left lateral recumbent position is advocated to improve uteroplacental perfusion. **The potentially viable fetus should be monitored with continuous fetal monitoring. Serial ultrasound examinations for amniotic fluid index (AFI) and growth will help to guide clinical management. If positive end-expiratory pressure (PEEP) greater than 10 cm H_2O is required to maintain oxygenation, central monitoring with a pulmonary artery catheter should be instituted to adequately monitor volume status** and maintain maternal and uteroplacental perfusion. **There is no evidence that elective delivery results in an overall improvement in respiratory function.**[29] Therefore, elective delivery should be undertaken with caution. **However, if there is clear evidence of fetal compromise or profound maternal compromise and impending demise, delivery should be accomplished.**

VIRAL PNEUMONIAS

Influenza Virus

There are an estimated 4 million cases of pneumonia complicating influenza annually in the United States, and this is the sixth leading cause of death in this country.[30] Although three types of influenza virus can cause human disease (types A, B, and C), **most epidemic infections are due to influenza A.**[8] **Influenza A typically has an acute onset after**

a 1- to 4-day incubation period and first manifests as high fever, coryza, headache, malaise, and cough. In uncomplicated cases, the chest examination and chest radiograph remain clear.[8] **If symptoms persist longer than 5 days, especially in a pregnancy, complications should be suspected.** Pneumonia may complicate influenza as the result of either secondary bacterial infection or primary viral infection of the lung parenchyma. **In the epidemic of 1957, autopsies demonstrated that pregnant women died from fulminant viral pneumonia most commonly, whereas nonpregnant patients died most often from secondary bacterial infection.**[31] A large nested case-control study evaluated the rate of influenza-related complications over 17 influenza seasons in women enrolled in the Tennessee Medicaid system.[32] This study demonstrated a high risk for hospitalization for influenza-related reasons in low-risk pregnant women during the last trimester of pregnancy. The authors predicted that 25 of 10,000 women in the third trimester during the influenza season will be hospitalized with influenza-related complications.[32] **A more recent matched cohort study using the administrative database of pregnant women enrolled in the Tennessee Medicaid population examined pregnant women aged 25 to 44 years with respiratory hospitalization during influenza seasons in 1985 to 1993.**[33] **In this population of pregnant women, those with asthma accounted for half of all respiratory hospitalizations during influenza season. Of pregnant women with the diagnosis of asthma, 6% required respiratory hospitalization during the influenza season** (odds ratio [OR], 10.63; 95% confidence interval [CI], 8.61 to 13.83) compared with women without a medical comorbidity. This study detected no significant increases in adverse perinatal outcome associated with respiratory hospitalization during flu season.[33]

Early data on pandemic 2009 influenza A(H1N1) suggest pregnant women had an increased risk for hospitalization and death. Siston and associates identified 788 pregnant women in the United States with 2009 influenza A (H1N1).[34] Thirty died (5% of all reported 2009 influenza A [H1N1] influenza deaths in this period). Among 509 hospitalized women, 115 (22.5%) were admitted to an ICU. **Pregnant women who began treatment more than 4 days after symptom onset were more likely to be admitted to an ICU (56.9% vs. 9.4%; relative risk [RR], 6.0; 95% confidence interval [CI], 3.5 to 10.6) than those treated within 2 days after symptom onset.**[34]

Primary influenza pneumonia is characterized by rapid progression from a unilateral infiltrate to diffuse bilateral disease. The gravida may develop fulminant respiratory failure requiring mechanical ventilation and PEEP. **When pneumonia complicates influenza in pregnancy, antibiotics should be started, directed at the likely pathogens that can cause secondary infection, including *S. aureus,* pneumococcus, *H. influenza,* and certain enteric gram-negative bacteria. Antiviral agents, such as amantadine and ribavirin, can be considered. It has been recommended that the influenza vaccine be given routinely to gravidas in pregnancy during the flu season** (October to March) regardless of the trimester in order to prevent the occurrence of influenza and the development of secondary pneumonia. In addition to maternal protection, **prospective studies have demonstrated higher cord blood antibody levels to influenza in babies born to mothers who were immunized during pregnancy.** There is a delay in the onset and decrease in severity of influenza in infants who have higher antibody levels.[35]

Varicella Virus

Varicella zoster is a DNA virus that usually causes a benign self-limited illness in children but may infect up to 2% of all adults.[36] **Varicella infection occurs in 0.7 of every 1000 pregnancies.**[37] Pregnancy may increase the likelihood of varicella pneumonia complicating the primary infection.[37,38] **Varicella pneumonia occurs most often in the third trimester, and the infection is likely to be severe.**[37,38] The **maternal mortality from varicella pneumonia may be as high as 35% to 40%, compared with 11% to 17% in nonpregnant individuals. One review reported a decreased mortality with only three deaths in 28 women with varicella pneumonia.**[37] **A recent paper described 347 pregnant women with varicella-zoster viral infection. Of these, 18 (5.2%) had pneumonia treated with acyclovir. None of these women died.** The authors also noted that **women with varicella-zoster viral pneumonia were significantly more likely to be current smokers (OR, 5.1; 95% CI, 1.6 to 16) and to have 100 or more skin lesions.**[39]

Varicella pneumonia usually presents 2 to 5 days after the onset of fever, rash, and malaise and is heralded by the onset of pulmonary symptoms, including cough, dyspnea, pruritic chest pain, and hemoptysis. The severity of the illness may vary from asymptomatic radiographic abnormalities to fulminant pneumonitis and respiratory failure (Figure 37-2). **All gravidas with varicella pneumonia should**

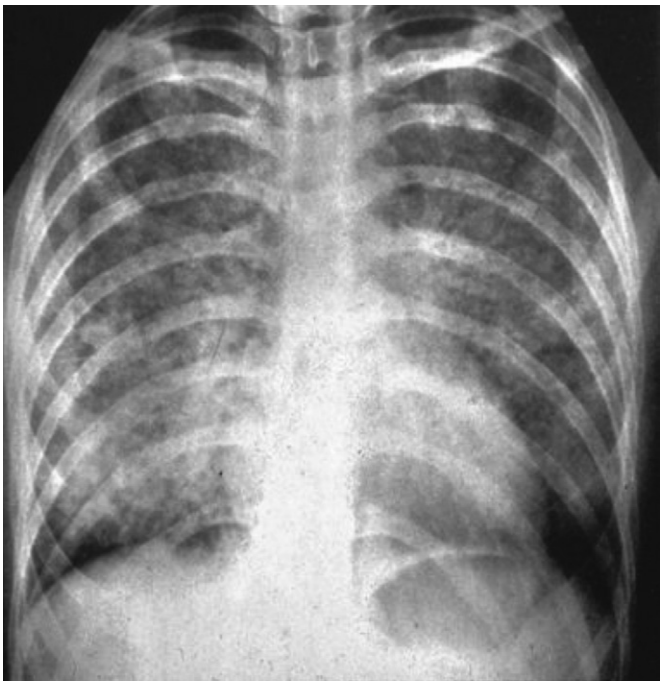

FIGURE 37-2. This chest radiograph demonstrates bilateral nodular and interstitial pneumonia characteristic of varicella pneumonia. The patient, a 27-year-old gravida 6, para 2, abortus 3 woman, was exposed to varicella infection in her two children. Characteristic skin vesicles of varicella occurred several days before the development of pulmonary symptoms. She required endotracheal intubation and mechanical ventilation for 6 days. She was treated with intravenous acyclovir and ceftazidime for possible superimposed infection. The patient recovered fully and delivered a healthy infant at term.

be aggressively treated with antiviral therapy and admitted to the ICU for close observation or intubation, if indicated. Acyclovir, a DNA polymerase inhibitor, should be started. **The early use of acyclovir has been associated with an improved hospital course after the fifth day and a lower mean temperature, lower respiratory rate, and improved oxygenation and survival.**[40] **The use of acyclovir is associated with improved survival as well.**[40] **Treatment with acyclovir is safe in pregnancy.** Among 312 exposed pregnancies, there was no increase in the number of birth defects and no consistent pattern of congenital abnormalities.[41] **A dose of 7.5 mg/kg intravenously every 8 hours has been recommended.** The use of varicella immune globulin to prevent infection in individuals exposed to varicella is not possible as it is no longer available in the United States.

Varicella vaccine is a live attenuated vaccine. It is the first vaccine against the herpesvirus. Extensive prelicensure studies have demonstrated that the **vaccine is safe and efficacious against varicella. Varicella vaccine was added to the universal childhood immunization schedule in the United States in 1995.** The program of universal childhood vaccination against varicella in the United States **has resulted in a sharp decline in the rate of death due to varicella.**[42] **This vaccine is not recommended for use in pregnancy.** However, the overall decline in the incidence of varicella secondary to vaccination will likely result in a decreased incidence of varicella infection and varicella pneumonia in pregnancy. **A recent study assessed the risk for congenital varicella syndrome and other birth defects in offspring of women who inadvertently received varicella vaccine during pregnancy or within 3 months of conception.**[43] **Fifty-eight women received their first dose of varicella vaccine during the first or second trimester. No cases of congenital varicella syndrome were identified among 56 live births** (rate, 0%; 95% CI, 0 to 15.6). Among the prospective reports of live births, five congenital anomalies were reported. No specific pattern of anomalies was identified in either the susceptible cohort or the sample population as a whole. Although the numbers in the study are small, the results should provide some reassurance to health care providers and women with inadvertent exposure before or during pregnancy.[43]

Pneumocystis jiroveci Pneumonia

PJP (formerly *Pneumocystis carinii* pneumonia, or PCP) remains the most prevalent opportunistic infection in patients infected with HIV.[44] **PJP, an AIDS-defining illness, occurs more frequently when the helper T-cell count ($CD4^+$) is less than 200 cells/mm^3.**[44] **When AIDS is complicated by PJP, the mortality rate is 10% to 20% during the initial infection, but this rate can increase substantially with the need for mechanical ventilation.** The transmission of *Pneumocystis* is not fully understood. There is some evidence that person-to-person transmission is the most likely mode; however, acquisition from environmental sources may also occur.[44]

The symptoms of PJP are nonspecific, and therefore, it may be difficult to diagnose. **Typical radiographic features of PJP are bilateral perihilar interstitial infiltrates that become increasingly homogeneous and diffuse as the disease progresses** (Figure 37-3). **The diagnosis of PJP requires microscopic examination to identify *Pneumocystis* from a clinical source such as sputum, bronchoalveolar fluid, or lung tissue** (Figure 37-4). *Pneumocystis* cannot be propagated in culture. The fungus has trophic forms as well as a cyst state. These can be detected with a modified Papanicolaou, Wright-Giemsa, or Gram-Weigert stain.[44] **Monoclonal antibodies are useful for detecting *Pneumocystis* as well.** The application of polymerase chain reaction (PCR) to detect *Pneumocystis* has been an area of active research and may be valuable for detection in sputum and bronchoalveolar lavage fluid.[44] **Trimethoprim-sulfamethoxazole is the preferred treatment for PJP. Thus far, resistance to this therapeutic agent has not been identified.**[44]

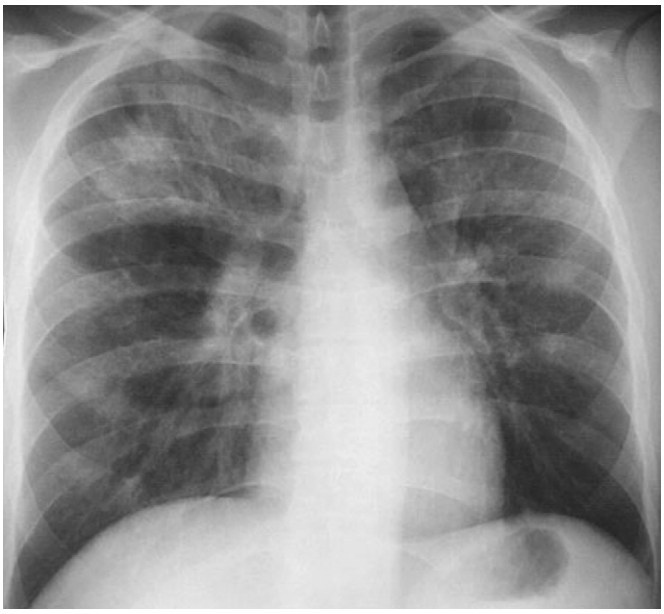

FIGURE 37-3. *Pneumocystis jiroveci (carinii)* pneumonia with mixed interstitial and alveolar opacities, ground-glass appearance.

A significant number of new infections with HIV are occurring in women of childbearing age. **As of 1995, more than 80% of women with AIDS were of reproductive age. PJP pneumonia is the most common cause of AIDS-related death in the United States.** Literature on PJP in pregnancy is scarce. A report describes five cases of PJP in pregnancy and also reviews the literature.[45] **In this series of 22 pregnant women with PJP, 11 patients (50%) died of pneumonia. The incidence of respiratory failure in this series was 59%.** In individuals who required mechanical ventilation, the survival rate was 31%. The average gestational age was 25 weeks, with a range of 6 weeks' gestation up to 1 week postpartum. Fifteen of the 22 patients had $CD4^+$ counts performed, and the mean was 93 cells/mm^3. The patients in this series were treated with a variety of regimens, including trimethoprim-sulfamethoxazole alone, trimethoprim-sulfamethoxazole and steroids, and pentamidine. Six patients received trimethoprim-sulfamethoxazole alone, and six were given trimethoprim-sulfamethoxazole and steroids; four patients (66%) survived in each group. Only 12 babies survived; there were five stillbirths, and four neonates died shortly after birth. In this series, **PJP pneumonia complicating**

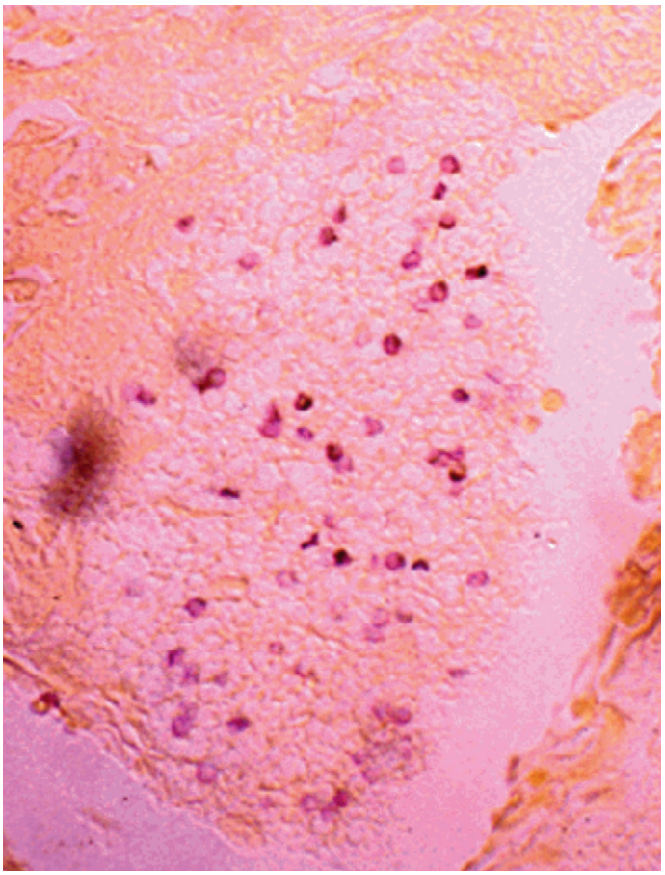

FIGURE 37-4. Wright-Giemsa stain of *Pneumocystis jiroveci (carinii)* pneumonia.

pregnancy in the third trimester had a better maternal and fetal outcome compared with disease in the first or second trimester. There was also a suggestion that treatment with trimethoprim-sulfamethoxazole with or without steroids was associated with an increased survival rate.[45]

The high mortality rate in this series may be skewed by the fact that this is a retrospective review, and severe cases are more likely to be reported than mild ones. In addition, all the women in this series were unaware of their HIV infection until the diagnosis of PJP was made. Therefore, none had received PJP prophylaxis.[45]

In summary, PJP pneumonia remains a dreaded complication of HIV infection and an AIDS-defining illness. There is a very high maternal and fetal mortality rate when PJP complicates pregnancy. **Primary prophylaxis against PJP with trimethoprim-sulfamethoxazole in HIV-infected adults, including pregnant women and patients receiving highly active antiretroviral therapy (HAART), should begin when the CD4$^+$ count is less than 200 cells/mm^3 or there is a history of oropharyngeal candidiasis**[46] (see Chapter 50). Prophylaxis should be discontinued when the CD4$^+$ cell count increases to more than 200 cells/mm^3 for a period of 3 months.[44] The use of HAART, as well as prophylaxis with trimethoprim-sulfamethoxazole, may decrease the incidence of PJP pneumonia in developed countries. However, many countries worldwide do not have the resources for HAART and, therefore, remain a reservoir for infection with PJP.

TABLE 37-1 HIGH-RISK FACTORS FOR TUBERCULOSIS

- Close contact with persons known or suspected to have tuberculosis
- Medical risk factors known to increase risk for disease if infected
- Birth in a country with a high tuberculosis prevalence
- Medically underserved status
- Low income
- Alcohol addiction
- Intravenous drug use
- Residency in a long-term care facility (e.g., correctional institution, mental institution, nursing home or facility)
- Health professionals working in high-risk health care facilities

TABLE 37-2 CLINICAL RISK FACTORS FOR DEVELOPING ACTIVE TUBERCULOSIS

- HIV infection
- Recent tuberculosis infection
- Injection drug use
- Silicosis
- Solid organ transplantation
- Chronic renal failure
- Jejunoileal bypass
- Diabetes mellitus
- Carcinoma of head or neck
- Underweight by >15%
- Human immunodeficiency virus infection

TUBERCULOSIS IN PREGNANCY

The incidence of TB in the United States began to decline in the early part of the 20th century and fell steadily until 1953, when the introduction of isoniazid led to a dramatic decrease in the number of cases, from 84,000 cases in 1953 to 22,255 cases in 1984.[47] However, since 1984, there have been significant changes in TB morbidity trends. **From 1985 through 1991, reported cases of TB increased by 18%, representing about 39,000 more cases than expected had the previous downward trend continued. This increase is due to many factors, including the HIV epidemic, deterioration in the health care infrastructure, and significantly more cases among immigrants.**[47] **The emergence of drug-resistant TB has also become a serious concern. In New York City, in 1991, 33% of TB cases were resistant to at least one drug, and 19% were resistant to both isoniazid (INH) and rifampin (RIF).**[48] Between 1985 and 1992, the number of TB cases in women of childbearing age increased by 40%.[47] One report noted TB-complicated pregnancies in 94.8 cases per 100,000 deliveries between 1991 and 1992.[49,50]

Diagnosis

Most gravidas diagnosed with TB in pregnancy are asymptomatic. The American Thoracic Society and the Centers for Disease Control and Prevention issued a statement on targeted tuberculin testing for latent tuberculosis infection (LTBI).[51] This is a strategic component of TB control that identifies persons at high risk for developing TB who would benefit by treatment of LTBI, if detected. **Persons at risk include those who have had recent infection with TB and those who have clinical conditions that are associated with an increased risk for progression of LTBI to active TB** (Tables 37-1 and 37-2).

All gravidas at high risk for TB should be screened with subcutaneous administration of intermediate-strength purified protein derivative (PPD).[52] If anergy is suspected, control antigens such as candida, mumps, or tetanus toxoids should also be placed. **The sensitivity of the PPD is 90% to 99% for exposure to TB. The tine test is not recommended for screening because of its low sensitivity.**

The onset of the recent TB epidemic stimulated the need for rapid diagnostic tests using molecular biology methods to detect *Mycobacterium tuberculosis* in clinical specimens. **Two direct amplification tests (DATs) have been approved by the FDA: the *Mycobacterium tuberculosis* Direct test (MTD; Gen-Probe, San Diego, CA) and the Amplicor *Mycobacterium tuberculosis* (Amplicor MTB) test (Roche Diagnostic Systems, Branchburg, NJ).**[53] Both tests amplify and detect *M. tuberculosis* 16S ribosomal DNA. When testing acid-fast stain smear-negative respiratory specimens, the specificity remains greater than 95%, but the sensitivity ranges from 40% to 77%.[53,54] **To date, these tests are FDA approved only for testing acid-fast stain smear-positive respiratory specimens obtained from untreated patients or those who have received no more than 7 days of anti-TB therapy.** The PPD remains the most commonly used screening test for TB. **Three cutoff levels have been recommended for defining a positive tuberculin reaction: greater than 5 mm, greater than 10 mm, and 15 mm or more induration** (Figure 37-5). **Induration of greater than 5 mm is a positive reaction in individuals with highest risk for conversion to active TB.** That includes individuals who are HIV positive, recent contacts with persons infected with TB, fibrotic changes on chest radiograph consistent with prior TB, and organ transplant recipients and other immunosuppressed persons[51] (see Table 37-2).

Immigrants from areas where TB is endemic may have received the Bacille Calmette-Guérin (BCG) vaccine. Such individuals likely have a positive response to the PPD. However, this reactivity should wane over time. Therefore, the PPD should be used to screen these patients for TB unless their skin tests are known to be positive. **If the BCG vaccine was given 10 years earlier and the PPD is positive with a skin test reaction of 10 mm or more, that individual should be considered infected with TB and managed accordingly.**[55]

Women with a positive PPD skin test must be evaluated for active TB with a thorough physical examination for extrapulmonary disease and a chest radiograph once they are beyond the first trimester. **Symptoms of active TB include cough (74%), weight loss (41%), fever (30%), malaise and fatigue (30%), and hemoptysis (19%).**[56] Individuals with active pulmonary TB may have radiographic findings including adenopathy, multinodular infiltrates, cavitation, loss of volume in the upper lobes, and upper medial retraction of hilar markings (Figure 37-6). **The finding of acid-fast bacilli in early-morning sputum specimens confirms the diagnosis of pulmonary TB.** At least three first-morning sputum samples should be examined for the presence of acid-fast bacilli. If sputum cannot be produced, sputum-induction, gastric washings, diagnostic bronchoscopy, or PTNA may be indicated.

Extrapulmonary TB occurs in up to 16% of cases in the United States; however, in patients with AIDS, the pattern may occur in 60% to 70%.[57] Extrapulmonary sites include lymph nodes, bone, kidneys, and breasts. Extrapulmonary TB appears to be rare in pregnancy. **Extrapulmonary TB that is confined to the lymph nodes has no effect on obstetrical outcome, but TB at other extrapulmonary sites does adversely affect the outcome of pregnancy.**[58] Rarely, mycobacteria invade the uteroplacental circulation, and

FIGURE 37-5. Positive PPD, induration greater than 10 mm. *PPD,* purified protein derivative.

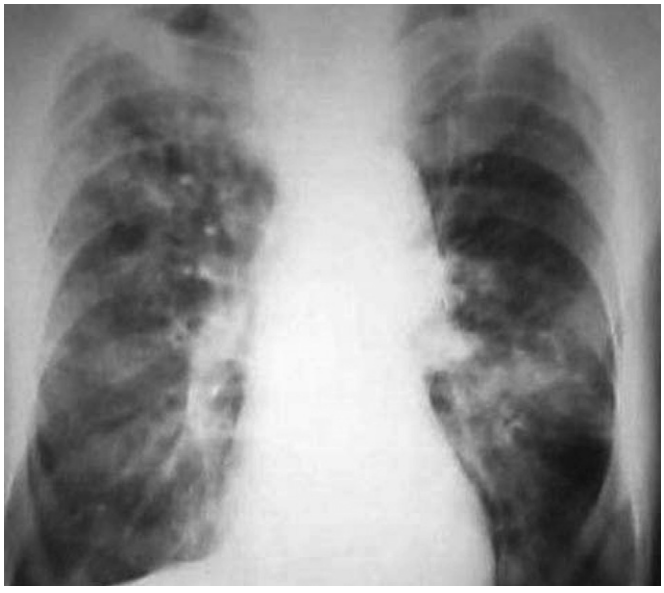

FIGURE 37-6. Pulmonary tuberculosis.

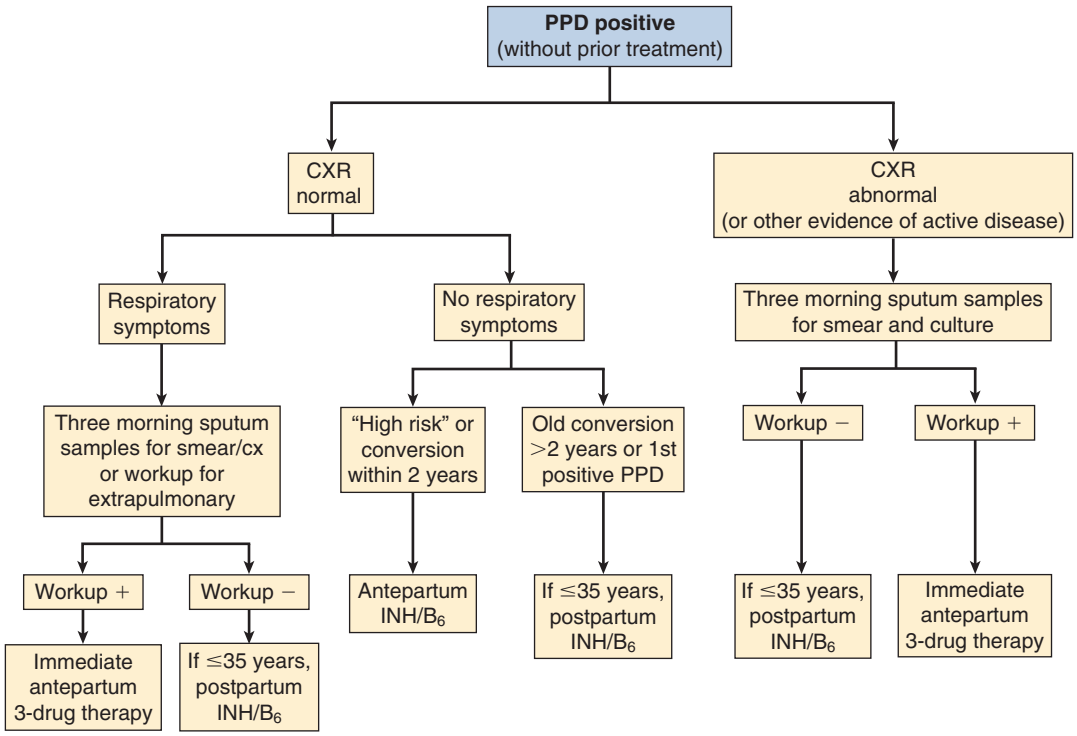

FIGURE 37-7. Algorithm for the management of positive purified protein derivative (PPD). *CX,* Culture; *CXR,* chest x-ray.

congenital TB results.[49] **The diagnosis of congenital TB is based on one of the following factors: (1) demonstration of primary hepatic complex or cavitating hepatic granuloma by percutaneous liver biopsy at birth; (2) infection of the maternal genital tract or placenta; (3) lesions noted in the first week of life; or (4) exclusion of the possibility of postnatal transmission by a thorough investigation of all contacts, including attendants.**[49]

Prevention

Most gravidas with a positive PPD in pregnancy are asymptomatic with no evidence of active disease and, therefore, are classified as having LTBI. The risk for progression to active disease is highest in the first 2 years of conversion. It is important to prevent the onset of active disease while minimizing maternal and fetal risk. An algorithm for management of the positive PPD is presented in Figure 37-7. In women with a **known recent conversion (2 years) to a positive PPD and no evidence of active disease, the recommended prophylaxis is INH, 300 mg/day, starting after the first trimester and continuing for 6 to 9 months. INH should be accompanied by pyridoxine (vitamin B_6) supplementation, 50 mg/day, to prevent the peripheral neuropathy that is associated with INH treatment.** Women with an unknown or prolonged duration of PPD positivity **(>2 years)** should receive INH, 300 mg/day, for 6 to 9 months after delivery. **INH prophylaxis is not recommended for women older than 35 years who have an unknown or prolonged PPD positivity in the absence of active disease.** The use of INH is discouraged in this group because of an **increased risk for hepatotoxicity. INH is associated with hepatitis in both pregnant and nonpregnant adults. The risk for liver inflammation in pregnancy from INH use is rare, and therefore, this therapy should be instituted when the risk for conversion to active disease is high.**[56] **Monthly monitoring of liver function tests may prevent this adverse outcome. Among individuals receiving INH, 10% to 20% develop mildly elevated liver function tests. These changes resolve once the drug is discontinued.**

Treatment

The gravida with active TB should be treated initially with INH, 300 mg/day, combined with RIF, 600 mg/day (Table 37-3).[59] Resistant disease results from initial infection with resistant strains (33%) or can develop during therapy. **If resistance to INH is identified or anticipated, ethambutol, 2.5 g/day, should be added, and the treatment period should be extended to 18 months.**[59] **Ethambutol is teratogenic in animals; however, this has not been demonstrated in humans. The most common side effect of ethambutol therapy is optic neuritis. Streptomycin should be avoided during pregnancy because it is associated with eighth nerve damage in neonates.**[60] **Antituberculous agents not recommended for use in pregnancy include ethionamide, streptomycin, capreomycin, kanamycin, cycloserine, and pyrazinamide. However, recent case reports documenting use of the above-mentioned antituberculous agents in pregnancy have revealed no adverse fetal or neonatal effects.** There were no congenital abnormalities, and pregnancy outcome in the individuals treated was good.[61,62] **Untreated TB has been associated with higher morbidity and mortality among pregnant women.** Therefore, the management of the gravida with multidrug-resistant TB should be individualized. The patient should be counseled about the small risk for teratogenicity, and the increased risk for maternal and fetal morbidity and mortality from

TABLE 37-3 ANTITUBERCULOSIS DRUGS

DRUG	DOSAGE FORM	DAILY DOSE	WEEKLY DOSE	MAJOR ADVERSE REACTIONS
First-Line Drugs (for Initial Treatment)				
Isoniazid	PO, IM	10 mg/kg up to 300 mg	15 mg/kg up to 900 mg	Hepatic enzyme elevation, peripheral neuropathy hepatitis, hypersensitivity
Rifampin	PO	10 mg/kg up to 600 mg	10 mg/kg up to 600 mg	Orange discoloration of secretions and urine, nausea, vomiting, hepatitis, febrile reaction, purpura (rare)
Pyrazinamide	PO	15-30 mg/kg up to 2 g	50-70 mg/kg	Hepatotoxicity, hyperuricemia, arthralgias, skin rash, gastrointestinal upset
Ethambutol	PO	15 mg/kg up to 2.5 g	50 mg/kg	Optic neuritis (decreased red-green color discrimination, decreased visual acuity), skin rash
Streptomycin	IM	15 mg/kg up to 1 g	25-30 mg/kg up to 1 g	Ototoxicity, nephrotoxicity
Second-Line Drugs (Daily Therapy)				
Capreomycin	IM	15-30 mg/kg up to 1 g		Auditory, vestibular, and renal toxicity
Kanamycin	IM	15-30 mg/kg up to 1 g		Auditory and renal toxicity, rare vestibular toxicity
Ethionamide	PO	15-20 mg/kg up to 1 g		Gastrointestinal disturbance, hepatotoxicity, hypersensitivity
Para-aminosalicylic acid	PO	150 mg/kg up to 1 g		Gastrointestinal disturbance, hypersensitivity, hepatotoxicity, sodium load
Cycloserine	PO	15-20 mg/kg up to 1 g		Psychosis, convulsions, rash

IM, intramuscular; *PO*, by mouth.

progression of disease when treatment is delayed. **The risk for postpartum transmission of TB to the baby may be higher among those born to patients with drug-resistant TB.**[62] **Therefore, in patients with active disease at the time of delivery, separation of the mother and newborn should be accomplished to prevent infection of the newborn.**

Women who are being treated with antituberculous drugs may breastfeed. Only 0.75% to 2.3% of INH and 0.05% of RIF is excreted into breast milk. Ethambutol excretion into breast milk is also minimal. However, if the infant is concurrently taking oral antituberculous therapy, excessive drug levels may be reached in the neonate, and breastfeeding should be avoided. **Breastfed infants of women taking INH therapy should receive a multivitamin supplement including pyridoxine.**[13] **Neonates of women taking antituberculous therapy should have a PPD skin test at birth and again at 3 months of age. Infants born to women with active TB at the time of delivery should receive INH prophylaxis (10 mg/kg per day) until maternal disease has been inactive for 3 months,** as evidenced by negative maternal sputum cultures. Active TB in the neonate should be treated appropriately with INH and RIF immediately upon diagnosis or with multiagent therapy should drug-resistant organisms be identified. **Infants and children who are at high risk for intimate and prolonged exposure to untreated or ineffectively treated persons should receive the BCG vaccine.**

Summary

In summary, high-risk gravidas should be screened for TB and treated appropriately with INH prophylaxis for infection without overt disease and with dual antituberculous therapy for active disease. In addition, the newborn should be screened for evidence of TB as well. Proper screening and therapy will result in a good outcome for mother and fetus in most cases.

ASTHMA IN PREGNANCY

About 8% of pregnancies are complicated by asthma; it may be the most common potentially serious medical condition to complicate pregnancy. In general, the prevalence and morbidity from asthma are increasing, although asthma mortality has decreased in recent years. Asthma is characterized by chronic airway inflammation with increased airway responsiveness to a variety of stimuli and airway obstruction that is partially or completely reversible. Insight into the pathogenesis of asthma has changed with the recognition that airway inflammation is present in nearly all cases. **Current medical management for asthma emphasizes treatment of airway inflammation to decrease airway responsiveness and prevent asthma symptoms. The National Asthma Education and Prevention Program (NAEPP) has found that "it is safer for pregnant women with asthma to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations."**[63]

Diagnosis

The enlarging uterus elevates the diaphragm about 4 cm with a reduction of the functional residual capacity. However, there are no clinically significant alterations in forced vital capacity, peak expiratory flow rate (PEFR), or forced expiratory volume in 1 second (FEV_1) in normal pregnancy.

Diagnosis of asthma in pregnancy is no different than for a nonpregnant patient. Asthma typically includes characteristic symptoms (wheezing, chest cough, shortness of

TABLE 37-4 CLASSIFICATION OF ASTHMA SEVERITY AND CONTROL IN PREGNANT PATIENTS

ASTHMA CONTROL*	WELL CONTROLLED	NOT WELL CONTROLLED		VERY POORLY CONTROLLED
Asthma severity†	Mild intermittent	Mild persistent	Moderate persistent	Severe persistent
Symptom frequency, albuterol use	≤2 days per week	>2 days per week, but not daily	Daily symptoms	Throughout the day
Nighttime awakening	≤2 times per month	>2 times per month	>1 time per week	≥4 times per week
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
FEV_1 or peak flow (% predicted/ personal best)	>80%	>80%	60% to 80%	<60%

*Assess in patients on long-term-control medications to determine whether step-up, step-down, or no change in therapy is indicated.
†Assess severity in patients who are not on long-term-control medications; see Table 37-5 to determine starting controller therapy based on severity.

breath, chest tightness), temporal relationships (fluctuating intensity, worse at night), and triggers (e.g., allergens, exercise, infections). Wheezing on auscultation would support the diagnosis, but its absence does not exclude the diagnosis. Ideally, the diagnosis of asthma would be confirmed by demonstrating airway obstruction on spirometry that is at least partially reversible, greater than 12% increase in FEV_1 after inhalation of albuterol.[64,65] However, reversible airway obstruction may not be demonstrable in some patients with asthma. In patients with a clinical picture consistent with asthma in whom reversible airway obstruction cannot be demonstrated, a trial of asthma therapy is reasonable. In such patients, a positive response to asthma therapy can establish the presumptive diagnosis during pregnancy. If methacholine testing is deemed necessary to confirm asthma, it should be delayed until postpartum.[64]

In patients presenting with new respiratory symptoms during pregnancy, the most common differential diagnosis would be dyspnea of pregnancy. Dyspnea (breathlessness) of pregnancy can usually be differentiated from asthma by its lack of cough, wheezing, chest tightness, or airway obstruction. Other differential diagnosis considerations include gastroesophageal reflux, chronic cough from postnasal drip, and bronchitis.

In 2004, the NAEPP defined mild intermittent, mild persistent, moderate persistent, and severe persistent asthma according to daytime and nighttime symptoms (wheezing, cough, or dyspnea) and objective tests of pulmonary function.[63] The most commonly used pulmonary function parameters are the PEFR and FEV_1. Current NAEPP guidelines suggest classifying degree of asthma *severity* in patients not on controller medication and degree of asthma *control* in patients on controller medication (Table 37-4).[65] Pregnant patients who have mild asthma by symptoms and pulmonary function, but who required regular medications to control their asthma, have been found to be similar to those with moderate asthma with respect to asthma exacerbations; those requiring regular systemic corticosteroids to control asthma symptoms were similar to severe asthma patients with respect to exacerbations.[66]

Effects of Pregnancy on Asthma

Asthma during pregnancy has been associated with considerable maternal morbidity. In a large prospective study, the effects of pregnancy on asthma were found to be variable, 23% improved and 30% become worse during pregnancy.[66] Women with mild asthma had an exacerbation rate of 12.6% and hospitalization rate of 2.3%; those with moderate asthma had an exacerbation rate of 25.7% and hospitalization rate of 6.8%; and those with severe asthma had an exacerbation rate of 51.9% and hospitalization rate of 26.9%.[66]

Effects of Asthma on Pregnancy

Compared with women without a history of asthma, women with asthma have been reported to have higher risks for several complications of pregnancy, including preeclampsia, preterm birth, low birthweight or intrauterine growth restriction, and perinatal mortality, even after adjustment for potential confounders.[67] A significant increase in congenital malformations has been associated with exacerbations during the first trimester.[68] Although residual confounding or common pathogenetic factors may explain some of these associations, observational data showing strong associations between poor asthma control (based on symptoms, pulmonary function, or exacerbations) and these increased risks suggest potential benefits of improved asthma control in pregnancy in terms of improved pregnancy outcomes.[67,69-71]

Prospective studies of the effects of asthma during pregnancy have generally had excellent perinatal outcomes.[69,72-79] Preterm birth before 37 weeks' gestation was increased among patients with asthma who had severe disease or required oral corticosteroids, preeclampsia and growth restriction was increased among those with daily symptoms, and the rate of cesarean delivery was increased among those with moderate or severe asthma.[69,77]

Although these studies show that the gravida with mild or moderate asthma can have excellent maternal and perinatal outcomes, there are important caveats when interpreting them. Prospective studies have tended to find fewer significant adverse associations, possibly because of better asthma surveillance and treatment. **The excellent maternal and perinatal outcomes were achieved at centers that tended to actively manage asthma in pregnancy.** In addition, women who enroll in research studies tend to be more compliant and better motivated than the general public. The lack of finding more adverse outcomes among women with severe asthma may also be a function of the relatively small numbers of this cohort and the resulting lack of power to find adverse outcomes that were statistically significant. Nonetheless, these prospective studies are reassuring in their consensus of good pregnancy outcomes among women with asthma. However, they do not suggest that asthma should be considered to be a benign condition because active asthma management was

a part of these studies and may have positively affected outcomes.

These findings do not contradict the possibility that suboptimal control of asthma during pregnancy is associated with increased risk to the mother or baby.[77] In fact, a significant relationship has been reported between lower FEV_1 during pregnancy and increased risk for low birthweight and prematurity.[80]

ASTHMA MANAGEMENT

The ultimate goal of asthma therapy during pregnancy is to maintain adequate oxygenation of the fetus by prevention of hypoxic episodes in the mother. Other goals include achievement of minimal or no maternal symptoms day or night, minimal or no exacerbations, no limitations of activities, maintenance of normal or near-normal pulmonary function, minimal use of albuterol, and minimal or no adverse effects from medications. Consultation or comanagement with an asthma specialist is appropriate, as indicated, for evaluation of the role of allergy and irritants, complete pulmonary function studies, or evaluation of the medication plan if there are difficulties in achieving the goals of therapy or the patient has severe asthma. A team approach is helpful if more than one clinician is managing the asthma and the pregnancy. **The effective management of asthma during pregnancy relies on four integral components: objective measures for assessment and monitoring, patient education, avoidance or control of asthma triggers, and pharmacologic therapy.**

Objective Measures for Assessment and Monitoring

Subjective measures of lung function by either the patient or physician can be an insensitive and inaccurate assessment of airway hyper-responsiveness, airway obstruction, and asthma severity. **The FEV_1 following a maximal inspiration is the single best measure of pulmonary function.** When adjusted for confounders, a mean FEV_1 lower than 80% predicted has been found to be significantly associated with increased preterm delivery before 32 weeks and before 37 weeks, and birthweight less than 2500 g.[80] However, measurement of FEV_1 requires a spirometer. **The PEFR correlates well with the FEV_1 and has the advantages that it can be measured reliably with inexpensive, disposable, portable peak flow meters.**

Patient self-monitoring of PEFR provides valuable insight to the course of asthma and helps detect early signs of deterioration so that timely therapy can be instituted. Patients with persistent asthma should be evaluated at least monthly, and those with moderate to severe asthma should have daily home PEFR monitoring.[63] The typical PEFR in pregnancy should be 380 to 550 L/minute. The pregnant woman should establish her "personal best" PEFR, then calculate her individualized PEFR zones: green zone, greater than 80% of personal best; yellow zone, 50% to 80% of personal best; and red zone, less than 50% of personal best PEFR.

Patient Education

The patient should be made aware that controlling asthma during pregnancy is especially important for the well-being of the fetus. She should have a basic understanding of the medical management of asthma during pregnancy, including self-monitoring of PEFRs and the correct use of inhalers. She should be instructed on proper PEFR technique: make the measurement while standing, take a maximal inspiration, and note the reading on the peak flow meter. Women who smoke should be encouraged to quit; active smoking, but not passive smoking, has been associated with increased asthma symptoms and fetal growth abnormalities.[81] Women should also be instructed to avoid and control other asthma triggers. **The importance of adherence to treatment should be stressed.**

Avoidance or Control of Asthma Triggers

Limiting adverse environmental exposures during pregnancy is important for controlling asthma. Irritants and allergens that provoke acute symptoms also increase airway inflammation and hyper-responsiveness. Avoiding or controlling such triggers can reduce asthma symptoms, airway hyper-responsiveness, and the need for medical therapy.[65] Association of asthma with allergies is common; 75% to 85% of patients with asthma have positive skin tests to common allergens, including animal dander, house dust mites, cockroach antigens, pollens, and molds. Other common nonimmunologic triggers include tobacco smoke, strong odors, air pollutants, food additives such as sulfites, and certain drugs including aspirin and ß-blockers. Another trigger can be strenuous physical activity. For some patients, exercise-induced asthma can be avoided with inhalation of albuterol, 10 to 30 minutes before exercise.

Specific measures for avoiding asthma triggers include using allergen-impermeable mattress and pillow covers, removing carpeting, weekly washing of bedding in hot water, avoiding tobacco smoke, inhibiting mite and mold growth by reducing humidity, and leaving the house when it is vacuumed. Ideal animal dander control involves removing the pet from the home; allergic women should at least keep furry pets out of the bedroom. Cockroaches can be controlled by poison baits or traps and eliminating exposed food or garbage.

The use of allergen immunotherapy, or "allergy shots," has been shown to be effective in improving asthma in allergic patients.[65] However, anaphylaxis is a risk for allergy injections, especially early in the course of immunotherapy when the dose is being escalated, and anaphylaxis during pregnancy has been associated with fetal and maternal death. In a patient who is receiving a maintenance or near-maintenance dose, not experiencing adverse reactions to the injections, and apparently deriving clinical benefit, continuation of immunotherapy is recommended.[63] In such patients, a dose reduction may be considered to further decrease the chance of anaphylaxis. Risk-benefit considerations do not usually favor *beginning* allergy shots during pregnancy.

Pharmacologic Therapy

Medications for asthma are divided into long-term controllers that prevent asthma manifestations (inhaled corticosteroids, long-acting β-agonists, leukotriene modifiers, and theophylline) and rescue therapy to provide quick relief of symptoms, primarily albuterol.

Women who have previously been prescribed asthma medications should be asked about their use to classify their current level of therapy according to a stepped care approach (Table 37-5) and to assess potential adherence problems and barriers. Adherence to inhaled corticosteroids has been reported to be poor in many studies. For example, reported adherence rates were about 50% in one study of asthmatic adults; decreased adherence was associated with an increased frequency of asthma exacerbations in this study.[82] **Women with asthma have been reported to decrease their inhaled corticosteroid use during early pregnancy compared to their prepregnancy use, which may be due to their reported concern regarding the safety of inhaled corticosteroids during pregnancy**. Moreover, a substantial proportion of asthma exacerbations during pregnancy have been associated with nonadherence to inhaled corticosteroids.[71] In addition to assessing adherence, asking about past medications and their effectiveness and any side effects can help guide subsequent management decisions.

The goals of asthma therapy include relieving bronchospasm, protecting the airways from irritant stimuli, mitigating pulmonary and inflammatory response to an allergen exposure, and resolving the inflammatory process in the airways, leading to improved pulmonary function with reduced airway hyper-responsiveness. It is safer for pregnant women with asthma to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations.[63] Current pharmacologic therapy emphasizes treatment of airway inflammation in order to decrease airway hyper-responsiveness and prevent asthma symptoms. Typical dosages of commonly used asthma medications are listed in Table 37-6. Low, medium, and high doses of inhaled corticosteroid are presented in Table 37-7. The step-care therapeutic approach uses the least amount of drug intervention necessary to control a patient's severity of asthma.

Step Therapy

The step-care therapeutic approach increases the number and frequency of medications with increasing asthma severity.[63,65] Based on clinical trials in patients of varying degrees of severity, medications (see Table 37-5) are considered to

TABLE 37-5 STEP THERAPY MEDICAL MANAGEMENT OF ASTHMA DURING PREGNANCY

STEP	ASTHMA SEVERITY AND MEDICATIONS*
1. No daily medications; albuterol as needed	Mild intermittent
2. Low-dose inhaled corticosteroid (alternative: LTRA or theophylline†)	Mild persistent
3. Medium-dose inhaled corticosteroid (alternative: low-dose inhaled corticosteroid and LABA, LTRA, or theophylline†)‡	Moderate persistent
4. Medium-dose inhaled corticosteroid and LABA (alternative: medium-dose inhaled corticosteroid plus LTRA, or theophylline†)	Moderate persistent
5. High-dose inhaled corticosteroid and LABA	Severe persistent
6. High-dose inhaled corticosteroid and LABA and oral prednisone	Severe persistent

*Starting therapy for a specific level of severity (NAEP, 2004; NAEP, 2007).
†Theophylline (serum level, 5-12 mcg/mL).
‡We have modified step 3 to reflect the choice of a medium-dose inhaled corticosteroid over a low-dose inhaled corticosteroid plus LABA because of the lack of safety data on the use of LABA during pregnancy.

TABLE 37-6 TYPICAL DOSAGES OF ASTHMA MEDICATIONS:

Albuterol MDI	2-4 puffs every 4-6 hours as needed
Salmeterol DPI	1 blister 2 times/day
Formoterol	1 capsule 2 times/day
Fluticasone/salmeterol (Advair) DPI	1 inhalation 2 times/day; strength (100, 250, 500) depends on severity of asthma
Montelukast	10-mg tablet at night
Zafirlukast	20-mg tablet twice daily
Prednisone	5-60 mg/day for active symptoms or maintenance therapy for severe asthma
Theophylline	Start 200 mg 2 times/day orally, target serum levels of 5-12 mcg/mL (decrease dosage by half if treated with erythromycin or cimetidine)
Ipratropium MDI	2-3 puffs every 6 hr

DPI, Dry-powder inhaler; *MDI*, metered-dose inhaler.

TABLE 37-7 COMPARATIVE DAILY DOSES* FOR INHALED CORTICOSTEROIDS

		LOW DOSE	MEDIUM DOSE	HIGH DOSE
Beclomethasone HFA	40 mcg/puff	2-6 puffs	>6-12 puffs	>12 puffs
	80 mcg/puff	1-3 puffs	>3-6 puffs	>6 puffs
Budesonide	180 mcg/inhalation	1-3 puffs	>3-6 puffs	>6 puffs
Flunisolide	250 mcg/puff	2-4 puffs	5-8 puffs	>8 puffs
Fluticasone HFA	44 mcg/puff	2-6 puffs		
	110 mcg/puff	2 puffs	3-4 puffs	>4 puffs
	220 mcg/puff	1 puff	2 puffs	>2 puffs
Fluticasone DPI	50 mcg/inhalation	2-6 puffs		
	100 mcg/inhalation	1-3 puffs	4-5 puffs	>5 puffs
	250 mcg/inhalation	1 puff	2 puffs	>2 puffs
Mometasone	200 mcg/inhalation	1 puff	2 puffs	>2 puffs
Triamcinolone	75 mcg/puff	4-10 puffs	11-20 puffs	>20 puffs

Modified from National Asthma Education and Prevention Program Full Report of the Expert Panel: Guidelines for the Diagnosis and Management of Asthma, 2007.
*Note that total daily puffs is usually divided as a twice-a-day regimen.
HFA, Hydrofluoroalkane.

be "preferred" or "alternative" at each step of therapy. Patients not optimally responding to treatment should be stepped up to more intensive medical therapy. Patients with not well-controlled asthma (see Table 37-4) should generally be stepped up one step, and those with very poorly controlled asthma (see Table 37-4) should be stepped up two steps. Once control is achieved and sustained for several months, a step-down approach can be considered but should be undertaken cautiously and gradually to avoid compromising the stability of the asthma control. For some patients, it may be prudent to postpone until after birth attempts to reduce therapy that is effectively controlling the patient's asthma.[63] In the case of a patient who had a favorable response to an alternative drug before becoming pregnant, it would be appropriate to maintain the therapy that successfully controlled the patient's asthma before pregnancy. However, when initiating new treatment for asthma during pregnancy, preferred medications should be considered first, rather than alternative treatment options.[63]

Patients with asthma exacerbations may require oral corticosteroids. In such cases, a short course of oral prednisone, 40 to 60 mg of prednisone per day in a single or two divided doses for 3 to 10 days, is recommended.[65]

Inhaled Corticosteroids

Inhaled corticosteroids are the preferred treatment for the management of all levels of persistent asthma during pregnancy.[63] Airway inflammation is present in nearly all cases; therefore, inhaled corticosteroids have been advocated as first-line therapy, even for patients with mild persistent asthma. The use of inhaled corticosteroids among nonpregnant asthmatic patients has been associated with a marked reduction in fatal and near-fatal asthma. Inhaled corticosteroids produce clinically important improvements in bronchial hyper-responsiveness that appear dose related, including prevention of increased bronchial hyperresponsiveness after seasonal exposure to an allergen.

In a prospective observational study of 504 pregnant subjects with asthma, 177 patients were not initially treated with inhaled corticosteroids (budesonide or beclomethasone).[75] This cohort had a 17% acute exacerbation rate compared with only a 4% rate among those treated with inhaled corticosteroids from the start of pregnancy. Randomized controlled trials with pregnant patients have shown that inhaled beclomethasone is more effective than theophylline in improving pulmonary function,[78] and that prescribing inhaled beclomethasone in addition to oral corticosteroids and inhaled β-agonists at the time of discharge after hospitalization for asthma reduces subsequent asthma readmissions compared with oral corticosteroids and inhaled β-agonists alone.[83]

The NAEPP Working Group reviewed 10 studies including 6113 patients who took inhaled corticosteroids during pregnancy for asthma.[63] **There was no evidence linking inhaled corticosteroid use to increases in congenital malformations or adverse perinatal outcomes.** Included among these studies was the Swedish Medical Birth Registry study that reported 2014 infants whose mothers had used inhaled budesonide in early pregnancy.[84] Because there are more data on using budesonide during pregnancy than on using other inhaled corticosteroids, the NAEPP considered budesonide to be the preferred inhaled corticosteroid for use during pregnancy. However, if a woman's asthma is well controlled by a different inhaled corticosteroid before pregnancy, it seems reasonable to continue that medication during pregnancy. All inhaled corticosteroids are currently labeled FDA pregnancy category C, except for budesonide, which is class B.

Inhaled β_2-Agonists

As-needed use of inhaled β_2-agonists is currently recommended for all levels of asthma during pregnancy.[63] Albuterol has a rapid onset of effect in the relief of acute bronchospasm through smooth muscle relaxation and is an excellent bronchoprotective agent for pretreatment before exercise. β_2-Agonists are associated with tremor, tachycardia, and palpitations. They do not block the development of airway hyper-responsiveness. **An increased frequency of bronchodilator use could be an indicator of the need for additional anti-inflammatory therapy.** Appropriate β_2-agonist use appears to be safe based on an NAEPP review of six published studies with 1599 women with asthma who took β_2-agonists during pregnancy.[63] Additionally, in a large prospective study, no significant relationship was found between the use of inhaled β_2-agonists (n = 1828) and adverse pregnancy outcomes.[85]

Salmeterol and formoterol are long-acting β-agonist (LABA) preparations. Data are lacking regarding the safety of LABAs during human pregnancy, although safety is considered likely based on the inhalational route and the generally reassuring data for short-acting β-agonists.[63] LABA should only be used in combination with inhaled corticosteroids during pregnancy. Long-acting β-agonists have been shown to be more effective than leukotriene receptor antagonists or theophylline as add-on therapy to inhaled corticosteroids.[65] The efficacy of these drugs during pregnancy is largely extrapolated from studies performed in nonpregnant patients.

Omalizumab

Omalizumab is a humanized monoclonal antibody to immunoglobulin E and is a Pregnancy Category B agent. An ongoing registry (sponsored by Genentech) of the use of omalizumab during pregnancy does not at this time have sufficient numbers to provide any definitive information. Because of the lack of safety data and potential risk of anaphylaxis, Omalizumab should not be initiated during pregnancy. A possible exception would be the patient who remains uncontrolled despite medical management presented in Table 37-5. However, it would seem reasonable to continue Omalizumab among women with severe asthma who become pregnant.

Theophylline

Theophylline is an alternative treatment for mild persistent asthma and an alternative add-on treatment for the step 3 or 4 management of moderate persistent asthma during pregnancy (see Table 37-5).[63] Subjective symptoms of adverse theophylline effects, including insomnia, heartburn, palpitations, and nausea, may be difficult to differentiate from typical pregnancy symptoms. High doses have been observed to cause jitteriness, tachycardia, and vomiting in mothers and neonates. **New dosing guidelines**

have recommended that serum theophylline concentrations be maintained at 5 to 12 mcg/mL during pregnancy.[63] Theophylline can have significant interactions with other drugs, which can cause decreased clearance with resultant toxicity; it may be appropriate to decrease the dosage of theophylline by half when the patient is treated with cimetidine, erythromycin, or azithromycin.[78] The main advantage of theophylline is the long duration of action, 10 to 12 hours with the use of sustained-release preparations, which is especially useful in the management of nocturnal asthma. Theophylline is only indicated for chronic therapy and is not effective for the treatment of acute exacerbations during pregnancy.

The NAEPP reviewed eight human studies that had a total of 660 women with asthma who took theophylline during pregnancy.[63] These studies and clinical experience confirm the safety of theophylline at a serum concentration of 5 to 12 mcg/mL during pregnancy. In a recent randomized controlled trial, there were no differences in asthma exacerbations or perinatal outcomes in a cohort receiving theophylline compared with the cohort receiving inhaled beclomethasone.[78] However, the theophylline cohort had significantly more reported side effects, discontinuation of study medication, and an increased proportion of those with an FEV_1 lower than 80% predicted.

Leukotriene Moderators

Leukotrienes are arachidonic acid metabolites that have been implicated in causing bronchospasm, mucous secretion, and increased vascular permeability. Bronchoconstriction associated with aspirin ingestion can be blocked by leukotriene receptor antagonists. Treatment with the leukotriene receptor antagonist montelukast has been shown to significantly improve pulmonary function as measured by FEV_1. The leukotriene receptor antagonists zafirlukast and montelukast are both pregnancy category B. Although human data are limited for leukotriene receptor antagonist use in pregnancy, their use has not been associated with an increase in congenital anomalies.[70,86] **Leukotriene modifiers are less effective as single agents than inhaled corticosteroids and less effective than LABA as add-on therapy**.[65]

Oral Corticosteroids

The NAEPP Working Group reviewed eight human studies of the use of oral corticosteroids during pregnancy, including one report of two meta-analyses.[63] Most subjects in these studies did not take oral corticosteroids for asthma, and the length, timing, and dose of exposure to the drug were not well described. The panel concluded that findings from the current evidence review were conflicting. Oral corticosteroid use during the first trimester of pregnancy was associated with a three-fold increased risk for isolated cleft lip with or without cleft palate. With a background incidence of about 0.1%, the excess risk attributable to oral steroids would thus be 0.2% to 0.3%.[87] Oral corticosteroid use during pregnancy in patients who have asthma has been associated with an increased incidence of preeclampsia, preterm delivery, and low birthweight.[69,73,85,87] A recent prospective study found that systemic corticosteroids resulted in a deficit of about 200 g in birthweight compared with nonasthmatic controls and asthmatic women exclusively treated with $ß_2$-agonists.[70] However, it is difficult to separate the effects of the oral corticosteroids on these outcomes from the effects of severe or uncontrolled asthma.

Because of the uncertainties in these data and the definite risks of severe uncontrolled asthma to the mother and fetus, **the NAEPP Working Group recommends the use of oral corticosteroids when indicated for the long-term management of severe asthma or for exacerbations during pregnancy.**[63]

Management of Allergic Rhinitis and Gastroesophageal Reflux

Rhinitis, sinusitis, and gastroesophageal reflux may exacerbate asthma symptoms, and their management should be considered an integral aspect of asthma care. Intranasal corticosteroids are the most effective medications for control of allergic rhinitis. Loratadine (Claritin) and cetirizine (Zyrtec) are recommended second-generation antihistamines. Oral decongestant ingestion during the first trimester has been associated with gastroschisis; therefore, short-term (≤3 days) intranasal decongestants or intranasal corticosteroids should be considered before use of oral decongestants.[63] Controlling gastroesophageal reflux with acid reducers may improve asthma control.

ANTENATAL MANAGEMENT

In general, data are lacking to guide the optimal obstetrical management of the woman with asthma, and recommendations are based on extrapolation of data from other clinical settings and expert opinion. Women with asthma should be offered influenza vaccination as appropriate. Those with asthma that is not well controlled may benefit from increased fetal surveillance. Patients with moderate and severe asthma should be considered to be at risk for pregnancy complications. Adverse outcomes can be increased by underestimation of asthma severity and undertreatment of asthma. The first prenatal visit should include a detailed medical history with attention to coexisting medical conditions that could complicate the management of asthma, including rhinitis, sinusitis, reflux, or depression. The patient should be questioned about smoking history and the presence and severity of symptoms, episodes of nocturnal asthma, the number of days of work missed, and emergency care visits associated with asthma. Asthma severity or control should be determined (see Table 37-4). The type and amount of asthma medications, including the number of puffs of albuterol used each day, should be noted.

Gravidas with moderate or severe asthma should have scheduling of prenatal visits based on clinical judgment. In addition to routine care, monthly or more frequent evaluations of asthma history (emergency visits, hospital admissions, symptom frequency, symptom interference with sleep or activity, medications, dosages, and compliance) and pulmonary function (FEV_1 or PEFR) are recommended. Patients should be instructed on proper dosing and administration of their asthma medications.

Daily PEFR monitoring should be considered for patients with moderate to severe asthma, and especially for patients who have difficulty perceiving signs of

worsening asthma.[63] It may be helpful to maintain an asthma diary containing daily assessment of asthma status, including peak flow measurements, symptoms and activity limitations, indication of any medical contacts initiated, and a record of regular and as-needed medications taken. Identifying and avoiding asthma triggers, especially smoking, can lead to improved maternal well-being with less need for medications. Specific recommendations can be made for appropriate environmental controls, based on the patient's history of exposure and, when available, results of blood or skin testing for immunoglobulin E–mediated sensitivity to inhalant allergen asthma triggers (see earlier).

Women with asthma that is not well controlled may benefit from additional fetal surveillance in the form of ultrasound examinations and antenatal fetal testing. Because asthma has been associated with intrauterine growth restriction (IUGR) and preterm birth, it is useful to establish pregnancy dating accurately by first-trimester ultrasound when possible. In the opinion of the Working Group,[63] the evaluation of fetal activity and growth by serial ultrasound examinations may be considered for women who have suboptimally controlled asthma, with moderate to severe asthma (starting at 32 weeks), and after recovery from a severe asthma exacerbation. The intensity of antenatal surveillance of fetal well-being should be considered on the basis of the severity of the asthma as well as any other high-risk features of the pregnancy that may be present. All patients should be instructed to be attentive to fetal activity.

Home Management of Asthma Exacerbations

An asthma exacerbation that causes minimal problems for the mother may have severe sequelae for the fetus. Therefore, asthma exacerbations in pregnancy should be optimally managed. Patients should be instructed on rescue management and educated to recognize signs and symptoms of early asthma exacerbations such as coughing, chest tightness, dyspnea, or wheezing, or by a 20% decrease in their PEFR. This is important so that prompt home rescue treatment may be instituted to avoid maternal and fetal hypoxia. In general, patients should use inhaled albuterol, 2 to 4 puffs every 20 minutes for up to 1 hour (Table 37-8). **A good response is considered if symptoms are resolved or become subjectively mild, normal activities can be resumed, and the PEFR is more than 80% of personal best.** The patient should seek further medical attention if the response is incomplete, or if fetal activity is decreased.

Hospital and Clinic Management of Asthma Exacerbations

The principal goal should be the prevention of hypoxia. Measurement of oxygenation through pulse oximetry is essential, and arterial blood gases may be obtained if oxygen saturation remains less than 95%. Chest radiographs are not commonly needed. **Continuous electronic fetal monitoring should be initiated if gestation has advanced to point of potential fetal viability. Albuterol (2.5 to 5 mg every 20 minutes for three doses, then 2.5 to 10 mg every 1 to 4 hours as needed, or 10 to 15 mg/hour continuously) should be delivered by nebulizer driven with oxygen.**[63]

TABLE 37-8 HOME MANAGEMENT OF ACUTE ASTHMA EXACERBATIONS*

Use albuterol MDI 2-4 puffs and measure PEFR.
Poor response:
PEFR is <50% predicted, or severe wheezing and shortness of breath, or decreased fetal movement, repeat albuterol 2-4 puffs by MDI and obtain emergency care.
Incomplete response:
PEFR is 50%-80% predicted or if persistent wheezing and shortness of breath, then repeat albuterol treatment 2-4 puffs MDI at 20-minute intervals up to two more times. If repeat PEFR 50%-80% predicted or if decreased fetal movement, contact caregiver or go for emergency care.
Good response:
PEFR is >80% predicted, no wheezing or shortness of breath, and fetus is moving normally. May continue inhaled albuterol 2-4 puffs MDI every 3-4 hours as needed

*Modified from NAEPP report (NAEPP, 2004).
MDI, Metered-dose inhaler; *PEFR*, peak expiratory flow rate.

Occasionally, nebulized treatment is not effective because the patient is moving air poorly; in such cases, terbutaline, 0.25 mg, can be administered subcutaneously every 20 minutes for three doses. The patient should be assessed for general level of activity, color, pulse rate, use of accessory muscles, and air flow obstruction determined by auscultation and FEV_1 or PEFR before and after each bronchodilator treatment. Guidelines for the management of asthma exacerbations are presented in Table 37-9. **For the treatment of acute exacerbations, prednisone, methylprednisolone, or prednisolone may be given, 40 to 80 mg per day in one or two divided doses.**[65] Consider adjunctive treatment such as magnesium sulfate in severe exacerbations if the patient is unresponsive to the initial treatments listed in Table 37-6.[65]

LABOR AND DELIVERY MANAGEMENT

Asthma medications should not be discontinued during labor and delivery. Although asthma is usually quiescent during labor, consideration should be given to assessing PEFR. The patient should be kept hydrated and should receive adequate analgesia to decrease the risk for bronchospasm. It is commonly recommended that women who currently or recently (during the previous 4 weeks) received systemic corticosteroids should be given intravenous corticosteroids (e.g., hydrocortisone, 100 mg every 8 hours) during labor and for the 24-hour period following delivery to prevent adrenal crisis.[63] An elective delivery should be postponed if the patient is having an exacerbation. It is rarely necessary to perform a cesarean delivery for an acute asthma exacerbation; maternal and fetal compromise usually responds to aggressive medical management.

Prostaglandin E_2 (PGE_2) or PGE_1 can be used for cervical ripening, the management of spontaneous or induced abortions, or postpartum hemorrhage, although the patient's respiratory status should be monitored.[64] **Carboprost (15-methyl $PGF_{2\alpha}$) and ergonovine and methylergonovine (Methergine) can cause bronchospasm.**[64] If tocolysis is needed, magnesium sulfate and terbutaline are preferable because they are bronchodilators; in contrast, indomethacin might induce bronchospasm in the aspirin-sensitive patient.[64] There are no reports of the use of calcium channel blockers for tocolysis among patients with

TABLE 37-9 EMERGENCY DEPARTMENT AND HOSPITAL-BASED MANAGEMENT OF ASTHMA EXACERBATION*

Initial Assessment and Treatment

History and examination (auscultation, use of accessory muscles, heart rate, respiratory rate), PEFR or FEV_1, oxygen saturation, and other tests as indicated.

- Initiate fetal assessment (consider fetal monitoring and/or BPP if fetus is potentially viable)
- **If severe exacerbation (FEV_1 or PEFR is <50% with severe symptoms at rest), then high-dose albuterol by nebulization every 20 minutes or continuously for 1 hour, and inhaled ipratropium bromide, and systemic corticosteroid**
- Albuterol by MDI or nebulizer, up to three doses in first hour
- Oral corticosteroid if no immediate response or if patient recently treated with systemic corticosteroid
- Oxygen to maintain saturation >95%
- Repeat assessment: symptoms, physical examination, PEFR, oxygen saturation
- Continue albuterol every 60 minutes for 1-3 hours provided there is improvement

Repeat Assessment

Symptoms, physical examination, PEFR, oxygen saturation, other tests as needed

Continue fetal assessment

Good Response

- FEV_1 or PEFR ≥70%
- Response sustained 60 minutes after last treatment
- No distress
- Physical examination: normal
- Reassuring fetal status
- Discharge home

Incomplete Response

- FEV_1 or PEFR ≥50% but <70%
- Mild or moderate symptoms
- Continue fetal assessment until patient stabilized
- Monitor FEV_1 or PEFR, oxygen saturation, pulse
- Continue inhaled albuterol and oxygen
- Inhaled ipratropium bromide
- Systemic (oral or intravenous) corticosteroid
- Individualize decision for hospitalization

Poor Response

- FEV1 or PEFR <50%
- P_{CO_2} >42 mm Hg
- Physical examination: symptoms severe, drowsiness, confusion
- Continue fetal assessment
- Admit to ICU

Impending or Actual Respiratory Arrest

- Admit to ICU
- Intubation and mechanical ventilation with 100% oxygen
- Nebulized albuterol plus inhaled ipratropium bromide
- Intravenous corticosteroid

Intensive Care Unit

- Inhaled albuterol hourly or continuously plus inhaled ipratropium bromide
- Intravenous corticosteroid
- Oxygen
- Possible intubation and mechanical ventilation
- Continue fetal assessment until patient stabilized

Discharge Home

- Continue treatment with albuterol
- Oral systemic corticosteroid if indicated
- Initiate or continue inhaled corticosteroid until review at medical follow-up
- Patient education
  - Review medicine use
  - Review/initiate action plan
  - Recommend close medical follow-up

*Modified from NAEPP report (NAEPP, 2004).

ICU, Intensive care unit; P_{CO_2}, partial pressure of carbon dioxide; *PEFR*, peak expiratory flow rate.

asthma, although an association with bronchospasm has not been observed with wide clinical use. Nonselective ß-blockers may trigger bronchospasm.

Lumbar anesthesia has the benefit of reducing oxygen consumption and minute ventilation during labor. Fentanyl may be a better analgesic than meperidine, which causes histamine release, but meperidine is rarely associated with the onset of bronchospasm during labor. A 2% incidence of bronchospasm has been reported with regional anesthesia. Communication between the obstetrical, anesthetic, and pediatric caregivers is important for optimal care.

Breastfeeding

In general, only small amounts of asthma medications enter breast milk. Prednisone, theophylline, antihistamines, inhaled corticosteroids, leukotriene receptor antagonists, and β_2-agonists are not considered to be contraindications for breastfeeding.[63,64] However, among sensitive individuals, theophylline may cause neonatal vomiting, feeding difficulties, jitteriness, and cardiac arrhythmias.

Summary

Asthma is an increasingly common problem during pregnancy. Mild and moderate asthma can be associated with excellent maternal and perinatal pregnancy outcomes, especially if patients are managed according to contemporary NAEPP recommendations. Severe and poorly controlled asthma may be associated with increased prematurity, need for cesarean delivery, preeclampsia, and growth restriction. Severe asthma exacerbations can result in maternal morbidity and mortality and can have commensurate adverse pregnancy outcomes. The management of asthma during pregnancy should be based on objective assessment, trigger avoidance, patient education, and step therapy. Asthma medications should be continued during pregnancy and while breastfeeding.

RESTRICTIVE LUNG DISEASE

Restrictive ventilatory defects occur when lung expansion is limited because of alterations in the lung parenchyma or because of abnormalities in the pleura, chest wall, or the neuromuscular apparatus. These conditions are characterized by a reduction in lung volumes and an increase in the ratio of FEV_1 to forced vital capacity (FVC).[88] The interstitial lung diseases include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, pneumoconiosis, drug-induced lung disease, and connective tissue disease. **Additional conditions that cause a restrictive ventilatory defect include pleural and chest wall diseases and extrathoracic conditions such as obesity, peritonitis, and ascites.**[88] Restrictive lung disease in pregnancy has not been well studied. Consequently, little is known about the effects of restrictive lung disease on the outcome of pregnancy or the effects of pregnancy on the disease process itself. A recent study presented data on nine pregnant women who were prospectively managed with interstitial and restrictive lung disease.[89] Diagnoses included idiopathic pulmonary fibrosis, hypersensitivity pneumonitis, sarcoidosis, kyphoscoliosis, and multiple pulmonary

emboli. Three of the gravidas presented in this paper had severe disease characterized by a vital capacity of 1.5 L or less (50% predicted) or a diffusing capacity less than or equal to 50% predicted. Five of the patients had exercise-induced oxygen desaturation, and four patients required supplemental oxygen. Of the group, one patient had an adverse outcome and was delivered at 31 weeks. She subsequently required mechanical ventilation for 72 hours. All other patients were delivered at or beyond 36 weeks, with no adverse intrapartum or postpartum complications. All infants were at or above the 30th percentile for growth.[89] The authors concluded that restrictive lung disease was well tolerated in pregnancy. However, exercise intolerance was common, and early oxygen supplementation may be required.[89]

Sarcoidosis

Sarcoidosis is a systemic granulomatosis disease of undetermined etiology that often affects young adults. Pregnancy outcome for most women with sarcoidosis is good.[90,91] In a study of 35 pregnancies in 18 patients with sarcoidosis, disease activity remained stable in 9 patients. During pregnancy, improvement was demonstrated in 6 patients, and in 3, there was a worsening of the disease.[90] During the postpartum period, 15 patients remained stable; however, in 3 women, a progression of the disease continued. Another retrospective study presented 15 pregnancies complicated by maternal sarcoidosis over a 10-year period.[91] **Eleven of these patients remained stable, 2 experienced disease progression, and 2 died as a result of severe complications of severe sarcoidosis. In this group, factors indicating a poor prognosis reportedly included parenchymal lesions on chest radiograph, advanced radiographic staging, advanced maternal age, low inflammatory activity, requirement for drugs other than steroids, and the presence of extrapulmonary sarcoidosis.**[91] **Both of the patients who succumbed during gestation had severe disease at the onset of pregnancy.** The overall **cesarean delivery rate was 40%;** in addition, 4 of 15 infants **(27%) weighed less than 2500 g**. None of the patients developed preeclampsia. One possible explanation for the commonly observed improvement in sarcoidosis may be the increased concentration of cortisol during pregnancy. However, because sarcoidosis improves spontaneously in many nonpregnant patients, the improvement may be coincident with but not due to pregnancy.

One study examined 17 pregnancies in 10 patients and concluded that pregnancy had no consistent effect on the course of the disease.[92] Scadding[93] separated patients into three categories based on characteristic patterns of their chest radiographs. When the chest radiograph had resolved before pregnancy, the normal radiograph persisted throughout gestation. In women with resolving radiographic changes before pregnancy, resolution continued throughout the prenatal period. Patients with inactive fibrotic residual disease had stable chest radiographs, and those with active disease tended to have partial or complete resolution of those changes during pregnancy. Most patients in this latter group, however, experienced exacerbation of the disease within 3 to 6 months after delivery.[93]

Patients with pulmonary hypertension complicating restrictive lung disease may suffer a mortality rate as high as 50% during gestation. These patients need close monitoring during labor, delivery, and the postpartum period. Invasive monitoring with a pulmonary artery catheter may be indicated to optimize cardiorespiratory function. **Gravidas with restrictive lung disease, including pulmonary sarcoidosis, may benefit from early institution of steroid therapy for evidence of worsening pulmonary status.** Individuals with evidence of severe disease need close monitoring and may require supplemental oxygen therapy during gestation as well.

During labor, consideration should be given to early use of epidural anesthesia, if it is not contraindicated. The early institution of pain management in this population will minimize pain, decrease sympathetic response, and therefore decrease oxygen consumption during labor and delivery. **The use of general anesthesia should be avoided, if possible,** because these patients may develop pulmonary complications after general anesthesia, including pneumonia and difficulty weaning from the ventilator. **In addition, close fetal surveillance throughout gestation is warranted because impaired oxygenation may compromise fetal growth.**

An additional consideration is the need to counsel all women with restrictive lung disease about the potential for continued impairment of their respiratory status during pregnancy, particularly if their respiratory disease is deteriorating at the time of conception. The individual with clinical signs consistent with pulmonary hypertension or severe restrictive disease should be cautioned about the possibility of maternal mortality resulting from worsening pulmonary function during gestation.

In summary, although the literature on restrictive lung disease in pregnancy is limited, it supports the conclusion that most patients with restrictive lung disease complicating pregnancy, including those with pulmonary sarcoidosis, will have a favorable pregnancy outcome. However, the clinician should keep in mind that a subgroup of women with restrictive lung disease can have significant worsening of their clinical condition during gestation.

Cystic Fibrosis

Cystic fibrosis involves the exocrine glands and epithelial tissues of the pancreas, sweat glands, and mucous glands in the respiratory, digestive, and reproductive tracts. **Chronic obstructive pulmonary disease, pancreatic exocrine insufficiency, and elevated sweat electrolytes are present in most patients with cystic fibrosis.** The disease is **genetically transmitted with an autosomal recessive pattern of inheritance.** The cystic fibrosis gene was identified and cloned in 1989. The gene is localized to chromosome 7, and the molecular defect accounting for the majority of cases has been identified. **In the United States, about 4% of the white population are heterozygous carriers of the cystic fibrosis gene. The disease occurs in 1 in 3000 live white births.** Morbidity and mortality in cystic fibrosis is usually secondary to progressive chronic bronchial pulmonary disease. Pregnancy and the attendant physiologic changes can stress the pulmonary, cardiovascular, and nutritional status of women with cystic fibrosis. The purpose of this section is to familiarize the obstetrician with the physiologic effects of this complex disease and the impact of the disease on pregnancy and the impact of

pregnancy on the disease. Additional factors that need to be addressed are the genetics of this disorder (see Chapter 10) and the implications for the newborn, as well as social issues, including who will raise the child should the mother succumb to her disease.

Survival for patients with cystic fibrosis has increased dramatically since 1940. According to the Cystic Fibrosis Foundation's Patient Registry, mean survival in 2008 had increased to 39.6 years. Women had a slightly lower median age of survival (27.3 years) compared with men (29.6 years). The reasons for sex differences in mortality are unclear. **Today more than 45% of individuals with cystic fibrosis in the United States are older than 18 years.** This increase in survival of patients with cystic fibrosis is likely secondary to earlier diagnosis and intervention and to advances in antibiotic therapy and nutritional support. **Therefore, more women with cystic fibrosis are now entering reproductive age. In contrast to men with cystic fibrosis, who for the most part are infertile, women with cystic fibrosis are more often fertile. Infertility in women with cystic fibrosis may occasionally be due to anovulatory cycles and secondary amenorrhea, which result from significant malnutrition associated with advanced disease. A more common reason for infertility appears to result from alteration in the physiologic properties of cervical mucus.**

The first case of cystic fibrosis complicating pregnancy was reported in 1960. The annual number of cystic fibrosis pregnancies reported to the Cystic Fibrosis Foundation's Patient Registry doubled between 1986 and 1990, with 52 pregnancies reported in 1986 and 111 pregnancies reported in 1990. This same registry recently reported on a total of 680 pregnancies in 8136 women between 1985 and 1997. This documents a dramatic increase in pregnancy complicated by cystic fibrosis. Increasing numbers are reported in other countries as well. **Because the number of women with cystic fibrosis achieving pregnancy is steadily increasing, it is important that the obstetrician is familiar with the disease. Liberal consultation with a cystic fibrosis specialist should be obtained because a team effort will increase the chance for an improved pregnancy outcome.**

Effect of Pregnancy on Cystic Fibrosis

The physiologic changes associated with pregnancy (see Chapter 3) are well tolerated by healthy gravidas; however, those with cystic fibrosis may adapt poorly. During pregnancy, there is an increase in resting minute ventilation that at term may approach 150% of control values. This increase in minute ventilation is due to the increased oxygen consumption and increased carbon dioxide burden that occur during pregnancy. In addition, increased levels of circulating progesterone stimulates the respiratory drive. Enlargement of the abdominal contents and upward displacement of the diaphragm lead to a decrease in functional residual volume and a decrease in residual volume. Pregnancy is also accompanied by subtle alterations in gas exchange with widening of the alveolar-arterial oxygen gradient that is most pronounced in the supine position. These alterations in pulmonary function are of little consequence to the normal pregnant woman. However, in the gravida with cystic fibrosis, these changes may contribute to respiratory decompensation that can lead to an increase in morbidity and mortality for the mother and the fetus.

During normal pregnancy, blood volume increases by an average of 50%. Cardiac output increases as well, reaching a plateau in midpregnancy. During labor, blood volume rises acutely, in large part because of the release of blood from the contracting uterus, and is additionally increased after delivery, secondary to augmented venous return with the release of caval obstruction. **Women with cystic fibrosis and advanced lung disease may suffer from pulmonary hypertension with high pulmonary artery pressures. Regardless of the etiology, pulmonary hypertension is associated with unacceptable maternal risk during pregnancy and is considered to be a contraindication to pregnancy.** Women with significant pulmonary hypertension may develop cardiovascular collapse at the time of labor and delivery, with a maternal mortality rate exceeding 25%. Additionally, **women with pulmonary hypertension may not be able to adequately increase cardiac output during pregnancy and, therefore, suffer uteroplacental insufficiency, leading to IUGR and stillbirth.**

Nutritional requirements are increased during pregnancy, with about 300 kcal/day in additional fuel being needed to meet the requirements of mother and fetus. **Most patients with cystic fibrosis have pancreatic exocrine insufficiency. As a result, digestive enzymes and bicarbonate ions are diminished, resulting in maldigestion, malabsorption, and malnutrition.**

There are several reports suggesting that **patients with mild cystic fibrosis, good nutritional status, and less impairment of lung function tolerate pregnancy well. However, those with poor clinical status, malnutrition, hepatic dysfunction, or advanced lung disease are at increased risk from pregnancy.**[94,95] Kent and Farquharson[95] reviewed the literature and reported 217 pregnancies. In this series, the frequency of preterm delivery was 24.3% and the perinatal death rate was 7.9%. **Poor outcomes were associated with a maternal weight gain of less than 4.5 kg and an FVC less than 50% of predicted. Edenborough and colleagues**[96] **also reported on pregnancies in women with cystic fibrosis. There were 18 live births (81.8%), one third of which were preterm deliveries, and 18.2% of patients had abortions. There were four maternal deaths within 3.2 years after delivery.** In this series, lung function was available before delivery, immediately after delivery, and after pregnancy. Although the patients demonstrated a decline of 13% in FEV_1 and 11% in FVC during pregnancy, most returned to baseline pulmonary function after pregnancy. Although most of the women in this series tolerated pregnancy well, **those with moderate to severe lung disease, an FEV_1 less than 60% of predicted, more often had preterm infants and had increased loss of lung function compared with those with milder disease.**[96] **In two series, prepregnancy FEV_1 was found to be the most useful predictor of outcome in pregnant women with cystic fibrosis.**[96,97] **In addition, there was a positive correlation of prepregnancy FEV_1 and maternal survival.**

A more recent report examined survival in 8136 women enrolled in the U.S. Cystic Fibrosis Foundation National Patient Registry from 1985 to 1997.[98] Six hundred and eighty of these women became pregnant. The authors matched the 680 women in an index year to 3327 control women with cystic fibrosis. Women who reported a pregnancy were more likely to have had a higher percentage of

predicted FEV_1 (67.5% predicted versus 67.1% predicted, respectively; $P > .001$) and a higher weight (52.9 versus 46.4 kg, respectively; $P > .001$). The 10-year survival rate in pregnant women (77%; 95% CI, 71% to 82%) was higher than in those women who did not become pregnant. A separate analysis, matching pregnant patient's FEV_1 percent of predicted, age, *Pseudomonas aeruginosa* colonization, and pancreatic function obtained similar results. In this cohort, pregnancy was not harmful in any subgroup, including patients with an FEV_1 40% of predicted or diabetes mellitus.[98] **The author concluded women with cystic fibrosis who became pregnant were initially healthier and had better 10-year survival rates than women with cystic fibrosis who did not become pregnant.**

Pulmonary involvement in cystic fibrosis includes chronic infection of the airways and bronchiectasis. There is selective infection with certain microorganisms, such as *S. aureus, H. influenzae, P. aeruginosa,* and *Burkholderia cepacia. P. aeruginosa* is the most frequent pathogen. Parenteral antibiotics are the mainstays of treatment of these acute infections. However, pregnancy- and cystic fibrosis–associated alterations in pharmacokinetics can have grave consequences for these patients. It is well known that pregnant subjects have lower serum levels and higher urine levels of antibiotics than nonpregnant subjects. The lower levels in plasma are attributed to the increase in volume of distribution and an increase in glomerular filtration and renal clearance of the drugs. Therefore, monitoring drug levels is indicated when therapeutic response is less than optimum.

Counseling Patients with Cystic Fibrosis in Pregnancy

Several factors must be considered when counseling a woman who has cystic fibrosis and is considering pregnancy, including the possibility that her fetus will have cystic fibrosis (see Chapter 10). **When the mother has cystic fibrosis and the proposed father is a white individual of unknown genotype, the risk for the fetus having cystic fibrosis is 1 in 50, compared with 1 in 3000 in the general white population. If the prospective father is a known carrier of a cystic fibrosis mutation, the risk to the fetus increases to 1 in 2.** If, however, DNA testing does not identify a cystic fibrosis mutation in the prospective father, it is still possible that the father is a carrier of an unidentified cystic fibrosis mutation, making the risk for cystic fibrosis to the offspring 1 in 492.[99]

It is important that the woman with cystic fibrosis be advised about the potential adverse effects of pregnancy on maternal health status. Factors that may predict poor outcome include prepregnancy evidence of poor nutritional status, significant pulmonary disease with hypoxemia, and pulmonary hypertension. Liver disease and diabetes mellitus are also poor prognostic factors. **Gravidas with poor nutritional status, pulmonary hypertension (cor pulmonale), and deteriorating pulmonary function early in gestation should consider therapeutic abortion because the risk for maternal mortality may be unacceptably high.**

The woman with cystic fibrosis who is considering pregnancy should also give consideration to the need for strong psychosocial and physical support after delivery. The rigors of child rearing may add to the risk for maternal deterioration during this period. Family members should also be willing to provide physical and emotional support and should be aware of the potential for deterioration in the mother's health and the potential for maternal mortality. **In addition, the need for care of a potentially preterm growth-restricted neonate with all of its attendant morbidities and potential mortality should be discussed.** Over the long term, the woman and her family should also consider the fact that her life expectancy may be shortened by cystic fibrosis. **Overall 20% of mothers with cystic fibrosis succumb to the disease before the child's 10th birthday, and this number increases to 40% if the FEV_1 is less than 40% of predicted.**[100] Plans should be made for rearing of the child in the event of maternal death.

Management of the Pregnancy Complicated by Cystic Fibrosis

Care of the gravida with cystic fibrosis should be a coordinated, team effort. Physicians familiar with cystic fibrosis, its complications, and management should be included, as well as a maternal-fetal medicine specialist and neonatal team. The gravida should be assessed for potential risk factors such as severe lung disease, pulmonary hypertension, poor nutritional status, pancreatic failure, and liver disease, preferably before attempting gestation, but certainly during the early months of pregnancy. **Gravidas should be advised to be 90% of ideal body weight before conception if possible. A weight gain in pregnancy of 11 to 12 kg is recommended.**[101] **Frequent monitoring of weight, blood glucose, hemoglobin, total protein, serum albumin, prothrombin time, and fat-soluble vitamins A and E is suggested.**[101] At each visit, the history of caloric intake and symptoms of maldigestion and malabsorption should be taken, and pancreatic enzymes should be adjusted if needed. **Patients who are unable to achieve adequate weight gain through oral nutritional supplements may be given nocturnal enteral nasogastric tube feeding. In this situation, the risk for aspiration should be considered, especially in patients with a history of gastroesophageal reflux, which is common in cystic fibrosis. If malnutrition is severe, parenteral hyperalimentation may be necessary for successful completion of the pregnancy. Baseline pulmonary function should be assessed, preferably before conception.** Assessment should include **FVC, FEV_1, lung volumes, pulse oximetry, and arterial blood gases,** if indicated. **These values should be serially monitored during gestation and deterioration in pulmonary function addressed immediately. An echocardiogram can assess the patient for pulmonary hypertension and cor pulmonale.** If pulmonary hypertension (cor pulmonale) is diagnosed, the gravida should be advised of the high maternal risk.

Early recognition and prompt treatment of pulmonary infections are important in the management of the pregnant woman with cystic fibrosis. **Treatment includes intravenous antibiotics in the appropriate dose, keeping in mind the increased clearance of these drugs secondary to pregnancy and cystic fibrosis.** Plasma levels of aminoglycosides should be monitored and adjusted as indicated. **Chest physical therapy and bronchial drainage are also important components of the management of pulmonary infections in cystic fibrosis. Because *P. aeruginosa* is the most frequently isolated bacterium associated with chronic endobronchitis**

and bronchiectasis, antibiotic regimens should include coverage for this organism.

If the patient with cystic fibrosis has pancreatic insufficiency and diabetes mellitus, careful monitoring of blood glucose and insulin therapy is indicated. As previously mentioned, pancreatic enzymes may need to be replaced in order to optimize the patient's nutritional status. **Because of malabsorption of fats and frequent use of antibiotics, the patient with cystic fibrosis is prone to vitamin K deficiency. Therefore, prothrombin time should be checked regularly, and parenteral vitamin K should be administered if the prothrombin time is elevated.**

It is imperative when managing pregnancy in a woman with cystic fibrosis to recognize that the fetus is at risk for uteroplacental insufficiency and IUGR. The maternal nutritional status and weight gain during pregnancy will likewise affect fetal growth. Therefore, **fundal height should be measured routinely, and serial ultrasound evaluations of fetal growth and amniotic fluid volume should be made.** Maternal kick counts may be useful for monitoring fetal status starting at 28 weeks. **Nonstress testing should be started at 32 weeks or sooner, if there is evidence of fetal compromise.** If there is evidence of severe fetal compromise such as no interval fetal growth, persistent decelerations, or poor biophysical profile scoring, delivery should be accomplished. Likewise, **evidence of profound maternal deterioration such as a marked and sustained decline in pulmonary function, development of right-sided heart failure, refractory hypoxemia, and progressive hypercapnia and respiratory acidosis may be maternal indications for early delivery.** If the fetus is potentially viable, the administration of betamethasone may be beneficial. Vaginal delivery should be attempted when possible.

Labor, delivery, and the postpartum period can be particularly dangerous for the patient with cystic fibrosis. The augmentation in cardiac output stresses the cardiovascular system and can lead to cardiopulmonary failure in the patient with pulmonary hypertension and cor pulmonale. These patients are also more likely to develop right-sided heart failure. **Heart failure should be treated with aggressive diuresis and supplemental oxygen. Management may be optimized by insertion of a pulmonary artery catheter to monitor right- and left-sided filling pressures. Pain control will reduce the sympathetic response to labor and tachycardia. This will benefit the patient who is demonstrating pulmonary or cardiac compromise.** In the patient with a normal partial thromboplastin time, insertion of an epidural catheter for continuous epidural analgesia may be beneficial. This is also useful in the event a cesarean delivery is indicated because general anesthesia and its possible effects on pulmonary function can be avoided. **If general anesthesia is needed, preoperative anticholinergic agents should be avoided because they tend to promote drying and inspissation of airway secretions.** Close fetal surveillance is also extremely important because the fetus who may have been suffering from uteroplacental insufficiency during gestation is more prone to develop evidence of fetal compromise during labor. **Cesarean delivery should be reserved for the usual obstetrical indications.**

In summary, more women with cystic fibrosis are living to childbearing age and are capable of conceiving. Clinical experience thus far has demonstrated that **pregnancy in women with cystic fibrosis and mild disease is well tolerated. Women with severe disease have an associated increase in maternal and fetal morbidity and mortality.** The potential risk to any individual with cystic fibrosis desirous of pregnancy should be assessed and discussed with the patient and her family in detail.

KEY POINTS

- Pneumonia is the most common nonobstetrical infection to cause maternal mortality. Preterm delivery complicates pneumonia in up to 43% of cases. *Streptococcus pneumoniae* is the most common bacterial pathogen to cause pneumonia. Empirical antibiotic coverage should be started, including a third-generation cephalosporin and a macrolide, such as azithromycin, to cover atypical pathogens. If CA-MRSA is suspected, add vancomycin or linezolid.
- The HIV-infected gravida with a $CD4^+$ count of less than 200 cells per cubic millimeter should receive prophylaxis with trimethoprim-sulfamethoxazole to prevent PJP pneumonia as well as HAART.
- High-risk gravidas should be screened for TB and treated appropriately with INH prophylaxis for infection without overt disease and with dual anti-TB therapy for active disease. If resistant TB is identified, ethambutol, 2.5 g/day, should be added to therapy, and the treatment period should be extended to 18 months.
- Asthma complicates about 8% of pregnancies.
- It is safer for pregnant women with asthma to be treated with asthma medications than it is for them to have asthma symptoms and exacerbations.
- Clinical evaluation of asthma includes subjective assessments and pulmonary function tests.
- Inhaled corticosteroids are the preferred treatment for persistent asthma in pregnancy.
- Identifying and controlling or avoiding such factors as allergens and irritants, particularly tobacco smoke, can lead to improved maternal well-being with less need for medication.
- The goal of asthma therapy during pregnancy is maintenance of near-normal pulmonary function.
- Step-care therapy uses the principle of tailoring medical therapy according to asthma severity.
- Women taking asthma medications may breastfeed.
- Asthma self-management education, including self-monitoring, correct use of inhalers, and an action plan, are part of optimal gestational asthma therapy.
- The interstitial lung diseases include idiopathic pulmonary fibrosis, sarcoidosis, hypersensitivity pneumonitis, drug-induced lung disease, and connective tissue disease. Restrictive lung disease is generally well tolerated in pregnancy; however, exercise intolerance and need for oxygen

supplementation may develop. Gravidas with pulmonary hypertension complicating restrictive lung disease may suffer a high mortality rate.

- An increasing number of women with cystic fibrosis are surviving to the reproductive years and usually maintain their fertility with meticulous management of pulmonary function, including pulmonary toilet and aggressive surveillance for signs of pulmonary infection and treatment with antibiotics in adequate doses. Close attention to nutrition is required secondary to maldigestion, malabsorption, and malnutrition, which can complicate cystic fibrosis. Gravidas with good clinical studies, good nutritional status, near-normal chest radiographs, and only mild obstructive lung disease will tolerate pregnancy well. Fetal growth should be monitored closely.

INTRODUCTION

Until relatively recently, women with preexisting renal disease were strongly discouraged from attempting pregnancy because of the expectation of poor perinatal outcome and the likelihood of renal disease progression. Currently, through better understanding of the prognosis of kidney disease during pregnancy, women with most renal conditions are no longer discouraged from attempting conception. This even holds true for women who have undergone renal transplantation.

This chapter first reviews the normal changes in the kidney and urinary collecting system in pregnancy and follows with the basic evaluation of the renal status, acute and chronic renal disorders in pregnancy, and the treatment of the post–renal transplant patient.

ALTERED RENAL PHYSIOLOGY IN PREGNANCY

Pregnancy is associated with significant anatomic changes in the kidney and its collecting system (see Chapter 3). These changes begin to occur shortly after conception and may persist for several months postpartum.[1,2] **The kidney is noted to increase in size and weight during the course of a pregnancy. Of more clinical significance is the marked dilation of the collecting system, including both the renal pelvis and ureters.** This dilation is most pronounced on the right side. This change is likely due to **hormonal changes** (i.e., progesterone, endothelin, relaxin) and as a result of mechanical obstruction by the gravid uterus (Figure 38-1).[3-5]

Renal plasma flow increases greatly during pregnancy.[6] It peaks by the end of the first trimester and, although it decreases near term, it remains higher than in the nonpregnant patient. This change is due in part to increased cardiac output and decreased renal vascular resistance. **The glomerular filtration rate (GFR) increases by 50% during a normal gestation.**[7] It rises early in pregnancy and remains elevated throughout gestation. The percentage increase in GFR is greater than the percentage increase in renal plasma flow. This elevation of the filtration fraction leads to a fall in the serum urea nitrogen (blood urea nitrogen [BUN]) and serum creatinine values.

Because GFR increases to such a great degree, electrolytes, glucose, and other filtered substances reach the renal tubules in greater amounts. The kidney handles sodium efficiently, reabsorbing most of the filtered load in the proximal convoluted tubule. Glucose reabsorption, however, does not increase proportionately during pregnancy. **The average renal threshold for glucose is reduced to 155 mg/dL from 194 mg/dL in the nonpregnant individual.**[8] **Glycosuria therefore can be a feature of normal pregnancy.**

Urate is handled by filtration and secretion. Its clearance increases early in pregnancy, leading to lower serum levels of uric acid. In late pregnancy, urate clearance and serum urate levels return to their prepregnancy values. Serum urate levels are elevated in women with preeclampsia. Whether this is due to decreased renal plasma flow,

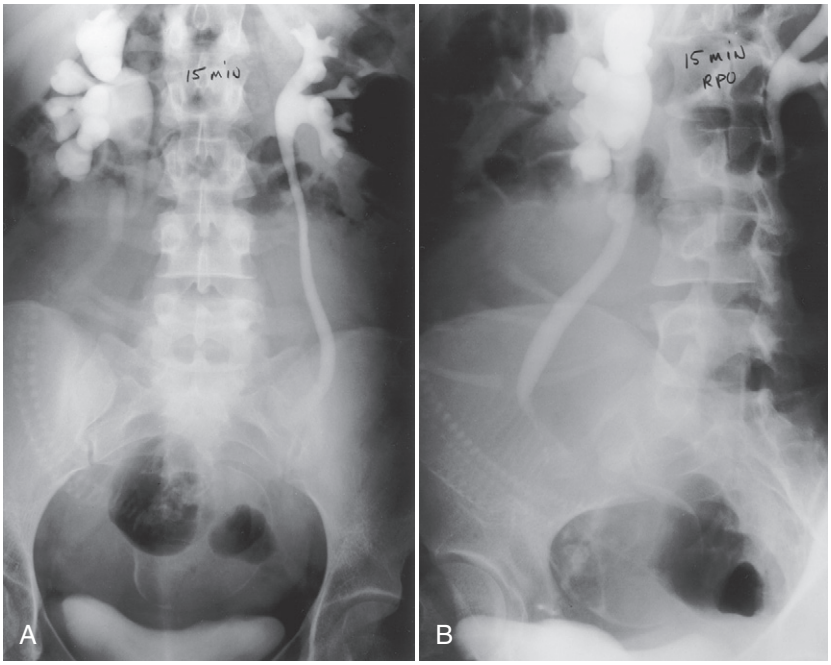

FIGURE 38-1. **A,** An intravenous pyelogram of a gravid patient in late second trimester with flank pain. The image was taken in the anteroposterior view 15 minutes after the instillation of contrast dye. Note the dilation of the renal pelves bilaterally, with the right side more dilated than the left. The fetus is seen in the vertex position. **B,** The same patient in the right lateral view.

TABLE 38-1 SUMMARY OF RENAL CHANGES IN NORMAL PREGNANCY

ALTERATION	MANIFESTATION	CLINICAL RELEVANCE
Increased renal size	Renal length about 1 cm greater on radiographs	Postpartum decreases in size should not be mistaken for parenchymal loss
Dilation of pelves, calyces, and ureters	Resembles hydronephrosis on ultrasound or IVP (usually more prominent on the right)	Not to be mistaken for obstructive uropathy Upper urinary tract infections are more virulent.
Changes in acid-base metabolism	Renal bicarbonate reabsorption threshold decreases	Serum bicarbonate is 4-5 mM/L lower in pregnancy P_{CO_2} is 10 mm Hg in normal pregnancy P_{CO_2} of 40 mm Hg actually represents retention in pregnancy
Renal water	Osmoregulation altered as the osmotic thresholds for AVP release decrease	Serum osmolarity decreased by approximately 10 mOsm/L

Modified from Lindheimer M, Grünfeld JP, Davison JM: Renal disorders. *In* Barron WM, Lindheimer M (eds): Medical Disorders during Pregnancy. St Louis, Mosby, 2000, pp 39-70.
AVP, Vasopressin; *IVP,* intravenous pyelography; P_{CO_2}, carbon dioxide tension.

hemoconcentration, renal tubular dysfunction, or other renal circulatory changes continues to be unknown. A summary of the renal changes in normal pregnancy is shown in Table 38-1.

ASYMPTOMATIC BACTERIURIA

The diagnosis of asymptomatic bacteriuria (ASB) is based on a clean catch voided specimen. The prevalence of ASB in sexually active woman has been reported as high as 5% to 6%.[9,10] **To secure a diagnosis, urine culture should reveal greater than 100,000 colonies/mL of a single organism.**[11] Some investigators have suggested that two consecutively voided specimens should contain the same organism before establishing the diagnosis of bacteriuria.[12,13] Bacteriuria occurs in 2% to 7% of pregnancies, particularly in multiparous women, a prevalence similar to that seen in nonpregnant women. The pathogenic organisms are also similar in species and virulence factors to those observed in nonpregnant women. Thus, the basic mechanism of entry of bacteria into the urinary tract is likely to be the same for both groups. Bacteriuria often develops in the first month of pregnancy and is frequently associated with a reduction in concentrating ability, suggesting involvement of the kidney.[2] The smooth muscle relaxation and subsequent ureteral dilation that accompany pregnancy are believed to facilitate the ascent of bacteria from the bladder to the kidney. As a result, bacteriuria during pregnancy has a greater propensity to progress to pyelonephritis (up to 40%) than in nonpregnant women.[14] If a urine culture is negative for bacteria at the first prenatal visit, the risk of developing acute cystitis is less than 1%.[10,15]

It is important to diagnose and treat ASB in pregnancy. If left untreated, a symptomatic urinary tract infection (UTI) will develop in up to 40% of these patients.[6,10,16] **Recognition and therapy for ASB can eliminate 70% of acute UTIs in pregnancy.** Nonetheless, 2% of pregnant women with negative first trimester urine cultures develop symptomatic cystitis or pyelonephritis. This group accounts for 30% of the cases of acute UTI that develop during gestation. The American College of Obstetricians and Gynecologists (ACOG) recommends routine screening of

all women for ASB at their first prenatal visit.[17] Other than progression to more serious infection, however, there is little evidence that ASB has an effect on pregnancy outcome.[9,18]

***Escherichia coli* is the organism responsible for most cases of ASB.** Women can therefore be safely treated with nitrofurantoin, ampicillin, cephalosporins, and short-acting sulfa drugs (see the accompanying box, Antimicrobial Treatment for the Pregnant Patient with Bacteriuria). Sulfa compounds should be avoided near term, as they compete for bilirubin-binding sites on albumin in the fetus and newborn and therefore pose a risk for kernicterus. Nitrofurantoin should not be used in patients with glucose-6-phosphate dehydrogenase deficiency (G6PD), as there is a risk for hemolytic crisis. If the fetus has G6PD, it may also experience hemolysis. Therapy for ASB should be continued for 7 days. A follow-up culture should be performed 1 to 2 weeks after discontinuing therapy. Approximately 15% of women will experience a reinfection and/or will not respond to initial therapy. Therapy in these cases should be reinstituted after careful microbial sensitivity testing. Women with recurrent UTI during pregnancy and those with a history of pyelonephritis should eventually undergo imaging of the upper urinary tract. This procedure should be delayed until the patient is 3 months postpartum so that the anatomic changes of pregnancy can regress.

Antimicrobial Treatment for the Pregnant Patient with Bacteriuria

- Amoxicillin 500 mg three times a day
- Ampicillin 250 mg four times a day
- Cephalosporin 250 mg four times a day
- Nitrofurantoin 100 mg four times a day
- Sustained-release nitrofurantoin 100 mg two times a day
- Trimethoprim (160 mg)/sulfamethoxazole (800 mg) two times a day

The agent of choice should be given for a 7-day course. A repeat urine culture is recommended 2 weeks after the treatment has been completed.

Occasionally it can be difficult to distinguish severe cystitis from pyelonephritis. Although the drugs used for treatment are similar, pyelonephritis treatment during pregnancy generally requires intravenous antibiotics. Sandberg and colleagues[19] studied symptomatic UTI in 174 women. They found that C-reactive protein was elevated in 91% of pregnant women with acute pyelonephritis and only 5% of women with cystitis. They also noted that the urine-concentrating ability was lower in women with acute pyelonephritis. Because the erythrocyte sedimentation rate is normally elevated in pregnancy, they found that this was not a useful parameter for distinguishing pyelonephritis from cystitis.

PYELONEPHRITIS

Pyelonephritis complicates 1% to 2% of all pregnancies, **and contributes substantially to maternal morbidity. It is among the most common nonobstetrical causes for hospitalization during pregnancy.[20] Recurrent pyelonephritis has been implicated as a cause of fetal death and intrauterine growth restriction (IUGR).** There also appears to be an association between acute pyelonephritis and preterm labor.[21,22] Fan and coworkers,[23] however, have shown that if pyelonephritis is aggressively treated, it does not increase the likelihood of prematurity, premature delivery, or low-birth-weight infants. Hill and colleagues,[24] reporting on 440 cases of acute pyelonephritis over a 2-year period, noted the disease to be more prevalent in younger primagravid women without racial predilection. The majority of cases (53%) presented during the second trimester. The most common pathogen was *E. coli*, accounting for 83% of cases, with gram-positive organisms accounting for another 11.6%.[24]

Acute pyelonephritis during pregnancy is most often treated on an inpatient basis, using intravenous antibiotics. Empiric therapy should be begun as soon as the presumptive diagnosis is made. Therapy can be tailored to the specific organism after sensitivities have been obtained. Because septicemia may occasionally result from pyelonephritis, blood cultures should be obtained if patients do not respond rapidly to initial antibiotic therapy. **Generally, a broad-spectrum first-generation cephalosporin is the initial therapy of choice.** Fan and colleagues[23] reviewed 107 cases of pyelonephritis in 103 pregnancies. The authors noted that 33% of the cases a decade ago were resistant to ampicillin and 13% to first-generation cephalosporins. Current rates of resistance to ampicillin and first-generation cephalosporins are likely higher. If resistance to more common therapies is encountered, a later-generation cephalosporin or an aminoglycoside can be safely administered. Peak and trough aminoglycoside levels should be measured when using aminoglycosides. Serum creatinine and BUN level should be followed as well. During the febrile period, acetaminophen treatment is advised to keep the temperature below 38° C.

Intravenous antibiotic therapy should be continued for 24 to 48 hours after the patient becomes afebrile and costovertebral angle tenderness disappears. After the cessation of intravenous therapy, treatment with appropriate oral antibiotics is recommended for 10 to 14 days. On termination of therapy, urine cultures should be obtained on each trimester for the remainder of gestation. After an episode of acute pyelonephritis, antibiotic suppression should also be implemented and continued for the remainder of the pregnancy. Nitrofurantoin 100 mg once or twice daily is an acceptable regimen for suppression. In a study by Van Dorsten and colleagues, nitrofurantoin suppression reduced the rate of subsequent positive cultures from 38% to 8%. However, nitrofurantoin did not lower the rate of positive cultures if inpatient antibiotic selection was inappropriate or if culture was positive at time of discharge.[25]

The most common maternal complications associated with pyelonepritis are anemia (23%), septicemia (17%), transient renal dysfunction (2%), and pulmonary insufficiency (7%).[24] **Pulmonary injury resembling adult respiratory distress syndrome (ARDS) can occur in pregnant women with acute pyelonephritis.**[26] Clinical manifestations of this complication usually occur 24 to 48 hours after the patient is admitted for pyelonephritis.[26,27] Some of these women will require endotracheal intubation, mechanical ventilation,[6] and positive end expiratory pressure (PEEP). **ARDS probably results from endotoxin-induced alveolar**

capillary membrane injury. Towers and colleagues[28] found evidence of pulmonary injury in 11 of 130 patients with pyelonephritis. A fever of greater than 103° F, a maternal heart rate above 110, and gestation beyond 20 weeks were factors associated with increased risk for pulmonary injury. The most predictive factors were fluid overload and tocolytic therapy.[28]

Austenfeld and Snow[29] reported 64 pregnancies in 30 women who had previously undergone ureteral reimplantation for vesicoureteral reflux. During pregnancy, 57% of these women experienced one or more UTIs, and 17% had more than one UTI or an episode of pyelonephritis.[29] More frequent urine cultures and aggressive therapy during pregnancy are recommended for this group of high-risk parturients.

ACUTE RENAL DISEASE IN PREGNANCY

Urolithiasis

Urolithiasis affects 0.03% of all pregnancies, a frequency similar to that of the general population.[30] Colicky abdominal pain, recurrent UTI, and hematuria suggest urolithiasis.[31] If the diagnosis is suspected, intravenous pyelography should be undertaken, limiting this study to the minimum number of exposures necessary to make the diagnosis. Ultrasound can often be used to establish the diagnosis without radiation exposure. Newer ultrasound flow studies can actually follow flow from the ureter to the bladder and detect obstruction without the use of ionizing radiation. If transabdominal ultrasound is not sufficient, transvaginal ultrasound can be employed to image the distal ureter.[32] Urine microscopy may detect crystals and help distinguish the type of stone before it is passed. For any women with renal calculi, serum calcium and phosphorous levels should be assayed to rule out hyperparathyroidism. Serum urate should also be determined.

Because of the physiologic hydroureter of pregnancy, 75% to 85% of women with symptomatic urolithiasis will spontaneously pass their stones.[31] Treatment should thus be conservative, consisting of hydration and narcotic analgesia.[33] Epidural anesthesia has been advocated to establish a segmental block from T11 to L2. It is unknown whether this promotes passage of the stone. Ureteral stenting to relieve obstruction is an option for managing pregnant women with renal stones. For refractory cases, nephrostomy tubes can also be employed. It should be noted that pregnancy increases the risk of stent encrustation requiring frequent stent exchange every 4 to 6 weeks until delivery.[34] Lithotripsy is contraindicated during pregnancy.[35]

Recurrent UTI with urease-containing organisms causes precipitation of calcium phosphate in the kidney that may lead to the development of staghorn calculi. Surgery is rarely indicated in these women during gestation. Individuals with staghorn calculi should have frequent urine cultures, and bacteriuria should be treated aggressively. Recurrent infections poses a risk for chronic pyelonephritis with resultant loss of kidney function.

Glomerulonephritis

Acute glomerulonephritis is an uncommon complication of pregnancy, with an estimated incidence of 1 per 40,000 pregnancies.[36] Poststreptococcal glomerulonephritis is rarely observed in the adult population. In this disorder, renal function tends to deteriorate during the acute phase of the disease, but usually later recovers.[37] **Acute glomerulonephritis can be difficult to distinguish from preeclampsia. Periorbital edema, a striking clinical feature of acute glomerulonephritis, is often seen in preeclampsia. However, hematuria, red blood cell (RBC) casts in the urine sediment, and depressed serum complement levels support glomerular disease.** Antistreptolysin O titers rise may secure the diagnosis of post-streptococcal glomerulonephritis.

Treatment of acute glomerulonephritis in pregnancy is similar to that for the nonpregnant individual. Blood pressure control is essential, and careful attention to fluid balance is imperative. Sodium intake should be restricted to 500 mg/day during the acute disease. Serum potassium levels must also be carefully monitored.

Packham and coworkers[38] extensively reviewed 395 pregnancies in 238 women with primary glomerulonephritis. Only 51% of infants were born after 36 weeks' gestation. Excluding therapeutic abortion, 20% of fetuses were lost with 15% occurring after 20 weeks' gestation. IUGR was noted in 15% of cases. Maternal renal function deteriorated in 15% of pregnancies and failed to resolve following delivery in 5% of the population.[38] Hypertension was recorded in 52% of the pregnancies and developed before 32 weeks' gestation in 26% of cases. In most cases, this blood pressure elevation was not an exacerbation of chronic hypertension. Eighteen percent of the women who developed de novo hypertension in pregnancy remained hypertensive postpartum. Increased proteinuria was recorded in 59% of these pregnancies and was irreversible in 15%.[38] The highest incidence of fetal and maternal complications occurred in patients with primary focal and segmental hyalinosis and sclerosis, whereas the lowest incidence of complications was observed in non-IgA diffuse mesangial proliferative glomerulonephritis.[38] The presence of severe vessel lesions on renal biopsy was associated with a significantly higher rate of fetal loss after 20 weeks' gestation. Packham and coworkers[39] also studied 33 pregnancies in 24 patients with biopsy-proven membranous glomerulonephritis. Fetal loss occurred in 24% of pregnancies, preterm delivery in 43%, and a term liveborn in only 33% of patients. Hypertension was noted in 46% of these pregnant women. Thirty percent of patients had proteinuria in the nephrotic range during the first trimester.[39] The presence of significant proteinuria during the first trimester correlated with poor fetal and maternal outcome.[39]

Jungers and colleagues[40] described 69 pregnancies in 34 patients with IgA glomerulonephritis. The fetal loss rate in this group was 15%. Preexisting hypertension was statistically associated with poor fetal outcome. Hypertension at the time of conception also correlated with a deterioration of maternal renal function during pregnancy. Hypertension in the first pregnancy was highly predictive of recurrence of hypertension in a subsequent pregnancy.[40] Kincaid-Smith and Fairley[41] analyzed 102 pregnancies in 65 women with IgA glomerulonephritis. They noted that hypertension occurred in 63% of pregnancies, with 18% being severe. In this subset of women, a decline in renal

function was observed in 22%.[41] Abe[42] reported 240 pregnancies in 166 women with preexisting glomerular disease. Eight percent of the pregnancies resulted in a spontaneous abortion, 6% resulted in stillbirth, and 86% were liveborn. Most losses occurred in women with a GFR less than 70 mL/min and preexisting hypertension. Even though the majority of women with significant renal insufficiency had good pregnancy outcomes, the long-term prognosis for these cases was worse if the GFR was less than 50 mL/min and the serum creatinine was more than 1.5 mg/dL.[42] The histopathogenic diagnosis of membranoproliferative glomerulonephritis seemed to carry the worst prognosis with 29% developing hypertension and 33% developing a long-term decrease in renal function.

Imbasciati and Ponticelli[43] summarized six studies containing a total of 906 pregnancies in 558 women with preexisting glomerular disease. The overall perinatal mortality rate was 13%. Hypertension, azotemia, and nephrotic range proteinuria were the strongest predictive factors for a poor pregnancy outcome. In this report, the histologic type of glomerulonephritis had little correlation with pregnancy outcome. Hypertension persisted in 3% to 12% of patients who developed hypertension for the first time during pregnancy. In 25% of patients, hypertension worsened during pregnancy and normalized postpartum.[43] Some of these cases represented superimposed preeclampsia; however, this diagnosis can be difficult to establish in women with baseline hypertension and proteinuria. Remarkably, only 3% of these 166 women experienced an acceleration of their glomerular disease after pregnancy.

Acute Renal Failure in Pregnancy

Acute renal failure (ARF) is defined as a urine output of less than 400 mL in 24 hours. To establish the diagnosis, ureteral and urethral obstruction must be excluded. The incidence of ARF during pregnancy is approximately 1 per 10,000. It is seen most frequently following septic first trimester abortions and in cases of sudden severe volume depletion resulting from hemorrhage.[44] It may also be observed with marked volume contraction associated with severe preeclampsia,[45,46] dehydration from hyperemesis gravidarum,[47] and with acute fatty liver of pregnancy.[45,48]

The incidence of ARF in pregnancy has decreased over the years. Stratta and colleagues[49] reported 81 cases of pregnancy-related ARF between 1958 and 1987, accounting for 9% of the total number of ARF cases needing dialysis during that interval. In three successive 10-year periods (1958-1967, 1968-1977, and 1978-1987), the incidence of pregnancy-related ARF fell from 43% to 2.8% of the total number of cases of ARF. The incidence changed from 1 in 3,000 to 1 in 15,000 pregnancies over the study period.[49] In these 81 ARF cases, 11.6% experienced irreversible renal damage with the majority occurring in the setting of severe preeclampsia/eclampsia.[49]

Renal ischemia is the common denominator in cases of ARF. With mild ischemia, quickly reversible prerenal failure results. With more prolonged ischemia, acute tubular necrosis occurs. This process is also reversible, as glomeruli are not affected. Severe ischemia, however, may produce acute cortical necrosis. This pathology is irreversible, although on occasion a small amount of renal function is preserved.[50] Stratta and colleagues[51] have reported 17 cases of ARF complicating pregnancies over 15 years, and all were secondary to preeclampsia/eclampsia. Cortical necrosis occurred in 29.5% of the cases.[51] Progression of ARF to cortical necrosis did not appear to be related to maternal age, parity, gestational age, duration of preeclampsia before delivery, or eclamptic seizures. The only significant risk factor associated with cortical necrosis was placental abruption.[51] In another study, Turney and coworkers[16] demonstrated that acute cortical necrosis, which occurred in 12.7% of their patients with ARF, carried a 100% mortality rate within 6 years.

Sibai and colleagues[52] studied the remote prognosis in 31 consecutive cases of ARF in patients with hypertensive disorders of pregnancy. Eighteen of the 31 patients had "pure" preeclampsia, while 13 pregnancies had other hypertensive disorders and renal disease. Five percent of the 18 patients with pure preeclampsia required dialysis during hospitalization, and all 18 patients had acute tubular necrosis. Of the other 13 women, 42% required dialysis and three patients had bilateral cortical necrosis. The majority of pregnancies in both groups were complicated by placental abruption and hemorrhage.[52] All 16 surviving patients in the pure preeclampsia group recovered normal renal function on long-term follow-up. Conversely, 9 of the 11 surviving patients in the nonpreeclamptic group required long-term dialysis, and four ultimately died of end-stage renal disease.[52] Turney and colleagues[16] also performed follow-up examinations of their patients. They found that maternal survival was adversely affected by increasing age. Their 1-year maternal survival rate was 78.6%. Follow-up of survivors showed normal renal function up to 31 years after ARF.[16]

Individuals with reversible ARF experience a period of oliguria of variable duration followed by polyuria, or a high-output phase. It is important to recognize that BUN and serum creatinine levels continue to rise early in the polyuric phase. During the recovery phase, urine output approaches normal. In these patients, it is important to monitor electrolytes frequently and to carefully treat any imbalance. The urine to plasma osmolality ratio should be determined early in the course of the disease. If the ratio is 1.5 or greater, prerenal pathology is likely, and the disorder tends to be of shorter duration and less severity. A ratio near 1.0 suggests acute tubular necrosis.

The main goal of treatment is the elimination of the underlying cause. **Volume and electrolyte balance** must be evaluated frequently. To assess volume requirements, invasive hemodynamic monitoring may be useful. This is especially true during the polyuric phase. Central hyperalimentation may also be required if renal failure is prolonged.

Acidosis frequently occurs in cases of ARF. Arterial blood gases therefore should be followed regularly. Acidosis must be treated promptly as it may exacerbate hyperkalemia, which may develop rapidly and can be fatal. If hyperkalemia develops, potassium restriction should be instituted immediately. Sodium bicarbonate, used to treat acidosis, may overload the patient with sodium and water. In such cases, peritoneal or hemodialysis may be necessary. The main indications for dialysis in ARF of pregnancy are hypernatremia, hyperkalemia, severe acidosis, volume overload, and worsening uremia. There is a single report

of a successful kidney transplant during pregnancy in the first trimester. Although unintentional, a patient received a kidney from her father at approximately 13 weeks' gestation and experienced a successful pregnancy.[53]

Hemolytic Uremic Syndrome

The postpartum hemolytic uremic syndrome is a rare idiopathic disorder that must be considered when a patient exhibits signs of hemolysis and decreasing renal function, particularly during in the postpartum period. This idiopathic syndrome may occur as early as the first trimester and up to 2 months postpartum.[16,54-56] In fact, it has even been reported following an ectopic pregnancy.[57] Most individuals have no predisposing factors. Prodromal symptoms include vomiting, diarrhea, and a flu-like illness. A review of forty-nine cases documented a 61% mortality rate, although with improved intensive care monitoring and treatment, the prognosis is now much improved.

Disseminated intravascular coagulation (DIC) with hemolysis usually accompanies hemolytic uremic syndrome. However, DIC is not the cause of the syndrome. Microscopically, the kidney shows thrombotic microangiopathy. The glomerular capillary wall is thick, and biopsy specimens taken later in the course of the disease show severe nephrosclerosis and deposition of the third component of complement (C_3).

Some investigators believe that this syndrome is due to decreased renal production of prostacyclin.[58,59] Prostacyclin infusions have been used to treat patients, but this therapy still remains experimental. One observer noted a decrease in antithrombin III in a woman with postpartum hemolytic uremic syndrome. This patient was successfully treated with an infusion of antithrombin III concentrate.[60]

Coratelli and coworkers[54] reported a case of hemolytic uremic syndrome that was diagnosed at 13 weeks' gestation and confirmed by renal biopsy. Circulating endotoxin was detected and was progressively reduced by hemodialysis performed daily from the third to the ninth days of the disease. Complete normalization of renal function occurred by day 34. These investigators propose that initiation of early dialysis may play an important role in supporting patients through the disease process. They also propose that endotoxins are key pathogenic factors in the disorder.[54] In contrast, Li and coworkers[61] failed to measure any endotoxin in the serum of a patient who developed hemolytic uremic syndrome after an uncomplicated cesarean delivery. This patient eventually underwent dialysis and recovered.[61] **Plasma exchange in cases of ARF caused by the postpartum hemolytic uremic syndrome can be vital to the treatment of this condition.**[62]

Polycystic Kidney Disease

Adult polycystic kidney disease is an autosomal dominant **disorder that usually begins to manifest itself in the fifth decade of life. Reproductive-age women may occasionally display symptoms. Hypertension is part of this disorder.** If a woman with adult polycystic kidney disease becomes pregnant, hypertension may be exacerbated and may not improve postpartum.[43] The overall prognosis for the disorder does not appear to worsen with an increasing number of pregnancies.

Vesicoureteral Reflux

Vesicoureteral reflux increases with pregnancy. It usually does not cause problems unless reflux becomes severe. If it is significant enough to warrant surgery, this should ideally be undertaken before pregnancy. Even with surgical correction, women with ureterovesical reflux are at increased risk for pyelonephritis and should have cultures performed frequently.[43] Antibiotic suppression, if indicated before pregnancy, should be continued.

Brandes and Fritsche[62] report a case of ARF due to ureteral obstruction by a gravid uterus. This case was complicated by a twin gestation with polyhydramnios at 34 weeks' gestation. The serum creatinine level peaked at 12.2 mg/dL, but resolved immediately after amniotomy.[62] In cases remote from term, ureteral stenting or dialysis may be necessary if significant obstruction and/or reflux is present.

Renal Artery Stenosis

Renal artery stenosis is an extremely rare complication of pregnancy.[63] This disorder may present as chronic hypertension with superimposed preeclampsia or as recurrent isolated preeclampsia. Although Doppler flow studies may be suggestive, renal angiography is the most specific and sensitive diagnostic test. Percutaneous transluminal angioplasty can be carried out at the time of angiography.[63]

Nephrotic Syndrome

The nephrotic syndrome was initially described as a 24-hour urine protein excretion of 3.5 g or more, reduced serum albumin, edema, and hyperlipidemia.[64] Currently, the syndrome is defined by massive proteinuria alone, which is often the result of glomerular damage.[64] The most common etiology of nephrotic syndrome in pregnancy (especially the third trimester) is preeclampsia. Other etiologies include membranous and mebranoproliferative glomerulpathy, minimal change disease, lupus nephropathy, hereditary nephritis, diabetic nephropathy, renal vein thrombosis, and amyloidosis.[65]

Women with newly diagnosed or persistent nephrotic syndrome need close monitoring during pregnancy. Whenever possible the etiology of the proteinuria should be determined. In some cases, steroid therapy may be employed to treat this condition; however, its use can actually aggravate the underlying disease process.[65] One common complication of nephrotic syndrome in pregnancy is profound edema secondary to protein excretion, which is further complicated by the normal decline in serum albumin associated with pregnancy.[65] A second complication is the development of a hypercoagulable state precipitated by urinary losses of antithrombin III, reduced levels of protein C and S, hyperfibrinogenemia, and enhanced platelet aggregation.[66]

CHRONIC RENAL DISEASE IN PREGNANCY

Chronic renal disease can be silent until its advanced stages. Because obstetricians routinely test a women's urine for the presence of protein, glucose, and ketones, they may be the first to detect chronic renal disease.

Any gravida with more than trace proteinuria should collect a 24-hour urine specimen for creatinine clearance and total protein excretion. Before pregnancy, 24-hour urinary protein excretion should not exceed 0.2 g. During gestation, quantities up to 0.3 g per day may be normal. Moderate proteinuria (less than 2 g per day) is often seen in glomerular disease.

Microscopic examination of the urine can reveal much about renal status. If renal disease is suspected, a catheterized specimen should be obtained. **More RBCs than one to two per high-power field or RBC casts are indicative of glomerular disease.** Less frequently, they suggest trauma or malignant hypertension. Increased numbers of white blood cells (WBCs) (more than one to two per high-power field) or the appearance of WBC casts is usually indicative of acute or chronic infection. Cellular casts are found in the presence of renal tubular dysfunction, and hyaline casts are associated with significant proteinuria.

The obstetrician can easily be misled when relying solely on BUN and serum creatinine levels to assess renal function. A 70% decline in creatinine clearance, an indirect measure of GFR, can be seen before a significant rise in serum BUN or serum creatinine occurs. Little change in serum creatinine or the BUN may be observed until the creatinine clearance falls to 50 mL/min. Below that level, small decrements in creatinine clearance can lead to large increases in the BUN and creatinine. A single creatinine clearance value less than 100 mL/min is therefore not diagnostic of renal diseases. An incomplete 24-hour urine collection is the most frequent cause of this finding. An abnormal clearance rate should therefore prompt a repeat assay.

Serum urate is an often overlooked but helpful parameter in detecting renal dysfunction. Excretion of uric acid is dependent not only on glomerular filtration but also on tubular secretion. An elevated serum urate in the presence of a normal BUN and serum creatinine may therefore implicate tubular disease. A solitary increase in uric acid may also signify impending or early preeclampsia.

Effect of Pregnancy on Renal Function

Although baseline creatinine clearance is decreased in women with chronic renal insufficiency, a physiologic rise will often occur in pregnancy. A moderate fall in creatinine clearance may then be observed during late gestation in patients with renal disease. This decline is typically more severe in women with diffuse glomerular disease and typically reverses after delivery.

The long-term effect of pregnancy on renal disease remains controversial. If the serum creatinine is less than 1.5 mg/dL, pregnancy appears to have little effect on the long-term prognosis. Pregnancy, however, is associated with an increased incidence of pyelonephritis in patients with chronic renal disease. There are few data concerning the long-term effect of pregnancy on renal disease in women with significant azotemia. Occasionally, some women with a baseline serum creatinine of more than 1.5 mg/dL will experience a significant decrease in renal function during gestation that does not improve during the postpartum period.[43,67] This deterioration occurs more frequently in women with diffuse glomerulonephritis. It is not possible, however, to predict which women with renal insufficiency will experience a permanent reduction in renal function. Moreover, if renal function significantly deteriorates during gestation, termination of pregnancy may not reverse the process. Termination therefore cannot be routinely recommended for patients who become pregnant and whose baseline serum creatinine level exceeds 1.5 mg/dL. Ideally, women with chronic renal disease should be counseled before conception about the possible deterioration in renal function.

Severe hypertension remains the greatest threat to a pregnant patient with chronic renal disease. Left uncontrolled, hypertension can lead to cerebral hemorrhage, as well as deteriorating renal function. Most pregnant women with chronic renal dysfunction also have preexisting hypertension.[11,68] Approximately 50% of these patients will have worsening hypertension as pregnancy progresses, and diastolic blood pressures of 110 mm Hg or greater will develop in about 20% of cases.[69] Those women with diffuse proliferative glomerulonephritis and nephrosclerosis are at greatest risk for the development of severe hypertension. It follows that blood pressure control is the cornerstone of successful treatment of chronic renal disease in pregnancy.

Worsening proteinuria is common during pregnancy complicated by chronic renal disease and often reaches the nephrotic range.[69] In general, massive proteinuria alone does not indicate an increased risk for mother or fetus.[70] Low serum albumin, however, has been correlated with low birth weight.[71] The development of massive proteinuria is not necessarily a harbinger of preeclampsia although such women are clearly at risk for this complication. In late pregnancy, it can be difficult to differentiate preeclampsia from worsening chronic renal disease. For this reason first trimester 24-hour urine collections to establish baselines for creatinine clearance and total protein are essential.

Effect of Chronic Renal Disease on Pregnancy

More than 85% of women with chronic renal disease will have a surviving infant if renal function is well preserved. Earlier reports were more pessimistic, citing a 6% incidence of stillbirth, a 5% incidence of neonatal deaths, and an increase risk for second trimester loss.[69] If hypertension is not controlled and if renal function is not well preserved, there is still a high likelihood of pregnancy loss.[38] Antepartum fetal surveillance and advances in neonatal care have contributed to an in improved perinatal outcome in these patients. One study reported a total fetal loss rate of 14%, including miscarriage, stillbirths, and neonatal deaths.[68]

The outlook for women with severe renal insufficiency whose baseline serum creatinine level is more than 1.5 mg/dL is less certain. This is due in part to the limited number of pregnancies in such patients. One study reported no surviving infants when the maternal BUN was greater than 60 mg/dL.[70] Other investigations, however, have found that about 80% of such pregnancies resulted in surviving infants.[68,72] **Preterm birth and IUGR remain important complications in these pregnancies. The reported incidence of preterm birth ranges from 20% to 50%.**[69,73]

Imbasciati and Ponticelli[43] summarize three studies containing 81 pregnancies in 78 women with serum creatinine

concentrations greater than 1.4 mg/dL.[43] The perinatal loss rate was only 9%. However, 33% of the infants were growth restricted, and 50% were born preterm secondary to either maternal or fetal indications. Of concern, 33% of the women showed acceleration of their renal disease after delivery. Some individuals believe that growth restriction may be due to the lack of normal plasma volume increase as the pregnancy progresses. Cunningham and colleagues[74] demonstrated that women with moderate renal dysfunction exhibit increased creatinine clearance and plasma volume expansion during gestation, whereas women with severe renal dysfunction generally do not.[74]

Management of Chronic Renal Disease in Pregnancy

A 24-hour urine collection for creatinine clearance and **total protein excretion should be obtained as soon as the pregnancy is confirmed. These parameters should be monitored periodically. A general guideline is to see patients every 2 weeks until 32 weeks' gestation and weekly thereafter.**

Control of hypertension is critical in managing patients with chronic renal disease. Home blood pressure monitoring is thus advised for women with underlying hypertension. β-Blockers, calcium channel blockers, and hydralazine can be used to treat blood pressure effectively as long as the dosages are monitored carefully. Clonidine is occasionally useful in refractory patients. Doxazosin and prazosin may also be used if necessary. Angiotensin-converting enzyme inhibitors are contraindicated. These drugs have been associated with fetal and neonatal oliguria/anuria,[75,76] as well as anomalies.[77] In one study, 1 of 19 infants had anuria and required dialysis.[75,77] Congenital anomalies, including microcephaly and encephalocele,[75] have been associated with the use of angiotensin-converting enzymes inhibitors.[76]

The use of diuretics in pregnancy is controversial.[78,79] For massive debilitating edema, a short course of diuretics can be helpful. Electrolytes must be monitored carefully. Salt restriction does not appear to be beneficial once edema has developed. Salt restriction, however, should be instituted without hesitation in pregnant women with true renal insufficiency.

Fetal growth should be assessed with serial ultrasonography, because growth restriction is common in women with chronic renal disease. Antepartum fetal heart rate testing is often initiated at 28 to 32 weeks' gestation.[11]

The timing of delivery should be individualized. Maternal indications for delivery include uncontrollable hypertension, the development of superimposed preeclampsia, and decreasing renal function after fetal viability has been reached. Fetal indications are dictated by assessment of fetal growth and biophysical testing.

Renal biopsy is rarely indicated during pregnancy. It is not advised after 34 weeks' gestation, when delivery of the fetus and subsequent biopsy would prove a safer alternative. Excessive bleeding secondary to the greatly increased renal blood flow has been reported by some but not all observers.[80,81] If coagulation indices are normal and blood pressure is well controlled, morbidity should be no greater than that observed in the nonpregnant patient.[81] Packham and Fairley[82] report a series of 111 renal biopsies performed in 104 pregnant women over 20 years. The complication rate was 4.5%. The most likely clinical dilemma necessitating renal biopsy in a pregnant woman would be the development of nephrotic syndrome and increasing hypertension between 22 and 32 weeks' gestation. In this case, renal biopsy may distinguish chronic renal disease from preeclampsia and have a significant impact on treatment.

Hemodialysis in Pregnancy

Women with chronic hemodialysis can have successful pregnancies.[83-89] Many women with chronic renal failure, however, experience oligomenorrhea, and their fertility is often impaired.[90] These women commonly fail to use a method of contraception. It is therefore important that pregnancy testing be undertaken if suspected.

As in all patients with impaired renal function, the most important aspect of care is meticulous control of blood pressure. **During dialysis, wide fluctuations in blood pressure can occur.[91] Sudden volume shifts therefore should be avoided as they may compromise fetal well-being.[92,93]** In late pregnancy, continuous fetal heart rate monitoring should be carried out during dialysis.[92] If possible, positioning on the left side with uterine displacement from the vena cava is preferred. During dialysis, careful attention to electrolyte balance is advised. Pregnant patients are in a state of chronic compensated respiratory alkalosis, and large drops in serum bicarbonate should be avoided. Dialysates containing glucose and bicarbonate are preferred, and those containing citrates should be avoided.[89]

Women should be counseled that a successful pregnancy will often require longer and more frequent periods of dialysis.[84,89,91,93] A careful diet, ingesting at least 70 g of protein and 1.5 g of calcium daily, is proscribed. Weight gain should be limited to 0.5 kg between dialysis sessions. Chronic anemia is often a problem in hemodialysis patients. The hematocrit should be kept above 25%, and transfusion with packed RBCs or erythropoietin therapy may be necessary to accomplish this objective.[84]

Criteria for initiating hemodialysis during pregnancy are controversial.[94] Some investigators believe that beginning of regular hemodialysis in patients with moderate renal insufficiency may improve pregnancy outcome.[86] Redrow and coworkers[87] report 14 pregnancies in 13 women undergoing dialysis. Ten of those pregnancies were successful. Five of eight pregnancies managed with chronic ambulatory peritoneal dialysis or chronic cycling peritoneal dialysis were successful. The investigators hypothesize several advantages for peritoneal dialysis. These include a more constant chemical and extracellular environment for the fetus, higher hematocrit levels, infrequent episodes of hypotension, and no heparin requirement. They also postulate that intraperitoneal insulin facilitates the management of blood glucose in diabetic patients and that intraperitoneal magnesium used in the dialysate reduces the likelihood of preterm labor.

Preterm birth occurs more frequently in women undergoing dialysis.[95] Progesterone is removed during dialysis and at least one group has advocated that parenteral progesterone therapy should be administered to the patient undergoing dialysis.[96] In their review, Yasin and Doun[89] report a 40.7% incidence of premature labor.

Renal Transplant

Pregnancy following renal transplantation has become increasingly common.[97] **Many previously anovulatory patients begin ovulating postoperatively and regain fertility as renal function normalizes.**[98] As with women receiving hemodialysis, many transplant recipients do not recognize they are pregnant until well into the second trimester.

Many transplant recipients will discontinue all medications after discovering they are pregnant. The importance of continuing immunosuppressive therapy cannot be emphasized strongly enough to renal allograft recipients. Glucocorticoids, especially prednisone, are metabolized in the placenta by 11 β-ol-dehydrogenase, with only limited amounts reaching the fetus.[99] Azathioprine cannot be activated in the fetus because of its lack of inosinate pyrophosphorylase.[100] Azathioprine has been shown to cause decreased levels of IgG and IgM as well as a smaller thymic shadow on chest x-ray in these neonates.[101] Chromosomal aberrations, which cleared within 20 to 32 months, have also been demonstrated in lymphocytes of infants exposed to azathioprine in utero.[102] The long-term implications of this treatment are not yet known. IUGR has been reported in infants born to mothers receiving this medication.[103] These risks are outweighed, however, by the disastrous consequences of allograft rejection that may occur if medication is discontinued.

Cyclosporin A appears to be relatively safe for use during gestation, but does hold some risks. Women may develop arterial hypertension secondary to its interference with the normal hemodynamic adaptation to pregnancy.[104] Cylosporin metabolism appears to be increased during pregnancy and, as such, the dose may need to be increased to maintain therapeutic levels.[105] Cyclosporin crosses the placenta; however, there is no evidence of teratogenesis although its safety in pregnancy has not been established.[106,107] IUGR, in the absence of maternal hypertension, has been reported with cyclosporin A use during pregnancy.[108] However, most women receiving cyclosporin have had no complications attributable to the drug and the risk of allograft rejection certainly outweighs the fetal risk of the medication.

Mycophenolate mofetil (MMF) has been shown to cause adverse effects on fetal development and is associated with first trimester loss and congenital defects. These anomalies include cleft lip and palate, limb anomalies, heart defects, and renal anomalies.[109] This drug is contraindicated in pregnancy.

Sirolimus is also contraindicated in pregnancy. This medication has been shown to be embryotoxic and is associated with increased fetal mortality.[109] It is recommended that women who wish to conceive be switched from this medication before becoming pregnant.[109]

Tacrolimus has been poorly studied in pregnancy. In a study of 100 pregnancies in patients who were exposed to tacrolimus there were 68 live births with 60% being premature. There were four infants with malformations, but no consistent pattern of anomally.[110] Patients taking tacrolimus require frequent monitoring of renal function and drug levels.

Davison[111] reviewed 1569 renal transplants in 1009 women. He found that 22% of the women elected to abort their pregnancies, 16% had a spontaneous abortion, and 8% experienced perinatal deaths. Furthermore, he observed that 45% of the surviving pregnancies were delivered preterm and 22% were complicated by IUGR.[111] Three percent of the infants were born with major malformations, a rate no different from expected in the background population. Preeclampsia complicated 30% of the pregnancies, but, as previously noted, the diagnosis is difficult to make in a patient who may already have hypertension and proteinuria. The allograft rejection rate in these women was 9%, a rate no different from that expected in a nonpregnant population.[111] The long-term rejection rate was also the same as for women who had not experienced a pregnancy.

During pregnancy, renal allograft recipients must be carefully watched for signs of rejection. As previously mentioned, significant episodes of rejection may occur in as many as 9% of transplant recipients during gestation. **Unfortunately, the clinical hallmarks of rejection—fever, oliguria, tenderness, and decreasing renal function—are not always exhibited by the pregnant patient. Occasionally, rejection may mimic pyelonephritis or preeclampsia, which occurs in approximately one third of renal transplant patients.** In these cases renal biopsy is indicated to distinguish rejection from preeclampsia. Rejection has been known to occur during the puerperium, when maternal immune competence returns to its prepregnancy level.[112] Therefore, it may be advisable to increase the dose of immunosuppressive medications in the immediate postpartum period.

Infection can be disastrous for the renal allograft. Therefore, urine cultures should be obtained at least monthly during pregnancy, and any bacteriuria should be aggressively treated. It is crucial to recognize that the allograft is denervated, and pain may not accompany the pyelonephritis. The only symptoms may be fever and nausea.

Renal function, as determined by 24-hour creatinine clearance and protein excretion, should be assessed monthly. Approximately 15% of transplant recipients will exhibit a significant decrease in renal function in late pregnancy.[65] This condition usually, but not always, reverses after pregnancy. Proteinuria develops in about 40% of patients near term, but most often disappears soon after delivery unless significant hypertension is present.

Similar to women with chronic renal disease, serial ultrasonography should be used to assess fetal growth, and antepartum fetal heart rate testing should be considered at 28 to 32 weeks' gestation. Approximately 50% of renal allograft recipients will deliver preterm. Preterm labor, preterm rupture of membranes, and IUGR are common. Cesarean delivery is reserved for obstetrical indications. Allograft recipients may have an increased frequency of cephalopelvic disproportion from pelvic osteodystrophy,[113] resulting from prolonged renal disease with hypercalcemia or extended steroid use. The transplanted kidney, however, rarely obstructs vaginal delivery despite its pelvic location.

Although there have been many successful pregnancies in renal allograft recipients, there is no consensus as to when it is safe to attempt pregnancy after transplantation. Lindheimer and Katz[114] have suggested some guidelines, which are summarized in the box Guidelines for Renal Allograft Recipients Who Wish to Conceive.

Guidelines for Renal Allograft Recipients Considering Pregnancy

- Wait 2 years after cadaver transplant or 1 year after graft from living donor
- Immunosuppression should be at maintenance levels
- Plasma creatinine <1.5 mg/dL
- Absent or easily controlled hypertension
- No or minimal proteinuria
- No evidence of active graft rejection
- No pelvicalyceal distention on a recent ultrasound or intravenous pyelogram
- Prednisone dose = 15 mg/day
- Azathioprine dose = 2 mg/kg/day
- Cyclosporin A dose 2-4 mg/kg (available data on the use of this drug in pregnancy includes <150 patients)

Modified from Lindheimer M, Katz A: Pregnancy in the renal transplant patient. Am J Kidney Dis 19:173, 2000.

KEY POINTS

- Asymptomatic bacteriuria complicates 5% to 7% of pregnancies and if left untreated will result in symptomatic urinary tract infections in 40% of patients.
- Pyelonephritis complicates 1% to 2% of pregnancies, making it a frequent nonobstetrical cause of hospitalization during pregnancy.
- Women with glomerulonephritis can have successful pregnancies, but pregnancy loss rates increase greatly if the patient has preexisting hypertension.
- Creatinine clearance can decline 70% before significant increases are seen in the BUN or serum creatinine level. Therefore, a 24-hour urine specimen for creatinine clearance should be collected from any woman in whom renal disease is suspected.
- The chance of successful pregnancy is reduced if the creatinine clearance is less than 50 mL/min or if the serum creatinine level is more than 1.5 mg/dL.
- Severe hypertension poses the greatest threat to the pregnant woman with chronic renal disease.
- Growth restriction and preeclampsia are common complications in women with chronic renal disease. Frequent sonograms and antepartum fetal surveillance at 28 weeks' gestation are recommended in affected pregnancies.
- Patients with chronic renal disease are often anovulatory. Following transplantation, as renal function returns, ovulation may resume with unplanned pregnancy possible.
- Women should wait 2 years after receiving a cadaver renal allograft and 1 year after receiving a living allograft before contemplating pregnancy. Furthermore, there should be no signs of allograft rejection.
- Renal transplant patients may remain on cyclosporine throughout gestation. Levels may need to be adjusted during pregnancy. Other immunosuppressive medications such as mycophenolate and sirolimus are contraindicated.
- Renal function may decline as a result of pregnancy among patients with renal disease. Increased risk for this decline is conferred by an elevated plasma creatinine concentration (above 1.5 mg/dL or 132 micromoles/L) and hypertension.

Insulin therapy was introduced 90 years ago and remains perhaps the important landmark in the care of pregnancy for the diabetic woman. Before insulin became available, pregnancy was not advised because it was likely to be accompanied by fetal mortality and a substantial risk for maternal death. Over the past several decades, management techniques have been developed that can prevent many complications associated with diabetic pregnancy. These advances, based on understanding of pathophysiology, now result in perinatal mortality rates in optimally managed cases that approach those of the normal population. This dramatic improvement in perinatal outcome can be largely attributed to clinical efforts to establish improved maternal glycemic control both before conception and during gestation (Figure 39-1). Excluding major congenital malformations, which continue to plague pregnancies in women with type 1 and type 2 diabetes mellitus, perinatal loss for the diabetic woman has fortunately become an uncommon event.

Although the benefit of careful regulation of maternal glucose levels is well accepted, failure to establish optimal glycemic control as well as other factors continue to result in significant perinatal morbidity. For this reason, both clinical and basic laboratory research efforts continue to focus on the etiology and prevention of congenital malformations and the pathophysiology of fetal growth abnormalities. Clinical experience has also resulted in recognition of the impact that vascular complications can have on pregnancy and the manner in which pregnancy may affect these disease processes. With modern management techniques and a skilled, organized team approach, successful

pregnancies have become the norm even for women with the most complicated diabetes.

Gestational diabetes mellitus (GDM), the most common type of diabetes found in pregnancy, has represented controversy to both clinicians and investigators. After nearly 50 years since the concept of GDM was introduced, the clinical significance of this disorder is now better understood as a recent result of large-scale observational studies and treatment trials. However, controversy remains concerning screening techniques, diagnostic criteria, thresholds for insulin initiation, and whether oral hypoglycemic agents are suitable treatment.

Before considering these clinical issues, it is important to review the metabolic effects of pregnancy in relation to the pathophysiology of diabetes mellitus.

PATHOPHYSIOLOGY

Normal Glucose Tolerance

There are significant alterations in maternal metabolism during pregnancy, which provide for adequate maternal nutritional stores in early gestation in order to meet the increased maternal and fetal demands of late gestation and lactation. Although we are apt to think of diabetes mellitus as a disorder exclusively of maternal glucose metabolism, in fact **diabetes mellitus affects all aspects of nutrient metabolism.** In this section we consider maternal glucose metabolism as it relates to pancreatic β-cell production of insulin and insulin clearance, endogenous (i.e., primarily hepatic) glucose production, and suppression with insulin and peripheral glucose insulin sensitivity. We also address maternal protein and lipid insulin metabolism. Lastly, the effects of these alternations on maternal metabolism are examined as they relate to maternal energy expenditure and fetal growth.

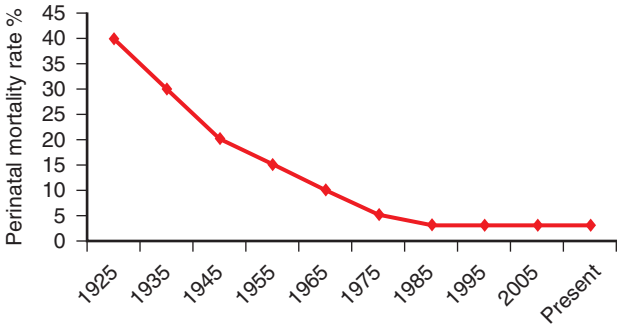

FIGURE 39-1. Perinatal mortality late in pregnancy complicated by insulin-dependent diabetes mellitus.

Glucose Metabolism

Normal pregnancy has been characterized as a "diabetogenic state" because of the progressive increase in postprandial glucose levels and increased insulin response in late gestation. **However, early gestation can be viewed as an anabolic state because of the increases in maternal fat stores and decrease in free fatty acid (FFA) concentration, particularly in non-overweight and obese women.** Garcia-Patterson and colleagues[1] have described significant decreases in maternal insulin requirements in early gestation (Figure 39-2). The mechanism for this decrease in insulin requirements has been ascribed to various factors, including increased insulin sensitivity, decreased substrate availability secondary to factors such as nausea, the fetus acting as a glucose sink, and enhanced maternal insulin secretion; however, the exact mechanism is not known. Longitudinal studies in women with normal glucose tolerance have shown significant alterations in all aspects of glucose metabolism as early as the end of the first trimester.[2]

There are progressive increases in insulin secretion in response to an intravenous glucose challenge with advancing gestation (Figure 39-3). The increases in insulin concentration are more pronounced in lean compared with obese women, most probably as a response to the greater decreases in insulin sensitivity in lean women, as described later. Data regarding insulin clearance in pregnancy are limited. In separate studies Bellman, Lind and colleagues, and Burt and Davidson reported no difference in insulin disappearance rate when insulin was infused intravenously in late gestation compared with nongravid subjects. In contrast, Goodner and Freinkel, using a radiolabeled insulin, described a 25% increase in insulin turnover in a pregnant compared with a nonpregnant rat model. Catalano and associates,[3] using the euglycemic-clamp model,

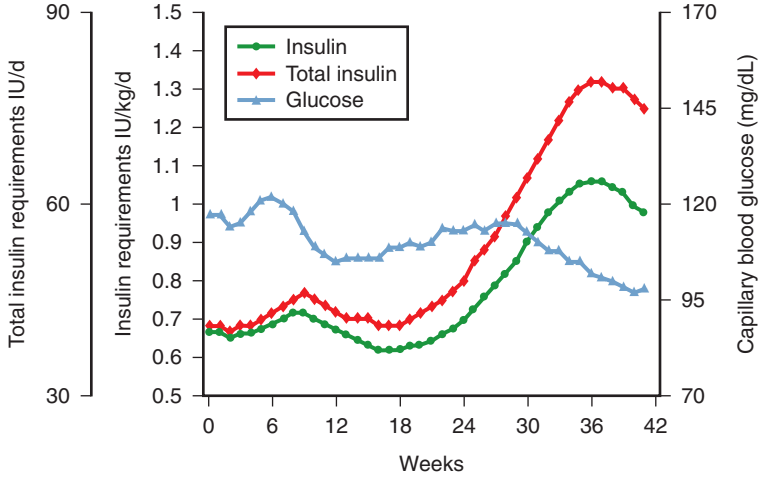

FIGURE 39-2. Mean insulin requirements and self-monitored blood glucose in women with type 1 diabetes. (Modified from Garcia-Patterson A, Gich I, Amini SB, et al: Insulin requirements throughout pregnancy in women with type 1 diabetes mellitus: three changes of direction. Diabetologia 53:446, 2010.)

reported a 20% increase in insulin clearance in lean women and a 30% increase in insulin clearance in obese women by late pregnancy (Figure 39-4). Although the placenta is rich in insulinase, the exact mechanism for the increased insulin clearance in pregnancy remains speculative.

Although there is a progressive decrease in fasting glucose with advancing gestation, the decrease is most probably a result of the increase in plasma volume in early gestation and the increase in fetoplacental glucose use in late gestation. Kalhan and Cowett, using various stable isotope methodologies in cross-sectional study designs, were the first to describe increased fasting hepatic glucose production in late pregnancy. Additionally, Catalano and coworkers,[4] using a stable isotope of glucose in a prospective longitudinal study design, reported **a 30% increase in maternal fasting hepatic glucose production with advancing gestation** (Figure 39-5), which remained significant even when adjusted for maternal weight gain. Tissue sensitivity to insulin involves both liver and peripheral tissues, primarily skeletal muscle. The increase in fasting maternal hepatic glucose production occurred despite a significant increase in fasting insulin concentration, thereby indicating a decrease in maternal hepatic glucose sensitivity in women with normal glucose tolerance. Additionally, in obese women, there was a decreased ability of infused insulin to suppress hepatic glucose production in late gestation compared with pregravid and early pregnancy measurements, thereby indicating a further decrease in hepatic insulin sensitivity in obese women.

Estimates of peripheral insulin sensitivity in pregnancy have included the measurement of insulin response to a fixed oral or intravenous glucose challenge or the ratio of

insulin to glucose under a variety of experimental conditions. In recent years, newer methodologies, such as the minimal model and the euglycemic-hyperinsulinemic clamp, have improved our ability to quantify peripheral insulin sensitivity. In lean women in early gestation, Catalano and colleagues[5] reported a 40% decrease in maternal peripheral insulin sensitivity using the euglycemic-hyperinsulinemic clamp. However, when adjusted for changes in insulin concentrations during the clamp and residual hepatic glucose production (i.e., the insulin sensitivity index) insulin sensitivity *decreased* only 10% (Figure 39-6). In contrast, there was a 15% *increase* in the insulin sensitivity index in obese women in early pregnancy compared with pregravid estimates.[6] Hence, the decrease in insulin requirements in early gestation observed in some women requiring insulin may be a consequence of an increase in insulin sensitivity, particularly in women with decreased insulin sensitivity before conception, for example, women with type 2 diabetes.

Compared with the metabolic alterations in early pregnancy, there is a uniformity of opinion regarding the decrease in peripheral insulin sensitivity in late gestation. Spellacy and Goetz were among the first investigators to report an increase in insulin response to a glucose challenge in late gestation. Additionally, Burt demonstrated that pregnant women experienced less hypoglycemia in response to exogenous insulin in comparison with nonpregnant subjects. **Later research by Fisher and associates using a high-dose glucose infusion test, Buchanan and colleagues using the Bergman minimal model, and Ryan and coworkers[7] and Catalano and associates[2] using the euglycemic-hyperinsulinemic clamp all have demonstrated a decrease in insulin sensitivity ranging from 33% to 78%.** It should be noted, however, that all these quantitative estimates of insulin sensitivity are very likely overestimates because of non-insulin-mediated glucose disposal by the fetus and placenta. Hay and colleagues reported that in the pregnant ewe model, about one third of maternal glucose use was accounted for by uterine, placental, and fetal tissue. Additionally, Marconi and coworkers reported that based on human fetal blood sampling, fetal glucose concentration was a function of fetal size and gestational age in addition to maternal glucose concentration.

Historically, the decrease in insulin sensitivity during pregnancy has been ascribed to an increased production of various placental and maternal hormones, such as human placental lactogen, progesterone, estrogen, cortisol, and prolactin. However, more recent evidence has focused on the role of several new mediators of insulin resistance such as leptin, tumor necrosis factor-α (TNF-α), and resistin. Among these factors, TNF-α and leptin are known to be produced in the placenta and therefore could play a central role in the development of insulin resistance. Kirwan and coworkers[8] reported that TNF-α was inversely correlated with the changes in insulin sensitivity from the time before conception through late gestation. In combination with other placental hormones, multivariate stepwise regression analysis revealed that **TNF-α was the strongest independent predictor of insulin sensitivity in pregnancy, accounting for about half of the variance in the decrease in insulin sensitivity during gestation.**

Pregnancy has been characterized as a chronic low-grade inflammatory condition because of the increase in activation of circulating blood leukocytes.[9] The inflammation of pregnancy is further enhanced by maternal prepregnancy obesity. This increase in low-grade inflammation, particularly observed in obese women in normal-term pregnancies, has been related to increases in macrophage infiltration in both maternal white adipose tissue and placenta. The increase in inflammation has been associated with increased circulating C-reactive protein (CRP) and interlukin-6 (IL-6). Both these factors may exacerbate the increased insulin resistance previously noted in obese women with normal glucose tolerance, because of effects on the post-receptor insulin-signaling cascade. These inflammatory factors may then relate to increased substrate availability for the developing fetus and resultant macrosomia.

Placenta glucose transport is a nonenergy process and takes place through facilitated diffusion. Glucose transport is dependent on a family of glucose transporters referred to as the GLUT glucose transporter family. **The principal glucose transporter in the placenta is GLUT1, which is located in the syncytiotrophoblast.[10] GLUT1 is located on both the microvillus and basal membranes**. Basal membrane GLUT1 may be the rate-limiting step in placental glucose transport. There is a twofold to threefold increase in the expression of syncytiotrophoblast glucose transporters with advancing gestation. Although GLUT3 and GLUT4 expression have been identified in placental endothelial cells and intervillous nontrophoblastic cells, respectively, the role they may play in placental glucose transport remains speculative.

DIABETES MELLITUS

Diabetes mellitus is a chronic metabolic disorder characterized by either absolute or relative insulin deficiency, resulting in increased glucose concentrations. Although

Modified from White P: Pregnancy complicating diabetes. Am J Med 7:609, 1949.

glucose intolerance is the common outcome of diabetes mellitus, the pathophysiology remains heterogeneous. The two major classifications of diabetes mellitus are type 1, formerly referred to as insulin-dependent or juvenile-onset diabetes, and type 2, formerly referred to as non-insulin-dependent or adult-onset diabetes. During pregnancy, classification of women with diabetes has often relied on the White classification,[11] first proposed in the 1940s. This classification is based on factors such as the age of onset of diabetes and duration as well as end-organ involvement, primarily retinal and renal (Table 39-1).

All forms of diabetes can occur during pregnancy. In addition to type 1 and type 2 diabetes, there are, however, genetic causes of diabetes, the most common of which is maturity-onset diabetes of youth (MODY). MODY is characterized by β-cell dysfunction and has an autosomal dominant mode of inheritance, usually becoming manifest in young adulthood. Mutations in the glucokinase gene are a frequent cause of MODY. Various mutations have been described, and each mutation is associated with varying degrees of disease severity. The most common of these mutations (MODY2) occurs in the European population and involves the glucokinase gene. Because the age of onset of diabetes in women with MODY coincides with the reproductive years, it may be difficult to distinguish between the two. The glucokinase gene acts as a sensor in the β cell, which leads to a secretory defect in insulin response**. Ellard and colleagues reported that 2.5% of women with GDM in the United Kingdom have the glucokinase mutation,** whereas Stoffel, in a small population in the United States, reported that 5% of patients had a glucokinase in mutation. The implication if the mother has the mutation is an increased risk for fetal macrosomia. The implications for the fetus, if inherited from the father, are a significant decrease in growth secondary to relative insulinopenia.

Type 1 Diabetes Mellitus

Type 1 diabetes mellitus is usually characterized by an abrupt onset at a young age and absolute insulinopenia with lifelong requirements for insulin replacement. Although depending on the population, the onset of type 1 diabetes may occur in individuals in their third or fourth decades of life. Patients with diabetes mellitus may have a genetic predisposition for antibodies directed against their pancreatic islet cells. The degree of concordance for the development of type 1 diabetes in monozygotic twins is 33%, suggesting that the events subsequent to the development of autoantibodies and appearance of glucose intolerance are also related to environmental factors. Because of the complete dependence on exogenous insulin, pregnant women with type 1 diabetes are at increased risk for the development of diabetic ketoacidosis. Additionally, because intensive insulin therapy is used in women with type 1 diabetes to decrease the risk for spontaneous abortion and congenital anomalies in early gestation, these women are at increased risk for hypoglycemic reactions. Studies by Diamond and Rosenn have shown that women with type 1 diabetes are at increased risk for hypoglycemic reactions during pregnancy because of diminished counterregulatory epinephrine and glucagon response to hypoglycemia. The deficiency in this counterregulatory response may be in part due to an independent effect of pregnancy.

The alterations in glucose metabolism in women with type 1 diabetes are not well characterized. Because of maternal insulinopenia, insulin response during gestation can only be estimated relative to pregravid requirements. Estimates of the change in insulin requirements are complicated by the degree of preconceptual glucose control and potential presence of insulin antibodies. Garcia-Patterson[1] reported on the change in insulin requirements in women with type 1 diabetes and strict glucose control prior to conception. In early pregnancy, both insulin requirements and total insulin peak at 9 weeks' gestation and nadir at 16 weeks to baseline prepregnancy levels. After 16 weeks, insulin requirements gradually increase through 37 weeks. This represents a total increase in insulin requirements of 5.19% per week and about a twofold increase relative to prepregnancy requirements. A 5% decrease in insulin requirements after 36 weeks' gestation was also noted by McManus and Ryan. The decrease in insulin requirements was associated with a longer duration of diabetes mellitus but not with adverse perinatal outcome. The fall in insulin requirements in early pregnancy in women with type 1 diabetes may be a reflection of increased pregravid insulin sensitivity as was described previously.

Schmitz and associates[12] have evaluated the longitudinal changes in insulin sensitivity in women with type 1 diabetes in early and late pregnancy as well as postpartum in comparison with nonpregnant women with type 1 diabetes. **In the pregnant women with type 1 diabetes, there was a 50% decrease in insulin sensitivity only in late gestation.**

There was no significant difference in insulin sensitivity in pregnant women with type 1 diabetes in early pregnancy or within 1 week of delivery compared with the nonpregnant women with type 1 diabetes. Therefore, based on the available data, women with type 1 diabetes appear to have a similar decrease in insulin sensitivity compared with women with normal glucose tolerance.

Relative to the issue of placental transporters (GLUT1), there is a report by Jansson and Powell[13] describing an increase in both basal GLUT1 expression and glucose transport activity from placental tissue in women with White class D pregnancies.

Type 2 Diabetes and Gestational Diabetes

The pathophysiology of type 2 diabetes involves abnormalities of both insulin-sensitive tissue (i.e., both a decrease in skeletal muscle and hepatic sensitivity to insulin) and β-cell response as manifested by an inadequate insulin response for a given degree of glycemia. Initially in the course of development of type 2 diabetes, the insulin response to a glucose challenge may be increased relative to that of individuals with normal glucose tolerance but is inadequate to maintain normoglycemia. Whether decreased insulin sensitivity precedes β-cell dysfunction in the development of type 2 diabetes continues to be debated. Arguments and experimental data support both hypotheses. As noted by Sims and Calles-Escadon, heterogeneity of metabolic abnormalities exists in any classification of diabetes mellitus.

Despite the limitations of any classification system, certain generalizations can be made regarding women with type 2 diabetes or GDM. These individuals are typically older and more often heavier compared with individuals with type 1 diabetes or normal glucose tolerance. The onset of the disorder is usually insidious, with few patients complaining of the classic triad of polydipsia, polyphagia, and polyuria. Individuals with type 2 diabetes are often initially recommended to lose weight, increase their activity (i.e., exercise), and follow a diet low in fats and high in complex carbohydrates. Oral agents are often used to either increase insulin response or, with newer drugs, enhance insulin sensitivity. Individuals with type 2 diabetes may eventually require insulin therapy to maintain euglycemia but are at significantly less risk for diabetic ketoacidosis. **Data from monozygotic twin studies have reported a lifetime risk for both twins developing type 2 diabetes that ranges between 58% and almost 100%, suggesting that the disorder has a strong genetic component.**

Type 2 pregestational diabetes is usually classified as class B diabetes according to the While classification system. Women developing GDM (i.e. glucose intolerance first recognized during pregnancy) share many of the metabolic characteristics of women with type 2 diabetes. Although earlier studies reported a 10% to 35% incidence of islet cell antibodies in women with GDM as measured by immunofluorescence techniques, more recent data using specific monoclonal antibodies have described a much lower incidence on the order of 1% to 2%,[14] suggesting a low risk for type 1 diabetes in women with GDM. Furthermore, postpartum studies of women with GDM have demonstrated defects in insulin secretory response and decreased insulin sensitivity, indicating that typical type 2 abnormalities in glucose metabolism are present in women with GDM. Of interest, the alterations in insulin secretory response and insulin resistance in women with a previous history of GDM compared with a weight-matched control group may differ depending on whether the women with previous GDM are lean or obese.[15] Thus, in women with GDM, the hormonal events of pregnancy may represent an unmasking of a genetic susceptibility to type 2 diabetes.

There are significant alterations in glucose metabolism in women who develop GDM relative to the changes in glucose metabolism in women with normal glucose tolerance. Decreased insulin response to a glucose challenge has been demonstrated by Yen, Fisher, and Buchanan and their colleagues in women with GDM in late gestation. In prospective longitudinal studies of both lean and obese women with GDM, Catalano and associates[5] also showed a progressive decrease in first-phase insulin response in late gestation in lean women developing GDM compared with a weight-matched control group (Figure 39-7). In contrast, in obese women developing GDM, there was no difference in first-phase insulin response, but rather a significant increase in second-phase insulin response, to an intravenous glucose challenge compared with a weight-matched control group (see Figure 39-7). These differences in insulin response may be related to the ethnicity of the various study groups. Although there is an increase in the metabolic clearance rate of insulin with advancing gestation, there is no evidence that there is a significant difference between women with normal glucose tolerance and those with GDM.[6]

There is a significant decrease in fasting glucose concentration with advancing gestation in women developing GDM. In late pregnancy, glucose and hepatic glucose production increase in women with GDM in comparison with a control group.[5,6] Whereas there was no significant difference in either fasting glucose concentration or hepatic glucose production in the longitudinal studies of Catalano and associates,[5,6] these differences may again be population specific or related to the degree of fasting hypoglycemia. However, to date all reports indicate that in late gestation, women with GDM have increased fasting insulin concentrations (Figure 39-8) and less suppression of hepatic glucose production during insulin infusion, thereby indicating decreased hepatic glucose insulin sensitivity in women with GDM compared with a weight-matched control group.[5,6,16] In the studies of Xiang and associates,[16] there was significant correlation between fasting FFA concentrations and hepatic glucose production, suggesting that increased FFA concentrations may contribute to hepatic insulin resistance.

Women with GDM have decreased insulin sensitivity in comparison with weight-matched control groups. Ryan and colleagues[7] were the first to report a 40% decrease in insulin sensitivity in women with GDM compared to a pregnant control group in late pregnancy using a hyperinsulinemic-euglycemic clamp. Xiang and associates[16] found that women with GDM who had normal glucose tolerance within 6 months of delivery had significantly decreased insulin sensitivity as estimated by the glucose clearance rate during a hyperinsulinemic-euglycemic clamp compared with a

matched control group. Catalano and coworkers,[5,6] using similar techniques, described the longitudinal changes in insulin sensitivity in both lean and obese women developing GDM in comparison with a matched control group. Women developing GDM had decreased insulin sensitivity compared with the matched control group (Figure 39-9). The differences in insulin sensitivity were greatest before and during early gestation; by late gestation, the differences in insulin sensitivity between the groups were less pronounced but still significant. Of interest, there was an increase in insulin sensitivity from the time before conception through early pregnancy (12 to 14 weeks), particularly in those women with greatest decreases in insulin sensitivity before conception. **The changes in insulin sensitivity from the time before conception through early pregnancy were significantly correlated with changes in maternal weight gain and energy expenditure.** The relationship between these alterations in maternal glucose insulin sensitivity and weight gain and energy expenditure may help explain the decrease in maternal weight gain and insulin requirements in women with diabetes in early gestation.[1]

The interactions of ß-cell response and insulin sensitivity are hallmarks of the metabolic adaptations of pregnancy. As described by Bergman, there is a fixed relationship between insulin response and insulin resistance in nonpregnant individuals following a hyperbolic curve (i.e., the disposition index). Buchanan described a similar relationship between insulin response and insulin action during pregnancy. Indeed, when the disposition index has been compared between women with normal glucose tolerance and GDM both during and after pregnancy, the failure of the ß cell to compensate for insulin resistance in GDM has been similar to the hyperbolic changes in the control group (Figure 39-10). This relationship between insulin

sensitivity and insulin resistance, however, may not hold in early pregnancy, when there is both an increase in insulin sensitivity and insulin response.

Studies in human skeletal muscle and adipose tissue have demonstrated that postreceptor defects in the insulin signaling cascade are related to decreased insulin sensitivity in pregnancy. Garvey and colleagues were the first to demonstrate that there were no significant differences in the glucose transporter (GLUT4) responsible for insulin action and skeletal muscle in pregnant compared with nonpregnant women. Based on the studies of Friedman and colleagues[17] in pregnant women with normal glucose tolerance and GDM, as well as weight-matched nonpregnant control subjects, there appeared to be defects in the insulin-signaling cascade relating to pregnancy as well as what may be additional abnormalities in women with gestational diabetes. **All pregnant women appeared to have a decrease in insulin receptor substrate-1 (IRS1) expression.** The downregulation of the IRS1 protein closely parallels the decreased ability of insulin to induce additional steps in the insulin-signaling cascade, resulting in movement of the GLUT4 to the cell surface membrane and to facilitate glucose transport into the cell. The downregulation of IRS1 protein closely parallels the ability of insulin to stimulate 2-deoxyglucose uptake in vitro. In addition to the previous mechanisms, **women with GDM demonstrate a distinct decrease in the ability of the insulin receptor-ß (that component of the insulin receptor not on the cell surface) to undergo tyrosine phosphorylation. The additional defect in the insulin-signaling cascade results in a 25% lower glucose transport activity** (Figure 39-11).

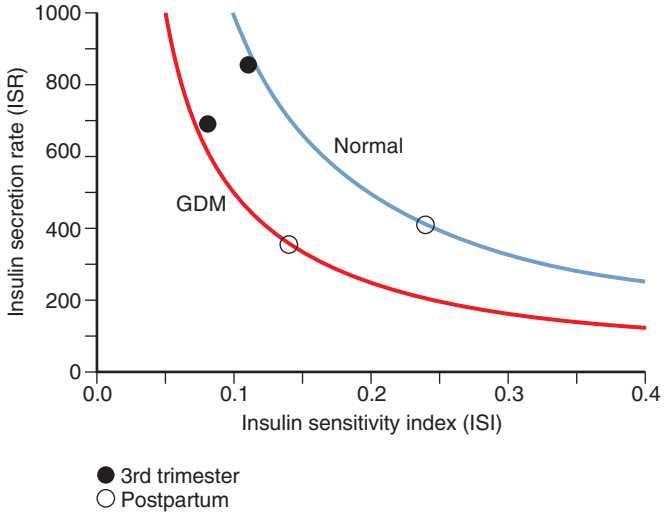

FIGURE 39-10. Insulin sensitivity index.

Amino Acid Metabolism

Although glucose is the primary source of energy for the fetus and placenta, there are no appreciable amounts of glucose stored as glycogen in the fetus or placenta. However, accretion of protein is essential for growth of fetoplacental tissue. There is increased nitrogen retention in pregnancy in both maternal and fetal compartments. There is an increase of about 0.9 kg of maternal fat-free mass by 27 weeks.[18] There is a significant decrease in most fasting maternal amino acid concentrations in early pregnancy before the accretion of significant maternal or fetal tissue. These anticipatory changes in fasting amino acid metabolism occur after a shorter period of fasting in comparison with nonpregnant women and may be another example of the accelerated starvation of pregnancy as described by Freinkel and coworkers.[19] Furthermore, amino acid concentrations such as serine correlate significantly with fetal growth in both early and late gestation.[20] Maternal amino acid concentrations were significantly decreased in mothers of small-for-gestational-age (SGA) neonates in comparison with maternal concentration in appropriately grown neonates.

Based on a review of various studies, Duggleby and Jackson have estimated that during a pregnancy, protein synthesis is similar to that in nonpregnant women in the first trimester. **However, there is a 15% increase in protein synthesis during the second trimester and a further increase**

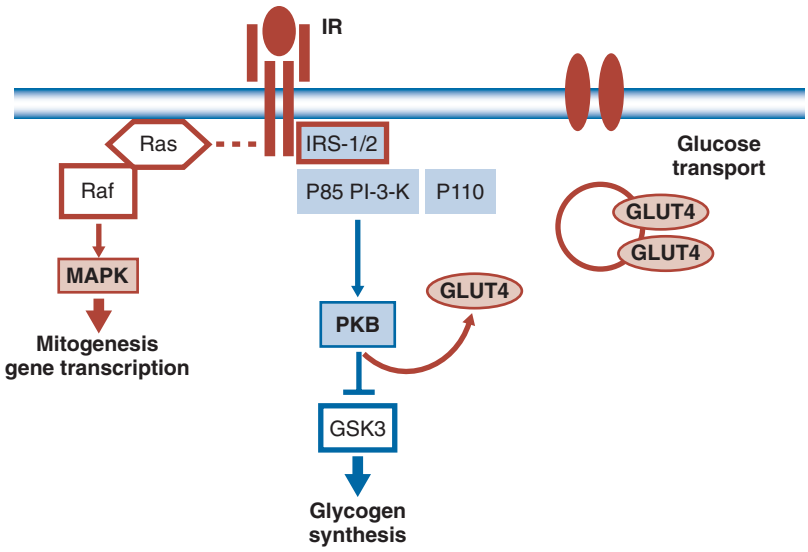

FIGURE 39-11. Schematic model of insulin signaling cascade in skeletal muscle. *GLUT,* Glucose transporter; *IR,* insulin receptor; *IRS,* insulin receptor substrate.

in the third trimester by about 25%. Additionally, there are marked interindividual differences at each time point. These differences have a strong relationship with fetal growth: mothers who had increased protein turnover in midpregnancy had babies who had increased lean body mass, after adjustment for significant covariables.

Amino acids can be used for protein accrual or oxidized as an energy source. Estimating urea synthesis using stable isotopes has been performed in a number of studies. In general, there is a modest shift in oxidation in early pregnancy with an accrual of amino acids for protein synthesis in late gestation. Furthermore, Kalhan and colleagues reported significant pregnancy-related adaptations in maternal protein metabolism early in gestation before any significant increase in fetal protein accretion. Catalano and associates have also reported decreased insulin sensitivity as manifested by a decreased suppression of leucine turnover during insulin infusion in late gestation in all pregnant women. There is evidence for an increase in basal leucine turnover in women with GDM compared with a matched control group. Whether these decreases in amino acid insulin sensitivity are related to decreased whole-body and liver protein synthesis or increased breakdown are not known at this time.

Cetin and associates reported that placental amino acid exchange is altered in pregnancies complicated by GDM. Ornithine concentrations were significantly increased in women with GDM compared with controls, and in the cord blood of infants of women with GDM, there were significant increases in multiple amino acids, including phenylalanine and leucine, but decreases in glutamate. The investigators speculate that in infants of women with GDM, the altered in utero fetal milieu affects fetal growth through multiple mechanisms affecting various nutrient compartments.

Amino acids are actively transported across the placenta from mother to fetus through energy-requiring amino acid transporters. These transporters are highly stereospecific, but they have low substrate specificity. Additionally, they may vary with location between the microvillus and basal membranes. Decreased amino acid concentrations have been reported in growth-restricted neonates in comparison with appropriately grown neonates. Decreased amino acid transporter activity has been implicated as a possible mechanism. However, the potential role, if any, of placental amino acid transporters in the development of fetal macrosomia in women with diabetes is currently unknown.

Lipid Metabolism

Although there is ample literature regarding the changes in glucose metabolism during gestation, the data regarding the alterations in lipid metabolism are meager by comparison. Darmady and Postle measured serum cholesterol and triglyceride before, during, and after pregnancy in 34 normal women.[21] There was a decrease in both cholesterol and triglyceride at about 7 weeks' gestation. Both of the levels increased progressively until term. There was then a decrease in serum triglyceride postpartum. The decrease was more rapid in women who breastfed compared with those women who bottle-fed their infants.[21] Additionally, Knopp and coworkers[22] have reported that there is a twofold to fourfold increase in total triglyceride concentration and a 25% to 50% increase in total cholesterol concentration during gestation. There is a 50% increase in low-density lipoprotein (LDL) cholesterol and a 30% increase in high-density lipoprotein (HDL) cholesterol by midgestation, which decreases slightly in the third trimester. Maternal triglyceride and very-low-density lipoprotein (VLDL) triglyceride levels in late gestation are positively correlated with maternal estriol and insulin concentrations.

A recent study by Vahratian and associates studied the changes in lipid levels during pregnancy in normal weight compared with overweight and obese women from 6 to 10 through 32 to 36 weeks' gestation. The levels of total cholesterol, triglycerides, and LDL and HDL cholesterol increased throughout gestation. Although the concentrations in the overweight and obese women were generally higher in early pregnancy, the rate of change of LDL cholesterol and total cholesterol was lower in later gestation.

FFAs have been associated with fetal overgrowth, particularly of fetal adipose tissue. There is a significant difference in the arteriovenous FFA concentration at birth, much as there is with arteriovenous glucose concentration. There are multiple clinical studies suggesting the contribution of maternal lipids to fetal growth and in particular adiposity. Knopp and coworkers[22] reported that neonatal birthweight was positively correlated with triglyceride and FFA concentration in late pregnancy. Similar conclusions were reached by Ogburn and colleagues, who showed that insulin concentrations decrease FFA concentrations, inhibit lipolysis, and result in increased fat deposition. Kleigman reported that infants of obese women had an increased birthweight and skinfold thickness and higher FFA levels compared with infants of lean women. More recently, DiCianni and associates reported that in women with a positive glucose screen but normal glucose tolerance, their serum triglycerides and prepregnancy body mass index (BMI) had a significant correlation with birthweight at term.[23] In Australia, Nolan and coworkers showed that nonfasting maternal triglycerides measured at 9 to 12 weeks' gestation were significantly correlated with neonatal birthweight ratio at term. Finally, Schaeffer-Graf and colleagues, in a well-controlled German GDM population, reported that **maternal FFA concentrations correlated with ultrasound estimates of neonatal abdominal circumference and anthropometric estimates of neonatal fat mass at delivery.**[24] Maternal FFA concentrations were positively correlated with cord FFA. Although cord FFA concentrations were higher in cord blood of large-for-gestational-age (LGA) neonates compared with either appropriate or SGA neonates, there was a paradoxical negative correlation of cord triglycerides and birthweight. The authors speculated that the SGA newborns have a lower lipoprotein lipase activity and hence were unable to hydrolyze triglycerides. In contrast, the LGA neonates have lower cord triglyceride activity because of enhanced lipoprotein lipase activity resulting from their increased number of fat cells. Similar findings were noted by Merzouk and coworkers in growth-restricted infants. In summary, in women with evidence of decreased insulin sensitivity (obesity and/or GDM) in addition to glucose, maternal lipid metabolism accounts for a significant proportion of fetal growth, particularly adiposity. These data support the original work by **Freinkel**

proposing that fetal growth or overgrowth is a function multiple nutritional factors in addition to glucose.[25]

Lipid metabolism in women with diabetes mellitus is influenced by whether the woman has type 1 or type 2 diabetes. This also applies when these women become pregnant. In women with type 2 diabetes and gestational diabetes, Knopp and coworkers[22] reported an increase in triglyceride and decrease in HDL concentration. However, Montelongo and colleagues reported little change in FFA concentrations through all three trimesters after a 12-hour fast. Koukkou and coworkers noted an increase in total triglyceride but a lower LDL cholesterol in women with GDM. Increased triglyceride concentrations during pregnancy have also been reported to be related to the development of gestational diabetes and preeclampsia in women with normal pregravid glucose tolerance, both of which are related to increased insulin resistance. In women with type 1 diabetes, there was no change in total triglyceride, but there was a lower cholesterol concentration secondary to a decrease in HDL. This is of interest because HDL acts as plasma antioxidant and thus may be related to the increase in congenital malformations in women with type 1 diabetes. Oxidative stress has been implicated as a potential factor in the incidence of anomalies in women with type 1 diabetes.

Hyperinsulinemic-euglycemic clamp studies in pregnant women with normal glucose tolerance and GDM revealed a decreased ability of insulin to suppress plasma FFAs with advancing gestation. Insulin's ability to suppress plasma FFA was lower in women with GDM compared with women with normal glucose tolerance.

Taken together, these studies demonstrate that there is decreased nutrient insulin sensitivity in all women with advancing gestation. These decreases in insulin sensitivity are further exacerbated by the presence of decreased pregravid maternal insulin sensitivity, manifesting in later pregnancy as GDM, resulting in greater nutrient availability and higher ambient insulin concentrations for the developing fetoplacental unit, which may eventually result in fetal overgrowth.

Maternal Weight Gain and Energy Expenditure

Estimates of the energy cost of pregnancy range from a cost of 80,000 kcal to a net saving of up to 10,000 kcal.[26] As a result, the recommendations for nutritional intake in pregnancy differ and depend on the population being evaluated. Furthermore, based on more recent data, recommendations for individuals within a population may be more diverse than previously believed, making general guidelines for nutritional intake difficult.

The theoretical energy cost of pregnancy was originally estimated by Hytten and Leitch[18] using a factorial method. The additional cost of pregnancy consisted of (1) the additional maternal and fetoplacental tissue accrued during pregnancy and (2) the additional "running cost" of pregnancy (e.g., the work of increased cardiac output). In Hytten's model, the greatest increases in maternal energy expenditure occur between 10 and 30 weeks' gestation, primarily because of maternal accretion of adipose tissue. However, the mean increases in maternal adipose tissue vary considerably among various ethnic groups. Forsum and associates reported a mean increase of more than 5 kg of adipose tissue in Swedish women, whereas Lawrence and colleagues found no increase in adipose tissue stores in women from the Gambia.

Basal metabolic rate accounts for 60% to 70% of total energy expenditure in individuals not engaged in competitive physical activity and correlates well with total energy expenditure. As with the changes in maternal accretion of adipose tissue, there are wide variations in the change in maternal basal metabolic rate during gestation, not only in different populations but again within relatively homogeneous groups. The cumulative energy changes in basal metabolic rate range from a high of 52,000 kcal in Swedish women to net savings of 10,700 kcal in women from the Gambia without nutritional supplementation. **The mean increase in basal metabolic rate in Western women relative to a nonpregnant, nonlactating control group averages about 20%.** However, the coefficient of variation of basal metabolic rate in these populations during gestation ranges from 93% in women in the United Kingdom to more than 200% in Swedish women.[27] When assessing energy intake in relation to energy expenditure, however, estimated energy intake remains lower than the estimates of total energy expenditure. These discrepancies have usually been explained by factors such as (1) increased metabolic efficiency during gestation, (2) decreased maternal activity, and (3) unreliable assessment of food intake.[26]

Data in nonpregnant subjects may help explain some of the wide variations in metabolic parameters during human gestation, even with homogeneous populations. Swinburn and colleagues reported that in the Pima Indian population, subjects with decreased insulin sensitivity gained less weight compared with more insulin-sensitive subjects (3.1 vs. 7.6 kg) over a period of 4 years. Furthermore, the percentage weight change per year was highly correlated with glucose disposal as estimated from clamp studies. Catalano and coworkers[28] conducted a prospective longitudinal study in early pregnancy of the changes in maternal accretion of body fat and basal metabolic rate in lean and obese women with normal GDM. Women with GDM had decreased glucose insulin sensitivity in early gestation compared with the control group and had significantly smaller increases in body fat than women with normal glucose tolerance. In these lean women, there was a significant inverse correlation between the changes in fat accretion and insulin sensitivity (i.e., women with decreased pregravid insulin sensitivity had less accretion of body fat compared with women with increased pregravid insulin sensitivity). These results are consistent with a previous report showing that total weight gain in women with GDM was 2.5 kg less compared with a weight-matched control group.

In the basal state, lean women increase the use of carbohydrate as a metabolic fuel, whereas in obese women, there is an increased use of lipids for oxidative needs. However, with the decreased in insulin sensitivity in late gestation, all women lean or obese with normal glucose tolerance or GDM have an increase in fat oxidation and decrease in nonoxidative glucose metabolism (storage). Of interest, these increases in lipid oxidation in pregnancy are positively correlated with the increases in maternal leptin concentrations, possibly accounting for a role of leptin in

human pregnancy. The results of these studies show that there is a relationship between the changes in maternal insulin sensitivity and accretion of adipose tissue in early gestation. The ability of women with decreased pregravid glucose insulin sensitivity (obese women and women with GDM) to conserve energy, not significantly increase body fat, and make sufficient nutrients available to produce a healthy fetus supports the hypothesis that decreased maternal insulin sensitivity may have a reproductive metabolic advantage in women when food availability is marginal. In contrast, decreased maternal insulin sensitivity before conception in areas where food is plentiful and a sedentary lifestyle is more common may manifest as GDM and increase the long-term risk for both diabetes and obesity in the woman and her offspring.[28]

PERINATAL MORBIDITY AND MORTALITY

Fetal Death

In the past, sudden and unexplained stillbirth occurred in 10% to 30% of pregnancies complicated by type 1 diabetes mellitus, also called *insulin-dependent diabetes mellitus* (IDDM). Although relatively uncommon today, such losses still plague the pregnancies of patients who do not receive optimal care. Stillbirths have been observed most often after the 36th week of pregnancy in patients with vascular disease, poor glycemic control, hydramnios, fetal macrosomia, or preeclampsia. Women with vascular complications may develop fetal growth restriction and intrauterine demise as early as the second trimester. In the past, prevention of intrauterine death led to a strategy of scheduled preterm deliveries for type 1 diabetic women. This empirical approach reduced the number of stillbirths, but errors in estimation of fetal size and gestational age as well as the functional immaturity characteristic of the infant of the diabetic mother (IDM) contributed to many neonatal deaths from hyaline membrane disease (HMD).

Excessive stillbirth rates in pregnancies complicated by diabetes have been linked to chronic intrauterine hypoxia. Extramedullary hematopoiesis, frequently observed in stillborn IDMs, supports chronic intrauterine hypoxia as a likely cause of these intrauterine fetal deaths. Studies of fetal umbilical cord blood samples in pregnant women with type 1 diabetes have demonstrated relative fetal erythremia and lactic acidemia. Maternal diabetes may also produce alterations in red blood cell oxygen release and placental blood flow. Reduced uterine blood flow is thought to contribute to the increased incidence of intrauterine growth restriction observed in pregnancies complicated by diabetic vasculopathy. Ketoacidosis and preeclampsia, two factors known to be associated with an increased incidence of intrauterine deaths, may further decrease uterine blood flow.

Alterations in fetal carbohydrate metabolism also may contribute to intrauterine asphyxia. There is considerable evidence linking hyperinsulinemia and fetal hypoxia. Hyperinsulinemia induced in fetal lambs by an infusion of exogenous insulin produces an increase in oxygen consumption and a decrease in arterial oxygen content. Persistent maternal-fetal hyperglycemia occurs independent of maternal uterine blood flow, which may not be increased enough to allow for enhanced oxygen delivery in the face of increased metabolic demands. Thus, hyperinsulinemia in the fetus of the diabetic mother appears to increase fetal metabolic rate and oxygen requirement in the fetus. Other factors, such as hyperglycemia, ketoacidosis, preeclampsia, and maternal vasculopathy, can also reduce placental blood flow and fetal oxygenation.

Congenital Malformations

With the reduction in intrauterine deaths and a marked decrease in neonatal mortality related to HMD and traumatic delivery, **congenital malformations have emerged as the most important cause of perinatal loss in pregnancies complicated by type 1 and type 2 diabetes mellitus.** In the past, these anomalies were responsible for only 10% of all perinatal deaths. Malformations account for 30% to 50% of perinatal mortality. Neonatal deaths exceed stillbirths in pregnancies complicated by pregestational diabetes mellitus, and fatal congenital malformations account for this pattern.

Most studies have documented a twofold to sixfold increase in major malformations in infants of type 1 and type 2 diabetic mothers. At the Ohio State University Diabetes in Pregnancy Program, we observed 29 congenital anomalies in 289 (10%) diabetic woman enrolled over a 10-year period. In a prospective analysis, Simpson and associates observed an 8.5% incidence of major anomalies in the diabetic population, whereas the malformation rate in a small group of concurrently gathered control subjects was 2.4%. Similar figures were obtained in the Diabetes in Early Pregnancy Study in the United States. The incidence of major anomalies was 2.1% in 389 control patients and 9% in 279 diabetic women. A recent case-control study of 13,030 infants with congenital anomalies and 4895 controls revealed a prevalence of type 1 diabetes of 2.2% versus 0.5% and of type 2 diabetes of 5.1% versus 3.7% in controls. In general, the incidence of major malformations in worldwide studies of offspring of diabetic mothers has ranged from 5% to 10% (Table 39-2).

The insult that causes malformations in IDM affects most organ systems and must act before the seventh week of gestation. Central nervous system malformations, particularly anencephaly, open spina bifida, and holoprosencephaly, are increased 10-fold. Cardiac anomalies are the most common malformations with IDM, with ventricular septal defects and complex lesions such as transposition of the great vessels increased fivefold. The congenital defect thought to be most characteristic of diabetic embryopathy is sacral agenesis or caudal dysplasia, an anomaly found 200 to 400 times more often in offspring of diabetic

women (Figure 39-12). However, this defect is not pathognomonic for diabetes because it occurs in nondiabetic pregnancies.

Impaired glycemic control and associated derangements in maternal metabolism appear to contribute to abnormal embryogenesis. Maternal hyperglycemia has been proposed by most investigators as the primary teratogenic factor, but hyperketonemia, hypoglycemia, somatomedin inhibitor excess, and excess free oxygen radicals have also been suggested (see the box, Proposed Factors Associated with Teratogenesis in Pregnancy Complicated by Diabetes Mellitus). The profile of a woman most likely to produce an anomalous infant would include a patient with poor periconceptional control, long-standing diabetes, and vascular disease. Genetic susceptibility to the teratogenic influence of diabetes may also be a factor.

PROPOSED FACTORS ASSOCIATED WITH TERATOGENESIS IN PREGNANCY COMPLICATED BY DIABETES MELLITUS

- Hyperglycemia
- Ketone body excess
- Somatomedin inhibition
- Arachidonic acid deficiency
- Free oxygen radical excess

Several mechanisms have been proposed by which the previously mentioned teratogenic factors produce malformations. Freinkel and colleagues[29] first suggested that anomalies might arise from inhibition of glycolysis, the key energy-producing process during embryogenesis. They found that the addition of D-mannose to the culture medium of rat embryos inhibited glycolysis and produced growth restriction and derangement of neural tube closure.[29] Freinkel and colleagues[29] stressed the sensitivity of normal embryogenesis to alterations in these key energy-producing pathways, a process he labeled "fuel-mediated" teratogenesis. Goldman and Baker suggested that the mechanism responsible for the increased incidence of neural tube defects in embryos cultured in a hyperglycemic medium may involve a functional deficiency of arachidonic acid because supplementation with arachidonic acid or myoinositol will reduce the frequency of neural tube defects in this experimental model. Pinter and Reece, along with Pinter and associates, confirmed these studies and demonstrated that hyperglycemia-induced alterations in neural tube closure include disordered cells, decreased mitoses, and changes indicating premature maturation. These authors further demonstrated that hyperglycemia during organogenesis has a primary deleterious effect on yolk sac function with resultant embryopathy.

Altered oxidative metabolism from maternal diabetes may cause increased production of free oxygen radicals in the developing embryo, which are likely teratogenic. Supplementation of oxygen radical-scavenging enzymes, such as superoxide dismutase, to the culture medium of rat embryos protects against growth delay and excess malformations. It has been suggested that excess free oxygen radicals may have a direct effect on embryonic prostaglandin biosynthesis. Free oxygen radical excess may enhance lipid peroxidation, and in turn, generated hydroperoxides might stimulate thromboxane biosynthesis and inhibit prostacyclin production, an imbalance that could have profound effects on embryonic development. Finally, oxidative stress on diabetic rats is associated with the accumulation of glycation products and altered vascular endothelial growth factor expression in cardiovascular regions of the developing heart associated with endocardial cushion defects.

Fetal Macrosomia

Macrosomia has been variously defined as birthweight greater than 4000 to 4500 g as well as LGA, in which birthweight is above the 90th percentile for population and sex-specific growth curves. Fetal macrosomia complicates as many as 50% of pregnancies in women with GDM and 40% of pregnancies complicated by type 1 and type 2 diabetes, including some women treated with intensive glycemic control (Figure 39-13). Delivery of an infant weighing greater than 4500 g occurs 10 times more often in women with diabetes compared with a population of women with normal glucose tolerance.

According to the Pedersen hypothesis, maternal hyperglycemia results in fetal hyperglycemia and hyperinsulinemia, resulting in excessive fetal growth. Increased fetal β-cell mass may be identified as early as the second trimester.[29] Evidence supporting the Pedersen hypothesis has come from the studies of amniotic fluid and cord blood insulin and C-peptide concentrations. Both are increased in the amniotic fluid of insulin-treated women with diabetes at term and correlate with neonatal fat mass. Lipids and amino acids, which are elevated in pregnancies complicated by GDM, may also play a role in excessive fetal growth by stimulating the release of insulin and other growth factors from the fetal pancreatic β cells and placenta. **Infants of mothers with GDM have an increase in fat mass compared with fat-free mass. Additionally, the growth is disproportionate, with chest-to-head and**

FIGURE 39-13. Two extremes of growth abnormalities in pregnancies complicated by diabetes mellitus. On the left is a severely growth-restricted infant, and on the right is a macrosomic infant.

shoulder-to-head ratios larger than those of infants of women with normal glucose tolerance. This factor may contribute to the higher rate of shoulder dystocia and birth trauma observed in these infants.

The results of several clinical series have validated the Pedersen hypothesis inasmuch as tight maternal glycemic control has been associated with a decline in the incidence of macrosomia. Landon and colleagues,[30] using daily capillary glucose values obtained during the second and third trimesters in women requiring insulin, reported a rate of 9% macrosomia when mean values were below 110 mg/dL compared with 34% when less optimal control was achieved. Jovanovic and associates have suggested that 1-hour postprandial glucose measurements correlate best with the frequency of macrosomia. After controlling for other factors, these authors noted that the strongest prediction for birthweight was third-trimester nonfasting glucose measurements.

In a series of metabolic studies, Catalano and associates[34] estimated body composition in 186 neonates using anthropometry. Fat-free mass, which represented 86% of mean birthweight, accounted for 83% of the variance in birthweight, and fat mass, which made up only 14% of birthweight, accounted for 46% of the variance in birthweight. There was also significantly greater fat-free mass in male compared with female infants. Using independent variables such as maternal height, pregravid weight, weight gain during pregnancy, parity, paternal height and weight, neonatal sex, and gestational age, the authors accounted for 29% of the variance in birth weight, 30% of the variance in fat-free mass, and 17% of the variance in fat mass. Including estimates of maternal insulin sensitivity in 16 additional subjects, they were able to explain 48% of the variance in birthweight, 53% in fat-free mass, and 46% in fat mass. Studies by Caruso and colleagues have corroborated these findings, reporting that women with unexplained fetal growth restriction had greater insulin sensitivity compared with a control group of women whose infants were appropriate weight for gestational age. The potential mechanisms for this relate to the possibility that maternal circulating nutrients for glucose, FFAs, and amino acids available for placental transport to the fetus are decreased because of the relative increase in maternal insulin sensitivity. A positive correlation between birthweight and weight gain has been observed in women with normal glucose tolerance. The correlation was strongest in women who were lean before conception and became progressively weaker as pregravid weight for height increased. In women with GDM, there were no significant correlations between maternal weight gain and birthweight, irrespective of pregravid weight for height. These studies emphasize the role of the maternal metabolic environment and fetal growth.

TABLE 39-3 NEONATAL BODY COMPOSITION

	GDM (*N* = 195)	NGT (*N* = 220)	*P* VALUE
Weight (g)	3398 ± 550	3337 ± 549	.26
FFM (g)	2962 ± 405	2975 ± 408	.74
Fat mass (g)	436 ± 206	362 ± 198	.0002
Body fat	12.4 ± 4.6	10.4 ± 4.6	.0001

Modified from Catalano PM, Tyzbir ED, Allen Sr, et al: Evaluation of fetal growth by estimation of body composition. Obstet Gynecol 156:1089, 1987.
FFM, Fat-free mass; *GDM*, gestational diabetes mellitus; *NGT*, normal glucose tolerance.

Normalization of birthweight in infants of women with GDM, however, may in itself not achieve optimal growth. In a study of approximately 400 infants of women with normal glucose tolerance and GDM, Catalano and coworkers[34] showed that the infants of women with GDM had increased fat mass but not lean body mass or weight compared with a control group, even after adjustment for potential confounding variables (Table 39-3). Similarly, when only infants who were appropriate size for gestational age (i.e., between the 10th and 80th percentiles) were examined, the infants of the women with GDM had significantly greater fat mass and percentage of body fat but had less lean mass compared with the control group but no difference in birthweight. Of note, in the infants of the women with GDM, the strongest correlates with fat mass were fasting glucose and gestational age. This accounted for 17% of the variance in infant fat mass.

Hypoglycemia

Neonatal hypoglycemia, a blood glucose level less than 35 to 40 mg/dL during the first 12 hours of life, results from a rapid drop in plasma glucose concentrations following clamping of the umbilical cord. Hypoglycemia, a byproduct of hyperinsulinemia, is particularly common in macrosomic newborns, in which rates exceed 50%. With near-physiologic control of maternal glucose levels during pregnancy, overall rates of 5% to 15% have been reported. The degree of hypoglycemia may be influenced by at least two factors: (1) maternal glucose control during the latter half of pregnancy and (2) control of maternal glycemia control during labor and delivery. Prior poor maternal glucose control can result in fetal β-cell hyperplasia, leading to exaggerated insulin release following delivery. IDMs exhibiting hypoglycemia have elevated cord C-peptide and free insulin levels at birth and an exaggerated pancreatic response to glucose loading.

Respiratory Distress Syndrome

Experimental animal studies have provided evidence that hyperglycemia and hyperinsulinemia can effect pulmonary surfactant biosynthesis. In vitro studies have documented

that insulin can interfere with substrate availability for surfactant biosynthesis. Smith has postulated that insulin interferes with the normal timing of glucocorticoid-induced pulmonary maturation in the fetus. Cortisol apparently acts on pulmonary fibroblasts to induce synthesis of fibroblast-pneumocyte factor, which then acts on type II cells to stimulate phospholipid synthesis. Carlson and coworkers demonstrated that insulin blocks cortisol action at the level of the fibroblast by reducing the production of fibroblast-pneumocyte factor.

Clinical studies investigating the effect of maternal diabetes on fetal lung maturation have produced conflicting data. The role of amniocentesis in determining fetal lung maturity is discussed with timing and mode of delivery. **Several studies suggest that in women with well-controlled diabetes whose fetus is delivered at 38 to 39 weeks' gestation, the risk for respiratory distress syndrome (RDS) is no higher than that observed in the general population**.[32,33] Kjos and Walther[33] studied the outcome of 526 diabetic gestations delivered within 5 days of amniotic fluid fetal lung maturation testing and reported HMD in five neonates (0.95%), all of whom were delivered before 34 weeks' gestation. Mimouni and associates compared outcomes of 127 IDMs with matched controls and concluded that diabetes in pregnancy as currently managed is not a direct risk factor for the development of RDS. Yet, cesarean delivery not preceded by labor and prematurity, both of which are increased in diabetic pregnancies, clearly increase the likelihood of neonatal respiratory disease. With cesarean delivery, many of these cases represent retained lung fluid or transient tachypnea of the newborn, which usually resolves within the first days of life.

Calcium and Magnesium Metabolism

Neonatal hypocalcemia, with serum levels below 7 mg/dL or an ionized level less than 4 mg/dL, occurs at an increased rate in the IDM when controlling for predisposing factors such as prematurity and birth asphyxia. With modern management, the frequency of neonatal hypocalcemia is less than 5% in the infants of diabetic women. Hypocalcemia in the IDM has been associated with a failure to increase parathyroid hormone synthesis following birth. Decreased serum magnesium levels have also been documented in pregnant diabetic women as well as their infants. Mimouni and associates described reduced amniotic fluid magnesium concentrations in women with type 1 diabetes mellitus. These findings may be explained by a drop in fetal urinary magnesium excretion, which would accompany a relative magnesium-deficient state. Magnesium deficiency paradoxically, then, may inhibit fetal parathyroid hormone secretion.

Hyperbilirubinemia and Polycythemia

Hyperbilirubinemia is frequently observed in the IDM. Neonatal jaundice has been reported in as many as 25% to 53% of pregnancies complicated by pregestational diabetes mellitus and 38% of pregnancies in women with GDM. In the past, the jaundice observed in the IDM often was attributed to prematurity. However, jaundice is increased in macrosomic IDMs.

Although severe hyperbilirubinemia may be observed independent of polycythemia, a common pathway for these complications most likely involves increased red blood cell production, which is stimulated by increased erythropoietin in the IDM. Presumably, the major stimulus for red cell production is a state of relative hypoxia in utero, as described previously. Cord erythropoietin levels generally are normal in IDMs whose mothers demonstrate good glycemic control during gestation; however, hemoglobin A_{1c} (HbA_{1c}) values in late pregnancy are significantly elevated in mothers of hyperbilirubinemic infants.

Cardiomyopathy

A transient form of cardiomyopathy may occur in infants of diabetic mothers. Among symptomatic infants, septal hypertrophy may cause left ventricular outflow obstruction. Although most infants are asymptomatic, respiratory distress or signs of cardiac failure may arise. Cardiac hypertrophy likely results from fetal hyperinsulinemia, which leads to fat and glycogen deposition in the myocardium. Thus, cardiomyopathy generally occurs in poorly controlled pregnancies complicated by macrosomia. In most cases, symptoms do improve over several weeks with supportive care, and echocardiographic changes resolve as well.

MATERNAL CLASSIFICATION AND RISK ASSESSMENT

Priscilla White first noted that the patient's age at onset of diabetes, the duration of the disease, and the presence of vasculopathy significantly influenced perinatal outcome. Her classification system has been widely applied to pregnant women with diabetes. A modification of this scheme is presented in Table 39-1. Counseling a patient and formulating a plan of management requires assessment of both maternal and fetal risk. The White classification facilitates this evaluation.

Class A_1 diabetes mellitus includes those women who have demonstrated carbohydrate intolerance during an oral glucose tolerance test (GTT); however, their fasting and postprandial glucose levels are maintained within physiologic range by dietary regulation alone. Class A_2 includes gestational diabetic women who require insulin or oral hypoglycemic therapy in response to repetitive elevations of fasting or postpartum glucose levels following dietary intervention.

Two International Workshop Conferences on Gestational Diabetes sponsored by the American Diabetes Association in cooperation with the American College of Obstetricians and Gynecologists (ACOG) recommended that the term gestational diabetes rather than class A diabetes be used to describe women with carbohydrate intolerance of variable severity with onset or recognition during the present pregnancy. The definition applies whether insulin or only diet modification is used for treatment and whether or not the condition persists after pregnancy. It does not exclude the possibility that unrecognized glucose intolerance may have antedates or have begun with pregnancy. The term gestational diabetes fails to specify whether the patient requires dietary adjustment alone or treatment with diet and insulin. This distinction is important because those women who are normoglycemic while fasting appear to have a significantly lower perinatal mortality rate. Women with GDM who require insulin are at

greater risk for a poor perinatal outcome than those whose diabetes is controlled by diet alone.

Women requiring insulin are designated by the letters B, C, D, R, F, and T. Class B patients are those whose onset of disease occurs after age 20 years. They have had diabetes for less than 10 years and have no vascular complications. Included in this subgroup of patients are those who have been previously treated with oral hypoglycemic agents.

Class C diabetes includes patients who have the onset of their disease between the ages of 10 and 19 years or have had the disease for 10 to 19 years. Vascular disease is not present.

Class D represents women whose disease is of 20 years' duration or more, or whose onset occurred before age 10 years, or who have benign retinopathy. The latter includes microaneurysms, exudates, and venous dilation.

Nephropathy

Renal disease develops in 25% to 30% of women with IDDM, with a peak incidence after 16 years of diabetes. **Overt diabetic nephropathy is diagnosed in women with type 1 or type 2 diabetes mellitus when persistent proteinuria exists in the absence of infection or other urinary tract disease.** The criteria for diagnosis in the nonpregnant state includes a total urinary protein excretion (TPE) of greater than 500 mg/24 hours or greater than 300 mg/24 hours of urinary albumin excretion (UAE).

Before the development of overt diabetic nephropathy, some individuals develop incipient diabetic nephropathy defined by repetitive increases in UAE known as *microalbuminuria*. The diagnosis is established from a 24-hour urine collection exhibiting UAE of 20 to 199 mcg/minute or 30 to 299 mg/24 hours. It is important to note that women who exhibit microalbuminuria in early pregnancy have a 35% to 60% risk for superimposed preeclampsia.[35] Without specific interventions, about 80% of individuals with type 1 diabetes who develop sustained microalbuminuria experience an increase in UAE of 10% to 20% per year to the stage of overt nephropathy. In the nonpregnant individual, improvement of glycemic and blood pressure control has been demonstrated to reduce the risk for or slow the progression of diabetic nephropathy. Renoprotective or antihypertensive therapy consisting of either angiotensin-converting enzyme (ACE) inhibitors or angiotensin II receptor blockers is indicated before pregnancy in women with microalbuminuria or overt nephropathy. **Both ACE inhibitors and angiotensin receptor blockers are contraindicated during pregnancy because they may result in fetal proximal tubal dysgenesis and oligohydramnios.** Two Israeli studies first suggested that ACE inhibitors were unlikely to be teratogenic. Thus, the practice by some has been not to discontinue such medications before conception and to discontinue use after pregnancy is confirmed. However, a population-based study has indicated potential teratogenesis in women who received ACE inhibitors in early pregnancy and thus calls into question whether such agents are advised in women attempting concraception.[36] Cooper and colleagues[36] studied a cohort of 29,507 infants enrolled in Tennessee Medicaid born between 1985 and 2000 for whom there was no evidence of maternal diabetes. A total of 209 infants with exposure to ACE inhibitors during the first trimester alone were compared with 202 infants exposed to other antihypertensives during the first trimester and to 29,096 infants with no exposure to any antihypertensive agents during pregnancy. Major congenital malformations were identified from linked vital records and hospitalization claims during the first year of life. Infants with only first-trimester exposure to ACE inhibitors had an increased risk for major congenital malformations (risk ratio, 2.71; 95% confidence interval, 1.72 to 4.27) compared with infants who had no fetal exposure to other antihypertensive medications during only the first trimester. The increased risk conferred by ACE inhibitor exposure manifested as primarily anomalies of the cardiovascular and central nervous systems. Clearly, given this information, the risk and benefits of use of ACE inhibitors in diabetic women planning pregnancy must be considered.

Women with diabetic nephropathy have a significantly reduced life expectancy. Disease progression is characterized by hypertension, declining glomerular filtration rate, and eventual end-stage renal disease requiring dialysis or transplantation. In women with overt nephropathy, end-stage renal disease occurs in 50% by 10 years and in greater than 75% by 20 years.

Class F describes the 5% to 10% of pregnant patients with underlying renal disease. This includes those with reduced creatinine clearance or proteinuria of at least 300 mg in 24 hours measured during the first 20 weeks of gestation. Two factors present before 20 weeks' gestation appear to be predictive of perinatal outcome in these women (e.g., preterm delivery, low birthweight, or preeclampsia):

1. Proteinuria greater than 3 g/24 hours
2. Serum creatinine greater than 1.5 mg/dL

In a series of 45 class F women, 12 women had such risk factors.[37] Preeclampsia developed in 92%, with a mean gestational age at delivery of 34 weeks, compared with an incidence of preeclampsia of 36% in 33 women without these risk factors who reached an average gestational age of 36 weeks. Remarkably, perinatal survival was 100% in this series, and no deliveries occurred before 30 weeks' gestation. Comparable series detailing perinatal outcomes in class F patients are presented in Table 39-4.

The management of the diabetic women with nephropathy requires great expertise. Limitation of dietary protein, which may reduce protein excretion in nonpregnant patients, has not been adequately studied during pregnancy. Although the method is controversial, some nephrologists recommend a modified reduction in protein intake for pregnant women with nephropathy. **Control of hypertension in pregnant women with diabetic nephropathy is crucial to prevent further deterioration of kidney function and to optimize pregnancy outcome.** Although debatable, some cautiously use diuretics when patients are extremely nephrotic because this group may be prone to volume-dependent forms of hypertension. Because calcium channel blockers have similar renoprotective effects as ACE inhibitors and do not appear to be teratogenic, these agents maybe a reasonable choice for treatment of hypertension in pregnant women with diabetic nephropathy. Whether such agents benefit normotensive pregnant women with microalbuminuria or nephropathy has not been determined.

>36 wk (%)	28.5	50	45.2	49	47%

Several studies have failed to demonstrate a permanent worsening of diabetic renal disease in women with mild to moderate renal insufficiency as a result of pregnancy. Furthermore, it has been suggested that pregnancy itself does not increase the risk for developing nephropathy, although development of proteinuria and poor glycemic control are markers for subsequent renal disease. Kitzmiller and colleagues[38] reviewed 35 pregnancies complicated by diabetic nephropathy. Proteinuria increased in 69%, and hypertension developed in 73%. After delivery, proteinuria declined in 65% of cases. In only two patients did protein excretion increase after gestation. In Gordon's series, 26 women (58%) had more than a 1-g increase in proteinuria, and by the third trimester, 25 (56%) excreted more than 3 g/24 hours. In most cases, protein excretion returned to baseline levels after gestation.

Normal pregnancy is marked by an approximate 50% increase in glomerular filtration rate and thus a rise in creatinine clearance accompanied by a modest decline in serum creatinine. Most women with diabetic nephropathy, however, do not exhibit a rise in creatinine clearance during gestation. In a study of 46 class F pregnancies, Gordon and colleagues reported a mean decrease in creatinine clearance of 7.9%. When evaluated according to initial creatinine clearance, no difference in the degree of change was noted when subjects were classified according to first trimester renal function. Whereas few patients exhibited a rise in creatinine clearance, other smaller studies have demonstrated an increase in creatinine clearance in about one third of women. Given the importance of blood pressure control in reducing cardiovascular and renal complications in the nonpregnant state, Carr and colleagues[39] studied the effect of poorly controlled hypertension in early pregnancy on renal function in 43 women with IDDM and nephropathy. Those women with mean arterial pressure exceeding 100 mm Hg demonstrated higher serum creatinine levels (1.23 vs. 0.895 mg/dL) compared with women with controlled hypertension.

With overt diabetic nephropathy, both albumin and total protein excretion may rise significantly during gestation. Importantly, a rise in total protein excretion to levels exceeding 300 mg/24 hours may also be observed in women both with and without microalbuminuria in early pregnancy. Biesenbach and Zazgornik reported an average increase by the third trimester in total protein excretion to 478 mg/24 hours in seven women with microalbuminuria in early pregnancy. This observation underscores the importance of obtaining baseline 24-hour urine measurements for total protein in all diabetic women because confusion arises as to the significance of when new-onset macroalbuminuria or proteinuria is detected during the third trimester. Despite this recommendation, it may be challenging to distinguish preeclampsia from the natural progression of diabetic nephropathy, which often manifests as progressive proteinuria during pregnancy.

Gordon and colleagues[37] have detailed the progressive rise in proteinuria during pregnancy in 46 class F pregnancies. The mean increase in proteinuria between initial values and third-trimester values was 3.08 ± 4 g/24 hours. Twenty-six women (58%) had more than 1 g increase in proteinuria, and by the third trimester, 25 (56%) excreted more than 3 g/24 hours, including 3 women exceeding 10 g/24 hours. The mean change in proteinuria was not correlated with alteration in creatinine clearance, and a similar increase in proteinuria was observed during pregnancy, regardless of the initial level present.

In summary, changes in creatinine clearance are variable during pregnancy in women with diabetic nephropathy. Most women with nephropathy will not exhibit a normal rise in creatinine clearance. Protein excretion will frequently rise during gestation to levels that can reach the nephrotic range.

With improved survival of diabetic patients after renal transplantation, a growing number of kidney recipients have now achieved pregnancy (class T). Armenti has described 28 pregnancies in diabetic renal transplant recipients. Most patients had underlying hypertension, although preeclampsia was diagnosed in only 17% of cases. Allograft rejection occurred in one case. Overall, despite an increase in deliveries before 37 weeks, perinatal survival was 100%. These excellent results have come from improvements in both perinatal management and newer immunosuppressive regimens.

Many transplantation centers strive to perform combined kidney-pancreas transplantations in diabetic individuals with end-stage renal disease. Gilbert-Hagn and colleagues reviewed pregnancy outcomes in 43 pancreas-kidney recipients, of whom 66% developed hypertension

and 77% had pregnancies that resulted in preterm birth. In this series, 6% of women experienced a rejection episode during pregnancy.

Retinopathy

Class R diabetes designates women with proliferative retinopathy, representing neovascularization or growth of new retinal capillaries. These vessels may cause vitreous hemorrhage with scarring and retinal detachment, resulting in vision loss. As with nephropathy, prevalence of retinal disease is highly related to the duration of diabetes. At 20 years, nearly 80% of diabetic individuals have some element of diabetic retinopathy. There are generally background changes, whereas proliferative diabetes retinopathy complicates approximately 77% of pregnancies. Excellent glycemic control prevents retinopathy and may slow its progression. Parity is not associated with a risk for subsequent retinopathy. However, pregnancy does convey a greater than a twofold independent risk for progression of existing retinopathy.[40] Progression of diabetic retinopathy during pregnancy is associated with: (1) retinal status at inception; (2) duration and early onset of diabetes; (3) elevated first-transfer HbA_{1c} and persisting poor glycemic control or rapid normalization of blood glucose, and (4) hypertension.[41] Retinopathy may worsen significantly during pregnancy despite the major advances that have been made in diagnosis and treatment of existing retinopathy. Ideally, women planning a pregnancy should have a comprehensive eye examination and treatment before conception. For those discovered to have proliferative changes during pregnancy, laser photocoagulation therapy with careful follow-up has helped maintain many pregnancies to a gestational age at which neonatal survival is likely.

In a large series of 172 patients, including 40 cases with background retinopathy and 11 with proliferative changes, only one patient developed new-onset proliferative retinopathy during pregnancy. A review of the literature by Kitzmiller and colleagues[42] confirms the observation that progression to proliferative retinopathy during pregnancy rarely occurs in women with background retinopathy or those without any eye ground changes. Of the 561 women in these two categories, only 17 (3%) developed neovascularization during gestation. In contrast, 23 of 26 (88.5%) with untreated proliferative disease experienced worsening retinopathy during pregnancy.

Pregnancy may increase the prevalence of some background retinal changes. Characteristic streak-blob hemorrhages and soft exudates have been noted, and such retinopathy may progress despite strict metabolic control. At least two studies have related worsening retinal disease to plasma glucose at the first prenatal visit as well as the magnitude of improvement in glycemia during early pregnancy. In a subset of 140 women without proliferative retinopathy at baseline followed in the Diabetes in Early Pregnancy Study, progression of retinopathy was seen in 10.3%, 21.1%, 18.8%, and 54.8% of patients with no retinopathy, microaneurysms only, mild nonproliferative retinopathy, and moderate to severe nonproliferative retinopathy at baseline, respectively. Elevated glycosylated hemoglobin at baseline and the magnitude of improvement of glucose control through week 14 were associated with a higher risk for progression of retinopathy. Women with an initial glycohemoglobin greater than 6 standard deviations (SDs) above the control mean were nearly three times as likely to experience worsening retinopathy compared with those within 2 SDs of the mean. Whether improving control or simply suboptimal control contributes to a deterioration of background retinopathy remains uncertain. Hypertension may also be a significant risk factor for the progression of retinopathy during pregnancy. **For women with proliferative changes, laser photocoagulation is indicated, and most will respond to this therapy. However, women who demonstrate severe florid disc neovascularization that is unresponsive to laser therapy during early pregnancy may be at great risk for deterioration of their vision.** Termination of pregnancy should be considered in this group of patients.

Women with proliferative retinopathy are generally advised to avoid the Valsalva maneuver to reduce the risk for retinal hemorrhage. Shortening of the second stage or cesarean delivery has been advocated; however, studies are lacking that address this issue.

In addition to background and proliferative eye disease, vaso-occlusive lesions associated with the development of macular edema have been described during pregnancy. Cystic macular edema is most often found in patients with proteinuric nephropathy and hypertensive disease leading to retinal edema. Macular capillary permeability is a feature of this process. The degree of macular edema is directly related to the fall in plasma oncotic pressure present in these women. In one series, seven women with minimal or no retinopathy before becoming pregnant developed severe macular edema associated with preproliferative or proliferative retinopathy during the course of their pregnancies. Although proliferation was controlled with photocoagulation, the macular edema worsened until delivery in all cases and was often aggravated by photocoagulation. Although both macular edema and retinopathy regressed after delivery in some patients, in others, these pathologic processes persisted, resulting in significant visual loss.

Coronary Artery Disease

Class H diabetes refers to the presence of diabetes of any duration associated with ischemic myocardial disease. Symptomatic coronary artery disease is rare in type 1 diabetic women who are younger than 35 years. It is unknown whether the small number of women who have coronary artery disease are at an increased risk for infarction during gestation. Maternal mortality rate exceeded 50% for cases of infarction during pregnancy reported before 1980; however, all but 1 of 23 cases reported from 1980 to 2005 survived. A high index of suspicion for ischemic heart disease should be maintained in women with long-standing diabetes because anginal symptoms may be minimal and infarction may thus present as congestive heart failure. Although there are in excess of one dozen reports of successful pregnancies following myocardial infarction in diabetic women, cardiac status should be carefully assessed early in gestation or, preferably, before pregnancy. If electrocardiographic abnormalities are encountered, echocardiography may be employed to assess ventricular function, or modified stress testing may be performed. The decision to undertake a pregnancy in a woman with type 1 or type 2 diabetes mellitus and coronary artery disease needs to be

made only after serious consideration. The potential for morbidity and mortality must be thoroughly reviewed with the patient and her family. The management of myocardial infarction during pregnancy is discussed in Chapter 36.

DETECTION AND SIGNIFICANCE OF GESTATIONAL DIABETES MELLITUS

It has been estimated that 6% to 7% of pregnancies are complicated by diabetes mellitus and that 90% of the cases represent women with GDM[43] (Figure 39-14). An increased prevalence of GDM is found in women of ethnic groups that have high frequencies of type 2 diabetes. These include women of Hispanic, African, Native American, Asian, and Pacific Island ancestry. Women with GDM represent a group with significant risk for developing glucose intolerance later in life. O'Sullivan projected that 50% of women with GDM would become diabetic at follow-up study of 22 to 28 years; however, Kjos and colleagues reported that 60% of Latina women will develop type 2 diabetes, and this level of risk may actually be manifest by 5 years after the GDM index pregnancy. The likelihood for subsequent diabetes increases when GDM is diagnosed in early pregnancy, and presumably some of these women with impaired β-cell function may represent cases of unidentified preexisting type 2 diabetes.

As noted earlier, GDM is a state restricted to pregnant women whose impaired glucose tolerance (IGT) is discovered during pregnancy. Because, in most cases, patients with GDM have normal fasting glucose levels, some challenge of glucose tolerance must be undertaken. Traditionally, obstetricians relied on historical and clinical risk factors to select those patients most likely to develop GDM. This group included patients with a family history of diabetes and those whose past pregnancies were marked by an unexplained stillbirth or the delivery of a malformed or macrosomic infant. Obesity, hypertension, glycosuria, and maternal age older than 25 years were other indications for screening. Interestingly, more than half of all patients who exhibit an abnormal GTT lack the risk factors mentioned earlier.

In the summary and recommendations of the Second and Third International Workshop-Conferences on GDM, screening was recommended for all pregnant women. Following the Fourth International Workshop-Conference in 1997, screening was recommended for women in ethnic groups with relatively high rates of carbohydrate intolerance during pregnancy and of diabetes later in life. It was recognized and reaffirmed at the Fifth International Workshop Conference in 2005 that certain features place women at low risk for GDM (Table 39-5), and it may not be cost-effective to screen this subgroup of women. Those at low risk include women who are not members of ethnic groups

TABLE 39-5 SCREENING STRATEGY FOR DETECTING GDM

GDM risk assessment: should be ascertained at the first prenatal visit
- Low risk: blood glucose testing not routinely required if *all* of the following characteristics are present:
  - Member of an ethnic group with a low prevalence of GDM
  - No known diabetes in first-degree relatives
  - Age <25 yr
  - Weight normal before pregnancy
  - No history of abnormal glucose metabolism
  - No history of poor obstetrical outcome
- Average risk: perform blood glucose testing at 24-28 wk using either:
  - Two-step procedure: 50-g glucose challenge test (GCT) followed by a diagnostic oral glucose tolerance test in those meeting the threshold value in the GCT
  - One-step procedure: diagnostic oral glucose tolerance test performed on all subjects
- High risk: perform blood glucose testing as soon as feasible, using the procedures described above if one or more of these are present:
  - Severe obesity
  - Strong family history of type 2 diabetes
  - Previous history of GDM, impaired glucose metabolism, or glucosuria

If GDM is not diagnosed, blood glucose testing should be repeated at 24-28 wk or at any time a patient has symptoms or signs that are suggestive of hyperglycemia.

at increased risk for developing adult-onset diabetes, who have no previous history of abnormal glucose tolerance or poor obstetrical outcomes usually associated with GDM, and who have all of the following characteristics: age younger than 25 years, normal body weight, and no family history of diabetes. Danilenko-Dixon and colleagues have reported that such low-risk women represent only 10% of their population, and thus identifying such women may add complexity to screening in a busy clinic or office practice. The ACOG recognizes that although universal screening is the most sensitive approach, selective screening may be employed with the criteria cited earlier.

Despite the widespread acceptance of screening for and treating of GDM in the United States, some expert panels have questioned the benefit of GDM screening programs altogether.[44] The criteria for the diagnosis of GDM originally designated a population at increased risk for the development of type 2 diabetes in later life. The fact that O'Sullivan's original work establishing the criteria used for the diagnosis of GDM failed to evaluate an association between mild carbohydrate tolerance and perinatal outcome has led many to question the overall significance of this diagnosis. Because of the lack of high-quality evidence concerning the benefit of treatment of milder cases of GDM, it is difficult to determine the extent to which screening affects maternal and neonatal health outcomes.[45] It has been suggested that the criteria for the diagnosis of GDM are conceptually flawed in that they represent a dichotomous definition of normal and abnormal gestational glucose tolerance, when the risk for adverse maternal-fetal outcomes and later diabetes should be logically graded upward with higher values on the oral GTT and with the degree of fasting hyperglycemia.

The Hyperglycemia and Adverse Pregnancy Outcome (HAPO) study was designed to aid in the development of internationally agreed-on diagnostic criteria for GDM, based on their predictive value for pregnancy outcome.[46] This landmark multicenter international study allowed for analysis of blinded 75-g 2-hour oral GTT data in more than 25,000 nondiabetic gravidas. Glycemia was evaluated in relation to various perinatal and maternal outcomes. **Increases in each of the three values on the 75-g, 2-hour oral GTT were associated with graded increases in the likelihood of outcomes such as LGA infant, cesarean delivery, fetal insulin levels, and neonatal adiposity** (Figure 39-15). The HAPO study investigators did not offer specific recommendations for the diagnostic criteria of GDM. Because there was a continuous association between glucose values and perinatal outcome, it was apparent that any new recommended diagnostic criteria would need to be arrived at by consensus. To meet this challenge, the International Association of Diabetes and Pregnancy Study Group (ISDPGS) convened a workshop conference in 2008.[47] An odds ratio of 1.75 was selected for the outcomes of increased neonatal body fat, LGA, and cord serum C-peptide greater than the 90th percentile, which yielded the recommended diagnostic criteria for GDM (Table 39-6).

Importantly, the IADPGSG task force recommended universal 75-g, 2-hour oral GTT be performed during pregnancy and the diagnosis of GDM be made when any

TABLE 39-8 TARGET PLASMA GLUCOSE LEVELS IN PREGNANCY

TIME	GLUCOSE LEVEL (mg/dL)
Before breakfast	60-90
Before lunch, supper, bedtime snack	60-105
Two hours after meals	≤120
2 AM to 6 AM	>60

single value on the oral GTT was met or exceeded.[47] Using the proposed criteria, 17.8% of the HAPO study population would be identified as having GDM. The resulting dramatic increase in the frequency of GDM and its consequences will now be considered by professional organizations charged with evaluating whether to endorse the proposed IADPSG criteria.

At the present time, practitioners in the United States continue to perform glucose challenge screening followed by a diagnostic 100-g oral GTT. The 50-g glucose challenge may be performed in the fasting or fed state. Sensitivity is improved if the test is performed in the fasting state. **A plasma value between 130 and 140 mg/dL is commonly used as a threshold for performing a 3-hour oral GTT.** Coustan and coworkers have demonstrated that 10% of women with GDM have screening test values between 130 and 139 mg/dL. This study indicated that the sensitivity of screening would be increased from 90% to nearly 100% if universal screening were employed using a threshold of 130 mg/dL. The prevalence of positive screening tests requiring further diagnostic testing increases from 14% (140 mg/dL) to 23% (130 mg/dL), which is accompanied by about a 12% increase in the overall cost to diagnose each case of GDM.

Whereas most women can be screened for GDM at about 24 to 28 weeks' gestation, it is advisable to screen earlier in pregnancy those with strong risk factors such as morbid obesity, a strong family history, previous GDM, prior macrosomic stillbirth, or an infant weighing more than 4500 g. If initial screening is negative, repeat testing is performed at 24 to 28 weeks. Using the plasma cut-off of 135 to 140 mg/dL, one can expect approximately 15% to 20% of patients with an abnormal screening value to have an abnormal 3-hour oral GTT. Patients whose 1-hour screening value exceeds 190 mg/dL (10.5 mmol/L) will exhibit an abnormal oral GTT in 90% of cases. In women with a screening value between 190 and 215 mg/dL, it is preferable to check a fasting blood glucose level before administering a 100-g carbohydrate load. If the fasting glucose is greater than 95 mg/dL, the patient is treated for GDM.

The criteria for establishing the diagnosis of gestational diabetes based on a 100-g, 3-hour oral GTT are listed in Table 39-7. The U.S. National Diabetes Data Group criteria represent a theoretical conversion of O'Sullivan's thresholds in whole blood. Carpenter and Coustan prefer to use another modification of these data, which is supported by a comparison of the old Somogyi-Nelson method and current plasma glucose oxidase assays. Several studies have confirmed that patients diagnosed using the less stringent Carpenter criteria experience as much perinatal morbidity (macrosomia and cesarean delivery) as subjects diagnosed by the National Diabetes Data Group Criteria. Using either 100-g, 30-hour oral GTT criteria, the patient must have at least two abnormal glucose determinations to be diagnosed with GDM.

TREATMENT OF THE PATIENT WITH TYPE 1 OR TYPE 2 DIABETES MELLITUS

Clinical efforts aimed at optimizing maternal control are considered the key component responsible for the decline in perinatal death in pregnancies complicated by diabetes mellitus over the past few decades. Self-blood glucose monitoring, combined with intensive insulin therapy, has resulted in improved glycemia for many pregnant diabetic women (Table 39-8). Women with pregestational diabetes should monitor their glucose control five to seven times daily using glucose-oxidase-impregnated reagent strips and a glucose reflectance meter.

Recently, the technology of continuous glucose monitoring (CGM) has been studied in pregnant diabetic women. By providing a total of 288 measurements daily compared with six to eight blood glucose measurements using self-blood glucose monitoring, CGM can provide a more complete glycemic profile and presumably detect unrecognized postprandial hyperglycemia as well as symptomatic hypoglycemia. A randomized trial of 71 women with pregestational diabetes confirmed lower third-trimester

A1c level and reduced birthweight and macrosomia in women receiving CGM.

To achieve the best glycemic control possible for each patient, conventional insulin therapy is abandoned during pregnancy in favor of intensive therapy. An attempt is made to stimulate physiologic insulin requirements by providing basal and prandial insulin needs through three or four daily injections or continuous insulin infusion (pump therapy) (CSII). Insulin regimens have classically included multiple injections of insulin, usually before breakfast, the evening meal, and often bedtime, complemented by self-blood glucose monitoring and adjustment of insulin dose according to glucose profiles. Patients are instructed on dietary composition, insulin action, recognition and treatment of hypoglycemia, adjusting insulin dosage for exercise and sick days, as well as monitoring for hyperglycemia and potential ketosis. These principles form the foundation for intensive insulin therapy in which an attempt is made to simulate physiologic insulin requirements. Insulin administration is provided for both basal needs and meals, and rapid adjustments are made in response to glucose measurements. The treatment regimen generally involves three to four daily injections or the use of CSII devices. With either approach, frequent self-blood glucose monitoring is fundamental to achieve the therapeutic objective of physiologic glucose control. Glucose determinations are made in the fasting state and before lunch, dinner, and bedtime. Postprandial and nocturnal values are also advised. Patients are instructed on an insulin dose for each meal and at bedtime, if necessary. Mealtime insulin needs are determined by the composition of the meal, the premeal glucose measurement, and the level of activity anticipated following the meal. Basal or intermediate-acting insulin requirements are determined by periodic 2:00 AM to 4:00 AM glucose measurements, as well as late afternoon values, which reflect morning intermediate-acting insulin action.

In patients in whom diabetes is not well controlled, a brief period of hospitalization may be necessary for the initiation of therapy. Patients are encouraged to contact their physician at any time if questions should arise concerning the management of their diabetes. During pregnancy, we advise women to report their glucose values by telephone, fax, or e-mail, on an at least weekly basis.

Insulin therapy must be individualized, with dosage determinations tailored to diet and exercise. Insulin requirements during pregnancy have been reported to average 0.7 U/kg in the first trimester, increasing to 1.1 U/kg by term, although the variation in requirements is considerable. Garcia-Patterson and colleagues have noted a steady increase in insulin requirements from 16 to 37 weeks, with unstable requirements common before 16 weeks. **Semisynthetic human insulin preparations and newer insulin analogs** (Table 39-9) **are preferred for use during pregnancy. Insulin lispro and insulin aspart are rapid-acting insulin preparations that have replaced regular insulin.**[48] Insulin lispro features reversal of proline and lysine at positions B28 and B29 and remains in monomeric form and is thus rapidly absorbed. Its duration of action is shorter than that of regular insulin, so that unexpected hypoglycemia hours after injection are avoided. Insulin lispro appears to be safe for use during pregnancy and is a category B drug. Insulin aspart has also been compared with human insulin (Actrapid) in women with type 1 diabetes during pregnancy, with comparable fetal outcomes observed among both groups; however, limited information exists concerning glycemia in treated women.

TABLE 39-9 TYPE OF HUMAN INSULIN AND INSULIN ANALOGUES

	SOURCE	ONSET (hr)	PEAK (hr)	DURATION (hr)
Short Acting				
Humulin R (Lilly)	Human	0.5	2-4	5-7
Velosulin H (Novo Nordisk)	Human	0.5	1-3	8
Novolin R (Novo Nordisk)	Human	0.5	2.5-5	6-8
Lispro	Analog	0.25	0.5-1.5	4-5
Aspart	Analog	0.25	1-3	3-5
Intermediate Acting				
Humulin Lente (Lilly)	Human	1-3	6-12	18-24
Humulin NPH (Lilly)	Human	1-2	6-12	18-24
Novolin l (Novo Nordisk)	Human	2.5	7-15	22
Novolin N (Novo Nordisk)	Human	1.5	4-20	24
Long Acting				
Humulin Ultralente (Lilly)	Human	4-6	8-20	>36
Glargine	Analogue	1	—	24
Determir	Analogue	1-2	—	24

The long-acting insulin analogs glargine and detemir have been designed to more accurately mimic basal insulin secretion, yet neither has been adequately evaluated for efficacy during pregnancy. Observational data would suggest that use of insulin glargine is safe during pregnancy. Insulin glargine has a flat profile compared with neutral protamine Hagedorn (NPH) so that when administered with short-acting insulin, unpredictable spikes in insulin levels with resulting hypoglycemia appear to be less common. **However, the flat profile of glargine may be undesirable during pregnancy when variation in basal insulin needs are likely. For this reason, we frequently suggest that women receiving glargine change to a twice-daily regimen of NPH insulin.**

Insulin is generally administered in two to three injections. We prefer a three-injection regimen, although most patients present taking a combination of intermediate-acting and short-acting insulin before dinner and breakfast. As a general rule, the amount of intermediate-acting insulin will exceed the short-acting component by a 2:1 ratio. Patients usually receive two thirds of their total dose with breakfast and the remaining third in the evening as a combined dose at dinner or split into components with short-acting or rapid-acting insulin at dinner and intermediate-acting insulin at bedtime in an effort to minimize periods of nocturnal hypoglycemia. These episodes frequently occur when the mother is in a relative fasting state, whereas placental and fetal glucose consumption continue. Finally, some women may require a small dose of short-acting insulin before lunch, thus constituting a four-injection regimen.

Open-loop CSII pump therapy is preferred by many IDDM women during pregnancy. The pump is a battery-powered unit, which may be worn during most daily

activities like a beeper. These systems provide continuous short-acting insulin therapy through a subcutaneous infusion. The basal infusion rate and bolus doses to cover meals are determined by frequent self-monitoring of blood glucose. The basal infusion rate is generally close to 1 U/hour.

Pregnant women may require hospitalization before initiation of pump therapy. Women must be educated regarding the strategy of continuous infusion and have their glucose stabilized over several days. This requires that multiple blood glucose determinations be made for the prevention of periods of hyperglycemia and hypoglycemia. Glucose values may become normalized with minimal amplitude of daily excursions in most patients.

Episodes of hypoglycemia are often reduced with pump therapy. When they do occur, they are usually secondary to errors in dose selection or failure to adhere to the required diet. The risk for nocturnal hypoglycemia, which is increased in the pregnant state, necessitates that great care be undertaken in selecting patients for CSII. Patients using the pump who fail to exhibit normal counterregulatory responses to hypoglycemia should probably check their glucose values at 2:00 AM to 3:00 AM to detect nocturnal hypoglycemia.

The mechanics of the CSII systems are relatively simple. A fine-gauge butterfly needle device is attached by connecting tubing to the pump. This cannula is reimplanted every 2 to 3 days at a different site in the anterior abdominal wall. Rapid-acting insulin (usually insulin lispro) is stored in the pump syringe. Infusion occurs at a basal rate, which can be fixed or altered for specific time of day by a computer program. For example, the basal rate can be programmed for a lower dose at night. Preprandial boluses can be adjusted manually before each meal and snack. Half of the total daily insulin is usually given as the basal rate and the remainder as premeal boluses infused before each meal. The largest bolus (30% to 35%) is administered with breakfast, followed by 25% before dinner and 15% to 20% before snacks.

Patients without any pancreatic reserve may have rapid elevations of blood glucose if there is pump failure or intercurrent infection. Since the advent of buffered insulin, insulin aggregation leading to occlusion of the Silastic infusion tubing is uncommon. Failure of the pump is associated with a steady rise in ketonemia in the nonpregnant patient.

It is unclear whether CSII is superior to multiple-injection regimens. Coustan and colleagues randomized 22 patients to intensive conventional therapy with multiple injections versus pump therapy. There were no differences between the two treatment groups with respect to outpatient mean glucose levels, glycosylated hemoglobin levels, or glycemic excursions. Gabbe and colleagues reported a large retrospective cohort study of women who began pump therapy during gestation compared with a group treated with multiple-injection regimens. Women using pumps, most with insulin lispro, had fewer hypoglycemic reactions and comparable glucose control and pregnancy outcomes. Notably, **a recent systematic review comparing randomized trials of CSII versus multiple-injection regimens revealed no difference in measures of glycemic control or pregnancy outcome.**[50]

Diet therapy is critical to successful regulation of maternal diabetes. A program consisting of three meals and several snacks is employed for most patients. Dietary composition should be 40% to 60% carbohydrate, 20% protein, and 30% to 40% fat with less than 10% saturated fats, up to 10% polyunsaturated fatty acids, and the remainder derived from monosaturated sources. Caloric intake is established based on prepregnancy weight and weight gain during gestation. Weight reduction is not advised. Patients with a BMI of 22 to 27 should consume about 35 kcal/kg ideal body weight. Obese women (BMI > 30) may be managed with an intake as low as 15 kcal/kg actual weight. Any further caloric restriction resulting in ketonuria requires an increase in caloric consumption.

The presence of maternal vasculopathy should be thoroughly assessed early in pregnancy. The patient should be evaluated by an ophthalmologist familiar with diabetic retinopathy. Ophthalmologic examinations are performed during each trimester and repeated more often if retinopathy is detected. Baseline renal function is established by assaying a 24-hour urine collection for creatinine clearance and protein. An electrocardiogram and urine culture are also obtained.

Most patients with type 1 and type 2 diabetes mellitus are followed with outpatient visits at 1-to 2-week intervals. At each visit, control is assessed, and adjustments in insulin dosage are made. However, patients should be instructed to call at any time if periods of hypoglycemia (<50 mg/dL) or hyperglycemia (>200 mg/dL) occur. Ketone testing is advised for persistent glucose levels exceeding 200 mg/dL. The increased risk for hypoglycemia in pregnant individuals may be related to defective glucose counterregulatory hormone mechanisms. Both epinephrine and glucagon appear to be suppressed in pregnant diabetic women during hypoglycemia. For these reasons, patients should test glucose levels frequently, and family members should be instructed on the technique of glucagon injection for the treatment of severe reactions. Table 39-10 provides some important lessons we have learned over the years in caring for our patients.

TABLE 39-10 LESSONS LEARNED

1. Remember that the patient is more than her blood glucose.
2. Do not underestimate the patient's insight; ask for the patient's input in determining what changes to make in order to improve her glucose control.
3. Keep the insulin program simple, and make changes based on patterns.
4. Enlist the support of the patient's family.
5. Avoid hypoglycemic reactions.
6. Work closesly with the healthcare team, including the nurse educator, nutritionist, and social worker.
7. When glucose control is poor, it's often the diet.
8. Weekends are not our "friends"—especially 3-day weekends; they change the patient's daily routine, and glucose control may worsen.
9. When changing the insulin regimen, try to change just one insulin and one dose at a time.
10. Insulin analogues are valuable.
11. Respond aggressively to nausea and vomiting and fever.

Gabbe SG, Carpenter LB, Garrison EA: New strategies for glucose control in patients with type 1 and type 2 diabetes mellitus in pregnancy. Clin Obstet Gynecol 50:1014, 2007.

Ketoacidosis

With the implementation of antenatal care programs stressing strict metabolic control of blood glucose levels for women requiring insulin, diabetic ketoacidosis (DKA) has fortunately become a less common occurrence. Kilvert and colleagues reported 11 cases of ketoacidosis in 635 insulin-treated pregnancies over a 20-year period. One fetal loss and one spontaneous miscarriage complicated the pregnancies affected by DKA.

DKA can occur in the newly diagnosed diabetic patient, and the hormonal milieu of pregnancy may become the background for this phenomenon. Because pregnancy is a state of relative insulin resistance marked by enhanced lipolysis and ketogenesis, DKA may develop in a pregnant woman with glucose levels barely exceeding 200 mg/dL (11.1 mmol/L). DKA occurs in a background impaired insulin action with an increase in counterregulatory hormones such as glucagon, cortisol, and catecholamine. Thus, DKA may be diagnosed during pregnancy with minimal hyperglycemia accompanied by a fall in plasma bicarbonate (anion gap acidosis), a pH value less than 7.30, and ketonemia.

Early recognition of signs and symptoms of DKA improves both maternal and fetal outcome. As in the nonpregnant state, clinical signs of volume depletion follow the symptoms of hyperglycemia, which include polydipsia and polyuria. Malaise, headache, nausea, and vomiting are common complaints. A pregnant woman with poor fluid intake and persistent vomiting over 8 to 12 hours should be evaluated for potential DKA. A low serum bicarbonate level prompts an arterial blood gas determination to rule out this diagnosis. Occasionally, DKA may present in a woman with undiagnosed diabetes receiving β-mimetic agents such as terbutaline to arrest preterm labor.

Once the diagnosis of DKA is established and the patient is stabilized, she should be transported to a facility where tertiary care in both perinatology and neonatology is available. Therapy hinges on the meticulous correction of metabolic and fluid abnormalities. An attempt at treatment of any underlying cause for DKA, such as infection, should be instituted as well. The general management of DKA in pregnancy is outlined in Table 39-11. **Fluid resuscitation and insulin infusion should be maintained even in the face of normoglycemia until bicarbonate levels return to normal, indicating that acidemia has cleared.** DKA does represent a substantial risk for fetal compromise. However, successful fetal resuscitation often accompanies correction of maternal acidosis. Therefore, every effort should be made to correct maternal condition before intervening and delivering a preterm infant.

TABLE 39-11 MANAGEMENT OF DIABETIC KETOACIDOSIS DURING PREGNANCY

Intravenous fluids: isotonic sodium chloride; total replacement 4-6 L in first 12 hr
- Insert intravenous catheters. Maintain hourly flow sheet for fluids and electrolytes, potassium, insulin, and laboratory results.
- Administer normal saline (0.9% NaCl) at 1 to 2 L/hr for first hour.
- Infuse normal saline at 250-500 mL/hr depending on hydration state × 8 hr. If serum sodium is elevated, use half-normal saline (0.45% NaCl).
- When plasma or serum glucose reaches 200 mg/dL, change to 5% dextrose with 0.45% NaCl at 150-250 mL/hr.
- After 8 hr, use half-normal saline at 125 mL/hr.

Potassium: establish adequate renal function (urine output ~50 mL/hr).
- If serum potassium is <3.3 mEq/L, hold insulin and give 20-30 mEq K^+/hr until K^+ >3.3 mEq/L or is being corrected.
- If serum K^+ is >3.3 mEq/L but <5.3 mEq/L, give 20-30 mEq K^+ in each liter of intravenous fluid to keep serum K^+ between 4 and 5 mEq/L.
- If serum K^+ is >5.3 mEq/L, do not give K^+, but check serum K^+ every 2 hr.

Insulin: use Regular insulin intravenously.
- Consider loading dose: 0.1-0.2 U/kg intravenous bolus depending on plasma glucose.
- Begin continuous insulin infusion at 0.1 U/kg/hr.
- If plasma or serum glucose does not fall by 50-70 mg/dL in first hour, double insulin infusion every hour until a steady glucose decline is achieved.
- When plasma or serum glucose reaches 200 mg/dL, reduce insulin infusion to 0.05-0.1 U/kg/hr.
- Keep plasma or serum glucose between 100 and 150 mg/dL until resolution of diabetic ketoacidosis.

Assess need for bicarbonate:
- pH >7.0: no HCO_3
- pH = 6.9-7.0: dilute $NaHCO_3$ (50 mmol) in 200 mL H_2O with 10 mEq KCl and infuse over 1 hr. Repeat $NaHCO_3$ administration every 2 hr until pH = 7.0. Monitor serum K^+.
- pH <6.9-7.0: dilute $NaHCO_3$ (100 mmol) in 400 mL H_2O with 20 mEq KCl and infuse for 2 hr. Repeat $NaHCO_3$ administration every 2 hr until pH = 7.0. Monitor serum K^+.

ANTEPARTUM FETAL EVALUATION

Maternal diabetes may result in fetal hyperglycemia and hyperinsulinemia and thereby increase the risk for fetal hypoxia. Thus, protocols for antepartum fetal assessment in pregnancies complicated by diabetes mellitus have been incorporated into the care plan for outpatient monitoring during the third trimester. During this time period, when the risk for sudden intrauterine death increases, a program of fetal surveillance is initiated. **Because improvement in maternal control has played a major role in reducing perinatal mortality in diabetic pregnancies, antepartum fetal monitoring tests are now used primarily to reassure the obstetrician and avoid unnecessary premature intervention.** These techniques have few false-negatives results, and in a woman in whom diabetes is well controlled and who exhibits no vasculopathy or significant hypertension, reassuring antepartum testing allows the fetus to benefit from further maturation in utero.

Maternal assessment of fetal activity serves as a simple screening technique in a program of fetal surveillance. During the third trimester, women are instructed to perform daily fetal movement counting. Women with a variety of high-risk antepartum conditions, including diabetes, appear to have an increased incidence of alarming fetal activity patterns. Although the false-negative rate with maternal monitoring of fetal activity is low (~1%), the false-positive rate may be as high as 60%. Maternal hypoglycemia, although generally believed to be associated with decreased fetal movement, may actually stimulate fetal activity.

The nonstress test (NST) remains the preferred primary method to assess antepartum fetal well-being in the patient with diabetes mellitus. If the NST is nonreactive, a

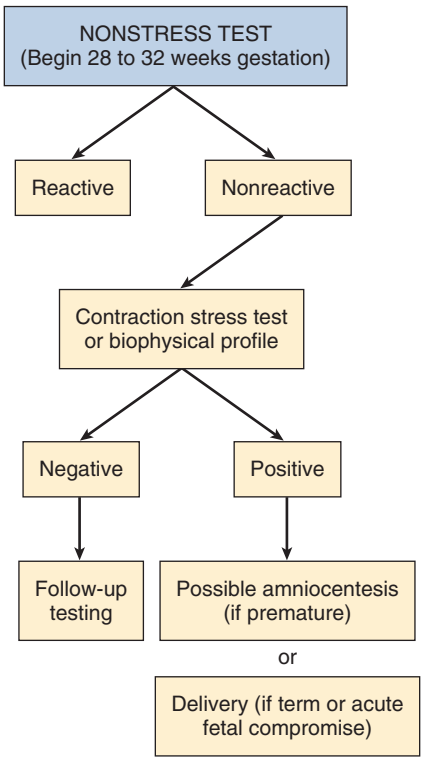

FIGURE 39-16. Scheme for antepartum fetal testing.

biophysical profile (BPP) or contraction stress test is then performed (Figure 39-16). Heart rate monitoring is begun early in the third trimester, usually by 32 weeks' gestation. Two studies have also demonstrated an increased fetal death rate within 1 week of a reactive NST in pregnancies complicated by IDDM compared with other high-risk gestations. **If the NST is to be used as the primary method of antepartum heart rate testing, we prefer that it be done at least twice weekly after the patient reaches 32 weeks' gestation. In patients with vascular disease or poor control, in whom the incidence of abnormal tests and intrauterine deaths is greater, testing is often initiated between 28 and 32 weeks' gestation.**

Doppler umbilical artery velocimetry has been proposed as a clinical tool for antepartum fetal surveillance in pregnancies at risk for placental vascular disease. We have found that Doppler studies of the umbilical artery may be predictive of fetal outcome in diabetic pregnancies complicated by vascular disease. Elevated placental resistance as evidenced by an increased systolic-to-diastolic ratio is associated with fetal growth restriction and preeclampsia in these high-risk patients In contrast, patients with well-controlled diabetes without vascular disease rarely demonstrate abnormal fetal umbilical artery waveforms.

It is important not only to include the results of antepartum fetal testing but also to weigh all of the clinical features involving mother and fetus before deciding to intervene for suspected fetal compromise, especially if this decision may result in a preterm delivery (Tables 39-12 and 39-13). Our review of nine series involving 993 diabetic women revealed that an abnormal test of fetal condition led to delivery 5% of the time.[51] It appears that outpatient testing protocols work well in diabetic patients requiring insulin.

TABLE 39-12 ANTEPARTUM FETAL SURVEILLANCE IN LOW-RISK INSULIN-DEPENDENT DIABETES MELLITUS*

Study	Indicated
Ultrasonography at 4- to 6-week intervals	Yes
Maternal assessment of fetal activity, daily at 28 weeks	Yes
Nonstress testing at 32 weeks; contraction stress test or biophysical profile if nonstress test nonreactive	Yes
Amniocentesis for lung profile	Yes, if elective delivery planned Before 39 weeks

*Excellent control, no vasculopathy (classes B, C), no stillbirth.

TABLE 39-13 ANTEPARTUM FETAL SURVEILLANCE IN HIGH-RISK INSULIN-DEPENDENT DIABETES MELLITUS*

Study	Indicated
Ultrasonography at 4- to 6-week intervals	Yes
Maternal assessment of fetal activity, daily at 28 weeks	Yes
Nonstress testing; contraction stress test or biophysical profile if nonstress test nonreactive	Initiate at 28-30 weeks
Consider amniocentesis for lung profile prior to 38 weeks	

*Poor control (macrosomia, hydramnios), vasculopathy (classes D, F, R), prior stillbirth.

Whether such testing is required for all women with diabetes mellitus remains controversial.[52] Abnormal fetal testing is more common in women whose diabetes is poorly controlled, who have hypertension, or who have significant vasculopathy that may be associated with fetal growth restriction. It follows that these subgroups probably benefit most from a program of antepartum fetal surveillance.

Ultrasound can be a valuable tool in evaluating fetal growth, estimating fetal weight, and detecting hydramnios and malformations. Maternal serum α-fetoprotein (MSAFP) determination at 16 weeks' gestation is often employed in association with a detailed ultrasound study during the midtrimester in an attempt to detect neural tube defects and other anomalies. Levels of MSAFP, unconjugated estriol (uES), and inhibin A in diabetic women are lower than in the nondiabetic population. A lower threshold for the upper limit of normal MSAFP, 1.5 multiples of the median, thus may be preferable in pregnancies complicated by diabetes mellitus in order to help detect spina bifida and other major malformations that are increased in this population. **A comprehensive ultrasound examination, including fetal echocardiography, is performed at 20 to 22 weeks' gestation for the investigation of possible cardiac anomalies.** Using such an approach, Greene and Benacerraf detected 18 of 32 malformations in a series of 432 diabetic pregnancies. The specificity was in excess of 99%, and the negative predictive value was 97%. Spina bifida was identified in all cases; however, ventricular septal defects, limb abnormalities, and facial clefts were missed. A review of the prenatal diagnosis experience in 289 women with IDDM in the Ohio State University

Diabetes in Pregnancy Program revealed 29 anomalies, of which 12 were cardiac, 14 were noncardiac, and 3 were combined. Twelve of 15 (80%) cardiac and 10 of 17 (59%) noncardiac lesions were identified prenatally. When considering cardiac defects alone, we could not identify a glycosylated hemoglobin cut-off for these anomalies. Therefore, we continue to offer cardiac imaging to women with type 1 or type 2 diabetes mellitus to assist in the detection of cardiac lesions, especially those of the great vessels and cardiac septum.

Ultrasound examinations should be performed during the third trimester to assess fetal growth. The detection of fetal macrosomia, the leading risk factor for shoulder dystocia, is important in the selection of patients who are best delivered by cesarean section. **An increased rate of cephalopelvic disproportion and shoulder dystocia, accompanied by significant risk for traumatic birth injury and asphyxia, has been consistently associated with the vaginal delivery of large infants. The risk for such complications rises exponentially when birthweight exceeds 4 kg and is greater for the fetus of a diabetic mother when compared with a fetus with similar weight whose mother does not have diabetes.**[53] Sonographic measurements of the fetal abdominal circumference have proved most helpful in predicting fetal macrosomia. The abdomen is likely to be large because of increased glycogen deposition in the fetal liver and subcutaneous fat deposition. However, a single ultrasound examination may have limited accuracy in predicting macrosomia at term in women with diabetes. Using serial sonographic examinations, accelerated abdominal growth may be identified between 28 and 32 weeks' gestation in pregnancies complicated by diabetes.[54]

TIMING AND MODE OF DELIVERY

Delivery should be delayed until fetal maturation has taken place, provided that diabetes is well controlled and antepartum surveillance remains normal. In our practice, induction of labor is often planned at 38½ to 40 weeks' gestation in patients with well-controlled diabetes without vascular disease. Women with vascular disease are delivered before term only if hypertension worsens, if significant fetal growth restriction is present, or if biophysical testing mandates early delivery. Depending on clinical circumstances, antenatal steroids may be administered to accelerate fetal lung maturity. Before undertaking delivery earlier than 39 weeks' gestation, an amniocentesis may be performed to document fetal pulmonary maturity. **Tests of fetal lung maturity appear to have the same predictive value in diabetic pregnancies as in the normal population.**

The presence of the acidic phospholipid phosphatidylglycerol (PG) is the final marker of fetal pulmonary maturation. Several authors have suggested that fetal hyperinsulinemia may be associated with delayed appearance of PG and an increased incidence of RDS. Landon and coworkers have correlated the appearance of PG in amniotic fluid with maternal glycemic control during gestation. RDS may occur in the IDM with a mature lecithin-to-sphingomyelin (L/S) ratio or fetal lung maturity index but absent PG. Moore[55] compared PG production in amniotic fluid specimens from 295 diabetic women and 590 matched controls and reported that the onset of PG production was delayed in GDM from 35.9 ± 1.1 weeks to 37.3 ± 1 weeks and to 38.7 ± 0.9 weeks in pregestational diabetic pregnancies. In this study, delayed appearance of PG was not associated with level of glycemic control. Currently, the fluorescence polarization test (TDX-FLM) is commonly employed to assess amniotic fluid for lung maturity. Cut-off values of diabetic pregnancy are similar to those in the nondiabetic population.

When antepartum testing suggests fetal compromise, delivery must be considered. If amniotic fluid analysis yields a mature test result, delivery should be accomplished promptly. In the presence of presumed lung immaturity, the decision to proceed with delivery should be based on confirmation of deteriorating fetal condition by several abnormal tests. For example, if the NST and the BPP indicate fetal compromise, delivery is indicated. Finally, there are several maternal indications for delivery, including significant preeclampsia, worsening renal function, and deteriorating vision secondary to proliferative retinopathy. If a patient reaches term gestation and is at significant risk for intrauterine demise because of poor control or a history of a prior stillbirth, options for management are individualized and include delivery or amniocentesis assessment for lung maturity before delivery.

Choosing the route of delivery for the diabetic patient remains controversial. Cesarean delivery rates as high as 50% are common in series of pregestational diabetic women. This figure is likely to represent the practice trends of most U.S. obstetricians and perinatologists. Trial of labor following previous cesarean delivery may be undertaken in select cases and has a reported success rate of 64%.

The increased rate of shoulder dystocia and brachial plexus injury in the offspring of diabetic women has prompted adoption of early induction strategies as well as selection of patients for cesarean delivery based on ultrasound estimation of fetal size. Such approaches are limited by the relative inaccuracy of ultrasound prediction of birthweight. Despite the limitations, Kjos and colleagues demonstrated that induction at 38 weeks in a population of women with GDM was associated with a lower frequency of LGA and shoulder dystocia without an increased rate of cesarean delivery.[56] This is in contrast to studies of induction in nondiabetic women, in which suspected macrosomia is apparently associated with an increased rate of cesarean delivery. In a *decision tree* analysis of cost-effectiveness, Rouse and colleagues found that whereas elective cesarean delivery for macrosomia to prevent permanent brachial plexus injury was prohibitively expensive in the nondiabetic woman at a cost of several million dollars per permanent brachial plexus injury prevented, 489 cesarean deliveries at a cost per avoided birth injury of $880,000 per case for those diabetic pregnancies with an estimated fetal size greater than 4000 g seemed to be at least tenable.[57]

The overall risk for shoulder dystocia in the macrosomic fetus of an IDM is greater than in large infants of normal pregnancy. The risk for shoulder dystocia with a fetal weight greater than 4000 g in diabetic gravidae is about 30%. Somewhat less impressive, yet significantly greater frequencies of shoulder dystocia for delivery of a macrosomic fetus of IDMs compared with non-IDMs have been reported by Nesbitt and colleagues[53] (Figure 39-17). At present, the ACOG recommends consideration of cesarean delivery in diabetic women when estimated fetal weight

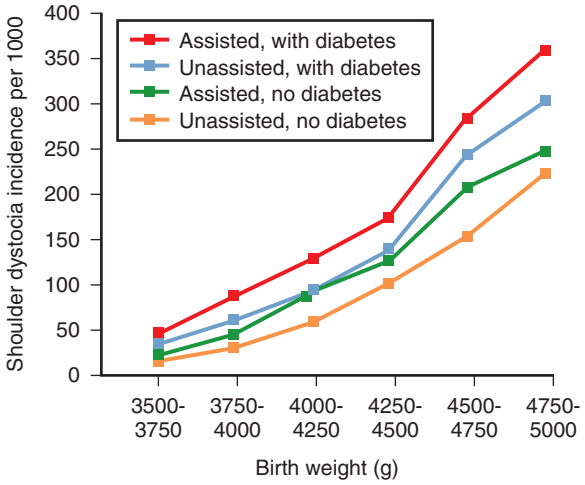

FIGURE 39-17. Frequency of shoulder dystocia for increasing birthweight by maternal diabetes status and method of vaginal delivery: spontaneous or assisted. (Modified from Nesbitt TS, Gilbert WM, Herrchen B: Shoulder dystocia and associated risk factors with macrosomic infants born in California. Am J Obstet Gynecol 17:476, 1998.)

exceeds 4500 g.[58] Our approach is to consider cesarean delivery when the estimated weight is 4000 to 4500 g, after evaluating obstetrical history and clinical pelvimetry. Despite attempts to select patients with obvious fetal macrosomia for elective cesarean delivery, arrest of dilation or descent despite adequate labor should alert the physician to the possibility of cephalopelvic disproportion. About 25% of deliveries of macrosomic infants (>4000 g) following a prolonged second stage are complicated by shoulder dystocia. It follows that cesarean delivery should be considered in a diabetic woman who demonstrates significant protracted labor or failure of descent.

GLUCOREGULATION DURING LABOR AND DELIVERY

Because neonatal hypoglycemia is in part related to maternal glucose levels during labor, it is important to maintain maternal plasma glucose levels within the physiologic normal range. The patient is given nothing by mouth after midnight of the evening before induction or elective cesarean delivery. The usual bedtime dose of insulin is administered, or for women receiving pump therapy, the infusion is continued overnight. Upon arrival to the labor and delivery department, early in the morning, the patient's capillary glucose level is assessed with a bedside reflectance meter. Continuous infusion of both insulin and glucose is then begun based on maternal glucose levels (Table 39-14). Ten units of short-acting insulin may be added to 1000 mL of solution containing 5% dextrose. An infusion rate of 100 to 125 mL/hour (1 U/hour), in most cases, will result in good glucose control. Insulin may also be infused from a syringe pump at a dose of 0.25 to 2 U/hour and adjusted to maintain normal glucose values. Glucose levels are recorded hourly, and the infusion rate is adjusted accordingly. Patients with well-controlled diabetes are often euglycemic once active labor begins and then require increased glucose infusion at a rate of 2.5 mg/kg per minute, which mimics strenuous exercise requirements. During the second stage of labor, in response to hyperglycemia associated with increased catecholamine secretion, it may be necessary to increase insulin infusion.

TABLE 39-14 INSULIN MANAGEMENT DURING LABOR AND DELIVERY

- Usual dose of intermediate-acting insulin is given at bedtime.
- Morning dose of insulin is withheld.
- Intravenous infusion of normal saline is begun.
- Once active labor begins or glucose levels fall below 70 mg/dL, the infusion is changed from saline to 5% dextrose and delivered at a rate of 2.5 mg/kg/min.
- Glucose levels are checked hourly using a portable reflectance meter allowing for adjustment in the infusion rate.
- Regular (short-acting) insulin is administered by intravenous infusion if glucose levels exceed 140 mg/dL.

From Jovanovic L, Peterson CM: Management of the pregnant, insulin-dependent diabetic woman. Diabetes Care 3:63, 1980.

When cesarean delivery is to be performed, it should be scheduled for early morning. This simplifies intrapartum glucose control and allows the neonatal team to prepare for the care of the newborn. The patient is given nothing by mouth, and her usual morning insulin dose is withheld. If her surgery is not performed early in the day, one third to one half of the patient's intermediate-acting dose of insulin may be administered. Regional anesthesia allows detection of hypoglycemia. Following surgery, glucose levels are monitored every 2 hours, and an intravenous solution of 5% dextrose is administered.

Following delivery, insulin requirements are usually significantly lower than were pregnancy or prepregnancy needs. The objective of tight control used in the antepartum period is relaxed for the first 24 to 48 hours. Patients delivered vaginally, who are able to eat a regular diet, are given one third to one half of their end of pregnancy dose of NPH insulin and short-acting or rapid-acting insulin the morning of the first postpartum day. Many women with type 2 diabetes will not require insulin for 24 to 48 hours postpartum. Frequent glucose determinations are used to guide insulin dosage. Most patients are stabilized on this regimen within a few days after delivery.

Women with diabetes are encouraged to breastfeed. The additional 500 kcal required daily are given as approximately 100 g of carbohydrate and 20 g of protein. The insulin dose may be somewhat lower in lactating diabetic women. Hypoglycemia appears to be common in the first week following delivery and immediately after nursing.

MANAGEMENT OF THE WOMAN WITH GESTATIONAL DIABETES

Is There a Benefit to the Treatment of Gestational Diabetes Mellitus?

The frequency of GDM is increasing worldwide, with 1% to 14% of pregnancies being affected.[59] The current U.S. economic burden of treatment for GDM, assuming a 4.5% incidence, translates to estimated maternal and newborn costs of $636 million annually. With both increased incidence and proposed lowering of the threshold for diagnosis, the health care cost of GDM can be expected to rise proportionately. It follows that whether a benefit exists to the treatment of GDM has assumed even greater importance now than in the past.

The 2008 guidelines of the U.S. Prevention Services Task Force concluded that there is insufficient evidence to assess the benefits and harms of screening and treatment of GDM.[60] This group, however, acknowledged that their review failed to consider intermediate outcomes such as macrosomia, cesarean delivery, and shoulder dystocia. The recent update to the Cochrane review identified eight randomized trials concerning treatment of GDM.[61] Of the 1418 women enrolled in these studies, 1000 were represented by the Australian Carbohydrate Intolerance Study in Pregnant Women (ACHOIS) study.[62] In fact, ACHOIS was the only treatment trial that included a large untreated control group because the remainder of the studies described were trials comparing various treatment modalities for GDM. The review concluded that women with GDM should only be *considered* for specific treatment in addition to routine obstetrical care.

Randomized Treatment Trials for Gestational Diabetes Mellitus

More than 40 years passed from O'Sullivan's work before the findings of the long-awaited ACHOIS study were reported.[62] The ACHOIS study was a multicenter, 10-year randomized treatment trial of 1000 women conducted at 14 sites in Australia. The study was designed to determine whether treatment of mild GDM would reduce the rate of perinatal complications.

Treatment was associated with a significant reduction in the rate of the primary outcome, a composite of serious perinatal complications (perinatal death, shoulder dystocia, birth trauma including fracture or nerve palsy) (adjusted relative risk, 0.33; 95% confidence interval, 0.14 to 0.75). Overall, 7 infants in the treatment group had a serious complication (all shoulder dystocia) compared with 23 infants in the untreated group, of whom 5 experienced perinatal death, 4 had birth trauma, and 16 had shoulder dystocia.

Among secondary neonatal outcomes, there were no significant differences in the rates of hypoglycemia requiring intravenous therapy, jaundice requiring phototherapy, respiratory disease requiring phototherapy, or respiratory disease requiring supplemental oxygen. Neonatal intensive care unit admissions were remarkably high in both groups: 71% in treated versus 61% in untreated ($P = .01$). Importantly, treatment did reduce the frequency of LGA infants from 22% to 13% and birthweight greater than 4000 g from 21% to 10%. Among maternal outcomes, preeclampsia was significantly reduced with treatment (12% vs. 18%).

The wide spectrum of views regarding the clinical significance of GDM prompted the National Institute of Child Health and Human Development (NICHD) Maternal-Fetal Medicine Unit (MFMU) Network to design a randomized controlled trial of 958 cases of mild GDM to determine whether intervention reduces perinatal mortality and obstetrical complications.[63] In this study, mild GDM was defined as a fasting glucose less than 95 mg/dL with two of the three postglucose values exceeding established thresholds.

These investigators found no significant difference in the frequency of the primary composite perinatal outcome (perinatal death, neonatal hypoglycemia, elevated cord C-peptide level, or birth trauma) in the treatment group (32.4%) compared with the usual care group (37%) ($P = .14$). Several key differences in secondary outcomes, however, were observed with treatment, including a lower frequency of LGA infants, birthweight exceeding 4000 g, and decreased neonatal fat mass.

TABLE 39-15 Results of Randomized Controlled Trials for Treatment of Gestational Diabetes Mellitus

	LANDON ET AL., 2009[63]	CROWTHER ET AL., 2005[62]
Preeclampsia	↓	↓
Weight gain	↓	↓
LGA	↓	↓
Neonatal fat mass	↓	—
Shoulder dystocia	↓	Not studied

LGA, Large for gestational age.

Among maternal outcomes, rates of labor induction were similar between groups; however, cesarean delivery was less often performed in treated women (26.9% vs. 33.8). This rate remained lower after exceeding cases of abnormal presentation, prior cesarean, placenta previa, and oligohydramnios (13% vs. 19.7%) ($P = .011$). A lower rate of shoulder dystocia (1.5% vs. 4%) and preeclampsia or gestational hypertension (8.6% vs. 13.6%) was also found in the treatment group.

In summary, the NICHD MFMU trial demonstrated that although treatment of mild GDM did not reduce the frequency of several neonatal morbidities characteristic of diabetic pregnancy, it did lower the risk for fetal overgrowth, neonatal fat mass, shoulder dystocia, cesarean delivery, and hypertensive disorders of pregnancy. These findings, along with those reported in the ACHOIS study, now confirm a benefit to treatment of even mild carbohydrate intolerance of pregnancy (Table 39-15).

Treatment of the Woman with Gestational Diabetes Mellitus

The mainstay of treatment of GDM remains nutritional counseling and dietary intervention. The optimal diet should provide caloric and nutrient needs to sustain pregnancy without resulting in significant postprandial hyperglycemia. Women with GDM generally do not need hospitalization for dietary instruction and management. Once the diagnosis is established, women are begun on a dietary program of 2000 to 2500 kcal daily. This represents approximately 35 kcal/kg of present pregnancy weight. Jovanovic-Peterson and Peterson have noted that such a diet composed of 50% to 60% carbohydrate will cause excessive weight gain and postprandial hyperglycemia, and require insulin therapy in 50% of patients. For this reason, these authors have suggested limiting carbohydrates to 33% to 40% of calories. Complex carbohydrates are preferred to simple carbohydrates because they are less likely to produce significant postprandial hyperglycemia. Once the patient with GDM is placed on an appropriate diet, surveillance of blood glucose levels is necessary to be certain that glycemic control has been established. We prefer to have patients perform daily self–blood glucose monitoring, which in two retrospective studies has been

associated with a decline in macrosomia at the expense of nearly half of all women requiring insulin therapy. A practical approach may be to provide women with GDM with a reflectance meter; however, if after a few weeks, both fasting and postprandial measurements are within the normal range, the frequency of testing can be reduced and tailored accordingly.

Whereas the ACOG has recommended that fasting plasma glucose levels be maintained below 105 mg/dL and 2-hour postprandial values below 120 mg/dL in women with GDM, thresholds of a fasting glucose less than 95 mg/dL and 1-hour postprandial glucose less than 140 mg/dL, as well as 2-hour postprandial glucose less than 120 mg/dL, have been suggested by the Fifth International Workshop Conference.[59] If a patient repetitively exceeds these thresholds, then insulin therapy is suggested. Approximately 25% of women with GDM require insulin therapy. Some cases are managed with a single dose of bedtime NPH insulin to treat isolated fasting hyperglycemia, whereas others require treatment of postprandial hyperglycemia with insulin lispro or aspart. Up to four injections daily may be necessary to achieve adequate control. The use of the previously mentioned cut-offs for initiating insulin are based on data regarding increased perinatal morbidity when such values are exceeded in women with preexisting diabetes. There continue to be no data from controlled trials to identify ideal glycemic targets for prevention of fetal risk for women with GDM.

Langer and colleagues have found that women with a fasting glucose between 96 and 105 mg/dL have a greater incidence of LGA infants (28.6%) when receiving diet therapy alone compared with those receiving both diet and insulin. In women with an initial fasting glucose between 95 and 104 mg/dL, 70% required insulin therapy to achieve optimal control.

Whereas Langer and coworkers have documented a relationship between maternal glycemia and macrosomia in GDM, which would establish guidelines for insulin therapy, some authors have suggested that estimation of glycemia alone may not be sufficient to optimally prescribe insulin therapy in these cases. Buchanan and colleagues have reviewed the utility of fetal ultrasound measurements to guide insulin therapy in women with GDM. In their study of diet-treated patients with GDM, ultrasound performed at 29 to 33 weeks was used to identify pregnancies with fetuses having a large abdominal circumference (>75th percentile). These patients were then randomized to diet versus diet and insulin treatment. The insulin-treated group ultimately had a frequency of LGA infants of 13%, which was far below the 45% present in the diet-treated group. Less intensified management has been suggested when normal fetal growth is apparent (fetal abdominal circumference <75th percentile for gestational age), although self-blood glucose monitoring is still advised.

During the past decade, oral hypoglycemic therapy has emerged as a suitable alternative to insulin treatment in women with GDM. Concerns with first-generation sulfonylurea agents included potential teratogenesis and increased neonatal hypoglycemia as a result of fetal β-cell stimulation. Nicholson and colleagues[64] performed **a systematic review of the evidence from randomized trials and observational studies and concluded that glycemia was equivalent in women receiving oral hypoglycemic agents compared with those receiving insulin**. Moreover, there was no evidence of increased adverse neonatal outcomes with oral hypoglycemic agent use. In a landmark study, Langer and colleagues reported results from a randomized trial of 404 women receiving insulin versus glyburide and noted similar improvement in glycemia with both regimens.[65] The frequency of macrosomia and neonatal hypoglycemia was similar in the two study groups. Only 4% of women failed glyburide therapy, requiring a change to insulin. Cord blood analysis revealed no detectable glyburide in exposed pregnancies. More recently, Hebert and colleagues reported that glyburide appears to cross the placenta in significant amounts. This observation has raised concerns regarding the safety of this agent. Importantly, clinical studies have failed to reveal increased rates of neonatal hypoglycemia with glyburide use in GDM. It is, however, unknown whether glyburide can affect progression to type 2 diabetes in treated women or whether glucose homeostasis is altered later in life in their offspring.

Following Langer's randomized trial, several smaller studies reported success in achieving good glycemic control with glyburide, but with slightly higher failure rates (15% to 20%). Jacobson and colleagues[66] recently reported on the implementation of glyburide as an alternative to insulin in a large managed care organization. These authors noted a similar frequency of LGA infants and macrosomia among 268 women treated with insulin compared with 236 receiving glyburide. In this nonrandomized study, more women in the glyburide group achieved lower mean fasting and postprandial glucose levels compared with insulin-treated subjects. Importantly, the authors noted an increased rate of preeclampsia, need for neonatal phototherapy, and birth injury in the "glyburide group," all of which point to the need for further study concerning safety.

Lain and colleagues performed a randomized trial of 99 women with GDM comparing glyburide versus insulin treatment.[67] These authors reported no increase in neonatal fat mass, body mass index, ponderal index, or anthropometric measures in glyburide-treated offspring, although a significantly greater rate of infant birthweights higher than 4000 g was observed in the glyburide treated group (22 vs. 2.4%). Similar to insulin therapy, glyburide action must be carefully balanced with meals and snacks to prevent maternal hyperglycemia. Observational data suggest that glyburide may be less successful in obese women or those marked hyperglycemia discovered early in gestation. The usual dose of glyburide is 2.5 to 20 mg daily in divided doses, although pharmacokinetic studies during pregnancy indicate daily dose as great as 30 mg may be necessary to achieve adequate control. In our experience, most women with fasting glucose levels of 115 mg/dL or higher will not be adequately controlled with glyburide and require insulin (Table 39-16).

Metformin has also been used for treatment of GDM.[68] Metformin clearly crosses the placenta; however, it does not appear to be teratogenic. Rowan and colleagues randomized 761 women with GDM at 20 to 33 weeks to metformin (and insulin as needed) versus insulin therapy. There were no differences in perinatal outcomes, and a composite of perinatal morbidity (neonatal hypoglycemia, respiratory distress, need for phototherapy, birth trauma, and prematurity) was observed in about one third of

TABLE 39-16 Summary of Glyburide Versus Insulin Treatment in Gestational Diabetes Mellitus

- Maternal fasting and postpartum glycemia is improved with Glyburide treatment
- Glyburide failure rate of 15%-20%
- Glyburide failures associated with earlier diagnosis of gestational diabetes, fasting >110-115 mg/dL
- Comparable neonatal outcomes
- Significant cost savings

women in each group. Metformin use was well tolerated; however, 46% of women receiving metformin required supplemental insulin to achieve glycemic control.

It appears that glyburide may be superior to metformin in achieving satisfactory control in women with GDM. A randomized trial of 149 women compared metformin to glyburide for the treatment of GDM.[69] Thirty-five percent of women randomized to metformin, compared with 16% receiving glyburide, required insulin to achieve adequate control.

Exercise may serve as a useful adjunctive treatment for women with GDM. Physical exercise may improve glycemia control because increased insulin sensitivity accompanies cardiovascular conditioning. Bung and colleagues conducted a prospective study of the utility of exercise in the treatment of GDM. These authors randomized 41 women with GDM who manifested elevated fasting glucose levels and would normally require insulin therapy. In the final analysis, 17 women completed a supervised bicycle ergometry training program compared with 17 women receiving insulin treatment. No statistical differences were observed in weekly blood glucose determinations between study groups. All fetal heart rate patterns were reactive before and after exercise. Thus, regular exercise may be an effective treatment for GDM. Brisk walking for 30 minutes at least three times each week may be recommended. Because the total number of women with GDM studied in randomized trials is limited, the role of exercise as a primary therapy in GDM remains unknown. Nonetheless, a program of moderate exercise has been advocated as part of the treatment of GDM.

Women with GDM that is well controlled are at low risk for an intrauterine death. For this reason, we do not routinely institute antepartum fetal heart rate testing in uncomplicated diet-controlled GDM patients unless the patient has a hypertensive disorder, a history of a prior stillbirth, or suspected macrosomia.[70] Women in these categories, as well as those who require insulin treatment of GDM, undergo twice-weekly heart rate testing at 32 weeks' gestation. Women with uncomplicated GDM undergo fetal heart rate testing at 40 weeks' gestation. Using such a protocol at the Ohio State University Hospital Diabetes in Pregnancy Program, only five intrauterine deaths in more than 2800 patients with uncomplicated GDM have been observed in the past 20 years. Thus, it appears that the third-trimester stillbirth rate in these patients is no higher than that of the general obstetrical population. A study of 389 women with GDM documented an antepartum stillbirth rate of 7.7 per 10,000, which was not significantly different from the rate of 4.8 per 1000 observed in nondiabetic low-risk patients. In this study, because 7% of fetuses were delivered on the basis of a low BPP score, the benefit of testing all GDM pregnancies remains in question. At present, without prospective studies comparing outcomes in monitored and nonmonitored women with GDM without other risk factors, it is not possible to determine whether any benefits exist to antepartum fetal surveillance in this population.

Because many obstetricians have extrapolated the increased risk for stillbirth in women with type 1 or type 2 diabetes to those with GDM, a remarkable number of these pregnancies are subject to scheduled delivery at term. If glycemic control is suboptimum, or maternal hypertension or a previous stillbirth exists, such an approach seems prudent. The use of amniocentesis to document fetal lung maturity in such cases should be based on clinical circumstances. As with antepartum fetal testing, in the otherwise uncomplicated group, should scheduled induction be the standard approach for these pregnancies complicated by GDM? Available observational and retrospective data do not permit an evidence-based recommendation. Lurie and coworkers have in part addressed this issue by retrospectively examining the outcomes of 124 women with GDM delivered beyond 40 weeks' gestation compared with the same number of women with GDM delivered before their expected date of confinement. Antepartum fetal surveillance was not routinely begun until 40 weeks' gestation. No significant differences in perinatal outcome, rates of cesarean delivery, or shoulder dystocia were found between study groups. A vaginal delivery rate of 75.8% was achieved in women with GDM delivering beyond 40 weeks' gestation. These authors concluded that elective induction before 40 weeks' gestation should be avoided and that every attempt should be made to allow women with GDM, both diet and insulin treated, to proceed to spontaneous labor. In contrast, a follow-up prospective study from the same institution of 96 insulin-requiring patients with GDM demonstrated that induction at 38 to 39 weeks was associated with a 1.4% shoulder dystocia rate versus 10.2% in historical controls.

Kjos and colleagues conducted a prospective randomized trial of active induction of labor at 38 weeks' gestation versus expectant management in a series that included 187 insulin-requiring women with GDM. The cesarean delivery rate was not significantly different in the expectant management group (31%) from the active induction group (25%). However, an increased prevalence of LGA infants (23% vs. 10%) was observed in the expectant management group. Moreover, the frequency of shoulder dystocia was 3% in this group, with no cases reported in those undergoing induction at 38 weeks' gestation. These data led the authors to conclude that scheduled elective induction should be considered in insulin-requiring patients with GDM because it does not increase the risk for cesarean delivery and lowers the risk for fetal death. In women managed expectantly, monitoring of fetal growth should be considered because of an apparent increasing risk for macrosomia with advancing gestational age.

POSTPARTUM FOLLOW-UP OF WOMEN WITH GESTATIONAL DIABETES MELLITUS

Women with GDM have a sevenfold increased risk for developing type 2 diabetes relative to women who do not

TABLE 39-17 DIAGNOSTIC CRITERIA FOR DIABETES MELLITUS, IMPAIRED FASTING GLUCOSE, AND IMPAIRED GLUCOSE TOLERANCE

TEST	DIABETES	IMPAIRED FASTING GLUCOSE	IMPAIRED GLUCOSE TOLERANCE
Fasting plasma glucose 75-g 2-hr oral glucose tolerance test	Fasting plasma glucose ≥126 Fasting plasma glucose ≥126 *or* 2-hr plasma glucose ≥200	Fasting plasma glucose = 100-125 Fasting plasma glucose = 100-226	Not applicable 2-hr plasma glucose = 140-199

have diabetes during pregnancy.[71] Follow-up studies for up to 28 years after O'Sullivan's original cohort of women indicated a prevalence of diabetes in 50% to 60% of women with former GDM. A recent follow-up study of up to 10 years in 11,270 women with GDM compared with 174,146 women without GDM revealed a 15.7% frequency of diabetes in former GDM compared with 1% in the non-GDM population.[72] Findings of abnormal carbohydrate intolerance may manifest early in the postpartum period depending on the population studied and its risk factors (Table 39-17). As many as one third of women with GDM will have overt diabetes, impaired fasting glucose, or IGT identified during postpartum testing conducted within 6 to 12 weeks of delivery.[73] Thus, both the American Diabetes Association and the ACOG (Figure 39-18) recommend postpartum glucose testing following a diagnosis of GDM.[74,75] Nevertheless, the prevalence of postpartum glucose screening with either a fasting plasma glucose or a 2-hour oral GTT has ranged from only 23% to 58% in seven reported studies.[73] A recent report of 11,825 women with GDM from a large health maintenance organization indicated that postpartum testing was performed in only 50% (n = 5939) of eligible women.[76] In this series, of 5857 women with test results, 16.3% (n = 956) had impaired fasting glucose or IGT, whereas 1.1% (n = 66) were found to have overt diabetes. After adjustment for demographic and clinical factors, abnormal postpartum test results were associated with having required insulin or oral agents during pregnancy and with a longer period from delivery to postpartum testing.

There is some debate about whether postpartum glucose testing can be limited to fasting glucose versus a 75-g 2-hour oral GTT. Whereas some have reported sufficiently high sensitivity using a fasting glucose alone (cut-off of 6 mmol/L or 108 mg/dL) to detect diabetes in prior GDM, more recent reports indicate the need for a complete 75-g 2-hour 75 oral GTT to achieve satisfactory sensitivity. McLean and colleagues reported 272 abnormal postpartum oral GTTs (27.6%), with 109 women identified as having frank diabetes. Eleven of these (10%) had fasting plasma glucose less than or equal to 6 mmol/L (<108 mg/dL), as did 62% of 114 cases of IGT. These authors concluded that a postpartum fasting plasma glucose is not sensitive enough in a high-risk population to classify glucose tolerance status accurately. However, only 5 of 109 women with overt diabetes did not require insulin during pregnancy, and of these, three had a postpartum fasting plasma glucose of less than or equal to 6 mmol/L. **Currently, the ACOG recommends using either a fasting plasma glucose or a 75-g 2-hour oral GTT at 6 to 12 weeks' postpartum. The optimal frequency of subsequent testing has not been established; however, the American Diabetes Association recommends repeat testing at least every 3 years for women with prior GDM and normal results of postpartum screening**.

Given the high risk for subsequent diabetes in women with former GDM, this population is ideally suited for preventive strategies to lower their risk for deteriorating carbohydrate tolerance.[77,78] There is substantial evidence that both lifestyle changes and pharmacotherapy can prevent or delay the progression of IGT to type 2 diabetes following GDM.[77,78] In the Diabetes Prevention Program, which compared lifestyle changes to metformin therapy, intensive lifestyle changes of diet and exercise resulted in

an average weight loss of 15 pounds, most of which was sustained throughout the study. Fewer individuals randomized to lifestyle intervention developed diabetes (14%) compared with the metformin group (22%) and placebo-treated subjects (29%). Unlike the findings in the entire study group, Ratner and colleagues found that metformin and lifestyle intervention were similarly effective in reducing the incidence of diabetes in women with a history of GDM. In women with a history of GDM and IGT, the incidence of subsequent diabetes was reduced by 50% and 53% in subjects receiving metformin and lifestyle intervention, respectively, compared with placebo. It follows that women with GDM found to have IGT on postpartum glucose tolerance testing should be referred for preventive therapy.

Women with GDM are at high risk for recurrence in future pregnancies. Getahun and colleagues found a 41.3% incidence in second pregnancies of 61,462 control women.[79] These authors also documented that the risk for GDM is significantly increased in the third pregnancy if the first pregnancy was with GDM compared with a first affected pregnancy followed by an unaffected pregnancy. **Because of the high recurrence risk in former GDM, we recommend early pregnancy screening or testing, followed by screening at 24to 28 weeks or testing in those not found to have GDM earlier in pregnancy.**

Long-Term Effects of Glucose Intolerance on Mother and Fetus

The metabolic syndrome encompasses a myriad of metabolic disturbances, including core metabolic problems such as obesity, insulin resistance, and hyperinsulinemia. Related metabolic dysfunctions include hyperlipidemia, hypertension, inflammation, and atherosclerotic vascular disease. The metabolic alterations in pregnancy provide a useful paradigm for the long-term risks of both mother and her fetus relative to metabolic dysfunction.

Based on the original work of O'Sullivan and colleagues, GDM is a significant risk factor for the later development of type 2 diabetes, These findings have been replicated in a number of studies. **Kim and associates, in a review of the incidence of type 2 diabetes in women with a previous history of GDM, reported the cumulative incidence of type 2 diabetes increased markedly in the first 5 years after delivery and plateau after 10 years to about 50%. Elevated fasting glucose during pregnancy was the most common risk factor.**[80]

During pregnancy women with GDM have an increased risk for hypertensive disorders such as preeclampsia. In women with a family history of type 2 diabetes and prior history of GDM, Carr and coworkers reported that these women were at a threefold higher risk for developing the metabolic syndrome. Additionally, they were at increased risk for cardiovascular dysfunction such as coronary artery disease and stroke. Hence, not only is the diagnosis of GDM in pregnancy a harbinger of maternal chronic metabolic disease, but it also offers an opportunity for the initiation of prevention in this at risk population.

The developmental origins of health and disease (DOHAD) or perinatal programming concept has recently gained wider acceptance because of the increase in childhood and adult obesity. However, the effect of a hyperglycemic environment on long-term fetal development has been recognized for decades. On the basis of the Pima Indian studies of Pettitt and associates, children of Pima women are at increased risk for both diabetes and obesity.[81] This risk persisted when the offspring of the women with diabetes were compared with their siblings born before the mother developed glucose intolerance. These studies were later confirmed and expanded on by Dabelea and colleagues, also in a Pima Indian population.[82] **In fact, the strongest risk factor for diabetes in Pima Indian children is maternal diabetes in utero, independent of maternal obesity and birthweight.**[83] In a white population, Boney reported not only that the LGA children of the women with GDM had an increased risk for diabetes and obesity but also that 50% had evidence of the metabolic syndrome. In a recent multiethnic study, Hillier and coworkers reported that increasing levels of hyperglycemia, particularly fasting hyperglycemia less than the level diagnostic for GDM, were associated with an increased risk for childhood obesity. More recently, **Clausen and associated reported that the risk for being overweight was twofold greater in the young adults of mothers with GDM or type 1 diabetes. The risk for the metabolic syndrome was also increased fourfold in comparison with a matched cohort from the same background population.** In summary, the infants of the women with GDM are also at increased risk for childhood obesity, glucose intolerance, and associated metabolic dysregulation. The potential improvement in long-term childhood outcomes from both antepartum and postpartum interventions awaits further study.

PREPREGNANCY COUNSELING OF WOMEN WITH PREEXISTING DIABETES MELLITUS

Anomalies of the cardiac, renal, and central nervous systems arise during the first 7 weeks of gestation, a time when it is most unusual for patients to seek prenatal care. Therefore, the management and counseling of women with diabetes in the reproductive age group should begin before conception. In the United Kingdom, about 50% of diabetic women receive preconception counseling, whereas estimates as low as 20% have been reported in the United States.[84] Prepregnancy counseling includes an assessment of vascular status and glycemic control. Physicians who care for young women with diabetes must be aware of the importance of such counseling. At this time, the nonpregnant patient may learn techniques for self–blood glucose monitoring as well as the need for proper dietary management. Folic acid dietary supplementation at a dose of at least 0.4 mg daily should be prescribed to reduce the frequency of neural tube defects, although it has not specifically been studied in the diabetic population. During counseling, questions may be answered regarding risk factors for complications and the plan for general management of diabetes in pregnancy. Planning for pregnancy should optimally be accomplished over several months. Glycosylated hemoglobin measurements are performed to aid in the timing of conception.

A reduced rate of major congenital malformation in patients optimally managed before conception has been

TABLE 39-18 COMPARATIVE RATES OF MAJOR MALFORMATIONS* IN OFFSPRING OF DIABETIC WOMEN RECEIVING PRECONCEPTIONAL COUNSELING

STUDY	WITH PRECONCEPTIONAL COUNSELING	WITHOUT PRECONCEPTURAL COUNSELING
Fuhrmann et al., 1983[102]	1/128 (0.8%)	22/292 (7.5%)

Tripathi et al., 2010[86]	14/240 (5.8%)	30/297 (10.1%)

*Includes adverse malformations as well as other adverse perinatal outcomes

consistently observed with special diabetes clinics (Table 39-18). Mills and associates reported that diabetic women registered before pregnancy had fewer infants with anomalies compared with late registrants (4.9% vs. 9%). Although the incidence of 4.9% remains higher than that in a normal control population (2%), normalization of glycemia was not established in the early entry group. Kitzmiller and colleagues[85] studied 84 women with pregestational diabetes mellitus who were recruited for preconception education and management during a 7-year period. A group of 110 pregnancies in women with IDDM presenting in the first trimester without preconceptional counseling served as controls in this study. One anomaly (1.2%) occurred in the preconception group compared with 12 (10.9%) malformations in the control population. Similar reductions in congenital anomalies and other adverse perinatal complications in women receiving preconceptional counseling have been reported by Tripathi and colleagues.[86]

Glycosylated hemoglobin levels obtained during the first trimester may be used to counsel diabetic women regarding the risk for an anomalous infant. Miller and colleagues[87] first observed that elevated HbA_{1c} concentrations early in pregnancy correlated with an increased incidence of malformations. In a series 58 patients with elevated glycosylated hemoglobin levels, 13 (22%) malformed infants were noted. This is in contrast to a 3.4% incidence of major malformations in 58 women whose glycosylated hemoglobin levels were in the normal range. Overall, the risk for a major fetal anomaly may be as high as 25% when the glycosylated hemoglobin level is several percent above normal values. Greene reported that 14 of 35 pregnancies with a glycosylated hemoglobin exceeding 12.8% were complicated by major malformations. In his series from the Joslin Clinic, the risk for major anomalies did not become evident until glycosylated hemoglobin values exceed 6 SD above the mean. In contrast to the investigations cited earlier is the Diabetes in Early Pregnancy study, in which malformation rates in IDMs were not correlated with first-trimester maternal glycosylated hemoglobin levels. The authors suggested that more sensitive measures are needed to identify teratogenic mechanisms or that not all malformations can be prevented by good glycemic control. Further review of these data, which included glycosylated hemoglobin levels only in the early-entry patients, demonstrates that these women were a relatively homogeneous group with respect to glycemic control; 93% had glycosylated hemoglobin levels less than 7 SD below the mean, a level of control that barely increases the risk for anomalies according to Greene's data. Regardless of the glycosylated hemoglobin value obtained, all diabetic women require a careful program of surveillance, as outlined earlier, to detect fetal malformations. The risk for spontaneous abortion also appears to be increased with marked elevations in glycosylated hemoglobin. However, for diabetic women in good control, there appears to be no greater likelihood of miscarriage. In summary, women with type 1 or type 2 diabetes mellitus should be advised to achieve an HbA_{1c} level close to the upper limit of the normal range before conceiving, to reduce the risk for a major fetal malformation or miscarriage.

CONTRACEPTION

There is no evidence that diabetes mellitus impairs fertility. Thus, family planning is an important consideration for the diabetic woman. A careful history and complete gynecologic examination and counseling are required before selecting a method of contraception. Barrier methods of birth control continue to be safe and inexpensive. The diaphragm, used correctly with a spermicide, has a failure rate of less than 10%. **Because there are no inherent risks to the diaphragm and other barrier methods, these have become the preferred interim method of contraception for women with diabetes mellitus.** The intrauterine device may also be used by diabetic women without concerns about an increased risk for infection.

Combined oral contraceptives (OCs) are the most effective reversible method of contraception with failure rates generally less than 1%. There is, however, continued controversy regarding their use in the diabetic woman. **The serious side effects of pill use, including thromboembolic disease and myocardial infarction, may be increased in diabetic women using combined oral contraceptive OCs.**[93] In a retrospective study, Steel and Duncan observed five cardiovascular complications in 136 diabetic women using primary low-dose pills. Three patients had cerebrovascular accidents; one had a myocardial infarction; and one had an axillary vein thrombosis. In a retrospective case-control study, despite diabetes increasing the risk for cerebral thromboembolism fivefold compared with controls, this risk was not enhanced by use of combined oral contraceptives.

In Steel and Duncan's report, several women exhibited rapid progression of retinopathy. Klein and colleagues[88] studied OC use in a cross-sectional study of 384 insulin-dependent women and reported no association between OCs and progression of vascular complications. For physicians who prescribe low-dose OCs to diabetic women, their use should probably be restricted to patients without serious vascular complications or additional risk factors such as a strong family history of myocardial disease or smoking. In these women, a monophasic preparation

(progestin only) may be considered. In women taking OCs, the lowest dose of estrogen and progesterone should be employed. Patients should have blood pressure monitoring after the first cycle and quarterly with baseline and follow-up lipid levels as well.

Women using OCs may demonstrate increased resistance to insulin as a result of a diminished concentration of insulin receptors. Despite the fact that carbohydrate metabolism may be affected by the progestin component of the pill; disturbances in diabetic control are actually uncommon with its use. In Steel and Duncan's study, 81% of patients using the pill did not require a change in insulin dose. Triphasic OCs may also be used safely in women with a history of GDM without other risk factors. Skouby and coworkers have demonstrated that normal glucose tolerance and lipid levels can be expected in nonobese women with a history of GDM followed after 6 months of therapy. Kjos and colleagues[89] performed a prospective randomized study of 230 women with recent GDM. OC users were randomized to low-dose norethindrone or levonorgestrel preparations in combination with ethinyl estradiol. The rate of subsequent diabetes in OC users was 15% to 20%, after 1 year of follow-up. This rate was not significantly different from that in non-OC users (17%). Importantly, no adverse effects on total cholesterol, LDL, HDL, or triglycerides were found with OC use.

At present, there is little information available concerning long-acting progestins in women with diabetes or previous GDM. A statistically significant yet clinically limited deterioration in carbohydrate tolerance has been reported in healthy depomedroxyprogesterone acetate (Depo-Provera; DMPA) users. As observed with other progestins, DMPA may lower serum triglyceride and HDL cholesterol levels but not total cholesterol or LDL cholesterol. For this reason, DMPA is not recommended as a first-line method of contraception for women with diabetes. The progestin-only OC would be preferred because it does not produce significant metabolic effects in diabetic women.

KEY POINTS

- Pregnancy has been characterized as a diabetogenic state because of increased postprandial glucose levels in late gestation.
- Both hepatic and peripheral (tissue) insulin sensitivity are reduced in normal pregnancy. As a result, a progressive increase in insulin secretion follows a glucose challenge.
- In women with GDM, the hormonal milieu of pregnancy may represent an unmasking of a susceptibility to the development of type 2 diabetes mellitus.
- According to the Pedersen hypothesis, maternal hyperglycemia results in fetal hyperglycemia and hyperinsulinemia, resulting in excessive fetal growth. Tight maternal glycemic control is associated with a reduced risk for fetal macrosomia.
- Congenital malformations occur with a twofold to sixfold increased rate in offspring of women with pregestational diabetes compared with the normal population. Impaired glycemic control and associated derangement in maternal metabolism appear to contribute to abnormal embryogenesis.
- Women with class F (nephropathy) diabetes have an increased risk for preeclampsia and preterm delivery that correlates with their degree of renal impairment.
- Diabetes retinopathy may worsen during pregnancy, yet for women optimally treated with laser photocoagulation *before* pregnancy, significant deterioration of vision is uncommon.
- Screening for GDM is generally performed between 24 and 28 weeks' gestation. Screening strategies include universal screening or limiting screening to women older than 25 years with risk factors for developing adult-onset diabetes mellitus.
- Treatment of women with type 1 and type 2 diabetes mellitus during pregnancy requires intensive therapy consisting of frequent self–blood glucose monitoring and aggressive insulin dosing by multiple injections or CSII (insulin pump).
- The cornerstone of treatment for GDM is dietary therapy. Insulin and glyburide are reserved for individuals who manifest significant fasting hyperglycemia or postprandial glucose elevations despite dietary intervention.
- Antepartum fetal assessment for women with both pregestational diabetes or GDM is based on the degree of risk believed to be present in each case. Glycemic control, prior obstetrical history, and the presence of vascular disease or hypertension are important considerations.
- Delivery should be delayed until fetal maturation has occurred, provided that diabetes is well controlled and fetal surveillance remains normal. The mode of delivery for the suspected large fetus remains controversial. In cases of suspected macrosomia, a low threshold for cesarean delivery has been recommended to prevent a traumatic birth.
- Women with type 1 and type 2 diabetes mellitus should seek prepregnancy consultation. Efforts to improve glycemic control before conception have been associated with a significant reduction in the rate of congenital malformations in the offspring of such women.

Thyroid diseases, along with diabetes mellitus, are the most frequent endocrine pathology seen in pregnancy; parathyroid diseases, on the other hand, are rare but may present a diagnostic and therapeutic challenge to the obstetrician. The obstetrician should be aware of the symptoms and signs of the particular disease, the effect of pregnancy on the interpretation of endocrine tests, and the transfer of hormones and medications across the placenta with potential complications for the fetus and neonate. In this chapter, we present a brief description of the disease, its etiology, the interpretation of functional endocrine tests, appropriate therapy, and the potential effects of both the disease and drug therapy on the concepts. It is imperative that a team approach be used in the management of these conditions; the close cooperation of the obstetrician, endocrinologist, and anesthesiologist will offer the patient the best maternal and perinatal outcomes.

PARATHYROID DISEASES

Parathyroid diseases, uncommon in pregnancy, may produce significant perinatal and maternal morbidity and mortality if not diagnosed and properly managed. After a

brief review of calcium homeostasis during pregnancy, primary hyperparathyroidism, hypoparathyroidism, osteoporosis, and vitamin D deficiency are discussed. Several reviews on these topics have been published.

Calcium Homeostasis During Pregnancy

Parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D, ($1,25[OH]_2D_3$) are responsible for maintaining calcium homeostasis. **About 50% of serum calcium is protein bound (mostly to albumin), 10% is complexed to anions, and 40% circulates free as ionized calcium. During pregnancy, there is an active transfer of maternal calcium to the fetus.** A full-term infant requires 25 to 30 g of calcium during the course of pregnancy for new bone mineralization, most in the third trimester.

Total serum calcium during gestation is 8% below postpartum levels.[1] The upper limit of normal is 9.5 mg/dL. This decrease in total serum calcium is due to the physiologic hypoalbuminemia secondary to the normal expansion of the intravascular volume observed early in pregnancy. **Ionized calcium levels, however, remain unchanged throughout gestation.** Serum phosphate and renal tubular reabsorption of phosphorus also remain normal throughout pregnancy. Maternal serum PTH levels, when determined by a sensitive assay that accurately measures the levels of intact PTH, are slightly decreased in the first half of pregnancy (about 20% of the mean nonpregnant values) and return to normal by midgestation.[2]

Blood levels of $1,25(OH)_2D_3$ (calcitriol) increase early in gestation to twice the nonpregnancy level in the third trimester. This increase is as a result of stimulation of maternal renal 1α-hydroxylase activity by estrogen, placental lactogen, and PTH, as well as synthesis of calcitriol by the placenta. Both free and total $1,25(OH)_2D_3$ are increased in pregnancy, the total because of an increase in vitamin D–binding protein.[3]

Twenty-four-hour urinary calcium excretion also increases with each trimester of gestation and decreases in the postpartum period,[2] reflecting the increased intestinal calcium absorption induced by higher levels of 1,25-hydroxyvitamin D during gestation. Pregnancy-induced hypertension is characterized by decreased urinary calcium excretion, probably explained by a decrease in serum 1,25-vitamin D serum levels.

Parathyroid hormone-related protein (PTHrP), a peptide responsible for the hypercalcemia found in many malignant tumors, increases in early pregnancy. Hirota and colleagues[4] measured PTHrP in each trimester of human pregnancy, in umbilical venous blood and postpartum. A steady increase in plasma values was observed throughout pregnancy, with a peak in the third trimester and high values in cord blood. The plasma concentration in the postpartum period was directly related to the degree of breastfeeding. The source of maternal serum PTHrP is multiple, and both fetal and maternal sites have been postulated (placenta, myometrium, amnion, decidua, fetal parathyroid glands, breast, umbilical cord). PTHrP increases 1α-hydroxylase activity with an increase in $1,25(OH_2)D$; PTHrP plays a role in placental calcium transport and also may have a role in protecting the maternal skeleton during pregnancy because the carboxyl-terminal portion of PTHrP ("osteocalcin") has been shown to inhibit osteoclastic bone resorption.[1] PTHrP may be involved in the transfer of maternal calcium into breast milk.

Serum calcitonin levels are higher during pregnancy and in the postpartum period, compared with nonpregnant controls. In 20% of patients, the values exceed the normal nonpregnant range. The origin of calcitonin is thyroidal C cells, breast, and placenta. Its role in pregnancy has not been elucidated, although it may protect the maternal skeleton from excessive resorption of calcium.

Osteocalcin is a bone-specific protein released by osteoblasts into the circulation proportional to the rate of new bone formation. It is slightly decreased during the second trimester of pregnancy, with an increase in the postpartum period.[2] **Markers of bone resorption increase during pregnancy, reaching values in the last trimester of pregnancy up to twice normal.** These changes are consistent with the increase in bone turnover at the time of maximal transfer of maternal calcium to the fetus.

After delivery, urinary calcium excretion is reduced; ionized serum calcium remains within normal limits; and total calcium, 1,25-hydroxyvitamin D, and serum PTH return to prepregnancy levels. Intestinal absorption of calcium decreases to the nonpregnant rate as a result of the previously mentioned return to normal levels of $1,25(OH)_2D_3$.[1] Early concern of calcium loss in lactating mothers, with the development of osteopenia, has not been confirmed, **and extra calcium supplementation during breastfeeding appears to be unnecessary** because calcium supplementation above normal does not reduce significantly the amount of loss bone during gestation.[5] The alteration in calcium and bone metabolism that accompanies human lactation represents a physiologic response that is independent of calcium intake.

Hyperparathyroidism

Primary hyperparathyroidism (PHP) is an uncommon disease in women of childbearing age. The prevalence of PHP in women of childbearing age is about 5 per 10,000. The incidence of the disease in pregnancy is unknown, but it is definitely rare, and most of the reported cases have been single ones complemented with a review of the literature. More than 150 cases have been reported in the English literature up to 1999. With the introduction of routine automated techniques in clinical medicine and early diagnosis, most patients with PHP are symptom free, and their serum calcium elevation is mild.

The first case of PHP during pregnancy was reported in 1931. Shortly thereafter, the first case of neonatal hypocalcemia causing tetany in a mother with undiagnosed hypercalcemia due to hyperparathyroidism was described by Friderichsen. **The most common cause of PHP in pregnancy is a single parathyroid adenoma, present in about 80% of all cases.** Primary hyperplasia of the four parathyroid glands accounts for about 15% of the cases reported, 3% are due to multiple adenomas, and only a few cases due to parathyroid carcinoma have been reported in the English literature. In 1962, Ludwig reviewed the literature on the subject, describing 21 women with 40 pregnancies. The incidence of fetal wastage was 27.5%. Neonatal tetany due to hypocalcemia representing the first indication of maternal hyperparathyroidism occurred in 19% of these cases. In 1972, Johnstone and coworkers confirmed a

perinatal mortality rate of 25% with a high incidence of neonatal hypocalcemia. Most of the patients reported in early years had significant metabolic complications of hyperparathyroidism, the two most common being renal and bone disease. In contrast to the previous high neonatal morbidity and mortality, Kelly,[6] reviewing the literature from 1976 to 1990, found only 2 perinatal deaths (5%) among 37 infants born of hyperparathyroid mothers. Two additional cases of perinatal deaths were reported in mothers with hypercalcemic crisis.

Currently, in the nonpregnant state, almost 70% of patients are symptom free, and the diagnosis is made through the routine use of biochemical screening. In pregnancy, because routine calcium determinations are not performed, manifestations of the disease are present in almost 70% of the diagnosed patients. In a review of 70 pregnant women, gastrointestinal symptoms such as nausea, vomiting, and anorexia were present in 36% of patients, whereas 34% presented with weakness and fatigue. In 26%, mental symptoms including headaches, lethargy, agitation, emotional lability, confusion, and inappropriate behavior were reported. Nephrolithiasis was detected in 36%, bone disease in 19%, acute pancreatitis in 13%, and hypertension in 10%. Only 24% of these patients were symptom free.

Parathyroid cancer is a rare cause of hyperparathyroidism, with very few cases documented in pregnancy. Serum calcium levels are significantly higher than in other causes of PHP. Perinatal mortality and morbidity are significant. Hypercalcemia with values above 13 mg/dL in the presence of a palpable neck mass should raise a strong suspicion of parathyroid carcinoma. On the contrary, in the presence of mild hypercalcemia and a neck mass, the most common cause of the neck lesion is a thyroid nodule. One other clinical feature of parathyroid carcinoma is poor response to the usual clinical therapeutic measures such as intensive hydration and loop diuretics. Surgery is the only effective therapy.

Hyperparathyroidism should be considered in the differential diagnosis of acute pancreatitis during pregnancy. Acute pancreatitis has been reported in 13% of women with primary hyperparathyroidism. The incidence in nonpregnant hyperparathyroid women is about 1.5% and is less than 1% in normal pregnancy. This complication is associated with significant neonatal and maternal morbidity.[7] It is more common in the primipara than in women who have had multiple pregnancies. Acute pancreatitis with PHP is mostly likely to occur during the last trimester of pregnancy or the postpartum period but has also been reported in the first trimester of pregnancy, mimicking hyperemesis gravidarum. Indeed, in two cases, hyperthyroidism was also present, which most likely represents the syndrome of transient hyperthyroidism of hyperemesis gravidarum (see Thyroid Diseases, later). **Serum calcium should be obtained in any pregnant woman with persistent significant nausea, vomiting, and abdominal pain.**

Hyperparathyroid crisis, a serious complication of PHP, has been reported during gestation and the postpartum period and is characterized by severe nausea and vomiting, generalized weakness, changes in mental status, and severe dehydration. Hypertension may be present and should be differentiated from preeclampsia. The serum calcium level is frequently higher than 14 mg/dL; hypokalemia and elevation in serum creatinine are routinely seen. If not recognized and treated promptly, hyperparathyroid crisis may progress to uremia, coma, and death. Of the 12 cases reported in the literature, 4 occurred in the postpartum period. Patients presented with severe nausea, vomiting, and elevation in serum creatinine due to dehydration. Serum calcium levels higher than 20 mg/dL were reported in 3 cases, and 3 patients died. Six cases have been associated with pancreatitis. Four fetal deaths have also been reported.

Bone disease in patients with PHP is now unusual. However, in early series, it was a common complication. Radiologic evaluation of the bones showed diffuse demineralization, subperiosteal resorption of the phalanges, and in severe cases, single or multiple cystic lesions and generalized osteoporosis. A 27-year-old woman was described with generalized musculoskeletal pain and radiographic evidence of advanced bone disease at 34 weeks' gestation.

Shani and associates reported[8] five cases of excessive amniotic fluid in mothers with PHP and serum calcium levels between 11.3 and 14 mg/dL. The mean amniotic fluid level (AFI) was 32 cm and mean gestational age nearly 30 weeks; other causes of polyhydramnios were ruled out. The authors suggested that the fetal polyuria was, similar to adult polyuria, a common symptom in patients with hyperparathyroidism.

The two most common causes of neonatal morbidity are prematurity and neonatal hypocalcemia, the latter related to levels of maternal hypercalcemia. In early reports, it was frequently the only clue of maternal hyperparathyroidism. It develops between the 2nd and 14th day of life and lasts for a few days.

Preeclampsia has been reported in some cases of PHP. Hultin and coworkers[9] recently reviewed the records of 52 women with the diagnosis of parathyroid adenoma, confirmed by surgery, and compared them with 519 women without the disease, all of whom had a subsequent singleton pregnancy between 1973 and 1997. They concluded that PHP due to a single adenoma, diagnosed before delivery, is significantly (P <.0001) associated with preeclampsia, with an adjusted odds ratio (OR) of 6.89 (95% confidence interval [CI], 2.30 to 20.58). Therefore, PHP should be considered a risk factor for preeclampsia.

The diagnosis of PHP is based on persistent hypercalcemia in the presence of increased serum PTH levels.[10] A persistent serum calcium value higher than 9.5 mg/dL is suspicious of hypercalcemia. Serum phosphorus is decreased in about 50% of pregnant women with PHP. A determination of 24-hour urinary calcium excretion is helpful in the diagnosis because most women with PHP have an increase in urinary calcium excretion, above the usual hypercalciuria of normal pregnancy. Urinary calcium excretion is low or low normal in the syndrome of familial hypocalciuric hypercalcemia (FHH), another cause of hypercalcemia that needs to be included in the differential diagnosis. The serum alkaline phosphatase level may be increased in PHP. However, it is also increased in normal pregnancy. High-resolution ultrasonography of the neck in expert hands is able to detect parathyroid lesions in a significant percentage of affected patients. Parathyroid imaging studies are contraindicated in pregnancy.

TABLE 40-1 CAUSE OF HYPERCALCEMIA IN PREGNANCY AND THE PUERPERIUM

Differential Diagnosis of Hypercalcemia

Although most young women with hypercalcemia have PHP, other unusual causes should be ruled out, mainly endocrine disorders, vitamin D or A overdose, the use of thiazide diuretics, or granulomatous diseases (Table 40-1). A brief discussion of three uncommon syndromes associated with hypercalcemia during pregnancy follows.

1. FHH is an autosomal dominant condition with a high penetrance for hypercalcemia. The disorder is associated with an inactivating mutation in the gene for the calcium-sensing receptor. The main function of the receptor is in the regulation of calcium balance through changes in the parathyroid and kidneys. Mild hypercalcemia, slight elevation in serum PTH, mild hypermagnesemia, and low urinary calcium excretion are the typical findings. There is moderate hyperplasia of the four parathyroid glands. Total parathyroidectomy is seldom indicated because of the benign course of the disease. Infants born to mothers with FHH may present with different clinical manifestations. First, asymptomatic hypercalcemia can develop in an affected offspring if the mother is a carrier for FHH. In a second situation, severe neonatal hypocalcemia can occur in a mother with FHH syndrome. Although neonatal hypocalcemia could be severe, neonatal parathyroid function returns to normal a few weeks after delivery. In the third situation, severe neonatal hypercalcemia, also called neonatal severe hyperparathyroidism, occurs in infants homozygous for the FHH gene defect. Some infants require parathyroidectomy soon after birth.
2. Postpartum hypercalcemia may occur in women with treated hypoparathyroidism. The mechanism for hypercalcemia is not well understood. Nausea and vomiting develop a few days after delivery, dehydration ensues, and other manifestations of hypercalcemia develop, mainly mental changes. Serum calcium may be significantly elevated. Patients with treated hypoparathyroidism should be followed postpartum with serum calcium determinations, and vitamin D should be discontinued if hypercalcemia occurs. In severe cases, intravenous fluids and glucocorticoid therapy are required (Figure 40-1).
3. A few cases of hypercalcemia, mediated by PTHrP, during pregnancy and in the postpartum period have been reported. In one case, hypercalcemia developed in two successive pregnancies. In the second pregnancy, serum PTHrP levels were elevated to three times normal, and the infant was born with mild hypercalcemia that returned to normal within 24 hours after delivery. In a second case, a 25-year-old woman had massive bilateral breast enlargement at 24 weeks' gestation. Her serum calcium level was 14.3 mg/dL, but her serum PTH level was undetectable. She underwent bilateral mastectomy during pregnancy. The immunohistochemical studies demonstrated PTHrP antigenic activity in breast tissue. A case of hypercalcemic crisis in the first postpartum day, with serum calcium up to 19.4 mg/dL, has been reported; hypercalcemia was due to excessive amounts of serum PTHrP (28.4 pmol/L, normal <1.1 pmol/L), whereas serum PTH levels were very low. There was no evidence of other causes of low PTH hypercalcemia, and it was assumed that the

placenta was the source of the high PTHrP levels. The patient had no evidence of disease 4 years after delivery.

Therapy

Surgery is the only effective treatment for PHP. A novel oral agent that acts directly on the calcium sensor, cinacalcet, has been used in isolated cases without benefit by itself, but it reduces serum calcium in combination with calcitonin.[11] Surgery is a safe procedure when performed by a surgeon with extensive experience in neck surgery.[12] Complications due to surgery, particularly in the presence of a single lesion, are low, and the cure rate is excellent.

Although guidelines for the management of PHP in nonpregnant individuals have been suggested, the proper medical management of PHP in pregnancy has not been uniformly agreed on. For asymptomatic pregnant women in whom serum calcium is not greater than 1 mg above normal range, close follow-up with proper hydration and avoidance of medications that could elevate calcium, such as thiazide diuretics, is reasonable, although there are no studies in the literature supporting this or any other approach. Because most of the neonatal complications have been reported in patients with symptomatic disease, a surgical approach is indicated in such patients, as well as in those with complications such as nephrolithiasis and bone disease and those with persistent hypercalcemia (above 1 mg of the normal range). It is preferable to perform the surgery in the second trimester of pregnancy. In the series reported by Carella and Gossain, 38 women underwent parathyroidectomy during pregnancy, 7 during the first trimester and 18 in the second trimester. In the total group of 25, there was only 1 fetal loss. In 12 women in whom surgery was performed during the third trimester of pregnancy, the incidence of perinatal complications was 58%. For women with PHP first diagnosed after 28 weeks' gestation, the optimal treatment strategy is unclear, and the decision in such a situation should be based on the general condition of the patient, severity of hypercalcemia, and other complicating circumstances. A significantly lower incidence of complications, both maternal and fetal, was reported in a review of 16 published cases of patients operated on after 27 weeks' gestation.

Medical therapy is reserved for patients with significant hypercalcemia who are not surgical candidates. Oral phosphate therapy of 1.5 to 2.5 g/day has been shown to be effective in controlling hypercalcemia. Side effects of oral phosphate therapy include nausea, vomiting, and hypokalemia. These problems can be easily avoided by decreasing the dose of the medication. In patients in whom surgery is not advisable, it is important to prevent elevations in serum calcium. Good hydration, early treatment of urinary tract infections, and avoidance of medications known to cause elevations in serum calcium such as vitamin D, vitamin A, aminophylline, and thiazide diuretics are all important therapeutic measures. Serum calcium should be determined on a regular basis. Calcitonin in combination with oral phosphates or cinacalcet[11] was effective in controlling hypercalcemia in isolated cases.

In patients undergoing surgical treatment, hypocalcemia, albeit transient, may occur after surgery in some cases. Serum calcium should be checked every 6 hours, and if the patient develops hypocalcemic symptoms, intravenous calcium in the form of calcium gluconate, intravenous calcium (1-2 g of calcium-gluconate, equivalent to 90-180 mg elemental calcium, in 50 mL of 5% dextrose) can be infused over 10 to 20 minutes. Intermittent infusions may be repeated, or calcium gluconate can be diluted in 5% dextrose or isotonic saline and infused continuously at 1 mg/kg body weight per hour. In patients with bone disease, postsurgical hypocalcemia may be profound, and aggressive treatment is needed. These patients may benefit from vitamin D supplementation in the form of calcitriol, 0.25 to 0.5 mcg/day, for a few days before operative intervention.

Hypoparathyroidism

The most common etiology of hypoparathyroidism is damage to or removal of the parathyroid glands in the course of surgery for thyroid gland pathology. The incidence of permanent hypoparathyroidism after thyroid surgery has been estimated between 0.2% and 3.5%. In many cases, hypocalcemia in the immediate postoperative period is only transitory. Idiopathic hypoparathyroidism is a much less common cause of the disease, frequently associated with other autoimmune endocrinopathies, as part of the polyglandular autoimmune syndrome type 1. Antibodies directed against parathyroid calcium-sensing receptor have been detected in 56% of patients with idiopathic hypoparathyroidism.

The requirement for calcium supplementation and vitamin D may decrease in some women with hypoparathyroidism during the second half of pregnancy and lactation. In a few cases, hypocalcemic symptoms ameliorate with progression of pregnancy. The explanation for these findings is not clear but may be related to the increased intestinal absorption of calcium or the production of vitamin D by the placenta.

Clinical clues for the diagnosis of hypoparathyroidism include a previous history of thyroid surgery and clinical, radiologic, and laboratory information. **Typical symptoms of hypocalcemia are numbness and tingling of the fingers and toes and around the lips.** Patients may complain of carpopedal spasm, laryngeal stridor, and dyspnea. Convulsions may be a manifestation of severe hypocalcemia. Symptoms of irritability, emotional lability, impairment of memory, and depression are common. On physical examination, patients with idiopathic hypoparathyroidism demonstrate changes in the teeth, skin, nails, and hair as well as papilledema and cataracts. Chvostek sign, a twitch of the facial muscles, notably those of the upper lip, when a sharp tap is given over the facial nerve, is seen in many patients with hypocalcemia. Chvostek sign has also been described in 10% of normal adults. Trousseau sign is another sign of hypocalcemia. It is the induction of carpopedal spasm by reducing the circulation in the arm with a blood pressure cuff. The constriction should be maintained above the systolic blood pressure for 2 minutes before the test is considered negative.

The diagnosis of hypoparathyroidism is confirmed by the presence of persistent low serum calcium and high serum phosphate levels. Plasma alkaline phosphatase is usually normal. The differential diagnosis of hypocalcemia includes rickets, osteomalacia, and hypomagnesemia.

Marked hypocalcemia may occur in severely ill patients. The etiology is unclear, and a return to normal serum calcium is the rule following the recovery from the acute event.

In 1942, Anderson and Musselman published a review of the literature on hypoparathyroidism and tetany in pregnancy, collecting 240 cases. Twenty-six of the cases were due to post-thyroid surgery, and 140 were the so-called idiopathic type. It is likely that in some of these cases tetany was not due to hypoparathyroidism. Therapeutic abortion was recommended because of the high fetal and maternal mortality rates. Other reports have confirmed that hypoparathyroidism, if not properly treated, may increase perinatal loss, including spontaneous abortions, stillbirths, and neonatal deaths. **Radiologic bone changes may be present in the newborn as a consequence of intrauterine hyperparathyroidism.** They are characterized by generalized skeletal demineralization, subperiosteal bone resorption, bowing of the long bones, osteitis fibrosa cystica, and rib and limb deformities. Loughead and colleagues[13] described 16 infants of hypoparathyroid mothers. Secondary hyperparathyroidism in the infants resolved by 1 month of age.

Treatment of hypoparathyroidism in pregnancy does not differ from the nonpregnant state, including a normal high-calcium diet and vitamin D supplementation. The normal calcium supplementation of pregnancy is about 1.2 g/day. Vitamin D requirements may decrease in some patients by the second half of gestation. Calcitriol, 1 to 3 mcg/day, is used almost routinely in most patients affected with hypoparathyroidism. Calcitriol must be given in single or divided doses because its half-life is much shorter than that of vitamin D. If vitamin D is used, the dose is in the range of 50,000 to 150,000 IU/week. The importance of compliance with medications should be strongly emphasized, particularly when calcitriol is prescribed, in view of its short half-life. The major problem in the treatment of hypoparathyroidism is the recurrence of hypercalcemia and hypocalcemia. Therefore, serum calcium determinations should be performed at regular intervals. The most common symptoms of vitamin D intoxication are nausea, constipation, fatigue, headaches, and in more severe cases, vomiting and dehydration. It is important to assess serum calcium and phosphorus during pregnancy, particularly in the postpartum period, to detect the early onset of hypercalcemia (see Figure 40-1).

Lactation in mothers taking vitamin D may be contraindicated because a metabolite of vitamin D, 25-hydroxyvitamin D, has been detected in breast milk in high concentration in a mother taking 50,000 IU of vitamin D daily. Regardless of the form of vitamin D prescribed, serum calcium determinations should be done in the postpartum period, particularly in breastfeeding mothers.

Pseudohypoparathyroidism

Pseudohypoparathyroidism encompasses several different disorders, having as a common feature varying degrees of target organ resistance to PTH. Somatic changes are present in some forms of the syndrome, including short stature, obesity, round face, brachydactyly, and mental retardation, with brain calcifications. This variant is known as Albright's syndrome type 1a. Most patients suffer from hypocalcemia due to a derangement of renal 1α-hydroxylase and production of calcitriol. A few cases have been reported during pregnancy. Spontaneous normocalcemia occurred in two patients during four pregnancies. The authors provided evidence of placental synthesis of calcitriol to account for the normocalcemia. In both patients, serum PTH, which was significantly increased before pregnancy, was reduced by 50% during gestation. Serum cord calcium, phosphorus, and calcitriol concentrations were within normal limits. These infants are at risk for intrauterine fetal hyperparathyroidism, perhaps because of the relative maternal hypocalcemia during pregnancy.

Vitamin D Deficiency

Classically, vitamin D deficiency was related to the development of rickets, with its subsequent impact on obstetrical care. Deformities of weight-bearing bones, including the pelvis, prevented vaginal delivery in mothers affected by the disease.[14] In recent years, significant work has been published on the deleterious effect of vitamin D deficiency in a variety of medical problems from autoimmune disease to cancer. Several obstetrical, fetal, and neonatal complications have been reported in the last few years and have been recently reviewed.[14] The normal values for serum vitamin D 25OH (25[OH]D), the active metabolite of vitamin D, are controversial, with values varying between 20 and 40 ng/mL, equivalent to 50 to 100 nmol/L. There are barriers to the measurement of 25(OH)D in clinical practice. There are no single accepted measurements, and as a consequence, there is significant variability within and among laboratories and assays. As suggested by Barrett and McEleduff,[14] the clinician should ensure that the laboratory participates in an appropriate, validated quality control process and that the assay has been standardized against a reference method.

Vitamin D deficiency in the mother has been associated with decreased fetal growth. In 1996, Brunvand and colleagues followed 30 Pakistani women during pregnancy: 13 with elevated serum PTH levels at the time of delivery and 29 with serum levels of 25-hydroxyvitamin D below normal. There was a positive correlation between serum maternal ionized calcium levels and the crown-heel length of the newborn. The authors suggested that vitamin D deficiency could interfere with fetal growth through an effect on maternal calcium homeostasis.

Many studies in the past few years had linked low maternal 25(OH)D levels with maternal, fetal, and neonatal complications. Confirming the study done in Pakistan, in a report from Amsterdam, mothers with singleton pregnancies and serum 25(OH)D levels below 29.9 nmol/L had infants with a lower birthweight and a higher incidence of growth restriction than mothers with values of over 50 nmol/L (20 ng/mL). Low maternal 25(OH)D was associated with reduced body and lumbar spine bone mineral content in children at 9 years of age.

Other reported potential complications in infants and or mothers with vitamin D insufficiency include cardiomyopathies, immune intolerance (asthma, eczema), and an increased incidence of type 1 diabetes mellitus.

The association of vitamin D deficiency with insulin resistance and type 2 diabetes may explain the reportedly high incidence of gestational diabetes found in women

with low levels of 25(OH)D. However, confounding factors have not always been considered in these studies. It was also pointed out in many of these studies that 25(OH)D was measured late in the second trimester of pregnancy. As suggested by Lewis, a randomized control trial (RCT) will be required to clarify the direction and magnitude of these effects.

The incidence of preeclampsia was higher in women with vitamin D levels lower than 37.5 nmol/L measured before 22 weeks, a fivefold increase adjusted for other cofounders such as pregnancy body mass index (BMI), ethnicity, season of the year, and gestational age. The authors reported that the risk for preeclampsia more than doubled for each 50-nmol/L decrease in maternal 25(OH)D. Calcium supplementation during pregnancy was reported to reduce the incidence of preeclampsia and its severity.[16]

Vitamin D deficiency was also reported to be an independent risk factor in the development of bacterial vaginosis in pregnancy as early as the first trimester. However, no control study is available to assess the beneficial effect of normalizing serum 25(OH)D concentration.

A inverse relationship between serum 25(OH)D and the rate of cesarean delivery in nulliparous women was recently reported.[17] It was speculated that proximal weakness and a decrease in lower extremity muscle function, an effect of 25(OH)D deficiency, contributed to the risk for cesarean delivery. The risk was fourfold higher in women with serum 25(OH)D levels below 15 ng/mL.

The information available suggests that a maternal deficiency in vitamin D could have a role in the development or progression of some maternal complications, such as gestational diabetes, preeclampsia, bacterial vaginosis, an increase in the cesarean delivery rate, and adverse fetal and neonatal outcome. It is apparent that more studies are needed, preferably an RCT to understand the interrelationship with other comorbidities such as age, ethnicity, seasonal variation, BMI, and the severity of diabetes. In the meantime, the practicing obstetrician will have to decide in a given patient if determination of 25(OH)D is indicated, what are the normal values for pregnancy, whether they are trimester-specific, what is the proper treatment, and how often the test needs to be repeated in pregnancy, also taking into consideration the cost of the tests and the possible implications for the fetus and newborn.

Just recently, a report from the Institute of Medicine (IOM)[18] became available. The committee took into account nearly 1000 published studies, including reports of protection from cancer, autoimmune disease, heart disease, and diabetes. In brief, they recommended that the lower normal limit for serum 25(OH)D should be "about" 20 ng/mL or 50 nmol/L. **The authors of the report recommended a daily vitamin D dietary allowance of 600 U, with an upper limit intake of 4000 U; for calcium, they recommended 1000 mg of dietary allowance and an upper limit intake of 2500 mg a day.**

Osteoporosis

The condition of idiopathic osteoporosis related to pregnancy was recognized in the 1950s. In the past few years, there has been increased interest in several clinical aspects of osteoporosis in pregnancy and lactation.[19] In general, osteoporosis is suspected in pregnancy when the patient presents with severe, persistent back or hip pain and radiologic examination shows signs of osteopenia. Studies measuring calciotropic hormones and biochemical markers of bone reabsorption in each trimester in pregnancy and in the postpartum period showed a slight decrease in bone mass by the third trimester, followed by recovery within the first 6 months postpartum. In a study of a group of white, upper middle class, postmenopausal women, **there was no association between the number of pregnancies and lactation as predictors of decreased bone mineral density.**

Osteoporosis may be diagnosed during pregnancy or in the postpartum period. Whether these are two different syndromes or they represent the same clinical entity is unclear because the symptoms may begin during pregnancy, but the diagnosis is made for the first time after delivery. Osteoporosis diagnosed during pregnancy may be localized in the hip or lumbar spine, or both. **Pain in one hip or back pain is the presenting symptom in most cases, usually in the second half of gestation.** Spontaneous recovery is the usual course a few months postpartum. A case has been reported of onset in the first trimester with recovery following abortion.

Although osteoporosis has been diagnosed during pregnancy, pregnancy unmasks rather than causes low bone mass. As suggested by Rizzoli and Bonjour and others, postural changes during pregnancy, including increased lordosis, when superimposed on a small and transient decrease in bone mass, may lead to pain and even fractures. In a study of 24 women with symptoms of bone pain for many years, 18 complained of back pain, 5 complained of hip pain, and 1 complained of ankle pain in late pregnancy and up to 8 months after delivery. Radiologic examination of the spine showed vertebral deformities in 17. Bone mass was measured in 21; 7 women had evidence of osteoporosis and 13 were osteopenic. The authors concluded that bone mass was probably low before pregnancy and that a transient and slight decrease in bone mass during pregnancy could have weakened the bone further. Radiologic examination of the localized painful area and studies of bone density after delivery are indicated. In some cases, a short course of calcitonin or bisphosphonate therapy plus calcium supplementation may be needed.

The impact of lactation on the progression of osteoporosis is controversial. The study by Kritz-Silverstein and associates revealed that lactation by itself was not a determinant of bone mineral density. Although one investigation reported that lactation for more than 8 months was associated with greater bone mineral at both the femoral neck and shaft, another study found that nursing for longer than 9 months produced a greater decrease in bone mass than observed during the first 6- to 9-month period of nursing. Given this controversy, the health care provider must decide whether cessation of lactation is advisable in the management of osteoporosis.

Heparin-associated osteoporosis has been reported in several cases during pregnancy. It may be related to the total dose of heparin. Treatment with calcium supplementation or calcitriol, although not proved, may be helpful in

those patients receiving heparin therapy. Barbour and coworkers[20] followed 14 pregnant women requiring heparin therapy. Five of the 14 women experienced a 10% decrease from baseline proximal femur bone density measurements, compared with none in a matched control group. **The authors concluded that heparin adversely affected bone density in about one third of exposed patients.**

THYROID DISEASES

Thyroid disorders in pregnancy present a unique opportunity for health care professionals to use a similar "team approach" that has successfully improved the care of women with diabetes mellitus. Because of changes in thyroid economy occurring early in pregnancy, it is imperative to advise women with chronic thyroid diseases to plan their pregnancies and contact their health care professionals before or as soon as the diagnosis of pregnancy is confirmed. Autoimmune thyroid disease occurs five to eight times more often in women than in men, and its course could be affected by the immunologic changes occurring in pregnancy and in the postpartum period.[21,22]

In early pregnancy, the maternal thyroid gland is challenged with an increased demand for thyroid hormones secretion, due mainly to three different factors: (1) the increase in thyroxine-binding globulin (TBG) secondary to the effect of estrogens on the liver, (2) the stimulatory effect of human chorionic gonadotropin (hCG) on the thyroid-stimulating hormone (TSH) receptor, and (3) the supply of iodine available to the thyroid gland. This last factor is of importance in areas of iodine deficiency. In the United States, the iodine content in the diet, although decreased in the past decades, appears to be insufficient in only about 10% of pregnancies. **The suggested total daily iodine ingestion for pregnant women is 229 mcg/day and for lactating women 289 mcg/day; prenatal vitamins should contain at least 150 mcg of iodine in the form of potassium iodine.**[23]

The normal thyroid gland is able to compensate for the increase in thyroid hormone demands by increasing its secretion of thyroid hormones and maintaining them within normal limits throughout gestation. However, in those situations in which there is a subtle pathologic abnormality of the thyroid gland, such as chronic autoimmune thyroiditis, the normal increase in the production of thyroid hormones is not met. As a consequence, the pregnant woman could develop biochemical markers of hypothyroidism (i.e., an elevation in serum TSH and an increase in the size of the thyroid gland).

Active secretion of thyroid hormones by the fetal thyroid gland commences at about 18 weeks' gestation, although iodine uptake by the fetal gland occurs between 10 and 14 weeks.[24] **Transfer of thyroxine (T_4) from mother to embryo occurs from early pregnancy.** Maternal T_4 has been demonstrated in coelomic fluid at 6 weeks and in the fetal brain at 9 weeks. Maternal transfer continues until delivery, but only in significant amounts in the presence of fetal hypothyroidism. Thyroid hormone receptor gene expression has been shown in human fetal brain by 8 weeks' gestation, supporting the important role of maternal thyroid hormone during the first trimester of human pregnancy in fetal brain development. Several studies suggest that even mild maternal thyroid deficiency in the first trimester could result in long-term neuropsychological damage to the offspring.[25,26]

The levels of maternal thyroid hormone concentrations, both total thyroxine (TT_4) and total triiodothyronine (TT_3), increase from early pregnancy as the result of an elevation in TBG and a reduced peripheral TBG degradation rate. TBG reaches a plateau by 20 weeks' gestation and remains unchanged until delivery. Despite these acute changes in total hormone concentration, **the serum free fractions of both T_4 and T_3 remain within normal limits,** unless there is a decreased supply of iodine to the mother or in the presence of abnormalities of the thyroid gland.

Human chorionic gonadotropin is a weak thyroid stimulator, acting on the thyroid TSH receptor. It is estimated that a 10,000-IU/L increment in circulating hCG corresponds to a mean T_4 increment in serum of 0.1 ng/dL and, in turn, to a lowering of TSH of 0.1 mIU/L; the peak hCG values are reached by 9 to 12 weeks' gestation. In situations in which there is a high production of hCG, such as in cases of multiple pregnancies, hydatidiform mole, and hyperemesis gravidarum, serum free T_4 (FT_4) concentrations rise to levels seen in thyrotoxicosis, with a transient suppression in serum TSH values. In twin pregnancies, hCG levels are higher and duration of its peak longer than in singleton pregnancies, resulting in many cases with symptoms and laboratory tests compatible with gestational hyperthyroidism.

Goiter is commonly seen in pregnancy in areas of iodine deficiency. However, in the United States and other areas of the world with sufficient iodine intake, the thyroid gland does not clinically increase in size during pregnancy. **Therefore, the detection of a goiter in pregnancy is an abnormal finding that needs careful evaluation.** The most common cause of diffuse goiter is chronic autoimmune thyroiditis or Hashimoto thyroiditis. Most patients are euthyroid, and the diagnosis is made by the determination of thyroid antibodies, mainly thyroid peroxidase (TPO). Antibody concentration decreases during pregnancy and increases in the postpartum period. High values in the first trimester of pregnancy are predictors of the syndrome of postpartum thyroid dysfunction.

Thyroid Function Tests

Measurement of serum TSH is the most practical, simple, and economic screening test for thyroid dysfunction.[27] Normal TSH concentrations, as well as serum T_4 determinations, are trimester specific, dependent on iodine intake in a given population, on ethnicity, and on assay performance; serum TSH is lower in the first trimester compared with prepregnancy values and with the second and third trimester of pregnancy. An elevated serum TSH value is consistent with the diagnosis of primary hypothyroidism, whereas a low one, with few exceptions, is a normal finding in the first trimester (Figure 40-2) secondary to the stimulatory effect of hCG on the thyroid gland TSH receptor. Glinoer and Spencer[27] reviewed recent studies using a sensitive serum TSH assay, reporting a range between 0.03 and 3.67 mIU/L, (2.5th and 97.5th percentiles); different TSH reference limits will still be observed, according to the assays used. There are significant clinical data to support an upper limit of normal for serum TSH in the

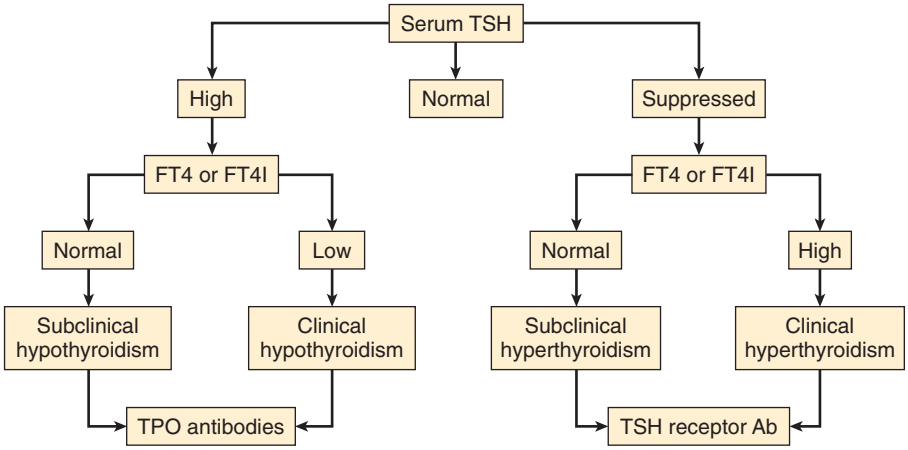

FIGURE 40-2. Algorithm for the interpretation of thyroid function test in pregnancy. Serum TSH upper limit of normal in the first trimester of pregnancy is 2.5 mIU/L; in the second and third trimesters, it is 3 mIU/L. Serum TSH lower limit of normal in the first trimester of pregnancy may be as low as 0.1 mIU/L or even undetectable. Subclinical hyperthyroidism in the absence of TSH receptor antibodies *(Ab)* is a normal first-trimester physiologic finding. Presence of serum TPO antibodies is consistent with a diagnosis of chronic thyroiditis. Presence of TSH receptor Ab is consistent with the diagnosis of Graves' disease. *FT4,* Free thyroxine; *FT4I,* free thyroxine index.

first trimester of pregnancy as a value of 2.5 to 3 mIU/L in the second and third trimesters.[28]

A word of caution is required regarding the determination of FT_4 levels in the different trimesters of pregnancy. Although discrepant findings have been reported, in most studies the free T_4 concentration increases slightly in the first trimester of pregnancy and declines with the progression of pregnancy. There is a significant inconsistency in FT_4 values in the second half of pregnancy among the different immunoassays, as reported by commercial laboratories, because of methodology used as well as variation in dietary iodine intake among the different populations studied. Currently, none of the manufactures of the automated free T_4 assays has provided trimester-specific reference ranges. Free T_4 values in the lower limits of normal and even in the hypothyroid range are not uncommonly seen in daily clinical practice, particularly in the third trimester of pregnancy. Lee and colleagues[29] compared the diagnostic performances of two different immunoassays to traditional approaches for estimating FT_4 (total T_4 and FT_4 index [FT_4I]) relative to the physiologic TSH changes that are known to occur throughout pregnancy. They studied euthyroid women who were thyroid peroxidase antibody negative in the first, second, and third trimesters of gestation. Control women were premenopausal, nonpregnant women matched for ethnicity. Serum TT_4, as expected, was elevated in all three trimesters, and serum FT_4I was elevated in the first trimester compared with controls (P <.05) and returned to the nonpregnant range in the second and third trimester; in contrast, FT_4 values, measured by two different immunoassays, were either comparable or lower than controls, and by the second and third trimesters, were about 65% of controls. The authors concluded that TT_4 and FT_4I retained an appropriate inverse relationship with serum TSH throughout pregnancy and appeared to provide a more reliable free T_4 estimate than the FT_4 test. Because the determination of FT_4 by the dialysis method, the gold standard for free T_4 assessment, or the use of tandem mass spectrometry are not routinely available because they are high-cost, cumbersome, and time-consuming procedures, the determination of total T_4 adjusted by a factor of 1.5 for pregnant patients has been suggested.[29] Therefore, it is imperative for the practicing physician to be familiar with the interpretation and significance of the thyroid tests as reported by a given commercial laboratory. The use of a limited number of thyroid function tests, properly ordered and interpreted, will allow the health care professional to assess thyroid function and make the proper therapeutic decisions.

A suppressed serum TSH value and high concentrations of FT_4 or FT_4I is diagnostic of hyperthyroidism. There are rare situations in which hyperthyroidism may be diagnosed in the presence of suppressed TSH and normal concentrations of FT_4, such as in the case of an autonomous thyroid nodule. In such cases, a serum TT_3 or free triiodothyronine index (FT_3I) determination should be obtained.

Prepregnancy Counseling

The physician may be faced with different clinical situations when counseling a woman suffering from thyroid disease contemplating pregnancy. With the advent of available information in the electronic media, it is important for the health care professional to offer the patient and her family objective and scientific data, supported by medical literature published in recognized peer-reviewed medical journals. The clinical situations may be summarized as follows:

1. *Hyperthyroidism under antithyroid drug treatment.* A choice of the three classic therapeutic options for hyperthyroidism treatment should be given: (1) long-term antithyroid drug therapy, (2) radioactive iodine-131 (^{131}I) ablation, or (3) near-total thyroidectomy. Potential side effects of antithyroid drugs on the fetus should be discussed with the future parents. If the patient opts for ^{131}I ablation therapy, there is no adverse long-term effect of ^{131}I given to the future mother or the offspring. However, it is customary to wait 3 to 6 months after the therapeutic dose is administered before pregnancy is contemplated in order to achieve target serum TSH values. Surgery is another option, selected by some physicians and patients concerned about the potential side effects of antithyroid drugs or radioactive treatment. Regardless of the form of therapy chosen, it is important for the patient to be euthyroid at the time of conception. One issue of clinical significance is the titer of maternal serum thyroid receptor antibodies (TRAbs), at the time of ablative therapy. TRAb-stimulating activity may be above normal values and does not normalize immediately after

either therapy, and may even increase after ^{131}I administration. Therefore, surgical therapy could be considered in patients contemplating pregnancy when serum TRAb titers are fivefold higher than normal and a potential risk to the fetus.[30] A high titer of TRAb in the second half of pregnancy presents a risk for fetal or neonatal hyperthyroidism. In a large series of hyperthyroid pregnant women, a doubling in incidence of congenital malformations was reported when hyperthyroidism was not controlled in the first trimester of pregnancy compared with that in women who were euthyroid early in gestation.

2. *Previous treatment with ^{131}I for thyroid carcinoma.* It is reasonable for patients treated with ablative doses of ^{131}I to wait 6 months to 1 year after completion of treatment before conception. No long-term effect on the offspring has been reported. Adjustment of the levothyroxine (L-thyroxine) dose should be done early in pregnancy and in each trimester; serum TSH should be kept in the low-normal range or undetectable, but clinical hyperthyroidism should be avoided. Data obtained from 2673 pregnancies in patients treated for thyroid carcinoma but without significant external radiation to the ovaries were analyzed by Garsi and colleagues. There was no evidence that exposure to radioiodine affects the outcome of subsequent pregnancies and offspring. The question of whether the incidences of malformations and thyroid and nonthyroid cancers are related to gonadal irradiation remains to be established.
3. *Treated hypothyroidism.* Women under treatment with thyroid hormone usually require an increase in L-thyroxine doses soon after conception.[31,32] The increase in requirements is observed as early as the first 4 to 8 weeks of gestation. As soon as the diagnosis of pregnancy is made, thyroid function tests should be performed and thyroid doses adjusted accordingly. It has been recommended to add two extra doses of L-thyroxine per week to the customary doses as soon as the diagnosis of pregnancy is confirmed until the results of thyroid function tests become available.[32] Recently, it was reported that in hypothyroid women (excluding those who underwent thyroidectomy because of thyroid cancer) on L-thyroxine replacement therapy, if the serum TSH was below 1.3 mIU/L before conception, only 17% of women needed an increase in L-thyroxine in the first trimester of pregnancy, compared with 58% of those with a serum TSH above 1.3 mIU/L.[33] After delivery, the dose should be reduced to prepregnancy levels in most women. Common medications may affect the absorption of L-thyroxine, such as ferrous sulfate and calcium, among others. Patients should take L-thyroxine at least 2 hours apart from other medications and 1 hour before or after food intake, ideally early in the morning on awakening and 1 hour before food ingestion. However, during pregnancy, in those women affected by nausea or vomiting, the dose may be taken at bedtime on an empty stomach.
4. *Euthyroid chronic thyroiditis.* Patients with Hashimoto thyroiditis are at a greater risk for developing hypothyroidism de novo early in pregnancy, spontaneous abortions, prematurity, and postpartum thyroiditis.[34]

Maternal-Placental-Fetal Interactions

Studies during the past few decades have shown an important role of maternal thyroid hormones in embryogenesis.[24,35] It is accepted that maternal T_4 crosses the placenta in the first half of pregnancy at the time when the fetal thyroid gland is not functional.

Maternal TSH does not cross the placenta. TRH does cross the placental barrier, but its physiologic significance is unknown. TRH has been given to mothers to accelerate fetal lung maturation in premature infants.

Methimazole (MM), propylthiouracil (PTU), and carbimazole (CZ), drugs used for the treatment of hyperthyroidism, do cross the placenta, and if given in inappropriate doses may produce fetal goiter and hypothyroidism. CZ is used in some European countries. Preparations containing iodine given in large doses or for prolonged periods of time are contraindicated in pregnancy because accumulation by the fetal thyroid may induce goiter and hypothyroidism.

Hyperthyroidism

Autoimmune hyperthyroidism affects pregnancy in about 0.1% to 0.4% of patients.[36] Classically, it has been stated that Graves' disease is the most common cause of hyperthyroxinemia in pregnancy, with other etiologies being uncommon (Table 40-2). As will be discussed subsequently, hyperthyroidism due to inappropriate secretion or action of hCG is recognized as the most common cause of transient hyperthyroidism in pregnancy.[37] In our experience, single toxic adenoma and multinodular toxic goiter are found in less than 10% of cases. Subacute thyroiditis is rarely seen during gestation.

Gestational Hyperthyroidism

Also known as *gestational thyrotoxicosis* or *transient gestational hyperthyroidism*, this condition is defined as transient hyperthyroidism in the first trimester of pregnancy, due, with

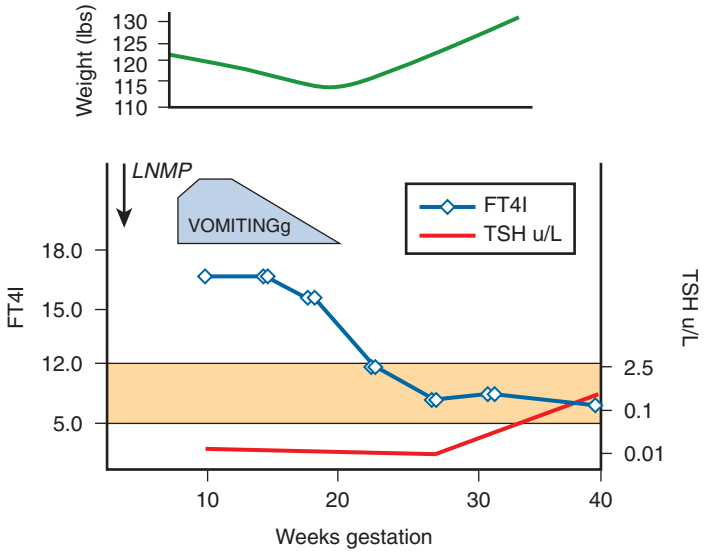

FIGURE 40-3. A representative example of transient hyperthyroidism of hyperemesis gravidarum. By week 6, vomiting begins and becomes severe by week 10. Serum free thyroxine index *(FT_4I)* is elevated, and thyrotropin is suppressed. By weeks 16 to 18, vomiting subsides, with marked improvement of the FT_4I value. During this period, the patient loses 3.6 kg. By week 18, the serum FT_4I returns to normal, but the serum thyrotropin remains suppressed until week 26. The patient regains and gains weight, with a term delivery of a healthy infant. The *gray band* indicates reference range. *LNMP,* Last normal menstrual period.

few exceptions, to high titers of hCG secretion stimulating the thyroid TSH receptor. The most common causes of gestational hyperthyroidism are hyperemesis gravidarum, multiple gestation, and hydatidiform mole. Other isolated reports included hyperplacentosis.

Transient Hyperthyroidism of Hyperemesis Gravidarum

This disorder is characterized by severe nausea and vomiting, with onset between 4 and 8 weeks' gestation, requiring frequent visits to the emergency room and sometimes repeated hospitalizations for intravenous hydration.[38] Weight loss of at least 5 kg, ketonuria, abnormal liver function tests, and hypokalemia are common findings, depending on the severity of vomiting and dehydration. FT_4 levels and TT_4 are elevated, sometimes up to four to six times the normal values, whereas TT_3 and FT_3 values are elevated in up to 40% of affected women, although FT_3 values are not as high as those of serum FT_4.[37] The T_3/T_4 ratio is less than 20, compared with Graves' hyperthyroidism, in which the ratio is more than 20. Serum TSH measured by a sensitive assay is consistently undetected or suppressed. **Despite the significant biochemical hyperthyroidism, signs and symptoms of hypermetabolism are mild or absent.** Patients may complain of mild palpitations and heat intolerance, but perspiration, proximal muscle weakness, and frequent bowel movements are rare. On physical examination, ophthalmopathy and goiter are absent, a mild tremor of the outstretched fingers is occasionally seen, and tachycardia may be present due in part to dehydration. Significant in the medical history is the lack of hyperthyroid symptoms before conception because most patients with Graves' disease diagnosed for the first time during gestation give a history of hypermetabolic symptoms antedating conception. Spontaneous normalization of hyperthyroxinemia parallels the improvement in vomiting and weight gain, with most of the cases resolving spontaneously between 14 and 20 weeks' gestation, although persistence of hyperthyroidism beyond 20 weeks' gestation has been reported in 15% to 25% of cases. Suppressed serum TSH may lag for a few more weeks after normalization of free thyroid hormone levels (Figure 40-3). **Antithyroid medications are not needed.** In one series in which antithyroid medication was used, pregnancy outcome was not significantly different in a similar group of patients receiving no therapy. Furthermore, a case has been reported in which vomiting persisted despite normalization of serum thyroid levels with antithyroid medications; vomiting subsided after termination of pregnancy. Occasionally, severe vomiting and hyperthyroidism may require parenteral nutrition.

The degree of thyroid abnormalities is directly related to the severity of vomiting and weight loss. In 67 patients studied by Goodwin and colleagues,[37] liver and electrolyte abnormalities were routinely found in women with worse symptoms, including severe vomiting, weight loss of at least 5 kg, and significant dehydration. They also presented with more significant elevations in FT_4 levels and suppression of serum TSH values; indeed, in 30% of their patients, serum TSH was undetectable (<0.04 mIU/L). Those with a lesser degree of hyperemesis had a less severe disorder of thyroid function.

Transient hyperthyroidism due to hyperemesis gravidarum should be suspected in women who present in the first few weeks after conception with sudden onset of severe nausea and vomiting and thyroid tests in the hyperthyroid range. These patients do not complain of hypermetabolic symptoms antedating pregnancy, goiter is not detected by palpation, and symptoms or signs of tissue thyrotoxicosis are mild or absent. In addition, thyroid anti-TPO antibodies and TRAb, markers of autoimmune thyroid disease, are negative. The differential diagnosis may also be difficult because vomiting may also be a presenting symptom of hyperthyroidism of Graves' disease (Table 40-3).

The cause of the elevations of thyroid hormones in patients with hyperemesis gravidarum is the endocrine effect of hCG.[39] Most likely, high levels of hCG, a known stimulator of the TSH receptor, play an important role, as well as prolongation in its biologic activity as seen in twin

pregnancies. There is a significant, albeit weak, correlation between the degree of thyroid stimulation and total hCG levels in normal women and those with hyperemesis.[39] hCG titers of more than 200,000 mIU/mL consistently bring serum TSH to undetectable values. Certain hCG fractions may have more potent biologic activity as thyroid simulators. The thyroid-stimulating activity of hCG in early pregnancy and in molar gestations correlates best with the percentage of basic, partially desialylated hCG in serum. A case has been reported in a mother and daughter with recurrent hyperemesis, in whom hCG levels were not elevated. Both were heterozygous for a missense mutation in the extracellular domain of the thyrotropin receptor. The mutant receptor was more sensitive than the wild-type receptor to hCG, accounting for the occurrence of hyperthyroidism despite the presence of normal hCG levels.

As noted previously, the diagnosis of transient hyperthyroidism of hyperemesis gravidarum should be considered in women with severe vomiting, no clinical manifestations of Graves' disease, and biochemical evidence of hyperthyroidism in early pregnancy, suppressed or undetectable serum TSH values, and elevated serum FT_4. Normal serum TSH in early pregnancy may be as low as 0.01 mIU/L; therefore, the presence of elevated serum FT_4 is required for the diagnosis. Vomiting should be persistent and severe with a significant weight loss, because most women with morning sickness of pregnancy have normal thyroid function tests. The syndrome may repeat in future pregnancies.

Hyperemesis gravidarum may also occur in women with Graves' hyperthyroidism. It may occur during remission of the disease, explained by the additional action of hCG early in gestation; the differential diagnosis between the two entities may be difficult, but the presence of TRAb favors the diagnosis of Graves' hyperthyroidism.[40]

Obstetrical outcome is not affected by gestational hyperthyroidism. Birthweight may be slightly lower, but not significantly different, compared with fetuses of control mothers and is related to maternal weight loss.

Gestational trophoblastic diseases, partial and complete hydatidiform moles, and choriocarcinoma are other causes of hyperthyroidism early in pregnancy. Patients may present without symptoms despite chemical hyperthyroidism or with various degrees of severity, including congestive heart failure. Evacuation of the mole eliminates the source of the excessive hCG and reverses the clinical and biochemical features of hyperthyroidism. Treatment with α-adrenergic blocking agents is effective in controlling the symptoms. Sodium iopanoate has been used to reduce the release of hormones by the thyroid gland and block peripheral conversion of T_4 to T_3.

TABLE 40-4 POTENTIAL MATERNAL AND FETAL COMPLICATIONS OF GRAVES' HYPERTHYROIDISM

MATERNAL	FETAL

Graves' Disease

The natural course of hyperthyroidism due to Graves' disease in pregnancy is characterized by an exacerbation of symptoms in the first trimester and during the postpartum period and an amelioration of symptoms in the second half of pregnancy. Stimulation of the thyroid gland by hCG in the first trimester and an elevation in TRAb values have been suggested as the cause of exacerbation. Immunologic responses caused by changes in lymphocyte subsets could explain spontaneous improvement in the second half of pregnancy and recurrences in the postpartum period. Kung and Jones, in a study comparing Graves' disease in pregnant and nonpregnant women, postulated that the amelioration of symptoms seen with progression of pregnancy was due to a decrease in the titers of TRAbs with stimulating activity and an increase in TRAbs with thyroid-blocking activity. The reverse was true in the postpartum period, when aggravation of Graves' hyperthyroidism usually occurs. In another study, it was suggested that the amelioration of Graves' disease in the last half of pregnancy is induced by a decrease of thyroid receptor antibodies (TRAb) (thyroid-stimulating immunoglobulins, or TSIs) but not by the appearance of thyroid stimulation–blocking antibodies (TSBAs).

When hyperthyroidism is properly managed throughout pregnancy, the outcome for mother and fetus is good; however, maternal and neonatal complications for mothers untreated or poorly controlled hypothyroidism are significantly increased (Table 40-4).[41]

In most patients in whom the diagnosis is made for the first time during pregnancy, hyperthyroid symptoms antedate conception. The clinical diagnosis of thyrotoxicosis may present difficulties during gestation because many symptoms and signs are commonly seen in normal pregnancy, such as mild palpitations, heart rate between 90 and 100 beats/minute, mild heat intolerance, shortness of breath on exercise, and warm skin. There are some clinical clues that increase the likelihood of the diagnosis of hyperthyroidism: presence of goiter, ophthalmopathy, proximal muscle weakness, tachycardia with a pulse rate of more than 100 beats/minute, and weight loss or inability to gain weight despite a good appetite. Occasionally, the patient may be seen for the first time in congestive heart failure, and the etiologic diagnosis is difficult because many of the physical findings are suggestive of cardiac valvular disease, particularly mitral insufficiency or stenosis. Hyperthyroidism under poor control is frequently complicated by preeclampsia, small-for-gestational-age (SGA) infants, and preterm delivery. The physician should suspect hyperthyroidism in the presence of systolic hypertension with an inappropriately low diastolic blood pressure and a wide pulse pressure, also seen in other conditions such as aortic insufficiency.

Classic symptoms of hyperthyroidism include nervousness, increased sweating, increased appetite, heat intolerance, insomnia, proximal muscle weakness, irritability, changes in personality, frequent bowel movements, decreased tolerance to exercise (sometimes manifested as shortness of breath), eye irritation, frequent lacrimation, pruritus, and weight loss. Not all symptoms are present in a given patient. The physician should be aware of subtle complaints, particularly in the presence of weight loss or inability to gain weight. As mentioned previously, in the first trimester of pregnancy, differentiating the diagnosis from transient hyperthyroidism of hyperemesis gravidarum presents a real challenge for the health care professional.

On physical examination, the thyroid gland is enlarged in almost every pregnant woman with Graves disease. Indeed, the absence of a goiter makes the diagnosis unlikely in young people. The gland is diffusely enlarged, between two and six times the normal size, and varies from soft to firm, sometimes being irregular to palpation, with one lobe being more prominent than the other one. A thrill may be felt or a bruit heard, indications of a hyperdynamic circulation. Examination of the eyes may reveal obvious ophthalmopathy, but in most cases, exophthalmos is absent or mild, with one eye slightly more prominent than the other. Extraocular movements may be impaired on careful eye examination. Stare is common, as is injection or edema of the conjunctiva. Severe ophthalmopathy is rare in pregnancy; glucocorticoid therapy and surgical orbital wall decompression may be required to restore visual activity. Pretibial myxedema is rare, seen in less than 10% of women. A hyperdynamic heart with a loud systolic murmur is a common finding. Proximal muscle weakness, fine tremor of the outstretched fingers, and hyperkinetic symptoms are seen frequently. The skin is warm and moist, and palmar erythema is accentuated.

As discussed previously (see Thyroid Function Tests), FT_4 determination or the calculation of FT_4I (using TT_4 levels and a test for assessment of TBG, such as resin T_3 uptake) are standard tests in most clinical laboratories, with the results available in 24 to 48 hours. Almost every patient with Graves disease will have an elevated FT_4 concentration. A undetected TSH value in the presence of a high FT_4 or TT_4 adjusted for pregnancy confirms the diagnosis of hyperthyroidism.[36] In some unusual situations, the serum FT_4 may be at the upper limit of normal or slightly elevated, in which case the determination of TT_3 or adjusted TT_3 will confirm the diagnosis of hyperthyroidism. Thyroid peroxidase antibodies (TPOAb) or thyroid antimicrosomal antibodies, markers of thyroid autoimmune disease, are elevated in most patients with Graves disease; TSHRAb, both thyroid-binding inhibitor immunoglobulin (TBII) and TSI, are elevated, and their titers have significant prognostic importance for fetal and neonatal hyperthyroidism (see later discussion).

Significant maternal and perinatal morbidity and mortality were reported in early studies of pregnancies complicated by hyperthyroidism. In the past 20 years, however, there has been a significant decrease in the incidence of maternal and fetal complications directly related to improved control of maternal hyperthyroidism (see Table 40-4).[41-43] In patients whose hypothyroidism is poorly controlled, one of the most common maternal complication is pregnancy-induced hypertension (PIH). In women with uncontrolled hyperthyroidism, the risk for severe preeclampsia was five times greater than in patients with controlled disease.[41] Other complications include preterm delivery, placental abruption, birthweight less than 2500 g, stillbirth, and miscarriage. Congestive heart failure may occur in women untreated or treated for a short period in the presence of PIH or operative delivery. Left ventricular dysfunction is usually detected by echocardiography in women with cardiovascular manifestations. Although these changes are reversible, they may persist for several weeks or months after achieving a euthyroid state. In one study, reduction in peripheral vascular resistance and higher cardiac output were still present despite normalization of T_4 levels. This is an important finding with significant clinical implications. Left ventricular decompensation in hyperthyroid pregnant women may develop in the presence of superimposed preeclampsia, at the time of delivery, or with undercurrent complications such as anemia or infection. We have seen congestive heart failure in the first half of pregnancy in women with long-standing hyperthyroidism. It is likely that the aggravation of hyperthyroidism seen in the first part of pregnancy played an important role in the development of this complication. Careful monitoring of fluid administration is imperative in these situations. Thyroid storm has been reported in pregnancy and was reported 2 weeks postpartum in a woman whose hyperthyroidism was uncontrolled during pregnancy in association with multiorgan failure.

Fetal and neonatal complications are also related to maternal control of hyperthyroidism. Intrauterine growth restriction (IUGR), prematurity, stillbirth, and neonatal morbidity are the most common complications. Millar and coworkers[41] demonstrated that uncontrolled hyperthyroidism during the entire gestation was associated with a ninefold greater incidence of low-birthweight infants compared with the control population. It was almost 2.5 times greater in those whose hyperthyroidism was treated during

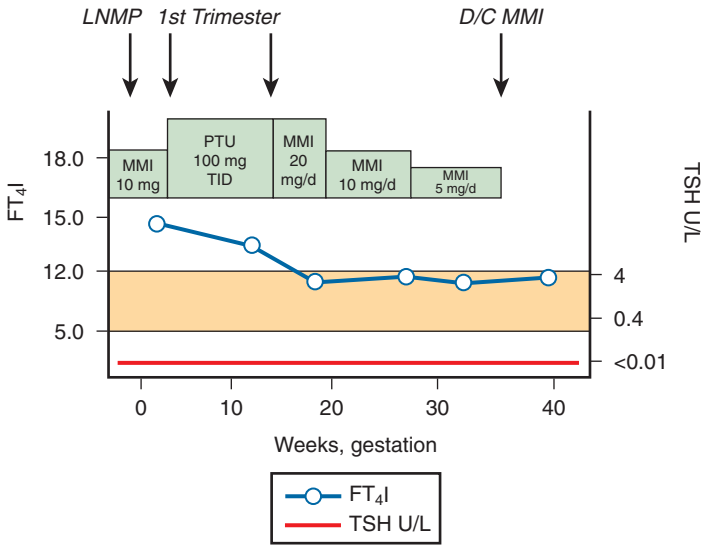

FIGURE 40-4. A representative example of management of hyperthyroidism in pregnancy. The patient is hyperthyroid at time of conception on methimazole *(MMI),* 10 mg daily. When pregnancy is diagnosed, MMI is discontinued, and propylthiouracil *(PTU)* is added at a dosage of 150 mg three times daily. By the end of the first trimester, PTU is discontinued, and MMI is given at a dosage of 20 mg daily. By week 20, the free thyroxine index *(FT_4I)* is almost normal, and the MMI dosage is reduced to 10 mg. By week 26, the FT_4I is in the upper reference range, and thyrotropin remains suppressed. The MMI dosage is reduced to 5 mg daily. The FT_4I remains in the upper reference range, and by week 34, MMI is discontinued *(D/C),* and the patient remains euthyroid until delivery. The *gray band* indicates reference range. *LNMP,* Last normal menstrual period.

pregnancy and became euthyroid at some time during gestation. In mothers achieving a euthyroid state before or early in pregnancy, the incidence of low-birthweight infants was no different from that in the control population. Mitzuda and associates correlated the risk of delivering an SGA infant to the presence of maternal thyrotoxicosis lasting more than 30 weeks of pregnancy, a duration of Graves disease for most of 10 years, and onset of Graves disease before age 20 years. Momotani and Ito reported the incidences of spontaneous abortions (25.7%) and premature delivery (14.9%) in mothers hyperthyroid at the time of conception, compared with 12.8% and 9.5%, respectively, in euthyroid mothers. Neonatal central hypothyroidism has been reported in infants whose mothers remained hyperthyroid throughout their pregnancies. Many of these infants recovered normal thyroid function in a few weeks, whereas another group have long-standing hypopituitary dysfunction.[44]

The use of ultrasonography for monitoring the size of the fetal thyroid gland as an indicator of thyroid dysfunction and possible therapeutic intervention was evaluated by Luton and associates in France.[45] In a group of hyperthyroid women considered to be at high risk (presence of TSHRAbs) and on antithyroid therapy, fetal goiter was detected in 11 of 41 patients. Four fetuses were hyperthyroid, and seven were hypothyroid secondary to high doses of maternal anti-thyroid drug treatment. All of them benefited from adjusting drug therapy. The authors concluded that ultrasonography of the fetal thyroid gland by an experienced ultrasonographer is an excellent diagnostic tool, in conjunction with close teamwork, to ensure normal fetal thyroid function.

Treatment of hyperthyroidism is essential to prevent maternal, fetal, and neonatal complications (Figure 40-4). The goal of treatment is normalization of thyroid tests as soon as possible and maintenance euthyroidism with the minimal amount of antithyroid medication. Excessive amounts of antithyroid drugs crossing the placenta may affect the fetal thyroid, with the development of fetal hypothyroidism with or without goiter. Patients should be monitored at regular intervals and the dose of their medications adjusted to keep the FT_4 or FT_4I very close to the upper limit of normal or just above it. Momotani and associates[42] showed that fetal serum TSH was elevated even in mothers with FT_4 within the normal range; furthermore, they demonstrated that normalization of serum TT_3 is a risk factor for the development of fetal hypothyroidism, supporting the recommendations that serum TT_3 determination should rarely be used to assess maternal function during gestation.

To achieved a euthyroid state and with the aim to keep the FT_4 in the upper limit of the nonpregnant reference range, and even slightly above normal, thyroid tests should be performed every 2 weeks at the beginning of treatment and every 2 to 4 weeks when euthyroidism is achieved. As mentioned earlier, because of the immunologic changes occurring with the progression of pregnancy, the requirement for antithyroid medications decreases after the second half of gestation. Some women with small goiters, short duration of symptoms, and on minimal amounts of antithyroid medication are able to discontinue antithyroid drugs by 34 weeks' gestation or beyond. It is estimated that 30% to 40% are able to remain euthyroid without therapy in the last few weeks of pregnancy.[41,43]

In a study of 44 women in 46 pregnancies, the correlation among TRAb activity, the dose of antithyroid therapy, and neonatal outcome was studied.[43] Medication was discontinued in 30 pregnancies 3 to 18 weeks before delivery. Neonatal thyrotoxicosis was seen in 4 infants whose mothers' TBII levels exceeded 70% (normal, <15%). Interestingly, of the infants born with elevated serum TSH, maternal TBII was less than 30% in most, suggesting that in Graves disease–associated hyperthyroid pregnancies, a low TBII titer is an indication to use the minimal amount of antithyroid therapy to avoid the development of fetal hypothyroidism with or without goiter.

In the United States, the two antithyroid drugs available are PTU and MM (Tapazole). Both drugs are effective in controlling symptoms. Recently, the risk for hepatic toxicity due to PTU was revisited. An alarming number of cases requiring liver transplantation and cases of death were noted (Table 40-5). MM can also induce liver toxicity, but

TABLE 40-5 SIDE-EFFECT PROFILES OF METHIMAZOLE VERSUS PROPYLTHIOURACIL

these effects are milder, confined to cholestasis, not associated with liver failure, and seen more frequently in patients older than 61 years. It is estimated that about 4000 pregnant women per year in the United States would be expected to be treated with antithyroid drugs, most of them with PTU, as recommended per previous practice guidelines. Although no specific incidence of PTU-induced liver injury in pregnancy is available, it has been estimated that 4 women per year will have severe PTU-related hepatic complications.[46] Although the incidence of both liver toxicity due to PTU and embryopathy from MM are very low, a panel convened by the U.S. Food and Drug Administration (FDA) and the American Thyroid Association (ATA) recommended the use of PTU only in the first trimester of pregnancy and then a change to MM the second trimester (see Figure 40-4).[47] Other indications for the preferential use of PTU over MM are drug allergy to MM and, in thyroid storm, because of the ability of PTU to inhibit peripheral conversion of T_4 to T_3.

To our knowledge, no studies have shown PTU to be superior to MM in the management of hyperthyroidism in pregnancy; both drugs having similar placental transfer kinetics. Furthermore, when the efficacies of both drugs were compared, euthyroidism was achieved equally with equivalent amounts of drugs and at the same weeks of treatment. Neonatal outcomes were no different in both groups.

Aplasia cutis congenita, a localized lesion in the parietal area of the scalp characterized by congenital absence of the skin and a punched-out ulcer-like lesion, has occurred in a small group of infants born to mothers on MM therapy. It has never been reported with the use of PTU. However, the incidence in the general population is 0.03% of newborns. In a letter to the editor, an observation of aplasia cutis in an animal whose feed was contaminated by MM was reported. Several studies have described a specific embryopathy in infants born to mothers treated with MM in the first trimester of pregnancy.[48] This has been named *methimazole embryopathy* and includes choanal atresia or esophageal atresia, minor dysmorphic features, and developmental delay. Very few cases have been described, and none with the use of PTU. The prevalence of these malformations in the general population is 1 in 2500 for esophageal atresia and 1 in 1000 for choanal atresia. The doses of MM were 5 to 50 mg/day in one study; in the second study, both affected mothers took more than 20 mg/day. Barbero and associates,[48] in a recent epidemiologic study, reported an OR of 18 (95% CI, 3 to 121) for choanal atresia among infants whose mothers received MM in the first trimester compared with the general population; however, the authors could not exclude the possibility that hyperthyroidism itself may be associated with this and other abnormalities.

The initial recommended dose of PTU is 100 to 450 mg/day, and for MM, 10 to 20 mg/day; very seldom is a larger initial dose required. MM is given once or twice daily, allowing for improvement in patient compliance. PTU, because of its shorter half-life, should be given every 8 hours. **In our experience, 20 mg/day of MM or 100 to 150 mg of PTU three times a day is an effective initial dose in most patients.** Drug side effects are related to the antithyroid drug dose. Those with large goiters and longer duration of the disease may need higher doses at the initiation of therapy. In patients with minimal symptoms, an initial dose of 10 mg of MM daily or PTU 50 mg two or three times a day may be initiated. In most patients, clinical improvement is seen in 2 to 6 weeks, and improvement in thyroid tests occurs within the first 2 weeks of therapy, with normalization to chemical euthyroidism in 3 to 7 weeks. Resistance to drug therapy is unusual, most likely a result of poor patient compliance. **Once clinical improvement occurs, mainly weight gain and reduction in tachycardia, the dose of antithyroid medication may be reduced by half of the initial dose.** The daily dose is adjusted every few weeks according to the clinical response and the results of thyroid tests. Serum TSH remains suppressed despite the normalization of thyroid hormone levels (see Figure 33-4 in Chapter 33). Normalization of serum TSH is an indicator to reduce the dose of medication. If there is an exacerbation of symptoms or worsening of the thyroid tests, the amount of antithyroid medication is doubled.

The main concerns of maternal drug therapy are the potential side effects in the fetus, mainly, goiter and hypothyroidism—hence the importance of using the minimal dose to keep FT_4 in the upper limit of normal or just above the normal nonpregnant range. However, small elevations in serum TSH in the neonate have been reported even with lower doses of antithyroid medication. Furthermore, in one study, cord blood FT_4 values were not correlated with the antithyroid medication dose at term. As mentioned previously,[43] in the presence of maternal TBII values over 50%, the dose of MM required to control hyperthyroidism may be higher than in women with negative or low TBII titers in order to protect the fetus from hyperthyroidism. We do not recommend adding T_4 to antithyroid drug therapy in the management of Graves' disease in pregnancy. It is difficult to interpret the serum T_4 level and may require more unnecessary antithyroid medications.

Side effects of antithyroid drugs occur in 3% to 5% of treated patients (see Table 40-5). **The most common complications of both drugs are pruritus and skin rash.** These usually resolve after switching to the other antithyroid medication. In general, the rash occurs 2 to 6 weeks after initiation of therapy. Because pruritus may be an initial symptom of hyperthyroidism, it is customary to ask the

patient during the first visit whether she is bothered by this. Other complications that are much less common are migratory polyarthritis, a lupus-like syndrome, and cholestatic jaundice. Agranulocytosis, a serious but unusual complication, has been reported in 1 in 300 patients receiving the drug. It manifests as fever, malaise, gingivitis, and sore throat. Agranulocytosis occurs in the first 12 weeks of therapy and appears to be related to the dose of medication. Bruner and associates reported a case of allergies to both antithyroid medications in a pregnant woman with type 1 diabetes mellitus. Patients should be made aware of the potential adverse effects of these drugs at the time the prescription is given and advised to discontinue the medication at once if these effects appear. In this setting, a leukocyte count should be obtained immediately. Although some have recommended routine white blood cell counts in patients on antithyroid therapy, such testing is not indicated because granulocytopenia or agranulocytosis may appear without warning symptoms.

β-Adrenergic blocking agents (propranolol, 20 to 40 mg every 6 hours, or atenolol, 25 to 50 mg/day) are very effective in controlling hyperdynamic symptoms and are indicated for the first few weeks in patients who have symptoms. One situation in which β-adrenergic blocking agents may be very effective is in the treatment of severe hyperthyroidism during labor. In a case reported in which both mother and fetus were affected, labetalol was infused at a rate of 2 mg/minute, controlling maternal and fetal tachycardia within 45 minutes.

Subtotal thyroidectomy in pregnancy is effective in managing the disease. However, currently, indications for surgical treatment are few and include allergy to antithyroid drugs, patients requiring large doses of medication, patient preference, and the exceptional case of resistance to drug therapy. Two issues are significant when advising surgical therapy: (1) the mother should be prepared with β-adrenergic blocking agents to render her hemodynamically stable and with Lugol's solution for at least 10 days to reduce thyroid gland vascularity (there is no contraindication to use potassium iodide for a short period of time); and (2) a determination of TRAb is of the utmost importance because a value three times greater than normal places the fetus at risk for fetal hyperthyroidism.[30]

^{131}I therapy is contraindicated in pregnancy because when given after 12 weeks' gestation, it could produce fetal hypothyroidism.[49] A pregnancy test is mandatory in any woman of childbearing age before a therapeutic or diagnostic dose of ^{131}I is administered.

Iodine crosses the placenta. If given in large amounts and for prolonged periods, it may produce a fetal goiter and hypothyroidism. Therefore, its therapeutic use is not recommended in pregnancy. However, iodine was used in small amounts, 6 to 40 mg/day, in a group of pregnant Japanese women with mild hyperthyroidism. Elevation in serum TSH was observed in 2 of 35 newborns, and the mothers were slightly hyperthyroid at the time of delivery. Despite this observation, iodine therapy is not routinely indicated in the treatment of hyperthyroidism in pregnancy.

Excessive amounts of antithyroid drugs have induced fetal hypothyroidism and goiter. The diagnosis of goiter is made by ultrasonography, which shows an increase in thyroid volume and in extreme cases hyperextension of the neck due to a large neck mass.[45] Few cases of hyperthyroidism have been confirmed by measuring serum T_4 and TSH in fetal blood obtained by cordocentesis.[50] Cordocentesis should be performed in a tertiary referral center and should be limited to the rare situations in which the diagnosis of fetal thyroid dysfunction cannot be established on clinical grounds.[51] Treatment with intra-amniotic injection of L-thyroxine, as well as discontinuation of antithyroid drugs, has resulted in resolution of the goiter.

Breastfeeding should be permitted if the daily dose of PTU or MM is less than 300 mg/day or 20 mg/day, respectively. It is prudent to give the total dose in divided doses after each feeding. Occasionally, thyroid function tests may be done in the baby.[52] In a very provocative study, PTU was given to lactating hyperthyroid mothers whose infants were born with elevated serum TSH levels. Infant TSH levels normalized even with continuation of PTU therapy by the mothers. In another study, thyroid tests were done at regular intervals in breastfed infants of mothers taking up to 20 mg of MM daily, showing no evidence of hypothyroidism. The authors followed the children up to 74 months of age, and there was no evidence of physical or intellectual developmental deficits compared with 176 controls.

Fetal surveillance with serial ultrasounds, nonstress testing, and the biophysical profile is indicated for cases with uncontrolled hyperthyroidism, in the presence of fetal tachycardia or IUGR, in pregnancies complicated by preeclampsia, or when indicated for other obstetrical or medical complications.

Treatment of Thyroid Storm

Thyroid storm is a clinical diagnosis based on severe signs of thyrotoxicosis, with significant hyperpyrexia (>103° F) and neuropsychiatric symptoms that are essential for the clinical diagnosis. Tachycardia with a pulse rate exceeding 140 beats/minute is not uncommon, and congestive heart failure is a frequent complication. Gastrointestinal symptoms such as nausea and vomiting, accompanied by liver compromise, have been reported. Burch and Wartofsky have derived a scoring system based on clinical symptoms to predict the likelihood of thyroid storm. Laboratory tests show the classic hyperthyroid changes, although the actual elevation in FT_4 values does not help in the diagnosis.

Management includes the following:

1. Admission to the intensive care unit for supportive therapy such as fluids and correction of electrolyte abnormalities, oxygen therapy as needed, and control of hyperpyrexia. Acetaminophen is the drug of choice because aspirin may increase free thyroid hormones.
2. Management of congestive heart failure, which may require large doses of digoxin.
3. Proper antibiotic therapy in case of infection.
4. β-Adrenergic blocker therapy to control hyperadrenergic symptoms, such as propranolol, 60 to 80 mg every 4 hours orally or 1 mg/minute intravenously. Esmolol, a short-acting β-acting antagonist, given intravenously with a loading dose of 250 to 500 mcg/kg of body weight followed by continuous infusion at 50 to 100 mcg/kg per minute, may be used.

5. MM, 30 mg, or PTU, 300 mg every 6 hours. If the patient is unable to take oral medications, a nasogastric tube may be needed; thioamides block the synthesis of thyroid hormones in a few hours.
6. One hour after the administration of thioamides, iodine is administered in the form of Lugol's solution, 10 drops three times a day or, if available, sodium iodide, given intravenously 1 g every 12 hours.
7. Glucocorticoids are also helpful because they reduce the peripheral conversion of serum T_4 to T_3, in the form of hydrocortisone every 8 hours; or equivalent amounts of other glucocorticoids.

In summary, thyroid storm is a life-threatening condition, with a mortality rate of 20% to 30%,[53] requiring early recognition and aggressive therapy in an intensive unit care setting.

Neonatal Hyperthyroidism

Neonatal hyperthyroidism is infrequent, with an incidence of less than 1% of infants born to mothers with Graves disease, therefore affecting 1 in 50,000 neonates. **In most cases, the disease is caused by the transfer of maternal immunoglobulin antibodies to the fetus.** These stimulating thyroid antibodies to the TSH receptor (TSIs), when present in high concentrations in maternal serum, cross the placental barrier, stimulate the TSH receptor of the fetal thyroid gland, and may produce fetal or neonatal hyperthyroidism. When the mother is treated with antithyroid medications, the fetus benefits from maternal therapy, remaining euthyroid during pregnancy despite the high circulating antibody titer. However, the protective effect of the antithyroid drug is lost after delivery, and neonatal hyperthyroidism may develop within a few days after birth. High titers of TSI receptor antibodies, a threefold to fivefold increase over baseline, in the third trimester of pregnancy are a predictor of neonatal hyperthyroidism. If neonatal hyperthyroidism is not recognized and treated properly, neonatal mortality could be as high as 30%. Because the half-life of the antibodies is only a few weeks, complete resolution of neonatal hyperthyroidism is the rule.

A few cases of familial neonatal Graves disease have been reported. The pathogenesis is not clearly understood. This condition may persist for several years.

Sporadic cases of neonatal hyperthyroidism without evidence of the presence of circulating TSI in mother or infant have been published. Activation of mutations in the TSH receptor molecule are the cause of this entity. It is inherited as an autosomal dominant trait and, in contrast to Graves neonatal hyperthyroidism, the condition persists indefinitely. Treatment with antithyroid medications followed by thyroid ablation therapy will eventually be needed.

Fetal Hyperthyroidism

In mothers with active hyperthyroidism due to Graves disease, high concentrations of TSIs crossing the placental barrier stimulate fetal T_4 receptor and may cause fetal hyperthyroidism. However, in mothers with active disease who are under treatment, the hyperactive fetal thyroid is controlled by maternal therapy, and the fetus remains euthyroid during fetal life. Within a few days after birth, when the beneficial effect of antithyroid therapy ceases, the neonate may develop neonatal hyperthyroidism (see previous section, Neonatal Hyperthyroidism). **Women at risk for fetal hyperthyroidism are those with a history of Graves disease previously treated with ablation therapy, either surgery or ^{131}I, because these immunoglobulin G (IgG) class antibodies may remain elevated after ablation therapy despite maternal euthyroidism.** The fetuses of women with Graves disease–associated hyperthyroidism who undergo therapeutic thyroidectomy in the second trimester of pregnancy are also at risk for hyperthyroidism if the mother carries high titers of TSHRAbs.[30] The fetal thyroid TSH receptor starts responding to TSI stimulation during the second trimester, and the placental transfer of IgG from mother to fetus increases by the end of the second trimester, reaching a level in the fetus similar to that of the mother at about 30 weeks' gestation. Therefore, the symptoms of fetal hyperthyroidism are not evident until 22 to 24 weeks of gestation.

Fetal hyperthyroidism is diagnosed in the presence of persistent fetal tachycardia (>160 beats/minute), IUGR, oligohydramnios, and occasionally a goiter identified on ultrasonography, sometimes manifested as hyperextension of the fetal neck.[45] The diagnosis may be confirmed by measuring thyroid hormone levels in cord blood obtained by cordocentesis. Serial cordocentesis for monitoring drug therapy has been proposed, but its value has been questioned.[51] A fetal heart monitor tracing demonstrating a sustained baseline of 170 to 180 beats/minute with moderate variability that exhibited acceleration with a lack of deceleration was present in two fetuses of hyperthyroid mothers. The authors stated that "this pattern is unique to fetal thyrotoxicosis." Heckel and associates reviewed nine cases of fetal hyperthyroidism treated by maternal administration of antithyroid medications. Fetal tachycardia was the most frequent sign, whereas oligohydramnios and IUGR were reported in only two cases. Fetal goiter was detected by ultrasonography in three cases. Treatment consisted of antithyroid medication given to the mother (MM, 10 to 20 mg/day).[54] The dose is guided by the improvement and resolution of fetal tachycardia, a decrease in the goiter size, and normalization of fetal growth. All are indicators of good therapeutic response.

Luton and associates[45] performed clinical fetal evaluation in 72 mothers with a past or present history of Graves hyperthyroidism. The main tools were the determination of maternal TSHRAbs and fetal ultrasonography. Cordocentesis was rarely indicated. In 31 mothers, TRAb titers were undetectable, and none of the patients received antithyroid medications. All infants were born euthyroid. Of 30 women positive for TRAb and on therapy, neonatal function was normal. Eleven fetuses were diagnosed with goiter by ultrasonography, and 7 of them were hypothyroid at birth. Their mothers had low TRAb titers and had received antithyroid therapy, probably in higher doses than needed. In the 4 hyperthyroid newborns, maternal TRAb titers were very high, and their mothers may not have received enough medication. The authors recommended monthly fetal ultrasonography after 20 weeks' gestation with determination of TRAbs early in gestation and again by 24 to 28 weeks' gestation.

TABLE 40-6 INDICATIONS FOR MATERNAL DETERMINATION OF THYROID-BINDING INHIBITOR IMMUNOGLOBULIN OR THYROID-STIMULATING IMMUNOGLOBULIN FOR DIAGNOSIS OF GRAVES DISEASE

- Fetal or neonatal hyperthyroidism in previous pregnancies
- Active disease or treatment with antithyroid drugs
- Thyroidectomy during pregnancy
- Euthyroid, postablation (surgery, iodine-131)
- In the presence of:
  - Fetal tachycardia
  - Intrauterine growth restriction
  - Incidental fetal goiter on ultrasound

From Mestman JH: Endocrine diseases in pregnancy. *In* Sciarra JJ (ed): Gynecology and Obstetrics. Philadelphia, Lippincott-Raven, 1997, p 27.

In summary, the diagnosis of fetal hyperthyroidism should be suspected in the presence of fetal tachycardia, IUGR, oligohydramnios or polyhydramnios, and accelerated bone maturation, with or without fetal goiter, in mothers with active hyperthyroidism or in women with a history of Graves disease treated previously by ablation therapy, and in the presence of high titers of serum TRAbs. The indications for ordering a determination of TRAbs are described in Table 40-6. This should be done in patients at risk between 22 and 28 weeks' gestation, although some investigators recommended this test early in pregnancy and late in the second trimester.[45] The diagnosis may be confirmed by the determination of fetal thyroid hormones by cordocentesis, in those centers with expertise in this technique.

Neonatal Central Hypothyroidism

Infants of untreated hyperthyroid mothers may be born with transient central hypothyroidism of pituitary or hypothalamic origin. High levels of T_4 cross the placental barrier and feed back to the fetal pituitary with suppression of fetal pituitary TSH. The diagnosis is made in the presence of a low FT_4 and a normal or low TSH level in cord blood. This complication should be avoidable with proper management of maternal hyperthyroidism.[44]

Resistance to Thyroid Hormone Syndrome

Described by Refetoff and colleagues, resistance to thyroid hormone (RTH) is a syndrome of reduced end-organ responsiveness to thyroid hormone, caused primarily by mutations in the thyroid hormone receptor β-gene. Unaffected fetuses of mothers with RTH syndrome and affected fetuses from normal mothers are at risk for poor obstetrical outcome. However, most of these pregnancies have no major consequences. Anselmo and associates reported 36 couples with 9 mothers and 9 fathers affected by the disease and 18 unaffected relatives. The rates of miscarriage were 23.7% in affected mothers, 6.7% in affected fathers, and 8.8% in unaffected first-degree relatives, with a rate of 8.1% in the general population. The birthweight of unaffected infants born to affected mothers was lower than the birthweight of affected newborns, who in addition had a lower serum TSH at birth. This finding suggests that high maternal thyroid hormone levels produced fetal thyrotoxicosis and had a direct toxic effect on the fetus. The approach to a pregnant patient with the RTH syndrome would depend on the genotype of the fetus. This requires obtaining the genotype of the fetus from DNA through amniocentesis, a history of the course and outcome of previous pregnancies, and information about other family members with RTH syndrome.[55]

Hypothyroidism

Until 1980, few cases of pregnancy in women with myxedema were published because it was believed that most hypothyroid women were infertile. Soon after the determination of serum TSH became available to establish the diagnosis of hypothyroidism, a few series of hypothyroidism in pregnancy were described.[56-58] The incidence of hypothyroidism, defined at the time of these publications as an elevation in serum TSH above 5 mIU/L, was reported to be between 2% and 4%.[59] Mild elevations in serum TSH are detected in 50% to 60% of treated hypothyroid women soon after conception as the result of the increased demand for thyroid hormones in the first weeks of gestation. There are many unresolved and controversial issues about the management of hypothyroidism, the incidence of abnormal obstetrical outcomes, universal versus selective screening, and the need for L-thyroxine therapy in subclinical hypothyroidism.[60,61] Several topics related to hypothyroidism will be discussed separately under the following headings: (1) Etiology and Classification of Hypothyroidism, Subclinical Hypothyroidism, Clinical Hypothyroidism, Isolated Hypothyroxinemia, and Universal Versus Selective Screening.

Etiology and Classification of Hypothyroidism

The two most common etiologies of primary hypothyroidism in countries with sufficient dietary iodine supply are autoimmune thyroiditis (Hashimoto thyroiditis) and post-thyroid ablation therapy, either surgical or ^{131}I induced. Other causes include congenital (about 1 in 3000 births in the United States), drug induced (lithium, amiodarone, iodine excess, antithyroid drugs), prior head and neck radiation for nonthyroid malignant disease, and congenital defects in thyroid hormone biosynthesis. Transient forms of hypothyroidism, rarely seen during pregnancy, are painful subacute thyroiditis and silent thyroiditis; the latter is observed in postpartum thyroiditis. Earlier studies in women with "hypothyroxinemia," diagnosed as a low serum protein-bound iodine (serum TSH was not available for the diagnosis of hypothyroidism), reported a high incidence of congenital malformations, perinatal mortality, and impaired mental and somatic development in infants of hypothyroid women. In contrast, recent reports showed no increase in the incidence of congenital malformations. However, there is an increased risk for adverse pregnancy complications as well as detrimental effects on neurocognitive development of the offspring.[25,26] Secondary hypothyroidism includes diseases of the pituitary gland or hypothalamus. Autoimmune hypophysitis as a cause of secondary hypothyroidism is of interest to the obstetrician for its relationship to Sheehan syndrome.

Regardless of the etiology, primary hypothyroidism is classified as subclinical hypothyroidism (normal serum T_4 and elevated serum TSH) and overt or clinical

hypothyroidism (low serum T_4 and elevated TSH). The spectrum of pregnant women diagnosed with hypothyroidism includes: (1) women with subclinical and overt hypothyroidism diagnosed for the first time during pregnancy; (2) hypothyroid women who discontinue thyroid therapy before or at the time of conception because of poor medical advice or because of the misconception that thyroid medications may affect the fetus; (3) women on thyroid replacement therapy requiring larger doses in pregnancy; (4) women previously diagnosed but not consistent in taking their medication; (5) hyperthyroid patients on excessive amounts of antithyroid drug therapy; and (6) some patients on lithium or amiodarone therapy because both drugs may affect thyroid function, particularly in women affected by chronic thyroiditis.

Subclinical Hypothyroidism

Most patients with subclinical hypothyroidism do not have symptoms. Thyroid tests may be requested by the physician because of vague symptoms resembling hypothyroidism, a past history of thyroid disease, a family history of thyroid disease, or findings in the physical examination such as the presence of a goiter. As discussed later, in women presenting for preconception counseling or at the time of the first obstetrical visit, a selective list of potential risk factors should be evaluated, and if any are positive, thyroid tests should be obtained. **Laboratory tests diagnostic of subclinical hypothyroidism are an elevated serum TSH in the presence of normal trimester-specific FT_4 levels.** A determination of TPOAbs is helpful to determine the etiology of hypothyroidism because they are present in 70% to 80% of hypothyroid patients of childbearing age. As mentioned earlier under Thyroid Function Tests, normal values for serum TSH are gestation-specific reference ranges, with an upper limit of normal of 2.5 mIU/L in the first trimester and up to 3 mIU/L in the second and third trimesters.[28] A significant number of hypothyroid women on thyroid replacement therapy are euthyroid before conception but become hypothyroid, most of them subclinical, at the time of the first obstetrical visit because of the physiologic increase in the need for thyroid hormones in the first trimester of pregnancy.[31,32] In some studies, women with subclinical hypothyroidism are at risk for adverse pregnancy complications, such as miscarriage, preterm delivery, and preeclampsia.[58-63] Lower IQs in their infants and other neurocognitive deficits have been described.[25,26]

In 1993, Leung and colleagues reported on a group of 45 women diagnosed with subclinical hypothyroidism, defined at that time as a serum TSH of more than 5 mIU/L and normal FT_4I.[58] Of the 7 women developing preeclampsia, 4 had serum TSH levels between 5 and 10 mIU/L at booking.

Casey and associates[62] undertook a prospective thyroid screening study to evaluate pregnancy outcomes in women with subclinical hypothyroidism diagnosed before 20 weeks' gestation. The mean age of their patients was 26.9 years, and their ethnicity included 84% Hispanics; 7% African American, and 4% Caucasians. Their body mass index (kg/m^2) was 32.1 ± 6.3. Four hundred and four women (2.3% of the 17,298 screened) were considered to have subclinical hypothyroidism. Compared with euthyroid women, pregnancies of women with subclinical hypothyroidism were three times more likely to be complicated by placental abruption (relative risk [RR], 3.0; 95% CI, 1.1 to 8.2); preterm birth (before 34 weeks' gestation) was almost twofold higher (RR, 1.8; 95% CI, 1.1 to 2.9); and admission of their newborns to the neonatal intensive care nursery and respiratory distress was twice as likely (RR, 1.8; 95% CIs, 1.1 to 2.9 and 1.0 to 3.3, respectively).

On the contrary, Cleary-Goldman and colleagues[63] reported no adverse outcomes in a group of 247 women with subclinical hypothyroidism diagnosed on the basis of a serum TSH more than the 97.5th percentile and free T_4 between the 2.5th and 97.5th percentiles. They included 10,990 women from the FASTER Trial, a National Institute of Child Health and Human Development (NICHD)-sponsored study. They included several centers in the United States; 86% of the women were Caucasian, 1.7% African American, and 7.2 % Hispanics. Serum TSH values between 0.004 and 0.035 mIU/L represented values less than the 2.5th percentile in the first trimester, and a FT_4 less than the 2.5th percentile was reported at between 0.3 and 0.71 ng/dL. Their conclusion was that "maternal thyroid hypofunction is not associated with adverse outcomes."

In a recent randomized study by Negro and colleagues[64] in southern Italy, 4657 women were screened for serum TSH and TPOAbs within the first 11 weeks of gestation. Of this group, 642 women presented with a serum TSH between 2.5 and 5 mIU/L and negative TPOAbs. The pregnancy loss rate was 6.1%, compared with 127 of 3481 (3.6%) in women with a serum TSH below 2.5 ($P = .006$). All the pregnancy losses were due to miscarriages. There were no significant differences in preterm deliveries or other obstetrical outcomes between the groups. None of the patients with an elevated TSH received L-thyroxine therapy. Of note, Kuppens and coworkers[65] reported an increased risk for breech presentation in women with TSH levels above 2.5 mIU/L at the end of gestation.

There are no published randomized prospective studies at the present time on the effect of L-thyroxine treatment of subclinical hypothyroidism in women early in pregnancy, on pregnancy outcome, or on the neurodevelopment of their offspring. Two large population-based studies are underway. One of them, in the United Kingdom, includes 22,000 pregnant women recruited before 16 weeks' gestation. Mothers diagnosed with hypothyroidism or hypothyroxinemia will be randomized to L-thyroxine therapy versus placebo; the outcome end point of the study will be the percentage of children with an IQ of less than 85 at 3.5 years of age, comparing children from both groups and a control group. The second study should be completed by 2015. It is organized by the NICHD and includes a total of 120,000 pregnant women from 14 institutions in the United States. In this randomized study, women with subclinical hypothyroidism or hypothyroxinemia will receive L-thyroxine or placebo, and the obstetrical outcome and the neurocognitive function of the offspring will be evaluated.

Negro and colleagues[66] reported the results in a subset of first-trimester women recruited as part of a study evaluating universal screening versus case finding for the detection of thyroid dysfunction. Patients were grouped in a

high-risk and a low-risk group according to risk factors for thyroid disease. An adverse obstetrical outcome was the end point of the study. In those women considered low risk, rates of pregnancy-related adverse events were reduced by nearly 40% after detection and treatment.[67]

Clinical Hypothyroidism

The clinical diagnosis of hypothyroidism in pregnancy is confirmed by the presence of an elevated serum TSH and an FT_4 below the trimester-specific reference range. Patients with overt hypothyroidism may complain of tiredness, cold intolerance, fatigue, muscle cramps, constipation, irregular menstrual periods, infertility, and deepening of the voice. On physical examination, the skin may be dry and cold, deep tendon reflexes may be delayed, and bradycardia may be detected as well as periorbital edema. A goiter is present in almost 80% of patients in whom the etiology is chronic thyroiditis. The characteristic goiter is a diffuse enlargement of the thyroid gland, about two to three times the normal size, firm to palpation, painless, and with a rubbery consistency. In the other 20% of women with chronic thyroiditis, no goiter is found (*atrophic thyroiditis*, also known as primary myxedema or chronic thyroiditis without goiter). A well-healed scar in the neck is seen in those patients with prior surgical thyroidectomy. The degree of severity of the clinical symptoms varies with the thyroid abnormalities on testing, although there is not always good correlation between clinical and chemical parameters. It is important to emphasize that many patients with frank hypothyroidism by laboratory tests offer no specific complaints. Spontaneous pregnancies have been reported in newly diagnosed women with a serum TSH higher than 150 mIU/L at the time of the first obstetrical visit![57]

Early studies had used a serum TSH above 5 to 6 mIU/L for diagnostic purposes, with normal values derived from a healthy nonpregnant population. In our own series,[58] the mean TSH value at the time of diagnosis of overt hypothyroidism was 89.7 + 86.2 mIU/mL (normal, 0.4 to 5.0), with a mean FT_4I of 2.1 + 1.5 (normal, 4.5 to 12). **Serum thyroid antibodies (TPOAbs, also known as antimicrosomal antibodies), are elevated in almost 95% of patients with autoimmune hypothyroidism.** Serum antithyroglobulin antibodies (TGAbs) are elevated in about 60% of patients with chronic thyroiditis; in a few patients, about 5%, TGAb is the only antibody present. The titer of antibodies does not correlate with the size of the goiter or the clinical severity of hypothyroidism but could be a predictor for the development of postpartum thyroiditis.

As in the case of hyperthyroidism, untreated overt hypothyroidism is associated with adverse neonatal outcomes, including premature birth, SGA infants, and in one study, an increased prevalence of fetal death. **One of the most common obstetrical complications is PIH, with an incidence of 21% in a combined study of 60 patients with overt hypothyroidism.**[57,58] PIH has not been reported in all series, although some of them were retrospective analyses. In some series, a higher incidence of PIH was reported in euthyroid women on thyroid replacement therapy. Low birthweight was detected in 16.6% of births, mostly related to preterm delivery. In one series,[57] 2 of 12 women with subclinical hypothyroidism developed postpartum hemorrhage. Abalovich and associates reported on 150 pregnancies in 114 hypothyroid women. Sixteen of these women were overtly hypothyroid at conception, 60% of them suffered a spontaneous abortion, and 20% of them had a premature delivery; all women properly treated carried their pregnancy to term.

The impact of maternal hypothyroidism on the intellectual development of the offspring has been the subject of several studies.[25,26] In the report by Haddow and coworkers,[25] children born to untreated mothers with elevations of serum TSH, measured between 16 and 18 weeks' gestation, were studied at age 7 to 9 years. They reported a seven-point decrease in IQ score on the Wechsler Intelligence Scale for Children and delays in motor, language, and attention. Nineteen percent of children of untreated mothers had an IQ below 75. In another study from Japan, Lui and colleagues examined a group of eight children at ages 4 and 10. IQs were compared in children whose mothers were hypothyroid in the first trimester, with their siblings when the mothers were euthyroid throughout gestation. There was no difference in the IQs of both groups of children. Mann and colleagues had reported lower IQs in children from a group of mothers considered hypothyroxinemic in pregnancy (serum TSH was not available at the time of the study). When they were studied at age 7 years, 5 of 21 (24%) had an IQ of less than 80, compared with a low IQ found in 10% of control children.

These earlier studies appear to support earlier animal research showing the importance of maternal transfer of T_4 in the first trimester of pregnancy, at a time when the fetal thyroid had not yet developed. From a practical point of view, these reports emphasize the importance of diagnosing thyroid insufficiency in women at risk for thyroid disease and promptly adjusting the dose of T_4 in women under treatment for hypothyroidism soon after conception.

Isolated Hypothyroxinemia

The term *isolated hypothyroxinemia* is reserved for those patients in areas of sufficient dietary intake with below trimester-specific FT_4 reference range in the presence of normal serum TSH values. The physiopathologic explanation for such an entity is not clear; maternal hypothyroxinemia is extremely frequent in endemic areas of iodine deficiency and is associated with increased perinatal morbidity and mortality and an increased incidence of hypothyroidism in neonates as well.[68] It is rare in nonendemic iodine-deficient areas. Pop and coworkers detected a lower Bayley Psychomotor Developmental Index at 10 months of age in a small group of children born to mothers with low FT_4 but normal TSH (hypothyroxinemia) at 12 weeks' gestation. They extended their studies to infants aged 1 to 2 years, reporting an 8 to 10 point deficit in psychomotor testing among offspring born to mothers with low FT_4 levels in the first 24 weeks of their pregnancies; babies whose mothers had a spontaneous normalization of FT_4 after 24 weeks' gestation had normal development, suggesting that prolonged hypothyroxinemia was the cause of impairment of fetal neural development. Recently, two reports from iodine-sufficient countries reaffirmed the adverse role of maternal hypothyroxinemia in neuropsychological development of children. Li and colleagues

collected serum from 1268 women at 16 to 20 weeks' gestation, selected from a cohort of women who underwent screening for Down syndrome at Shenyang Maternal and Neonatal Health Clinic, in an area described as "iodine sufficient." Serum TSH, TT_4, FT_4, and TPOAb were measured. Women with other medical conditions were excluded from the study. Gestation-specific reference ranges were determined from a control group of 120 healthy pregnant women randomly selected from the enrolled cohort group; three groups of patients were identified, and intellectual and motor development scores were evaluated in the children from these pregnancies at 25 to 30 months of age, using the Bayley Scales of Infant Development. Eighteen women (1.8%) were diagnosed as having subclinical hypothyroidism; 19 women were hypothyroxinemic (1.5%), and 34 (2.6%) were euthyroid with an elevated level of TPOAbs. The authors concluded that maternal subclinical hypothyroidism, hypothyroxinemia, and euthyroidism with elevated serum TPOAb titers are all statistically significant predictors of lower motor and intellectual development at 25 to 30 months. Henrichs and colleagues,[26] in a population-based cohort study in the Netherlands, studied a group of pregnant women at about 13 weeks' gestation with severe hypothyroxinemia, defined as FT_4 concentrations below the 10th and 5th percentiles, respectively. Verbal and nonverbal cognitive development was assessed at 18 and 30 months of age in their children. Expressive vocabulary at 18 months was assessed by the MacArthur Communicative Development Inventory, and at 30 months, mothers were asked to complete the Language Development Survey. Of the mothers in this study, 1.5% had hypothyroidism, 8.5% had mild hypothyroxinemia, and 4.3% had severe hypothyroxinemia. The authors observed that mild and severe hypothyroxinemia were associated with a higher risk for expressive language delay across all ages (mild: OR = 1.44; 95% CI = 1.09 to 1.91; $P = .010$, and severe: OR = 1.8; 95% CI = 1.24 to 2.61; $P = .002$). Severe maternal hypothyroxinemia predicted a higher risk for both verbal and nonverbal cognitive delay (OR = 2.03; 95% CI = 1.22 to 3.93; $P = .007$). It is of interest in this study that a significant percentage of women had hypothyroxinemia, a total of 12.8%, compared with 1.5% with hypothyroidism. Perhaps iodine deficiency in this population could be the explanation for the high incidence of hypothyroxinemia. Hypothyroxinemia was observed in 0.9% of 2899 women tested between 4 and 12 weeks' gestation by Wang and coworkers in China, with a median urinary iodine level of 177.15 mcg/L, well within the accepted range in areas of iodine sufficiency. No adverse obstetrical outcomes were reported by Casey and associates[69] in evaluating 17,289 women before 20 weeks' gestation; the prevalence of hypothyroxinemia was 1% and subclinical hypothyroidism 3%: Cleary-Goldman and colleagues[63] reported a prevalence of hypothyroxinemia of 2.1% (232 of 10,990 women) in the first trimester and 2.3% in the second trimester of pregnancy.

Universal versus Selective Screening for Thyroid Disease

Despite the potential obstetrical and offspring complications due to maternal thyroid dysfunction reported in the past 50 years, the consistency of reports on the incidence of maternal subclinical and clinical hypothyroidism in the first trimester, and our recognized difficulty in diagnosing the disease, both by medical history and physical examination, **when and how to screen for thyroid disease in pregnant and nonpregnant individuals remains a very controversial issue, with different positions adapted by several medical organizations.** A consensus Development Conference regarding subclinical thyroid disease was sponsored by the American Association of Clinical Endocrinologist, the ATA, and the Endocrine Society. Their recommendation, based on an extensive review of the published literature available at that time, limited thyroid tests to women at high risk for thyroid disease[70]; the Committee on Obstetric Practice of the American College of Obstetricians and Gynecologists, in 2007, stated that "without evidence that identification and treatment of pregnant women with subclinical hypothyroidism improves maternal or infant outcomes, routine screening for subclinical hypothyroidism currently is not recommended." **It is reasonable to perform a determination of serum TSH at the first obstetrical visit in those women at higher risk for thyroid dysfunction** (Table 40-7). In the revised version of the Endocrine Society Guidelines (in preparation), and the ATA Clinical Guidelines for Thyroid and Pregnancy,[70a] universal screening is not recommended, but it is strongly suggested that health care professionals personally ask during preconception counseling or in the first obstetrical visit about risk factors for thyroid disease. The main barrier to universal screening is the lack of RCTs demonstrating a reversal of both obstetrical and intellectual abnormalities in the offspring after normalization of thyroid deficiency by maternal L-thyroxine replacement therapy.

Several studies have consistently demonstrated the failure to recognize women at risk for thyroid dysfunction when using a case-finding strategy, based on actual thyroid dysfunction symptoms, a personal or family history of thyroid disease, and past obstetrical history.

Vaidya and coworkers[71] offered thyroid function tests early in pregnancy to 1560 women to evaluate the effectiveness of universal screening versus case finding. They showed that targeted screening would still have missed about one third of all pregnant women with an elevated serum TSH. They divided women early in pregnancy into two groups: a low-risk group, which included 75% of the women; and a high-risk group, including the remaining

TABLE 40-7 INDICATIONS FOR THYROID TESTING IN PREGNANCY

1. History of thyroid dysfunction or prior thyroid surgery
2. Age >30 years
3. Symptoms of thyroid dysfunction or the presence of goiter
4. Thyroid peroxidase antibody positive
5. Type I diabetes or other autoimmune disorders
6. History of head/neck radiation
7. Family history of thyroid dysfunction
8. Morbid obesity (body mass index ≥40 kg/m^2)
9. Use of amiodarone or lithium, or recent administration of iodinated radiologic contrast
10. Unexplained fertility
11. Residing in an area of known moderate to severe iodine sufficiency

Stagnaro-Green A et al: Guidelines of the American Thyroid Association for the Diagnosis and Management of Thyroid Disease During Pregnancy and Postpartum. Thyroid 21:1081, 2011.

25%. The high-risk group included those with a personal and family history of thyroid disorders or other autoimmune disease and current and past treatment with antithyroid drugs, L-thyroxine, radioiodine, or thyroid surgery. Forty women, 2.6% of the total group, had an elevated serum TSH, and 70% of them were in the high-risk group.

Similar conclusions have been reported in other studies. Wang and coworkers performed thyroid tests in the first trimester of pregnancy and classified 367 (12.7%) women out of 2899 as high risk, following the recommendations of the Endocrine Society Guidelines.[28] Of the 2899, 294 had thyroid dysfunction: hypothyroidism in 7.5% (most of them with subclinical hypothyroidism); 1% hyperthyroidism, and 0.9% hypothyroxinemia. Positive antibodies were detected in 279 (9.6%), and 196 of them were euthyroid. The prevalence of thyroid dysfunction in the high-risk group was higher than in the low-risk group (15% vs. 9.4%; $P = .001$). However, of the 217 women with an elevated serum TSH, 171 (78.8%) belonged to the low-risk group. The authors concluded that a case-finding strategy for screening thyroid function in the high-risk group would miss about 81.6% of women with an elevated serum TSH and 80.4% women with hyperthyroidism. Horacek and colleagues, in a study from the Czech Republic, concluded that more than 55% of pregnant women at risk would be missed if only those with high-risk criteria were examined. The authors stated that a more extensive screening of thyroid autoimmunity and dysfunction seems warranted.

Negro and colleagues[66] reported on a prospective randomized study of 4562 women in southern Italy. Thyroid tests were done very early in pregnancy. Their conclusion was that universal screening did not affect the rate of adverse events in comparison to targeted high-risk case finding, implying a negative outcome. As discussed in the section on Subclinical Hypothyroidism, in the same article by Negro and colleagues, a subgroup of low-risk patients detected to be hypothyroid were treated with L-thyroxine and compared with a nontreated group. The rate of pregnancy-related adverse events was reduced by nearly 40% after detection and treatment.

A cost-effectiveness approach comparing universal screening and case finding was reported in two studies, both concluding that universal screening is cost-effective compared with a case-finding strategy.[72] However, Thung and colleagues added in their conclusions that a wide range of circumstances should be considered before universal screening is adapted. The same position was voiced by Stagnaro-Green and Schwartz.

There are a number of barriers before universal routine thyroid function screening can be recommended in pregnancy.[73] They include the selection of thyroid tests to be used (TSH, FT_4, TPOAb), the threshold applied to characterize an abnormality, weeks of gestation, appropriate intervention, and monitoring. The second issue still in dispute is the management of hypothyroid women in the preconceptional period. It is accepted that most of these women will need an increase in the L-thyroxine dose soon after conception.[31,32] It could be argued whether the target of serum TSH between 0.3 to 2.5 mIU/L before pregnancy is reasonable in anticipation of the increase in T_4 requirements. Abalovich and associates[74] reported that when the serum TSH is below 1.3 mIU/L before conception, only 17% of women need an increase in L-thyroxine in the first trimester. It has also been recommended that women on L-thyroxine therapy be advised at the time of confirmation of pregnancy to increase their dose empirically by two doses a week until the results of the thyroid tests are available.[32]

Therefore, until the British study and the NICHD Maternal-Fetal Medicine Units Network studies are completed, the issue of universal screening and L-thyroxine treatment for women with subclinical hypothyroidism or euthyroid chronic thyroiditis diagnosed before conception or during pregnancy is open for discussion. **The practicing physician should decide based on his or her own clinical practice whether universal screening versus case finding is warranted, and which women may benefit from T_4 therapy.**

Euthyroid Chronic or Hashimoto Thyroiditis

Chronic or Hashimoto thyroiditis[75] is a benign inflammatory disorder of the thyroid gland, the incidence depending on the definition of the entity. For example, in a long-term follow-up study in the Whickham survey, the incidence in women was 3.5 cases per 1000 per year, as contrasted with an incidence in men of 0.8 case per 1000 per year. The prevalence increases with age. In most cases, there is a family history of thyroid disease, with 18% of relatives affected in one study. **Chronic autoimmune thyroid disease is more common in women with other autoimmune diseases, particularly type 1 diabetes.**

With the advent of more sensitive assays for the determination of anti-TPO antibodies, the prevalence of chronic thyroiditis in women of childbearing age is estimated to be between 5% and 20%, depending on the type of population. The classic clinical picture is characterized by the presence of a goiter, moderate in size, bilateral in most cases, with one lobe larger than the other, with a firm, rubbery consistency, and moving freely on swallowing. It is painless, although rapid growth of the gland may elicit some tenderness on palpation. Absence of goiter (atrophic thyroiditis) may be present in 20% to 30% of patients.

On presentation, patients have no symptoms of thyroid dysfunction. A goiter is discovered on routine physical examination or detected by the patient herself or a family member or acquaintance. The diagnosis may be suggested by a hyperechoic pattern on an ultrasound of the thyroid gland. The diagnosis is confirmed by the presence of thyroid autoantibodies (anti-TPO or antithyroglobulin autoantibodies). The actual antibody titer is not correlated with the size of the goiter, symptoms, or severity of the disease. From a practical point of view, there is no need to perform a determination of TGAb if TPOAb are positive. Serum TSH should be ordered to rule out thyroid dysfunction. If the serum TSH is elevated, a serum FT_4 will determine whether the patient suffers from subclinical or clinical hypothyroidism (see earlier section, Hypothyroidism). Patients with euthyroid chronic thyroiditis may develop hypothyroidism over time. The OR was 8 over 20 years in those women with a normal serum TSH and positive antibodies.[34]

The importance of diagnosing chronic thyroiditis in women of childbearing age relates to the potential consequences in pregnancy and the postpartum period.

Women with chronic thyroiditis known to be euthyroid should be evaluated early in pregnancy because they are at risk for developing hypothyroidism de novo, miscarriages, prematurity (according to some studies), and breech presentation.[76]

In a rare situation, women with chronic thyroiditis, particularly those without a goiter, the atrophic form, may have high titers of serum TSHRAb, blocking antibodies (TRAb), compared with the stimulating antibodies present in women with Graves hyperthyroidism. These antibodies cross the placenta and, at high titers, block the fetal TSH receptor, causing transient congenital hypothyroidism.[77] The neonatal disease resolves spontaneously over 3 to 6 months as the maternal antibody is degraded. In a large population of patients screened in New York, of 788 infants with suspected congenital hypothyroidism, 9 mothers and their infants had these antibodies.[78] Therefore, in mothers who have given birth to infants with congenital hypothyroidism, thyroid tests, including TRAb, should be determined.

In 1990, Stagnaro-Green and colleagues[76] reported a twofold to threefold increased risk for spontaneous abortion in euthyroid women with positive thyroid autoantibodies, studies confirmed by later publications. One of the caveats in the early studies was that the upper normal range for serum TSH values was up to 5 mIU/L, compared with the accepted value of up to 2.5 mIU/L recommended by recent guidelines; therefore it is possible that some of the reported TPOAb-positive pregnant women had subclinical hypothyroidism. Prematurity and its relationship to thyroid autoimmunity was recently reviewed by Stagnaro-Green, who concluded that preterm delivery was associated with the presence of thyroid antibodies in three out of four reports from Belgium, Italy, Japan, and Pakistan. Haddow and coworkers[79] reported on the relationship between preterm delivery in euthyroid TPOAb-positive women studied late in the first trimester from the FASTER trial. The authors did not confirm previous studies of an association between preterm delivery and euthyroid chronic thyroiditis. They reported, however, a significant increase in preterm premature rupture of the membranes in the TPOAb-positive euthyroid group and concluded that from the six studies published, four of them reviewed by Stagnaro-Green, the evidence for a relationship between preterm delivery and chronic thyroiditis was not conclusive. The relationship was reported in three and refuted in the other three reports. Mannisto and associates,[80] in a prospective study including 9247 singleton pregnancies in Finland, found that the presence of TPOAbs in the first trimester was a risk factor for perinatal death, but not thyroid hormones status as such. In a group of 288 TPOAb-positive women, there was a twofold to threefold greater perinatal mortality than in antibody-negative mothers; four of seven perinatal deaths occurred preterm, before 28 weeks' gestation. Regarding the therapeutic use of L-thyroxine in women with euthyroid chronic thyroiditis (normal serum TSH and positive TPO antibodies), there is only one published study.[81] The authors performed thyroid tests including TPOAbs in a group of 984 women early in pregnancy; 113 (11.7%) of them were TPOAb positive, with normal serum TSH values (reference range, 0.27 to 4.2 mIU/L). Their first obstetrical visit was at 10.3 ± 3.1 weeks. Fifty-seven TPOAb-positive women were treated with L-thyroxine, with a dose between 0.5 and 1 mcg/kg per day according to TSH values and TPOAb titers. They were compared with 58 untreated TPOAb-positive women and a control group of TPOAb-negative women. Two end points were evaluated: the incidences of miscarriage and preterm delivery. The L-thyroxine-treated group had an incidence of complications similar to that of the control group, whereas the untreated chronic thyroiditis group had a threefold increase in miscarriages and preterm deliveries and in addition developed impaired thyroid function in the second half of pregnancy.

Pregnancy outcome in TPOAb-positive women was recently reported from the University of Texas Southwestern Medical Center,[82] the same population studied previously.[63] All women were screened before 20 weeks' gestation, at a mean gestational age of 11.9 weeks. Six percent of these women were TPOAb positive. As expected, the incidence in women with overt or clinical hypothyroidism was 61%, 31% in women with subclinical hypothyroidism, 5% in hypothyroxinemia, and 4% in euthyroid women. Of the entire cohort of women with positive antibodies, they were significantly older ($P < .001$), weighed more, and were more often parous than TPO-negative women. African American women had an incidence significantly lower than Hispanic and Caucasian women. The authors reported that the incidence of hypertensive disorders, diabetes, preterm birth, preterm premature rupture of the membranes, and cesarean delivery were not significantly different either before or after adjustment for demographic differences. The exception was the incidence of placental abruption; euthyroid TPOAb-positive women had a fourfold increased incidence compared with similar euthyroid TPOAb-negative women (OR = 4.0; 95% CI, 1.9 to 8.6). Of the 10 women with placental abruption who were TPOAb positive, 7 had euthyroid neonates. This finding and the rate of preterm birth were not significantly different between the two groups. Furthermore, they analyzed their observation of obstetrical and neonatal complications in subclinical hypothyroid women[63] and concluded that women with subclinical hypothyroidism and positive TPOAb were not at further increased risk for adverse outcomes, with the only exception being placental abruption. They recognized that their findings were not confirmed in other, similar studies.[62,81]

There is also agreement in the literature that the presence of TPOAb in the first trimester of pregnancy is a risk factor for the development of postpartum thyroiditis (see later section, Postpartum Thyroid Dysfunction).

Treatment of Hypothyroidism

L-Thyroxine is the drug of choice for the treatment of hypothyroidism. **In view of the complications mentioned previously, it is important to normalize thyroid tests as early as possible before conception or soon after the diagnosis of pregnancy.** In women on L-thyroxine replacement therapy, how much the dose will need to be increased from prepregnancy levels depends on the etiology of hypothyroidism.[83] The authors reported an increase in L-thyroxine dose of 16% by the second trimester in patients with primary hypothyroidism and a 51% increase following ablation therapy for Graves disease by surgery or ^{131}I

therapy. For patients with a history of thyroid cancer, the increase was 21% by the second trimester, depending on the level of TSH suppression recommended for cancer patients. In newly diagnosed pregnant women, an initial dose of 100 mcg of L-thyroxine is well tolerated by most young hypothyroid patients. The dose may be calculated according to body weight (2 to 2.4 mcg/kg per day), a dose higher than recommended in nonpregnant patients (1.7 to 2 mcg/kg per day). In patients with severe hypothyroidism, there is a delay in the normalization of serum TSH, but normal serum FT_4 or FT_4I values are achieved in the first 2 weeks of therapy if sufficient L-thyroxine is administered. The maintenance dose required for most patients is between 75 and 250 mcg of L-thyroxine per day.

Women planning their pregnancies should have a serum TSH below 2.5 mIU/L, ideally closer to 1 mIU/L, given the greater requirements expected early in gestation. The serum TSH should be repeated every 2 to 6 weeks during the first 20 weeks' gestation and at 24 to 28 weeks' and at 32 to 34 weeks' gestation. The aim is to keep serum TSH, as well as serum FT_4 or FT_4I, within normal trimester-specific reference ranges. The T_4 dose should be adjusted. Increased thyroid requirements are seen in about 20% to 30% of patients in the second half of pregnancy. Immediately after delivery, patients should return to their prepregnancy dose. Interference in the absorption of T_4 was discussed previously.[28]

Single Nodule of the Thyroid Gland

The incidence of thyroid nodularity in pregnancy was studied by several groups using ultrasonography. The three studies available were done in Belgium, Germany, and China in areas of mild iodine deficiency, where the incidence of thyroid nodules is increased. They examined the frequency of nodules, the effect of progression of pregnancy on nodule size, and new nodule formation. Together, they showed a prevalence of 3% to 23%, the incidence higher with increasing parity. In one prospective study of 212 Chinese women, the incidence of thyroid nodules was 15.3%. None of them was malignant. The mean diameter of the nodules was 5.1 mm in the first, 5.1 mm in the second, and 5.5 mm in the third trimesters. Struve and associates in Germany showed that increasing age and parity were associated with an increase in the number of thyroid nodules. In the Belgium study, 20 women, TPOAb negative, were diagnosed with thyroid nodular disease early in pregnancy. Although it was reported that 60% of the nodules increased in size with progression of pregnancy, the final nodule size was between 5 and 12 mm, making them difficult to recognize on thyroid palpation.

It is estimated that nodular thyroid disease is clinically detectable in 10% of pregnant women. In most cases, it is discovered during the first routine clinical examination or detected by the patient herself. The probability for a single or solitary thyroid nodule to be malignant is between 5% and 10% depending on risk factors such as previous radiation therapy to the head, neck, or chest; rapid growth of a painless nodule; patient age; and family history of thyroid cancer. Papillary carcinoma accounts for almost 75% to 80% of malignant tumors, and follicular neoplasm for 15% to 20%; a few percent are represented by medullary thyroid carcinoma. Undifferentiated thyroid carcinoma is extremely rare in patients younger than 50 years.

The incidence of thyroid carcinoma in the general population has risen significantly in the past two decades, perhaps because of the increased detection of small papillary cancers, from 3.6 per 100,000 in 1973 to 8.7 per 100,000 in 2002, a 2.4-fold increase (95% CI, 2.2 to 2.6; $P < .001$ for trend). In part, this increase could be explained by the routine use of thyroid ultrasonography.

It is estimated that as many as 14 of every 100,000 pregnancies in the United States are complicated by a new diagnosis of thyroid cancer. In a retrospective study from the California Cancer Registry from 1991 to1999, 129 cases of thyroid cancer were diagnosed during pregnancy: 3.3 per 100,00 diagnosed before pregnancy; 0.3 per 100,000 at the time of delivery and 10.8 per 100,000 within 1 year after delivery. In a selective group of patients operated on during or in the few months after delivery, the incidence of thyroid cancer was reported to be near 40%. In both studies, fine-needle aspiration biopsy (FNAB) of the thyroid nodule was obtained before surgery, with findings consistent with papillary carcinoma or a highly suspicious lesion. In this and other studies, patients were referred for management of potential malignant nodules and do not represent the true incidence of malignant thyroid tumors in pregnancy.

There is a paucity of information in the literature regarding the management and timing of the workup in the presence of thyroid nodularity. The ATA management guidelines for patients with thyroid nodules and differentiated thyroid carcinoma[84] recommended a similar evaluation of thyroid nodules in pregnancy as for the nonpregnant patient, with the exception, of course, that a radionuclide scan is contraindicated. In the presence of a thyroid nodule, they stressed the importance of a careful medical history, including a family history of malignant thyroid disease. If the family history is positive for familial medullary thyroid carcinoma or multiple endocrine neoplasia type 2, the evaluation of the nodule and management requires a more aggressive approach.

Careful examination of the neck enables the physician to define and characterize the thyroid lesion (Figure 40-5). In addition to the size of the nodule, the consistency, tenderness, fixation to the skin, and presence of metastasis in the thyroid bed should be noted. A hard, painless nodule, measuring more than 2 cm in diameter, is suspicious of malignancy. Thyroid, serum TSH, and FT_4 need to be assessed. A suppressed or undetectable TSH value in the presence of a single or dominant thyroid nodule is consistent with an autonomous or "hot" thyroid nodule, rarely malignant, in which case FNAB is not indicated. Interpretation of TSH values requires caution because a low or suppressed value may be present in a number of pregnancies in the first trimester. Serum calcitonin determination is reserved for patients with a family history of medullary thyroid carcinoma.[84] High-resolution real-time ultrasound, in expert hands, is very helpful in defining the size of the lesion, characterizing the dominant nodule in a multinodular gland, and identifying characteristics of the lesion suspicious for malignancy—solid, cystic, or mixed; microcalcifications; a hypoechoic pattern; irregular margins, among other findings. If FNAB of the nodule is indicated,

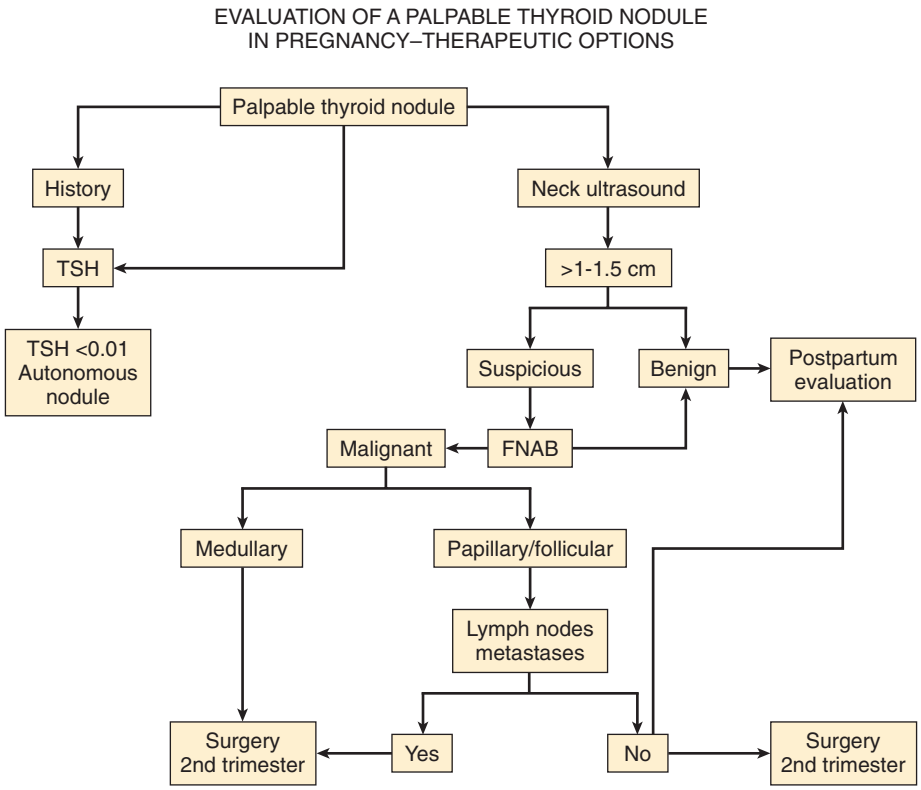

FIGURE 40-5. American Thyroid Association clinical guidelines for thyroid and pregnancy. *FNAB,* Fine-needle aspiration biopsy; *TSH,* thyroid-stimulating hormone.

pregnancy is not a contraindication and may be performed at any time during gestation, irrespective of gestational age. The importance of a competent cytopathologist in the interpretation and diagnosis of the specimens cannot be overemphasized. Radionuclide scanning is contraindicated in pregnancy, because of the risk for damaging the fetal thyroid gland, causing fetal and neonatal hypothyroidism. If performed before 12 weeks' gestation, the procedure does not affect the fetal thyroid gland because the fetal thyroid starts to incorporate iodine by 14 to 18 weeks' gestation.

In the presence of a single thyroid nodule detected on physical examination, or a dominant nodule in a multinodular gland, the following approach is recommended by the ATA Clinical Guidelines for Thyroid and Pregnancy[70a] (see Figure 40-5):

1. In the presence of a solid lesion smaller than 1 to 1.5 cm, follow up in the postpartum period is indicated.
2. Nodules larger than 1 to 1.5 cm should be considered for FNAB if there are suspicious findings on ultrasound.
3. In the presence of tracheal obstruction, immediate surgery is indicated.
4. If the FNAB is diagnostic of malignancy or it is a suspicious lesion, surgery may be postponed until after delivery, unless there are lymph node metastases or the diagnosis is a large primary lesion, or there is extensive lymph node involvement in a medullary cancer.
5. Surgery can be postponed until after delivery during the last weeks of pregnancy, and FNAB could be safely postponed until after delivery.
6. A woman with a malignant lesion or a rapidly growing lesion should be offered surgery in the second trimester of gestation.
7. Women with follicular lesions or early-stage papillary carcinoma may postpone the surgery until they are postpartum because these lesions are not expected to progress rapidly.

When advising pregnant women on the evaluation of a thyroid nodule, it has to be kept in mind that the incidence of malignancy is between 5% and 10%, and in most cases, the tumors are slow growing. As will be discussed, most published studies showed no evidence that the course of the disease or survival rate was affected when surgery was postponed until after delivery. On the other hand, knowing the result of the FNAB could be helpful to the mother in planning the postpartum course, including decisions about lactation and ^{131}I therapy if needed after the resection of the cancer.

It is generally agreed that elective surgery should be avoided in the first trimester and after 24 weeks' gestation because of the potential risks for spontaneous abortion and premature delivery, respectively. The recommendations for total thyroidectomy in the second trimester, based on clinical experience, is to avoid unnecessary exposure to the embryo to anesthetic drugs and to avoid potential prematurity due to surgery. However, there is not a well-controlled study supporting such recommendations.[85] One report

showed a higher risk for complications from thyroid and parathyroid surgery during pregnancy. Thyroidectomy during pregnancy was associated with a complication rate of 21% compared with 8% for malignant lesions and of 27% compared with 14% for benign lesions. This was a retrospective, cross-sectional analysis of hospital discharge data. Complications included suspected fetal compromise, abortion, and cesarean delivery and hysterectomy. A skilled surgeon with ample experience in thyroid surgery should perform the procedure.

In the presence of papillary carcinoma without evidence of advanced disease or significant tumor growth (>50% on ultrasonography), surgical treatment may be postponed until after delivery. Follicular neoplasms or Hürthle cell neoplasms have a risk for malignancy of about 15% to 25%; in cases reported as follicular lesions or atypia, the malignancy rate is up to 10%, and surgery could be postponed safely until the postpartum period.

In one retrospective study, a conservative approach to the management of a single thyroid nodule was recommended.[86] In this report, 61 women were pregnant at the time of the diagnosis of differentiated thyroid carcinoma. The diagnoses were papillary cancer in 87% and follicular cancer in 13%. Fourteen women were operated on during pregnancy, whereas the other 47 women underwent surgical treatment 1 to 84 months after delivery. The outcome was compared with a group of 598 nonpregnant women matched for age. The median follow-up was 22.4 years, compared with 19.5 years in the nonpregnant group. Treatment and outcome were similar in both groups: those operated on during pregnancy and those in whom thyroidectomy was performed postpartum. The authors concluded that both diagnostic studies and initial therapy might be delayed until after delivery in most patients. Yasmeen and associates reviewed cancer registry data, comparing disease-related survival in 6505 women diagnosed with thyroid cancer during pregnancy or 1 year after delivery. There was no significant difference in outcome up to 11 years later compared with an age-matched nonpregnant cohort.

In a recent report, 15 women diagnosed with thyroid cancer during pregnancy or within 1 year postpartum were compared with 61 women matched for age whose cancer was treated before pregnancy. The authors reported that women diagnosed in pregnancy or in the first year postpartum are more likely to have persistent or recurrent disease and suggested that estrogen may play a role in these poorer outcomes because a higher percentage of women diagnosed during pregnancy or 1 year after delivery were estrogen receptor-α positive compared with women diagnosed 1 year after pregnancy or never pregnant.[86]

Therefore, it is imperative for the attending physician to discuss the different therapeutic options with the patient and her family. If the lesion is diagnosed before 24 weeks' gestation, they should be informed of the data showing no deleterious effect on postponing therapy until after delivery. The anxiety of the patient and her family and their wishes should be considered in making the final decision. The long-term prognosis of most thyroid cancers is good, but patients should be followed for many years. General principles of care include the determination of serum thyroglobulin before surgery and at regular intervals thereafter; the decision to use radioactive iodine, which is indicated in selective cases for completeness of thyroid ablation; and the importance of thyroid therapy to maintain serum TSH within recommended ranges in order to prevent possible recurrence of the lesion.[84]

Patients with Known Thyroid Cancer before Pregnancy

Pregnancy does not appear to be a risk factor for recurrences in women with a previous history of treated thyroid cancer. In two earlier studies, there was no evidence of recurrence or progression of the disease during pregnancy.

Recently, Leboeuf and colleagues[88] published a retrospective analysis of 36 women who became pregnant a median of 4.3 years after initial therapy for differentiated thyroid carcinoma. They were evaluated a median of 4 months after delivery (0.1 to 1.7 years). Total thyroidectomy was performed in 80% of the patients and lobectomy in 20%. Twenty-four of the 36 patients were diagnosed with papillary carcinoma, 10 with a follicular variant of poorly differentiated thyroid cancer. Twenty-three of the patients received postsurgery ^{131}I therapy. Only 1 patient had metastases at diagnosis. Serum thyroglobulin values were available before and after pregnancy. Two women treated with thyroidectomy and radioactive iodine and 1 patient treated with thyroidectomy alone, whose serum thyroglobulin values were elevated before pregnancy, had new evidence of disease with an increase in thyroglobulin values and cervical nodes detected by ultrasonography. In 8 women, the serum thyroglobulin value was higher than the prepregnancy value, and 5 of them had no evidence of metastasis by ultrasonography or clinical examination. Unfortunately, the authors did not have complete data on TSH values during pregnancy in many of their patients. The authors concluded that pregnancy "is probably a mild stimulus to cancer growth as evidenced by minor disease progression in some patients with known structural disease before pregnancy." The changes also could be explained by the lack of TSH suppression during pregnancy because the data obtained on serum TSH were retrospective.

Hirsch and associates[89] evaluated 63 consecutive women for a total of 90 births, who were followed at their institution from 1992 to 2009 and had given birth at least once after total thyroidectomy plus ^{131}I in 58 for papillary thyroid cancer. Serum thyroglobulin values and neck ultrasound were compared before and after pregnancy. In this study, levels of serum TSH during pregnancy were correlated with disease persistence before pregnancy and disease progression during pregnancy. They concluded that pregnancy does not cause thyroid cancer recurrence in survivors who have no structural or biochemical evidence of disease persistence at the time of conception. Six of the 63 women showed disease progression during the first pregnancy, and 2 had disease progression only during the second pregnancy. An interesting finding was that a nonsuppressed TSH level during pregnancy did not stimulate disease progression during pregnancy, one of the concerns in Lebouf's study. The conclusions from both studies indicate no progression of the disease in women free of disease before pregnancy. However, there is possibility of progression in those patients with evidence of residual cancer at the time

of conception. Further studies are needed before a firm recommendation can be offered to patients.

Women on suppressive T_4 therapy for thyroid cancer before pregnancy may continue with therapy as long as the free T_4 remains within normal limits, following the recommendations by the ATA task force, of a serum TSH value between 0.1 and 0.5 mIU/L in women free of disease and of less than 0.1 mIU/L in those with persistent disease.[84] In women treated with ^{131}I therapy after thyroidectomy for thyroid cancer, there is a potential concern for future fertility and a risk for complications, mainly birth defects. Miscarriages, preterm delivery, stillbirth, and congenital abnormalities were not reported in a systemic review of the literature by Sawka and coworkers.[90] Irregular menses in the first year after treatment occurred in 27% of women following radioactive iodine treatment, and early menopause occurred in some women. Garsi and colleagues[91] reported on 483 patients exposed to ^{131}I treatment for thyroid carcinoma. The authors concluded that there is no evidence that exposure to radioiodine affects the outcome of subsequent pregnancies and offspring, even in women receiving cumulative radiation doses to the ovaries as high as 1 Gy. The authors cautioned, however, that adverse events could occur if thyroid function tests are not normalized at the time of conception, recommending postponing conception until the thyroid hormone status has been verified.

In men, there is a transient elevation of serum follicle-stimulating hormone, luteinizing hormone, and inhibin in the months following treatment, along with a reduced sperm count.[92] It has been suggested sperm banking before radioactive iodine treatment be considered.

In a 20-year follow-up of children whose mothers were exposed during pregnancy to radiation during the Chernobyl fallout, an increase in thyroid carcinoma was observed, but it was not statistically significant.

Postpartum Thyroid Dysfunction

Postpartum thyroiditis (PPT) is defined as transient thyroid dysfunction in the first year after delivery in women who were euthyroid before pregnancy.[93,94] However, in most of the published studies, thyroid status in the first trimester of pregnancy was not reported, which could explain the discrepancies in prevalence among the publications. PPT also occurs following spontaneous or medically induced abortions.[95] The etiology in most cases is autoimmune chronic (Hashimoto) thyroiditis, with a few cases due to hypothalamic or pituitary lesions. In one study, 27% of PTT women were positive for antipituitary antibodies; in such cases, the serum TSH is normal and serum FT_4 is low, characteristic of secondary or central hypothyroidism (Table 40-8).[96]

PPT, a variant of Hashimoto or chronic thyroiditis, is the most common cause of thyroid dysfunction in the postpartum period. The prevalence is between 1.1% and 16.7% of all women,[93,94,97-99] with the difference between studies depending on the design of the study, the definition of PPT, the time of postpartum testing, genotype, the exclusion of women with preexisting thyroid dysfunction, iodine intake, and other factors. Women with type 1 diabetes mellitus and other autoimmune diseases are at higher risk for developing PPT.[100] The clinical diagnosis is not always obvious, and the clinician should be concerned about nonspecific symptoms such as tiredness, fatigue, depression, palpitations, and irritability in women following the birth of their child or a miscarriage or abortion. Fatigue is the most common complaint.[97] In some cases, the clinical symptoms resemble the syndrome of postpartum depression. Indeed, thyroid antibodies have been found more frequently in euthyroid women with postpartum depression, but this is still a controversial issue. Because the clinical symptoms are mild and many times are confused with the usual tiredness of women in the months following delivery, an argument can be made for routine screening in the postpartum period; this controversial issue has been reviewed. Several factors have been mentioned as predictors for the development of PPT, among them high titers of TPOAb in the first trimester of gestation, family or personal history of thyroid disease, presence of goiter, and smoking. In a recent study from southern Italy,[94] the best predictors of PPT were the presence of TPOAb regardless of the titer and risks factors for thyroid dysfunction, including a family history of autoimmune thyroid disease, presence of goiter, signs or symptoms of thyroid disease, personal history of autoimmune disease, neck irradiation, and prior preterm delivery or miscarriage. Previous pregnancy, age, smoking status, and week of first obstetrical visit were not significantly associated with PPT. A careful history and physical examination will allow the physician to decide whether thyroid tests are indicated in a given situation. Recognizing the mild degree of the symptoms, the presence of a goiter, the history of similar symptoms in previous pregnancies, family history of thyroid disease, and autoimmune disease in addition to type 1 diabetes mellitus, among other features, will prompt the health care professional to order serum TSH with TPOAb. Patients at risk should be evaluated in the first year postpartum at 3, 6, and 12 months after delivery.

Postpartum thyroiditis may also develop in women with negative antibodies. In a study from the Netherlands, the authors suggested two forms of PPT: an autoimmune form, which is most common and eventually will develop into chronic hypothyroidism, and a nonautoimmune form, without antibodies, that appears to be transient without progressing to permanent hypothyroidism. This has recently been confirmed.[94] The incidence of PTT in women with negative TPOAb was 1.7%.

The clinical course of PPT is not uniform in most patients (Figure 40-6). In about one third of cases, mild

symptoms of hyperthyroidism may develop between 2 and 4 months postpartum. On physical examination, a goiter is felt in most cases and is firm and nontender to palpation. Tachycardia may be detected. The goiter may be discovered for the first time, or the patient may have noticed an increase in the size of a previously diagnosed goiter. Thyroid tests are in the hyperthyroid range, and thyroid antibodies (TPOAbs) are elevated in most cases. Titers of TRAb, a marker of Graves disease, are negative. Spontaneously, without specific therapy, there is a return to euthyroidism. If the symptoms are bothersome for the patients, a short course of β-adrenergic blockers is recommended. Symptoms are controlled in most patients with 20 to 40 mg of propranolol every 6 to 8 hours.

In one third of the patients, the hyperthyroid phase is followed by hypothyroidism, with spontaneous recovery and return to a euthyroid state by 7 to 12 months after delivery. Antibody titers have a tendency to increase during this process, and a change in the size of the goiter is usually noted.

In one third of patients, the course of PPT is different, characterized by an initial episode of hypothyroidism between 3 and 7 months postpartum without the initial hyperthyroid phase.

The permanent incidence of hypothyroidism 12 months after delivery ranges from 2% to 21%. However, Stagnaro-Green and colleagues found a rate of 54%, much higher than reported previously.[94] By 5 years after the diagnosis of PPT, most studies report an incidence of permanent hypothyroidism of 50%.

Graves hyperthyroidism may recur after delivery with an exacerbation in the first 3 months or between 6 and 12 months postpartum. The symptoms of hyperthyroidism are more severe than those in patients with PPT. The differential diagnosis between recurrent Graves hyperthyroidism and PPT is of clinical importance because patients with Graves' hyperthyroidism will benefit from antithyroid medications. On physical examination, women with Graves hyperthyroidism may present with ophthalmopathy, a visible goiter, and in many situations, the presence of a bruit. Titers of TRAb are positive. If not contraindicated, as in breastfeeding mothers, a 4- or 24-hour thyroid radioactive iodine uptake (RAIU) is helpful in establishing the etiology. It will be very low in patients with PPT, whereas it is high normal or elevated in patients with recurrent hyperthyroidism due to Graves disease. When hyperthyroidism is due to recurrent Graves disease, treatment with antithyroid medications is indicated, or the physician may advise ablation therapy.

Therefore, the classic presentation of PPT is characterized by symptoms of thyroid dysfunction that present in four different forms: (1) an episode of hyperthyroidism (2 to 4 months), followed by hypothyroidism (4 to 6 months) and reverting to euthyroidism (after the seventh month); (2) an episode of hyperthyroidism (3 to 4 months) reverting to euthyroidism; (3) an episode of hypothyroidism (4 to 6 months) reverting to a euthyroid state; and (4) permanent hypothyroidism after the hypothyroid phase (see Figure 40-6). However, there are exceptions to these chronologic phases. It is recommended that a diagnosis of PPT be considered for any thyroid abnormality occurring within 1 year after a delivery or miscarriages.

Although most cases of PPT recover spontaneously, treatment is indicated for symptomatic patients. In the presence of hyperthyroid symptoms, β-adrenergic blocking drugs (propranolol, 20 to 40 mg every 6 hours, or atenolol, 25 to 50 mg every 24 hours) are effective in controlling the symptoms. Antithyroid medications are not effective because the hyperthyroxinemia is secondary to the release of thyroid hormones due to the acute injury to the gland (destructive hyperthyroidism). There is no new hormone production, and therefore medications that work by blocking new thyroid hormone formation are ineffective. For hypothyroid symptoms, small amounts of L-thyroxine (50 mcg/day) will control symptoms, allowing for a spontaneous recovery of thyroid function after discontinuation of the drug. However, in women desiring future pregnancies, it has been recommended that L-thyroxine therapy be continued because these patients are at high risk for developing hypothyroidism in a future pregnancy.[98]

As noted previously, there are some features that may predict the development of PPT: presence of a goiter and high titers of thyroid antibodies in the first half of pregnancy, episodes of PPT in previous pregnancies, and a strong family history of autoimmune thyroid disease. Women with type 1 diabetes mellitus are at high risk for developing PPT. PPT may recur in future pregnancies, with a recurrence rate between 30% and 70%.[100] PPT has been reported to be associated with other autoimmune endocrine disorders, such as adrenal insufficiency and lymphocytic hypophysitis.[96]

Preventing PPT with the administration of selenium during pregnancy in women with chronic thyroiditis was evaluated by Negro and associates. They studied two groups of pregnant women: 77 received 200 mcg/day of selenium during pregnancy and postpartum, and 74 were given a placebo. There was a significant reduction in the incidence of PPT between both groups; 28.6% of women receiving selenium developed PPT compared with 48.6% of those taking placebo (P <.01). Future studies will be needed to confirm these findings.

KEY POINTS

- Hyperthyroidism due to Graves' disease needs to be differentiated in the first trimester of pregnancy from the syndrome of gestational thyrotoxicosis.
- Recent reports indicate increased for risk liver failure with the use of PTU; it is recommended that PTU be used in the first trimester of pregnancy and MM after 13 weeks' gestation. MM is not indicated in the first trimester because of the potential risk for the syndrome of methimazole embryopathy.
- The dose of antithyroid medications should be adjusted frequently, aiming to use the minimal amount of drug that will keep the FT_4 at the upper limits of normal.
- Breastfeeding is not contraindicated in women on antithyroid therapy, provided that the maximal daily dose is 200 mg of PTU and 20 mg of MM.
- Hypothyroid women on thyroid replacement therapy should have their thyroid tests checked early in pregnancy. An increase in dosage is needed in more than 50% of patients on thyroid replacement therapy.
- Women with risk factors for thyroid disease, such as a family history of thyroid disease, the presence of a goiter, a previous history of PPT, should be studied before or early in pregnancy. Determinations of serum TSH, FT_4, or FT_4I, and TPOAb are recommended in these women.
- Postpartum thyroiditis affects up to 16.7% of all women in the postpartum period. Women with chronic thyroiditis are at higher risk for developing the syndrome. Long-term follow-up is strongly advised because up to 50% of these patients will develop permanent hypothyroidism in 5 to 10 years.

Pheochromocytoma 958

KEY ABBREVIATIONS

Adrenocorticotropic Hormone	ACTH
Arginine Vasopressin	AVP
Clinically Nonfunctioning Adenoma	CNFA
Desmopressin	dDAVP
Diabetes Insipidus	DI
Follicle-stimulating Hormone	FSH
Growth Hormone	GH
Human Chorionic Gonadotropin	hCG
Insulin-like Growth Factor-1	IGF-1
Luteinizing Hormone	LH
Magnetic Resonance Imaging	MRI
Prolactin	PRL
Thyroid-stimulating Hormone	TSH

ANTERIOR PITUITARY

Anterior Pituitary Hormone Changes in Pregnancy

During pregnancy, the normal pituitary gland enlarges considerably as a result of the estrogen-stimulated lactotroph hyperplasia.[1,2] **Prolactin** (PRL) levels rise gradually throughout gestation, preparing the breast for lactation.[3] Beginning in the second half of pregnancy, circulating levels of a **growth hormone** (GH) variant made by the syncytiotrophoblastic epithelium of the placenta increase and pituitary GH secretion decreases because of negative feedback effects of insulin-like growth factor-1 (IGF-1).[4,5] In patients with **acromegaly** who have autonomous GH secretion and become pregnant, both forms of GH persist in the blood.[6] **Cortisol** levels rise progressively over the course of gestation, resulting in a twofold to threefold increase by term, as a result of both to the estrogen-induced increase in cortisol-binding globulin (CBG) levels and an increase in cortisol production, so that the bioactive "free" fraction, urinary free cortisol levels, and salivary cortisol levels are also increased.[7,8]

Pituitary Tumors

Pituitary adenomas cause problems because of hormone hypersecretion and also by causing hypopituitarism. The pregnancy-induced alterations in hormone secretion complicate the evaluation of patients with pituitary neoplasms. The influence of various types of therapy on the developing fetus may also affect therapeutic decision making.

Prolactinoma

Hyperprolactinemia commonly causes symptoms of galactorrhea, amenorrhea, and infertility.[9] The differential diagnosis of hyperprolactinemia is extensive,[9] but this discussion will focus on women with a **prolactinoma**. The choice of therapy has important consequences for decisions regarding pregnancy. Transsphenoidal surgery is curative in 50% to 60% and rarely causes hypopituitarism when it is performed on individuals with microadenomas (tumors <10 mm in diameter).[10] For patients with macroadenomas (tumors >10 mm in diameter), surgical cure rates are lower, and there is a considerably greater risk for resulting hypopituitarism.[10]

The dopamine agonists **bromocriptine** and **cabergoline** are the primary modes of therapy, restoring ovulatory menses in about 80% and 90%, respectively.[10] In addition, macroadenoma size can be reduced by 50% or more in 50% to 75% of patients with bromocriptine and in more than 90% of patients with cabergoline.[10]

The stimulatory effect of the hormonal milieu of pregnancy and the withdrawal of the dopamine agonist may result in significant prolactinoma enlargement (Figure 41-1). Tumor enlargement requiring intervention during pregnancy has been reported in 13 of 584 (2.2%) women with microadenomas, 50 of 201 (28%) with macroadenomas that had not undergone prior surgery or radiotherapy, and 7 of 161 (4.3%) with macroadenomas that had undergone prior surgery or radiotherapy.[10-12] In almost all cases, such enlargement was successfully treated with reinstitution with a dopamine agonist. If the pregnancy is sufficiently advanced, another approach is to proceed with delivery. Surgical decompression is reserved for cases in which these other approaches fail.

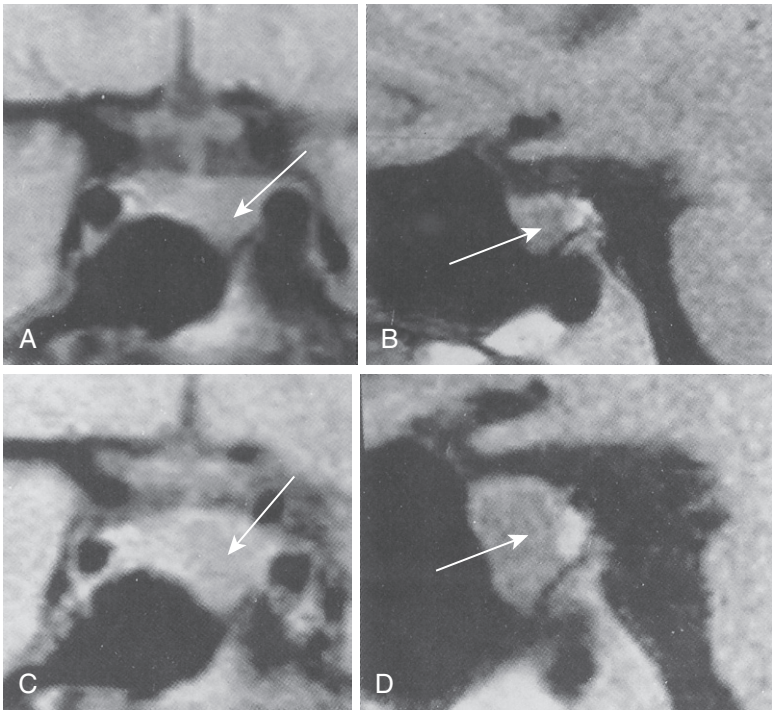

FIGURE 41-1. Coronal and sagittal magnetic resonance images of an intrasellar prolactin: secreting macroadenoma in a woman before conception **(A, B)** and at 7 months of gestation **(C, D).** Note the marked tumor enlargement at the latter point, at which time the patient was complaining of headaches. (From Molitch ME: Medical treatment of prolactinomas. Endocrinol Metab Clin North Am 28:143, 1999.)

Usually the dopamine agonist is discontinued once pregnancy is diagnosed, in order to limit fetal exposure. When used in this fashion, no increase in spontaneous abortions, ectopic pregnancies, trophoblastic disease, multiple pregnancies, or malformations were found in more than 6000 pregnancies in which bromocriptine was used and 760 pregnancies in which cabergoline was used.[11-16] Although safety data regarding the use of continuous dopamine agonist therapy during pregnancy are scarce, the use of such medications is probably not harmful.

Patients with large macroadenomas should be assessed monthly for symptoms of tumor enlargement, and visual fields should be tested each trimester. PRL levels may rise without tumor enlargement and not rise with tumor enlargement, and therefore are often misleading[17] and are not advised.

Acromegaly

About 30% to 40% of patients with **acromegaly** have hyperprolactinemia,[18] and treatment with a dopamine agonist may be necessary to permit ovulation and conception in these patients.[19] Most patients with acromegaly are treated with surgery as primary therapy, and those not cured by surgery are usually treated medically with the **somatostatin analogs octreotide** and **lanreotide**.[20] Cabergoline may also be helpful in some cases.[20]

Conventional assays cannot distinguish between normal pituitary GH and the placental GH variant.[4] If it is critical to make a diagnosis during pregnancy, it may be possible by demonstrating GH pulsatility with frequent sampling because GH secretion in acromegaly is highly pulsatile but that of the variant is not.[6,21]

Only four patients with tumors secreting GH have been reported to have enlargement of their tumors, with a resultant visual field defect in one patient during pregnancy.[22-25] However, in one of these cases, tumor enlargement likely was due to octreotide withdrawal, and in another it was due to hemorrhage into the tumor. Therefore, as with prolactinomas, women with acromegaly and macroadenoma should be monitored for symptoms of tumor enlargement and visual field testing.

Because of the GH-induced insulin resistance, the risk for gestational diabetes is increased in acromegalic patients.[25] There is increased salt retention, and gestational hypertension is also increased.[25] Cardiac disease has not proved to be an issue in pregnant women with acromegaly.[19,24,25]

The considerations regarding the use of bromocriptine and cabergoline in women with prolactinomas also apply to those with acromegaly. Only 36 pregnant women treated with somatostatin analogs have been reported; no malformations were found in their children.[25,26] However, a decrease in uterine artery blood flow has been reported with short-acting octreotide,[26] and one fetus appeared to have intrauterine growth restriction (IUGR) that responded to a lower dose of octreotide LAR.[25] Octreotide binds to somatostatin receptors in the placenta[26] and crosses the placenta[26]; therefore, it can affect developing fetal tissues where somatostatin receptors are widespread, especially in the brain. Because of the limited data documenting safety, most authors recommend[25,27] that octreotide and other somatostatin analogs be discontinued if pregnancy is considered and that contraception be used when these drugs are administered; but not all others concur.[26] Considering the prolonged nature of the course of most cases of acromegaly, interruption of medical therapy for 9 to 12 months generally does not have a particularly adverse effect on the long-term outcome. On the other hand, these drugs can control tumor growth, and for enlarging tumors, their reintroduction during pregnancy may be warranted instead of

operating. Pegvisomant, a GH receptor antagonist, has been given to a patient with acromegaly during pregnancy without harm,[28] but the safety of this medication has not been established.

Thyrotropin-Secreting Tumors

Only three cases of pregnancy occurring in women with thyroid-stimulating hormone (TSH; thyrotropin)-secreting tumors have been reported.[29-31] In one of these cases, octreotide, which had been stopped, had to be reinstituted to control tumor size[29]; in a second case, octreotide was continued during pregnancy for tumor size control.[30] The most pressing issue with such tumors is the need to control hyperthyroidism during pregnancy, which can usually be accomplished with standard antithyroid drugs.[30] However, with growing macroadenomas, octreotide may be necessary for tumor size control,[29,30] and it is possible that it may be necessary to control the hyperthyroidism if thioamides are ineffective.

Clinically Nonfunctioning Adenomas

Pregnancy would not be expected to influence tumor size in patients with clinically nonfunctioning adenomas (CNFAs), and only two cases have been reported in which tumor enlargement during pregnancy resulted in a visual field defect.[22,32] In the second case, the patient responded rapidly to bromocriptine treatment, probably because of shrinkage of the lactotroph hyperplasia with decompression of the chiasm and probably with little or no direct effect on the tumor itself.[32]

Most CNFAs are actually gonadotroph adenomas. Two patients have been reported who had gonadotroph adenomas secreting intact follicle-stimulating hormone (FSH) with a resultant ovarian hyperstimulation syndrome[33,34]; both became pregnant, one after having the FSH hypersecretion controlled by bromocriptine[33] and the second after surgical removal of the tumor.[34]

Hypopituitarism

Hypopituitarism may be partial or complete, and loss of gonadotropin secretion is common. Induction of ovulation may be difficult, and a variety of techniques have been used, including administration of human chorionic gonadotropin (hCG) and FSH,[35,36] pulsatile gonadotropin-releasing hormone,[35,36] and in vitro fertilization.[37,38] Although the malformation rate is not increased in such pregnancies, there appears to be an increased frequency of cesarean deliveries, miscarriage, and small-for-gestational-age infants.[35,36,38]

Because of increased thyroxine (T_4) turnover and volume of distribution in pregnancy, T_4 levels usually fall, and TSH levels rise with a fixed $\mathbf{T_4}$ dose over the course of gestation.[39] The average increase in T_4 need in these patients is about 0.05 mg/day. Because women with hypothalamic-pituitary dysfunction may not elevate their TSH levels normally in the face of increased need for T_4, it is reasonable to increase the T_4 supplementation by 0.025 mg after the first trimester and by additional 0.025 mg after the second trimester, also following free T_4 levels.

The dose of chronic glucocorticoid replacement usually does not need to be increased during pregnancy.[8] **Hydrocortisone** is metabolized by the placental enzyme 11β-hydroxysteroid dehydrogenase-2, so the fetus is generally protected from excess hydrocortisone; the usual dose is in the range of 12 to 15 mg/m^2 given in two or three divided doses.[8] Additional glucocorticoids are needed for the stress of labor and delivery, such as 75 mg of hydrocortisone given intravenously every 8 hours with rapid tapering postpartum.[8] Prednisolone does not cross the placenta, and prednisone crosses only minimally.[40] Suppression of neonatal adrenal function in offspring of women taking prednisone during pregnancy is very uncommon,[41] and the amounts passed in breast milk are negligible.[42]

There are few data on the use of GH during pregnancy in hypopituitary individuals, and in most series, GH therapy has been stopped at conception.[43] Because the GH variant, which is biologically active, is produced by the placenta in substantial amounts beginning in the second half of pregnancy and can access the maternal circulation (see earlier), at most the mother would be GH deficient only in the first half of pregnancy. When Curran and colleagues analyzed 25 pregnancies that occurred in 16 patients with GH deficiency during which GH therapy was not continued, they found that there was no adverse outcome of omitting GH therapy on either the fetus or mother and concluded that GH replacement therapy during pregnancy is not essential for GH-deficient women.[43]

Table 41-1 Symptoms and Signs of Sheehan Syndrome

Acute Form	Chronic Form
Hypotension	Light-headedness
Tachycardia	Fatigue
Failure to lactate	Failure to lactate
Hypoglycemia	Persistent amenorrhea
Extreme fatigue	Decreased body hair
Nausea and vomiting	Dry skin
	Loss of libido
	Nausea and vomiting
	Cold intolerance

Sheehan Syndrome

Sheehan syndrome consists of pituitary necrosis secondary to ischemia occurring within hours of delivery.[44] It is usually secondary to hypotension and shock from an obstetrical hemorrhage. The degree of ischemia and necrosis dictates the subsequent patient course (Table 41-1). It rarely occurs with current obstetrical practice.[45]

Acute necrosis is suspected in the setting of an obstetrical hemorrhage in which hypotension and tachycardia persist following adequate replacement of blood products. Failure to lactate and hypoglycemia may also occur.[44] Investigation should include obtaining blood samples for adrenocorticotropic hormone (ACTH), cortisol, prolactin, and free T_4. The ACTH stimulation test would be normal because the adrenal cortex would not be atrophied. Free T_4 levels might prove normal initially because the hormone has a half-life of 7 days, and an additional sample should be sent after 1 week. Prolactin levels are usually low.

Treatment with saline and stress doses of corticosteroids should be instituted immediately after drawing the blood tests. If later free T_4 levels become low, then therapy with

levothyroxine is indicated. Additional pituitary testing with subsequent therapy should be delayed until recovery. Diabetes insipidus may also occur.[46]

When milder forms of infarction occur, the diagnosis may be delayed for months or years.[44] These women generally have a history of amenorrhea, decreased libido, failure to lactate, breast atrophy, loss of pubic and axillary hair, fatigue, and symptoms of secondary adrenal insufficiency with nausea, vomiting, diarrhea, and abdominal pain.[44] Rarely, some women retain gonadotropin secretion and may have normal menses and fertility.[44]

Lymphocytic Hypophysitis

Lymphocytic hypophysitis is thought to be autoimmune and is manifested by infiltration and destruction of the parenchyma of the pituitary and infundibulum by lymphocytes and plasma cells.[47-49] It generally occurs during pregnancy or the postpartum period.[47-49] It is associated with symptoms of hypopituitarism or an enlarging mass lesion with headaches and visual field defects, and is suspected based on its timing and lack of association with an obstetrical hemorrhage or prior history of menstrual difficulties or infertility.[47-49] Diabetes insipidus may also occur.[47-49] On magnetic resonance imaging (MRI), there is usually diffuse enhancement rather than a focal lesion that might indicate a tumor.[47-49] The clinical picture often allows a clinical diagnosis to be made without invasive procedures.

Treatment is generally conservative and involves identification and correction of any pituitary deficits, especially of ACTH secretion, which is particularly common in this condition.[48-49] Data regarding high-dose corticosteroid treatment are inconclusive. Surgery to debulk but not remove the gland is indicated in the presence of uncontrolled headaches, visual field defects, and progressive enlargement on scan. Spontaneous regression and resumption of partial or normal pituitary function may occur, although most patients progress to chronic panhypopituitarism.[47-49]

POSTERIOR PITUITARY

The set point for plasma osmolality at which **arginine vasopressin** (AVP) is secreted and thirst is stimulated is reduced about 5 to 10 mOsm/kg in pregnancy.[50] The placenta produces vasopressinase, an enzyme that rapidly inactivates AVP, thereby greatly increasing its clearance.[51]

Standard water deprivation tests, which require 5% weight loss, should be avoided during pregnancy because they may cause uterine irritability and alter placental perfusion. Instead, **desmopressin (dDAVP)** is used to assess urinary concentrating ability over 11 hours, with a value greater than 700 mOsm/kg considered normal.[52] Urinary concentrating ability in the pregnant patient should be determined in the seated position because the lateral recumbent position inhibits maximal urinary concentration.[50,53]

Diabetes Insipidus

Central **diabetes insipidus** (DI) may newly develop in pregnancy due to an enlarging pituitary lesion, with lymphocytic hypophysitis, or with hypothalamic disease. Because of the increased clearance of AVP by the vasopressinase, DI usually worsens during gestation, and subclinical DI may become manifest.[53-55] dDAVP is resistant to vasopressinase and provides satisfactory, safe treatment during gestation, although a higher dose may be required.[53,56] During monitoring of the clinical response, clinicians should remember that normal basal plasma osmolality and sodium concentration are 5 mEq/L lower during pregnancy.[50] dDAVP transfers minimally into breast milk.[53]

Transient AVP-resistant forms of DI secondary to placental production of vasopressinase may occur spontaneously in one pregnancy, but not in a subsequent one.[57] Some of these patients may respond to dDAVP therapy.

Acute fatty liver of pregnancy and other disturbances of hepatic function such as hepatitis may be associated with late-onset transient DI of pregnancy in some patients.[58] In some cases, this has been associated with the HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelets) syndrome.[59] It is presumed the hepatic dysfunction is associated with reduced degradation of vasopressinase, further increasing vasopressinase levels and the clearance of AVP. The polyuria may develop either before delivery or postpartum.

DI that develops postpartum may be a result of Sheehan syndrome. Transient DI of unknown etiology has been described postpartum, lasting only days to weeks.[60]

Congenital nephrogenic DI is a rare X-linked disorder caused by a mutation in the vasopressin V2 receptor gene and predominantly affects males. Female carriers of this disease may have significant polyuria during pregnancy. Treatment is with thiazide diuretics,[53] which should be used with caution in pregnant women.

ADRENALS

In addition to the changes during pregnancy in cortisol outlined previously, plasma renin activity, angiotensin II, and aldosterone increase threefold to sevenfold during pregnancy, and there is an increase in blood volume.[61]

Cushing Syndrome

Less than 150 cases of **Cushing syndrome** in pregnancy have been reported.[62-69] Less than 50% of the pregnant women described had pituitary adenomas, a similar number had **adrenal adenomas,** and more than 10% had **adrenal carcinomas.**[62-69] Pregnancies associated with the **ectopic ACTH syndrome** have been reported only rarely.[64,67,69] In many cases, the hypercortisolism first became apparent during pregnancy, with improvement and even remission after parturition.[64,66,69] Recently, cases have been reported of pregnancy-induced Cushing syndrome from hCG-induced stimulation of ectopic luteinizing hormone and hCG receptors on the adrenal.[70]

Diagnosing Cushing syndrome during pregnancy may be difficult. Both conditions may be associated with weight gain in a central distribution, fatigue, edema, emotional upset, glucose intolerance, and hypertension. The striae associated with normal pregnancy are usually pale and red or purple in Cushing syndrome. Hirsutism and acne may point to excessive androgen production. Proximal myopathy and bone fractures suggest Cushing syndrome.

The laboratory evaluation is difficult. Elevated total and free serum cortisol and ACTH levels and urinary free cortisol excretion are compatible with that of normal pregnancy. The overnight dexamethasone test usually demonstrates inadequate suppression during normal pregnancy.[8,69] ACTH levels are normal to elevated even with adrenal adenomas,[8,62,63,64] perhaps because of the production of ACTH by the placenta or from the nonsuppressible stimulation of pituitary ACTH by placental corticotropin-releasing hormone (CRH).

A persistent circadian variation in the elevated levels of total and free serum cortisol during normal pregnancy may be most helpful in distinguishing Cushing syndrome from the hypercortisolism of pregnancy because this finding is characteristically absent in all forms of Cushing syndrome.[7,8] Midnight levels of salivary cortisol during pregnancy have not yet been standardized.[66] In many cases, MRI of the pituitary (without contrast) or ultrasound of the adrenal may be helpful. Little experience has been reported with CRH stimulation testing or petrosal venous sinus sampling during pregnancy.[64,67,69]

Cushing syndrome is associated with a pregnancy loss rate of 25% due to spontaneous abortion, stillbirth, and early neonatal death because of extreme prematurity.[62,66-69] The passage of cortisol across the placenta may rarely result in suppression of the fetal adrenals.[71] Hypertension develops in most mothers with Cushing syndrome, and diabetes and myopathy are frequent. Postoperative wound infection and dehiscence are common after cesarean delivery.

In a review of 136 pregnancies collected from the literature, Lindsay and associates found that the frequency of live births increased from 76% to 89% when active treatment was instituted by a gestational age of 20 weeks.[67] Therefore, treatment during pregnancy has been advocated.[62,67,69]

Medical therapy for Cushing syndrome during pregnancy with metyrapone and ketoconazole is not very effective.[66,67,69] IUGR has been reported with ketoconoazole.[65] Aminoglutethimide and mitotane should be avoided. Transsphenoidal resection of a pituitary ACTH-secreting adenoma and laparoscopic resection of adrenal adenomas have been carried out successfully in several patients during the second trimester.[66,67,69,71] The live birth rate is about 87% after unilateral or bilateral adrenalectomy.[67,68] Although any surgery poses risks for the mother and fetus,[72] it appears that the benefit of treatment with Cushing syndrome outweighs the risks.

Adrenal Insufficiency

In developed countries, the most common etiology for primary **adrenal insufficiency** is **autoimmune adrenalitis**. Primary adrenal insufficiency from infections (**tuberculosis** or fungal), bilateral metastatic disease, hemorrhage, or infarctions is uncommon. Secondary adrenal insufficiency, from pituitary neoplasms or glucocorticoid suppression of the hypothalamic-pituitary-adrenal axis, may also occur.

Recognition of adrenal insufficiency may be difficult because many of the clinical features are found in normal pregnancies, including weakness, lightheadedness, syncope, nausea, vomiting, hyponatremia, and increased pigmentation. Addisonian hyperpigmentation may be distinguished from chloasma of pregnancy by its presence on the mucous membranes, extensor surfaces, and nonexposed areas. Weight loss, hypoglycemia, salt craving, and excessive hyponatremia should prompt a clinical evaluation. If unrecognized, adrenal crisis may ensue at times of stress, such as a urinary tract infection or labor.[73-75] The fetoplacental unit largely controls its own steroid milieu, so maternal adrenal insufficiency generally causes no problems with fetal development. Severe maternal hyponatremia or metabolic acidosis and poor maternal compliance with therapy may cause a poor fetal outcome.[73-75] Association with other autoimmune conditions such as anticardiolipin antibodies may lead to additional risks such as miscarriage.[76]

Adrenal insufficiency may be associated with laboratory findings of hyponatremia, hyperkalemia, hypoglycemia, eosinophilia, and lymphocytosis. Early morning plasma cortisol levels of 3 mcg/dL (83 nmol/L) or less confirms adrenal insufficiency, whereas a cortisol level higher than 19 mcg/dL (525 nmol/L) in the first or early second trimester excludes the diagnosis in a clinically stable patient.[77] However, plasma cortisol levels may fall in the normal nonpregnant range as a result of the increase in cortisol-binding globulin concentrations in the second and third trimesters, but will not be appropriately elevated for the stage of pregnancy.[78] Appropriate pregnancy-specific cut-offs for diagnosis with the standard cosyntropin test using a 250-mcg dose have not been established, with plasma cortisol levels 60% to 80% above nonpregnant responses in normal pregnant women tested in the second and third trimesters in one series.[78] The 1-mcg low-dose cosyntropin test has been reported to be more accurate at 24 to 34 weeks' gestation, using a cut-off of 30 mcg/dL (828 nmol/L).[77] With primary adrenal insufficiency, ACTH levels will be elevated, and a level above 100 pg/mL (22 pmol/L) is consistent with the diagnosis.[79] However, ACTH will not be low with secondary forms because of the placental production of this hormone, which is nevertheless insufficient to maintain normal maternal adrenal function.

In the unstable patient, empirical glucocorticoid therapy of hydrocortisone, 50 to 75 mg given intravenously, should be administered pending the results of diagnostic testing. Thereafter, doses of 50 to 75 mg every 6 to 8 hours should be given in the face of severe stress and during labor.[75] Despite the normal increase in plasma cortisol during pregnancy, baseline maternal replacement doses of corticosteroids usually are not different from those required in the nonpregnant state.[75] Mineralocorticoid replacement requirements usually do not change during gestation, although some clinicians have reduced doses of fludrocortisone in the third trimester in an attempt to treat addisonian patients who develop edema, exacerbation of hypertension, and preeclampsia.[73]

Patients who have received glucocorticoids as anti-inflammatory therapy are presumed to have adrenal axis suppression for at least 1 year after cessation of such therapy.[80] These patients should be treated with stress doses of glucocorticoids during labor and delivery as noted previously. They are at risk for postoperative wound infection and dehiscence, as are patients with endogenous Cushing syndrome, and their offspring are at risk for transient adrenal insufficiency.

Primary Hyperaldosteronism

Primary **hyperaldosteronism** rarely has been reported in pregnancy and is most often caused by an adrenal adenoma.[81-84] There are rare reports of glucocorticoid-remediable hyperaldosteronism in pregnancy.[85] The elevated aldosterone levels found in affected patients during pregnancy are similar to those in normal pregnant women, but the plasma renin activity is suppressed.[81] Moderate to severe **hypertension** develops in 85%, proteinuria in 52%, and hypokalemia in 55% of patients,[82] and symptoms may include headache, malaise, and muscle cramps. Placental abruption and preterm delivery are also risks.[86] Interestingly, the very high progesterone levels of pregnancy may have an antimineralocorticoid effect at the renal tubules, and thus the hypertension and hypokalemia may ameliorate during pregnancy in some women.[84]

Spironolactone, the usual nonpregnant therapy, is contraindicated in pregnancy because it crosses the placenta and is a potent antiandrogen that can cause ambiguous genitalia in a male fetus.[81] There is no published experience with the use during pregnancy of eplerenone, the new aldosterone receptor antagonist. Surgical therapy may be delayed until postpartum if hypertension can be controlled with agents safe in pregnancy, such as amiloride, methyldopa, labetalol, and calcium channel blockers.[87,88] On the other hand, laparoscopic removal of an aldosterone-producing adenoma during pregnancy has been reported.[83] Potassium supplementation may be required, but the hypokalemia may ameliorate in pregnancy because of the antikaliuretic effect of progesterone. Both hypertension and hypokalemia may exacerbate postpartum because of removal of the progesterone effect.[84]

Pheochromocytoma

Exacerbation of hypertension is a typical presentation of **pheochromocytoma** and may be frequently mistaken for pregnancy-induced hypertension or preeclampsia.[89,90] As the uterus enlarges and an actively moving fetus compresses the neoplasm, maternal complications such as severe hypertension, hemorrhage into the neoplasm, hemodynamic collapse, myocardial infarction, cardiac arrhythmias, congestive heart failure, and cerebral hemorrhage may occur. In 10% of patients, tumors may be outside of the adrenal, such as at the aortic bifurcation, and are particularly prone to hypertensive episodes with changes in position, uterine contractions, fetal movement, and Valsalva maneuver.[90] Unrecognized pheochromocytoma has been associated with a maternal mortality rate of 50%.[89,90]

There is minimal placental transfer of catecholamines,[91] likely because of high placental concentrations of catechol-O-methyltransferase and monoamine oxidase.[91] Adverse fetal effects such as hypoxia are a result of catecholamine-induced uteroplacental vasoconstriction and placental insufficiency[89,90,92] and of maternal hypertension, hypotension, or vascular collapse. Placental abruption may also occur.[89]

The diagnosis of pheochromocytoma requires a high index of suspicion. Preconception screening of families known to have multiple endocrine neoplasia type 2, von Hippel-Lindau disease, and neurofibromatosis is important.[93] The diagnosis should be considered in pregnant women with severe or paroxysmal hypertension, particularly during the first half of pregnancy or in association with orthostatic hypotension or episodic symptoms of pallor, anxiety, headaches, palpitations, chest pain, or diaphoresis.

Laboratory diagnosis of pheochromocytoma is unchanged from the nonpregnant state because catecholamine metabolism is not altered by pregnancy per se and consists of measuring urine **metanephrines** and **catecholamines** and plasma metaneprhines.[89,90] If possible, methyldopa and labetalol should be discontinued because these agents may interfere with the quantification of the catecholamines.[94] Tumor localization with MRI, with high-intensity signals noted on T2-weighted images, provides the best sensitivity without fetal exposure to ionizing radiation.[89,90]

Differentiation from preeclampsia is generally simple. The edema, proteinuria, and hyperuricemia found in women with preeclampsia are absent in those with pheochromocytomas. Plasma and urinary catecholamines may be modestly elevated in severe preeclampsia and other serious pregnancy complications requiring hospitalization, although they remain normal in mild preeclampsia or pregnancy-induced hypertension.[95] Catecholamine levels are two to four times normal after an eclamptic seizure, however.[96]

Initial medical management involves α-blockade with **phenoxybenzamine,** phentolamine, prazosin, or **labetalol.** All these agents are well-tolerated by the fetus, but phenoxybenzamine is considered the preferred agent because it provides long-acting, stable, noncompetitive blockade.[89] Phenoxybenzamine is started at a dose of 10 mg twice daily, with titration until the hypertension is controlled. Placental transfer of phenoxybenzamine occurs[97] but is generally considered safe.[89] However, two neonates of mothers treated with phenoxybenzamine have been reported with respiratory distress and hypotension requiring ventilatory and inotropic support.[98] β-Blockade is reserved for treating maternal tachycardia or arrhythmias that persist after full α-blockade and volume repletion.[90] β-Blockers may be associated with fetal bradycardia and with IUGR but generally are safe, and there is wide experience with their use.[90] All these potential fetal risks are small compared with the risk for fetal wastage from unblocked high maternal levels of catecholamines. Hypertensive emergencies should be treated with phentolamine (1 to 5 mg) or nitroprusside, although the latter should be limited because of potential fetal cyanide toxicity.

The timing of surgical excision of the neoplasm is controversial and may depend on the success of the medical management and the location of the tumor. Pressure from the uterus, motion of the fetus, and labor contractions are all stimuli that may cause an acute crisis. In the first half of pregnancy, surgical excision may proceed once adequate α-blockade is established, although there may be a higher risk for fetal loss with first trimester surgery. In the early second trimester, fetal loss is less likely with surgery compared with the first trimester, and the size of the uterus will not make excision difficult. If the pheochromocytoma is not recognized until the second half of gestation, increasing uterine size makes surgical exploration difficult. Successful laparoscopic excision of pheochromocytomas has been described in the second trimester.[89,90] Other options

include combined cesarean delivery and tumor resection or delivery followed by tumor resection at a later date.

Although successful vaginal delivery has been reported,[99] it has been associated with higher rates of maternal mortality than cesarean delivery. Labor may result in uncontrolled release of catecholamines secondary to pain and uterine contractions. Severe maternal hypertension may lead to placental ischemia and fetal hypoxia. In the well-blocked patient, however, vaginal delivery may be possible with pain management with epidural anesthesia and may be facilitated by instrumental delivery.

KEY POINTS

- About 30% of prolactin-secreting macroadenomas enlarge significantly during pregnancy.
- Dopamine agonists can be used safely for the treatment of prolactinomas in women attempting conception.
- In patients with acromegaly, the risks for gestational diabetes and hypertension are increased.
- Gonadotropins, gonadotropin-releasing hormone, and in vitro fertilization techniques have been used successfully to achieve pregnancy in women with hypopituitarism.
- Sheehan syndrome is very uncommon with modern obstetrical practice but still must be considered in the postpartum unstable patient following hemorrhage.
- Lymphocytic hypophysitis occurring during pregnancy is often associated with ACTH deficiency and may be fatal.
- Subclinical diabetes insipidus may become manifest during pregnancy because of secretion of placental vasopressinase.
- Cushing syndrome is associated with adverse outcomes for mother and fetus and should be treated aggressively during pregnancy.
- Although maintenance glucocorticoid replacement does not need to be increased in pregnant women with either hypopituitarism or primary adrenal insufficiency, stress doses of hydrocortisone are required during labor and delivery and other stressful situations.
- Pheochromocytomas should be treated aggressively and usually require surgical resection during the pregnancy.

KEY ABBREVIATIONS

Hemolysis, Elevated Liver Enzymes, Low Platelets	HELLP
Hemolytic Uremic Syndrome	HUS
Immune Thrombocytopenic Purpura	ITP
Immunoglobulin G	IgG
Intravenous Immunoglobulin	IVIG
Polymerase Chain Reaction	PCR
Red Blood Cell	RBC
Thrombotic Thrombocytopenic Purpura	TTP
Unusually Large Multimers of von Willebrand's Factor	ULVWf
Urinary Tract Infection	UTI
von Willebrand's Cleaving Enzyme	ADAMTS-13
von Willebrand's Disease	vWD
von Willebrand's Factor	vWF

PREGNANCY-ASSOCIATED THROMBOCYTOPENIA

Affecting approximately 4% of pregnancies, thrombocytopenia is the most frequent hematologic complication of pregnancy resulting in consultation. Hospital laboratories vary on their lower limit of a normal platelet count, but it is usually between 135,000 and 150,000/mm^3. Platelet counts generally fall slightly, owing to hemodilution and increased destruction, as gestation progresses.[1] Platelet counts, however, should not fall below the normal range. **In pregnancy, the vast majority of cases of mild to moderate thrombocytopenia are caused by gestational thrombocytopenia.[2] This form of thrombocytopenia has little likelihood of causing maternal or neonatal complications.[3]** The obstetrician, however, is obliged to rule out other etiologies of thrombocytopenia that are associated with severe maternal or perinatal morbidity. The common and rare causes of thrombocytopenia in the gravida at term are shown in the box Causes of Thrombocytopenia during Pregnancy.

CAUSES OF THROMBOCYTOPENIA DURING PREGNANCY

Common Causes

- Gestational thrombocytopenia
- Severe preeclampsia
- HELLP syndrome
- Disseminated intravascular coagulation

Rare Causes

- Immune thrombocytopenic purpura
- Lupus anticoagulant/antiphospholipid antibody syndrome
- Systemic lupus erythematosus
- Thrombotic thrombocytopenic purpura
- Hemolytic uremic syndrome
- Type 2b von Willebrand's syndrome
- Hemoglobin SC crisis with splenic sequestration
- Folic acid deficiency
- Human immunodeficiency virus infection
- Hematologic malignancies
- May-Hegglin syndrome (congenital thrombocytopenia)

Gestational Thrombocytopenia

Patients with gestational thrombocytopenia generally have mild (platelet count = 100,000 to 149,000/mm^3) to moderate (platelet count = 50,000 to 99,000/mm^3) thrombocytopenia. These patients require no therapy, and the fetus appears to be at negligible risk of being born with profound thrombocytopenia (platelet count below 50,000/mm^3) or a bleeding diathesis. This distinct entity was first suggested but not specifically defined in a study published in 1986 by Hart and colleagues.[4] In this study, 28 of 116 pregnant women

(24%) who were evaluated prospectively during an 8-month period had platelet counts less than 150,000/mm^3 at least once during pregnancy. In all 17 patients who were followed after delivery, platelet counts returned to normal. Hart and colleagues[4] were actually describing gestational thrombocytopenia before the condition had been recognized as a distinct entity. Samuels and colleagues[5] also investigated 74 mothers with gestational thrombocytopenia. Regardless of platelet antibody status, none of the infants born to these mothers demonstrated thrombocytopenia. Burrows and Kelton[6] have further shown that there is little risk to the mother or neonate in cases of gestational thrombocytopenia. In their study of 1357 healthy, pregnant women, 112 (8.3%) had platelet counts less than 150,000/mm^3.[6] The lowest platelet count was 97,000/mm^3. The incidence of thrombocytopenia (platelet count less than 150,000/mm^3) in the infants of these 112 women was 4.3%, not statistically significantly different from infants born to healthy pregnant women without thrombocytopenia (1.5%).[6] None of these infants had platelet counts less than 100,000/mm^3. Indeed, the reports by Samuels and colleagues[5] and Burrows and Kelton[6] have convincingly demonstrated that gestational thrombocytopenia is an entity distinct from immune thrombocytopenic purpura (ITP).

The decrease in platelet count, occurring in gestational thrombocytopenia, is not merely due to dilution of platelets with increasing blood volume. It also appears to be due to an acceleration of the normal increase in platelet destruction that occurs during pregnancy. This is demonstrated by the fact that the mean platelet volume (MPV) is increased in patients with gestational thrombocytopenia. Pregnant women who have gestational thrombocytopenia do not require any special therapy during the puerperium. In fact, intervention, including unnecessary glucocorticoids or bone marrow aspirations, will be more harmful and confusing. However, if the platelet counts fall below 20,000/mm^3 or if there is clinical bleeding, further investigation and intervention are warranted. These complications, however, are rare, and it is difficult to determine whether these patients with profound thrombocytopenia have gestational thrombocytopenia, the new onset of ITP, or a blood dyscrasia.

Immune Thrombocytopenic Purpura

Immune thrombocytopenic purpura (ITP) affects 1 to 3 per 1000 pregnancies and rarely causes neonatal complications. Although there are rare cases of neonatal thrombocytopenia, fetal complications are almost nonexistent.[5] Therefore, the maternal-fetal medicine specialist should focus on maternal disease and well-being.

In general, **pregnancy has not been determined to cause ITP or to change its severity**, but there are rare exceptions. Harrington and colleagues[7] were the first to demonstrate that ITP was humorally mediated. Shulman and colleagues[8] showed that the mediator of this disorder was IgG. These findings were confirmed when Cines and Schreiber[9] developed the first platelet antiglobulin test, a radioimmunoassay, in 1979. Today, this test is usually performed using enzyme-linked immunosorbent assay or flow cytometry. Newer assays have shown that these autoantibodies may be directed against specific platelet surface glycoproteins, including the IIb/IIIa and Ib/IX complexes.[10] In vivo, after the platelets are coated with antibody, they are removed from circulation by binding to the Fc receptors of macrophages in the reticuloendothelial system, especially the spleen. Approximately 90% of women with ITP have platelet-associated IgG.[9] Unfortunately, this is not specific for ITP, because studies have shown that these tests are also positive in women with gestational thrombocytopenia and preeclampsia.

To make the issue more confusing, the pathogenesis of ITP in children and adults usually differs. Childhood ITP most often follows a viral infection and clinically presents with petechiae and bleeding. This form of ITP is generally self-limited and disappears over time. Conversely, adults have milder bleeding and easy bruisability, and are often diagnosed after a prolonged period of subtle symptoms. Adult ITP usually runs a chronic course, and long-term therapy is often eventually needed. Many pregnancies occur in women in their late teens and early twenties. In these women, with a history of ITP, it may be difficult to ascertain whether the patient has childhood ITP or adult ITP. The distinction is important for counseling concerning long term prognosis.

ITP has a predisposition for women ages 18 to 40, with an overall female-male ratio of 1.7.[11] It is a diagnosis of exclusion. The patient must have isolated thrombocytopenia with an unremarkable peripheral smear. She must have only bleeding clinically consistent with a depressed platelet count, such as petechiae. She must not be taking any medication, herbal compound, or illicit drug that may cause thrombocytopenia. Finally, the patient must have no other disease process than can cause thrombocytopenia, such as those listed in the box earlier in this chapter.[11,12]

Thrombotic Thrombocytopenic Purpura and Hemolytic Uremic Syndrome

These two conditions are characterized by microangiopathic hemolytic anemia and severe thrombocytopenia. Pregnancy does not predispose a patient to these conditions, but they should be considered when evaluating the gravida with severe thrombocytopenia. Thrombotic thrombocytopenic purpura (TTP) is characterized by a pentad of findings, which are shown in the box Pentad of Findings in TTP.[13,14] The complete pentad occurs only in approximately 40% of patients, but approximately 75% have a triad of microangiopathic hemolytic anemia, thrombocytopenia, and neurologic changes.[15] Pathologically, these patients have thrombotic occlusions of arterioles and capillaries.[13] These occur in multiple organs, and there is no specific clinical manifestation for the disease. The clinical picture reflects the organs that are involved.

Pentad of Findings in Thrombotic Thrombocytopenic Purpura (TTP)*

†Microangiopathic hemolytic anemia
†Thrombocytopenia
†Neurologic abnormalities, including confusion, headache, paresis, visual hallucinations, seizures
Fever
Renal dysfunction

*The classic pentad is found in only 40% of patients.
†These three findings are present in 74% of patients.[32]

TTP/HUS may mimic preeclampsia. Because preeclampsia is much more common than this disorder, it should be considered first. However, **delay in diagnosing TTP/HUS can have fatal consequences**.

To diagnose the hemolytic anemia associated with TTP, the indirect antiglobulin (Coomb's) test must be negative. This rules out an immune-mediated cause for the hemolytic anemia. Lactic dehydrogenase should be elevated, the indirect bilirubin should be increased, and haptoglobin should be decreased, indicating ongoing hemolysis. Schistocytes are usually seen on the peripheral smear, if it is carefully reviewed. To be classified as TTP, the platelet count should be less than 100,000/mm^3. In renal insufficiency associated with TTP, the urine sediment is usually normal with an occasional red blood cell (RBC). This finding helps distinguish this disorder from a lupus flare, which more often has associated hematuria and casts. The serum creatinine is usually greater than 2 mg/dL. This degree of renal dysfunction is unusual, but not rare, in preeclampsia. There is usually 1 to 2 proteinuria on urine dipstick.

The neurologic findings in TTP are usually nonspecific. They include headache, confusion, and lethargy. Infrequently tonic-clonic seizures occur, and rarely lateralizing signs are noted.

Terrell and coworkers[16] examined the epidemiology of TTP/HUS occurring in Oklahoma between 1996 and 2004. In 206 reported cases, they found that 37% were idiopathic. However, 13% were associated with an autoimmune disease, and 7% occurred in pregnancy and the postpartum period. These researchers were able to project that the incidence of suspected TTP/HUS is 11 cases/million population/year, whereas the incidence of proven cases is 4.5 cases/million population/year.[16] If this disease is so rare, why include it in a text on obstetrics? If untreated, TTP carries a 90% mortality rate, whereas treatment with plasma exchange decreases the mortality rate to 20%.[17] Therefore, obstetricians must be aware of this disease process, so it can be quickly and aggressively treated.

Recent work has helped to determine the pathophysiology of many cases of TTP. **Tsai and colleagues have found that a decrease of ADAMTS-13 activity is strongly associated with TTP.**[18,19] This metalloprotease, also known as von Willebrand's cleaving enzyme, cleaves unusually large multimers of von Willebrand factor (ULVWf). Activity can be decreased from a decrease in the metalloprotease or antibodies against it. If there is a deficiency in the activity and/or concentration of ADAMTS-13, ULVWf circulate in increased amounts, leading to increased platelet aggregation and the initiation of TTP. ADAMTS-13 can be readily assayed in commercial laboratories. Ferrari and colleagues[20] have shown all four Ig subclass of anti-ADAMTS 13 antibodies are associated with TTP, but the IgG(4) subclass is most common. Fakhouri and colleagues[21] found that there were complement gene mutations in 18 of 21 patients with TTP. These findings may lead to the development of therapies that will specifically target the etiology of TTP.

Weiner[22] has published the most extensive literature review concerning TTP. In this series of 45 patients, 40 developed the disease antepartum, with 50% occurring before 24 weeks' gestation. The mean gestational age at onset of symptoms was 23.4 weeks. This finding may be helpful when trying to distinguish TTP from other causes of thrombocytopenia and microangiopathic hemolytic anemia occurring during gestation. In Weiner's review, the fetal and maternal mortality rates were 84% and 44%, respectively. These mortality rates are overly pessimistic, because this series included many patients who contracted the disease before plasma infusion/exchange therapy was utilized to treat TTP.

However, TTP may be confused with rarely occurring early-onset severe preeclampsia. In preeclampsia, antithrombin III levels are frequently low, and this is not the case with TTP. This test, therefore, may be a useful discriminator between these two disorders.

Although the HUS has many features in common with TTP, it usually has its onset in the postpartum period. Patients with HUS display a triad of microangiopathic hemolytic anemia, acute nephropathy, and thrombocytopenia. HUS is rare in adults, and the thrombocytopenia is usually milder than that seen in TTP, with only 50% of patients having a platelet count less than 100,000/mm^3 at the time of diagnosis. The thrombocytopenia worsens as the disease progresses. A major difference between TTP and HUS is that 15% to 25% of patients with the latter develop chronic renal disease. HUS often follows infections with verotoxin-producing enteric bacteria. Cyclosporine therapy, cytotoxic drugs, and oral contraceptives may predispose adults to develop HUS. The majority of cases of HUS occurring in pregnancy develop at least 2 days after delivery. In fact, in one series, only nine of 62 cases (6.9%) of pregnancy-associated HUS occurred antepartum. Four of these nine patients developed symptoms on the day of delivery. The mean time from delivery to development of HUS in patients in this series was 26.6 days. The maternal mortality rate may exceed 50% in postpartum HUS. However, this mortality rate is based on old data. With plasmapheresis and dialysis, the likelihood of maternal death is probably much less. It is not important to make the distinction between TTP and HUS, because the initial therapy for both disorders is plasmapheresis.

EVALUATION OF THROMBOCYTOPENIA DURING PREGANCY AND THE PUERPERIUM

Before deciding on a course to follow in treating the patient with thrombocytopenia, the obstetrician must evaluate the patient and attempt to ascertain the etiology of her low platelet count. Important management decisions are dependent on arriving at an accurate diagnosis. A complete medical history, although time consuming, is critically important. It is essential to learn whether the patient has previously had a depressed platelet count or bleeding diathesis. It is also important to know whether these clinical conditions occur coincidentally with pregnancy. A complete medication history should be elicited, because certain medications, such as heparin, can result in profound maternal thrombocytopenia. The obstetrical history should focus on whether there have been any maternal or neonatal bleeding problems in the past. Excessive bleeding from an episiotomy site or cesarean delivery incision site, or bleeding from intravenous sites during labor should alert the physician to the possibility of thrombocytopenia in the

previous pregnancy. The obstetrician should also question whether the infant had any bleeding diathesis or if there was any problem following a circumcision. The obstetrician should also ask pertinent questions to determine whether severe preeclampsia or HELLP (*H*emolysis, *E*levated *L*iver enzymes, *L*ow *P*latelets) syndrome is the cause of her thrombocytopenia. The treatment of preeclampsia and HELLP are discussed elsewhere in this text. All thrombocytopenic pregnant women should be carefully evaluated for the presence of risk factors for HIV infection, because this infection can cause an ITP-like syndrome. Also, a family history should be elicited, as there are familial forms of thrombocytopenia.

An accurate assessment of gestational age should also be carried out. This is important, because some of the etiologies of thrombocytopenia in pregnancy are dependent on the gestational age. A thorough physical examination of the patient should be performed. The physician should look for the presence of ecchymoses or petechiae. The conjunctivae often show petechiae, as do the nail beds. Blood pressure should be determined to ascertain whether the patient has impending preeclampsia. If the patient is developing HELLP syndrome, scleral icterus may be present. The eye grounds should be examined for evidence of arteriolar spasm or hemorrhage.

It is imperative that a peripheral blood smear be examined by an experienced hematologist or pathologist whenever a case of pregnancy-associated thrombocytopenia is diagnosed. The presence or absence of evidence of microangiopathic hemolysis on the smear will help in establishing a diagnosis. This specialist can also rule out platelet clumping, which will result in a factitious thrombocytopenia. Platelet clumping in EDTA, a lavender top tube, occurs in about 3 per 1000 individuals and may lead to a spurious diagnosis of thrombocytopenia. If platelet clumping is suspected, the physician should ask the laboratory to perform a platelet count on citrate collected blood, a blue top tube. If the count is normal, then there is probably platelet clumping, and the patient is not thrombocytopenic. Other laboratory evaluation should be performed as necessary to rule out preeclampsia and HELLP syndrome, as well as disseminated intravascular coagulopathy. If a diagnosis of ITP is entertained, appropriate platelet antibody testing may aid in the diagnosis but is of limited utility during pregnancy.

After determining the etiology of thrombocytopenia, the physician can better determine whether imminent delivery is necessary, if the thrombocytopenia should be treated before initiating delivery, or if the low platelet count should be monitored during an ongoing pregnancy.

THERAPY OF THROMBOCYTOPENIA DURING PREGNANCY

Gestational Thrombocytopenia

Gestational thrombocytopenia, the most common form of thrombocytopenia encountered in the third trimester, requires no special intervention or therapy. The most important therapeutic issue is to refrain from treatment and testing that may lead to unnecessary intervention or iatrogenic preterm delivery. In patients with mild to moderate thrombocytopenia and no antenatal or antecedent history of thrombocytopenia, the patient should be treated as a normal pregnant patient. If the maternal platelet count drops below 50,000/mm^3, the patient may still have gestational thrombocytopenia, but there are not enough data on mothers with counts this low to determine if there are any maternal or fetal risks. These patients, therefore, should be treated as if they have de novo ITP. Although approximately 4% of patients have gestational thrombocytopenia, less than 1% of uncomplicated pregnant women have gestational thrombocytopenia with platelet counts less than 100,000/mm^3.[6]

Immune Thrombocytopenic Purpura

Treatment of the gravida with ITP during pregnancy and the puerperium requires special attention to the mother, because platelet counts can drop to very low numbers during pregnancy. As in other cases of thrombocytopenia, maternal therapy needs to be instituted only if there is evidence of a bleeding diathesis or to prevent a bleeding complication if surgery is anticipated. **There is usually no spontaneous bleeding unless the platelet count falls below 20,000/mm^3.**[23] In a meta-analysis of 17 studies, the risk of fatal hemorrhage in an individual younger than 40 years of age with a platelet count less than 30,000/mm^3 was 0.4%. The predicted 5-year mortality rate in this setting was 2.2%.[23] Surgical bleeding does not usually occur until the platelet count is less than 50,000/mm^3.

The conventional forms of raising the platelet count in the patient with ITP include glucocorticoid therapy, intravenous gamma globulins, platelet transfusions, and splenectomy. If the patient has clinical bleeding or if the platelet count is below 20,000/mm^3, there is usually a need to raise the platelet count in a relatively short period of time. Although oral glucocorticoids can be used, intravenous glucocorticoids may work more rapidly. Any steroid with a glucocorticoid effect can be used. However, hematologists have had the most experience with methylprednisolone. This medication can be given intravenously and has very little mineralocorticoid effect. It is important to avoid steroids with strong mineralocorticoid effects because these agents can disturb electrolyte balance, cause fluid retention, and result in hypertension. The usual dose of methylprednisolone is 1.0 to 1.5 mg/kg of *total body weight* intravenously daily in divided doses. It usually takes approximately 2 days for a response, but it may take up to 10 days for a maximum response. Even though methylprednisolone has very little mineralocorticoid effect, some may be observed because of the large dose that is being administered. Therefore, it is important to follow the patient's electrolytes. There is little likelihood that methylprednisolone will cause neonatal adrenal suppression because little crosses the placenta. It is metabolized by placental 11-β-ol-dehydrogenase to an inactive 11-keto metabolite. Park-Wyllie and colleagues performed a meta-analysis, which confirmed the general safety of glucocorticoids during pregnancy.[24] They did, however, find a 3.4-fold increased risk of cleft lip and palate with first trimester exposure. The risk/benefit ratio should be discussed with the patient before initiation of therapy.

After the platelet count has risen satisfactorily using intravenous methylprednisolone, the patient can be

switched to oral prednisone. The usual dose is 60 to 100 mg/day. Prednisone can be given in a single dose, but there is less gastrointestinal upset with divided doses. The physician can rapidly taper the dose to 30 to 40 mg/day and decrease it slowly thereafter. The dose should be titrated to keep the platelet count at approximately 100,000/mm^3. If therapy is initiated with oral prednisone, the usual daily dose is 1 mg/kg total body weight.

The likelihood of a favorable response to glucocorticoids is about 70%. It is important to realize that if the patient has been taking glucocorticoids for a period of at least 2 to 3 weeks, she may have adrenal suppression and should undergo increased doses of steroids during labor and delivery in order to avoid an adrenal crisis. Tapering should be slowly thereafter. Also, if the patient has been on glucocorticoids for some time, she may experience significant side effects, including fluid retention, hirsutism, acne, striae, poor wound healing, and monilia vaginitis. In rare circumstances, patients on long-term steroids during gestation can develop osteopenia or cataract formation. The chance of any fetal or neonatal side effects from the glucocorticoids, however, is remote.

Although glucocorticoids are the mainstays of treating maternal thrombocytopenia, up to 30% of patients do not respond to these medications. In such cases, intravenous immunoglobulin (IVIG) is used. This agent probably works by binding to the IgG Fc receptors on reticuloendothelial cells and preventing destruction of platelets. It may also adhere to receptors on platelets and prevent antiplatelet antibodies from binding to these sites. The usual dose is 0.4 g/kg/day for 3 to 5 days. However, it may be necessary to use as much as 1 g/kg/day. The response usually begins in 2 to 3 days and peaks in 5 days. An alternative regimen is to give 1 g/kg once and observe the patient. Often this single dose will result in an adequate increase in platelets. The length of this response is variable, and the timing of the dose is extremely important. If the obstetrician wants a peak platelet count for delivery, therapy should be instituted about 5 to 8 days before the planned delivery. The most frequent adverse reaction is postinfusion headache. This may be lessened by slowing the infusion rate.

IVIG is a blood product from many pooled donors. Early in its use, there were concerns about hepatitis C transmission. There are no recent cases of viral infection from IVIG use. This is due to careful donor screening, as well as an intensive purification process. These steps include ethanol fractionation and polyethylene glycol precipitation, as well as solvent/detergent treatments. These techniques have been tested against hepatitis B, hepatitis C, HIV, mumps, vaccinia, vesicular stomatitis, and enteric cytopathic human orphan viruses. There has been no evidence that these viruses survive the purification process.

IVG should be used before seriously contemplating splenectomy, because some patients experience long-term remission with IVIG and others have a spontaneous increase in platelet counts postpartum. In severe life-threatening hemorrhage, recombinant factor VIIa can be used in conjunction with other therapies. This is a very expensive and complicated therapy that should only be undertaken with the assistance of a physician familiar with its use.

Intravenous anti-D has been used in emergent settings in Rh-positive, direct antiglobulin–negative patients. In life-threatening situations, when other methods fail, one could consider this option. The usual dose is 50 to 75 mcg/kg.[25] Anti-D binds to IgG Fc receptors different than those bound by IVIG.

In midtrimester, splenectomy can also be used to raise the maternal platelet count. This procedure is reserved for those who do not respond to medical management, with the platelet count remaining below 20,000/mm^3 with clinical bleeding. It can also be performed postpartum if the patient does not respond to medical management. In extremely emergent cases of life-threatening bleeding or unresponsiveness to other therapies, splenectomy can be performed at the time of cesarean delivery after extending a midline incision cephalad.

Platelet transfusions are indicated when there is clinically significant bleeding, while awaiting other therapies to become effective. Platelets can be transfused during cesarean delivery if significant clinical bleeding is evident. Platelets can be transfused before a vaginal delivery if the mother's platelet count is less than 20,000/mm^3. Each "pack" of platelets increases the platelet count by approximately 10,000/mm^3. The half-life of these platelets is extremely short because the same antibodies and reticuloendothelial cell clearance rates that affect the mother's endogenous platelets also affect the transfused platelets. However, if platelets are transfused at the beginning of surgery, hemostasis adequate to carry out the surgical procedure should be provided.

If the patient with profound thrombocytopenia undergoes cesarean delivery, certain surgical precautions should be taken. The bladder flap may be left open to avoid hematoma formation. If the parietal peritoneum is closed, subfascial drains are helpful if hemostasis is imperfect. If the peritoneum is not closed, the peritoneal edges should be carefully inspected to make certain there are no bleeding vessels. If severe, life-threatening hemorrhage occurs, recombinant factor VIIa and platelet transfusion can be used.

In summary, the treatment of thrombocytopenia during gestation is dependent on its etiology. The obstetrician need not act on the mother's platelet count unless it is below 30,000/mm^3,[9] if it is below 50,000/mm^3 with evidence of clinical bleeding, or if surgery is anticipated. In these cases, the treatment depends on the diagnosis. Furthermore, whether delivery needs to be expedited or can be delayed is also dependent on the etiology of thrombocytopenia, the patient's physical health, the fetal well-being, and the gestational age.

MANAGEMENT OF THROMBOTIC THROMBOCYTOPENIC PURPURA AND HEMOLYTIC UREMIC SYNDROME

Before the use of plasma exchange, maternal and fetal outcomes in pregnancies complicated by TTP were uniformly poor.[17] The first cases treated with plasma exchange for TTP during pregnancy were reported in 1984. There are no large series of patients with TTP in pregnancy. A review of 11 patients described in case reports reveals that the prognosis has improved greatly with plasma infusion

and plasma exchange.[25] These researchers also demonstrated that cyclosporin may increase the duration of remission. There is one case report where TTP relapses were prevented by using prophylactic monthly exchange throughout gestation.[26] **If TTP is suspected, plasma exchange should be initiated immediately.**

HUS has been more difficult to treat. Only a few case reports have appeared. Supportive therapy remains the mainstay in cases of HUS. Dialysis is often necessary with close attention to fluid management. Platelet function inhibitors were used in two cases during pregnancy. Plasma infusion and plasma exchange can be attempted, but the results have not been as good as observed in cases of TTP. Vincristine has been administered with some success in nonpregnant patients, but has not been tried in pregnancy. Prostacyclin infusion has been effective in children but has not been used during pregnancy.

FETAL/NEONATAL ALLOIMMUNE THROMBOCYTOPENIA

In neonatal alloimmune thrombocytopenia, a rare disorder, the mother lacks a specific platelet antigen and develops antibodies to this antigen. The disease is somewhat analogous to Rh isoimmunization, but involves platelets. If the fetus inherits an antigen from its father and the mother lacks the antigen, maternal antibody can develop and cross the placenta. This results in severe neonatal thrombocytopenia and possibly fetal intracranial hemorrhage. The mother, however, will have a normal platelet count. The most common antibodies noted in these patients is anti-PLA 1 antibodies. Several other antibodies have been identified. If this disorder is suspected, the mother's blood should be sent to a reference laboratory with experience in diagnosing neonatal alloimmune thrombocytopenia. Transfusion of maternal platelets into the neonate also improved outcome in these cases. After birth or in utero, the child can be transfused with the mother's platelets (because she lacks the antigen) or with donor platelets known to lack the antigen. Bussel and colleagues[27] have demonstrated that the antenatal use of intravenous immunoglobulin can prevent thrombocytopenia in infants at risk for neonatal alloimmune thrombocytopenia. These investigators administrated 1 g/kg per week to at-risk mothers and observed no toxicity. The concomitant use of glucocorticoids has not necessarily been shown to boost the effect of the intravenous immunoglobulin.[28] McQuilten and colleagues[29] reviewed the experience in Australia and show that cordocentesis with transfusion, IVIG administration, and corticosteroids are all used with good results. Kamphuis and Oepkes[30] reviewed the experience in the Netherlands. They demonstrate that weekly IVIG alone can virtually prevents fetal/neonatal intracranial hemorrhage in neonatal alloimmune thrombocytopenia. Therefore, they think that fetal blood sampling should be abandoned because of the risks. Rayment and coworkers[31] searched the Cochrane database and Childbirth Group's Trial Register to ascertain if they could discern the optimal management of alloimmune thrombocytopenia. They reviewed four trials involving 206 patients. Because of incomplete data and differences in interventions, they could not conclude the best treatment plan for these patients.[31] They convincingly show that more randomized studies to look at medication doses and timing need to be performed.[31] These patients should be managed in a tertiary care center where there has been experience caring for mothers and infants with this rare disorder.

IRON DEFICIENCY ANEMIA

During a singleton pregnancy, maternal plasma volume gradually expands by approximately 50% (1000 mL). The total RBC mass also increases, but only by approximately 300 mg (25%), and this starts later in pregnancy. It is not surprising, therefore, that **hemoglobin and hematocrit levels usually fall during gestation. These changes are not necessarily pathologic but usually represent a physiologic alteration of pregnancy.** By 6 weeks postpartum, in the absence of excessive blood loss during the puerperium, hemoglobin and hematocrit levels have returned to normal, if the mother has adequate iron stores.

Most researchers and clinicians diagnose anemia when the hemoglobin concentration is less than 11 g/dL or the hematocrit is less than 32%.[32] Using these criteria, 50% of pregnant women are anemic. The incidence of anemia changes depending on the population studied. It is unfortunate that this problem is often ignored. In the developing nations, iron deficiency is an overwhelming problem. Worldwide there are many maternal deaths because of excessive blood loss in women who were already anemic. Beaton[33] suggests that these numbers should be adjusted downward and different targets should be established for different times in pregnancy. As pregnancy progresses, hemoglobin levels are often in the range of 10 to 10.5 g/dL in the late second and early third trimesters. These patients, if iron stores are present, do regain their normal hemoglobin/hematocrit postpartum. Causes of anemia in pregnancy are shown in the box Causes of Anemia during Pregnancy.

Causes of Anemia During Pregnancy

Common Causes—85% of Anemia

Physiologic anemia
Iron deficiency

Uncommon Causes

Folic acid deficiency
Vitamin B_{12} deficiency(due to the rapid increase in bariatric surgery)
Hemoglobinopathies
- Sickle cell disease
- Hemoglobin SC
- β-Thalassemia minor

Bariatric surgery
Gastrointestinal bleeding

Rare Causes

Hemoglobinopathies
- β-Thalassemia major
- α-Thalassemia

Syndromes of chronic hemolysis
- Hereditary spherocytosis
- Paroxysmal nocturnal hemoglobinuria

Hematologic malignancy

Approximately 75% of anemias that occur during pregnancy are secondary to iron deficiency. Ho and colleagues[34] performed elaborate hematologic evaluations of 221 gravidas at term in Taiwan. None of the studied patients received an added iron preparation during gestation. Of the previously nonanemic patients, 10.4% developed clinical anemia after a full-term delivery. Of these 23 patients, 11 (47.8%) developed florid iron deficiency anemia, and another 11 demonstrated moderate iron depletion.[34] The other anemic patient in the group had folate deficiency. Of the 198 nonanemic gravidas at term, 46.5% showed evidence of iron depletion even though they had a normal hematocrit.[34]

To distinguish the normal physiologic changes of pregnancy from those of pathologic iron deficiency, one must understand the normal iron requirements of pregnancy (Table 42-1) and the proper use of hematologic laboratory parameters. In adult women, iron stores are located in the bone marrow, liver, and spleen in the form of ferritin. Ferritin constitutes approximately 25% (500 mg) of the 2 g of iron stores found in the normal woman. Approximately 65% of stored iron is located in the circulating RBCs. If the dietary iron intake is poor, the interval between pregnancies is short, or the delivery is complicated by hemorrhage, iron deficiency anemia readily and rapidly develops.

The first pathologic change to occur in iron deficiency anemia is the depletion of bone marrow, liver, and spleen iron stores. The serum iron level falls, as does the percentage saturation of transferrin. The total iron-binding capacity rises, because this is a reflection of unbound transferrin. A falling hemoglobin and hematocrit follow. Microcytic hypochromic RBCs are released into the circulation. If iron deficiency is combined with folate or vitamin B_{12} deficiency, normocytic and normochromic RBCs are observed on the peripheral blood smear.

Care must be taken when using laboratory parameters to establish the diagnosis of iron deficiency anemia during gestation. A serum iron concentration less than 60 mg/dL with less than 16% saturation of transferrin is suggestive of iron deficiency. Conversely, a single normal serum iron concentration does not rule out iron deficiency. For example, a patient may take iron for several days, and this may result in a transiently normal serum iron concentration while iron stores are still negligible. An increase in iron-binding capacity is not reliable, because 15% of pregnant women without iron deficiency show an increase in this parameter.[35] If a patient has been iron deficient for an extended period of time, her serum iron level can rise before she has depleted her iron stores. The ferritin level indicates the total status of her iron stores. Serum ferritin levels normally decrease minimally during pregnancy. However, a significantly reduced ferritin concentration is indicative of iron deficiency anemia and is the best parameter to judge the degree of iron deficiency. Ferritin levels are variable and can change 25% from one day to the next.[36] Harthoorn-Lasthuizen and colleagues[37] examined erythrocyte zinc protoporphyrin testing in pregnancy. They found that serum ferritin levels did not predict the development of iron-deficient erythropoiesis. However, erythrocyte zinc protoporphyrin measurements did help determine which patients were developing iron deficiency before they developed frank anemia, and these patients benefited from iron therapy.[37] Van den Broek and colleagues[38] believed that the erythrocyte zinc protoporphyrin level was not particularly helpful and that a serum ferritin of less than 30 mcg/L was more than adequate to determine iron deficiency.

Ahluwalia[39] believes that measuring serum transferrin receptors can give a better index of true iron status. Ferritin can be elevated in acute and chronic infections, whereas transferrin receptors do not change in response to an infection. This is important in countries where chronic infection is common in pregnant women. Also receptor concentrations are not confounded by the hemodynamic changes of pregnancy. This test is not yet readily available but may help us in the future to detect iron-deficient patients.[39] Mei and colleagues,[40] working through the National Centers for Chronic Disease Prevention and Health Promotion, assessed total body iron using ferritin and soluble transferrin receptor concentrations. This was part of a large study between 1999 and 2006 and incorporated 1171 pregnant women. The found that iron deficiency increased during pregnancy from 6.9% ± 2.2% in the first trimester to 29.5% ± 2.7% in the third trimester. The prevalence of iron deficiency was highest in women with a parity of at least 2. Iron deficiency was significantly higher in Mexican American and non-Hispanic Black women. Statistical analysis showed that this difference was not due to educational level or family income.[40] Bone marrow aspiration is rarely necessary. It is reserved for persistent anemia with confusing hematologic parameters. It can be safely performed during pregnancy.

Whether all women should receive prophylactic iron in addition to that contained in prenatal vitamins during pregnancy remains controversial. In reviewing the Cochrane database, Milman and colleagues[41] found that 20% of fertile women have iron stores greater than 500 mg, which is the required minimum for pregnancy. They also noted that 40% of women have iron stores between 100 and 500 mg, and 40% have virtually no iron stores. Based on these data, most women do need some iron supplementation.[41] There was no consensus, however, on how much iron supplementation may be needed in patients with iron deficiency.

In pregnancy, iron absorption from the duodenum increases, providing 1.3 to 2.6 mg of elemental iron daily. An acid environment in the duodenum helps this absorption. Therefore, the frequent ingestion of antacid medications, commonly used by many patients, decreases the absorption of iron. Chronic use of H_2 blockers and proton pump inhibitors also diminishes iron absorption. Vitamin C, in addition to the iron, may increase the acid environment of the stomach and increase absorption. In patients

Table 42-1 Iron Requirements for Pregnancy and the Puerperium

FUNCTION	REQUIREMENT
Increased red blood cell mass	450 mg
Fetus and placenta	360 mg
Vaginal delivery	190 mg
Lactation	1 mg/day

TABLE 42-2 Elemental Iron Available from Common Generic Iron Preparations

PREPARATION	ELEMENTAL IRON (mg)
Ferrous gluconate 325 mg	37-39
Ferrous sulfate 325 mg	60-65
Ferrous fumarate 325 mg	107

who do not show clear signs of iron deficiency, it is uncertain whether prophylactic iron, in addition to what is in prenatal vitamins, leads to an increased hemoglobin concentration at term. Iron prophylaxis, however, is safe as only amounts that can be used are absorbed. With the exception of dyspepsia and constipation, side effects are few. One 325 mg tablet of ferrous sulfate daily provides adequate prophylaxis. It contains 60 mg of elemental iron, 10% of which is absorbed. If the iron is not needed, it will not be absorbed and will be excreted in the feces. The standard generic iron tablets and the amount of elemental iron they provide are listed in Table 42-2.

In iron-deficient patients, one iron tablet three times daily has been recommended, although the evidence-based source of this recommendation is difficult to ascertain. Most individuals can absorb as much iron as they need taking iron twice daily. Iron should be taken 30 minutes before meals to allow maximum absorption. However, when taken in this manner, dyspepsia and nausea are more common. Therapy, therefore, must be individualized to maximize patient compliance. Reveiz and colleagues[32] examined the Cochrane database to see if there is an optimal treatment for iron deficiency during pregnancy. They identified 23 trials involving 3198 women. Many of the trials were from low-income countries, were generally small, and had poor methodology. Although oral iron showed a reduction in the incidence of anemia, it was not possible to assess the effects of treatment by severity of anemia.[32] The authors conclude that despite a high incidence and large ramifications of this disease, there is a paucity of good-quality trials. These trials could be relatively easy to design and would be relatively inexpensive compared to so many other trials being carried out. There appears to be a lack of interest among researchers and funding institutions in the United States.

Young and colleagues[42] studied the effectiveness of weekly iron supplementation. They found that weekly iron supplementation was almost as effective as daily supplementation in raising the hemoglobin concentration in iron deficient patients. This approach can be used in patients with less than optimal compliance. Yakoob and Bhutta[43] systematically reviewed the Cochrane database and reviewed 31 studies to see if routine iron supplementation affected the incidence of anemia in pregnancy. They included studies that used iron alone and iron with folic acid. They showed that there was a 73% reduction in anemia with routine supplementation. There was, however, no difference in rates of anemia at term with intermittent iron-folate when compared to daily supplementation (RR, 1.61; CI, 0.82-3.14).[43]

For those patients who are noncompliant or are unable to take oral iron and are severely anemic, intravenous iron can be given. Singh and colleagues[44] found that parenteral iron can be safely given and significantly raises the hematocrit in patients. It also raises the serum ferritin. There were no adverse effects in their study of patients.[44] Hallak and colleagues[45] examined the safety and efficacy of parenteral iron administration. Of 26 patients receiving parenteral iron, only one developed signs of mild allergy during the test dose and was excluded from the study. The remaining 21 pregnant patients completed the course of therapy and received a mean of 1000 mg of elemental iron. Their hemoglobin increased an average of 1.6 g/dL from the beginning to the end of therapy and rose another 0.8 g/dL during the following 2 weeks. Ferritin levels increased from 2.9 ng/mL at the beginning of therapy to 122.8 ng/dL by the end of treatment.[45] Ferritin levels decreased to a mean of 109.4 ng/mL 2 weeks later, demonstrating that the iron was being utilized. Only mild transient side effects were noted. The authors concluded that parenteral iron therapy can be used safely during pregnancy.[45]

TABLE 42-3 Parenteral Iron Administration

MEDICATION	DOSE	PREPARATION
Iron dextran	Total dose (mL) = 0.0442 (Desired hgb − Observed hgb) × LBW + (0.26 × LBW), 100 mg/dose maximum	50 mg elemental iron/mL
Iron sucrose	100 mg/dose, usually 1 dose/day, usually 10 doses needed	20 mg elemental iron/mL
Sodium ferric gluconate complex	125 mg/dose, usually 1 dose/day, usually 8 doses needed	12.5 mg of elemental iron/mL

hgb, Hemoglobin; *LBW*, lean body weight.

Parenteral iron is indicated in those who cannot or will not take oral iron therapy and are not anemic enough to require transfusion. In fact, by building iron stores in the patients before delivery, we may be able to prevent a need for transfusion postpartum in the severely anemic patient. Iron dextran comes in a concentration of 50 mg/mL. It can be given intramuscularly or intravenously, although intramuscular injection is very painful. **Iron dextran can result in anaphylaxis,** which is caused by dissociation of the iron component and carbohydrate component. The reaction may be immediate or delayed. Therefore, a 0.5 mL test dose should be given, and epinephrine should be readily available. Anaphylaxis usually occurs within several minutes but may take 2 days to develop. In the past 3 years, our group has given iron dextran to 14 patients. Two developed a severe reaction within minutes of the test dose. Although neither patient developed shortness of breath, both exhibited severe bone pain and myalgias. The dosage for iron dextran therapy is shown in Table 42-3.

In addition to iron dextran, there are two other parenteral iron preparations. Both of these compounds have the disadvantage of requiring multiple doses to accomplish what can be done with one dose of iron dextran. However, they have the advantage of less likelihood of a severe adverse reaction. Iron sucrose complex is given intravenously with a maximum dose of 100 mg. It is usually given daily. Patients generally require 10 doses (1 g) to obtain

the rise in ferritin and subsequent rise in hemoglobin concentration that are desired. Sodium ferric gluconate complex can be used similarly. The maximum dose is 125 mg. It is usually given daily, and eight doses (1 g) are most often required to obtain the desired results. Sodium ferric gluconate appears to have the least risk of adverse side effects. If the patient has concomitant renal insufficiency, subcutaneous erythropoietin can be given to help raise the hemoglobin concentration if iron stores have already been raised. These agents should be used only in patients with severe iron deficiency who cannot absorb iron or who will not or cannot take oral iron. A parenteral iron overdose can lead to hemosiderosis.

It is still not certain whether anemia results in an increased risk for poor pregnancy outcome. In their literature review, Scholl and Hediger[46] concluded that anemia diagnosed in early pregnancy is associated with preterm delivery and low birth weight. In this study, women with iron deficiency anemia had twice the risk of preterm delivery and three times the risk of delivering a low-birthweight infant.[46] Preterm labor, however, is a multifactorial problem, and there were many confounders in this study. Yip[47] reviewed the literature concerning pregnancy outcome with anemia. He found through epidemiologic studies that there is an association between moderate anemia and poor perinatal outcome, yet he was unable to determine whether this relationship was causal. Sifakis and Pharmakides[48] observed that hemoglobin concentrations less than 6 g/dL are associated with preterm birth, spontaneous abortion, low birth weight, and fetal deaths. Nevertheless, a mild to moderate anemia did not appear to have any significant effect on fetal outcomes.[48] Hemminki and Starfield[49] reviewed controlled trials, concluding that routine iron administration did not decrease preterm labor or raise birth weight. Conversely, Stephansson and colleagues[50] found an increased risk of stillbirth and growth-restricted infants in women with hemoglobin concentrations greater than 14.6 g/dL at their prenatal visit. Demmouche and colleagues[51] found that 46.86% of 207 women were anemic, with 14.43% being severely anemic with a hemoglobin less than 9 g/dL. There was no difference in birth weight between anemic and non-anemic pregnant women.[51]

In summary, iron deficiency is very prevalent in the general pregnant population. **In developing nations, severe anemia is alarmingly common and is a major cause of maternal morbidity and mortality.** Routine iron administration like that found in prenatal vitamins should be used unless it is certain that the patient is iron replete. Iron prophylaxis can be taken as one iron tablet daily, or as one study showed, can be given on a weekly basis. There may be an association between adverse pregnancy outcome and maternal anemia, especially severe anemia. It is uncertain, however, if this is a causal relationship.

MEGALOBLASTIC ANEMIA

Folic acid, a water-soluble vitamin, is found in green vegetables, peanuts, and liver. Folate stores are located primarily in the liver and are usually sufficient for 6 weeks. After 3 weeks of a diet deficient in folate, the serum folate level falls. Two weeks later, hypersegmentation of neutrophils occurs. After 17 weeks without folic ingestion, RBC folate levels drop. In the next week a megaloblastic bone marrow develops. During pregnancy, folate deficiency is the most common cause of megaloblastic anemia. The daily folate requirement in the nonpregnant state is approximately 50 mcg, but this rises at least fourfold during gestation. Fetal demands increase the requirement, as does the decrease in the gastrointestinal absorption of folate during pregnancy.

Clinical megaloblastic anemia seldom occurs before the third trimester of pregnancy. If the patient is at risk for folate deficiency or has mild anemia, an attempt should be made to detect this disorder before megaloblastosis occurs. Serum folate and RBC folate levels are the best tests for folate deficiency. While serum folate reflects recently ingested folate, RBC folate levels give a better idea of folate status at the tissue level.

Folate deficiency rarely occurs in the fetus and is not a cause of significant perinatal morbidity. There is some evidence that fetuses that are homozygous for the C677T variant of the gene encoding for 5, 10-methylene tetrahydrofolate reductase have a 20% lower folate level and may be at risk for a neural tube defect. Because infants born to mothers with type 1 and type 2 diabetes mellitus have an increased incidence of neural tube defects, Kaplan and colleagues[52] studied 31 pregnant diabetic women and 54 controls to determine if there are aberrations in folate metabolism in patients with diabetes. They found that there were no differences in how ingested folate is processed in the pregnant patient with diabetes.[52] Prenatal vitamins that require physician prescription contain 1 mg of folic acid. Most nonprescription prenatal vitamins contain 0.8 mg of folic acid. These amounts are more than adequate to prevent and treat folate deficiency. **Women with significant hemoglobinopathies, patients taking anticonvulsant medications, women carrying a multiple gestation, and women with frequent conception may require more than 1 mg of supplemental folate daily.** If the patient is folic acid deficient, her reticulocyte count will be depressed. Within 3 days after the administration of sufficient folic acid, reticulocytosis usually occurs. In fact, folic acid deficiency should be considered when a patient has unexplained thrombocytopenia. The leukopenia and thrombocytopenia, which accompany megaloblastosis, are rapidly reversed. The hematocrit level may rise as much as 1% per day after 1 week of folate replacement.

Vollsett and colleagues[53] performed a retrospective analysis of 14,492 pregnancies in 5883 women in Norway to determine if elevated homocysteine levels were associated with pregnancy complications. An elevated homocysteine level is often found with depressed folate levels. They compared those in the upper quartile of homocysteine levels with those in the lower quartile. They noted a 32% (odds ratio 1.32) higher risk for preeclampsia, 38% (odds ratio 1.38) higher risk for prematurity, and a 10% (odds ratio 2.01) higher risk for very low birth weight. All trends were statistically significant, but the limitations inherent in retrospective epidemiologic studies apply here.[53] Munger and colleagues[54] investigated serum folate, RBC folate, active pyridoxine, and homocysteine concentrations in 347 pregnancies complicated by facial clefting and 469 controls. Low RBC and serum folate levels were

significantly associated with an increased risk of clefting, whereas pyridoxine and homocysteine levels were not.[54] Therefore, homocysteine does not appear to have an etiologic role in clefting.

Iron deficiency is frequently observed in association with folic acid deficiency. If a patient with folate deficiency does not develop a significant reticulocytosis within 1 week after administration of sufficient replacement therapy, appropriate tests for iron deficiency should be performed.

Until recently, vitamin B_{12} deficiency in pregnancy was either very rare or not recognized. However, bariatric surgery has become increasingly common. Individuals who were morbidly obese and not ovulating, suddenly ovulate and become pregnant. However, **we are now regularly encountering individuals with vitamin B_{12} deficiency following bariatric surgery.** Cobalamin is found only in animal products, and the daily minimum required intake is 6 to 9 mcg. Total body stores are 2 to 5 mg, and one half of this is stored in the liver. For cobalamin to be absorbed, an individual needs the following: (1) acid-pepsin in the stomach; (2) intrinsic factor secreted by parietal cells in the stomach; (3) pancreatic proteases; and (4) an intact ileum with receptors to bind the cobalamin-intrinsic factor complex. Because of the abundant vitamin B_{12} stores in the body, it takes several years for a clinical vitamin B_{12} deficiency to develop.[94] Prolonged vitamin B_{12} deficiency can result in subacute combined degeneration, which involves the dorsal horns and lateral columns of the spinal cord. This can result in sensory and proprioception deficits, which can progress and cause serious disabilities. Fortunately, these changes are reversible when detected early.

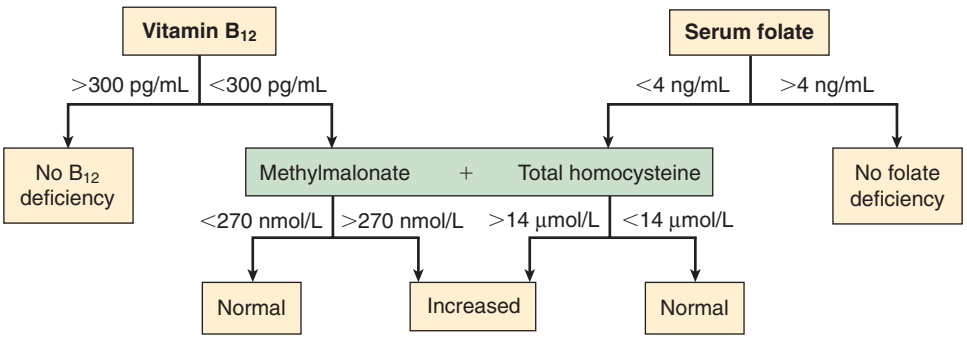
In addition to bariatric surgery, gastrointestinal diseases such as Crohn's disease may lead to an inability to absorb vitamin B_{12}. Because of advances in medical care, more individuals with these chronic disorders are becoming pregnant. As primary care physicians for women, we must be prepared to diagnose and coordinate care in these complex patients. Furthermore, we are encountering more patients taking metformin, which is being prescribed for polycystic ovarian syndrome and other disorders in addition to type 2 diabetes mellitus. It is important to note that this medication can also result in vitamin B_{12} deficiency.[55] Approximately 10% to 30% of patients taking metformin may have depressed vitamin B_{12} levels. This can be reversed with increased calcium intake.[55] The major causes of vitamin B_{12} deficiency are listed in the box Causes of Vitamin B_{12} Deficiency That May Be Encountered in Pregnancy.

Causes Of Vitamin B_{12} Deficiency that may Be Encountered in Pregnancy

- Strict vegetarian diet
- Use of proton pump inhibitors
- Metformin
- Gastritis
- Gastrectomy
- Ileal bypass
- Crohn's disease
- Sprue
- *Helicobacter pylori* infection

Megaloblastic anemia usually leads to a suspicion of folate or vitamin B_{12} deficiency. As noted earlier, if there is an associated iron deficiency, the RBC indices may portray a normocytic, normochromic picture. Therefore, it is important to look at more specific tests for vitamin B_{12} and folate deficiencies. Vitamin B_{12} levels may fall during pregnancy, but this finding may not represent a pathologic process. Also, serum vitamin B_{12} levels may be normal in up to 5% of individuals with a true deficiency.[56]

Evaluation of methylmalonate and homocysteine levels can be used to distinguish folate deficiency from vitamin B_{12} deficiency. Vitamin B_{12} is a cofactor in the metabolism of both methylmalonic acid and homocysteine. A deficiency in vitamin B_{12}, therefore, will lead to an increased concentration of both of these compounds. Folic acid is a cofactor in the metabolism of homocysteine. A folate deficiency, therefore, will lead to an elevated homocysteine level. Savage[56] found elevated methylmalonic acid levels in 98% of individuals with a vitamin B_{12} deficiency but in only 12% of individuals with a folate deficiency. He also found elevated homocysteine levels in 96% of individuals with a vitamin B_{12} deficiency and 91% of individuals with a folate deficiency.[56] Figure 42-1 schematically shows how to incorporate methylmalonic acid and homocysteine testing into the evaluation of megaloblastic anemia.



Increased methylmalonate and folate levels indicate vitamin B_{12} deficiency.
Normal methylmalonate and increased homocysteine levels indicate folate deficiency.

Figure 42-1. Use of methylmalonate and homocysteine levels in the workup of megaloblastic anemia.

HEMOGLOBINOPATHIES

Hemoglobin is a tetrameric protein composed of two pairs of polypeptide chains with a heme group attached to each chain. The normal adult hemoglobin A_1 comprises 95% of hemoglobin. It consists of two α-chains and two β-chains. The remaining 5% of hemoglobin usually consists of hemoglobin A_2 (containing two α-chains and two δ-chains) and hemoglobin F (with two α-chains and two γ-chains). In the fetus, hemoglobin F (fetal hemoglobin) declines during the third trimester of pregnancy, reaching its permanent nadir several months after birth. Hemoglobinopathies arise when there is a change in the structure of a peptide chain or a defect in the ability to synthesize a specific polypeptide chain. The patterns of inheritance are often straightforward. The prevalences of the most common hemoglobinopathies are listed in Table 42-4.

Hemoglobin S

Hemoglobin S, a variant form of hemoglobin, is present in patients with sickle cell disease (hemoglobin SS) and sickle cell trait (hemoglobin AS). A single substitution of valine for glutamic acid at the sixth position in the β-polypeptide chain causes a significant change in the physical characteristics of this hemoglobin. At low oxygen tensions, RBCs containing hemoglobin S assume a sickle shape. Sludging in small vessels occurs, resulting in microinfarction of the affected organs. Sickle cells have a life span of 5 to 10 days, compared with 120 days for a normal RBC. Sickling is triggered by dehydration, hypoxia, or acidosis. Infants with sickle cell anemia show no signs of the disease until the concentration of hemoglobin F falls to adult levels. Some patients do not experience symptoms until adolescence.

Approximately 1 of 12 black adults in the United States is heterozygous for hemoglobin S and, therefore, sickle cell trait (hemoglobin AS) and carries the affected gene. These individuals generally have 35% to 45% hemoglobin S and are asymptomatic. The child of two individuals with sickle cell trait has a 50% probability of inheriting the trait and a 25% probability of actually having sickle cell disease. One of every 625 black children born in the United States is homozygous for hemoglobin S, and the frequency of sickle cell disease among blacks is 1 in 708. All at-risk patients should undergo hemoglobin electrophoresis. Although it is more expensive, it will identify all patients with aberrant hemoglobin types.

The traditional teaching is that women with sickle cell trait are not at increased risk for maternal and perinatal morbidity. A report by Larrabee and Monga[57] questions this. In their study, 162 women with hemoglobin AS had a 24.7% incidence of preeclampsia compared with 10.3% of controls. Furthermore, the mean birth weight of infants born to women with hemoglobin AS was 3082 g compared with 3369 g for controls (P <0.0001). The rate of postpartum endometritis was 12.3% for sickle trait patients compared with 5.1% for controls (P <0.001) despite similar rates of cesarean delivery.[57] This study indicates that we should increase our surveillance in patients with hemoglobin AS.

If a patient has hemoglobin AS, the spouse/partner should be tested, and if both are carriers of a hemoglobinopathy, prenatal diagnosis should be offered. Prenatal diagnosis can be performed rapidly by DNA analysis with polymerase chain reaction (PCR) amplification of DNA fragments. Testing can be performed on amniocytes, and diagnosis can also be made by chorion villus sampling.

A recent study conducted on patients from Michigan highlights the possibility that adolescents with sickle cell disease may not receive adequate contraceptive counseling.[58] These researchers at Nationwide Children's Hospital found that of 250 women with sickle cell disease, only 20 had filled prescriptions for contraception. Among the 195 adolescents, 49 underwent 59 pregnancies during the study period.[58] The authors suggest that significant gaps may exist in family planning care for young women with sickle cell disease.

Painful vaso-occlusive episodes involving multiple organs are the clinical hallmark of sickle cell disease. The most common sites for these episodes are the extremities, joints, and abdomen. Vaso-occlusive episodes can also occur in the lung, resulting in pulmonary infarction. **Analgesia, oxygen, and hydration are the clinical foundations for treating these painful crises. Physicians often underestimate the pain associated with these crises.** These patients have often received many narcotics and may have a tolerance to the usual dosage of these medications. It is very important to treat this pain, no matter how much narcotic pain medication is needed. If the obstetrician is uncomfortable with these large doses, she or he should consult with a pain specialist with experience in this area.

Sickle cell disease can affect virtually all organ systems. Osteomyelitis is common, and osteomyelitis caused by salmonella is found almost exclusively in these patterns. The risk of pyelonephritis is increased, especially during pregnancy. Sickling may also occur in the renal medulla, in which oxygen tension is reduced, resulting in papillary necrosis. These patients also exhibit renal tubular dysfunction and hyposthenuria. Because of chronic hemolysis and decreased RBC survival, patients with sickle cell anemia often demonstrate some degree of jaundice. Biliary stasis commonly occurs during crises, and cholelithiasis is seen in about 30% of cases. Because of chronic anemia, high-output cardiac failure can occur. Left ventricular hypertrophy and cardiomegaly are common.

Pregnancies complicated by sickle cell disease are at risk for poor perinatal outcomes. The rate of spontaneous abortion may be as high as 25%. The perinatal mortality rate is approximately 15%. Powars and coworkers[59] studied 156 pregnancies in 79 women with sickle cell anemia. In this group, the perinatal mortality rate was 52.7% before 1972,

TABLE 42-4 Frequency of Common Hemoglobinopathies in Black Adults in the United States

HEMOGLOBIN TYPE	FREQUENCY
Hemoglobin AS	1 in 12
Hemoglobin SS	1 in 708
Hemoglobin AC	1 in 41
Hemoglobin CC	1 in 4790
Hemoglobin SC	1 in 757
Hemoglobin S/β-thalassemia	1 in 1672

and 22.7% after that time. In a report by Seoud and coworkers,[60] the perinatal mortality rate was 10.5%. Much of this poor perinatal outcome is related to preterm birth. Approximately 30% of infants born to mothers with sickle cell disease have birth weights less than 2500 g. In the report by Seoud and colleagues,[60] the mean birth weight was 2443 g. In a multicenter study, Smith and colleagues[61] reported that 21% of infants born to mothers with sickle cell disease were small for gestational age. It has been hypothesized that sickling in the uterine vessels may lead to decreased fetal oxygenation and intrauterine growth restriction. Persistent hemoglobin F in the mother decreases episodes of painful crises during pregnancy and may also have a protective effect on the neonate. Morris and colleagues[62] studied 270 singleton pregnancies in 175 women with sickle cell disease. The overall rate of fetal wastage was 32.2%. Mothers with high hemoglobin F levels had a significantly lower perinatal mortality rate. Hydroxyurea reduces the incidence of painful crises and increases hemoglobin F concentration and is especially useful in children. Its safety in pregnancy has not been established. If an individual becomes pregnant while using hydroxyurea, it should be discontinued, but pregnancy termination is not justified. Parvovirus B-19 infection is usually asymptomatic in pregnant women but can cause fetal hydrops. In women with sickle cell disease, parvovirus B-19 can cause an aplastic crisis.[63]

Stillbirth rates of 8% to 10% have been described in patients with sickle cell disease. These rates include studies that took place many years ago. With the widespread use of antenatal fetal testing, the rates are significantly lower, but the rates of preterm delivery are higher. These fetal deaths happen not only during crises but also unexpectedly. Therefore, careful antepartum fetal testing must be used, including serial ultrasonography to assess fetal growth. In another study, Anyaegbunam and coworkers[64] examined Doppler flow velocimetry in patients with hemoglobinopathies. They showed abnormal systolic/diastolic ratios for the uterine or umbilical arteries in 88% of patients with hemoglobin SS compared with 7% with hemoglobin AS and 4% with hemoglobin AA. Howard and colleagues[65] observed that maternal exchange transfusions did not change uteroplacental Doppler blood flow velocimetry in these patients. These findings suggest that although maternal well-being may be improved, there is no change in uteroplacental pathology.

Although maternal mortality is rare in patients with sickle cell anemia, maternal morbidity is significant. Infections are common, occurring in 50% to 67% of women with hemoglobin SS. Most are urinary tract infections (UTIs), which can be detected by frequent urine cultures. Common infecting organisms for the bladder, kidneys, lungs, and other sites include *Streptococcus pneumoniae*, *Haemophilis influenzae* type B, *Escherichia coli*, salmonella, and klebsiella. Patients with hemoglobin AS are at greater risk for a UTI and should be screened as well. Pulmonary infection and infarction are also common. Patients with sickle cell anemia should receive pneumococcal vaccine before pregnancy. Maternal deaths have been reported in association with pulmonary complications in sickle cell disease. Any infection demands prompt attention, because fever, dehydration, and acidosis results in further sickling and painful crises. The incidence of pregnancy-induced hypertension is increased in patients with sickle cell anemia and may complicate almost one third of pregnancies in these patients.[61] Although painful crises appear to be more common during gestation,[66] this was not observed in one study.[61]

The care of the pregnant patient with sickle cell anemia must be individualized and meticulous. These patients benefit from care in a medical center experienced in treating the multitude of problems that can complicate such pregnancies. From early gestation, good dietary habits should be promoted. A folate supplement of at least 1 mg/day should be administered as soon as pregnancy is confirmed. Although hemoglobin and hematocrit levels are decreased, iron supplements should not be routinely given. Serum iron and ferritin levels should be checked monthly and iron supplementation started only when these levels are diminished. Often, because of ongoing hemolysis, serum ferritin values are significantly higher in pregnant women with hemoglobin SS disease than in those with hemoglobin AA. Routine iron supplementation, even that in prenatal vitamins, should not be given, because iron overload may lead to hemosiderosis and possibly hemochromatosis.

Most clinicians now feel that prophylactic exchange transfusion carry risk without benefit. This therapy, which replaces the patient's sickle cells with normal RBCs, can both improve oxygen-carrying capacity and suppress the synthesis of sickle hemoglobin. A previous study showed a sevenfold reduction in perinatal mortality in patients receiving prophylactic transfusions.[67] In the same group of patients, there was a significant decrease in fetal growth restriction and preterm births. Morrison and coworkers[68] have also previously reported reduced perinatal wastage and maternal morbidity using a regimen of exchange transfusion. Koshy and colleagues[69] followed 72 pregnant patients with sickle cell anemia, half of whom received prophylactic transfusions and one half transfusions only for medical or obstetrical emergencies. There was no significant difference in perinatal outcome between the offspring of mothers who received prophylactic transfusions and those who did not. Two risk factors were identified as harbingers of an unfavorable outcome: (1) the occurrence of a perinatal death in a previous pregnancy and (2) twins in the present pregnancy. Even though there was no difference in perinatal morbidity and mortality, prophylactic transfusion did appear to decrease significantly the incidence of painful crises.

Mahomed[70] reviewed the Cochrane database and found that there was not enough evidence to make any conclusions about the use of prophylactic RBC transfusion in patients with sickle cell disease. Many of the cited studies did not show evidence of benefit to the fetus from exchange transfusion. A review by Hassell[71] summarizes the various small studies and concludes that prophylactic transfusion does not improve fetal and neonatal outcome. He did not, however, attempt to quantify changes in maternal well-being.

In a study of 128 patients, Ngo and colleagues[72] attempted to delineate whether or not prophylactic partial exchange transfusion improved fetal/neonatal outcomes. Although their control group was patients with

hemoglobin AA, they demonstrated that there were still significant perinatal/neonatal complications in patients with sickle cell disease receiving prophylactic exchange transfusions.[72] The study would have been much stronger if they had used a control group of patients with hemoglobin SS who had not received exchange transfusions. Before stating that there is no place for prophylactic exchange transfusions in patients with sickle cell disease, a study should be undertaken to look at maternal well-being during the 40 weeks of pregnancy. Very few studies have addressed this variable.

If one chooses to perform prophylactic transfusion, the goal is to maintain a percentage of hemoglobin A above 20% at all times and preferably above 40%, as well as to maintain the hematocrit above 25%. Morrison and colleagues[68] recommend that prophylactic transfusion begin at 28 weeks' gestation. Buffy-coat–poor washed RBCs are used to reduce the risk of isosensitization. Other risks of transfusion therapy include viral infection, transfusion reactions, and hemochromatosis.

Either booster or exchange transfusions can be used. Exchange transfusions are preferable. They provide more normal RBCs in less volume, therefore resulting in less stress on the cardiovascular system. This decreases the possibility of congestive heart failure. Exchange transfusions also raise the percentage of hemoglobin A more efficiently. These are usually carried out by erythrocytapheresis. If only booster transfusions are used, diuretics should probably be administered to prevent fluid overload. The patient should be positioned on her left side during the transfusion procedure to maximize uterine blood flow.

Vaginal delivery is preferred for patients with sickle cell disease, and cesarean delivery should be reserved for obstetrical indications. Patients should labor in the left lateral recumbent position and receive supplemental oxygen. Although adequate hydration should be maintained, fluid overload must be avoided. Conduction anesthesia is recommended, because it provides excellent pain relief and can be used for cesarean delivery, if necessary. Winder and colleagues[73] report a case in which epidural anesthesia was used antepartum to relieve a painful crisis. This patient's hospital stay was significantly shortened. Figure 42-2 provides a schematic presentation of the care

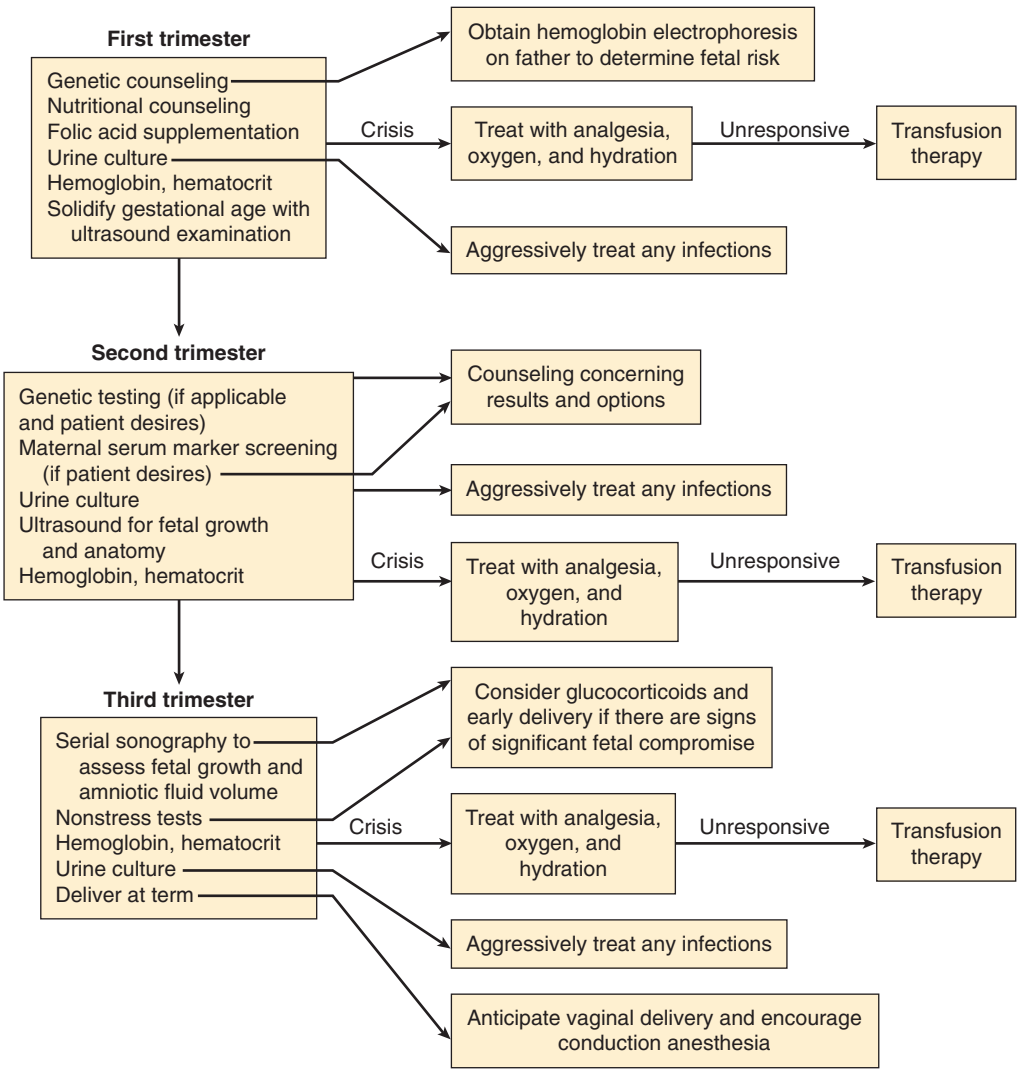


FIGURE 42-2. Schematic presentation of the care of patients with sickle cell anemia.

of patients with sickle cell anemia. It can also be adapted to patients with other hemoglobinopathies.

Hemoglobin SC Disease

Hemoglobin C is another β-chain variant. It results from a G to A point mutation in the first nucleotide of codon 6. The gene is present is 2% of blacks. Clinically significant hemoglobin SC disease occurs in 1 in 833 black adults in the United States. Women with both S and C hemoglobin suffer less morbidity in pregnancy than do patients with only hemoglobin S. As in sickle cell disease, however, there is an increased incidence of early spontaneous abortion and pregnancy-induced hypertension.

Because patients with SC disease can have only mild symptoms, this hemoglobinopathy may remain undiagnosed until a crisis occurs during pregnancy.

Whereas patients with hemoglobin SS often undergo "autosplenectomy," patients with hemoglobin SC may have an enlarged, tender spleen. **Crises in patients with hemoglobin SC may be marked by sequestration of a large volume of RBCs in the spleen accompanied by a dramatic fall in hematocrit.**[74] **Because these patients have increased splenic activity, they may be mildly thrombocytopenic throughout pregnancy and may become profoundly thrombocytopenic during a crisis.** During gestation, patients with hemoglobin SC should receive the same program of prenatal care outlined for women with hemoglobin SS (see Figure 42-2).

Thalassemia

Thalassemia is due to a defect in the rate of globin chain synthesis. Any of the polypeptide chains can be affected. As a result, there is production and accumulation of abnormal globin subunits, leading to ineffective erythropoiesis and a decreased life span of RBCs. The disease may range from minimal suppression of synthesis of the affected chain to its complete absence. Either α- or β-thalassemia can occur. Heterozygous patients are often asymptomatic.

Thalassemia can be detected by prenatal diagnosis. Prenatal diagnosis of β-thalassemia can be accomplished by DNA from villi or amniocytes. Because there are many beta globin mutations, it is important to report the patient's ethnicity and the geographic region of the family when submitting specimens. The laboratory can then test for specific mutations based on this information and will be able to identify β-thalassemia in 90% of cases. α-Thalassemia is also amenable to prenatal diagnosis using quantitative PCR or Southern blot analysis.[75]

Homozygous α-thalassemia results in the formation of tetramers of β-chains known as hemoglobin Bart. This hemoglobinopathy can result in hydrops fetalis. Ghosh and coinvestigators[76] reported their experience caring for 26 Chinese women who were at risk to deliver a fetus with homozygous α-thalassemia. Six of the 26 fetuses were affected. In two of the six cases, progressive fetal ascites appeared before 24 weeks' gestation. These pregnancies were terminated and the diagnoses confirmed. In the remaining four patients, there was evidence of intrauterine growth restriction by 28 weeks' gestation. At later gestational ages, an increase in the transverse cardiac diameter was seen in the affected fetuses. Woo and colleagues[77] reported that umbilical artery velocimetry reveals a hyperdynamic circulatory state in fetuses that are hydropic because of α-thalassemia. In a study from Taiwan, Hsieh and colleagues[78] demonstrated that umbilical vein blood flow measurements can help to distinguish hydrops fetalis caused by hemoglobin Bart from hydrops fetalis having other causes. The umbilical vein diameter, blood velocity, and blood flow in fetuses with hemoglobin Bart were usually higher than those in fetuses with hydrops fetalis due to other etiologies.

β-Thalassemia is the most common form of thalassemia. Patients with the heterozygous state are usually asymptomatic. They are detected by an increase in their level of both hemoglobin A_2 and hemoglobin F. Hemoglobin E is another β-chain variant found generally in patients from Southeast Asia. The clinical course is variable and similar to that described for β-thalassemia. In the homozygous state of β-thalassemia, synthesis of hemoglobin A_1 may be completely suppressed. Hemoglobin A_2 levels of greater than 50% are found in 40% of patients with β-thalassemia, and an elevated hemoglobin F level is observed in 50% of these patients. The homozygous state of β-thalassemia is known as thalassemia major, or Cooley's anemia. Patients with this disorder are transfusion dependent and have marked hepatosplenomegaly and bone changes secondary to increased hematopoiesis. These individuals usually die of infectious or cardiovascular complications before they reach childbearing age. They also have a high rate of infertility, although successful full-term pregnancies have been reported. The few patients who do become pregnant generally exhibit severe anemia and congestive heart failure.[79] Prenatal care is dependent on transfusion therapy similar to that used in the care of the patient with sickle cell disease.

Heterozygous β-thalassemia has different forms of expression. Patients with thalassemia minima have microcytosis but are asymptomatic. Those with thalassemia intermedia exhibit splenomegaly and significant anemia and may become transfusion dependent during pregnancy. Their anemia can be significant enough to produce high-output cardiac failure. If these patients have not undergone splenectomy, they are at risk for a hypersplenic crisis. Also, extramedullary hematopoiesis may impinge on the spine, resulting in neurologic symptoms.

These patients should be managed with a treatment program similar to that followed for patients with sickle cell disease (see Figure 42-2). **As in the case of sickle hemoglobinopathies, iron supplementation should be given only if necessary, because indiscriminate use of iron can lead to hemosiderosis and hemochromatosis.** White and coworkers[80] have shown that patients with a β-thalassemia usually have a much higher ferritin concentration than normal patients and those who are α-thalassemia carriers. In β-thalassemia carriers, the incidence of iron deficiency anemia is four times less common than it is in α-thalassemia carriers and normal patients.[80] Although iron is not necessary, folic acid supplementation appears important in β-thalassemia carriers. Leung and coinvestigators showed that the daily administration of folate significantly increased the predelivery hemoglobin concentration in both nulliparous and multiparous patients.

Patients who are transfusion dependent can develop iron overload. There are very little data on the safety of

iron chelating agents during pregnancy. Ricchi and colleagues[81] report a case of successful pregnancy while using deferasirox in the first trimester. The pregnancy went to term and there were no fetal malformations.

As in the case of sickle cell disease, antepartum fetal evaluation is essential in patients with thalassemia who are anemic. Patients with thalassemia should undergo frequent ultrasonography to assess fetal growth, as well as nonstress testing to evaluate fetal well-being. Asymptomatic thalassemia carriers need no special testing.

Occasionally, individuals will inherit two hemoglobinopathies, such as sickle cell thalassemia (hemoglobin S thal). The prevalence of this disorder among adult blacks in the United States is 1 in 1672.[82] The clinical course is variable. If minimal suppression of β-chains occurs, patients may be free of symptoms. However, with total suppression of β-chain synthesis, a clinical picture similar to that of sickle cell disease will develop. The course of these patients during pregnancy is quite variable, and their therapy must be individualized.

In summary, Figure 42-3 presents a stepwise approach to the workup of anemia and the diagnosis of the conditions discussed in this chapter.

VON WILLEBRAND'S DISEASE

Von Willebrand's disease (vWD) is the most common congenital bleeding disorder in humans, and up to 1% of the population may have some form of the disorder. Type 1 is an autosomal dominant disorder, whereas type 3 and occasionally type 2 are autosomal recessive.[83] vWD is related to quantitative or qualitative abnormalities of von Willebrand's factor (vWF). This multimeric glycoprotein serves as carrier protein of factor VIII, prolonging its life span in plasma. It also promotes platelet adhesion to the damaged vessel and platelet aggregation. Distinct abnormalities of vWF are responsible for the three types of vWD. Types 1 and 3 are characterized by a quantitative defect of vWF, whereas type 2, comprising subtypes 2A, 2B, 2M, and 2N, refers to molecular variants with a qualitative defect of vWF. In these type s subtypes, there are various problems in binding of vWF to factor VII or platelet surface.[84] The knowledge of the structure of the vWF gene and the use of PCR have led to the identification of the molecular basis of vWD in a significant number of patients.[85] In type 2B, the only clinical symptom in pregnancy may be thrombocytopenia.[86] Therefore, this diagnosis should be considered in the gravida with isolated thrombocytopenia during pregnancy.

The clinical severity of vWD is variable. Menorrhagia, easy bruising, gingival bleeding, and epistaxis are common. Menorrhagia is most severe in patients with types 2 and 3 vWD and most common in patients with type 1 disease. In a compilation of two studies, 17% of women with severe menorrhagia had a form of vWD.[87] Some patients may be entirely asymptomatic until they have severe bleeding after surgery or trauma. Von Willebrand's disease does not appear to affect fetal growth or development.

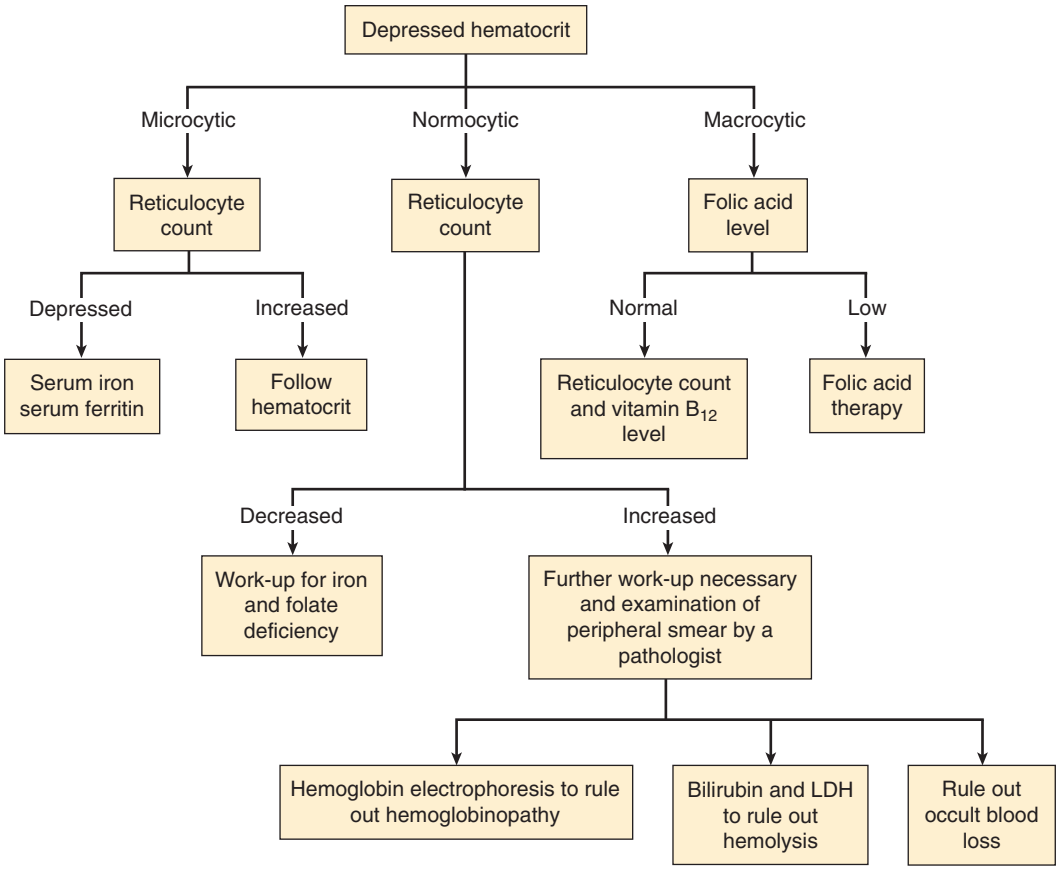

FIGURE 42-3. Evaluation of anemia.

Classically, the bleeding time is prolonged in patients with vWD as a result of diminished platelet aggregation. Occasionally, the activated partial thromboplastin time (APTT) is also abnormal. This is only seen when the factor VIII activity is extremely low.[88] In pregnancy, clotting factors including the factor VIII complex increase, and the patient's bleeding time may improve as gestation progresses.[87] This is especially true for type 1A vWD. In type 1B, the patient may not correct her bleeding time.[87] In type 2B, the platelet count decreases. This may be exacerbated in pregnancy.[88] There will, however, be an improvement in the vWF multimeric pattern.[89]

Heavy bleeding may be encountered in patients with vWD undergoing elective or spontaneous first-trimester abortion because the levels of factor VIII have not yet risen.[90] **Most important, postpartum hemorrhage may be a serious problem.** The concentration of factor VIII appears to determine the risk of hemorrhage. If the level is greater than 50% of normal and the patient has a normal bleeding time, excessive bleeding should not occur at vaginal delivery.[84] In a study by Kadir and colleagues,[90] 18.5% of patients with vWD experienced a significant postpartum hemorrhage, and 6 of 31 patients required transfusion. The clinical course during labor is variable. In a study by Chediak and colleagues,[91] bleeding complications were seen in six of eight (75%) pregnancies. Five of the newborns had vWD, one of whom was born with a scalp hematoma. Conti and associates,[92] conversely, reported no bleeding complications during the puerperium in five women with vWD. Ieko and colleagues[93] demonstrated that factor VIII concentrate could raise the platelet levels in patients with type 2B vWD. Ito and colleagues[94] followed six women with type 1 vWD in 10 term pregnancies, three induced abortions, and one spontaneous abortion. They found that bleeding complications occurred within 1 week after term delivery and immediately after both spontaneous and induced abortions.

As noted earlier, bleeding during pregnancy is rare because levels of factor VIII and vWF increase during pregnancy. However, shortly after delivery, they drop. If the factor VIII level is less than 50%, treatment during labor and delivery should be initiated. Hemorrhage can also occur several days postpartum. Therefore, factor VIII levels should be checked before the patient goes home after delivery. Desmopressin is the treatment of choice for type 1 vWD.[95] It elicits the release of vWF from endothelial cells. Intranasal preparations of 300 mcg are usually employed. The half-life of desmopressin is about 8 hours, so the dose should be repeated every 12 hours. In emergent or preoperative situations, 0.3 mcg/kg of desmopressin can be given intravenously over 30 minutes.[95] **Desmopressin can rarely cause hyponatremia and fluid retention.[96] Also, patients can develop tachyphylaxis with desmopressin, so it should not be used for prolonged periods of time.**

For those patients who do not respond to desmopressin or for those with vWD types other than 1A, Humate-P or Alphanate should be employed. These commercially available concentrates of antihemophiliac factor have been tested extensively in clinical studies. They contain 2 to 3 times more vWF than they do factor VIII concentrate.[96] The usual dose of Humate-P or Alphanate is 20 to 50 units/kg. During labor, this can be given every 12 hours. For labor and delivery, usually the lower end of the dosage range will suffice. If a cesarean delivery is needed, the upper end of the dosage range should be used.

These compounds have been heated at high temperature and treated with solvents and detergents to inactivate blood-borne viruses. It is important to note that products containing highly purified factor VIII, obtained by recombinant DNA, should not be used. They contain very little vWF and are ineffective in vWD. Therefore, the infused factor VIII has a very short half-life, because vWF is essential to prevent the degradation of factor VIII.

Bleeding during pregnancy is rare. Patients with classic type 1 vWD usually need no treatment owing to the increase in factor VIII levels during pregnancy. Those with a history of postpartum hemorrhage should be given an intravenous dose of desmopressin immediately after delivery, and the dose should be repeated 24 hours later. For those with types 2 and 3 disease, factor VIII/vWF concentrates are occasionally needed. Before a cesarean delivery, factor VIII activity should be measured. If it is less than 50% of expected, patients with type 1 vWD should be given desmopressin and patients with vWD type 2 or type 3 should receive factor VIII/vWF concentrate.[97] **If you encounter an emergent situation and the type of vWD is not known with certainty, factor VIII/vWF concentrate should be used.**

KEY POINTS

- Four percent of pregnancies will be complicated by maternal platelet counts of less than 150,000/mm^3. The vast majority of these patients have gestational thrombocytopenia with a benign course and need no intervention.
- Surgical bleeding occurs if the platelet count falls below 50,000/mm^3 and spontaneous bleeding occurs if the platelet count falls below 20,000/mm^3.
- Glucocorticoids are the first-line medication used to raise a low platelet count.
- Iron deficiency anemia is the most common cause of anemia in pregnancy, and serum ferritin is the single best test to diagnose it.
- If a patient with presumed iron deficiency does not increase her reticulocyte count with iron therapy, she may also have a concomitant folic acid deficiency.
- Patients pregnant with twins, those on anticonvulsant therapy, those with a hemoglobinopathy, and those who conceive frequently need supplemental folic acid during gestation.
- Most hereditary hemoglobinopathies can be detected in utero, and prenatal diagnosis should be offered to the patient early in pregnancy.
- As in the nonpregnant patient, analgesia, hydration, and oxygen are the key factors in treating pregnant women with sickle cell crisis.
- Patients with sickle cell disease are at high risk of having a fetus with growth restriction and adverse fetal outcomes. Therefore, they warrant frequent sonography and antepartum fetal evaluation.
- In the pregnant patient with vWD, the normal increase in the factor VIII clotting complex reduces the risk of bleeding.

KEY ABBREVIATIONS

Activated Partial Thromboplastin Time	aPTT
Activated Protein C	APC
Acute Pulmonary Embolus	APE
Adenosine Diphosphate	ADP
Antiphospholipid Antibody	APA
Antiphospholipid Antibody Syndrome	APAS
Computed Tomography	CT
Computed Tomographic Pulmonary Angiography	CTPA
Deep Venous Thrombosis	DVT
Enzyme-linked Immunosorbent Assay	ELISA
Factor V Leiden	FVL
Heparin-induced Thrombocytopenia	HIT
Inferior Vena Cava	IVC
International Normalized Ratio	INR
Low-molecular-weight Heparin	LMWH
Magnetic Resonance Angiography	MRA
Magnetic Resonance Imaging	MRI
Plasminogen Activator Inhibitor-1	PAI-1
Protein Z–Dependent Protease Inhibitor	ZPI
Pulmonary Embolus	PE
Systemic Lupus Erythematosus	SLE
Thrombin-activatable Fibrinolysis Inhibitor	TAFI
Thromboxane A_2	TXA_2
Tissue Factor	TF
Tissue Factor Pathway Inhibitor	TFPI
Venous Thromboembolism	VTE
Venous Ultrasonography	VUS
Ventilation Perfusion Scan	V/Q

Pregnancy, childbirth, and the puerperium create serious challenges to a woman's hemostatic system. The development of the high-volume, high-flow, low-resistance uteroplacental circulation requires an enhanced hemostatic response to avoid hemorrhage. The price paid for this essential hemostatic adaptation to human hemochorial placentation is an increased risk for superficial and deep venous thrombosis (DVT) and pulmonary embolus (PE). Mothers with underlying acquired or inherited thrombophilias are at particular risk. The expeditious identification and prompt treatment of such thrombotic events is critical to avoiding death and serious postphlebitic sequelae.

Epidemiology

Occurring in about 1 in 1500 pregnancies, venous thromboembolism (VTE) is a relatively uncommon disorder but a leading cause of mortality and serious morbidity in pregnant women.[1-8] This rate represents a nearly 10-fold increase compared with nonpregnant women of comparable childbearing age. According to the most recent U.S. vital statistics, PE is the leading cause of maternal mortality, contributing to 19.6% of maternal deaths, or 2.3 pregnancy-related deaths per 100,000 live births.[9] Classic teaching viewed the postpartum period as the period of maximal thrombotic occurrence; however, management styles of prior eras (e.g., prolonged puerperal bedrest, and estrogen to suppress lactation) likely inflated this risk.[6] More recent studies have shown that most thromboembolic events happen in the antepartum period.[1,3,10-12] However, given its shorter duration and after adjusting for duration of exposure, the relative risk for VTE is about threefold to eightfold higher in the puerperium.[8]

Risk Factors

Virchow's triad—**vascular stasis, hypercoagulability, and vascular trauma**—describes the three classic antecedents

to thrombosis, and many of the physiologic changes of pregnancy contribute to these criteria. Other pregnancy-specific risk factors for thrombosis include increased parity, postpartum endomyometritis, operative vaginal delivery, and cesarean delivery. The latter is associated with a substantial ninefold increase in the risk for thromboembolism compared with vaginal delivery.[10] Risk factors not unique to pregnancy include age greater than 35 years, obesity, trauma, immobility, infection, smoking, nephrotic syndrome, hyperviscosity syndromes, cancer, surgery (particularly orthopedic procedures), and a prior history of DVT or PE.

PHYSIOLOGY OF HEMOSTASIS

Vasoconstriction and Platelet Action

Vasoconstriction and platelet activity play a primary initial role in limiting blood loss following vascular disruption and endothelial damage. Vasoconstriction limits blood flow as well as the size of thrombus necessary to repair the defect. Platelet adherence to damaged vessels is mediated by the formation of von Willebrand factor "bridges" anchored at one end to subendothelial collagen and at the other to the platelet GPIb/IX/V receptor.[13] Platelet adhesion stimulates release of α-granules containing von Willebrand factor, thrombospondin, platelet factor-4, fibrinogen, β-thromboglobulin, and platelet-derived growth factor, as well as dense granules containing adenosine diphosphate (ADP) and serotonin. These latter molecules, when combined with the release of thromboxane A_2 (TXA_2), contribute to further vasoconstriction and platelet activation, and ADP causes a conformational change in the platelet GPIIb/IIa receptor that promotes aggregation by forming interplatelet fibrinogen, fibronectin, and vitronectin bridges.[14]

Coagulation Cascade

Platelet action alone is insufficient to provide adequate hemostasis in the face of a substantial vascular insult; in this setting, the coagulation cascade, with resultant fibrin-plug formation, is required to restore hemostasis. Tissue factor (TF), a cell membrane–bound glycoprotein, is the primary initiator of the coagulation cascade.[15] It is expressed constitutively by epithelial, stromal, and perivascular cells throughout the body and in abundance by endometrial stromal cells and the pregnant uterine decidua.[15,16] TF is also present in low concentrations in blood, on activated platelets, and in high levels in amniotic fluid, accounting for the coagulopathy seen in amniotic fluid embolism.[17] It is interesting to note that although intrauterine survival is possible in the absence of platelets or fibrinogen, it is not possible in the absence of TF.[18] Clotting is initiated by the binding of TF to factor VII (Figure 43-1).

After endothelial injury and in the presence of ionized calcium, perivascular cell- or platelet-bound TF comes into contact with factor VII on anionic cell membrane phospholipids. Factor VII has low intrinsic clotting activity but can be autoactivated after binding to TF or can be activated by thrombin or factors IXa, Xa, or XIIa.[15,19] The TF/FVIIa complex initiates the elements of the coagulation cascade by activating both factors X and IX. The latter (IXa) complexes with its cofactor, factor VIIIa, to indirectly activate factor X. Once generated, factor Xa binds with its cofactor Va to convert prothrombin (factor II) to thrombin (IIa). The cofactors V and VIII can each be activated by either thrombin or factor Xa. Activated factor XII activates factor XI on the surface of activated platelets, which provides an alternative route to factor IX activation. Factor XII can be activated by kallikrein/kininogen as well as by plasmin. The key event of hemostasis occurs when thrombin cleaves fibrinogen to produce fibrin. Fibrin monomers self-polymerize and are cross-linked by thrombin-activated factor XIIIa. Although TF is the initiator of hemostasis, thrombin is the ultimate arbiter of clotting because it not only activates platelets and generates fibrin but also activates critical clotting factors and cofactors (V, VII, VIII, and XIII). Figure 43-1 provides a diagram of the interaction of the various components of the coagulation cascade.

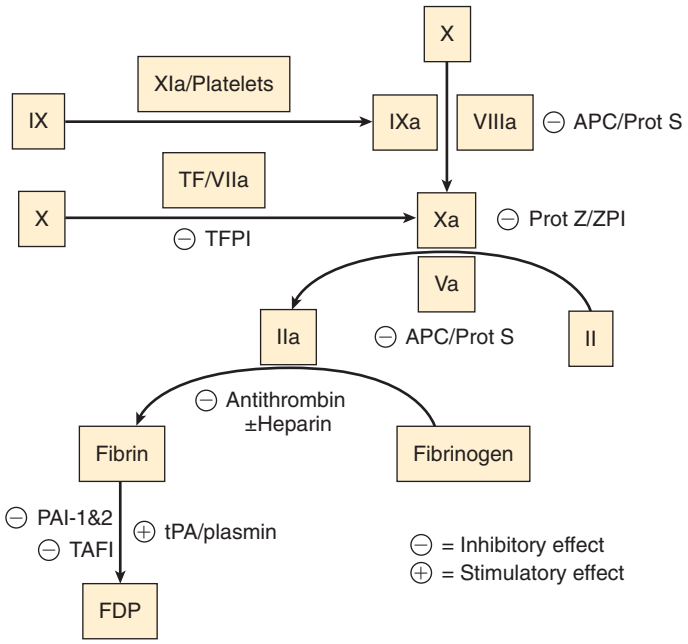

FIGURE 43-1. Hemostatic, thrombotic, and fibrinolytic pathways. *FDP,* Fibrin degradation product; *tPA,* Tissue-type plasminogen activator.

Anticoagulant System

The risk for thrombosis, the inappropriate and excessive activation of the clotting cascade, is restrained by the anticoagulant system (see Figure 43-1). There is evidence that the coagulation system "idles" like a car engine to quickly respond to vascular injury, and, thus, the anticoagulant system performs the critical role of preventing inappropriate acceleration of clotting.[19] Tissue factor pathway inhibitor (TFPI) binds to the prothrombinase complex (factor Xa/TF/VIIa) to stop TF-mediated clotting.[20] However, as noted, factor XIa generation can bypass this block. Moreover, in the 10 to 15 seconds before TFPI-mediated prothrombinase inhibition, sufficient quantities of factors Va, VIIIa, IXa, and Xa and thrombin are generated to sustain clotting for some time. As a result, additional physiologic anticoagulant molecules are required to maintain blood fluidity.

Paradoxically, thrombin also plays a pivotal role in the anticoagulant system by binding to thrombomodulin, which causes a conformation change that allows it to

activate protein C (APC). The APC molecule binds to anionic endothelial cell membrane phospholipids on damaged vessels or to the endothelial cell protein C receptor (EPCR) to inactivate factors Va and VIIIa.[21] Protein S is an important cofactor in this process, enhancing APC activity. Factor Va is also a cofactor in APC-mediated factor VIIIa inactivation.

Factor Xa can also be inhibited by the protein Z–dependent protease inhibitor (ZPI). When ZPI forms a complex with its cofactor, protein Z, its inhibitory activity is enhanced 1000-fold, although ZPI can also inhibit factor XIa independent of protein Z.[22] Deficiencies of protein Z can promote both bleeding and thrombosis, although the latter predominates particularly in the presence of other thrombophilias.

Thrombin activity is modulated by a number of serine protease inhibitors (e.g., heparin cofactor II, α_2-macroglobulin, antithrombin) that serve to inactivate thrombin and Xa. The most active inhibitor within this group is antithrombin (also known as antithrombin III). Antithrombin binds to either thrombin or factor Xa and then to heparin or other glycosaminoglycans, augmenting the antithrombin rate of thrombin inactivation 1000-fold.[23,24] The other two inhibitors work in a similar fashion.

Clot Lysis and Fibrinolysis

Fibrinolysis is a further critical element in preventing overwhelming thrombosis (see Figure 43-1). Tissue-type plasminogen activator, embedded in fibrin, cleaves plasminogen to generate plasmin, which, in turn, cleaves fibrin into fibrin degradation products. The latter are indirect measures of fibrinolysis. These fibrin degradation products can also inhibit thrombin action, a favorable effect when production is limited but a contributor to disseminated intravascular coagulation (DIC) when production is excessive. A second plasminogen activator, urokinase-type plasminogen activator (uPA), is produced by endothelial cells. There is also a series of fibrinolysis inhibitors that prevent hemorrhage from premature clot lysis. The α_2-plasmin inhibitor is bound to the fibrin clot, where it prevents premature fibrinolysis. Platelets and endothelial cells release plasminogen activator inhibitor-1 (PAI-1), an inactivator of tissue-type plasminogen activator. In pregnancy, the decidua is also a rich source of PAI-1, and the placenta produces mostly PAI-2.[25] The thrombin-activatable fibrinolysis inhibitor (TAFI) is another fibrinolytic inhibitor that is also activated by the thrombin-thrombomodulin complex.[26] TAFI modifies fibrin, rendering it resistant to inactivation by plasmin.

PATHOPHYSIOLOGY OF THROMBOSIS IN PREGNANCY

Characteristic physiologic changes in the local decidual and systemic hemostatic systems occur in pregnancy in preparation for the hemostatic challenges of implantation, placentation, and childbirth. Decidual TF and PAI-1 expression are greatly increased in response to progesterone, and levels of PAI-2, which are negligible before pregnancy, increase until term.[25,26] Pregnancy is associated with systemic changes that enhance hemostatic capability but promote thrombosis. For example, there is **a doubling in circulating concentrations of fibrinogen and 20% to 1000% increases in factors VII, VIII, IX, X, and XII, all of which peak at term in preparation for delivery.**[27] Levels of von Willebrand factor also increase up to 400% at term.[27] In contrast, levels of prothrombin and factor V remain unchanged, whereas levels of factor XIII and XI decline modestly. Concomitantly, there is a **40% decrease in the levels of free protein S, conferring an overall resistance to APC.**[27] Further reductions in free protein S concentrations are caused by cesarean delivery and infection, accounting for the high rate of PE in such patients. Coagulation parameters may normalize as early as 3 weeks postpartum, but they generally return to baseline at 6 weeks postpartum.

The risk for thrombosis in pregnancy is also related to physical changes in the gravid woman. Venous stasis in the lower extremities results from compression of the inferior vena cava and pelvic veins by the enlarging uterus.[28,29] Despite the presence of the sigmoid colon promoting uterine dextrorotation, ultrasound findings indicate lower flow velocities in the left leg veins throughout pregnancy.[30] This would explain why multiple studies have confirmed that the incidence of thrombosis is far greater in the left leg than right leg.[1,11] Hormone-mediated increases in deep vein capacitance secondary to increased circulating levels of estrogen and local production of prostacyclin and nitric oxide also contribute to the increased risk for thrombosis.

Antiphospholipid Antibody Syndrome

Overall, antiphospholipid antibody syndrome (APAS) is responsible for about 14% of thromboembolic events in pregnancy.[31,32] The diagnosis of APAS requires the presence of prior or current vascular thrombosis, or characteristic obstetrical complications, together with at least one laboratory criterion (e.g., anticardiolipin antibodies, anti-β_2-glycoprotein-I, or lupus anticoagulant).[33] The antiphospholipid antibodies (APAs) are a class of self-recognition immunoglobulins whose epitopes are proteins bound to negatively charged phospholipids. Anticardiolipin antibodies and the lupus anticoagulants represent the two most widely employed end points, but other applicable tests include anti-ß$_2$-glycoprotein, and recently, antiprothrombin and antiannexin antibodies have been identified.[34] These antibodies must be present on two or more occasions at least 12 weeks apart for diagnosis.[33] These antibodies are present in 2.2% of the general obstetrical population, and most affected patients have uncomplicated pregnancies.[35] Thus, providers should use caution when ordering and interpreting tests in the absence of APAS-qualifying clinical criteria.

APAS has been associated with both venous (DVT, PE) and arterial (stroke) vascular events. A meta-analysis of 18 studies has shown elevated risk for DVT, PE, and recurrent VTE among patients with systemic lupus erythematous (SLE) who test positive for the APAs. Overall, when compared with SLE patients who do not test positive for either test, those with lupus anticoagulants and anticardiolipin antibodies have sixfold and twofold increased risks for venous thrombosis, respectively.[36] These antibodies pose a risk to patients without SLE as well. The lifetime prevalence of arterial or venous thrombosis in affected non-SLE patients is about 30%, with an

OR, Odds ratio; *RR*, relative risk.

event rate of 1% per year.[37,38] The risks for thromboembolic events are highly dependent on the presence of other predisposing factors, including pregnancy, estrogen exposure, immobility, surgery, and infection. APAS has also been associated with adverse pregnancy outcome and accounts for 14% of VTE in pregnancy.[31,32] In fact, there is a 5% risk for a thrombotic event in pregnancy, even with prophylaxis.[39]

Inherited Thrombophilias

The inherited thrombophilias are a heterogeneous group of genetic disorders associated with arterial and venous thrombosis as well as fetal loss. As with APAS, the occurrence of a thromboembolic event is highly dependent on other predisposing factors such as pregnancy, exogenous estrogens, immobility, obesity, surgery, infection, trauma, and the presence of other thrombophilias. However, the most important risk modifier is a personal or family history of venous thrombosis.[40] **Table 43-1 presents the prevalence and risk of venous thrombosis among pregnant patients with and without a personal or family history of venous thrombosis.** As noted, the thrombophilias are divided into high and low risks based on the overall risk for VTE. The screening for and management of inherited thrombophilias during and around the time of pregnancy was recently addressed by the American College of Obstetricians and Gynecologists (ACOG).[41]

Recent prospective studies have suggested that lower-risk inherited thrombophilias may have an even lower association with maternal thrombosis than observed in the retrospective studies[42-51] cited in Table 43-1. For example, a prospective study of 4885 low-risk women screened in the first trimester of pregnancy noted that 134 (2.7%) carried the factor V Leiden mutation, but none had a thromboembolic event during pregnancy or puerperium (95% confidence interval [CI], 0% to 2.7%).[52] In two other prospective studies involving 584 Irish and 4250 British pregnant women again screened for factor V Leiden early in pregnancy, no thrombotic episodes were noted among carriers.[53,54] Said and associates blindly tested 1707 Australian nulliparous women for factor V Leiden, the prothrombin gene *G20210A* mutation, and a thrombomodulin polymorphism before 22 weeks and reported expected prevalences of heterozygosity for the factor V Leiden and prothrombin *G20210A* gene mutations and homozygosity for the thrombomodulin polymorphism of 5.39%, 2.38%, and 3.51%, respectively, but again none of the patients developed venous thromboembolic events.[55] However, one prospective study of 2480 women tested for APC resistance and factor V Leiden early in pregnancy observed affected patients had an eightfold increase in VTE.[56] Thus, the true risk for thrombosis in patients with low-risk inherited thrombophilias is probably lower than suggested by retrospective case control and cohort studies and also likely dependent on the presence of concomitant risk factors such as a strong family history, obesity, and surgery.

DIAGNOSIS OF VENOUS THROMBOEMBOLISM

Deep Venous Thrombosis

Clinical Signs and Symptoms

The clinical findings typical of DVT include erythema, warmth, pain, edema, and tenderness localized to the area of the thrombosis. Occasionally, a palpable cord may correspond to a thrombosed vein, and Homans sign is the pain

and tenderness elicited on compression of the calf muscles by squeezing the muscles or dorsiflexion of the foot. These are rather nonspecific signs and symptoms that involve a broad differential diagnosis, including cellulitis, ruptured or strained muscle or tendon, trauma, ruptured popliteal (Baker) cyst, cutaneous vasculitis, superficial thrombophlebitis, and lymphedema. In fact, evidence suggests that the specificities of these manifestations are less than 50%, and among patients with these signs and symptoms, the diagnosis of DVT is confirmed by objective testing in only about one third of the group.[57,58]

Risk Scoring System

Work by Chan and colleagues demonstrated that subjective assessment by "thrombosis experts" of clinical risk for DVT in symptomatic pregnant patients can categorize patients, before diagnostic testing, into two groups with low risk (1.5% prevalence, 98.5% negative predictive value) and "non-low" risk (25% prevalence).[59] Three factors **(symptoms in the left leg a leg circumference discrepancy of ≥2 cm, and first-trimester presentation)** were highly predictive of DVT. Thus, determination of prediagnostic study risk can be helpful before proceeding to the selection and interpretation of diagnostic tests.

Imaging

Contrast venography, an invasive technique involving the injection of dye into a vein distal to the site of suspected thrombosis, followed by radiographic imaging, is now rarely used for diagnosis of DVT. The risks for radiation and contrast allergy, as well as its technical difficulty, particularly preclude its use in pregnancy.[60]

The most common diagnostic modality employed in the evaluation of patients with suspected DVT is venous ultrasonography (VUS), with or without color Doppler. This modality has virtually replaced the cumbersome and less accurate impedance plethysmography technique. The ultrasound transducer is placed over the common femoral vein beginning at the inguinal ligament and then sequentially moved to image the greater saphenous vein, the superficial femoral vein, and the popliteal vein to its trifurcation with the deep veins of the calf. Compression VUS involves the application of pressure with the probe to determine whether the vein under investigation is compressible. The most accurate ultrasonic criterion for diagnosing venous thrombosis is noncompressibility of the venous lumen in a transverse plane under gentle probe pressure using duplex and color-flow Doppler imaging.[57] The overall sensitivity and specificity of VUS have been reported to be 90% to 100% for proximal vein thromboses, but traditionally have been considered lower for the detection of calf vein thromboses.[61] This is confirmed by a more recent meta-analysis demonstrating that, in nonpregnant patients, duplex ultrasound has a pooled sensitivity of 96.4% for proximal (knee or thigh) DVT, 75.2% for distal (calf) DVT, and total specificity of 94.3%.[62]

Magnetic resonance imaging (MRI) appears to have equivalent test performance characteristics to VUS. One meta-analysis demonstrated a sensitivity of 91.5% and specificity of 94.8% for diagnosis of DVT in nonpregnant patients with suspected DVT or PE.[63] Similar to VUS, there is also improved sensitivity for distal compared with proximal thrombi (93.9% versus 62.1%). The advantage of MRI may be in the ability to detect more centralized DVT, like those in the pelvic, iliac, or femoral veins.

D-Dimer Assays

Laboratory evaluation of serum concentrations of D-dimer, a product of the degradation of fibrin by plasmin, has been increasingly advocated as a helpful test in the diagnosis of DVT. Testing relies on the use of monoclonal antibodies to D-dimer fragments. The most accurate and reliable tests for D-dimers appear to be two rapid enzyme-linked immunosorbent assays (ELISAs) (Instant-IA D-dimer, Stago, Asniéres, France and VIDAS DD, bioMérieux, Marcy-l'Etoile, France) and a rapid whole blood assay (SimpliRED D-dimer, Agen Biomedical, Brisbane, Australia).

The test is limited by factors that may contribute to false-positive testing, including pregnancy, the postpartum and postoperative periods, and superficial thrombophlebitis.[64,65] In particular, normal pregnancy causes a physiologic increase in D-dimer, with levels exceeding the threshold for normal in 78% and 100% of patients in the second and third trimesters, respectively.[66]

The performance of the SimpliRED D-dimer test was evaluated in a prospective cohort of patients at risk for DVT by Chan.[66a] In this population, who had a DVT prevalence of 8.7%, sensitivity of D-dimer testing was 100%, and specificity was 60%. Utility particularly appeared to be stratified across gestation; false-positive rates were 0%, 24%, and 51% for the first, second, and third trimesters, respectively. The value of D-dimer testing in pregnancy appears to be its ability to rule-out disease because this same study showed a negative predictive value of 100%, with 95% CI interval of 95% to 100%. The value of D-dimer testing in the late-second and third trimesters is likely to be lower than in the first half of pregnancy because the former patients will likely have levels above the threshold.

Workup of Patients with Suspected Deep Venous Thrombosis

The diagnostic paradigm outlined in Figure 43-2 can be employed to diagnose DVT in pregnant patients with maximal sensitivity and specificity. A major assumption of this strategy is the availability of a sensitive assay for D-dimer. When a D-dimer test is unavailable or inappropriate (particularly in the third trimester), the testing algorithm should begin with lower extremity compression sonography. Risk may be stratified as in the section above (see Risk Scoring System).

Pulmonary Embolus

Clinical Signs and Symptoms

Tachypnea (>20 breaths/minute) and tachycardia (>100 beats/minute) are present in 90% of patients with acute PE, but these findings lack specificity and generate a broad differential diagnosis.[67] Presyncope and syncope are rarer symptoms and indicate a massive embolus.[68]

Nonspecific Studies

The classic electrocardiographic changes associated with PE are the S1, Q3, and inverted T3. Other findings include

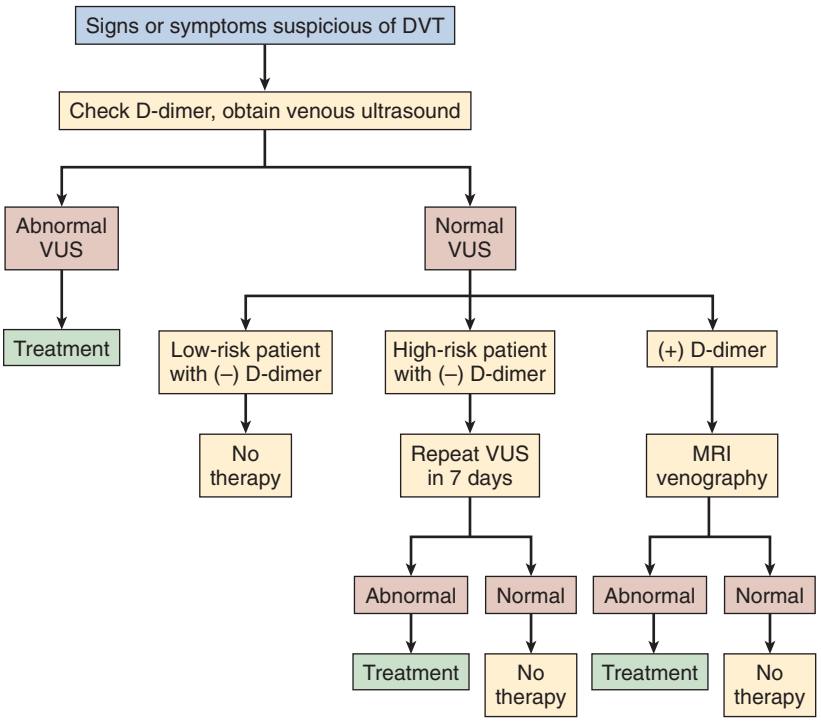

FIGURE 43-2. Diagnostic algorithm for suspected deep venous thrombosis.

nonspecific ST changes, right bundle branch block, and right axis deviation. These findings are usually associated with cor pulmonale and right-sided heart strain or overload, reflective of more serious cardiopulmonary compromise. About 26% to 32% of patients with massive PE had the previously mentioned electrocardiographic changes.[69] Arterial blood gases and oxygen saturation have limited value in the assessment of acute PE (APE), particularly in a pregnant population. Measurements of P_{O_2} are greater than 80 mm Hg in 29% of PE patients younger than 40 years of age.[70] In another study, up to 18% of patients with APE had P_{O_2} measurements of more than 85 mm Hg. The chest radiograph may be abnormal in up to 84% of affected patients.[67] The common findings on radiograph are pleural effusion, pulmonary infiltrates, atelectasis, and elevated hemidiaphragm. The eponymous findings of pulmonary infarction, such as a wedge-shaped infiltrate (Hampton hump) or decreased vascularity (Westermark sign), are rare.[71] Although a normal chest radiograph in the setting of dyspnea, tachypnea, and hypoxemia in a patient without known preexistent pulmonary or cardiovascular disease is suggestive of PE, a chest radiograph cannot be used to confirm the diagnosis.[71]

A large APE can create changes consistent with cor pulmonale and right-sided heart strain. Large emboli in the main pulmonary artery and its primary branches can result in acute right-sided heart failure, which is the ultimate cause of death in most patients with APE. Between 30% and 80% of patients with PE display echocardiographic abnormalities in right ventricular size or function.[72-74] Typical findings include a dilated and hypokinetic right ventricle, tricuspid regurgitation, and absence of preexisting pulmonary arterial or left-sided heart pathology. Transesophageal echocardiography with or without contrast appears to improve the imaging of main or right pulmonary artery emboli and, occasionally, of left pulmonary artery clots.[75] For these reasons, bedside echocardiography can be very useful for the unstable patient or the patient unable to travel for other imaging studies.

Pulmonary Arteriography

Until the advent of sensitive multidetector-row computed tomographic pulmonary angiography (CTPA, or spiral CT), intravenous contrast pulmonary arteriography or angiography was considered the gold standard for diagnosis of PE and, as such, was considered to have a sensitivity and specificity of 100%.[71] However, the sensitivity and interobserver agreement of traditional pulmonary angiography for smaller peripheral lesions decreases from 98% for lobar emboli, to 90% for segmental, and to 66% for subsegmental emboli.[76] Of all diagnostic modalities, this technique involves the highest risk, including a 0.5% mortality risk and a 3% complication rate, primarily because of the risks of contrast injection and catheter placement, including respiratory failure, renal failure, cardiac perforation, and groin hematoma requiring transfusion.[68] Furthermore, patients with evidence of cardiopulmonary compromise pose an even higher complication risk. Given its poor diagnostic efficacy and its attendant risks, pulmonary angiography is rarely used.

Ventilation-Perfusion Scanning

Perfusion scanning employs intravenously injected radioisotope-labeled albumin macroaggregates that deposit in the pulmonary capillary bed. Ventilation scanning involves the inhalation of radiolabeled aerosols whose distribution is evaluated by gamma camera. The comparison of these two images allows for interpretation of characteristic patterns that were then used to assign diagnostic probabilities (high, intermediate, or low). Greater than 90% of

high-risk patients with high-probability V/Q scans have PE, whereas less than 6% of low-risk patients with low-probability scans have a PE. Given that most young healthy women have little underlying lung pulmonary pathology, the diagnostic efficacy of V/Q scanning in pregnant women is substantially higher than in older, nonpregnant patients.

Spiral Computed Tomographic Pulmonary Angiography

Spiral CT scanning requires injecting intravenous contrast while simultaneously imaging the distribution of contrast in the pulmonary vasculature with a CT scanner.[71] Although this can be an effective judge of large, segmental, and central emboli, CT is of limited value with small subsegmental vessels and horizontally oriented vessels in the right middle lobe. One strength of CTPA is its utility in diagnosing nonembolic pulmonary phenomena such as pneumonia or pulmonary edema.

In nonpregnant patients, CTPA is often the modality of choice; however, this is not likely the case in pregnancy. Several studies have shown that **CTPA performs less well in pregnant compared with nonpregnant cohorts.** Andreou demonstrated in a small study of 32 patients with suspected PE that contrast enhancement of the pulmonary arteries is less in pregnant women than nonpregnant patients, likely because of the increased cardiac output of pregnancy.[77] Another reason may be the more frequent dilution or interruption of contrast by unopacified blood from the lower vena cava in pregnancy.[78] Comparing CTPA imaging in 40 pregnant patients with 40 nonpregnant patients, U-King-Im and associates also demonstrated a threefold higher rate of suboptimal studies in the pregnant population (27.5% versus 7.5%).[79]

Ventilation-Perfusion Scanning Versus Computed Tomographic Pulmonary Angiography

V/Q scanning and CTPA have been directly compared in pregnant patients by Cahill and colleagues, who retrospectively evaluated a cohort of 304 pregnant or postpartum women evaluated for PE.[80] CTPA was performed in 108 women and V/Q in 196. In women with a normal chest radiograph, CTPA yielded nondiagnostic results 5.4 times more often than V/Q scanning (30% versus 5.4%). As would be expected, in patients with an abnormal chest radiograph, V/Q scanning was more often nondiagnostic. Ridge and colleagues evaluated these two techniques prospectively in 50 total patients.[78] Again, they found that CTPA more often gave a nondiagnostic result (35.7% versus 2.1%), and V/Q scanning was adequate for diagnosis more frequently (35.7% versus 4%). For these reasons, as well as considerations of radiation exposure (see later), **V/Q scanning is the modality of choice for patients with suspected PE and a normal chest radiograph.**

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) may be performed using MRI of a patient during intravenous injection of gadolinium. Faster image acquisition rates and improved image timing to respiratory and cardiac motion have allowed this technique to develop. Preliminary experience by Meaney and colleagues suggested a sensitivity of 100%, specificity of 95%, and positive and negative predictive values of 87% and 100%, respectively, for MRA in 30 patients also assessed by classic pulmonary angiography.[81] Another prospective study involving 141 patients showed an overall sensitivity of only 77% in comparison to pulmonary angiography, with the sensitivity broken down to 40%, 84%, and 100% for isolated subsegmental, segmental, and central pulmonary emboli, respectively.[82] Because MRA does not involve ionizing radiation, it is an appealing alternative to CT scanning and angiography for pregnancy, and further assessment in large trials is needed to prove its ultimate utility as a primary diagnostic modality. Gadolinium contrast does cross the placenta and enters the amniotic fluid through excretion by the fetal kidneys. Most animal studies suggest no teratogenic effects by gadolinium, and it is considered a pregnancy category C drug by the U.S. Food and Drug Administration (FDA), although it should be used with caution.

D-Dimer Assays

The D-dimer assay appears to have less sensitivity in patients with PE and thus is less helpful as a test for ruling out disease. Negative D-dimer testing has been observed in patients with confirmed PE.[83] Damadoram and coworkers reported a sensitivity and specificity of 73% and 15%, respectively, for D-dimer in testing for suspected PE in pregnancy.[84] The difference in D-dimer test performance for PE in pregnancy may be due to the smaller clot burden compared with DVT coupled with the increase in intravascular plasma volume of pregnancy. This unacceptably high false-negative rate indicates **no role for D-dimer testing in the workup of pregnant patients with suspected PE.**

Lower Extremity Evaluation

Most PEs (90%) arise from lower extremity DVTs, and among patients with the diagnosis of PE, half will be found to harbor a lower extremity DVT, including up to 20% of PE patients without signs or symptoms of lower extremity DVT.[85-87] In patients presenting with signs or symptoms of PE who also have left-sided lower extremity symptoms, it is reasonable to begin with lower extremity VUS to detect DVT because the need for therapeutic anticoagulation is similar. This avoids exposure to the ionizing radiation as well as the burden of more complicated testing associated with CTPA and V/Q scanning. Furthermore, in high-risk patients in whom CTPA or V/Q scanning is not diagnostic (or even negative), evaluation of the leg veins for DVT can help to reinforce results. In such cases, however, a negative VUS study is still associated with a 25% risk for PE, suggesting that further studies are generally needed.[88]

Workup of Patients with Suspected Pulmonary Embolus

Workup of patients with suspected PE should begin with evaluation of their cardiorespiratory status in order to determine whether they are critically ill. Patients who are stable hemodynamically, with favorable oxygenation status (oxygen saturation >80%), should be evaluated in a carefully ordered fashion, taking into account the possibility of lower extremity DVT and chest radiograph results (Figure 43-3).

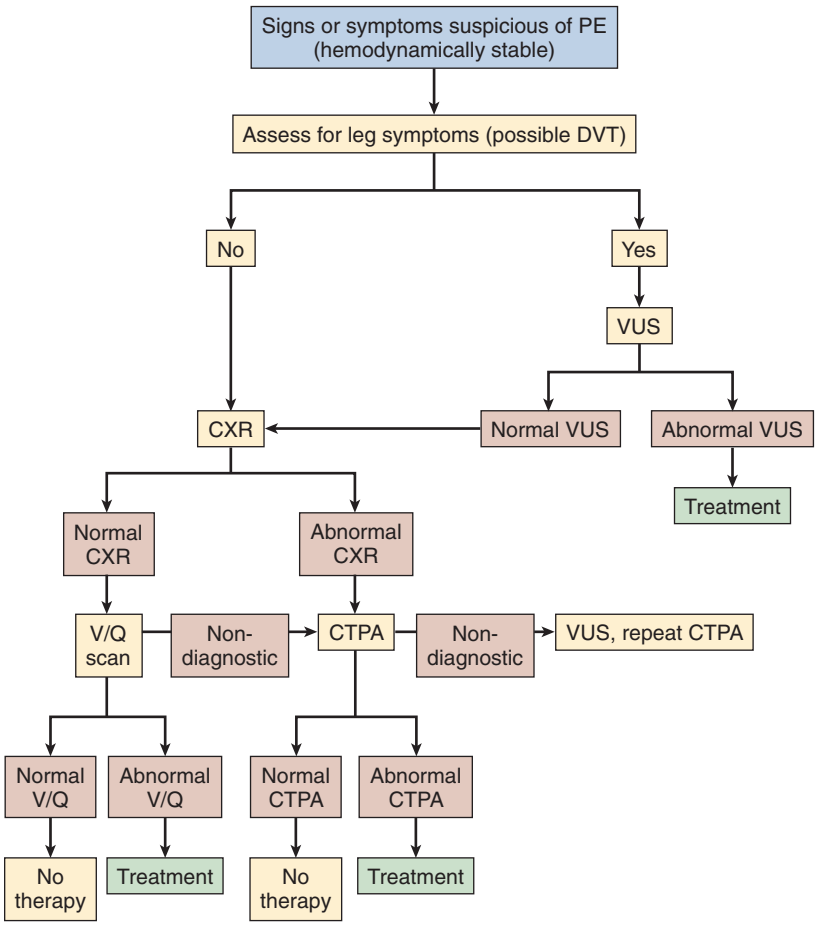

FIGURE 43-3. Diagnostic algorithm for suspected pulmonary embolus in a hemodynamically stable patient. *CXR,* Chest x-ray.

As noted previously, **D-dimer testing is no longer deemed of value in the workup in pregnant patients with suspected APE.** If lower extremity symptoms are present, particularly if left-sided, VUS is performed, and if positive, therapeutic anticoagulation should begin. **Chest radiographs should be performed for cases in which VUS is negative or in which there are no lower extremity signs or symptoms. Although the chest radiograph is not used in the actual diagnosis, it allows for proper selection of the next diagnostic test. V/Q scan is performed if the chest radiograph is normal.** A positive (high- or intermediate-probability) V/Q scan should prompt therapeutic anticoagulation. A negative test should exclude the diagnosis. A nondiagnostic result (e.g., intermediate-probability or equivocal test in any patient and a low-probability result in a high-risk patient with prior venous thrombosis, known thrombophilia, family history of thrombosis in a first-degree relative younger than 50 years, or other clinical risk factors) should trigger performance of CTPA. For such patients and those with an abnormal chest radiograph, CTPA is the diagnostic modality of choice. Positive tests prompt initiation of anticoagulation. In the patient with an abnormal chest radiograph who has a negative CTPA, the true etiology of the chest pathology is often seen on CT. Alternatively, if the CTPA is nondiagnostic, further testing is performed, such as MRA or serial lower extremity VUS.

In the critically ill patient, anticoagulation should be started, in the absence of contraindications, and a similar protocol is followed (Figure 43-4). Very unstable patients who cannot be transported safely can be evaluated with a bedside echocardiogram, which may have more test accuracy in this setting.

Radiation Exposure in Pregnancy

Fetal Exposure

The diagnosis of DVT and PE in pregnant patients poses unique challenges because of concerns about fetal radiation exposure. The ACOG advises that exposure to less than 5 cGy has not been associated with increases in pregnancy loss or fetal anomalies.[89] Exposure to ionizing radiation doses above 1 cGy, however, may create a marginally increased risk for childhood leukemia (from 1/3000 baseline to 1/2000).[90,91] Table 43-2 outlines the ***fetal*** radiation exposure of different radiation modalities. **A combination of chest radiograph, V/Q scan, and pulmonary angiography exposes the fetus to less than 0.5 cGy.**[6] CTPA is associated with only slightly lower radiation levels for the fetus compared with V/Q scanning. Although the concern for possible adverse effects should not prevent a medically important test from being performed, judicious use and selection of tests is advised.

Maternal Exposure

Radiation exposure to the maternal breast is also an important consideration when choosing tests because the increased glandularity and proliferative state of the

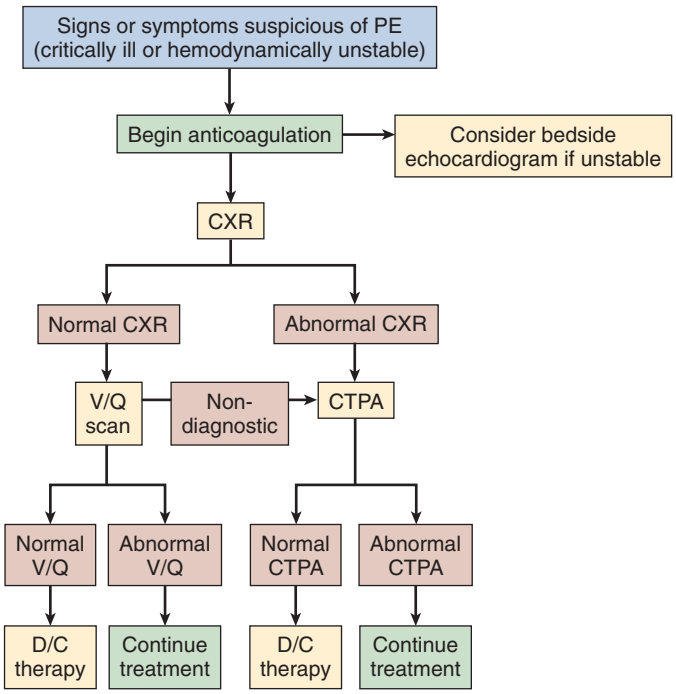

FIGURE 43-4. Diagnostic algorithm for suspected pulmonary embolism in a critically ill or hemodynamically unstable patient. *CXR,* Chest x-ray; *D/C,* discontinue.

TABLE 43-2 FETAL RADIATION EXPOSURE OF VARIOUS IONIZING MODALITIES

RADIOLOGIC MODALITY	FETAL RADIATION EXPOSURE (CGY)
Chest radiograph	<0.01

V/Q scan	0.007-0.031
Ventilation scan	0.001-0.019
Perfusion scan	0.006-0.012
CTPA (spiral CT)	0.013

Modified from Toglia M, Weg J: Venous thromboembolism during pregnancy. N Engl J Med 335:108-114, 1996.

pregnant breast presumably make it more radiosensitive. This is an important concern with respect to cumulative radiation exposure and cancer risk.[92] V/Q scanning results in substantially lower maternal breast radiation exposure. CTPA is estimated to expose maternal breast tissue to 150 times more ionizing radiation than V/Q scanning,[93] with doses estimated at 2 to 6 cGy.[94,95] This dose can be reduced about 50% to 60% with breast shielding, without significant reduction in image quality.[96]

MRI and ultrasonography have not been associated with any adverse fetal effects, and teratogenic effects have not been described after administration of gadolinium contrast media.[97] Concerns about fetal goiter following maternal radiographic contrast exposure suggest that fetal heart rates should be assessed to rule out hypothyroidism, and neonatal thyroid function should be tested during the first week of life.[97]

TREATMENT OF THROMBOEMBOLISM IN PREGNANCY

Unfractionated Heparin

Unfractionated heparin effects anticoagulation by enhancing antithrombin activity, increasing factor Xa inhibitor activity, and inhibiting platelet aggregation.[98] Unfractionated heparin (FDA pregnancy category C) does not cross the placenta and is not teratogenic.[99] The chief side effects of heparin include hemorrhage, osteoporosis, and thrombocytopenia. The former is more common with treatment coinciding with surgery or liver disease or concomitant aspirin use. Heparin-associated bone loss is usually reversible, correlates more with therapy exceeding 15,000 units/day for more than 6 months, and can be opposed by supplemental calcium use (1500 mg/day).[100] **Heparin-induced thrombocytopenia (HIT) occurs in 3% of patients.** Type I HIT is the most common form, occurs within days of exposure, is self-limited, and is not associated with a significant risk for hemorrhage or thrombosis. Immunoglobulin-mediated type II HIT, on the other hand, is rare, usually occurs 5 to 14 days after initiation of therapy, and paradoxically increases the risk for thrombosis. Monitoring for HIT should include serial platelet counts until day 14 or until heparin is stopped, whichever occurs first. A 50% decline in platelet count from its pretreatment maximum suggests immune-mediated HIT type II and should prompt cessation of all heparin exposure, including that in intravenous flushes. The diagnosis of HIT type II can be confirmed by serotonin release assays, heparin-induced platelet aggregation assays, flow cytometry, or solid-phase immunoassays.

Protamine sulfate reverses the effect of intravenously administered unfractionated heparin. It is given by low intravenous infusion of less than 20 mg/minute, with no more than 50 mg given over 10 minutes. The total dose of protamine required is calculated based on the residual amount of circulating heparin, with a ratio of 1 mg of protamine sulfate necessary for every 100 units of residual circulating heparin. Residual heparin is calculated by assuming a half-life of 30 to 60 minutes of intravenous heparin. However, repeated serial administrations of lower doses of protamine, coinciding with serial measurements of the activated partial thromboplastin time (aPTT), are required when the heparin is dosed subcutaneously.

Low-Molecular-Weight Heparin

The low-molecular-weight heparins (LMWHs; dalteparin, enoxaparin, and tinzaparin) are reliable and safe alternatives to unfractionated heparin and have fewer side effects. Enzymatic manipulation of standard heparin produces lower-molecular-weight molecules with equivalent antifactor Xa, but little or no antithrombin effects. The LMWHs have longer half-lives and a closer correlation between antifactor Xa activity and body weight than subcutaneously administered unfractionated heparin. However, we follow antifactor Xa levels in pregnant patients because there is far greater variability in binding, distribution, metabolism, and excretion. The LMWHs (pregnancy category B) do not cross the placenta and do

not enter breast milk. There is a lower risk for hemorrhage associated with LMWH. **However, regional anesthesia is contraindicated within 18 to 24 hours of therapeutic LMWH administration.** Accordingly, we recommend switching to unfractionated heparin at 36 weeks' gestation or earlier if preterm delivery is expected. Protamine is not as effective in fully reversing the antifactor Xa activity of LMWH, although it may reduce bleeding. Dosing of 1 mg of protamine for every 100 antifactor Xa units of LMWH can normalize aPTT values, but antifactor Xa levels can only be reversed by 80%. The risk for HIT type II is also lower in patients receiving LMWH, but platelet counts should still be checked every 2 to 3 days from day 4 to day 14.

Fondaparinux

Fondaparinux is a synthetic heparin pentasaccharide that complexes with the antithrombin binding site for heparin to permit the selective inactivation of factor Xa, but not thrombin. A major advantage of this medication is that there does not appear to be a risk for HIT type II. It has comparable efficacy to both LMWH and unfractionated heparin in nonpregnant patients. Although it has been used in a small number of pregnant patients without complication, umbilical cord plasma concentrations at 10% of those of maternal plasma have been demonstrated, suggesting limited transplacental passage. Use of fondaparinux should be limited to women without other therapeutic alternatives, such as those with a history of HIT type II or heparin allergies or those who have failed other anticoagulants.

Coumarin

The coumarins are vitamin K antagonists that block the vitamin K–dependent, function-enhancing posttranslational modifications of prothrombin and factors VII, IX, and X, as well as the anticlotting agents proteins C and S. Coumadin (warfarin) has been shown to be effective for both the primary and secondary prevention of VTE, stroke, myocardial infarction, and systemic embolism due to artificial valves and atrial fibrillation. Coumadin is a pregnancy category X medication because fetal exposure can cause nasal and midface hypoplasia, microphthalmia, mental retardation, and other ocular, skeletal, and central nervous system malformations (see Chapter 8). Teratogenic potential is greatest between the 6th and 12th weeks of pregnancy. The risk of warfarin also includes fetal hemorrhage. As a result, warfarin is rarely employed, although the exceptional case of a patient requiring therapeutic anticoagulation, who cannot be sufficiently treated with the heparins, may require its use. Warfarin is also a favored drug for the postpartum period because it is safe to use during lactation.

Therapy is started at a dose of 5 to 10 mg for 2 days, with subsequent doses titrated to achieve an international normalized ratio (INR) of 2 to 3. Peak effects occur within 72 hours, and its half-life is from 36 to 42 hours. Warfarin metabolism is greatly affected by genetic polymorphisms, making the response to particular dosing regimens unpredictable. A pharmacogenetic approach to warfarin dosing includes testing for particular variations in vitamin K and warfarin metabolic enzymes and using this information to formulate a dosing regimen that expeditiously achieves a proper maintenance dose. A criticism of this approach is that pharmacogenetics accounts for only 30% to 50% of the variability in response because environment, diet, and comorbidities often have a significant influence as well. A nomogram for predicting warfarin dosing, based on patient-specific responses to warfarin doses as assessed by day 3 and day 5 INRs, has been proposed by Lazo-Langer. Avoiding the need for costly genetic testing, this protocol accounts for individual variation of warfarin metabolism.

Because of protein C's shorter half-life relative to the other vitamin K–dependent clotting factors, warfarin may initially create a prothrombotic state, particularly in pregnancy. Thus, patients who are initiated on warfarin postpartum should be on therapeutic doses of unfractionated or LMWH for 5 days and until the INR is therapeutic for 48 hours. Coumadin effects can be reversed by vitamin K. The INR generally normalizes within 6 hours of a 5-mg dose of vitamin K and within 4 days with cessation of warfarin therapy. Fresh-frozen plasma can be used to achieve immediate reversal of effects.

Treatment of Acute Deep Venous Thrombosis or Pulmonary Embolus

Women with new-onset VTE diagnosed during pregnancy should receive therapeutic anticoagulation. Therapeutic anticoagulation should be continued for at least 20 weeks. If this period of time expires before the end of the postpartum period, prophylactic anticoagulation should be initiated in patients without highly thrombogenic thrombophilias and continued for 6 weeks to 6 months postpartum, depending on the severity of the thrombotic event and the underlying risk factors. During pregnancy, unfractionated heparin and the LMWHs are the drugs of choice, given their efficacy and safety profile. **Therapeutic doses of the LMWH enoxaparin may start at 1 mg/kg, subcutaneously, twice daily.** Dosing should be titrated to achieve antifactor Xa levels of 0.6 to 1 U/mL when tested 4 hours after injection because of inconsistent efficacy of this weight-based regimen in pregnant patients. Unfractionated heparin for acute DVT or PE is initially given intravenously and titrated to keep the aPTT 1.5 to 2.5 times control (checked every 4 to 6 hours during the titration period), usually according to weight-based protocols (Table 43-3). Intravenous heparin should be continued for 5 to 10 days or until clinical improvement is noted. This can be changed to subcutaneous injections every 8 to 12 hours to keep the aPTT 1.5 to 2 times control, when tested 6 hours after injection.

As noted earlier, the major concerns of therapeutic anticoagulation in pregnancy are regional anesthesia use and hemorrhage risk. Regional anesthesia is contraindicated within 18 to 24 hours of therapeutic LMWH use; thus, LMWH should be converted to unfractionated heparin at 36 weeks' gestation or earlier if clinically indicated. Vaginal or cesarean delivery more than 24 hours after therapeutic LMWH dosing should not pose a risk for hemorrhage, although protamine sulfate may be necessary to partially reverse anticoagulation. Protamine sulfate may also be used to normalize completely an elevated aPTT in patients on therapeutic unfractionated heparin near the time of delivery. Heparin anticoagulation may be restarted

TABLE 43-3 WEIGHT-BASED NOMOGRAM FOR UNFRACTIONATED HEPARIN

Give a bolus of 80 U/kg, followed by a maintenance dosage of 18 U/kg/hr, following aPTT values every 6 hours and with following adjustments for aPTT values obtained:

aPTT VALUE	ADJUSTMENT
<35 sec (<1.2× control value)	Repeat full bolus (80 U/kg), then increase infusion rate by 4 U/kg/hr
35-45 sec (1.2-1.5× control)	Repeat half bolus (40 U/kg), then increase infusion rate by 2 U/kg/hr
46-70 sec (1.6-2.3× control)	No change in infusion rate
71-90 sec (2.4-3× control)	Decrease infusion rate by 2 U/kg/hr
>90 sec (>3× control)	Stop infusion for 1 hour, then decrease by 3 U/kg/hr

Modified from Raschke R, Reilly B, Guidry J, et al: The weight-based heparin dosing nomogram compared with a "standard care" nomogram: a randomized controlled trial. Ann Intern Med 119:874-881, 1993.

3 to 6 hours after vaginal delivery and 6 to 8 hours after cesarean delivery. Coumadin anticoagulation may be started on the first postpartum or postoperative day. As noted earlier, because of the paradoxical increase in APC resistance and factor VIII after starting warfarin, therapeutic doses of the heparins should be continued for 5 days and until the INR reaches therapeutic range (2 to 3) for 2 successive days.

Prophylactic Applications and Dosing

We recommend prophylactic *antepartum* and postpartum anticoagulation in patients with high-risk thrombophilias and no personal or family history of venous thrombosis, and in patients with low-risk thrombophilias but with a family (first-degree relative) or a personal history of venous thrombosis or significant other risk factor (e.g., body mass index >30, prolonged immobilization, surgery during pregnancy). Prophylactic postpartum therapy is warranted in all patients with low-risk thrombophilias without a personal or family history of thrombosis after a cesarean delivery. These issues have recently been addressed by ACOG in a 2010 Practice Bulletin (Number 283). **Prophylactic doses of the LMWH enoxaparin may start at 40 mg subcutaneously daily.** Weight-based dosing in pregnant patients may be unreliable, and some investigators recommend titrating doses to achieve antifactor Xa levels of 0.1 to 0.2 U/mL 4 hours after injection. Unfractionated heparin prophylaxis may range from 5000 to 10,000 units subcutaneously every 12 hours. Because of inconsistent efficacy in pregnant patients, this dosing should be titrated to achieve heparin levels (by protamine titration assay) of 0.1 to 0.2 U/mL.

The risk for hemorrhage or complication from regional anesthesia is minimal more than 12 hours after prophylactic LMWH. Again, given the difficulty of timing administration with the onset of labor, we recommend converting from LMWH to unfractionated heparin at 36 weeks' gestation or earlier as clinically indicated. As with therapeutic use, anticoagulation may be restarted 3 to 6 hours and 6 to 8 hours after vaginal and cesarean delivery, respectively.

Other Considerations of Therapy and Prevention

Perioperative Prevention

There is very limited evidence regarding the value of perioperative thromboprophylaxis with cesarean delivery. Perioperative administration of low-dose unfractionated heparin may be appropriate in patients undergoing cesarean delivery with clear risk factors such as obesity, malignancy, immobility, or a high-risk chronic medical disease. As noted, patients with low thrombogenic thrombophilias require postoperative prophylaxis.

Nonpharmacologic interventions aimed at preventing VTE include graduated elastic compression stockings and pneumatic compression devices. In pregnancy, a cohort study suggested that the use of graduated compression stockings reduced the prevalence of postpartum VTE from 4.3% to 0.9%. Because these stockings and pneumatic compression devices pose no hemorrhagic risk and little harm, they should be strongly considered for thromboprophylaxis in all pregnant patients. The left lateral decubitus position in the third trimester may also reduce the risk for VTE.

Inferior Vena Cava Filters

The use of inferior vena cava (IVC) filters is primarily restricted to patients with absolute contraindications to medical anticoagulation or those who have failed therapeutic anticoagulation. Pregnant patients with a history of HIT type II or with true heparin or LMWH allergies in need of prophylaxis are potential candidates for IVC filters. However, the introduction of fondaparinux may eliminate this need. The use of IVC filters is discouraged in younger patients, but newer retrievable filters may be appropriate.

KEY POINTS

- Pregnancy, childbirth, and the puerperium pose serious hemorrhagic challenges that are met by increased decidual and systemic clotting potential.
- Venous thromboembolism is a leading cause of mortality and serious morbidity in pregnant women, having a prevalence of 1 in 1000 to 2000 pregnancies, with the greatest risk for fatal PE following caesarean delivery.
- Inherited and acquired thrombophilias account for most VTEs in pregnancy.
- D-dimer testing is used in the evaluation of low-risk patients with suspected DVT because of its high negative predictive value. However, for evaluation of PE, D-dimer is associated with an intolerable rate of false-negative results and thus should not be used.
- VUS is the most common diagnostic modality employed in the evaluation of patients with suspected DVT, with an overall sensitivity and specificity of 90% to 100% for proximal vein thromboses.

- In stable patients with suspected PE and leg signs or symptoms, VUS should be performed because it may avoid the risks of radiation exposure and may detect a DVT, the cause of the PE.
- Stable patients with suspected PE should have a chest radiograph to determine the diagnostic test of choice. A normal chest radiograph should prompt performance of a V/Q scan. A patient with an abnormal chest radiograph should be evaluated with CTPA.
- Heparin remains the mainstay of therapy for patients with VTE, with its most serious but rare complication being immunoglobulin-mediated HIT type II, which usually occurs 5 to 14 days after initiation of therapy and paradoxically increases the risk for thrombosis.
- Protamine sulfate can entirely reverse the anticoagulant effect of unfractionated heparin and partially (80%) reverse the effect of LMWH.
- Graduated elastic compression stockings and pneumatic compression devices appear to reduce the likelihood of VTE in pregnancy and, at a minimum, should be used in all high-risk patients undergoing cesarean delivery.

Sjögren Syndrome 1010

KEY ABBREVIATIONS

Anticentromere Antibody	ACA
Anticitrullinated Peptide Antibody	ACPA
Anti–double-stranded DNA	anti-dsDNA
Antinuclear Antibody	ANA
Antiphospholipid Antibody	aPL
Antiphospholipid Syndrome	APS
Azathioprine	AZA
β_2-Glycoprotein-I	β_2-GP-I
Congenital Heart Block	CHB
Disease-modifying Antirheumatic Drug	DMARD
Human Leukocyte Antigen	HLA
Intrauterine Growth Restriction	IUGR
Intravenous Immune Globulin	IVIG
Low-molecular-weight Heparin	LMWH
Lupus Anticoagulant	LA
Lupus Nephritis	LN
Major Histocompatability Complex	MHC
Metacarpophalangeal	MCP
Methotrexate	MTX
Mycophenolate Mofetil	MMF
Neonatal Lupus Erythematosus	NLE
Nonsteroidal Anti-inflammatory Drug	NSAID
Partial Thromboplastin Time	PTT
Preterm Birth	PTB
Preterm Premature Rupture of the Membranes	PPROM
Proximal Interphalangeal	PIP
Regulatory T Cell	Treg cell
Rheumatoid Arthritis	RA
Rheumatoid Factor	RF
Ribonucleoprotein	RNP
Single-stranded DNA	ssDNA
Systemic Lupus Erythematosus	SLE
Systemic Sclerosis	SSc
Tumor Necrosis Factor-α	TNF-α
U.S. Food and Drug Administration	FDA

Collagen vascular diseases are systemic autoimmune conditions characterized by the formation of autoantibodies directed against one's own tissues. The manifestations of these diseases range from mild and remitting to life-threatening. Reproductive-aged women are disproportionately affected by collagen vascular diseases, and frequently an initial diagnosis is made during the course of evaluation for pregnancy losses or pregnancy complications or during a postpartum flare of symptoms. With the exception of rheumatoid arthritis, most of these autoimmune conditions are associated with adverse maternal and pregnancy outcomes if there is significant multiorgan involvement or if the disease is not in remission at the onset of pregnancy. However, with appropriate pregnancy planning, close antenatal surveillance, and careful choice of medications, many women with collagen vascular diseases can achieve successful pregnancies and have healthy children.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is a chronic inflammatory disorder with multisystem organ involvement, including skin, joints, kidneys, lungs, serous membranes, nervous system, liver, and heart. Similar to other autoimmune diseases, SLE is characterized by periods of increased disease activity or "flares," interspersed with periods of remission. Frequently presenting symptoms of SLE include arthralgias, fatigue, fever, malaise, weight loss, hair loss, and rash (Table 44-1).

TABLE 44-1 Approximate Frequency of Clinical Symptoms in Systemic Lupus Erythematosus

SYMPTOMS	PATIENTS (%)
Fatigue	80-100
Fever	80-100
Arthralgia, arthritis	95
Myalgia	70
Weight loss	60
Skin	
Butterfly rash	50
Photosensitivity	60
Mucous membrane lesions	35
Renal involvement	50
Pulmonary	
Pleurisy	50
Effusion	25
Pneumonitis	5-10
Cardiac (pericarditis)	10-50
Lymphadenopathy	50
Central nervous system	
Seizures	15-20
Psychosis	25

Epidemiology and Etiology

The overall reported prevalence of SLE is 20 to 150 cases per 100,000 individuals.[1,2] More recently, the incidence of SLE has nearly tripled, most likely because of increased diagnosis. There are significant gender and racial differences in the prevalence of SLE. The disease occurs 7 to 15 times more frequently among adult women than adult men.[2] White women have a prevalence of 164 per 100,000, compared with African-American women, who have a prevalence of 406 per 100,000.[2] Most women with SLE are affected at some point during their reproductive years, with a median age at diagnosis of 30 to 50 years.

A genetic predisposition to SLE is evident in that about 5% to 12% of relatives of individuals with SLE also have the disease, and the concordance rate among monozygotic twins has been reported to be as high as 57%. Within the past several years, genome-wide association studies have allowed the identification of single nucleotide polymorphisms (SNPs) and mutations in dozens of genes that are associated with SLE.[3] Genetic factors with the most significant associations with SLE include deficiencies in complement components, particularly C1q, C2, or C4, and the presence of a mutated *TREX1* gene, which encodes a DNA-degrading enzyme.[3] The most frequent genetic predisposition, however, involves loci within the major histocompatability complex (MHC), particularly genes for human leukocyte antigens (HLA)-A1, -B8, and -DR3. The MHC contains genes that code for antigen-presenting proteins, some complement components, and cytokines.

Clinical Manifestations

Diagnosis

In 1971, the American Rheumatism Association (now the American College of Rheumatology) devised a set of diagnostic criteria for SLE, primarily to distinguish SLE from other rheumatic diseases for research purposes. These criteria were subsequently revised in 1982 and 1997 (Table 44-2) and are very sensitive and specific for SLE. To be classified as having SLE, a patient must have at least 4 of the 11 clinical and laboratory criteria, either at one time or serially. **Some patients may not meet strict criteria for SLE but still benefit from typical SLE therapies and warrant extra surveillance in pregnancy.**

TABLE 44-2 Revised American College of Rheumatology Classification Criteria for Systemic Lupus Erythematosus (1982 and 1997)

CRITERION	DEFINITION
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
Discoid rash	Erythematous, raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	a. Pleuritis—convincing history of pleuritic pain or rubbing heard by a physician or evidence of pleural effusion b. Pericarditis documented by electrocardiogram or rub or evidence of effusion
Renal	a. Persistent proteinuria greater than 0.5 g/day or greater than 3+ if quantitation not performed b. Cellular casts—red cell, hemoglobin, granular, tubular, or mixed
Neurologic	a. Seizures—in the absence of offending drugs or known metabolic derangements; e.g., uremia, ketoacidosis, or electrolyte imbalance b. Psychosis—in the absence of drugs or metabolic derangements
Hematologic	a. Hemolytic anemia–with reticulocytosis b. Leukopenia—less than 4000/mm on two or more occasions c. Lymphopenia—less than 1500/mm on two or more occasions d. Thrombocytopenia—less than 100,000/mm in absence of drugs
Immunologic	a. Anti-DNA: antibody to native DNA in abnormal titer b. Anti-Sm: presence of antibody to Sm nuclear antigen c. Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of IgG or IgM anticardiolipin antibodies, (2) a positive test result for lupus anticoagulant using a standard method, or (3) a false-positive serologic test for syphilis for 6 months
Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome

Clinical Features

Constitutional symptoms, such as myalgias, fatigue, weight change, and fever, occur in nearly all women with SLE at some point in the disease course. One of the most common and debilitating symptoms is generalized fatigue. Although

fatigue does appear to increase with disease exacerbations, confounding factors such as sleep disturbance, anxiety, and depression are also important contributors. Although women frequently report weight loss before the diagnosis of SLE, weight gain may occur with the development of nephrotic syndrome or glucocorticoid treatment. A significant proportion of women with an SLE exacerbation also have fever that cannot be attributed to an infectious cause. **A myriad of organ-specific signs and symptoms may also be present among women with SLE, including arthritis, skin lesions, lupus nephritis (LN), pleurisy, pericarditis, and neurologic abnormalities such as seizures or psychosis.** Arthritis is one of the most common symptoms, occurring in more than 90% of patients at some point in the disease course. It is usually migratory in nature, with the most frequently affected sites being the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints, knees, and wrists. Arthritis in SLE is typified by morning stiffness that improves as the day progresses. **Most patients also have skin manifestations at some point in the disease.** The classic skin presentation is the "butterfly rash," or erythema over the cheeks and nose, exacerbated by sun exposure. Some SLE patients may experience discoid lupus, which consists of inflammatory papules and plaques with a central depressed area that results in scarring.

Clinical evidence of renal disease is present in about 50% of patients with SLE. However, the confirmation of LN requires a renal biopsy. LN is likely the result of immune complex deposition (primarily DNA and anti-DNA antibodies) leading to complement activation and an influx of inflammatory cells in the kidneys. Multiple forms of glomerulonephritis can occur. In 2003, the International Society of Nephrology and the Renal Pathology Society published a classification system for LN aimed at standardizing definitions and resolving ambiguity.[4] The system divides LN into six classes, dependent on renal biopsy results. Class IV, diffuse LN, the most common and most severe form, is associated with hematuria and proteinuria among all patients with active disease and with nephrotic syndrome, hypertension, and renal insufficiency in a significant subset.

Laboratory Findings

Virtually all individuals with SLE have an elevated antinuclear antibody (ANA) titer. As a result, the ANA test should be ordered in all women with symptoms suspicious for SLE. The ANA staining pattern (homogenous, peripheral, speckled, nucleolar, centromeric) has traditionally been used to detect a specific antigen-antibody complex. However, interpretation of staining patterns is subjective, and the sensitivity and specificity for different autoimmune disorders are relatively poor. As a result, the interpretation of staining patterns has been largely supplanted by tests for specific antibodies. **A negative ANA test makes it very unlikely that a woman has SLE.** However, the predictive value of a positive test is relatively low because many other diseases are associated with a positive result, including rheumatoid arthritis, scleroderma, and Sjögren syndrome. Immunofluorescent assays for specific nuclear antigen-antibody reactions are more specific (albeit less sensitive) for SLE than the ANA test. Anti-double-stranded DNA (anti–dsDNA) antibodies are found in greater than 90% of patients with active disease. In a prospective study of 72 patients with SLE, 24 of 33 disease exacerbations were preceded by a significant increase in anti-dsDNA titers.[5] SLE patients may have antibodies to RNA-protein conjugates, also described as soluble or extractable antigens. These include the Sm antigen, ribonucleoprotein (RNP), and Ro/SSA and La/SSB antigens. Anti-Sm antibodies are found in 30% to 40% of SLE patients, are highly specific for the disease, and are correlated with renal involvement. Anti-RNP antibodies can be found in both SLE and systemic sclerosis and are associated with myositis and the Raynaud phenomenon. Anti-Ro/SSA and anti-La/SSB antibodies are found in the sera of both SLE and Sjögren syndrome patients and are particularly relevant to obstetrical management because of their association with neonatal lupus erythematosus (NLE) and congenital heart block (CHB).

Systemic Lupus Erythematosus and Pregnancy

Lupus frequently occurs in women of reproductive age but does not appear to impair fertility. As a result, obstetricians should be aware of the potential complications of SLE in pregnancy and be prepared to provide appropriate monitoring and treatment. They must also understand the benefits and risks of therapies most commonly used in the treatment of SLE. Maternal complications include disease exacerbation, nephritis, venous thromboembolism, and preeclampsia. Fetal and neonatal complications include miscarriage, stillbirth, intrauterine growth restriction (IUGR), preterm birth (PTB), and NLE.

Risk for Systemic Lupus Erythematosus Exacerbation (Flare)

Whether pregnancy is associated with SLE exacerbation continues to be a matter of debate. **Overall, the reported rate of flare during pregnancy or the postpartum period varies widely between 15% and 60% of women, depending mostly on how SLE flare is defined.** Studies in the 1960s and 1970s, which reported high rates of disease exacerbation as well as severe maternal morbidity and mortality, were limited by retrospective design, small sample size, the lack of a uniform definition for flare, and poor differentiation between normal pregnancy manifestations and SLE signs and symptoms.

More recent studies have produced conflicting results as to whether pregnancy is associated with SLE flare. Lockshin and colleagues matched 28 pregnant women with SLE (a total of 33 pregnancies) to nonpregnant women with SLE of similar severity and organ involvement and found no difference between the groups in terms of disease activity.[6] In a separate prospective study, Lockshin followed 80 pregnant women with SLE for manifestations of disease activity. Disease activity was scored by global assessment, prednisone therapy, total number of organ systems involved, and the presentation of abnormalities within each organ system. Disease exacerbation among this cohort occurred in less than 13% of women.[7] Meehan and Dorsey retrospectively evaluated the effect of pregnancy on SLE exacerbation among 22 pregnant patients who were all on glucocorticoids or azathioprine at conception and an equal number of nonpregnant women with

SLE, matched by disease duration and organ system involvement.[8] They found no significant difference in the number of flares between the pregnant and nonpregnant groups. Mintz and associates studied 102 pregnancies among 75 women with SLE and a control group of nonpregnant women with SLE taking oral contraceptives.[9] There was a 59.7% exacerbation rate among women who started with inactive disease, but the rate of SLE flares per month at risk was similar between cases and controls. Interestingly, among the pregnant women, about half of the flares occurred during the first trimester. Most of the exacerbations responded well to low-to-moderate doses of glucocorticoids. Urowitz and coworkers compared 79 pregnancies in women with active SLE with a matched group of 59 nonpregnant active SLE patients as well as 216 women with inactive disease.[10] Flares occurred in similar percentages of cases and controls. Importantly, inactive disease at the onset of the study was protective against flare among the pregnant patients. Georgiou and colleagues reported the results of 59 pregnancies in 47 SLE patients compared with 59 pregnancies in 57 healthy control women and 59 nonpregnant SLE patients.[11] All but one of the pregnant SLE patients had inactive disease at the onset of pregnancy and were being treated with glucocorticoids, hydroxychloroquine, or azathioprine. Using accepted clinical criteria, the authors reported SLE exacerbation in 13.5% of the pregnant SLE women and 22% of the nonpregnant SLE group.

In contrast to the studies discussed previously, two groups have reported increased SLE flares in pregnancy. Petri and associates prospectively studied 40 pregnancies in 37 women with SLE and found that they had increased rates of disease exacerbation compared with the same women outside of pregnancy and nonpregnant SLE patients.[12] Flares occurred in 60% of the pregnancies, but most were mild to moderate. Women with inactive disease at the onset of pregnancy had fewer flares (41%). Ruiz-Irastorza and coworkers studied 78 pregnancies among 68 women and a matched control group of 50 nonpregnant SLE women and found that 65% of the cases had a flare in pregnancy compared with 42% of the control group, which translated to a statistically significant difference in the flare rate per patient-month followed.[13]

Although the data on whether pregnancy increases the likelihood of flare are conflicting, it appears that disease activity at the onset of pregnancy is an important determinant of exacerbation in pregnancy.[10,11,14] Derksen and associates prospectively followed 35 pregnancies in 25 SLE patients.[14] There was sustained disease remission at the start of all but one pregnancy. In 82% of the pregnancies, the disease remained inactive, and there were no serious postpartum flares. Cortes-Hernandez and coworkers found that SLE flares in pregnancy occurred more frequently among women who had stopped maintenance therapy before pregnancy.[15] Hayslett and associates, in a review of the literature, concluded that among women with disease remission for at least 6 months before pregnancy, flare occurs in about one third of pregnancies compared with two thirds of pregnancies among women with active disease at conception.[16] **It thus appears that women with SLE should be advised to postpone pregnancy until sustained remission for at least 6 months has been achieved.** This requires not only a focus on SLE therapies but also a discussion of family planning and attention to effective contraception.

The available literature suggests that there is no more than a modest increased risk for flare among women with sustained SLE remission at the onset of pregnancy. Thus, **the prophylactic use of glucocorticoids in all women with SLE does not appear warranted.** Most flares in pregnancy appear to be mild to moderate and easily treated with glucocorticoids.

The detection of flare in pregnancy requires frequent assessment and astute clinical judgement, frequently combined with laboratory evaluation. Flare in pregnancy is most often associated with fatigue, skin and joint signs and symptoms, and renal involvement.[12] In confusing cases, serologic evaluation with anti-dsDNA and complement levels may be helpful. As mentioned previously, elevated anti-dsDNA titers are found in nearly all patients with active disease. Complement levels rise during normal pregnancy but fall with an SLE exacerbation. It has been suggested that serial evaluation of complement components is beneficial in the prediction of SLE exacerbation in pregnancy. Devoe and colleagues reported that serial assessment of C3 and C4 levels was helpful in predicting SLE flare and that levels were associated with pregnancy outcome.[17] Buyon and associates found that serum C3 and C4 levels were significantly lower among pregnant SLE patients with flare compared with normal pregnancies or those with preeclampsia.[18] In contrast, Wong and coworkers found that C3 and C4 levels were not significantly different between pregnant SLE women who had disease exacerbation and those who did not have a flare.[19] Another study found that complement activation can occur in the setting of preeclampsia, with C4 levels significantly decreased in preeclamptic women compared with normal pregnant women.[20] Furthermore, hypocomplementemia may occur in pregnancies without SLE or adverse pregnancy outcomes. Thus, the clinical utility of routinely following complement levels in otherwise asymptomatic women in pregnancy is doubtful.

Lupus Nephritis and Pregnancy

Pregnancy in women with LN is associated with significant risk, including an increased rate of preeclampsia (with attendant maternal and fetal morbidity) and a potentially permanent decline in renal function.

As with SLE flares in general, whether or not renal flares occur more commonly in pregnancy remains controversial. Two studies have reported high frequencies of renal flares (43% to 46%) during pregnancy,[19,21] whereas others have reported lower figures (9% to 28%).[9,13] Similar to the risk for SLE flare in general, it appears that disease activity at conception is an important predictor of renal flare. Jungers and associates studied 106 pregnancies in 36 women with LN and found that disease exacerbation occurred in only 9% of cases in which disease was in remission for at least 5 months before conception compared with 66% of cases in which SLE was clinically active.[22]

Data regarding the risk for permanent decline in renal function during pregnancy in LN patients are also conflicting. Fine and associates found that 9.6% of LN patients had a sustained depression in renal function for

3 to 12 months postpartum.[23] Oviasu and colleagues reviewed eight studies (151 pregnancies) published from 1973 to 1991 and found that permanent deterioration in renal function occurred in 8% of pregnancies complicated by LN.[24] In contrast, Hayslett and Lynn reported no permanent change in renal function in pregnant LN patients.[25] Petri and associates, in their experience at the Hopkins Lupus Pregnancy Center between 1987 and 1996, reported that only women with nephrotic syndrome at the onset of pregnancy went on to renal failure postpartum.[21] Given the data, the clinically prudent approach is to counsel women with SLE and a history of renal disease who are contemplating pregnancy about the potential for renal deterioration.

On occasion, it may be challenging to distinguish between a renal flare and preeclampsia. Women with LN and established proteinuria have increasing proteinuria associated with increased renal perfusion in pregnancy. Also, women without a history of significant LN may suffer the new onset of glomerulonephritis during pregnancy, presenting with proteinuria and hypertension. The distinction is important, however, particularly in significantly preterm gestations, because the treatment for preeclampsia is delivery, whereas the treatment for an SLE flare is immunosuppression. The situation may be even more confusing based on the fact that women with LN are at significantly increased risk for developing superimposed preeclampsia. Table 44-3 lists features that may be helpful in distinguishing these two entities. Examination of the urinary sediment should be performed. As mentioned previously, serologic evaluation of anti-dsDNA titers and complement levels, looking for obviously low complement levels, may be helpful. A renal biopsy should be considered in difficult cases. In practice, however, situations involving either severe SLE flare with glomerulonephritis or severe preeclampsia frequently threaten both maternal and fetal well-being and, depending on the gestational age, may prompt delivery before the establishment of a definitive diagnosis.

In summary, women with LN should ideally be in sustained remission for at least 6 months before attempting pregnancy. Pregnancy should be avoided in women with class IV LN, nephrotic syndrome, and severe hypertension because of the significant risk for maternal and fetal morbidity. **Moderate renal insufficiency (serum creatinine, 1.5 to 2 mg/dL) is a relative contraindication to pregnancy, and advanced renal insufficiency (creatinine > 2 mg/dL) should be considered an absolute contraindication to pregnancy.**

TABLE 44-3 Distinguishing Between Preeclampsia and Systemic Lupus Erythematosus or Lupus Nephritis Flare

TEST	PREECLAMPSIA	SLE
Serologic		
Decreased complement C3, C4	±	+++
Elevated anti-dsDNA	–	+++
Elevated Ba or Bb fragments with low CH50	±	++
Antithrombin III deficiency	++	±
Hematologic		
Microangiopathic hemolytic anemia	++	–
Coombs-positive hemolytic anemia	–	++
Thrombocytopenia	++	++
Leukopenia	–	++
Renal		
Hematuria	+	+++
Cellular casts	–	+++
Elevated serum creatinine	±	++
Elevated ratio of serum blood urea nitrogen to creatinine	++	±
Hypocalciuria	++	±
Liver		
Liver transaminases	++	±

+++, Present; ++, occasionally present; ±, may or may not be present; –, not present; SLE, systemic lupus erythematosus.

Pregnancy Loss

Women with SLE are at increased risk for pregnancy loss compared with the general obstetrical population. More recent reports suggest that the pregnancy loss rate associated with SLE may be declining, perhaps because of improved antenatal surveillance and treatment. Petri and Allbritton compared 481 pregnancies in 203 women with SLE with 566 pregnancies in 177 healthy relatives and 356 pregnancies in 166 healthy unrelated women and found that pregnancy loss occurred significantly more often in women with SLE (21%) compared with the healthy relatives (8%) or the unrelated controls (14%).[26] A recent smaller study of women with SLE who were all in remission at the onset of pregnancy and were maintained on low-dose glucocorticoids, hydroxychloroquine, or azathioprine found a modest, although significantly increased, rate of spontaneous abortion and stillbirth (17%) in these women compared with a control group without SLE (5%).[11]

Antiphospholipid antibodies are the most important determinant of pregnancy loss in women with SLE. Antiphospholipid syndrome (APS) is associated with an increased risk for fetal death (≥10 weeks' gestation),[27] even outside of a diagnosis of SLE. For women with SLE and a prior fetal death, the predictive value of antiphospholipid antibodies (aPL) for subsequent fetal loss has been reported at more than 85%.[28] Recurrent pre-embryonic (<6 weeks) and embryonic loss (6 to 9 weeks) also is included as an obstetrical criterion for the diagnosis of APS. In comparison with fetal loss, however, studies have generally been less consistent with regard to an association between APS and recurrent early loss.[29]

Disease activity and severity are important determinants of the risk for pregnancy loss in women with SLE. Clowse and coworkers, in a prospective study of 267 pregnancies among SLE patients between 1987 and 2002, found that only 77% of pregnancies among women with high-activity disease resulted in a live birth compared with 88% in women with low-activity SLE.[30] Furthermore, high-activity SLE in the first and second trimesters led to a three-fold increase in pregnancy loss. Pregnancy loss is also more likely if SLE is diagnosed during the index pregnancy.[22]

Preexisting renal disease appears to increase the risk for pregnancy loss among women with SLE, with higher loss rates seen among women with more severe renal impairment. One study reported a fetal loss rate of 50% in women with LN and moderate to severe renal insufficiency (serum creatinine ≥ 1.5 mg/dL).[25] Another study found that spontaneous abortions occurred in 26% of women with LN

and minimally impaired renal function (serum creatinine <1 mg/dL, creatinine clearance >80 mL/minute, and proteinuria <1 g/day) compared with 36% of women with "mild" impairment (clearance, 50 to 80 mL/minute; proteinuria, 1 to 3 g/day).[23]

Preeclampsia

Hypertensive disorders, including gestational hypertension and preeclampsia, are frequent complications of pregnancies in women with SLE, occurring in 10% to 30% of cases.[7,31] Women with LN are at particular risk for developing preeclampsia. In one study, preeclampsia occurred in two thirds of pregnancies among women with LN.[32] Other risk factors for preeclampsia among SLE patients include chronic hypertension, APS, chronic glucocorticoid use, diabetes, and preeclampsia in a previous pregnancy. As mentioned earlier, it can be difficult to distinguish between preeclampsia and an SLE flare because they often have similar manifestations. Sound clinical judgment is required, but if the gestation is beyond 28 to 30 weeks, delivery after antenatal steroid administration may be the most prudent course of action. If signs and symptoms resolve relatively quickly postpartum, the diagnosis is most likely preeclampsia.

Intrauterine Growth Restriction

Lupus in pregnancy has generally been considered a significant risk factor for uteroplacental insufficiency resulting in IUGR and small-for-gestational-age neonates. Although the rate of IUGR among SLE pregnancies has been reported to be as high as 40%,[33] more recent and larger studies suggest a considerably lower rate. Clowse and coworkers, using the National Inpatient Sample, studied more than 16.7 million hospital admissions for childbirth (13,555 to women with SLE) and found that only 5.6% of SLE patients carried a diagnosis of IUGR.[31] Although this was higher than among non-SLE patients (1.5%), the difference was not statistically significant after adjusting for maternal age. Georgiou and colleagues reported no significant difference in the rate of IUGR between SLE pregnancies and healthy controls.[11] In this study, nearly all women were in remission at the onset of pregnancy. It appears less likely that SLE itself confers an increased risk for IUGR but instead that particular manifestations of the disease, such as renal impairment and chronic hypertension, play the most important roles. In addition, chronic glucocorticoid use, especially at higher doses, is a known risk factor for IUGR.

Preterm Birth

PTB is a frequent outcome among women with SLE, occurring in approximately one third of SLE pregnancies, and most PTBs in SLE pregnancies are the result of iatrogenic delivery for obstetrical or maternal medical indications.[15,26] The risk for PTB is significantly greater among women with increased SLE activity, APS, or hypertension and in those taking higher doses (>10 mg/day) of glucocorticoids.[11,15,30] In a recent study of 267 pregnancies, a full-term delivery was achieved in only 26% of women with high-activity SLE compared with 61% of those with no or mild SLE activity.[30] An association between SLE and preterm premature rupture of membranes (PPROM) has been reported; in one study, PPROM occurred in 39% of SLE pregnancies delivered between 24 and 36 weeks' gestation, and the association was independent of glucocorticoid treatment.[34] Not all studies of SLE patients indicate a particularly high frequency of PTB. In a large retrospective case-control study from the Hopkins Lupus Cohort, a 12% rate of PTB occurred among women with SLE compared with 4% among controls (relatives and nonrelatives without SLE).[26] The relatively low rate of PTB in this study may be due to the inclusion of SLE patients with quiet or less severe disease.

Neonatal Lupus Erythematosus

NLE is a transplacentally acquired autoimmune disease that occurs in a small percentage of infants born to women with SLE and is associated with the presence of maternal antibodies to the extractable nuclear antigens, Ro/SSA and La/SSB. Fortunately, the incidence of NLE is low; among all mothers with SLE, the risk for NLE is less than 5%. Of women with SLE who test positive for anti-Ro/SSA and anti-La/SSB, at most 15% to 20% will have an affected infant. Many mothers of affected neonates do not carry a current diagnosis of SLE and are unaware that they have anti-Ro/SSA and anti-La/SSB antibodies. A significant proportion of these women will develop symptomatic autoimmune disease in the future (typically Sjögren syndrome). As a result, appropriate counseling, testing, and surveillance of these mothers is important.

The most common manifestation of NLE is a lupus rash. This appears as erythematous, scaling, annular, or elliptical plaques on the face or scalp that develop in the first few weeks of life and can persist for up to 6 months. Less frequently, hematologic NLE occurs and manifests as autoimmune hemolytic anemia, leukopenia, thrombocytopenia, and hepatosplenomegaly.

The most serious manifestation of NLE is CHB. It is often diagnosed at a routine prenatal visit by detecting a fixed bradycardia of 60 to 80 beats/minute. Fetuses at 16 to 24 weeks appear to be at greatest risk; CHB rarely develops in the third trimester. CHB is caused by binding of antibodies to antigens present in the fetal cardiac tissues, with subsequent damage to the cardiac conduction system. The atrioventricular (AV) node and adjacent conduction system are particularly susceptible to damage, and the result is complete AV dissociation. In very severe cases, widespread endomyocardial damage leads to fibroelastosis, impaired myocardial contractility, hydrops fetalis, and stillbirth.

Complete CHB is irreversible, and there is no effective in utero treatment. In a report of 113 infants affected with CHB from a national NLE registry, overall mortality was 19%, with 5% of deaths occurring in utero. Sixty-three percent of the surviving infants required a pacemaker.[35]

Among women with anti-Ro/SSA and anti-La/SSB antibodies, the risk for having a fetus develop CHB is low, probably in the range of 1% to 2%. In women with a prior fetus with CHB, the risk for recurrent CHB is much higher, occurring in 15% to 20% of subsequent pregnancies.[36] The recurrence rate is unaffected by maternal health, use of steroids, antibody status, severity of disease in the first affected child, or sex of the subsequent child. Genetic factors in the fetus may play a role in determining which

fetuses of antibody-positive mothers are most likely to be affected with CHB. Significant associations with NLE have been found for SNPs in the HLA region and near the tumor necrosis factor-α (TNF-α) gene.[37]

If CHB is suspected prenatally, fetal echocardiography, to rule out fetal cardiac structural abnormalities and confirm the diagnosis of CHB, and maternal testing for anti-Ro/SSA and anti-La/SSB antibodies (if not done previously) should be performed. Some experts recommend screening fetuses of antibody-positive mothers who have had a previously affected infant using weekly Doppler fetal echocardiography to measure the PR interval from 16 through at least 26 weeks. More recent experience leaves the clinical utility of this approach in doubt. Progression from first- or second-degree block to complete (third-degree) heart block can occur rapidly, and it also appears that complete block can occur without a detectable preceding prolongation of the PR interval. Moreover, the early identification of developing heart block has not been shown to alter outcome.

The optimal treatment of fetuses with CHB is somewhat uncertain. A 2004 report of 37 consecutive cases from two institutions found that a combination of dexamethasone and a β-sympathomimetic when the fetal heart rate is less than 55 beats/minute resulted in a 1-year survival rate of 95%, which is a significant improvement compared with no treatment.[38] The rationale for dexamethasone treatment is based on the belief that the etiology of CHB is an inflammatory carditis. However, results of the recently published PRIDE study are less favorable.[39] The PRIDE investigators enrolled 40 pregnant women at 33 centers with anti-Ro/SSA antibodies and a fetus with CHB. Thirty women elected to take dexamethasone, whereas 10 declined treatment. There were 31 fetuses with complete heart block, 22 treated with dexamethasone and 9 untreated. No reversals of third-degree block were seen in either group. Of the 6 fetuses who had second-degree heart block and who were treated with dexamethasone, 3 progressed to third-degree block, 2 stabilized at second degree, and only 1 reverted to normal sinus rhythm. Two fetuses with first degree heart block reverted to normal sinus rhythm with dexamethasone treatment. Premature and small-for-gestational-age infants were restricted to the dexamethasone group. Although case selection likely played a role, there were no fetal or neonatal deaths in the nondexamethasone group, but there were 6 (20%) in the dexamethasone group. And chronic steroid therapy is not without controversy, primarily because of the potential risks associated with long-term treatment, including oligohydramnios, growth restriction, and impaired neurologic development.

Heart block associated with fetal hydrops may pose a special circumstance. A retrospective analysis of 50 cases of CHB found that dexamethasone or betamethasone use was associated with improvement or resolution of hydrops, although steroid treatment had no effect on third-degree heart block.[40] Based on the available, albeit limited, data, most experts recommend a trial of dexamethasone if first- or second-degree heart block is found or in selected cases of CHB with hydrops (Table 44-4).

Intravenous immune globulin (IVIG) has the potential to lower the transplacental passage of autoantibodies against Ro/SSA and La/SSB and is being investigated as a potential treatment for high-risk women (those with antibodies and a previously affected child). The Preventive IVIG Therapy for Congenital Heart Block (PITCH) study enrolled women with positive anti-SSA/Ro or anti-SSB/La titers (or both), maternal rheumatic disease (symptomatic or not), and a previously affected child with CHB or NLE and administered IVIG every 3 weeks from 12 to 24 weeks' gestation.[41] The results were recently published. Recruitment was stopped at 20 women after three of the fetuses developed third-degree block (a predetermined stopping point of the study). One infant had a rash consistent with NLE. Sixteen infants were unaffected. Although there were no identified safety issues with IVIG therapy, there were also no significant changes in maternal anti-Ro/SSA or anti-La/SSB antibody titers with treatment. A European prospective observational study of 24 pregnancies in 22 women with a previous child affected with CHB found that IVIG was not effective at preventing third-degree block, which developed in 3 of 15 (20%) fetuses in the treatment group versus 1 of 9 (11%) in the nontreatment group.[42] These recent results strongly suggest that IVIG is not indicated for the prevention of CHB; certainly, insufficient evidence exists to recommend IVIG therapy except under an approved experimental protocol.

Fetuses with a heart rate of less than 55 beats/minute are at increased risk for hydrops and demise.[43] Case

Table 44-4 Management Approaches to Anti-Ro/SSA–Associated Congenital Heart Block

CLINICAL SCENARIO	MANAGEMENT
Maternal anti-Ro/SSA antibodies	Expectant management.
No previously affected fetus *or* Previous fetus with CHB	Some experts recommend serial fetal echocardiography to evaluate PR interval from 16-28 weeks, although the clinical utility of this is debated.
Fetal first-degree heart block	No management regimen has been proved effective in avoiding progression to complete heart block.
or Fetal second-degree heart block or alternating second- and third-degree block	Some experts initiate dexamethasone, 4 mg/day.* Taper and discontinue steroid treatment if there is progression to third-degree block.
Fetal third-degree (complete) heart block	No management regimen has been proved effective in reversing heart block or avoiding associated fetal or neonatal complications. Serial evaluation for hydrops. When fetal heart rate is <50-55 beats/minute, some experts initiate a trial of oral terbutaline (2.5-7.5 mg every 4-6 hours, max. 30 mg/day).†
Fetal third-degree heart block with hydrops	When fetal heart rate is <50-55 beats/minute, some experts initiate a trial of oral terbutaline (2.5-7.5 mg every 4-6 hours, max. 30 mg/day).[2] Some experts recommend a trial of dexamethasone, 4 mg/day, at least until improvement in fetal sonographic findings.

*Monitor for maternal glucose intolerance, impaired fetal growth, and oligohydramnios with chronic steroid therapy.
†Terbutaline should be used with caution or not at all in women with diabetes, hypertension, hyperthyroidism, seizures, or a history of arrhythmias.

reports and case series of maternally administered β-sympathomimetic agents suggest that these agents may increase the fetal heart rate, improve signs of cardiac insufficiency, and result in higher fetal-neonatal survival rates.[44] Jaeggi and associates compared the outcomes of fetuses diagnosed with CHB before and after 1997, when a standardized treatment protocol was initiated at the authors' institutions involving dexamethasone and β-stimulation for a fetal heart rate of less than 55 beats/minute.[43] Of those pregnancies with a fetal heart rate of less than 55 beats/minute, 9 were treated with β-sympathomimetics and 16 were not. The fetal heart rate increased spontaneously in about half of all fetuses, regardless of treatment. Although those who were treated had a lower baseline fetal heart rate, they did not have any further decrease in heart rate, in contrast to those who were untreated.

Table 44-4 details a management strategy for pregnancies at risk for CHB.

Drug Therapy and Systemic Lupus Erythematosus in Pregnancy

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used for analgesia in SLE patients outside of pregnancy. NSAIDs readily cross the placenta and block prostaglandin synthesis in a variety of fetal tissues. **The safety of NSAIDs in pregnancy is dependent on dose, timing in pregnancy, and the specific drug used.** The use of low-dose aspirin in pregnancy generally appears to be safe. First-trimester use is not associated with a significant increase in congenital anomalies. Low-dose aspirin used during pregnancy in women with APS or women at high risk for developing preeclampsia has not been associated with an increased risk for pregnancy complications.

Adult doses of aspirin near delivery have been associated with abnormal bleeding in mothers and neonates. Although short-term (≤48 hours) tocolytic therapy with indomethacin appears to be safe, chronic use has been associated with oligohydramnios and constriction of the fetal ductus arteriosus. **Given these risks, chronic use of adult dosages of NSAIDs should be avoided during pregnancy. Acetaminophen and narcotic-containing preparations are acceptable alternatives if analgesia is needed. NSAIDs are considered safe during breastfeeding.**

Glucocorticoids

Glucocorticoids are often used for the treatment of SLE in pregnancy, either as maintenance or in short courses for the treatment of disease exacerbations. Prednisone, U.S. Food and Drug Administration (FDA) category C (see Chapter 8), has been the oral glucocorticoid of choice in pregnancy secondary to its extensive metabolism by the placenta, with conversion to an inactive metabolite. The long-term use of fluorinated steroids such as dexamethasone and betamethasone should be avoided because these drugs freely cross the placenta, with fetal concentrations approximating maternal concentrations. Glucocorticoid use in pregnancy is not without risk. Multiple studies have reported an association between periconceptional glucocorticoid use and cleft lip and palate,[45] although the magnitude of risk is small. **Prolonged glucocorticoid use is associated with bone demineralization, gestational diabetes, preeclampsia, PROM, and IUGR.** Women chronically treated with glucocorticoids should be screened multiple times during pregnancy for gestational diabetes, generally around 20, 28, and 32 weeks' gestation. Chronic glucocorticoid use may also cause significant side effects in the mother, including fluid retention, weight gain, hirsutism, striae, acne, and gastrointestinal discomfort and ulceration. A low-salt diet, antacids, weight-bearing exercise, and calcium and vitamin D supplementation should be recommended to all women on chronic glucocorticoids. Women who are in sustained remission at the onset of pregnancy have been shown to have generally good maternal and fetal outcomes without prophylactic glucocorticoids.[14] The doses used in pregnancy are the same as those used in nonpregnant patients. However, carefully tapering to the lowest dose needed to manage the disease is reasonable given the potential adverse effects.

Antimalarials

Hydroxychloroquine (HCQ), an antimalarial agent, is an increasingly important treatment option for SLE in pregnancy and is an FDA category C drug (see Chapter 8). Although there were early reports of associated teratogenicity, specifically ocular toxicity and ototoxicity, more recent studies suggest that HCQ is safe at the doses typically used to treat SLE. Costedoat-Chalumeau and coworkers compared 133 pregnancies in 90 women treated with HCQ with 70 pregnancies in 53 women with similar disorders but not treated with HCQ.[46] There were no differences in the percentage of live births or congenital malformations between groups. There were also no differences in vision, hearing, growth, or development between those offspring exposed to HCQ and those unexposed (mean, 26 months of follow-up).

More recent information supports a possible salutary impact of HCQ in SLE pregnancy. In a prospective study of 257 pregnant women with SLE, disease activity was significantly higher among women who stopped taking HCQ 3 months before or during the first trimester of pregnancy.[47] Women who continued on HCQ were maintained on a lower average dose of prednisone during pregnancy. **Given the body of evidence that now indicates that HCQ is safe in pregnancy, and the known risks for chronic glucocorticoid treatment, HCQ may be the best maintenance therapy for SLE in pregnancy.** Women who become pregnant while taking HCQ should generally be continued on this medication.

Azathioprine

Azathioprine (AZA), an FDA category D drug (see Chapter 8), is metabolized to 6-mercaptopurine (6-MP) in vivo. The placenta metabolizes the majority of AZA to an inactive metabolite, thiouric acid. Studies are conflicting with regard to the fetal or neonatal risks of AZA use in pregnancy. Data have mostly come from organ transplant recipients or inflammatory bowel disease patients. Increased rates of IUGR, PTB, and impaired neonatal immunity associated with maternal AZA use have been reported.[48] However, these findings are difficult to interpret because of the use of multiple immunosuppressants among some women and difficulty in determining whether outcomes are due to drug exposure or severe illness in the mother.

TABLE 44-5 DRUGS USED IN COLLAGEN VASCULAR DISEASES

DRUG	MECHANISM OF ACTION	PREGNANCY CONCERNS
NSAIDs	Anti-inflammatory	Avoid high dose. Risk depends on timing in pregnancy. Acetaminophen preferred.
Glucocorticoids	Anti-inflammatory, immunosuppressive	Prednisone doses of ≤10 mg/day preferred. Risks for GDM, PPROM, preeclampsia, IUGR.
Acetaminophen	Analgesic	Considered safe in pregnancy. Dosages should not exceed 4 g/day.
Hydroxychloroquine	Antimalarial—exact mechanism unknown	Likely safe. Pregnant women should generally continue this medication.
Azathioprine	Inhibits purine synthesis	Possible increased risks for PTB, IUGR, impaired neonatal immunity. May be preferred over other immunosuppressants for severe SLE.
Cyclosporine	Calcineurin inhibitor	Risk for teratogenicity appears low. Possible increased risks for PTB, small-for-gestational age.
Cyclophosphamide	Alkylating agent	Teratogenic, abortifacient—avoid in pregnancy unless exceptional circumstances.
Leflunomide	Inhibits pyrimidine synthesis	Teratogenic, abortifacient—avoid in pregnancy. Extensive washout procedure recommended.
Methotrexate	Inhibits dihydrofolate reductase	Teratogenic, abortifacient—avoid in pregnancy.
Mycophenolate mofetil	Inhibits purine synthesis	Teratogenic, abortifacient—avoid in pregnancy.
TNF antagonists	Binds TNF-α and TNF-β	Alert for severe bacterial infections. Generally appear safe in pregnancy, but long-term data are lacking.

GDM, Gestational diabetes mellitus; *IUGR,* intrauterine growth restriction; *NSAIDs,* nonsteroidal anti-inflammatory drugs; *PROM,* preterm premature rupture of membranes; *PTB,* preterm birth; *SLE,* systemic lupus erythematosus; *TNF,* tumor necrosis factor.

Although AZA is an FDA category D drug in pregnancy, it may be indicated for the treatment of severe, active SLE that does not respond adequately to glucocorticoids. In these situations, it is generally preferred over other immunosuppressants in pregnancy.

Cyclosporine

Cyclosporine, a calcineurin inhibitor, selectively inhibits the transcription of interleukin-2 and several other cytokines. It may occasionally be used in more severe cases of SLE. It is an FDA category C drug (see Chapter 8). Data regarding cyclosporine use in pregnancy are mainly derived from studies of organ transplant recipients. The risk for teratogenicity with cyclosporine use in the first trimester appears to be low. An increased risk for PTB and small-for-gestational-age infants among pregnancies exposed to cyclosporine has been reported.[49] It is difficult to tell, however, whether these findings are a result of the drug itself or the mother's underlying medical condition.

Drugs with Moderate to High Risk for Fetal Harm

Cyclophosphamide, an alkylating agent, is an FDA category D drug and carries a significant risk for teratogenesis and should not be used in the first trimester (see Chapter 8). Outside of the first trimester, use should be limited to unusual circumstances, such as in women with severe, progressive proliferative glomerulonephritis. Case series of breast cancer patients treated with cyclophosphamide in the second and third trimesters have reported generally good pregnancy outcomes.

Methotrexate, a folate antagonist and FDA category X drug, is teratogenic and can induce miscarriage (see Chapter 8). Among surviving fetuses, about 10% to 20% will have anomalies that include cleft palate, hydrocephalus, anencephaly, hypertelorism, wide nasal bridge, micrognathia, ear anomalies, and delayed ossification. **Methotrexate is absolutely contraindicated in pregnancy.** Women taking methotrexate who desire to become pregnant should be advised to have several menstrual cycles off of the drug before attempting to conceive.

Mycophenolate mofetil (MMF), an inhibitor of purine biosynthesis, is sometimes used in SLE patients. It is an FDA category D drug in pregnancy because of the risk for teratogenicity and miscarriage (see Chapter 8). In a 2006 review of 119 pregnancies exposed to MMF, 31% ended in miscarriage and 15% had congenital anomalies.[49] **MMF is contraindicated in pregnancy.**

Table 44-5 lists medications used in the treatment of collagen vascular diseases and issues related to their use in pregnancy.

Obstetrical Management

Ideally, all women with SLE would have a preconceptional discussion of the complications of SLE in pregnancy with their reproductive health care provider and their rheumatologist. Women with SLE who are considering pregnancy should be advised of the risks for SLE flare, pregnancy loss, preeclampsia, IUGR, PTB, and NLE. They should also be informed of the risks of SLE drug therapies in pregnancy. **To minimize their risk, women with active SLE should be counseled to postpone pregnancy until they have been in a sustained remission for at least 6 months.** Drugs with a moderate to high risk for fetal harm should be discontinued before conception if at all possible. Every effort should be made to taper or eliminate high-dose chronic NSAID therapy. Maintenance therapy with low-dose glucocorticoids or HCQ is acceptable if deemed necessary to sustain remission. Baseline laboratory assessment should include the following:

- Evaluation for anemia and thrombocytopenia
- Assessment of renal function (urinalysis, serum creatinine, and quantification of proteinuria with a 24-hour urine collection or a spot protein-to-creatinine ratio). Women with LN should have their renal function assessed at least every trimester (more

frequently if there is suspicion of flare or preeclampsia).
- aPL (lupus anticoagulant, anticardiolipin and anti-β_2-glycoprotein-I antibodies)

Some clinicians also assess all SLE patients for anti-Ro/SSA and anti-La/SSB status before pregnancy; however, the clinical utility of this is questionable unless the patient has had an infant with CHB.

Chronic hypertension is best managed with labetalol or calcium channel blockers. Angiotensin-converting enzyme (ACE) inhibitors and receptor blockers are contraindicated in pregnancy owing to an increased risk for congenital anomalies, oligohydramnios, and neonatal renal failure.[50,51] Many experts recommend low-dose daily aspirin to decrease the risk for preeclampsia.

Because of the increased maternal and fetal risks, close antenatal surveillance is indicated. Prenatal visits should occur every 2 weeks in the first and second trimesters and weekly in the third trimester. The primary goal of those visits after 20 weeks is to detect hypertension, proteinuria, and possible IUGR. Ultrasonography to evaluate fetal growth and amniotic fluid adequacy should occur every 4 to 6 weeks after 20 weeks. Fetal surveillance for evidence of placental insufficiency should begin around 30 to 32 weeks and typically consists of daily fetal kick counts and weekly or twice-weekly nonstress tests with amniotic fluid assessment or biophysical profiles, or both. Some centers routinely include Doppler assessments of umbilical artery blood flow for fetal surveillance. In patients with disease exacerbations, hypertension, proteinuria, IUGR, or APS, earlier or more frequent maternal and fetal surveillance may be indicated.

Management of SLE during labor and delivery is a continuation of antenatal management. Any maintenance SLE medications should be continued through labor and delivery or resumed immediately postpartum at the antenatal dose. Chronic glucocorticoid therapy can suppress the hypothalamic-pituitary-adrenal (HPA) axis. Patients at greatest risk for HPA suppression are those who have been taking at least 20 mg/day of prednisone for at least 3 weeks or have a Cushingoid appearance, and such patients should receive stress-dose steroids during labor and delivery. A regimen of intravenous hydrocortisone, 100 mg every 8 to 12 hours for two or three doses, is generally sufficient. Patients who have received any dose of steroids for less than 3 weeks or have taken 5 mg/day or less of prednisone are generally considered not to be at risk for HPA axis suppression. For those taking between 5 and 20 mg/day, appropriate management is less clear, but the risk for adrenal insufficiency appears to be very low with continuation of the regular steroid dose. As a result, in the nonobstetrical fields, many have concluded that stress-dose steroids are not indicated in cases of chronic intermediate-dose steroid therapy. However, reliable data on the risk for secondary adrenal insufficiency in pregnant women taking chronic glucocorticoids are lacking.

Some women experience a postpartum SLE flare. Women who have had active disease in pregnancy or have more severe SLE manifestations are at greatest risk. Close surveillance of all women with SLE should continue postpartum, and plans for appropriate follow-up with a rheumatologist should be made.

ANTIPHOSPHOLIPID SYNDROME

The aPLs are a heterogenous group of autoantibodies directed against either negatively charged phospholipids or proteins bound to these phospholipids. **The three major aPLs are lupus anticoagulant (LA), anticardiolipin antibody (aCL), and antibody to β_2-glycoprotein-I (β_2-GP-I). The diagnosis of APS rests on the occurrence of either arterial or venous thrombosis or pregnancy morbidity and repeatedly positive testing for at least one aPL autoantibody.** Classification criteria for APS have been developed primarily for research purposes. These criteria were first published in 1999 and then revised in 2005 (Table 44-6).[52] The criteria are critical for defining relatively homogenous populations to include in research studies.

Epidemiology

APS may occur alone or in combination with another autoimmune disease, most commonly SLE. The actual prevalence and incidence of APS are not known. **aPLs are found in a small percentage (typically, <5%) of healthy controls (including healthy pregnant women) and in up to 35% of patients with SLE.**[53,54] The risks associated with an incidentally discovered positive test for aPL among otherwise healthy women are not well understood. Positive testing for aPL also may occur in association with certain bacterial or viral infections, medications, neoplasms, and advancing age. Typically, aPLs associated with these conditions occur

TABLE 44-6 REVISED CLASSIFICATION CRITERIA FOR THE ANTIPHOSPHOLIPID ANTIBODY SYNDROME*

Clinical Criteria

Vascular Thrombosis

a. One or more clinical episodes of arterial, venous, or small-vessel thrombosis in any tissue or organ, *and*
b. Thrombosis confirmed by objective, validated criteria (i.e. unequivocal findings of appropriate imaging studies or histopathology, *and*
c. For histopathologic confirmation, thrombosis should be present without significant evidence of inflammation in the vessel wall.

Pregnancy Morbidity

a. One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, with normal fetal morphology documented by ultrasound or by direct examination of the fetus, *or*
b. One or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of eclampsia or severe preeclampsia or placental insufficiency, *or*
c. Three or more unexplained consecutive spontaneous abortions before the 10th week of gestation, with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal causes excluded.

Laboratory Criteria

a. Lupus anticoagulant present in plasma, on two or more occasions at least 12 weeks apart, detected according to the guidelines of the International Society on Thrombosis and Hemostasis
b. Anticardiolipin antibody of IgG and/or IgM isotype in blood, present in medium or high titer, on at least two occasions at least 12 weeks apart, measured by standardized enzyme-linked immunosorbent assay, *or*
c. Anti-β_2-glycoprotein-I antibody of IgG and/or IgM isotype in blood, present in medium or high titer, on at least two occasions at least 12 weeks apart, measured by standardized enzyme-linked immunosorbent assay.

*Definite antiphospholipid syndrome is considered to be present if at least one of the clinical and one of the laboratory criteria are met.

in low titer and are of the immunoglobulin M (IgM) isotype.

Pathophysiology

Although still debated, it appears that aPLs, through a direct antibody-mediated effect, are the primary mediators of adverse obstetrical outcomes associated with APS. In studies using mouse models, the administration of human IgG fractions containing aPL or monoclonal aPL from mice or humans results in prolongation of the partial thromboplastin time (PTT), a prothrombotic state, and an increase in fetal loss.[55,56] aPLs have been shown to activate endothelial cells, monocytes, and platelets and to induce complement. Activated endothelial cells, in turn, express adhesion molecules such as intercellular adhesion molecule-1, vascular cell adhesion molecule-1, E-selectin, and both endothelial cells and monocytes upregulate the production of tissue factor. Activated platelets increase expression of glycoprotein 2b-3a and synthesis of thromboxane A_2.

The clinical manifestations of APS also may result from a variety of effects of aPL on phospholipids and phospholipid-binding proteins critical to coagulation pathways, including interference with the activity of protein S. In addition, aPLs may have procoagulant effects on prostacyclin, serum proteases, toll-like receptors, prothrombin, protein C, and tissue factor. Interference with annexin-A5, a natural anticoagulant, might favor placental thrombosis and fetal loss. Complex interactions of aPLs with other antibodies (including those directed against coagulation factors, annexins, tissue-type plasminogen activator, and platelet-activating factor) have been suggested to play a role in APS.

More recent work suggests that an important cause of pregnancy complications in women with APS is inflammation, not thrombosis. Complement activation is required for fetal loss and growth restriction in mouse models of APS.[57,58] Clinical studies in humans support the important role of complement in APS. Compared with a healthy control group, patients with primary APS have been found to have lower levels of CH50, C3, and C4 and increased levels of complement fragments indicative of complement activation.[59] Furthermore, placentas from women with aPLs have increased levels of complement deposition compared with controls.[60]

Regardless of the underlying mechanism, the pregnancy complications of APS appear to be tied to abnormal maternal-fetal circulation. Pathologic findings in cases of APS-associated fetal loss include narrowing of the spiral arterioles, intimal thickening, acute atherosis, fibrinoid necrosis, and placental necrosis, infarction, and thrombosis.

Clinical Manifestations

Diagnosis

The International Consensus Statement on criteria for APS is detailed in Table 44-6. **Patients with definite APS must manifest either vascular thrombosis or pregnancy morbidity.** Pregnancy morbidity is divided into three categories:

- Otherwise unexplained recurrent early miscarriages: pre-embryonic (<6 weeks' gestation) or embryonic (6 to 9 weeks' gestation) losses
- Otherwise unexplained fetal death (≥10 weeks' gestation)
- PTB occurring at less than 34 weeks' gestation secondary to severe preeclampsia or placental insufficiency

Some patients with APS have autoimmune thrombocytopenia, typically greater than 50,000 and less than 150,000. Isolated thrombocytopenia, however, is not a diagnostic criterion for APS.

Laboratory Findings

Although the diagnosis of APS rests first and foremost on clinical features, confirmation with laboratory testing for aPL is necessary. To be diagnosed with APS, a patient must have medium to high titers of aCL or anti-β_2-GP-I IgG or IgM antibodies or LA. **Because other conditions can result in transient aPLs, persistent positive testing should be present on two or more occasions at least 12 weeks apart to satisfy the laboratory criteria for APS.**

LA is reported as positive or negative and is identified by its ability to cause prolongation of in vitro clotting assays. It is critical that published laboratory criteria for the diagnosis of LA be followed because a significant number of samples thought to have LA activity are false-positive results when measured at a reference laboratory.

Both aCL and anti-β_2-GP-I antibody testing are performed using enzyme-linked immunosorbent assay (ELISA), and results are reported in international units. In the absence of a positive LA, experts agree that only repeatedly positive, medium to high titers of aCL or anti-β_2-GP-I should be used to diagnose APS. Traditionally, the cut-off for a medium to positive titer was considered 20 international units or more. However, the most recent international consensus defined medium or higher titers at more than 40 GPL or MPL units or higher than the 99th percentile of the laboratory. Clinicians should be aware that substantial variation in ELISA results from different laboratories continues to plague the field. Positive standard serum is available, and recommendations for a standardized approach to testing and reporting results have been published.[61] The standard aCL antibody assay detects β_2-GP-I-dependent aCL antibodies, those that require the presence of β_2-GP-I for binding. Notably, IgA isotypes, antiprothrombin antibodies, and antibodies directed against phosphatidylserine-prothrombin complex are not accepted as diagnostic of APS.

In general, LA and IgG anti-β_2-GP-I antibodies are more specific and aCL antibodies are more sensitive for APS. Low-positive antibody titers should be viewed with suspicion because they may be found in up to 5% of normal individuals; they therefore should not be used to make the diagnosis of APS. Isolated IgM results are also believed to have reduced specificity for APS.

Pregnancy in Women with Antiphospholipid Syndrome

As mentioned in the section on SLE, there is good evidence that aPLs are associated with an increased risk for fetal death. This association with fetal death is particularly strong in the presence of LA or medium to high titers of aCL IgG.[27,53,62] This association appears to be independent of any coexisting autoimmune disease such as SLE. In

serologic evaluation of women with recurrent early miscarriage (<10 weeks), 10% to 20% are found to have detectable aPLs.[63,64]

In addition to the risk for fetal death, women with APS are at significantly increased risk for developing severe preeclampsia and IUGR. These risks are particularly elevated among women with APS and a history of SLE, prior fetal death, or thrombosis. Among such highly selected patients, hypertensive disorders complicate a median of 32% of APS pregnancies,[27,53,65] and IUGR occurs in up to 30% of births.[65] It also has been reported that women with early-onset, severe preeclampsia are more likely to test positive for aPLs compared with healthy controls.[66] Screening the general pregnant population for aPLs, however, is not recommended. Pregnancies complicated by APS are also more likely to exhibit non-reassuring antenatal and intrapartum fetal monitoring.[27,65] As a result of these pregnancy complications, it is not surprising that the rate of PTB (mostly iatrogenic) is elevated in women with APS.[65] In addition to adverse obstetrical outcomes, women with APS also appear to be at significantly increased risk for vascular thromboses during pregnancy and the puerperium.[65]

It is worth emphasizing that the risk for APS-related pregnancy complications varies with the population in which the diagnosis of APS is made. Women who meet criteria for APS because of recurrent early miscarriage, but are otherwise healthy, do not appear to be at high risk for thrombosis, fetal death, preeclampsia, or placental insufficiency.[52,63,64] However, a cautious approach and close clinical surveillance are still warranted in these women.

Treatment of Antiphospholipid Syndrome in Pregnancy

Ideally, treatment of women with APS would improve maternal, fetal, and neonatal outcomes by minimizing or eliminating the risks for the disorders discussed earlier, including maternal thrombosis, fetal loss, preeclampsia, IUGR, and the need for iatrogenic PTB. Currently, heparin and low-dose aspirin are the treatments of choice for APS in pregnancy. Heparin is usually started in the early first trimester after demonstrating either an appropriately rising human chorionic gonadotropin level or the presence of a live embryo on ultrasonography. Most investigators recommend preconceptional aspirin because of its possible beneficial effect on early stages of implantation. In the past, glucocorticoids were used to treat APS in pregnancy; however, enthusiasm for this treatment waned in the early 1990s when two small randomized trials found no benefit.[67,68] Also, results from randomized trials have shown no benefit from the use of IVIG, either when added to heparin or used alone.[69-71] A subsequent Cochrane analysis concluded that IVIG was associated with an increased risk for pregnancy loss or PTB compared with heparin and low-dose aspirin.[72]

Pregnant patients with APS diagnosed on the basis of obstetrical criteria and *who have not had a previous thrombotic event* can be classified into one of two groups for the purposes of discussing treatment: (1) patients with recurrent early (pre-embryonic or embryonic) miscarriage and no other features of APS, or (2) those with one or more previous fetal deaths (≥10 weeks' gestation) or previous early delivery (<34 weeks' gestation) because of severe preeclampsia or placental insufficiency. A third group of APS patients consists of those *with a history of thrombosis*. Recommended treatments during pregnancy for these three groups are summarized in Table 44-7.

TABLE 44-7 TREATMENT REGIMENS FOR ANTIPHOSPHOLIPID SYNDROME DURING PREGNANCY

Recurrent Pre-embryonic and Embryonic Loss; No History of Thrombotic Events

Lose-dose aspirin alone or together with unfractionated heparin:
- 5000 to 7500 U every 12 hours in the first trimester, *or*
- LMWH (usual prophylactic doses)

Prior Fetal Death or Early Delivery Because of Severe Preeclampsia or Severe Placental Insufficiency; No History of Thrombotic Events

Low-dose aspirin plus unfractionated heparin:
- 7500 to 10,000 U every 12 hours in the first trimester and 10,000 U every 12 hours in the second and third trimesters, *or*
- Administered every 8-12 hours at a dose to maintain the midinterval aPTT* 1.5 times the control mean, *or*
- LMWH (usual prophylactic doses)

Anticoagulation Regimens for Women with a History of Thrombotic Events

Low-dose aspirin plus unfractionated heparin:
- Administered every 8-12 hours to maintain the midinterval aPTT* or anti-Xa activity in the therapeutic range, *or*
- LMWH (therapeutic doses): weight-adjusted (e.g., enoxaparin, 1 mg/kg every 12 hr, or dalteparin, 200 U/kg every 12 hr)

*Women without a lupus anticoagulant in whom the aPTT is normal can be monitored with the aPTT. Women with lupus anticoagulant should be monitored with anti–factor Xa activity.

aPTT, Activated partial thromboplastin time; *LMWH*, low-molecular-weight heparin.

Heparin treatment of APS pregnancy is not without controversy. Four well-designed studies have addressed pregnancy in patients with APS who have predominantly recurrent early miscarriage.[64,73-75] In two trials, the proportion of successful pregnancies substantially improved with the addition of unfractionated heparin to low-dose aspirin.[64,73] However, the other two trials, both of which used low-molecular-weight heparin (LMWH), proved negative,[74,75] largely because the live-birth rates in the low-dose-aspirin-only patients were quite good (70% to 75%). Interestingly, two studies showed no differences in pregnancy outcomes when comparing unfractionated heparin with LMWH, both combined with aspirin.[76,77] There also are several observational studies that have reported pregnancy success rates of 79% to 100% with low-dose aspirin alone.[78,79] **Despite the obvious controversies raised by the discrepancies in these trials, a 2005 Cochrane systematic review concluded that women with APS and recurrent miscarriage should be given a combination of heparin, 5000 U subcutaneously twice daily, and low-dose aspirin.**[72] Published expert guidelines are similar and include the option of LMWH.[80]

The optimal treatment for women with APS and fetal death (≥10 weeks' gestation) or previous early delivery (<34 weeks' gestation) due to severe preeclampsia or placental insufficiency is not defined by well-designed studies. Most experts recommend low-dose aspirin and either prophylactic or intermediate-dose heparin or LMWH (see Table 44-7). The preponderance of available data show that favorable pregnancy outcomes are achieved with heparin started in the early first trimester.

Women with APS who have had a previous thrombotic event should be treated with low-dose aspirin and full anticoagulation with therapeutic doses of heparin or LMWH (see Table 44-7). Vitamin K antagonists are teratogenic and should be avoided between 6 and 12 weeks' gestation. Because of the risk for fetal bleeding, warfarin after 12 weeks' gestation should be given only in exceptional circumstances. **Antithrombotic coverage of the postpartum period is recommended in all women with APS, with or without previous thrombosis.**[80] Generally, women with previous thrombosis will need long-term anticoagulation with warfarin. In patients with no previous thrombosis, the recommendation is prophylactic-dose heparin or LMWH therapy for 4 to 6 weeks after delivery,[80] although warfarin is an option. Both heparin and warfarin are safe for breastfeeding mothers.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a debilitating disease involving chronic symmetrical inflammatory arthritis of the synovial joints. **RA affects 1% to 2% of the U.S. adult population and, similar to other autoimmune diseases, occurs more commonly among females than males.** The incidence of RA increases steadily with age but is frequently encountered among reproductive-aged women.

Pathophysiology

The exact cause of RA is unknown. Although the diagnosis of RA is not made by histologic examination of synovial tissue, characteristic histologic features of RA have been described and include hyperplasia of the synovial lining, an inflammatory infiltrate, and the deposition of fibrin. Eventually a "pannus" is formed that degrades and destroys cartilage and bone and is responsible for much of the morbidity associated with RA.

The inflammatory damage in RA appears to be primarily mediated by $CD4^+$ T cells. These T cells are activated by as yet unknown antigens and stimulate monocytes, macrophages, and synovial fibroblasts to produce cytokines such as interleukin-1, interleukin-6, and TNF-α. These cytokines play a key role in the inflammation of RA. The activated $CD4^+$ T cells also stimulate B cells to produce immunoglobulins, including rheumatoid factor (RF). Autoantibodies alone do not cause disease but clearly play an important role. Patients with high titers of RF are more likely to manifest extra-articular disease. During inflammation, citrulline is incorporated into proteins, and anticitrullinated peptide antibodies (ACPAs) have emerged as an important diagnostic tool, particularly for early-stage RA. The presence of RF and ACPAs in the blood of asymptomatic patients represents an important risk factor for later development of disease.

A large body of evidence confirms the importance of genetic susceptibility to the development of RA. Concordance is higher among monozygotic twins than dizygotic twins (15% vs. 5%). Relatives of patients with RA have not only an increased risk for RA, but also an increased risk for other autoimmune and connective tissue disease. The HLA class II *DRB1* gene is of primary importance in RA susceptibility. Variant alleles of *DRB1* have been associated with RA and include DRB1*0401, *0404, *0405, *0101, *1402, *10, and *1001. The strength of association of these individual alleles varies with the ethnic group studied. More recently, a large number of other RA susceptibility genes have been identified.[81] One of the more significant associations (particularly among whites) is the *PTPN22* gene, which encodes a protein tyrosine phosphatase involved in the regulation of T and B cells.

Given that RA occurs two to three times more commonly in women than men, sex-specific factors likely play an important role in the pathophysiology of RA. Nulliparity is associated with an increased risk for RA. The Nurses' Health Study found a dose-dependent association between breastfeeding duration and a decreased risk for RA.[82]

Clinical Manifestations and Laboratory Findings

The onset of RA is typically insidious and involves symmetrical peripheral polyarthritis and morning stiffness. Arthritis involving the MCP and PIP joints of both hands is characteristic of RA. Fatigue, weakness, weight loss, and malaise may also frequently occur. Eventually, severe joint deformities may develop and are particularly obvious at the MCP and PIP joints of the hands. Rheumatoid nodules are composed of a local proliferation of small vessels, histiocytes, fibroblasts, and other cells and are present in 20% to 30% of patients with RA. They occur most commonly on pressure points, such as in the subcutaneous tissues of the extensor surfaces of the forearms. Nodules that become painful or interfere with joints and nerves can be treated with local injections of glucocorticoids and an anesthetic. Surgery is rarely required.

Less commonly, extra-articular tissues may be affected. These manifestations include pleuritis, pericarditis, neuropathy, vasculitis, scleritis, and renal disease. Most patients with extra-articular involvement also have classic joint symptoms.

In 2010, the American College of Rheumatology, in collaboration with the European League Against Rheumatism, released revised classification criteria for RA (Table 44-8).[83] The new criteria represent a shift in focus to features of early disease that are most likely to represent high risk for progression to erosive disease as opposed to defining the disease by its late-stage features. "Definite" RA is based on confirmed synovitis in at least one joint, absence of a better diagnosis to explain the synovitis, and a total score of at least 6 of 10 from the summation of scores in four domains: number and site of involved joints, serologic abnormality, elevated acute phase response, and symptom duration.

RFs are present in 70% to 80% of patients with RA. However, RFs may also be found in 5% to 10% of the general, healthy population, as well as in individuals with viral infections and other connective tissue diseases such as Sjögren syndrome and SLE. ACPAs have a similar diagnostic sensitivity to RF but are more specific for RA. Multiple other nonspecific laboratory abnormalities may occur in RA patients and include an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), anemia, thrombocytosis, leukocytosis, and a positive ANA.

Rheumatoid Arthritis and Pregnancy

Most women with RA, perhaps as many as 80% to 90%, experience improvement in their disease during pregnancy.

TABLE 44-8 2010 American College of Rheumatology/European League Against Rheumatism Classification Criteria for Rheumatoid Arthritis

Target Population	
• Patients with at least one joint with definite clinical synovitis (swelling)	
• Patients with synovitis that is not better explained by another disease	
Classification Criteria	**Score**
• Score-based algorithm: a total score for categories A to D that is ≥6/10 is needed for classification of definite RA)	
A. Joint Involvement	
1 large joint	0
2-10 large joints	1
1-3 small joints (with or without involvement of large joints)	2
4-10 small joints (with or without involvement of large joints)	3
>10 joints (at least one small joint)	4
B. Serology (at least one test result is needed for classification)	
Negative RF *and* negative ACPA	0
Low-positive RF *or* low-positive ACPA	2
High-positive RF *or* high-positive ACPA	3
C. Acute-phase reactants (at least one test result is needed for classification)	
Normal CRP *and* normal ESR	0
Abnormal CRP *or* abnormal ESR	1
D. Duration of symptoms	
<6 weeks	0
≥6 weeks	1

ACPA, Anticitrullinated protein antibody; *CRP*, C-reactive protein; *ESR*, erythrocyte sedimentation rate; *RA*, rheumatoid arthritis; *RF*, rheumatoid factor.

Improvement in joint stiffness and pain generally begins in the first trimester and persists until several weeks postpartum. Most women who experience improvement in symptoms have a similar improvement in subsequent pregnancies. Currently, there are no laboratory or clinical characteristics that predict which patients will have the most improvement in symptoms during pregnancy.

Until recently, the reason for improvement in RA symptoms during pregnancy has been little more than speculative. However, evidence is now emerging that regulatory T cells (Treg cells), which increase in number during pregnancy, may play an important role in autoimmune conditions, including RA. Treg cells are a family of T lymphocytes that are potent suppressors of autoimmunity and function by inhibiting $CD4^+$ and $CD8^+$ T-cell proliferation and cytokine production, B-cell proliferation and immunoglobulin production, natural killer cell cytotoxicity, and maturation and function of antigen presenting cells. An expanding Treg cell population plays a critical role in the maintenance of allogeneic (but not syngeneic) murine pregnancy. RA patients have been shown to have functionally defective Treg cells, and the expansion of apparently normal Treg cells in RA patients results in improvement in disease.[84] It is reasonable to assume that Treg cell expansion in pregnancy might contribute to RA improvement. Indeed, Forger and colleagues found that among pregnant RA patients, an increased number of Treg cells inversely correlated with disease activity in the third trimester and postpartum. This effect appeared to be mediated, at least in part, by higher levels of interleukin-10 and lower levels of TNF-α and interferon-γ.[85]

A role for endogenous steroid hormones affecting RA cannot be excluded. Many women report an improvement in RA symptoms during the luteal phase of the menstrual cycle, when progesterone levels are highest. Sex hormones may play a role in immunoregulation and interactions with the cytokine system.

Nelson and coworkers reported that improvement in RA during pregnancy is associated with a greater maternal-fetal mismatch in HLA class II antigens.[86] Mismatch was noted in 75% of pregnancies with improvement in RA symptoms compared with only 25% of pregnancies with unchanged or worsened disease. A subsequent study, however, did not confirm these results.[87]

In general, there is little evidence that RA disease activity at the onset of pregnancy significantly affects pregnancy outcomes. Furthermore, the long-term prognosis of RA patients does not appear to be affected by pregnancy. Oka and Vainio compared 100 consecutive pregnant RA patients with age- and disease-matched controls and found no significant differences between the groups in terms of disease severity.[88]

Unfortunately, almost all patients who have experienced improvement in their RA symptoms during pregnancy will experience a disease flare postpartum, usually within the first 3 months. It also has been suggested that women are at increased risk for developing RA in the postpartum period, particularly after a first pregnancy.

Obstetrical Complications

Women with RA have been reported to have a slightly increased miscarriage rate compared with healthy controls. Kaplan found that women with RA had a higher frequency of miscarriage both before (25% vs. 17%) and after (27% vs. 17%) the onset of their disease compared with healthy controls.[89] Other studies, however, failed to find an increased rate of pregnancy loss among women with RA. In general, women with well-controlled RA do not appear to be at significantly increased risk for PTB, preeclampsia, IUGR, or stillbirth, and their pregnancies are typically uneventful. One recent prospective study of 152 women with RA examined the independent effects of steroid treatment and disease activity on perinatal outcomes.[90] Women who were taking steroids had a significantly lower gestational age at delivery. High-activity disease had an independent and negative affect on birthweight.

Obstetrical Management

Ideally, a woman with RA should undergo preconceptional counseling with an obstetrician and rheumatologist to discuss and possibly adjust her drug therapy in an attempt to minimize fetal harm. Given that RA typically improves in pregnancy, many women will be able to successfully discontinue some, if not all, of their antirheumatic drugs. Women with RA do not typically require increased obstetrical surveillance during pregnancy. Those with persistent or worsening symptoms will benefit from regular visits with a rheumatologist. Increased rest and visits with an experienced physical therapist may also be helpful to women with persistent symptoms. Routine antenatal testing, including serial ultrasounds, nonstress tests, and biophysical profiles, are not necessary in women with RA and should generally be reserved for typical obstetrical

indications. Because of the increased incidence of disease flares postpartum, clinicians and patients should be alert to potential symptoms. Some experts recommend reinitiating RA drug therapy immediately postpartum.

Antirheumatic Medications

If at all possible, treatment of women with symptomatic RA in pregnancy should be limited to acetaminophen (FDA category A) and low-dose glucocorticoids (see Chapter 8). The use of glucocorticoids in pregnancy, including their maternal and fetal risks, is discussed in the section covering SLE. NSAIDs (also discussed previously), particularly their chronic or high-dose use, should generally be avoided in pregnancy.

However, because of changes during the past several decades in pharmacotherapy for RA, many patients present in pregnancy taking other types of medications (see Table 44-5). The obstetrician should be educated about the potential risks of these medications and be able to provide appropriate counseling. Leflunomide, a disease modifying antirheumatic drug (DMARD), is an FDA category X drug in pregnancy (see Chapter 8). It is an antimetabolite that inhibits dihydroorotate dehydrogenase, an enzyme involved in the rate-limiting step of pyrimidine biosynthesis. **Leflunomide is a teratogen and has been associated with fetal death. It is contraindicated in pregnancy.** Although the half-life of leflunomide is 15 days, its major metabolite (teriflunomide) is detectable in serum up to 2 years after discontinuing the drug. As a result, discontinuing the drug immediately before pregnancy may not be adequate to avoid embryonic exposure. The administration of cholestyramine can speed the elimination of the drug and its metabolite. Confirmation should be made by monitoring leflunomide plasma levels. Methotrexate is also considered a DMARD, is contraindicated in pregnancy, and should be discontinued for 1 to 3 months before attempting to conceive.

TNF inhibitors include the medications etanercept, infliximab, and adalimumab and the newer agents, certolizumab pegol, and golimumab. These medications are FDA category B (see Chapter 8) in pregnancy and antagonize TNF-α (an inflammatory cytokine that plays a key role in RA). TNF inhibitors have been found to increase the number of circulating Treg cells and restore the capacity of Treg cells to inhibit cytokine production.[84] An important potential side effect of these medications is an increased number of serious bacterial infections. Observational studies and case reports indicate that pregnancy complications are not significantly more common among women taking TNF inhibitors compared with women with similar diseases who are not on these medications.[49] More recently, a potential association between TNF inhibitor use in pregnancy and fetal *v*ertebral anomalies, *a*nal atresia, *c*ardiac defects, *t*racheoesophageal fistula, *e*sophageal atresia, *r*enal anomalies, and *l*imb dysplasia (VACTERL) association has been reported[91] but remains controversial. Long-term follow-up of children exposed to TNF inhibitors in utero is lacking, as are data on outcomes of pregnancies exposed to newer agents, including certolizumab pegol and golimumab.

Adequate data on the safety of more recently introduced biologic agents, including anakinra (interleukin-1 receptor antagonist), rituximab (chimeric monoclonal antibody leading to B-cell depletion), abatacept (inhibitor of T-cell co-stimulation), and tocilizumab (interleukin-6 receptor inhibitor), are generally lacking, and prudence would suggest avoiding these medications in pregnancy if possible.

TABLE 44-9 SUBSETS OF SYSTEMIC SCLEROSIS

Diffuse Cutaneous Systemic Sclerosis
• Onset of Raynaud phenomenon within 1 year of onset of skin changes
• Truncal and acral skin involvement
• Presence of tendon friction rubs
• Early and significant incidence of interstitial lung disease, oliguric renal failure, diffuse gastrointestinal disease, and myocardial involvement
• Absence of anticentromere antibodies (ACAs)
• Nailfold capillary dilation and capillary destruction
• Antitopoisomerase antibodies (30% of patients)
Limited Cutaneous Systemic Sclerosis
• Raynaud phenomenon for years (occasionally decades)
• Skin involvement limited to hands, face, feet, and forearms (acral), or absent
• Significant late incidence of pulmonary hypertension, with or without interstitial lung disease, trigeminal neuralgia, skin calcifications, telangiectasia
• High incidence of ACAs (70% to 80%)
• Dilated nailfold capillary loops, usually without capillary dropout

From LeRoy EC, Black C, Fleischmgjer R, et al: Scleroderma (systemic sclerosis): classification, subsets and pathogenesis. J Rheumatol 15:202, 1988.

SYSTEMIC SCLEROSIS

Systemic sclerosis (SSc) is an autoimmune disorder manifested by progressive fibrosis of the skin and visceral tissues and vasculopathy that includes features such as Raynaud phenomenon and renal crisis. Experts recognize two main subsets of SSc (Table 44-9): (1) diffuse cutaneous disease, usually involving cutaneous fibrosis proximal to the forearms and associated with scleroderma renal crisis and pulmonary fibrosis, and (2) limited cutaneous disease, usually involving fibrosis of the distal extremities and face and associated with digital ulcerations and pulmonary fibrosis. **SSc is relatively rare, with an annual incidence in the United States of 1 to 2 per 100,000 individuals.[1] The disease occurs about 10 times more frequently in women than men, with a peak age of onset in the fifth decade.**

Pathogenesis

The pathogenesis of SSc is complex and incompletely understood but involves an interplay between endothelial cells, monocytes, lymphocytes, fibroblasts, and noncellular matrix. Vasoconstriction, cytokine production, immunologic abnormalities, and excessive collagen synthesis are all important features of the disease. Alterations in small arteries and arterioles appear to be inciting events in SSc. The balance between endothelin-1 (a very potent vasoconstrictor as well as a promoter of fibrogenesis) and nitric oxide may be altered in SSc. These early vascular changes trigger the production of cytotoxic proteins, cytokines, growth factors, endothelial adhesion molecules, and ultimately activated fibroblasts that produce excessive amounts of collagen.

Early in the disease process, the dermis contains mononuclear cell infiltrates, edema fluid, and sometimes calcium. Collagen deposition may be subtle initially while vascular changes predominate, particularly intimal thickening, thrombosis, and occlusion of lumens by fibrosis. Remaining vessels become dilated and appear as telangiectasias.

A similar pathologic process occurs in the internal organs. Gastrointestinal tract involvement consists of gut wall fibrosis and smooth muscle cell atrophy, as well as degeneration of autonomic nerves. The kidneys demonstrate a characteristic intimal proliferation and thickening of the small arteries and glomeruli. Lung involvement mainly consists of interstitial fibrosis, capillary congestion and thickening, and occlusion of alveolar walls and arteriolar intima. Patchy fibrosis occurs in the myocardium.

Although the pathogenesis of SSc is complex and the etiology unknown, there are genetic factors that appear to influence the susceptibility of an individual to SSc. Multiple studies have focused on the Choctaw Native Americans in Oklahoma,[92,93] a group with a significantly increased rate of SSc compared with the general population. In this population, risk-associated alleles have been identified in the HLA haplotypes DRB1*1602, DQA*0501, and DQB*0301, in the fibrillin-1 gene, and at sites near the genes for SPARC (secreted protein acidic and rich in cysteine) and topoisomerase-I, a target for SSc autoantibodies. HLA has also been associated with particular SSc-specific autoantibodies.

The trigger for the development of SSc in a susceptible individual is not known, but many theories have been proposed, including viral infection, environmental exposures, organic solvents, certain drugs, and maternal microchimerism with subsequent immunologic response to circulating fetal cells associated with a prior pregnancy.

Clinical Manifestations and Diagnosis

The skin manifestations of SSc are described as either linear scleroderma or morphea. Linear scleroderma occurs more commonly in children, and skin abnormalities typically follow a dermatomal distribution. Morphea can be either localized or generalized and consists of patches of yellowish sclerotic skin, typically on the trunk. Patients with *limited* cutaneous SSc typically have skin thickening restricted to the hands and possibly the neck and face. CREST syndrome falls under the category of limited SSc and involves calcinosis of the skin, Raynaud phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias. *Diffuse* cutaneous SSc refers to skin thickening proximal to the wrists, often over the limbs and trunk. **The diffuse form of the disease is associated with a greater risk for significant and serious internal organ involvement.**

The diagnosis of SSc is based on the presence of skin thickening at more than one site in combination with internal organ manifestations. Early symptoms of the disease may be nonspecific and include subcutaneous tissue swelling and muscle and joint pain. Raynaud phenomenon occurs in more than 90% of patients with SSc and is often the first symptom. When combined with the characteristic skin changes, Raynaud phenomenon is specific for SSc. However, Raynaud phenomenon also occurs in 5% of the general population. Abnormal findings on nailfold capillaroscopy can help determine whether a patient with Raynaud phenomenon may have SSc. **The most frequent visceral complication of SSc is esophageal dysmotility resulting in heartburn and dysphagia.** The lower gastrointestinal tract may also be affected, resulting in malabsorption, diarrhea, or constipation. **Of particular concern to the obstetrician, women with long-standing or severe disease may have pulmonary hypertension.** Myocardial fibrosis is common with diffuse disease and can result in dysrhythmias. Although most patients have mild renal involvement, 10% to 20% with diffuse disease develop scleroderma renal crisis, consisting of acute-onset severe hypertension, progressive renal insufficiency, microangiopathic hemolytic anemia, and urine sediment that is either normal or shows only mild proteinuria with few cells or casts. **Scleroderma renal crisis results in progression to end-stage renal disease in a significant proportion of affected individuals and is a major cause of mortality in SSc patients.**

The diagnosis of SSc may be supported by the detection of circulating autoantibodies. ANAs are present in most patients with SSc. Antitopoisomerase-I (anti-Scl-70), anticentromere (ACA), and antiRNA polymerase III antibodies are highly specific for SSc but have moderate sensitivity. Different antibodies are associated with different clinical manifestations. For example, ACAs are more common among patients with CREST syndrome, but less so among those with diffuse disease. Anti-Scl-70 antibodies are associated with diffuse disease and a higher risk for severe interstitial pulmonary fibrosis. Both aCL and anti-β_2-GP-I antibodies also can be seen in SSc.

Systemic Sclerosis and Pregnancy

Effects of Pregnancy on Systemic Sclerosis

Pregnancy in women with SSc is uncommon. As a result, data regarding the impact of pregnancy on SSc disease activity are generally limited to case reports and case series.[94] **In general, it appears that maternal outcomes are good when SSc is clinically stable at the onset of pregnancy and the woman is without obvious renal, cardiac, or pulmonary disease.** Pregnancy has been associated with an improvement in Raynaud phenomenon. However, gastroesophageal symptoms may worsen or appear during pregnancy.

Pregnancy does not appear to increase the risk for renal crisis, a life-threatening manifestation of SSc. However, the distinction between renal crisis and preeclampsia may pose a clinical dilemma.

As mentioned earlier, some investigators have proposed that fetal microchimerism may contribute to the pathogenesis of SSc. This is based on the observation that SSc shares many features with graft-versus-host disease and that increased numbers of persistent fetal cells have been found in the circulation of affected women with a history of pregnancy (compared with women without SSc but a history of pregnancy).[95] Fetal DNA and cells also have been identified in the affected skin of SSc patients.[96] However, because this does not prove causality, the question of whether microchimerism contributes to the development of SSc remains unanswered.

Effects of Systemic Sclerosis on Pregnancy

Several studies have suggested that women with SSc have an increased risk for spontaneous abortion before,

and possibly subsequent to, their diagnosis. Silman and Black mailed a questionnaire to 155 women with scleroderma and to 155 healthy controls and found that women with scleroderma had twice the rate of miscarriage before disease onset compared with controls.[97] Giordano and associates studied 299 pregnancies in 80 SSc patients and found a 17% miscarriage rate, significantly higher than among controls (10%).[98] Several other studies have not found a difference in pregnancy loss rates between women with SSc and controls.[94,99] A prospective study found that 16% of 80 SSc pregnancies ended in miscarriage compared with 14% in the control group.[94] However, the subset of women in this study with late, diffuse SSc did have a significantly increased rate of miscarriage. Thus, the available data suggest that women with SSc may be at a slightly increased risk for miscarriage compared with controls.

Although the data are generally limited to case series, it appears that up to one third of pregnancies in women with SSc will be delivered preterm.[94,98,99] In Steen's series, of 91 pregnancies in 59 women, 29% were delivered preterm.[94] PTB may be particularly prevalent among women with diffuse cutaneous disease.[94] Given the vascular pathology of SSc and the relatively frequent renal involvement, it is not surprising that these women appear to be at increased risk for preeclampsia and IUGR. A recent study using the Nationwide Inpatient Sample identified 504 deliveries (out of a total of 11.2 million) that occurred in women with SSc. SSc was significantly associated with hypertensive disorders in pregnancy (odds ratio, 3.71) and IUGR (odds ratio, 3.74).[100]

Obstetrical Management

Preconceptional counseling is important in patients with scleroderma. Women with early, progressive, diffuse SSc or significant cardiac, pulmonary, or renal disease should be appropriately counseled regarding the risks of pregnancy. Any suspicion of pulmonary hypertension should prompt appropriate diagnostic studies to exclude significant disease before recommending pregnancy.

Even in the nonpregnant state, there is no satisfactory therapy for SSc. Treatment of diffuse SSc is typically organ specific. Symptomatic relief of arthralgias and myalgias should be limited to acetaminophen if possible. Many patients take proton pump inhibitors (FDA category C) for upper gastrointestinal symptoms, and these medications may be continued in pregnancy (see Chapter 8); typical doses are unlikely to pose a substantial risk to the fetus, although data are limited. Oral vasodilators, in particular calcium channel blockers (FDA category C), may be continued in pregnancy for the treatment of Raynaud phenomenon, although definitive proof of fetal safety is also lacking (see Chapter 8). ACE inhibitors are used to treat renal crisis in nonpregnant patients. These agents should usually be avoided during pregnancy because of their known teratogenicity and adverse effects on fetal renal function (see Chapter 8). However, in pregnant women with SSc renal crisis and severe hypertension, the benefits of ACE inhibitors may outweigh the fetal risks.

Evidence-based recommendations for prenatal care are lacking. However, it seems reasonable to increase maternal surveillance with prenatal visits every 1 to 2 weeks in the first half of pregnancy and weekly thereafter. Serial laboratory evaluation is not warranted, but clinicians should have a low threshold to pursue any new and unusual symptoms. **Women should be monitored closely for preeclampsia because SSc appears to increase this risk.** Serial fetal ultrasonography to monitor for IUGR seems prudent. Most experts would recommend antenatal testing beginning at 30 to 32 weeks or earlier depending on the clinical scenario.

Among patients with mild to moderate disease, special precautions are generally not needed during labor and delivery. Women with advanced skin disease may have problems with delivery or wound healing (particularly if taking steroids). **Depending on the extent of disease, women with SSc may be at increased anesthetic risk, including problems with intravenous access, difficult intubation, and an increased risk for aspiration.** A prenatal anesthesiology consult may be indicated. For patients with significant pulmonary, cardiac, or renal involvement, intensive care management may be needed.

SJÖGREN SYNDROME

Sjögren syndrome is a chronic inflammatory disorder characterized by diminished lacrimal and salivary gland function (keratoconjunctivitis sicca). It occurs in a primary form and in a secondary form in association with other rheumatic conditions, most commonly RA. Few data exist regarding pregnancies in women with primary Sjögren syndrome. Clinicians should recognize, however, that a high proportion of women with primary Sjögren syndrome have circulating anti-Ro/SSA or anti-La/SSB antibodies, or both, and are thus at risk for a pregnancy affected by NLE and CHB. Outside of monitoring for NLE, management of Sjögren syndrome in pregnancy is usually dictated by that for any associated rheumatic disease.

KEY POINTS

- SLE is the most common, serious autoimmune disease affecting women of reproductive age.
- Overall, 15% to 60% of women with SLE have a flare during pregnancy or in the postpartum period.
- Because SLE disease activity at the onset of pregnancy is an important determinant of flare in pregnancy, women with SLE should be advised to postpone pregnancy until sustained remission for at least 6 months has been achieved.
- For women with lupus nephritis, moderate renal insufficiency (serum creatinine, 1.5 to 2 mg/dL) is a relative contraindication to pregnancy, and advanced renal insufficiency (creatinine > 2 mg/dL) should be considered an absolute contraindication to pregnancy.
- The risk for NLE, and in particular CHB, in fetuses or neonates of women with SLE is low. Among women with anti-Ro/SSA and anti-La/SSB antibodies, the risk for having an infant affected with CHB is increased if the mother had a prior affected child.

- Hydroxychloroquine may be the best maintenance therapy for SLE in pregnancy. Women who become pregnant while taking hydroxychloroquine should generally be continued on this medication.
- The diagnosis of APS rests on the occurrence of either arterial or venous thrombosis or pregnancy morbidity and repeatedly positive testing for lupus anticoagulant and/or medium to high titers of anticardiolipin or anti-β_2-GP-I IgG or IgM antibodies.
- All women with APS and a history of arterial or venous thrombosis should receive full anticoagulation during pregnancy and postpartum.
- Women with APS diagnosed on the basis of recurrent pre-embryonic and embryonic losses and without prior thrombosis should receive low-dose aspirin alone or together with prophylactic dose heparin.
- Women with APS diagnosed on the basis of fetal death, early preeclampsia, or placental insufficiency and without prior thrombosis should receive low-dose aspirin together with prophylactic or intermediate-dose heparin.
- Most women with rheumatoid arthritis will have improvement in their disease during pregnancy but will relapse in the postpartum period, usually within the first 3 months.
- Obstetrical and maternal outcomes are generally good when systemic sclerosis is clinically stable at the onset of pregnancy and the woman is without obvious renal, cardiac, or pulmonary disease.

KEY ABBREVIATIONS

Acute Fatty Liver of Pregnancy	AFLP
Acute Intermittent Porphyria	AIP
Computed Tomography	CT
Disseminated Intravascular Coagulation	DIC
Endoscopic Retrograde Cholangiopancreatography	ERCP
Esophagogastroduodenoscopy	EGD
Hemolysis, Elevated Liver Enzymes, and Low Platelet Count Syndrome	HELLP
Hepatocellular Cancer	HCC
Intrahepatic Cholestasis of Pregnancy	ICP
Long-chain 3-hydroxyacyl Coenzyme A Dehydrogenase	LCHAD
Magnetic Resonance Imaging	MRI

Hepatic Disorders During Pregnancy

Hepatic, biliary, and pancreatic disorders are relatively uncommon but not rare during pregnancy. For example, about 3 per 100 women develop serum liver function test abnormalities during pregnancy, and about 1 per 500 women develop potentially life-threatening hepatic diseases during pregnancy.[1,2]

Hepatic, biliary, and pancreatic disorders are often complex and clinically challenging problems during pregnancy. First, the differential diagnosis during pregnancy is extensive. It includes both disorders related to pregnancy and disorders unrelated to pregnancy. Second, the clinical presentation and natural history of these disorders may be altered during pregnancy. Indeed, some disorders, such as intrahepatic cholestasis of pregnancy, are unique to pregnancy. Third, the diagnostic evaluation may be constrained by pregnancy. For example, radiologic tests may raise concern about fetal safety during pregnancy. Fourth, the interests of both the mother and the fetus must be considered in therapeutic decision making. Occasionally, maternal therapy must be modified to substitute alternative but safer therapy because of concerns about drug teratogenicity.[3] Rarely, maternal and fetal interests may be diametrically opposed, as in the use of certain chemotherapeutic agents or radiation for maternal cancer, in which therapy that is potentially life-saving to the mother can harm the developing fetus.[4] These conflicts raise significant medical, legal, and ethical issues.

Obstetricians, hepatologists, surgeons, and internists should be familiar with hepatic, biliary, and pancreatic disorders that can occur in pregnancy and how these conditions affect and in turn are affected by pregnancy. This chapter reviews hepatic, biliary, and pancreatic disorders

during pregnancy, with a focus on features unique to pregnancy.

PHYSIOLOGIC EFFECTS OF PREGNANCY AND ASSESSMENT OF LIVER DISEASE

Assessment of the abdomen is modified during pregnancy. The expanding gravid uterus can displace abdominal viscera and may conceal an abdominal mass on physical examination.[4] During pregnancy the blood pressure normally declines modestly. A rise in blood pressure during pregnancy may, therefore, portend preeclampsia or eclampsia. Physiologic alterations of laboratory values during pregnancy include mild leukocytosis, physiologic anemia of pregnancy, and electrolyte changes, particularly mild hyponatremia.[5] The risk of thromboembolic phenomena is increased during pregnancy due to mild hypercoagulopathy (increased fibrinogen levels) from hyperestrogenemia and vascular stasis from vascular compression by the enlarged gravid uterus. The changes in serum glucose levels during pregnancy are complex. Normal pregnancy is characterized by fasting hypoglycemia despite increased hepatic insulin resistance, postprandial hyperglycemia, and hyperinsulinemia. Pregnancy does not affect the liver span. The liver may be pushed cephalad by the gravid uterus, but a liver span greater than 12 cm, when appreciated, remains a valid indicator of hepatomegaly. **Spider angiomata and palmar erythema, cutaneous lesions often associated with chronic liver disease, may appear transiently during normal pregnancy without underlying liver disease.** During pregnancy the serum alkaline phosphatase level normally increases mildly due to placental production. **The serum albumin level declines during pregnancy primarily from hemodilution and secondarily from decreased hepatic synthesis. Serum bilirubin levels tend to change little during pregnancy due to the effect of mildly impaired hepatic excretion balanced by the opposing effects of hemodilution and hypoalbuminemia.**[6] Serum bile acids tend to progressively increase during pregnancy due to impaired hepatic transport and biliary secretion. Serum levels of cholesterol, triglycerides, and phospholipids increase moderately during pregnancy due to increased hepatic synthesis. The serum aminotransferase levels are largely unaffected by pregnancy. Changes of serum levels of common blood tests during pregnancy are summarized in the box Changes in Routine Laboratory Tests and Liver Function Tests During Pregnancy.

CHANGES IN ROUTINE LABORATORY TESTS AND LIVER FUNCTION TESTS DURING PREGNANCY

Mildly Decreased Values

Sodium
Albumin

Moderately Decreased Value

Hematocrit—physiologic anemia of pregnancy

Mildly Increased Values

Leukocyte count
Alkaline phosphatase
Amylase

Moderately Increased Values

Serum bile acids
Cholesterol
Triglycerides

Other

Glucose level—fasting hypoglycemia, postprandial hyperglycemia

DIFFERENTIAL DIAGNOSIS OF HEPATOBILIARY SYMPTOMS AND CONDITIONS DURING PREGNANCY

Jaundice

As in the general population, acute viral hepatitis is the most common cause of jaundice during pregnancy.[1,2] **The differential diagnosis of jaundice during the first and second trimesters of pregnancy also includes drug hepatotoxicity and gallstone disease such as acute cholecystitis, choledocholithiasis, ascending cholangitis, or gallstone pancreatitis.** In addition to these disorders, the differential of jaundice during the third trimester includes the following pregnancy-related causes: intrahepatic cholestasis of pregnancy, acute fatty liver of pregnancy, and HELLP (hemolysis, elevated liver function tests, and low platelet count) syndrome. Moderate direct hyperbilirubinemia without jaundice during the third trimester may also be due to preeclampsia, eclampsia, and Budd-Chiari syndrome. Predominantly indirect hyperbilirubinemia during pregnancy is usually due to hemolysis (including the HELLP syndrome) or Gilbert's syndrome.

Right Upper Quadrant Abdominal Pain

As shown in the box Differential Diagnosis of Right Upper Quadrant Abdominal Pain During Pregnancy, the differential diagnosis is extensive. In addition to hepatic, biliary, gastrointestinal, and renal disorders that can occur in nonpregnant patients, the differential includes diseases related to pregnancy. Careful medical history, including the pain intensity, nature, temporal pattern, radiation pattern, exacerbating factors, and alleviating factors, helps narrow the differential diagnosis. Biliary colic produces a waxing and waning intensity of pain. Acute cholecystitis is associated with right upper quadrant pain, as well as pain referred to the right shoulder. The pain of acute pancreatitis is often boring in quality, located in the abdominal midline and radiating to the back. Physical examination of the abdomen including inspection, palpation, and auscultation can further pinpoint the cause of the pain. **Laboratory evaluation of significant abdominal pain routinely includes a hemogram, serum electrolytes, and liver function tests and often includes a leukocyte differential, coagulation profile, and serum lipase determination.** In evaluating the laboratory results, gestational changes in normative values, as mentioned, must be considered. Radiologic tests may be extremely helpful diagnostically, but the choice of

radiologic imaging is constrained by the pregnancy, as discussed later. **Right upper quadrant pain and abnormal liver function tests in the setting of new-onset hypertension should strongly suggest preeclampsia with liver involvement.** Right upper quadrant pain and abnormal liver function tests in the setting of thrombocytopenia and microangiopathic hemolysis, as demonstrated by the presence of schistiocytes in a peripheral blood smear, should strongly suggest HELLP syndrome.

Occasionally, the patient is unaware of pregnancy or it is not revealed to the physician, particularly in early pregnancy, when physical findings are absent. The physician should be vigilant for possible pregnancy in a fertile woman with abdominal pain, particularly in the setting of missed menses, because pregnancy affects the differential diagnosis, clinical evaluation, and treatment. Pregnancy testing should be performed early in the evaluation of acute abdominal pain in reproductive-age women.

Differential Diagnosis of Right Upper Quadrant Abdominal Pain During Pregnancy

Hepatic Disorders

Hepatitis
Hepatic vascular engorgement
Hepatic hematoma
Hepatic malignancy

Biliary Tract Disease

Biliary colic
Choledocholithiasis
Cholangitis
Cholecystitis

Diseases Related to Pregnancy

Preeclampsia or eclampsia
Hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome
Acute fatty liver of pregnancy
Hepatic hemorrhage or rupture

Renal Disorders

Pyelonephritis
Nephrolithiasis

Gastrointestinal Disorders

Peptic ulcer disease
Perforated duodenal ulcer

Other Conditions in RUQ

Rib fracture
Shingles

Referred Pain from Other Organ Disease

Pneumonia
Pulmonary embolus or infarct
Pleural effusion
Radiculopathy
Inferior wall myocardial infarction
Colon cancer

Nausea and Vomiting

Nausea and vomiting is ubiquitous during pregnancy. Nausea and vomiting of pregnancy is the most common cause. It typically begins at about 6 weeks of gestation and abates at about 18 weeks of gestation.[7] It is caused by the physiologic effects of the pregnancy without demonstrable mucosal or mural disease. **Hyperemesis gravidarum is a serious and potentially life-threatening form of nausea and vomiting of pregnancy associated with loss of more than 5% of the pregravid weight. Hyperemesis gravidarum is a diagnosis of exclusion, based on nausea and vomiting occurring early in pregnancy, gradually resolving during the middle second trimester, and unassociated with other symptoms.** The differential diagnosis of nausea and vomiting during pregnancy also includes hepatic disorders related to pregnancy, such as fatty liver and intrahepatic cholestasis of pregnancy. Other hepatic causes include viral hepatitis, symptomatic cholelithiasis, and acute cholecystitis. Gastrointestinal causes include gastroesophageal reflux disease (GERD), peptic ulcer disease, viral gastroenteritis, appendicitis, gastroparesis diabeticorum, and gastrointestinal obstruction. Uncommon causes include adnexal torsion, pyelonephritis, urolithiasis, and Addison's disease (glucocorticoid deficiency).

Pruritus

The differential of pruritus during pregnancy includes intrahepatic cholestasis of pregnancy, cholestatic viral hepatitis, primary sclerosing cholangitis, primary biliary cirrhosis, and mechanical choledochal obstruction from benign or malignant strictures. Pruritus sometimes occurs physiologically during pregnancy or in association with various dermatoses. It is typically mild, localized, unassociated with other symptoms, and unassociated with abnormal liver function tests.

Hepatic Lesions

Hepatic lesions identified on abdominal imaging studies are classified as cystic or solid. The differential of cystic hepatic lesion(s) includes simple hepatic cysts, hepatic cysts associated with polycystic kidney disease, Caroli's disease, bacterial abscesses, amebic abscesses, intraparenchymal hemorrhage, hemangiomas, ecchinococcal cysts, and rarely hepatic malignancies. The differential of a solid hepatic mass includes hepatic adenoma, focal nodular hyperplasia, hepatocellular carcinoma, and hepatic metastases.

Ascites

Hepatic causes of ascites during pregnancy include cirrhosis, acute fatty liver of pregnancy, Budd-Chiari syndrome, portal vein thrombosis, hepatic fibrosis, and hepatocellular carcinoma. Other causes of ascites during pregnancy include ovarian cancer, abdominal tuberculosis, cardiac failure, protein-losing nephropathy, and severe protein malnutrition (kwashiorkor).

ABDOMINAL IMAGING DURING PREGNANCY

Fetal safety of diagnostic imaging is a concern for pregnant women. Ultrasonography is considered safe and is the

preferred abdominal imaging modality during pregnancy.[8] Unfortunately, test sensitivity depends on operator technique, patient cooperation, and patient anatomy. For example, test sensitivity is decreased by abdominal fat and bowel distention.[8] There are no reported harmful effects from magnetic resonance imaging (MRI) during pregnancy, but there are few data on safety during the first trimester or with use of gadolinium.[9] MRI is preferable to computed tomography (CT) scanning during pregnancy to avoid ionizing radiation, but gadolinium administration should be avoided during MRI in the first trimester.[9] Rapid-sequence MRI is preferable to conventional MRI because of briefer exposure.

Radiation can cause fetal mortality, growth restriction, genetic mutations, and neurologic abnormalities, including mental retardation. Radiation may also increase the risk of childhood leukemia.[10] Dosage is the most important risk factor, but fetal age at exposure is also important. Fetal mortality is greatest from radiation exposure during the first 2 weeks after conception, and the risk of neurologic malformations is greatest during the first trimester when organogenesis occurs.[10] Women should undergo counseling before diagnostic roentgenography. Exposure to more than 15 rads during the second and third trimesters or more than 5 rads during the first trimester should prompt consideration of elective termination of pregnancy.[10] Diagnostic studies with high radiation exposure, such as abdominal CT, typically expose the fetus to less than 1 rad and can be considered when extremely strongly indicated.

THERAPEUTIC ENDOSCOPY DURING PREGNANCY

Therapeutic Endoscopic Retrograde Cholangiopancreatography

Choledocholithiasis usually requires urgent therapy because of potentially life-threatening ascending cholangitis or gallstone pancreatitis. Symptomatic choledocholithiasis is best managed by therapeutic endoscopic retrograde cholangiopancreatography (ERCP) in the nonpregnant patient to avoid complex biliary surgery during cholecystectomy. In experienced hands, therapeutic ERCP in the general population has acceptable morbidity of about 5% and low mortality of about 0.5%.[11] Therapeutic ERCP is theoretically more attractive than biliary surgery for choledocholithiasis during pregnancy because surgery entails a significant risk of fetal loss. Aside from maternal risks, therapeutic ERCP during pregnancy entails theoretical risks to the fetus of premature labor, medication and radiation exposure, fetal hypoxia during endoscopic intubation, cardiac arrhythmias, and systemic hypotension.[11] In the largest clinical series, 68 therapeutic ERCPs were performed on 65 pregnant patients for indications including biliary pancreatitis, cholangitis, abnormal liver function tests, or choledochal dilation on abdominal ultrasonography.[12] Maternal postprocedure complications included only pancreatitis in 11 patients. Of 59 patients followed through delivery, preterm delivery occurred in 6 (10%), and low birth weight in 4 (7%). There were no fetal deaths, perinatal deaths, or fetal malformations. Jamidar and colleagues[13] analyzed 29 ERCPs performed on 23 pregnant patients, including 15 performed in the first trimester. Excluding two unknown pregnancy outcomes and two elective abortions, 17 of the 19 pregnancies (89%) resulted in healthy infants, including 16 born at term. Only 1 neonatal death was attributed to the procedure, which occurred in a mother who suffered pancreatitis after ERCP. Excluding these studies, a literature review encompassing another 95 ERCPs, including 72 endoscopic sphincterotomies, during pregnancy, revealed no maternal mortality and only 1 fetal death.[14] Maternal morbidity after ERCP included pancreatitis in four, bleeding in two, and preeclampsia in two. A total of four infants were delivered prematurely.

The accumulated data suggest that therapeutic ERCP can be performed during pregnancy for strong indications to avoid complex biliary surgery or to postpone cholecystectomy until after parturition. Special precautions to minimize fetal risks of ERCP during pregnancy include consultation with a neonatologist, radiation physicist, and anesthesiologist before ERCP; referral to a tertiary medical center for management by a team of experts; lead shielding of the mother's abdomen except for the region of the proximal pancreas and biliary tree; use of a modern fluoroscope to minimize radiation leakage; avoidance of spot radiographs for documentation because they entail considerable radiation exposure; and, if possible, delaying ERCP until the second trimester to reduce early pregnancy radiation exposure.[11]

Endoscopic Variceal Sclerotherapy or Banding

Pregnancy appears to increase the risk of variceal bleeding from portal hypertension because of the gestational increase in plasma volume. Endoscopic sclerotherapy or ligation (banding) are particularly attractive therapies for variceal bleeding during pregnancy because the radiologic alternative of transjugular intrahepatic portosystemic shunt (TIPS) requires radiation, and the surgical alternatives may be associated with fetal loss. Esophagogastroduodenoscopy (EGD) can be performed during pregnancy with relatively low fetal risks, and should be undertaken for cases of acute upper gastrointestinal hemorrhage.[11,15] Endoscopic sclerotherapy or banding raises concerns beyond that of diagnostic EGD from the additional procedure time, the typically severe underlying maternal illness, and the therapy itself. Although variceal banding is preferred over sclerotherapy in the general (nonpregnant) population, there are scant data, based on isolated case reports, on the fetal safety of variceal banding during pregnancy and more data available on sclerotherapy during pregnancy. In one clinical series, 10 women underwent a mean of three endoscopic sclerotherapy sessions during pregnancy for active variceal bleeding in five and for prophylaxis in five.[16] Hemostasis was achieved in all actively bleeding patients. One patient suffered a complication from sclerotherapy of an esophageal stricture, successfully treated using peroral esophageal dilators. All women had a normal vaginal delivery at term.[16] Nine other patients successfully underwent endoscopic sclerotherapy for actively or recently bleeding esophageal varices with delivery of healthy infants in all cases.[11] One study reported less favorable pregnancy outcomes after endoscopic sclerotherapy, attributable to the underlying

maternal disease. Four of 17 pregnant patients undergoing endoscopic sclerotherapy for variceal bleeding due to noncirrhotic portal hypertension had poor pregnancy outcomes (stillbirth or neonatal death).[17] **The available data thus appear to justify endoscopic banding or sclerotherapy during pregnancy for actively bleeding esophageal varices, due to the poor outcomes associated with alternative available therapies.**

PANCREATOBILIARY DISEASE

Acute Pancreatitis

Acute pancreatitis occurs in about 1 per 3000 pregnancies, most commonly during the third trimester. Gallstones cause about 70% of cases, as alcoholism is relatively uncommon during pregnancy. The risk of cholesterol stones is increased during pregnancy because of increased cholesterol secretion into bile. Other causes include drugs, abdominal surgery, trauma, hyperlipidemia, hyperparathyroidism, vasculitis, and infections such as mumps or mononucleosis. The risk of pancreatitis from hyperlipidemia is increased during pregnancy due to significant triglyceride elevation during late pregnancy. Some cases of pancreatitis, as in nonpregnant individuals, are idiopathic.

The clinical presentation, diagnostic tests, and treatment of pancreatobiliary disorders during pregnancy are summarized in Table 45-1. **Pregnancy does not significantly alter the clinical presentation of acute pancreatitis. Epigastric pain is the most common symptom.** The pain commonly radiates to the back. Nausea, emesis, and pyrexia frequently occur. Signs include midabdominal tenderness, abdominal guarding, hypoactive bowel sounds, abdominal distention, and increased tympany. Severe cases are associated with shock and pancreatic ascites. Grey-Turner's sign or Cullen's sign suggests retroperitoneal bleeding.

Acute pancreatitis is diagnosed by the clinical presentation, laboratory tests, and radiologic examinations. Serum amylase and lipase are reliable markers of acute pancreatitis during pregnancy. Serum lipase is unchanged during normal pregnancy, and the amylase level rises only mildly during normal pregnancy.[18] Hyperamylasemia may also occur in diabetic ketoacidosis, renal failure, bowel perforation, or bowel obstruction, but the serum lipase and amylase-to-creatinine clearance ratio are normal in these conditions and are elevated in acute pancreatitis. Hypertriglyceridemia can falsely lower the serum amylase level in pancreatitis; however, the lipase level remains elevated.[3] A serum alanine aminotransferase level greater than 3 times the upper limit of normal strongly suggests biliary pancreatitis. Abdominal ultrasonography is useful in gauging pancreatic inflammation in thin patients with mild to moderate acute pancreatitis, but CT scanning is better at delineating areas of pancreatic necrosis in patients with severe pancreatitis. Abdominal ultrasonography is also useful to detect cholelithiasis and bile duct dilation, but endoscopic ultrasonography is required to reliably detect choledocholithiasis. Magnetic resonance cholangiopancreatograpy (MRCP) is preferable to ERCP as a diagnostic study to visualize the common bile duct during pregnancy, unless endoscopic therapy is contemplated, because of potential fetal risks associated with ionizing radiation with ERCP.

Acute pancreatitis during pregnancy is usually mild and usually responds to medical therapy, including discontinuing oral intake, intravenous fluid administration, gastric acid suppression, analgesia, and sometimes nasogastric suction. Meperidine is the traditional choice for analgesia because it does not cause contraction of the sphincter of Oddi. Short-term administration of meperidine appears to be relatively safe during pregnancy.[19] **Pancreatitis complicated by a pancreatic phlegmon, abscess, sepsis, or hemorrhage necessitates antibiotic therapy, total parenteral nutrition, and possible radiologic aspiration or surgical debridement, with patient monitoring in an intensive care unit.** Large and persistent pancreatic pseudocysts require endoscopic or radiologic drainage or surgery. Endoscopic sphincterotomy can be performed for gallstone pancreatitis during pregnancy with minimal fetal radiation exposure. Pregnancy should not delay these therapies. **Laparoscopic cholecystectomy can be performed during pregnancy, and**

TABLE 45-1 Clinical Presentation and Treatment During Pregnancy of Common Pancreatic Disorders Minimally Affected by Pregnancy

DISEASE OR DISORDER	SYMPTOMS AND SIGNS	LABORATORY FINDINGS	TREATMENT
Acute pancreatitis	Epigastric pain radiating to back, nausea and vomiting, pyrexia, abdominal tenderness, guarding, abdominal distention.	Increased serum lipase, leukocytosis. Abdominal ultrasound—pancreatomegaly, peripancreatic inflammation, inhomogeneous pancreas.	Discontinue oral intake, aggressive IV hydration, analgesia, nasojejunal feeding or TPN for prolonged bout of pancreatitis.
Acute cholecystitis	Epigastric or RUQ pain, nausea and vomiting, tachycardia, Murphy's sign.	Leukocytosis, variably, mildly elevated LFTs. Abdominal ultrasound—thickened gallbladder wall, pericholecystic fluid, gallstones in gallbladder.	Discontinue oral intake, IV hydration, analgesia, antibiotics. Cholecystectomy can be performed during pregnancy, particularly during second trimester.
Choledocholithiasis with ascending cholangitis	RUQ pain, pyrexia, jaundice (Charcot's triad). Epigastric tenderness.	Leukocytosis, jaundice, variably elevated other LFTs. Abdominal ultrasound—dilated choledochus, possible gallstones in gallbladder.	Discontinue oral intake, IV hydration, antibiotics. Therapeutic ERCP may be performed during pregnancy to remove CBD stones (see text).

CBD, Common bile duct; *ERCP*, endoscopic retrograde cholangiography; *IV*, intravenous; *LFTs*, liver function tests; *RUQ*, right upper quadrant; *TPN*, total parenteral nutrition.

is best performed during the second trimester after organogenesis has occurred and before the growing gravid uterus interferes with visualization of the laparoscopic field. Maternal mortality rate is low in uncomplicated pancreatitis, but may exceed 10% in complicated pancreatitis. Pancreatitis is occasionally associated with fetal death during the first trimester, and is associated with premature labor in the third trimester.

Cholelithiasis and Cholecystitis

Pregnancy promotes bile lithogenicity and sludge formation because estrogen increases cholesterol synthesis and progesterone impairs gallbladder motility. In large population surveys using abdominal ultrasonography, 12% of pregnant women in Chile had cholelithiasis[20] and 8% of pregnant women in the United States had cholelithiasis or biliary sludge detected by abdominal ultrasonography. **Most gallstones are asymptomatic during pregnancy.**[21] **Complications of cholelithiasis include biliary colic, cholecystitis, choledocholithiasis, jaundice, ascending cholangitis, hepatic abscess, and gallstone pancreatitis. Pregnancy does not increase the frequency or severity of these complications.**[21] Symptoms of gallstone disease during pregnancy are the same as in nonpregnant individuals.[20,21] The usual initial symptom is biliary colic that is located in the epigastrium or right upper quadrant and may radiate to the back or shoulders. Pain can occur spontaneously or be induced by eating a fatty meal. The pain typically lasts for several hours. Diaphoresis, nausea, and emesis are common. Physical examination is unremarkable, other than occasional right upper quadrant tenderness. About two thirds of patients with biliary colic will experience recurrent attacks during the ensuing 2 years.[3]

Acute cholecystitis is a chemical inflammation usually caused by cystic duct obstruction by a gallstone. It is the third most common nonobstetrical surgical emergency during pregnancy, with an incidence of about 4 cases per 10,000 pregnancies. As in biliary colic, the pain is located in the epigastrium and right upper quadrant, but the pain is usually more severe and prolonged. Other clinical findings include nausea, emesis, pyrexia, tachycardia, right-sided subcostal tenderness, Murphy's sign, and leukocytosis. Serum biochemical parameters of liver function and serum levels of amylase may be mildly abnormal. Jaundice suggests choledocholithiasis, and pronounced hyperamylasemia suggests gallstone pancreatitis.

Most cases of biliary colic and some cases of mild acute cholecystitis can be managed conservatively with close observation, expectant management, and deferral of surgery to immediately postpartum.[14] **However, women with recurrent biliary colic or with acute cholecystitis usually require cholecystectomy.**[20,22] Preoperative management includes discontinuing oral intake, administration of intravenous fluids, analgesia, and, usually, antibiotics. Ampicillin, cephalosporins, and clindamycin are relatively safe antibiotics during pregnancy.[23] Cholecystectomy is best performed during the second trimester. Cholecystectomy has, however, become increasingly accepted during the first and third trimesters because of improved surgical outcomes.[22] Tocolysis may be necessary during cholecystectomy performed in the third trimester. Intraoperative cholangiography is only performed during pregnancy for strong indications to avoid radiation teratogenicity. Laparoscopic cholecystectomy is safe during pregnancy and is best performed during the second trimester.[3,21]

Choledocholithiasis

Symptomatic choledocholithiasis is uncommon during pregnancy. Choledocholithiasis can produce gallstone pancreatitis, manifested by pyrexia, nausea, and severe abdominal pain; or ascending cholangitis manifested by pyrexia, right upper quadrant pain, and jaundice (Charcot's triad). Endoscopic ultrasound is relatively safe in pregnancy and is sensitive in detecting choledocholithiasis.[8] Patients with choledocholithiasis and gallstone pancreatitis should undergo endoscopic retrograde cholangiography and sphincterotomy with stone extraction, as previously described. Pancreatography can be avoided to minimize fetal radiation exposure. These women then usually undergo cholecystectomy postpartum, but can, if necessary, undergo cholecystectomy antepartum, especially during the second trimester, with acceptable maternal and fetal mortality.

Choledochal Cysts

Choledochal cysts are rare. They typically produce a diagnostic triad of abdominal pain, jaundice, and a palpable abdominal mass in nonpregnant patients. Choledochal cysts are classified as types I to V according to which segment of the biliary tree is dilated. Pregnancy can exacerbate the abdominal pain and can increase the jaundice because of choledochal compression by the enlarged gravid uterus. However, pregnancy can mask the palpable abdominal mass due to the enlarged gravid uterus.[24] Severe pain suggests cyst rupture or concomitant pancreatitis.[24] A choledochal cyst can be diagnosed by abdominal ultrasound, although cholangiography is sometimes required. MRI is preferred over abdominal CT or diagnostic ERCP. Surgical management is generally recommended for symptomatic choledocholithiasis because of the risk of recurrent cholangitis and malignant degeneration. The standard surgery is cystectomy, cholecystectomy, and reconstitution of biliary-intestinal flow by either a Roux-en-Y hepaticojejunostomy or choledochojejunostomy. Medical management, including antibiotics and temporary percutaneous or endoscopic drainage, may sometimes suffice until delivery.[24]

COMMON LIVER DISEASES INCIDENTAL TO PREGNANCY

Acute Viral Hepatitis A, B, and C

Acute viral hepatitis A, B, and C (see Chapter 50) present similarly in pregnancy as in the nonpregnant state. For example, acute hepatitis B is usually self-limited and mild during pregnancy. Typical symptoms of acute viral hepatitis include anorexia, nausea, malaise, and right upper quadrant discomfort. Patients with acute hepatitis A or hepatitis B typically have highly elevated serum aminotransferase levels. Jaundice may occur. Acute hepatitis C is frequently subclinical and typically causes only mild serum aminotransferase level elevations. Maternal mortality is rare from acute hepatitis A, B, or C during pregnancy.

Fetal mortality and neonatal morbidity are increased by acute hepatitis A or B, but are still relatively low.

Wilson's Disease

Noncirrhotic women treated for early Wilson's disease have relatively intact fertility and may therefore become pregnant. Their serum levels of copper and ceruloplasmin increase during pregnancy. They require maintenance therapy during pregnancy to prevent a flare of disease that can increase maternal morbidity and fetal mortality. Although the data are limited, trientine (triethylene tetramine dihydrochloride) or zinc therapy for Wilson's disease may be maintained during pregnancy without significant fetal toxicity.[25] D-penicillamine is regarded as potentially teratogenic, and its use during pregnancy should be discouraged when alternatives are available. Women with cirrhosis from Wilson's disease have increased risks of complications during pregnancy, including intrauterine growth retardation and preeclampsia.

Autoimmune Hepatitis

Women with autoimmune hepatitis should be maintained on immunosuppressive therapy during pregnancy. Glucocorticoids such as prednisone are relatively safe during pregnancy.[26] Patients with well-compensated and well-controlled autoimmune hepatitis tolerate pregnancy well.[26] These women typically have a reversible mild deterioration of serum parameters of liver function during pregnancy, particularly of the serum bilirubin and alkaline phosphatase, attributed to the cholestatic effects of pregnancy. Women who discontinue the immunosuppressive therapy can develop severe acute flares during pregnancy.

Hepatic Hemangiomas, Cysts, and Abscesses

Hepatic hemangiomas are the most common benign tumors of the liver in the general population. The vast majority of hepatic hemangiomas less than 5 cm are asymptomatic in the general population. Hepatic hemangiomas appear to behave similarly during pregnancy. Rare symptoms attributable to hemangiomas include right upper quadrant pain, abdominal distention, or symptoms, such as nausea, attributable to impingement of adjacent viscera. Serious complications during pregnancy include consumptive coagulopathy with hemolysis, thrombocytopenia, and hypofibrinogenemia (Kasabach-Merritt syndrome); intrahepatic hemorrhage; and spontaneous hepatic rupture. Immense hemangioma size is the major risk factor for these complications. Warning signs include progressively increasing symptoms and rapid lesion growth. These complications are rare during pregnancy. Among 20 patients with mostly very large hemangiomas, only one case of hepatic rupture and one case of intrahepatic hemorrhage occurred during 27 pregnancies.[27] Focal nodular hyperplasia is the second most common cause of a benign hepatic mass. It is usually asymptomatic during pregnancy and detected incidentally during obstetrical ultrasound.[8] This lesion occasionally grows during pregnancy, possibly because of estrogen stimulation. Most cases can be observed during pregnancy without intervention. It rarely causes hepatic hemorrhage or biliary obstruction due to compression by the enlarged gravid uterus.[27,28] Clinical findings may include abdominal pain, jaundice, or hypotension. Surgical intervention is occasionally necessary for these complications.[28]

Hepatic cysts may be isolated or associated with polycystic kidney disease, malignancy, or amebic or ecchinococcal infection.[28] Pyogenic liver abscesses during pregnancy arise from ascending cholangitis, appendicitis, or diverticulitis.[28] Both antibiotics and percutaneous drainage are usually indicated.

Hepatocellular Carcinoma and Hepatic Metastases

Hepatocellular carcinoma (HCC) usually occurs in the setting of cirrhosis secondary to chronic viral hepatitis, hemochromatosis, or alcoholism. It is rarely diagnosed during pregnancy.[28] The poor prognosis during pregnancy may result from delayed diagnosis or mild immunosuppression during pregnancy. Screening high-risk patients by serum alpha-fetoprotein determination and abdominal ultrasonography can detect HCC earlier.[28] The fibromellar variant of HCC, typically found in younger women, has a better prognosis. Hepatic metastases, particularly from colon cancer, can occur during pregnancy.[4]

LIVER DISEASES SIGNIFICANTLY AFFECTED BY PREGNANCY

Hepatitis E

Hepatitis E, although rare and sporadic in industrialized countries, is the most common epidemic water-borne form of hepatitis in developing countries. It is usually transmitted by fecal-oral transmission through a contaminated water supply. Infected patients typically have a prodrome with malaise and pyrexia, followed by an acute illness with anorexia, nausea, vomiting, abdominal pain, and jaundice. Patients often have hepatomegaly and usually have significant elevations of the serum aminotransferase levels. The infection is typically mild and self-limited without chronicity or clinical sequelae.

Pregnant patients with hepatitis E have a more severe illness, with frequent fulminant hepatitis. The mortality rate rises progressively with the term of pregnancy up to about 20% mortality rate for acute infection in the third trimester.[29] Maternal infection is likewise associated with a high risk of fetal or neonatal mortality. Medical management is supportive. Fulminant hepatitis should be managed in an intensive care unit (ICU) and may require liver transplantation. The cause of the increased severity of this hepatitis during pregnancy is unknown, but may relate to attenuated cellular immunity during pregnancy.

In the United States, this infection is rare and not routinely tested for in the evaluation of acute hepatitis, but should be tested for when patients with an acute hepatitis have recently traveled to an endemic area and have had hepatitis A, B, and C excluded by serologic tests. The infection is generally diagnosed by detecting anti-HEV antibodies in the serum. Acute infection is diagnosed by detection of IgM antibodies, whereas prior infection is

TABLE 45-2 Clinical Presentation and Treatment During Pregnancy of Hepatic Disorders Significantly Affected by Pregnancy

DISEASE OR DISORDER	SYMPTOMS AND SIGNS	LABORATORY FINDINGS	TREATMENT
Hepatitis E	Anorexia, nausea and vomiting, RUQ abdominal pain, jaundice, hepatomegaly.	Significantly elevated aminotransferase levels, mild jaundice. IgM antibodies to hepatitis E. PCR for hepatitis E virus.	Supportive care. Prevention by public health measures: avoid drinking municipal water in endemic areas.
Acute intermittent porphyria	Diffuse abdominal pain, vomiting, constipation, neuropsychiatric abnormalities.	Increased porphobilinogen and delta-aminolevulinic acid levels in urine.	Hematin, parenteral glucose. Avoid precipitating drugs, avoid fasting. Narcotics or phenothiazines for symptomatic relief.
Budd-Chiari syndrome	Abdominal pain, hepatomegaly, and ascites.	Moderately elevated bilirubin and alkaline phosphatase. Relatively normal aminotransferase levels. Doppler ultrasound, hepatic venography, or MRA—no flow in hepatic vein.	Low-sodium diet and diuretics to manage ascites and fluid retention. Consider anticoagulation while balancing benefits versus risks. Consider thrombolytic therapy or angioplasty for an acute clot (but scant data on this therapy during pregnancy).

IgM, Immunoglobulin M; *MRA*, magnetic resonance angiography; *PCR*, polymerase chain reaction; *RUQ*, right upper quadrant.

diagnosed by detection of IgG antibodies. Detection of the virus in blood by PCR is more accurate than serologic tests. Tests for hepatitis E are not commercially available in the United States, but may be obtained via the Centers for Disease Control and Prevention (CDC). The infection is largely prevented by public health measures, such as a clean water supply. Pregnant women should avoid travel to endemic areas, should not drink water from the municipal water supply in endemic areas, should not consume uncooked shellfish or vegetables from endemic areas, and should wash all fruit from endemic areas using uncontaminated water. Table 45-2 summarizes the clinical presentation, diagnostic tests, and treatment during pregnancy of hepatitis E, as well as other hepatic disorders significantly affected by pregnancy.

Chronic Hepatitis B

Pregnancy does not appear to significantly affect the progression of chronic hepatitis B.[30] **Maternal chronic hepatitis B infection may, however, be transmitted to the neonate, usually during delivery. The risk of vertical transmission is about 90% in mothers who are hepatitis B-e antigen positive, but is only about 25% in mothers who are hepatitis B-e antigen negative.**[31] Perinatal infection is clinically important because infected neonates tend to become chronic carriers and then have a markedly increased risk of developing hepatocellular carcinoma in adulthood. All pregnant women should be tested for hepatitis BsAg in the United States.[30] Infants born to infected mothers should be passively immunized with hepatitis B hyperimmune globulin (HBIG) and actively immunized with hepatitis B vaccine immediately after birth to prevent neonatal infection from intrapartum exposure.

Chronic Hepatitis C

Women with chronic hepatitis C may exhibit transient normalization of their serum aminotransferase levels associated with an increase in the serum viral load during pregnancy, possibly due to mildly attenuated immunity. The clinical significance of this phenomenon in terms of progression of the liver disease is unclear, but chronically infected patients may develop mild progression of their liver disease, as evidenced by increased hepatic fibrosis, during pregnancy.

The risk of vertical transmission of hepatitis C from a chronically infected mother with viremia to the neonate is about 5%.[32] Viral transmission to the neonate is unlikely in mothers who have an undetectable viral load. Infants born to mothers with hepatitis C infection should undergo periodic testing for hepatitis C during the first 18 months of life to detect persistent infection.

Hepatic Adenomas

Hepatic adenomas are benign hepatic tumors that are promoted by hyperestrogenemia. They are composed of large plates of adenoma cells that are typically larger than ordinary hepatocytes. Pregnancy is associated with accelerated adenoma growth and consequent development of symptoms, such as nausea, vomiting, and right upper quadrant pain. Risks during pregnancy include adenoma hemorrhage or intraperitoneal rupture. On MRI, adenomas are typically well demarcated, hyperintense on T2-weighted images, and enhance further with gadolinium administration. Hepatic adenomas that are symptomatic or larger than 5 cm in diameter should be considered for surgical excision before conception in women contemplating pregnancy.

Acute Intermittent Porphyria

The porphyrias are rare diseases caused by deficiency of various heme biosynthetic enzymes that result in accumulation of toxic porphyrin precursors. Acute intermittent porphyria (AIP), due to porphobilinogen deaminase deficiency, is the most common hepatic porphyria, with a frequency of about 1 per 10,000 people. Acute intermittent porphyria is transmitted as an autosomal trait with incomplete penetrance and is strongly affected by environmental factors, including female sex hormone levels. Women have more severe symptoms than men, and their symptoms are exacerbated by oral contraceptive administration or during

menstruation and pregnancy.[33] About one third of female patients present initially during pregnancy or immediately postpartum. Hyperemesis gravidarum is a common precipitant. Diffuse abdominal pain is common. Other symptoms include vomiting, constipation, and neuropsychiatric abnormalities. Autonomic abnormalities can cause tachycardia, hypertension, or ileus. Unlike other porphyrias, AIP lacks dermatologic manifestations.

AIP should be considered in any pregnant patient with abdominal pain and a puzzling diagnostic evaluation. Increased urinary levels of porphobilinogen and delta-aminolevulinic acid are diagnostic. Management includes avoidance of precipitating drugs, avoidance of fasting, and possible administration of hematin or parenteral glucose. Abdominal pain and nausea and vomiting should also be treated with narcotic analgesics or phenothiazines. The maternal mortality rate is less than 10%, with a fetal mortality rate of 13% and frequent low-birth-weight infants.[33] Genetic counseling is recommended.

Sickle Cell Hemoglobinopathies

The sickle hemoglobinopathies, including hemoglobin SS, hemoglobin SC, and hemoglobin S/β-thalassemia, are the most common hematologic disorders during pregnancy. They mostly occur in African Americans. Patients with these hemoglobinopathies are prone to develop preeclampsia, eclampsia, or sickle crisis during pregnancy.[34] They can develop ischemia and microinfarction of multiple organs including extremities, joints, and abdominal viscera.[34] The abdominal pain in sickle crisis can be excruciating. Hemoglobin SS patients have an increased risk of acute cholecystitis during pregnancy.[21,34]

Portal Hypertension

Pregnancy is uncommon in cirrhotic women because they frequently experience anovulation and amenorrhea secondary to abnormal estrogen and endocrine metabolism.[35] However, patients with well-compensated, early cirrhosis occasionally become pregnant. The plasma volume gradually increases during pregnancy to a maximum of about 40% above baseline.[36] The primary contributing factor is sodium retention mediated by increased serum aldosterone, estrogen, and rennin levels, but water retention is a secondary factor.[36] The maternal cardiac output increases in proportion with the plasma volume. Portal pressure appears to physiologically increase during pregnancy due to these increases in plasma volume and cardiac output, as well as increased vascular resistance due to external compression of the inferior vena cava by the gravid uterus. **Pregnancy can therefore exacerbate preexisting portal hypertension; can cause shunting of blood into portosystemic collaterals, particularly esophageal varices; can increase intravariceal pressure; and can increase the risk of variceal hemorrhage. About 30% of pregnant patients with portal hypertension develop variceal hemorrhage, and about 75% of pregnant women with preexisting esophageal varices develop variceal hemorrhage.**[36] The risk of variceal hemorrhage is highest during the second trimester when the portal hypertension peaks, and during labor when venous collateral resistance abruptly increases from use of the Valsalva maneuver to push the fetus through the birth canal. Pregnancy has variable effects on the progression of cirrhosis. **About 25% of cirrhotics experience hepatic failure during pregnancy. Others have relatively stable hepatic function during pregnancy.** Some treatments for specific liver diseases during pregnancy have to be modified during pregnancy to avoid fetal toxicity. Maternal mortality rate in cases of cirrhosis may be as high as 10%.[35]

Portal hypertension without cirrhosis is usually due to portal vein obstruction or hepatic fibrosis. Female fertility is much better preserved in portal hypertension without cirrhosis than with cirrhosis. Pregnant patients, therefore, more frequently have portal hypertension without cirrhosis than with cirrhosis. Noncirrhotic patients with portal hypertension have a much lower mortality risk from each episode of variceal hemorrhage than cirrhotic patients due to better preserved liver function, a lower incidence of coagulopathy or thrombocytopenia, and a much lower risk of hepatic failure precipitated by variceal hemorrhage.

Women with prior variceal hemorrhage or with borderline liver function contemplating pregnancy should be advised of the high risks of maternal hepatic decompensation or variceal hemorrhage during pregnancy and associated poor fetal outcomes. They should also be advised of the risk of transmitting genetic hepatic diseases, such as α_1-antitrypsin deficiency, or of transmitting hepatotropic viral infections, such as hepatitis B, to their offspring. Women with well-compensated chronic liver disease without prior variceal hemorrhage should undergo esophagogastroduodenoscopy before conception for risk stratification. Women with silent esophageal varices are at high risk of variceal hemorrhage during pregnancy, whereas patients without esophageal varices are at low risk of this complication during pregnancy. Women with esophageal varices should be informed of the benefits of β-adrenergic receptor antagonists during pregnancy to reduce portal pressure, but should also be advised of the association of fetal bradycardia and growth retardation with these medications.

About 2.5% of cirrhotics experience splenic artery rupture during pregnancy. Pregnant women with portal hypertension should undergo an ultrasound examination with Doppler studies of the upper abdomen to screen for splenic artery aneurysms at the time of their routine antenatal pelvic ultrasound. Administration of iron is contraindicated in pregnant patients with hemochromatosis and is inadvisable in pregnant patients with several other types of chronic liver disease, such as chronic hepatitis C. Routine serum parameters of liver function, including a coagulation profile, should be serially monitored during pregnancy. Variceal hemorrhage during pregnancy, like variceal hemorrhage without pregnancy, should be initially treated with endoscopic variceal banding or sclerotherapy, as mentioned. Octreotide therapy is normally administered before the endoscopic therapy and maintained for several days after the endoscopic therapy in nonpregnant patients. Several cases of prolonged administration of octreotide for pituitary tumors have been reported in pregnant patients with good pregnancy outcomes. During parturition, the second part of labor should be kept brief to minimize portal hypertension, intravenous fluids should be administered cautiously to avoid volume overload, and any coagulopathy should be corrected to minimize the risk of intrapartum variceal hemorrhage.[36]

Budd-Chiari Syndrome

The Budd-Chiari syndrome refers to hepatic vein thrombosis or occlusion that increases the hepatic sinusoidal pressure and can lead to portal hypertension or hepatic necrosis.[37] Many cases are secondary to congenital vascular anomalies or hypercoagulopathies. This syndrome is rare in pregnancy even though pregnancy tends to promote this syndrome due to pregnancy-related increases in the serum level of estrogen and pregnancy-related decreases in the serum level of antithrombin III.[38] This syndrome usually manifests in the last trimester or the puerperium. The characteristic clinical triad is abdominal pain, hepatomegaly, and ascites.[38] Acute and chronic manifestations occur. The serum bilirubin and alkaline phosphatase levels are typically moderately elevated, with normal to mildly elevated serum aminotransferase levels. This syndrome is diagnosed by pulsed Doppler ultrasound, hepatic venography, or magnetic resonance angiography.[38] Without therapy death usually occurs within one decade after diagnosis. The definitive therapy is liver transplantation. Selective thrombolytic therapy and surgical or radiologic remedy of portal hypertension for intractable ascites or variceal bleeding have also been described.[38] Anticoagulant therapy is often administered chronically during pregnancy to prevent further thrombotic events, but is associated with a moderate risk of bleeding events such as intrauterine hematomas.[39] Maternal outcome is generally good, but about 30% of pregnancies result in fetal demise.[39] Patients have had subsequent successful pregnancies after undergoing liver transplantation for Budd-Chiari syndrome manifesting during the puerperium.

Pregnancy After Liver Transplantation

Although cirrhotic women are often infertile, women often regain fertility after successful liver transplantation for cirrhosis with restoration of liver function. Immunosuppressive therapy should be maintained during pregnancy after liver transplantation even though the fetal safety of many immunosuppressive therapies is not established. **Pregnancy appears to be relatively well tolerated after liver transplantation provided the transplanted liver functions well in the recipient before conception. Maternal complications during pregnancy include hypertension, preeclampsia, infections associated with immunosuppression, and occasionally acute hepatic rejection.**[40] Chronic immunosuppression with prednisone may result in gestational diabetes.

Fetal outcome is variable following liver transplantation, with an increase in prematurity and low birth weight observed.[40]

LIVER DISEASE STRONGLY RELATED OR UNIQUE TO PREGNANCY

Alcoholism During Pregnancy

Alcoholism during pregnancy can result in the fetal alcohol syndrome characterized by facial abnormalities such as an absent philtrum, and by growth retardation and neurodevelopmental deficits. Affected infants occasionally develop hepatic dysfunction, manifested by hepatomegaly, fatty liver, or elevations of serum aminotransferase or alkaline phosphatase levels.[41]

Hepatic Involvement in Hyperemesis Gravidarum

About 15% of women with hyperemesis gravidarum experience liver dysfunction, including several-fold elevations of the serum aminotransferase levels, jaundice, or pruritus. The hepatic dysfunction may be related to dehydration, malnutrition, and electrolyte abnormalities. This dysfunction is typically mild and resolves with cessation of the vomiting and reversal of the underlying metabolic abnormalities.

Herpes Simplex Hepatitis

Herpes simplex hepatitis is uncommon during pregnancy. However, about half of all cases of this hepatitis in immunocompetent adults occur during pregnancy, possibly due to attenuated immunity during pregnancy. **Herpes simplex hepatitis has a high mortality rate during pregnancy due to a propensity for viral dissemination and delayed diagnosis.**[42] Patients typically have right upper quadrant pain, very high serum aminotransferase levels, and moderate hyperbilirubinemia after a brief viral prodrome with fever and upper respiratory tract symptoms. An oral or genital cutaneous vesicular eruption in association with highly elevated serum aminotransferase levels should suggest the diagnosis. The diagnosis may be made by viral culture or histologic analysis of infected tissue. Acyclovir therapy is recommended. Table 45-3 summarizes the clinical presentation and treatment during pregnancy of herpes simplex hepatitis and other hepatic disorders that are strongly related or unique to pregnancy.

Intrahepatic Cholestasis of Pregnancy

The incidence of intrahepatic cholestasis of pregnancy (ICP) ranges from about 2 per 10,000 in the United States to about 20 per 10,000 in Europe.[43] The cardinal symptom is pruritus resulting from cholestasis and accumulated bile salts in the dermis. The pruritus typically most severely affects the palms and soles, becomes worse at night, and begins in the third trimester. The pruritus can be intense and can cause psychologic distress. Affected women occasionally experience anorexia, nausea, and vomiting. Proposed etiologic factors include genetic predisposition, as illustrated by the extremely high rate in the Araucanian Indians in Chile, and by familial clustering; gestational hyperestrogenemia, as supported by the known cholestatic effect of estrogen; and abnormal progesterone metabolism as supported by the cholestatic effects of sulfated progesterone metabolites.[36] This syndrome is sometimes related to defects in the multidrug resistance type-3 (MDR-3) gene that encodes for the canalicular phospholipid pump protein. Aside from family history, risk factors include multiple gestations and occurrence of this syndrome during previous pregnancies. **Patients typically develop hyperbilirubinemia that is mild and predominantly conjugated. About 10% of patients develop jaundice. Typically, the serum level of alkaline phosphatase is modestly elevated, whereas the level of gamma glutamyl transpeptidase (GGTP) is normal. The serum aminotransferase levels are typically several-fold higher than normal.** Patients have elevated fasting serum levels of total bile acids, particularly conjugated bile acids, and especially cholic acid.[36] Hepatic imaging studies reveal normal hepatic parenchyma and

TABLE 45-3 CLINICAL PRESENTATION AND TREATMENT DURING PREGNANCY OF COMMON HEPATIC DISORDERS STRONGLY RELATED OR UNIQUE TO PREGNANCY

DISEASE OR DISORDER	SYMPTOMS AND SIGNS	LABORATORY FINDINGS	TREATMENT
Herpes simplex hepatitis	RUQ abdominal pain after prodrome of upper respiratory tract symptoms and pyrexia.	Highly elevated serum aminotransferase levels, moderately increased serum bilirubin. Viral culture or histologic analysis of infected tissue—diagnostic.	Acyclovir.
Intrahepatic cholestasis of pregnancy	Intense pruritus, occasional anorexia and nausea.	Modestly elevated serum bilirubin and alkaline phosphatase. Moderately elevated aminotransferase levels. Elevated total bile acid level—diagnostic.	Ursodeoxycholic acid (also antihistamines, phenobarbitol, or cholestyramine). Parturition rapidly and completely relieves cholestasis.
Preeclampsia and eclampsia	Hypertension, peripheral edema, RUQ abdominal pain, nausea and vomiting Seizures with eclampsia.	Proteinuria. Marked serum transaminase elevations and mild bilirubin elevation.	Tight control of blood pressure, frequent nonstress testing of fetus. Magnesium to prevent seizures. Abnormalities rapidly resolve with prompt delivery after 34 weeks of gestation.
HELLP syndrome	RUQ abdominal pain, nausea, vomiting, headache, mucocutaneous bleeding, RUQ tenderness.	Hemolytic anemia, low platelet count. Mildly elevated serum AST and bilirubin levels. Often associated with preeclampsia.	Treatment of coagulopathy. Frequent nonstress testing of fetus. Abnormalities rapidly resolve with prompt delivery after 34 weeks of gestation. Occasionally requires plasmapheresis.
Hepatic hemorrhage	RUQ pain, pyrexia, hypotension, hepatic tenderness. Commonly associated with HELLP syndrome or preeclampsia with DIC.	Anemia, leukocytosis, highly elevated serum aminotransferase levels. Abdominal CT—most accurate diagnostic test.	Correct coagulopathy and hemodynamically stabilize patient. Treatments—angiography with embolization, surgical evacuation of hematoma.
Acute fatty liver of pregnancy	Anorexia, nausea and vomiting, malaise, fatigue, RUQ abdominal pain.	Variable mildly elevated LFTs. Hepatic imaging—excludes other disorders. Test for LCHAD mutation. Long-chain 3-hydoxylacyl metabolites accumulate. Liver biopsy—microsteatosis in hepatocytes (liver biopsy usually unnecessary). DIC in severely ill patients.	Specific treatments for specific complications (e.g., blood products for DIC). Prompt fetal delivery after maternal stabilization. Patients rapidly improve after fetal delivery.

AST, Aspartate aminotransferase; *CT,* computed tomography; *DIC,* disseminated intravascular coagulation; *HELLP,* hemolysis, elevated liver function tests, and low platelets; *LCHAD,* long-chain 3-hydroxyacyl coenzyme A dehydrogenase; *LFTs,* liver function tests; *RUQ,* right upper quadrant.

anatomy. Liver biopsy reveals bile staining of hepatocytes and bile plugs in biliary cannaliculi, without necroinflammatory activity, findings consistent with cholestasis. **Ursodeoxycholic acid is the generally recommended therapy. It tends to normalize the serum bile acid profile by stimulating bile acid excretion and thereby decrease the pruritus.**[44] Other treatments designed to ameliorate the pruritus and/or lower the serum bile acid concentration have included hydroxyzine, an antihistamine, phenobarbitol, cholestyramine, and, possibly, S-adenosyl methionine.[36]

Parturition results in rapid and complete relief of the cholestasis. The maternal outcome is usually good without long-term sequelae. However, gestational cholestasis increases the risk of postpartum cholesterol cholelithiasis. Vitamin K deficiency resulting from mild steatorrhea, associated with the cholestasis itself or the cholestyramine therapy for the cholestasis, increases the risk of postpartum hemorrhage. The prothrombin time should be monitored during pregnancy, especially near parturition, and vitamin K administered as necessary. ICP results in a significantly increased incidence of poor fetal outcomes such as meconium ileus, premature delivery, or stillbirth. **Fetal testing is recommended to confirm the diagnosis; testing (bile acid elevation) may require up to 1 to 2 weeks to perform. In the absence of fetal distress, the delivery should be considered at or near term or after fetal maturity has been documented**. Cholestasis recurs in about two thirds of subsequent pregnancies.

Preeclampsia and Eclampsia

Preeclampsia, defined by new onset of hypertension and proteinuria, complicates 3% to 6% of pregnancies (see Chapter 35).[45] About 10% of patients with severe preeclampsia develop hepatic dysfunction attributed to hepatic hypoperfusion from vasoconstriction.[45,46] Symptoms include nausea, emesis, and right upper quadrant pain that may radiate to the right shoulder.[1] Severe pain may herald hepatic infarction, hemorrhage, or rupture.[2]

Right upper quadrant tenderness is common. Marked serum aminotransferase elevations and minimal to mild bilirubin elevations often occur.[1,45] Pathologic examination of a liver biopsy usually demonstrates sinusoidal fibrin deposition and periportal hemorrhage, and occasionally demonstrates hepatocellular necrosis. Hepatic involvement is often accompanied by hemolysis, thrombocytopenia, renal dysfunction, altered sensorium, eclampsia, or hepatic decompensation.[37]

Patients who present near term with mild preeclampsia have minimally increased mortality risk.[37,45] Eclampsia is a severe, life-threatening form of preeclampsia characterized by seizures.[1,45] Mortality rate exceeds 20% in women without prenatal care, but is less than 1% in cases managed in tertiary hospitals.[37,45] About 15% of the maternal mortality from eclampsia is attributable to hepatic complications including hepatic failure, hemorrhage, or infarction.[2,45] Fetal mortality rate is less than 5% in deliveries performed later than 34 weeks of gestation,[45] but is much higher in deliveries occurring during the second trimester.[37]

Hemolysis, Elevated Liver Function Tests, and Low Platelet Count (HELLP) Syndrome

The HELLP syndrome occurs in about 4 per 1000 pregnancies (see Chapters 35 and 42).[1,2] Women typically present in the third trimester or occasionally present postpartum.[47] Typical clinical findings include hemolytic anemia, thrombocytopenia, and abnormal results of serum liver function tests. Laboratory criteria for this syndrome include microangiopathic hemolysis with schistocytes present on the peripheral blood smear, platelet count less than 50,000/mm^3, serum total bilirubin greater than 1.2 mg/100 mL, serum lactate dehydrogenase greater than 600 U/L, and serum aspartate aminotransferase greater than 70 U/L. Risk factors include advanced maternal age, multiparity, white ethnicity, and preeclampsia.

Women usually have epigastric or right upper quadrant pain. Other symptoms include right shoulder pain, nausea, emesis, malaise, headache, visual disturbances, mucocutaneous bleeding, and jaundice.[47] Physical examination may reveal right upper quadrant tenderness and peripheral edema.[47] Patients usually have hypertension and proteinuria. Liver injury is caused by hepatic hypoperfusion due to intravascular fibrin deposition and hypovolemia.[35] Hepatic pathologic abnormalities include periportal hemorrhage, focal parenchymal necrosis with hyaline deposition, fibrin microthrombi, and steatosis. Liver biopsy is, however, rarely performed due to the thrombocytopenia.

This syndrome is a medical emergency, with risk for both maternal and fetal mortality that depends on the gestational age at diagnosis.[2,47]

Management of Preeclampsia, Eclampsia, and HELLP Syndrome

Preeclampsia, eclampsia, and HELLP syndrome are related disorders with shared pathogenic, pathologic, and clinical features.[1] Indeed, about 15% of patients with preeclampsia or eclampsia develop the HELLP syndrome.[2] Management is tailored to the clinical manifestations as well as the clinical diagnosis. Women with severe preeclampsia, eclampsia, or HELLP syndrome should be managed at a tertiary medical center. Delivery is the definitive therapy.[2,37] If these disorders manifest after 34 weeks of gestation and after documentation of fetal lung maturity, the fetus should be promptly delivered.[2,47] Vaginal delivery can usually be performed, but cesarean section is sometimes necessary, with use of general anesthesia and preoperative transfusion of platelets. Laboratory abnormalities usually peak during the first 48 hours postpartum. During this time period the patient should remain in an ICU and receive transfusions of platelets or clotting factors as necessary for DIC.[2,47] Hypertension is managed aggressively, with parenteral agents if necessary. Plasmapheresis has been used for persistence of the HELLP syndrome beyond 72 hours postpartum.[2,47] The platelet count normalizes within 1 week after delivery.[47]

Hepatic Hemorrhage and Rupture

One percent or more of women with the HELLP syndrome have a subcapsular hepatic hematoma. Other causes of hepatic hematomas include eclampsia or preeclampsia complicated by DIC, hepatic trauma, hepatic adenoma, and hepatocellular carcinoma.[48] Pain commonly occurs in the right upper quadrant, epigastrium, or right shoulder.[49] Signs include pyrexia, hypotension, hepatomegaly, hepatic tenderness, and rebound tenderness with peritonitis.[47,49] Patients may be in shock and with acute renal failure or acute respiratory failure. Laboratory findings include leukocytosis, anemia, and highly elevated serum aminotransferase levels. Laboratory findings may reflect HELLP or DIC if they are present, but are otherwise nonspecific. Pathologic examination of the liver reveals sinusoidal fibrin deposition and extensive, primarily periportal, hepatic hemorrhage.[2] Hepatic subcapsular hematoma can be diagnosed by ultrasonography or MRI, but CT scanning is the most sensitive and specific imaging test.

Both the maternal and perinatal mortality rates from hepatic hemorrhage exceed 30%. Women should be hemodynamically stabilized, and any coagulopathy should be corrected preoperatively.[47,49] **An unruptured, contained, subcapsular hematoma may sometimes be managed medically and expectantly, with frequent serial CT scans and close clinical monitoring.**[47] **Angiography is useful to diagnose and treat ongoing active hemorrhage in situations in which it is unclear if the hemorrhage has stopped.** Invasive therapies include evacuation of the hematoma with packing and drainage, angiographic embolization, hepatic artery ligation, or hepatic resection. The mortality rate is highest with hepatic lobectomy and lowest with transarterial embolization of a bleeding hepatic artery identified at angiography.[47,49]

Hepatic rupture is a rare but catastrophic complication of pregnancy resulting from progressive hepatic bleeding and stretch of Glisson's capsule.[48] Patients are usually multiparous and older.[48,49] The rupture usually involves the right hepatic lobe and usually occurs just before or just after delivery.[49] **Hepatic rupture is a medical emergency because the fetus poorly tolerates concomitant shock. The fetus should be rapidly delivered and the liver surgically repaired.** Patients with hepatic hemorrhage rarely have recurrence during subsequent pregnancies.

Acute Fatty Liver of Pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare (1 in 10,000 pregnancies) but severe disease characterized by hepatic microvesicular steatosis associated with mitochondrial dysfunction. It is related to an autosomally inherited mutation that causes deficiency of the long-chain 3-hydroxyacyl coenzyme A dehydrogenase (LCHAD), a fatty acid beta-oxidation enzyme.[3] This mutation leads to accumulation of long-chain 3-hydroxyacyl metabolites produced by the fetus and placenta that are hepatotoxic. It usually manifests in the third trimester and rarely manifests immediately postpartum.[37,50] It is more common in primiparas and twin pregnancies. About half of patients exhibit signs of preeclampsia.[50,51]

The initial symptoms, including anorexia, nausea, emesis, malaise, fatigue, and headache, are nonspecific.[37,50] **About half of women have epigastric or right upper quadrant pain, and about half have hypertension.**[51] Physical examination may reveal hepatic tenderness, usually without hepatomegaly. Serum aminotransferase and bilirubin levels are variably elevated. Jaundice usually manifests later in the course of the illness or after delivery. Characteristic laboratory abnormalities in severely affected patients include a prolonged prothrombin time, hypofibrinogenemia, and increased serum levels of fibrin-split products. Other laboratory abnormalities include increased serum levels of ammonia, uric acid, blood urea nitrogen, and creatinine.[37,51] Hepatic imaging studies primarily help to exclude other disorders or to detect hepatic hemorrhage.[50]

Liver biopsy is usually diagnostic but is not indicated for suspected AFLP unless the presentation is atypical or the postpartum jaundice is prolonged.[1,51] Hepatic pathology reveals intracytoplasmic microsteatosis in hepatocytes, preservation of hepatic architecture, and isolated foci of inflammatory and necrotic cells.[51] Sinusoidal deposition of fibrin is usually not present in AFLP, but is usually present in preeclampsia and eclampsia.[51] AFLP differs from severe acute viral hepatitis in that the serum aminotransferase levels in AFLP rarely exceed 1000 U/L, the viral serologic tests are negative, and hepatic pathologic analysis reveals much less inflammatory infiltration and hepatocytic necrosis.[37,45,51] AFLP may be difficult to distinguish from HELLP syndrome and preeclampsia or eclampsia with DIC.[47] Fortunately, the definitive treatment for all these disorders is prompt fetal delivery after maternal stabilization that may include glucose infusion, reversal of coagulopathy, and administration of albumin. Most women improve clinically, and their liver function tests normalize within several days after delivery.[50]

Complications include pulmonary edema; pancreatitis; diabetes insipidus; DIC; seizures; coma; and hepatic failure manifested by jaundice, encephalopathy, ascites, or variceal bleeding.[50] The complications may require specific therapy: hepatic encephalopathy with lactulose, renal failure with hemodialysis, gastrointestinal bleeding with blood transfusions and endoscopic therapy, DIC with blood products, and diabetes insipidus with desmopressin (DDAVP). The maternal mortality rate is very low with early diagnosis, appropriate supportive therapy, and early delivery. The fetal mortality rate of AFLP is less than 15%.[2,51] The mother, neonate, and father should be tested for LCHAD mutations. Genetic testing is available for the most common mutation leading to LCHAD deficiency (G1528C mutation), but is unavailable for the other less common mutations.[52] AFLP rarely recurs in subsequent pregnancies.

KEY POINTS

- The differential of hepatobiliary conditions complicating pregnancy is extensive in that it includes pregnancy-related as well as pregnancy-unrelated disorders. Several clinical syndromes, such as intrahepatic cholestasis of pregnancy and acute fatty liver of pregnancy, are unique to pregnancy.
- Pregnancy affects the normative values of serum parameters of liver function and pancreatic injury. During pregnancy the serum level of albumin declines, whereas the serum levels of amylase, alkaline phosphatase, bile acids, cholesterol, and triglycerides rise.
- Many causes of significant liver dysfunction during pregnancy—including preeclampsia, eclampsia, HELLP syndrome, and acute fatty liver of pregnancy—are often rapidly relieved and completely reversed by delivery. Early delivery is generally the definitive therapy for these disorders.
- Pregnancy aggravates preexisting portal hypertension and increases the risk of variceal hemorrhage. Endoscopic sclerotherapy and banding are first-line therapies for esophageal variceal bleeding in pregnant patients.
- Pregnancy greatly aggravates acute hepatitis E infection, hepatocellular adenomas, acute intermittent porphyria, and herpes simplex hepatitis.
- Neonates born to mothers who have acute or chronic hepatitis B are at high risk of vertical transmission of infection during delivery. Such infants should be passively immunized with hepatitis B hyperimmune globulin and actively immunized with hepatitis B vaccine.

Gastrointestinal complaints and disorders are common in women of all ages, including during the childbearing years, and thus often occur during pregnancy. These complaints and disorders present unique clinical challenges during pregnancy. First, the differential diagnosis during pregnancy is extensive. Aside from gastrointestinal disorders unrelated to pregnancy, complaints may signify underlying obstetrical disorders or other intra-abdominal diseases incidental to pregnancy. Moreover, some gastrointestinal conditions, such as hyperemesis gravidarum, are unique to pregnancy. Second, the clinical presentation and natural history of gastrointestinal disorders can be altered during pregnancy. Third, the diagnostic evaluation is altered and constrained by pregnancy. For example, radiologic tests and invasive examinations may raise concern about fetal safety. Fourth, the interests of both the mother and the fetus must be considered in therapeutic decision making during pregnancy.[1,2]

The obstetrician and gynecologist, as well as the gastroenterologist and surgeon, should be familiar with the medical and surgical gastrointestinal conditions that can occur in pregnancy and how these conditions affect and are in turn influenced by pregnancy. This chapter reviews gastrointestinal symptoms and disorders during pregnancy, with a focus on aspects of these disorders unique to pregnancy.

PHYSIOLOGIC EFFECTS OF PREGNANCY ON ABDOMINAL DISORDERS

Abdominal assessment during pregnancy is modified by displacement of abdominal viscera by the expanding gravid uterus. For example, the location of maximal abdominal pain and tenderness from acute appendicitis migrates superiorly and laterally as the appendix is displaced by the growing gravid uterus.[3] A rigid abdomen with rebound tenderness remains a valid indicator of peritonitis during pregnancy, but abdominal wall laxity and the interposition of the gravid uterus between the appendix and the anterior abdominal wall in late pregnancy may mask the classical signs of peritonitis. An abdominal mass may not be palpable on physical examination due to an enlarged gravid uterus.[2]

Many extraintestinal abdominal conditions or disorders are affected by pregnancy. Mild hydronephrosis and hydroureter are common during pregnancy, particularly during the early third trimester, due to diminished muscle tone in the urinary tract from elevated progesterone levels and mechanical obstruction from fetal compression. Hydronephrosis in pregnancy is usually asymptomatic, but can cause positional abdominal discomfort. Mucosal immunity may be attenuated during pregnancy as part of physiologic immunologic tolerance of the foreign fetal antigens in the uterus. This phenomenon, as well as urinary stasis during pregnancy, contributes to an increased rate of cystitis and pyelonephritis during pregnancy. Pregnancy also promotes cholelithiasis because of increased cholesterol synthesis and gallbladder hypomotility related to gestational hormone production.

Pregnancy modifies gastrointestinal physiology. Gastroesophageal reflux is promoted by gastric compression by the enlarged gravid uterus and by decreased lower esophageal sphincter tone due to decreased serum progesterone and motilin levels during pregnancy. Pregnancy also increases the risk of aspiration of gastric contents for the same reasons. Pregnancy may decrease gastric acid secretion due to increased progesterone levels. Small bowel motility decreases during pregnancy.[4] Constipation is promoted by decreased intestinal motility, mild intestinal compression by the enlarged gravid uterus, and increased recumbency from bed rest during pregnancy.

Physiologic alterations of laboratory values during pregnancy include mild leukocytosis, physiologic anemia of pregnancy, mild dilutional hypoalbuminemia, mildly increased alkaline phosphatase level, and electrolyte changes, particularly mild hyponatremia.[3,5] The erythrocyte sedimentation rate is physiologically elevated and is a less reliable monitor of inflammatory activity during pregnancy. The fetus poorly tolerates maternal hypotension, hypovolemia, anemia, and hypoxia. This intolerance affects the type and timing of therapy for abdominal disorders during pregnancy. The gravid uterus can compress the inferior vena cava in the supine position and thereby compromise venous return, aggravating systemic hypoperfusion from hypovolemia or gastrointestinal bleeding. Simply turning the patient to the left side to displace the uterus may relieve this compression, improve venous return, and normalize the blood pressure.[5]

DIFFERENTIAL DIAGNOSIS AND EVALUATION OF GASTROINTESTINAL SYMPTOMS DURING PREGNANCY

Physiologic changes during pregnancy may cause abdominal symptoms, including nausea, emesis, early satiety, bloating, pyrosis, and abdominal discomfort. Serious disorders that produce these symptoms may, therefore, be difficult to distinguish from physiologic changes during pregnancy. Significant symptoms should not be dismissed as normal during pregnancy without a careful history, physical examination, and appropriate evaluation. Pregnancy

testing should be performed early in the evaluation of significant abdominal symptoms in all reproductive-age women.

Abdominal Pain

The differential diagnosis of abdominal pain during pregnancy is extensive in that it includes obstetrical conditions as well as the usual gastrointestinal and other intra-abdominal conditions in the general population.[3] Abdominal discomfort without other symptoms or signs can be due to an enlarging uterus, fetal pressure against adjacent organs, and uterine contractions associated with normal pregnancy. The abdominal pain is typically localized to the abdominal quadrant in which the afflicted organ is located, as illustrated for pain in the right lower quadrant in the box Differential Diagnosis of Right Lower Quadrant Abdominal Pain. This general rule has occasional exceptions in nonpregnant patients due to referred pain from other nearby regions, but has more frequent exceptions during pregnancy due to displacement of viscera by the growing gravid uterus and due to referred or poorly localized pain from obstetrical conditions.In the medical history, the pain intensity, nature, temporal pattern, radiation, exacerbating factors, and alleviating factors help narrow the differential diagnosis. Abdominal pain is typically progressive in appendicitis but is nonprogressive in viral gastroenteritis. The pain from small intestinal obstruction may be intermittent but is severe. Renal colic and biliary colic also produce a waxing and waning intensity of pain. Acute cholecystitis is associated with right upper quadrant pain, as well as pain referred to the right shoulder. The pain of acute pancreatitis is often boring in quality, located in the abdominal midline, and radiating to the back. Careful physical examination of the abdomen including inspection, palpation, and auscultation can further pinpoint the etiology. Laboratory evaluation of significant abdominal pain routinely includes a hemogram, serum electrolytes, and liver function tests, and often includes a leukocyte differential, coagulation profile, and serum lipase determination. In evaluating the laboratory results, gestational changes in normative values, as mentioned, must be considered. Radiologic tests may be extremely helpful diagnostically, but the choice of radiologic imaging may be influenced by pregnancy.

When the diagnosis is uncertain, close and vigilant monitoring by a surgical team, with frequent abdominal examination and regular laboratory tests, can often clarify the diagnosis. The character, severity, localization, or instigating factors of abdominal pain often change with time. For example, acute appendicitis typically changes from a dull, poorly localized, moderate pain to an intense and focal pain as the inflammation extends from the appendiceal wall to the surrounding peritoneum. The differential diagnosis of severe abdominal pain is described in Table 45-4.

Differential Diagnosis of Right Lower Quadrant Abdominal Pain

Gastrointestinal Disorders

Appendicitis
Crohn's disease
Ruptured Meckel's diverticulum
Intestinal intussusception
Cecal perforation
Colon cancer
Ischemic colitis
Irritable bowel syndrome

Renal Diseases

Nephrolithiasis
Cystitis
Pyelonephritis

Obstetrical and Gynecologic Diseases

Ruptured ectopic pregnancy
Ovarian tumors
Ovarian cyst rupture
Ovarian torsion
Endometriosis
Uterine leiomyomas

Other

Trochanteric bursitis

Table 45-4 Common Causes of Acute, Severe Abdominal Pain during Pregnancy: Pain Characteristics and Diagnostic Tests

CONDITION	PAIN LOCATION	CHARACTER	RADIATION	DIAGNOSTIC TESTS
Ruptured ectopic and abdominal pregnancy	Lower abdominal or pelvic	Localized, severe	None	Serum βhCG, abdominal ultrasound
Pelvic inflammatory disease	Lower abdominal or pelvic	Gradual in onset, localized	Flanks and thighs	Abdominal ultrasound
Appendicitis	First periumbilical, later RLQ (RUQ in late pregnancy)	Gradual in onset, becomes focal	Back or flank	Abdominal ultrasound in appropriate clinical setting
Acute cholecystitis	RUQ	Focal	Right scapula, shoulder, or back	Abdominal ultrasound and serum liver function tests
Pancreatitis	Epigastric	Localized, boring	Middle of back	Serum lipase and amylase, abdominal ultrasound
Perforated peptic ulcer	Epigastric or RUQ	Burning, boring	Right back	Abdominal ultrasound, laparotomy
Urolithiasis	Abdomen or flanks	Varies from intermittent and aching to severe and unremitting	Groin	Urinalysis, abdominal ultrasound, and occasionally fluoroscopy with contrast urography

hCG, Human chorionic gonadotropin; *RLQ*, right lower quadrant, *RUQ*, right upper quadrant.

Gastrointestinal causes of abdominal pain are discussed later under their individual headings in this section, and hepatobiliary causes are discussed in the previous section of this chapter. Obstetrical causes of abdominal pain are also prominent during pregnancy. Ectopic pregnancy (EP) classically manifests with abdominopelvic pain with or without vaginal bleeding after a period of amenorrhea. The pain may initially be diffuse and vague but later becomes focal and severe.[6]

Patients typically exhibit uterine tenderness and frequent uterine contractions. Sonography may be diagnostic.[6] Uterine rupture usually occurs in laboring women with abnormal fetal heart rate recordings or fetal death, uterine tenderness, peritoneal irritation, hypotension, and vaginal bleeding.

Severe preeclampsia can cause right upper quadrant (RUQ) pain and elevated serum transaminase levels. Women exhibit hypertension and proteinuria that starts after 20 weeks of gestation. Women with the HELLP (hemolysis, elevated liver enzymes, and low platelets) syndrome often have epigastric or RUQ pain. The patients have hemolysis with a microangiopathic peripheral blood smear, elevated liver transaminase levels, and thrombocytopenia. Acute fatty liver often causes abdominal pain, as well as nausea and vomiting, anorexia, and jaundice. The definitive treatment for these three pregnancy-related conditions of preeclampsia, HELLP syndrome, and acute fatty liver of pregnancy is prompt delivery after maternal stabilization.

Adnexal torsion typically causes lower abdominal pain that is sharp and sudden in onset. Signs include unilateral lower quadrant tenderness, a palpable adnexal mass, cervical tenderness, or rebound tenderness from peritonitis. Ultrasonography, including duplex scanning, is valuable in the detection of adnexal masses, particularly cysts.

The differential of abdominal pain during pregnancy includes renal disorders.[7] Symptoms from cystitis may include suprapubic discomfort, without frank abdominal pain, but patients usually have urinary frequency, urgency, or dysuria. The diagnosis is made by urinalysis and urine culture in the appropriate clinical setting.

Upper Gastrointestinal Symptoms

Nausea and Vomiting

Nausea and vomiting during pregnancy is most commonly due to nausea and vomiting of pregnancy or hyperemesis gravidarum, idiopathic disorders without demonstrable mucosal or mural disease. See the accompanying box, Differential Diagnosis of Nausea and Vomiting During Pregnancy, for many other conditions. Nausea and vomiting of pregnancy should be diagnosed only after exclusion of organic disorders by the history, physical findings, bloods tests, and appropriate diagnostic studies. Misdiagnosis of nausea and vomiting as nausea and vomiting of pregnancy rather than more severe diseases can be catastrophic.

Dyspepsia or Pyrosis

During pregnancy, gastroesophageal reflux disease (GERD) is extremely common, whereas peptic ulcer disease (PUD) is relatively uncommon (see the accompanying box, Differential Diagnosis of Dyspepsia or Pyrosis During Pregnancy). The diagnosis of GERD rather than PUD is suggested by pain radiating substernally, with the pain exacerbated by drinking acidic citrus drinks and by recumbency; symptoms of water brash or regurgitation; and presence of extraintestinal manifestations, including nocturnal asthma, hoarseness, laryngitis, or periodontal disease.

Differential Diagnosis of Nausea and Vomiting During Pregnancy

- Nausea and vomiting of pregnancy
- Hyperemesis gravidarum
- Pancreatitis
- Symptomatic cholelithiasis
- Viral hepatitis
- Peptic ulcer disease
- Gastric cancer
- Intestinal obstruction
- Intestinal pseudo-obstruction
- Gastroparesis diabeticorum
- Gastritis
- Gastroesophageal reflux disease
- Acute pyelonephritis
- Drug toxicity
- Vagotomy
- Preeclampsia/eclampsia
- Acute fatty liver of pregnancy
- Hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome
- Anorexia nervosa/bulimia
- Other neuropsychiatric disorders

Differential Diagnosis of Dyspepsia or Pyrosis During Pregnancy

- Gastroesophageal reflux disease
- Peptic ulcer disease
- Nausea and vomiting of pregnancy
- Hyperemesis gravidarum
- Pancreatitis
- Biliary colic
- Acute cholecystitis
- Viral hepatitis
- Appendicitis
- Acute fatty liver of pregnancy (in late pregnancy)
- Irritable bowel syndrome/nonulcer dyspepsia

Hematemesis

Upper gastrointestinal bleeding is uncommon during pregnancy. Nausea and vomiting during pregnancy increases the risk of hemorrhage from a Mallory-Weiss tear. Decreased lower esophageal sphincter (LES) pressure and increased intragastric pressure during pregnancy promote gastroesophageal reflux that can cause hemorrhage. **The most common causes of gastrointestinal hemorrhage during pregnancy are GERD, gastritis, Mallory-Weiss tears, and ulcers.**[8] Unusual causes include esophageal varices and gastric cancer. Women with upper gastrointestinal bleeding that causes hemodynamic instability are approached like nonpregnant individuals, with the following caveats. In the general population the hematocrit is not a reliable indicator of bleeding severity because of the lag between blood loss and hematocrit decline. The hematocrit may be an even less reliable indicator of bleeding severity during pregnancy because of the conflicting effects of intravascular fluid accumulation and increased erythrocyte mass.

Fluid, including transfusions of packed erythrocytes when indicated, should be aggressively administered to pregnant women with acute gastrointestinal bleeding because of the extraordinary fetal sensitivity to hypoperfusion, the difficulty in assessing volume status during pregnancy, and the usually healthy cardiac function of pregnant patients.

Dysphagia

The differential of dysphagia during pregnancy is similar to that in the general adult population, except that esophageal cancers are uncommon in these relatively young adults. Pregnant women with acquired immunodeficiency syndrome may have dysphagia or odynophagia from esophageal candidiasis or esophageal lymphoma. Dysphagia from a peptic stricture is uncommon in pregnant patients, despite their high frequency of GERD, because they typically have short-term and uncomplicated GERD. Achalasia is a motility disorder that typically manifests with a high resting LES pressure, failure of the LES to relax with swallowing, and nonperistaltic esophageal muscle contractions. Achalasia causes dysphagia and weight loss.

Definitive therapy for severe dysphagia is best performed before, rather than during, pregnancy to ensure adequate nutrition during pregnancy, a paramount concern for normal fetal development. Thus, surgery for severe achalasia or other benign esophageal diseases should be performed before contemplated pregnancy.

Lower Gastrointestinal Symptoms

Diarrhea

The pathogenesis and differential diagnosis of diarrhea in pregnant women is similar to that in the nonpregnant population.[9] Acute diarrhea is usually caused by viral, bacterial, or parasitic enteropathogens. Viral agents, such as rotavirus and Norwalk virus, typically cause an acute self-limited diarrhea, with upper gastrointestinal symptoms, and rare long-term sequelae. Bacterial causes of diarrhea include Campylobacter, Shigella, pathogenic *Escherichia coli*, and Salmonella. Pseudomembranous colitis due to *Clostridium difficile* must be considered in the differential diagnosis when the diarrhea starts after antibiotic administration. Bacterial pathogens tend to produce frequent small-volume stools, abdominal pain, and pyrexia. Inflammation of intestinal mucosa may produce fecal blood or leukocytes. Bacterial colitis is usually diagnosed by stool analysis and stool cultures. Pregnant women with advanced human immunodeficiency virus infection are prone to opportunistic enteric bacterial, fungal, parasitic, and viral infections, which often cause diarrhea. Noninfectious causes of diarrhea include medications, functional causes, food intolerances, and inflammatory bowel disease. Hyperthyroidism can cause hyperdefecation. The initial management of severe acute diarrhea includes intravenous hydration, correction of electrolyte disorders, and consideration of discontinuing oral feedings. Stool studies include bacterial culture and sensitivity, ova and parasites, *C. difficile* toxin, and fecal leukocytes. Flexible sigmoidoscopy can be considered, despite pregnancy, for persistent, refractory diarrhea if the stool studies are unrevealing.

Constipation

Constipation is common in pregnancy, affecting up to one fourth of gravidae.[10] Pregnancy tends to promote constipation from poor fluid intake due to nausea and vomiting; iron supplementation; decreased patient mobility; slowed gastrointestinal transit predominantly due to the effects of progesterone[4]; and gastrointestinal compression by the enlarged gravid uterus.[9] General measures can reverse these constipating factors during pregnancy. Adequate fluid intake and moderate exercise are important. Increased fiber intake—either by increasing dietary fiber, such as wheat bran, or by administering medications, such as methylcellulose—is recommended to promote stool bulk and softness. Patients should be advised to defecate in the morning or after meals when colonic motor activity is stimulated via the gastrocolonic reflex. Sorbitol and lactulose, poorly absorbed sugars that cause an osmotic diarrhea, may be effective for constipation during pregnancy. However, they may cause abdominal bloating and flatulence; they should be used with caution in diabetic patients; and they should be avoided in pregnant patients with nausea because they can exacerbate this symptom. Stimulant laxatives, such as senna or bisacodyl, may be considered in patients with severe constipation who fail to respond to conservative measures, bulk laxatives, or osmotic laxatives. Laxatives to be avoided during pregnancy include castor oil because it may initiate premature uterine contractions, and hypertonic saline laxatives, such as phosphosoda, because they promote sodium and water retention, which may cause renal failure in patients who are dehydrated or have preexisting renal insufficiency.[9]

Rectal Bleeding

Hemorrhoids are the most common cause of rectal bleeding during pregnancy. Other causes in the differential diagnosis of rectal bleeding during pregnancy include ulcerative colitis, Crohn's disease, rectal fissure, and infectious colitis, as well as unusual diagnoses during pregnancy, such as diverticular bleeding, bowel ischemia, or colon cancer.

DIAGNOSTIC TESTING DURING PREGNANCY

Radiologic Imaging

Fetal safety during diagnostic imaging is a concern for pregnant patients and pregnant medical personnel. Ultrasonography is considered safe during pregnancy and is the preferred imaging modality for abdominal pain during pregnancy.[6] Unfortunately, test sensitivity depends on operator technique; patient cooperation; and patient anatomy, in that sensitivity is decreased by abdominal fat and intestinal gas.[6] Magnetic resonance imaging (MRI) is preferable to computed tomography during pregnancy to avoid ionizing radiation, but gadolinium administration should be avoided during the first trimester.[11] Rapid-sequence MRI is preferable to conventional MRI because of briefer exposure. The patient should undergo counseling before diagnostic roentgenography.[11] The safety of radiologic abdominal imaging during pregnancy is briefly summarized in Table 45-5.

TABLE 45-5 General Principles Regarding Abdominal Imaging Tests during Pregnancy

TEST	SAFETY DURING PREGNANCY
Abdominal ultrasound	Considered safe during pregnancy and is the preferred imaging modality during pregnancy. Unfortunately, test is less sensitive and less specific than other imaging modalities for many abdominal disorders.
Magnetic resonance imaging (MRI)	Considered relatively safe based on limited clinical data. Avoid administering gadolinium, particularly during the first trimester.
Abdominal radiographs	Occasionally radiographs are required, (e.g., abdominal supine and upright radiographs for suspected intestinal obstruction). Limit fetal radiation exposure by shielding, collimation, rapid-sequence studies, and modern x-ray equipment.
Computed tomography (CT) of abdomen	Generally avoid during pregnancy, especially during first trimester. Consider MRI as alternative when abdominal ultrasound is nondiagnostic. CT may be required in rare circumstances (e.g., to avoid surgery for possible but unproven appendicitis). Consult with a radiation physicist to minimize fetal radiation exposure.

Endoscopy during Pregnancy

Endoscopy is often performed in the evaluation of abdominal symptoms in nonpregnant patients. Flexible sigmoidoscopy is performed to evaluate minor lower gastrointestinal complaints, including rectal symptoms, and esophagogastroduodenoscopy (EGD) is performed to evaluate epigastric pain, dyspepsia, or pyrosis. Although endoscopy is extremely safe in the general population, endoscopy during pregnancy raises the unique issue of fetal safety.

Sigmoidoscopy seems to be relatively safe during pregnancy. No woman suffered endoscopic complications in a study of 46 patients undergoing sigmoidoscopy during pregnancy.[12] Excluding 1 unknown pregnancy outcome and 4 voluntary abortions, 38 of 41 pregnant women delivered healthy infants, including 27 at full term. Their mean Apgar scores were not significantly different from the mean national Apgar scores. Moreover, study patients did not have a worse outcome than pregnant controls matched for sigmoidoscopy indications who did not undergo sigmoidoscopy, in terms of mean infant Apgar scores at birth and in terms of the rates of fetal or neonatal demise, premature delivery, low birthweight, and delivery by cesarean section. Additionally, no endoscopic complications were reported in 13 flexible sigmoidoscopies during pregnancy analyzed by a mailed survey of 3300 gastroenterologists. All pregnancies resulted in delivery of healthy infants at term.

Data are limited on colonoscopy during pregnancy. The two largest studies consist of 20 and 8 pregnant patients.[12,13] In the study of 20 pregnant patients, 16 colonoscopies were performed during the second trimester. Excluding one successful therapeutic colonoscopy to decompress a severely dilated colon from colonic pseudo-obstruction, colonoscopy was diagnostic in 10 of 19 cases, including diagnoses of ulcerative colitis, ischemic colitis, Crohn's colitis, and lymphocytic colitis. Colonoscopy led to therapeutic changes in 7. Two minor maternal procedural complications of mild transient hypotension occurred without clinical sequelae. Fetal outcomes were generally favorable: all infants were born relatively healthy except for one spontaneous abortion and 1 infant born with congenital defects. Colonoscopy should be considered, particularly during the second trimester, for very strong indications during pregnancy, such as suspected colon cancer, after obtaining informed consent that includes the theoretical but unsubstantiated fetal risks of colonoscopy. A polyethylene glycol (PEG) balanced electrolyte solution is generally preferred over a sodium phosphate (Fleet's phophosoda) solution to cleanse the colon for colonoscopy because sodium phosphate is associated with renal failure or electrolyte abnormalities in dehydrated or otherwise at-risk patients.

EGD is relatively safe for the fetus and the pregnant mother. In a case-controlled study of 83 EGDs during pregnancy, the mean week of gestation was 20 weeks. Indications for EGD included gastrointestinal bleeding in 37, abdominal pain in 28, vomiting in 14, and other indications in 4.[8] EGD did not cause any maternal complications. EGD did not induce labor. Excluding 6 voluntary abortions and 3 unknown pregnancy outcomes, 70 (95%) of 74 patients delivered healthy infants. In this study, the 4 bad pregnancy outcomes, including 3 stillbirths or deaths from severe prematurity and 1 involuntary abortion, occurred in high-risk pregnancies and were unrelated to EGD temporally or etiologically. This study and two other studies of 60 pregnant patients undergoing EGD during the first trimester[14] and of 30 pregnant patients undergoing EGD during pregnancy[15] suggest that EGD is at least as safe as not performing EGD in pregnant patients with a strong indication for EGD. Similar results were reported in a study of 73 pregnant patients undergoing EGD, analyzed by a mailed survey of 3300 gastroenterologists.

EGD is recommended during pregnancy for hemodynamically significant upper gastrointestinal bleeding. EGD is rarely helpful and rarely necessary for nausea and vomiting, or even hyperemesis gravidarum, during pregnancy. EGD is reserved for atypical situations, such as severe and refractory nausea and vomiting accompanied by significant abdominal pain, hematemesis, or signs of gastroduodenal obstruction. EGD is neither necessary nor indicated to evaluate typical symptoms of gastroesophageal reflux during pregnancy. EGD is useful in diagnosing complicated PUD, including gastric outlet obstruction, malignant gastric ulcer, refractory ulcer, and persistently bleeding ulcer. EGD should be performed in relatively stable patients with electrocardiographic monitoring after obstetrical consultation and after normalization of vital signs, which may require transfusion of packed erythrocytes and supplemental oxygenation. Fetal monitoring should be performed, if available, once the fetal heart sounds become detectable. General measures to increase the benefit-to-risk ratio of endoscopy during pregnancy are listed in Table 45-6.[16,17]

TABLE 45-6 General Principles to Improve the Benefit-to-Risk Ratio of Gastrointestinal Endoscopy During Pregnancy

PRINCIPLE	EXAMPLE
Perform endoscopy only for strong indications.	Colonoscopy for suspected colon cancer.
Avoid endoscopy or defer it until after delivery for weak or elective indications.	Colonoscopy for routine colon cancer screening.
Use the safest drugs for sedation and analgesia (Food and Drug Administration category B preferable or at most category C) in lowest possible dosages.	Use propofol (category B) or fentanyl (category C). Avoid diazepam (category D) because of possible, albeit unlikely, association with congenital cleft palate.
Consult an anesthesiologist regarding drug safety during pregnancy.	Monitored anesthesia care (MAC) with anesthesiologist present during endoscopy.
Preferably perform endoscopy in the second trimester, if possible, to avoid potential teratogenicity during fetal organogenesis in the first trimester, and to avoid premature labor or adverse effects on the neonate after delivery in the third trimester.	Defer endoscopy during first trimester, if possible, until second trimester. Defer endoscopy during third trimester, if possible, until after delivery.
Minimize procedure time.	Performance by an individual fellow-in-training, under supervision.
Obstetrical support should be available for a pregnancy-related procedure complication.	Perform procedure in an in-hospital endoscopy suite rather than a physician's office or an ambulatory surgical center.

Based on data from references 16 and 17.

Video capsule endoscopy is routinely used for recurrent gastrointestinal bleeding after nondiagnostic EGD and colonoscopy. The most common serious complication of video capsule endoscopy in the general population is capsule retention. Pregnancy may theoretically promote capsule retention due to displacement and impingement of bowel loops by the enlarged gravid uterus. Few data exist on video capsule endoscopy safety during pregnancy.[18]

GASTROINTESTINAL DISORDERS

Key differences during pregnancy in the clinical presentation, diagnosis, and therapy of gastrointestinal disorders are summarized in Table 45-7.

Predominantly Upper Gastrointestinal Disorders

Hyperemesis Gravidarum

Nausea and vomiting occurs in more than 50% of pregnancies. It typically begins at about 5 weeks of gestation and abates by about 18 weeks of gestation. It is commonly called morning sickness but may be designated more simply as nausea and vomiting of pregnancy or *emesis gravidarum* because it occurs throughout the day. This condition should be viewed as a physiologic rather than pathologic process during early pregnancy because this condition is generally not associated with unfavorable maternal or fetal outcomes. **Hyperemesis gravidarum (HG) is a severe, pathologic form of nausea and vomiting of pregnancy characterized by greater than 5% loss of prepregnancy weight and otherwise unexplained ketonuria.** The weight loss is paradoxic because patients normally gain weight during pregnancy. HG occurs in about 0.5% of pregnancies.[19] Risk factors include primigravidas, multiple gestation, molar pregnancy, prior unsuccessful pregnancy, and prior HG.[19] Like nausea and vomiting of pregnancy, HG typically begins early in pregnancy; severe vomiting beginning after the first trimester is unlikely from HG. In other pregnancy-related conditions that cause nausea and vomiting, including acute fatty liver of pregnancy, preeclampsia, and HELLP syndrome, the nausea and vomiting typically begins in the second half of pregnancy.

Nausea and vomiting of pregnancy and HG are diagnoses of exclusion, which are diagnosed only after other conditions are excluded by appropriate tests. An abdominopelvic ultrasound is performed to exclude other causes of nausea and vomiting and to exclude gestational trophoblastic disease and multiple gestation, conditions associated with HG. Women with epigastric or right upper quadrant pain should have serum liver function tests and serum lipase determination to exclude hepatobiliary and pancreatic disease. Women with nausea and vomiting complicated by dysphagia or hematemesis may require EGD. Women with nausea and vomiting during pregnancy associated with heartburn and regurgitation should be instructed about antireflux measures of diet and lifestyle modifications and should receive mild antireflux medications, as described later.

The pathophysiology is unknown, but is believed to be multifactorial. Human chorionic gonadotropin (hCG) has been proposed as an etiologic factor because the serum hCG level peaks when HG is most severe, and the serum hCG level is higher in patients with HG than in other pregnant patients. Other postulated etiologic factors include gestational hyperestrogenemia, gastric dysrhythmias, and hyperthyroidism.[19] Aside from nausea and vomiting, symptoms of HG include xerostomia, sialorrhea, and dysgeusia. Physical findings reflective of hypovolemia include dry mucous membranes, poor skin turgor, and hypotension or orthostatic hypotension. Serum electrolyte abnormalities include hyponatremia, hypocalcemia, and hypokalemia. An increased hematocrit reflects hemoconcentration from hypovolemia. Patients with severe vomiting may develop abnormal liver function tests, particularly elevations of the serum aminotransferases. Patients may exhibit mild, transient hyperthyroidism manifesting as low thyroid-stimulating hormone levels due to elevated serum hCG levels. Chronic vomiting of gastric contents may cause hypochloremic metabolic alkalosis. Inadequate nutrition can lead to vitamin or micronutrient deficiencies.

Therapy is initially focused on aggressive intravenous rehydration and restoration of electrolyte deficiencies. Vitamins should be repleted. Thiamine should be administered before administering dextrose to prevent Wernicke's encephalopathy. After intravenous repletion, the diet is gradually advanced, initially to salty fluids and then to a bland diet, as tolerated. Nutritional consultation is recommended. Nasoenteral or nasogastric feedings are useful alternatives in patients who cannot tolerate oral

TABLE 45-7 KEY DIFFERENCES DURING PREGNANCY IN THE CLINICAL PRESENTATION AND DIAGNOSIS OF GASTROINTESTINAL DISORDERS

DISEASE OR DISORDER	KEY DIFFERENCES DURING PREGNANCY
Mallory-Weiss tear	Much more common cause of upper gastrointestinal bleeding during pregnancy due to mechanical trauma at the GE junction from nausea and vomiting of pregnancy or hyperemesis gravidarum.
Nausea and vomiting of pregnancy	Extremely common during pregnancy. Condition is unique to pregnancy. Begins at about 5 weeks of gestation and abates by about 18 weeks of gestation. May be related to elevated serum human chorionic gonadotropin levels during early pregnancy.
Hyperemesis gravidarum	Very severe form of nausea and vomiting during pregnancy characterized by >5% loss of prepregnancy weight, serum electrolyte disorders, and ketonuria. Condition requires aggressive therapy.
Gastroesophageal reflux	Extremely common during pregnancy due to reduced lower esophageal sphincter tone due to gestational elevation of serum progesterone level and gastric compression by the enlarged gravid uterus. Although it may produce bothersome symptoms during pregnancy, serious complications of gastroesophageal reflux are unusual during pregnancy.
Acute appendicitis	Displacement of appendix by the enlarged gravid uterus during late pregnancy may cause the point of maximal abdominal pain and tenderness to migrate several cm superiorly and laterally from McBurney's point. Rate of appendiceal perforation from appendicitis is increased during pregnancy attributed to delayed diagnosis. Ultrasound is imaging test of choice during pregnancy to diagnose appendicitis to avoid fetal exposure to ionizing radiation. Appendectomy may be performed during pregnancy, but is most safe during the second trimester.
Intestinal obstruction	More common in third trimester because of mechanical effects of enlarged gravid uterus. Can occur during parturition because of mechanical effects of fetal head descent and abrupt decrease in uterine size. Despite pregnancy, supine and upright radiographs are necessary to diagnose and monitor intestinal obstruction. Unremitting, complete intestinal obstruction generally requires surgery despite pregnancy.
Intestinal pseudo-obstruction	Although risk of intestinal pseudo-obstruction or adynamic ileus is increased after cesarean section or vaginal delivery, this complication is still uncommon. This complication is generally managed medically without surgical intervention as in nonpregnant patients.
Colonic pseudo-obstruction	Despite limited clinical data, colonoscopy can be considered for colonic decompression when the only alternative is surgery provided that colonic necrosis is not suspected. Parenteral neostigmine is often administered therapeutically in nonpregnant patients, but may be contraindicated during pregnancy.
Colon cancer	Uncommon during pregnancy because of relative youthfulness of pregnant patients. Iron deficiency anemia is common during pregnancy due to increased gestational demands and is much less frequently associated with colon cancer in pregnant patients than in the elderly. Colon cancer diagnosed during pregnancy often located in rectum or sigmoid colon. Frequently manifests at an advanced pathologic stage attributed to delayed diagnosis. Pregnant patients have a high incidence (25%) of ovarian metastases from colon cancer. Colonoscopy may be necessary during pregnancy before colon cancer surgery to obtain a pathologic diagnosis and to exclude synchronous lesions. When cancer diagnosed during first half of pregnancy, cancer surgery should be promptly performed to minimize risk of metastases. Bilateral salpingo-oophorectomy is indicated for ovarian metastases.
Inflammatory bowel disease	Ulcerative colitis does not generally affect female fertility, whereas Crohn's disease mildly decreases fertility. Patients with inactive or mild inflammatory bowel disease at conception tend to have the same disease activity during pregnancy. Patients with active disease at conception can have active disease during pregnancy with an increased risk of poor fetal outcomes, especially for Crohn's disease. Flexible sigmoidoscopy is generally well tolerated during pregnancy and can be used to help diagnose a disease flare. Corticosteroids, sulfasalazine, and 5-aminosalicylates can be administered during pregnancy. Azathioprine is classified as FDA class D during pregnancy, but gastroenterologists sometimes continue this medication during pregnancy to maintain remission. However, the tumor necrosis factor inhibitors of infliximab, adalimumab, and certolizumab are apparently safer alternatives during pregnancy and are rated as FDA category B during pregnancy. Methotrexate is contraindicated during pregnancy.
Hemorrhoids	Extremely common during pregnancy due to vascular engorgement during pregnancy, vascular compression from the enlarging gravid uterus, and increased straining at defecation because of constipation. Medical therapy is generally recommended because hemorrhoidal symptoms usually resolve spontaneously soon after delivery.
Mesenteric ischemia and infarction	Mildly increased risk of mesenteric ischemia due to mild hypercoagulability from hyperestrogenemia during pregnancy, but risk is still relatively low because mesenteric ischemia is predominantly a disease of the elderly.
Splenic artery rupture	Risk of splenic artery aneurysm rupture markedly increases during pregnancy due to estrogen weakening the elasticity of the arterial wall, but overall risk is still relatively low.

FDA, Food and Drug Administration.

feedings. Total parenteral nutrition (TPN) is rarely necessary. Patients should avoid environmental stimuli that trigger their nausea and vomiting. Patients should eat as soon as they feel hungry to avoid eating on an empty stomach, which can exacerbate nausea.

Nausea and vomiting of pregnancy differs from HG by less severe symptoms, absence of weight loss, and lack of dehydration, vitamin deficiencies, and other nutritional deficiencies. Patients with mild nausea during pregnancy typically require counseling and reassurance without treatment. Patients may benefit from a diet that emphasizes salty liquids, soups, starches, and chicken and avoids fatty foods, vegetables, and fibrous foods.[19] Bendectin (containing doxylamine, an antihistamine and vitamin B_6) was commonly administered for nausea and vomiting of pregnancy, but was withdrawn in 1983 due to unproven

allegations of teratogenicity.[19] A subsequent meta-analysis reported no increase in the incidence of birth defects after in utero exposure to Bendectin.[20] Vitamin B_6 (pyridoxine), a component of Bendectin, has been used by itself to treat mild-to-moderate nausea and vomiting of pregnancy with some success.[19,20] A delayed-release form of doxylamine-pyridoxine (Diclectin) is currently approved in Canada to treat nausea and vomiting of pregnancy. Dopamine antagonists, such as promethazine, or selective serotonin antagonists, such as ondansetron, have been used as antiemetics for these conditions. Experimental therapies for HG include ginger, methylprednisone, and erythromycin.

Nausea and vomiting of pregnancy is classically associated with a favorable pregnancy outcome, but has recently been associated with possible physical and psychosocial disorders later in childhood after delivery, as well as psychologic stress in the expectant mother. The maternal and fetal prognosis of HG is relatively favorable provided that the nausea and vomiting are reversed and the mother gains adequate weight during the remainder of the pregnancy.[21]

Gastroesophageal Reflux and Peptic Ulcer Disease

The incidence of pyrosis approaches 80% during pregnancy.[3] The incidence of GERD is likewise high during pregnancy. This high incidence may relate to a hypotonic LES and delayed gastrointestinal transit, attributed to gestational hormones, especially progesterone, and gastric compression by the gravid uterus. GERD manifests in pregnancy, as in nonpregnant patients, by pyrosis, regurgitation, water brash, dyspepsia, hypersalivation, or, rarely, pulmonary symptoms. Symptoms may be exacerbated by ingesting certain foods, such as acidic drinks, or by recumbency. Complications of GERD include gastrointestinal hemorrhage from hemorrhagic esophagitis, dysphagia from a reflux-induced esophageal stricture, and Barrett's esophagus or adenocarcinoma. These complications generally relate to severe, long-standing, poorly controlled GERD. During pregnancy GERD tends to be mild and of short duration (coincident with the pregnancy), so these complications are rare. Esophagogastroduodenoscopy (EGD) is the best test to diagnose reflux esophagitis. Characteristic findings are erosions, exudates, erythema, or ulcers just above the gastroesophageal junction. EGD can be performed during pregnancy if necessary but is generally reserved for complications from GERD of gastrointestinal hemorrhage or dysphagia.

Symptomatic peptic ulcer disease (PUD) is uncommon during pregnancy, and antecedent PUD often improves during pregnancy.[22] Nausea, emesis, dyspepsia, and anorexia are so frequent during pregnancy that PUD cannot be diagnosed by symptomatology during pregnancy. The most common cause of a peptic ulcer in the duodenum is *Helicobacter pylori* infection. Nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin, can cause gastric or duodenal ulcers. These ulcers more commonly cause gastrointestinal bleeding than abdominal pain, possibly because of the analgesic properties of NSAIDs.

Although the efficacy of modern acid-suppressive drugs has rendered lifestyle modifications less important in the nonpregnant patient with GERD or PUD, lifestyle modifications remain important in the pregnant patient because of concern about potential fetal effects of medications. Pregnant patients with GERD or PUD should avoid caffeine, alcohol, smoking cigarettes, and NSAIDs, although acetaminophen is safe and the cyclo-oxygenase II (COX-II) inhibitors are less gastrotoxic than the nonselective NSAIDs. Women with GERD should elevate the head of their bed and avoid wearing tight belts. They should avoid recumbency after eating and discontinue oral intake beginning 3 hours before bedtime.

Antacids are generally safe for the fetus, but those containing sodium bicarbonate should be avoided throughout pregnancy because such antacids may cause fluid overload or metabolic alkalosis.[23] Antacids and dietary measures often suffice during the first trimester for minimally symptomatic disease.[1] Antacids must be administered frequently because of low potency, and frequent administration can cause diarrhea or constipation and electrolyte or mineral abnormalities. Sucralfate has minimal systemic absorption, and is generally believed to be safe during pregnancy, but its aluminum content is of concern to the fetus in mothers with renal insufficiency. Misoprostil is an abortifacient that is contraindicated during pregnancy. Histamine$_2$-receptor antagonists are useful in treating GERD and PUD when symptoms are more severe or occur later in pregnancy.[1] Ranitidine and famotidine are preferable, because nizatidine is possibly toxic to the fetus and cimetidine has antiandrogenic effects.[24] Proton-pump inhibitors were initially reserved for refractory, severe, or complicated GERD or PUD during pregnancy, but have recently been increasingly used due to accumulating evidence of relative fetal safety. Lansoprazole, rabeprazole, and pantoprazole (Food and Drug Administration [FDA] pregnancy category B) appear to be relatively safe and are therefore the recommended agents in this class during pregnancy.[25] Omeprazole is rated only as an FDA category C drug during pregnancy, but a study in 2001 involving 863 infants exposed to omeprazole during the first trimester revealed a rate of stillbirth and of congenital malformations comparable to that of unexposed controls. Drug therapy to eradicate *Helicobacter pylori* should be deferred until after parturition and lactation because of concern about the fetal safety of administered antibiotics.[26]

Surgery for GERD is best performed either before or after pregnancy.[1] Endoscopic therapy is the initial intervention for active bleeding from GERD or PUD,[17,22] but a hemodynamically unstable patient refractory to endoscopic therapy requires expeditious surgery, because the fetus poorly tolerates maternal hypotension. Patients in advanced pregnancy should undergo cesarean section just before gastric surgery for gastrointestinal bleeding. Pregnant PUD patients may also require surgery for gastric outlet obstruction, refractory ulcer, or malignant ulcer.

Diaphragmatic Rupture

In diaphragmatic rupture, abdominal contents herniate through a diaphragm weakened by congenital defects or abdominal or chest trauma. The risk of rupture is increased during pregnancy because of increased pressure on the diaphragm from recurrent vomiting during the first half of pregnancy, rapid growth of the gravid uterus during the second trimester, or Valsalva/Kristeller maneuvers during labor. Diaphragmatic rupture is still rare even during

pregnancy. It is potentially catastrophic during pregnancy, with both maternal and fetal mortality rates from strangulation exceeding 40%.[27] Increased intra-abdominal pressure from the enlarged gravid uterus increases the risk of bowel strangulation. Herniorrhaphy is recommended during the first two trimesters for bowel penetration through a diaphragmatic hernia, even if asymptomatic, because of high mortality risk without surgery.[27] Expectant management is recommended for asymptomatic patients during the third trimester, with cesarean section and herniorrhaphy performed when the fetus is sufficiently mature. Cesarean section is performed to avoid increased abdominal pressure during active labor, which can cause bowel strangulation.

Predominantly Lower Gastrointestinal Disorders

Acute Appendicitis

Acute appendicitis is the most common nonobstetrical surgical emergency during pregnancy, with an incidence of about 1 per 1000 pregnancies.[28] Appendiceal obstruction, usually from an appendicolith, is the primary etiologic event, although stasis and other factors are also implicated. As the appendiceal lumen distends, the patient initially experiences poorly localized pain. Severe luminal distention, mural inflammation and edema, and bacterial translocation produce somatic pain that becomes severe and well-localized at McBurney's point, which is located in the right lower quadrant one third of the way from the anterior superior iliac spine to the umbilicus. Displacement of the appendix by the gravid uterus during late pregnancy may cause the point of maximal abdominal pain and tenderness to migrate superiorly and laterally from McBurney's point, but this migration is typically only a few centimeters away from McBurney's point during late pregnancy.[3] Rectal or pelvic tenderness may occur in early pregnancy but is unusual in late pregnancy as the appendix migrates from its pelvic location. Other clinical findings include anorexia, nausea, emesis, pyrexia, tachycardia, and abdominal tenderness. Periappendiceal inflammation or peritonitis causes involuntary guarding and rebound tenderness. Involuntary guarding and rebound tenderness are less reliable signs of peritonitis in late pregnancy because of abdominal wall laxity and lifting of the anterior abdominal wall away from the inflamed appendix by the growing gravid uterus. Patients may have significant leukocytosis and a predominance of neutrophils in the leukocyte differential.[29]

Radiologic imaging is indicated when the diagnosis is suspected but still ambiguous after routine laboratory studies to reduce the incidence of negative appendectomy. **Although computed tomography is the imaging test of choice in nonpregnant patients because of high diagnostic accuracy, sonography is the test of choice during pregnancy to avoid fetal exposure to radiation from CT.** In a comprehensive review, ultrasound was 86% sensitive and 81% specific in the diagnosis of appendicitis in adults or adolescents.[30] Diagnostic findings include appendiceal mural thickening, periappendiceal fluid, and a noncompressible tubular structure closed at one end and open at the other end with a 6 mm or greater diameter lumen. **Appendicitis cannot be excluded if the appendix is nonvisualized at ultrasound.**[6]

MRI is the appropriate next test in the pregnant patient if the abdominal ultrasound is inconclusive. In a study of 148 pregnant women with suspected appendicitis during pregnancy, MRI was 100% sensitive and 93% specific for the diagnosis of acute appendicitis.[31] CT can be performed with modifications to limit fetal radiation exposure to less than 300 mrad if MRI is unavailable. Abnormal CT findings with appendicitis include right lower quadrant inflammation, a nonfilling, enlarged tubular structure, and an appendicolith.

Up to one quarter of pregnant women with appendicitis develop appendiceal perforation.[3] This high rate is attributed to delayed diagnosis during pregnancy. The diagnosis may be missed in pregnant patients because: (1) leukocytosis, a classic sign of acute appendicitis, occurs physiologically during pregnancy; (2) nausea and emesis, common symptoms of acute appendicitis, are also common during pregnancy; and (3) the abdominal pain is sometimes atypically located.[29] Other diseases are often confused with appendicitis (see the accompanying box, Differential Diagnosis of Appendicitis During Pregnancy). Appendiceal displacement predisposes to rapid development of generalized peritonitis after perforation because the omentum may not be in close proximity to the appendix.

Differential Diagnosis of Appendicitis During Pregnancy

Gynecologic Conditions

Ruptured ovarian cyst
Adnexal torsion
Pelvic inflammatory disease or salpingitis
Endometriosis
Ovarian cancer

Obstetrical Causes

Abruptio placentae
Chorioamnionitis
Endometritis
Uterine fibroid degeneration
Labor (preterm or term)
Viscus perforation after abortion
Ruptured ectopic pregnancy

Gastrointestinal Causes

Crohn's disease
Colonic diverticulitis (right side)
Cholecystitis
Pancreatitis
Mesenteric lymphadenitis
Gastroenteritis
Colon cancer
Intestinal obstruction
Hernia (incarcerated inguinal or internal)
Colonic intussusception
Ruptured Meckel's diverticulum
Colonic perforation
Acute mesenteric ischemia

Other Causes

Pyelonephritis
Urolithiasis

Appendicitis during pregnancy mandates surgery, after intravenous hydration and correction of electrolyte abnormalities. Appendectomy is safer for the fetus during the second trimester than the first trimester. Antibiotics are usually administered for uncomplicated appendicitis and are clearly required for appendicitis complicated by perforation, abscess, or peritonitis.[3] Clindamycin is preferred over metronidazole for anaerobic coverage, even though both are category B drugs in pregnancy.[26] Clindamycin and gentamicin is a relatively inexpensive, effective, and safe antibiotic combination. **Laparoscopy may be considered during the first two trimesters for nonperforated appendicitis or when the diagnosis is uncertain.** Appendectomy is recommended even if appendicitis is not evident at surgery.[29] Maternal mortality rate from appendicitis is about 0.1% without perforation, but may exceed 4% with appendiceal perforation.[28] Fetal mortality rate is about 2% without perforation, but has been reported to exceed 30% with appendiceal perforation.[28]

Intestinal Obstruction

Acute intestinal obstruction is the second most common nonobstetrical abdominal emergency, with an incidence of 1 per 2500 pregnancies.[32] It may be incidental or secondary to pregnancy. Obstruction more commonly occurs in the third trimester because of the mechanical effects of the enlarged gravid uterus. In particular, some cases occur at term because of the mechanical effects from fetal head descent and the abrupt decrease in uterine size at delivery.[32] Adhesions, particularly from prior gynecologic surgery or appendectomy, are etiologic in 60% to 70% of small bowel obstruction (SBO) during pregnancy.[32,33] Other causes of SBO include neoplasms, particularly ovarian, endometrial, or cervical malignancy; Crohn's disease; external or internal hernias; volvulus; and intussusceptions.[32] Rare causes of SBO include EP; prior radiotherapy; and intraluminal gallstones, fecoliths, or other concretions. Colonic obstruction is caused by adhesions, colon cancer, other neoplasms, diverticulitis, and volvulus.[32]

Intestinal obstruction classically manifests with a symptomatic triad of abdominal pain, emesis, and obstipation.[32] The pain may be constant or periodic. Small bowel obstruction is more painful than colonic obstruction. The pain with SBO may be diffuse and poorly localized and may radiate to the back, flanks, or perineum. Abdominal pain is milder with volvulus and intussusception. Intestinal malrotation may produce nonspecific symptoms of mild, crampy, abdominal pain and nonbilious emesis. Intestinal strangulation, with compromised bowel perfusion, may be heralded by abdominal guarding and rebound tenderness. Emesis occurs more frequently and earlier in small bowel than colonic obstruction.[32] Constipation from complete intestinal obstruction is usually severe and unremitting and associated with abdominal pain.[32] The abdomen is typically distended and tympanitic to percussion due to inability to defecate or pass flatus. Bowel sounds are high-pitched, hypoactive, and tinkling in early intestinal obstruction and become absent in late obstruction.

The approach to intestinal obstruction is the same in pregnancy as in the general population except that decisions are more urgently required because of combined fetal and maternal risk. The diagnosis is strongly suggested by radiographic findings of distended bowel loops containing air-fluid levels, particularly with differential air-fluid levels. An abrupt transition between distended and nondistended bowel favors the diagnosis of intestinal obstruction over intestinal pseudo-obstruction. Volvulus is suspected when a single bowel loop is grossly dilated. Surgery is recommended for unremitting and complete intestinal obstruction, whereas medical management is recommended for intermittent or partial obstruction. Parenteral fluids are aggressively administered to reverse the fluid and electrolyte deficits caused by emesis and fluid sequestration. Nasogastric suction helps decompress the bowel. Maternal mortality rate is about 5%, and fetal mortality rate may range from 20% to 30%.[33]

Intestinal Pseudo-obstruction

Intestinal pseudo-obstruction (adynamic ileus) is characterized by severe abdominal distention detected on physical examination and diffuse intestinal dilation noted on abdominal roentgenogram. Intestinal pseudo-obstruction is diagnosed only after exclusion of (mechanical) intestinal obstruction by the clinical presentation, laboratory studies, and early clinical evolution. Patients with mechanical obstruction tend to be much sicker than those with pseudo-obstruction for the same degree of intestinal dilation detected by abdominal imaging and tend to progress more rapidly. **Intestinal pseudo-obstruction is a well-described, but uncommon, complication of cesarean section or vaginal delivery. Patients with pseudo-obstruction have nausea, emesis, obstipation, and diffuse abdominal pain that typically develops over several days.** Patients often have hypoperistalsis. Pyrexia, leukocytosis, and increasing abdominal tenderness may herald gastrointestinal ischemia. Treatment includes nasogastric aspiration, parenteral fluid administration, repletion of electrolytes, and rectal tube decompression. Mild pseudo-obstruction or adynamic ileus usually spontaneously resolves.

Therapeutic options for severe colonic pseudo-obstruction (Ogilvie's syndrome), manifested by a colonic luminal diameter greater than 10 cm on abdominal roentgenogram, include colonoscopic decompression or surgical therapies, including cecostomy, cecectomy with diverting ileostomy, or colonic resection when intestinal necrosis supervenes.[34] Colonoscopy can be considered for colonic pseudo-obstruction during the second trimester of pregnancy when the only alternative is surgery.[13] Parenteral neostigmine is often administered for colonic pseudo-obstruction in nonpregnant patients and may therefore be administered postpartum. Mortality rate approaches 10% with impending perforation, but can reach 70% after cecal perforation.[34]

Colon Cancer

Colon cancer is uncommon during pregnancy, with an estimated incidence of 1 per 13,000 to 1 per 50,000 pregnancies.[2,35] With approximately 4 million pregnancies per annum in the United States these incidence estimates translate into 80 to 300 colon cancers during pregnancy per annum in the United States.

The clinical presentation and evaluation of colon cancer in pregnant patients is similar to that in other patients, with

notable exceptions. **Common symptoms of colon cancer in pregnant patients include abdominal pain, rectal bleeding, nausea and vomiting, and abdominal distention.**[2,36] **Colon cancer tends not to produce signs until advanced.** About one fifth of colon cancers occur in the rectum in the general population, whereas about two thirds of colon cancers occur in the rectum during pregnancy.[37] This shift during pregnancy may artifactually result from increased self-referral due to increased patient attention to rectal symptoms because of rectal compression by the gravid uterus or from increased physician detection due to frequent pelvic and rectal examinations during pregnancy.[2] Rectal examination is essential in the evaluation of suspected colon cancer during pregnancy. The cancer often arises in the rectum during pregnancy. Rectal cancer may be palpable by digital rectal examination. Stool should be tested for the presence of occult blood, even though the finding of occult blood has a low positive predictive value for colon cancer or adenomas during pregnancy because of the low disease prevalence in this rather young patient population. Iron deficiency anemia is common during pregnancy due to increased gestational demands. Iron deficiency anemia, therefore, is not nearly as strongly associated with colon cancer in the pregnant patient as it is in the elderly patient.[2] Patients with colon cancer during pregnancy are relatively young and therefore more likely than elderly patients with colon cancer to have predisposing factors, including hereditary nonpolyposis colon cancer (HNPCC), familial polyposis coli, Peutz-Jeghers syndrome, and long-standing inflammatory bowel disease.

During pregnancy, colon cancer often manifests at an advanced pathologic stage attributed to delayed diagnosis.[37] Advanced pathologic stage is highly correlated with a poor prognosis. MRI may be required to diagnose suspected hepatic metastases.[38] Complete colonoscopy is indicated preoperatively in nonpregnant patients for pathologic diagnosis and for excluding synchronous colonic lesions. Colonoscopy may, therefore, be necessary during pregnancy before colon cancer surgery for the same reasons. Colonoscopy may be technically difficult during late pregnancy because of colonic compression by the enlarged gravid uterus. If the gestation is advanced, and the fetus is viable, it may be preferable to induce labor and then perform colonoscopy and cancer surgery.

When the cancer is diagnosed during the first half of pregnancy, cancer surgery should be promptly performed to minimize the risk of metastases.[2] Such surgery can often be performed without removing the gravid uterus and disturbing the pregnancy.[37] Total abdominal hysterectomy is recommended to facilitate access to the rectum when needed for intraoperative exposure; when the mother's life expectancy is less than the time needed for the fetus to become viable; or when the cancer extends into the uterus. Otherwise, when the cancer appears resectable, curative surgery should be performed leaving the pregnancy intact.[2] When the cancer is diagnosed during the second half of pregnancy, cancer surgery should ideally be delayed until, but not beyond, the time that fetal viability is normally expected (at about 32 weeks of gestation) because further delay permits cancer growth and metastasis.[36] Bilateral salpingo-oophorectomy is indicated for ovarian metastases.[39] Colon cancer surgery is associated with a moderately increased, but still acceptable, rate of fetal death, but is associated with a high risk of preterm delivery and low birth weight. Serum carcinoembryonic antigen (CEA) levels obtained before surgery provide a baseline to monitor response to surgery and chemotherapy. Pregnancy does not significantly alter the serum CEA level.

Patients younger than 40 years old generally have a poor prognosis from colon cancer, attributed to a delayed diagnosis and an advanced pathologic stage at diagnosis. Likewise, the maternal prognosis from colon cancer, whether colonic or rectal, diagnosed during pregnancy is poor. Fetal prognosis depends on the pathologic stage of the maternal cancer, gestational age at diagnosis, and type and timing of therapy. Novel diagnostic modalities for colon cancer diagnosis with promising applications in pregnancy include video capsule endoscopy in which the colon may be imaged by a microcamera placed within a pill-sized device swallowed by the patient, and a large array of genetic markers to detect genetic abnormalities associated with colon cancer in minute quantities of DNA in stool shed from colonic mucosa.

Inflammatory Bowel Disease

The inflammatory bowel diseases (IBDs), including ulcerative colitis and Crohn's disease, are idiopathic, immunologically mediated disorders that peak in incidence during a woman's reproductive period. The incidence of UC in women less than 40 years of age is 40 to 100 per 100,000 and of CD is 2 to 4 per 100,000.[3] **Ulcerative colitis is a colonic disease manifested by bloody diarrhea, crampy abdominal pain, and pyrexia. Crohn's disease can involve any part of the gastrointestinal tract but most commonly involves the terminal ileum.** It is characterized by diarrhea, abdominal pain, anorexia, pyrexia, and malnutrition. Patients with CD may have fistulas and anorectal disease. Extraintestinal manifestations of IBD include arthritis, uveitis, sclerosing cholangitis, and cutaneous lesions.

Ulcerative colitis does not significantly affect fertility except that fertility decreases after colonic resection for ulcerative colitis.[40] Crohn's disease, however, mildly decreases fertility because of extension of ileal inflammation to the nearby oviducts or ovaries and the systemic effects of malnutrition.[41] Inflammatory bowel disease activity is mostly independent of pregnancy. Patients with inactive or mild disease before conception tend to have the same disease activity during pregnancy. Active disease at conception increases the likelihood of active disease during pregnancy and of a poor pregnancy outcome, including spontaneous abortion, miscarriage, stillbirth, or premature delivery.[42] The onset of CD, and to a lesser extent UC, during pregnancy is associated with increased fetal loss.

Differentiating the signs and symptoms of IBD from physiologic changes related to pregnancy or from other obstetrical, gynecologic, or surgical conditions may be difficult. Nausea, emesis, abdominal discomfort, and constipation may be noted during any pregnancy but may also signal a flare of IBD. The differential diagnosis of acute RLQ abdominal pain in a pregnant woman with CD includes CD exacerbation, EP, appendicitis, or adnexal disease. Pyrexia, bloody diarrhea, and weight loss suggest CD exacerbation.

The diagnostic evaluation is influenced by the pregnancy, but indicated tests should be performed. Laboratory evaluation includes a hemogram, serum chemistry profile, and electrolyte determinations, taking into account the physiologic alterations of late pregnancy including anemia, leukocytosis, and hypoalbuminemia. Flexible sigmoidoscopy is well tolerated during pregnancy without maternal complications or fetal toxicity.[17] Colonoscopy has been safely performed during pregnancy, especially during the second trimester, but the experience in the first and third trimesters is relatively limited.[13]

The beneficial effects of IBD therapy on the mother and fetus must be weighed against the potential of fetal toxicity and teratogenicity (Table 45-8). Active disease poses greater risk to the fetus than most therapies.[43] Sulfasalazine and 5-aminosalicylates seem to be safe and can be used when required during pregnancy.[42] Methotrexate, however, is an abortifacient and is associated with congenital skeletal malformations. The FDA categorizes azathioprine and 6-mercaptopurine (6-MP) as class D drugs during pregnancy. Some gastroenterologists, however, continue these medications during pregnancy if required to maintain remission.[42] Anti–tumor necrosis factor biologic therapies appear to be safer alternatives during pregnancy (see Table 45-8). Their safety during pregnancy is, however, somewhat controversial because of conflicting reports and limited data. One study noted a high rate of congenital malformations reported to the FDA associated with this drug class, but another study noted a low rate.[44] This class of drugs should generally be discontinued before contemplated pregnancy, but may be used during pregnancy to control extremely active recent disease. Metronidazole is probably best avoided during the first trimester and perhaps administered only for brief durations during the other trimesters. The antidiarrheal agent diphenoxylate should be avoided during pregnancy because of case reports of teratogenicity when administered during the first trimester.[3] Emergency surgery for toxic megacolon, intestinal obstruction, or massive bleeding should be done expeditiously, whereas elective surgery, such as fistulectomy, should be performed during the second trimester or postpartum . Severe perianal CD may necessitate cesarean section, because episiotomy during vaginal delivery can exacerbate perianal disease.

Hemorrhoids

Hemorrhoids are common in adults and are particularly common during pregnancy, with an estimated incidence of 25% during pregnancy.[45] Contributing factors during pregnancy include increased constipation resulting in increased straining at defecation, gestational increases in the circulating blood volume resulting in venous dilation and engorgement, and vascular compression from the enlarging gravid uterus resulting in venous stasis.[9] Hemorrhoids above the dentate line are internal, whereas those below the dentate line are external.

Hemorrhoids characteristically produce a clinical triad of bright red blood per rectum resembling the color of arterial blood; blood coating rather than admixed with stool; and postdefecatory bleeding, most commonly noted on the toilet paper.[46] Other clinical manifestations include anorectal discomfort, pruritus, or pain associated with prolapse, thrombosis, or incarceration of hemorrhoids.

When the pain from external hemorrhoids is mild to moderate, conservative treatment, including stool softeners, increased liquid intake, topical analgesics, and warm sitz baths, is recommended.[9] Surgical excision under local anesthesia can be performed safely during pregnancy for severely painful or acutely thrombosed external hemorrhoids. General measures for internal hemorrhoids include

Table 45-8 Pharmacologic Therapy for Inflammatory Bowel Disease during Pregnancy

DRUG	FDA CATEGORY DURING PREGNANCY	RECOMMENDATION DURING PREGNANCY
Sulfasalazine	B	Relatively safe. Concern about sulfa moiety causing neonatal jaundice.
Mesalamine	B	Relatively safe.
Infliximab (anti-TNF)	B	Not teratogenic in mice exposed to an analogous antibody. Insufficient clinical data.
Adalimumab (anti-TNF)	B	Believed to be relatively safe drug during pregnancy based on animal data. Little clinical data. Drug manufacturer is placing patients receiving this drug during pregnancy on a national registry.
Certolizumab (anti-TNF)	B	Animal studies have not revealed fetal toxicity. Few clinical data.
Loperamide	B	Relatively safe.
Metronidazole	B	Avoid during first trimester since carcinogenic in rodents.
Corticosteroids	C	Relatively safe. Concern regarding fetal adrenal function and maternal hyperglycemia. Monitor the neonates of mothers who received substantial doses of corticosteroids during pregnancy.
Ciprofloxacin	C	Use with caution, small studies show no significant risk during pregnancy.
Diphenoxylate	C	Avoid, possible teratogen.
Cyclosporine	C	Embryotoxic and fetotoxic at very high doses in rats and rabbits.
6-Mercaptopurine	D	Avoid starting after conception. Might cause IUGR.
Azathioprine	D	Avoid starting after conception. Might cause IUGR. Teratogenic in laboratory animals.
Methotrexate	X	Contraindicated. Teratogen and abortifacient.

FDA, Food and Drug Administration; *IUGR*, intrauterine growth restriction; *TNF*, tumor necrosis factor.

fiber supplements, fluids, and a high-fiber diet to decrease constipation; switching to a slow-release iron supplement to mitigate the constipating effects of iron; topical local anesthetics for anorectal discomfort; skin protectants applied after defecation to reduce anal pruritus; and avoidance of straining during bowel movements.[9] Therapies for severe or refractory symptoms from internal hemorrhoids include band ligation, injection, sclerotherapy, and coagulation. These therapies are generally safe and effective during pregnancy.[47] Invasive therapy, however, is rarely necessary for external or internal hemorrhoids as the symptoms spontaneously resolve soon after delivery.[45]

Mesenteric Ischemia and Infarction

Bowel infarction can occur during pregnancy secondary to intestinal obstruction or mesenteric venous thrombosis.[48] Digoxin, ergot alkaloids, cocaine, and other vasoconstrictors are also associated with mesenteric ischemia. Mild hypercoagulability from hyperestrogenemia during pregnancy may contribute to a mildly increased risk of mesenteric ischemia during pregnancy as compared to other middle-aged patients, but this risk is not high because mesenteric ischemia is predominantly a disease of the elderly. Patients with mesenteric venous thrombosis typically have an insidious onset of poorly localized abdominal pain, with a relatively unremarkable physical examination.[49] The thrombosis is diagnosed by the noninvasive modalities of MRI or CT scanning, and by the invasive modality of the venous phase of angiography. Hematologic evaluation for hypercoagulopathy is recommended.[48]

Irritable Bowel Syndrome

The irritable bowel syndrome (IBS) is most common in younger women. The pathogenesis is poorly defined. Both intestinal motor and sensory abnormalities, particularly hyperalgesia, have been described. IBS is diagnosed, according to the Rome III criteria, by the presence of both abdominal pain and disordered defecation for at least 6 months, with at least two of the following: pain relief by a bowel movement, onset of pain related to a change in stool frequency, and onset of pain related to a change in stool appearance. Endoscopic, radiologic, and histologic intestinal studies reveal no evident organic disease. **Young women typically have diarrhea-predominant IBS but sometimes have predominantly constipation or alternating diarrhea and constipation. Abdominal bloating and distention are common symptoms.**

Few data exist concerning the effect of pregnancy on IBS.[50] The onset of IBS typically predates the pregnancy and rarely begins during pregnancy. Gestational hormones, particularly progesterone, may exacerbate the symptoms of IBS. Presumed IBS in the absence of warning signs or symptoms (e.g., rectal bleeding, pyrexia, or weight loss) should not require invasive tests, such as sigmoidoscopy, during pregnancy. Contrariwise, signs and symptoms of organic disease, such as rectal bleeding or involuntary weight loss, should not be attributed to IBS without proper evaluation. In particular, sigmoidoscopy is indicated for significant nonhemorrhoidal rectal bleeding during pregnancy.[12] **Symptoms of IBS are best treated during pregnancy by dietary modification or behavioral therapy rather than systemic drugs**.[51] Patients with diarrhea-predominant IBS may benefit from elimination of foods from the diet that precipitate diarrhea, such as alcohol, caffeinated beverages, poorly digestible sugars, and fatty foods. Pregnant patients usually require a large amount of dairy products in their diet to ensure adequate calcium intake. Patients may benefit from lactase supplements when ingesting dairy products. Dietary fiber and fluid ingestion may improve constipation-predominant IBS. Polysaccharide bulking agents, such as methylcellulose, appear to be safe during pregnancy due to a lack of systemic absorption. IBS is not believed to affect fertility and pregnancy outcome in the absence of nutritional deficiencies or concomitant disorders.[50]

Splenic Artery Aneurysm Rupture

Splenic artery aneurysm rupture is associated with pregnancy, possibly because of the effects of gestational hormones on the elastic properties of the arterial wall. Rupture most commonly occurs in the third trimester. Patients typically are in shock with left upper quadrant abdominal pain. The diagnosis is suggested by demonstration of a calcified rim from the aneurysm on plain abdominal roentgenogram and is confirmed by abdominal CT scanning or angiography. Treatment consists of fluid resuscitation and prompt surgery, with hemostasis and splenectomy. The maternal mortality rate exceeds 75%, and the fetal mortality rate exceeds 90%.[52] Splenic artery aneurysms should therefore be surgically corrected even if asymptomatic.[52] Abdominal aortic and renal aneurysms can also rupture during pregnancy.

KEY POINTS

- Aside from gastrointestinal and other intra-abdominal disorders incidental to pregnancy, the differential of abdominal pain includes obstetrical, gynecologic, and gastrointestinal disorders related to pregnancy.
- Pregnancy can affect the clinical presentation, frequency, or severity of gastrointestinal diseases. Gastroesophageal reflux disease markedly increases in frequency, whereas peptic ulcer disease markedly decreases in frequency (or becomes inactive) during pregnancy.
- Abdominal ultrasound is the safest and most commonly used abdominal imaging modality to evaluate gastrointestinal conditions during pregnancy.
- Esophagogastroduodenoscopy and flexible sigmoidoscopy can be performed when strongly indicated during pregnancy, such as for significant acute upper and lower gastrointestinal bleeding, respectively.
- Most gastrointestinal drugs appear to be relatively safe for the fetus (FDA category B and C) and can be used when indicated during pregnancy. Gastrointestinal drugs to be avoided during pregnancy include misoprostil, which is an abortifacient (category X) and methotrexate (category X).

SEIZURE DISORDERS

Because they affect approximately 1% of the general population, seizure disorders are the most frequent major neurologic complication encountered in pregnancy. It is important that the practicing obstetrician become familiar with the basic treatment of these disorders. During pregnancy, many non-obstetricians are reticent to evaluate, much less treat, disorders that may coexist or develop during pregnancy. It is the obstetrician's duty to communicate with medical specialists and encourage them to treat the patient appropriately. The obstetrician's responsibility is to ascertain if the treatment may have a detrimental effect on the developing fetus. Together, with the patient, the physicians must establish a risk/benefit analysis and then move forward with therapy. This model not only applies to seizure disorders but to any of the myriad of medical/surgical problems that can coexist with pregnancy.

Seizure disorders may be divided into those that are acquired and those that are idiopathic. Acquired seizure disorders, which account for less than 15% of all seizures, may result from trauma, infection, space-occupying lesions, or metabolic disorders. More than 85% of seizure disorders are classified as idiopathic, meaning that no etiologic agent or inciting incident can be identified. Idiopathic seizures can be divided into types such as tonic-clonic, partial complex with or without generalization, myoclonic, focal, or absence.

In general, initial therapy is based on the type of seizure disorder experienced by the patient. There are, however, many crossovers, and patients may respond differently to each medication despite their seizure type. Therefore, it is not unusual to encounter a patient with any seizure type who may be taking any of the major antiepileptic medications. Furthermore, patients may be placed on a certain medication because they did not tolerate the side effect profile of another anticonvulsant (Table 46-1). Over the past 15 years, therapies have changed, as many new medications have been developed and marketed. Many patients with epilepsy have done very well on their medications, and have not been evaluated by a neurologist for many years. Some patients have been seizure free for many years. Often they have stopped their medications with no untoward effects. Frequently, they abruptly stop all medications as soon as they find out that they are pregnant.[1] Still others have poorly controlled seizures, and it is unclear whether this is due to noncompliance with or ineffectiveness of their medication regimen. Other patients may be taking two medications when they may need only one. **The obstetrician and neurologist must work closely together to guide the patient through her pregnancy and find the safest and most effective medical therapy for the patient.**

TABLE 46-1 COMMON SIDE EFFECTS OF ANTICONVULSANTS

DRUG	MATERNAL EFFECTS	FETAL EFFECTS
Phenytoin	Nystagmus, ataxia, hirsutism, gingival hyperplasia, megaloblastic anemia	Possible teratogenesis and carcinogenesis, coagulopathy, hypocalcemia
Carbamazepine	Drowsiness, leukopenia, ataxia, mild hepatotoxicity	Possible craniofacial and neural tube defects
Valproic acid	Ataxia, drowsiness, alopecia, hepatotoxicity, thrombocytopenia	Neural tube defects and craniofacial and skeletal defects
Lamotrigine	Rash, headache, ataxia, diplopia, blurred vision, dizziness	Possible increase in oral clefts

Through this cooperation, the majority of pregnant women with seizure disorders can have a successful pregnancy with minimal risk to mother and fetus.

Effects of Epilepsy on Reproductive Function

Women with seizure disorders should seek care from an obstetrician/gynecologist as soon as they become sexually active. Contraception may present a challenge to women with epilepsy, and the use of oral contraceptives may require special adjustments. Certain antiepileptic medications have been associated with contraceptive failure, especially the older medications. Carbamazepine, phenobarbital, and phenytoin enhance the activities of hepatic microsomal oxidative enzymes.[2] The cytochrome P450 system is shared by these medications and the steroid hormones. This increased enzymatic activity may lead to rapid clearance of these hormones, which may allow ovulation to occur. **Therefore, medicated patients taking low-dose oral contraceptives may have more breakthrough bleeding[3] and may be at increased risk for unplanned pregnancy.[4,5] This rapid clearance does not appear to be induced by valproate, benzodiazepines,[2] or the new antiepileptic medications.[6]**

Fertility rates may be lower in patients with epilepsy. A retrospective study by Webber and colleagues[3] reviewed fertility rates in individuals with epilepsy over a 50-year period. They found that fertility rates were significantly lower in both men and women with epilepsy, and that this could not be explained solely by the rate of marriage in these patients. Men appeared to be more adversely affected than women. Women with epilepsy had fertility rates 85% of the expected rate. Furthermore, in this retrospective review, women with partial seizures seemed to have lower fertility rates than those with generalized seizures. In a study by Dansky and colleagues,[4] fertility rates appeared to be lower in those women with early-onset epilepsy than those with late-onset disease. Cramer and Jones[2] also investigated the fertility rate in 263 unselected patients with epilepsy. They found that the fertility rate was half that of the general population, and 25% of married patients had no children.[2] In Finland, the birth rate was lower in patients with epilepsy than in the referenced cohort. The hazard ratio (HR), a type of relative risk (RR), was 0.58 in men and 0.88 in women. Yet, even in these studies, the majority of patients with epilepsy were able to conceive without difficulty.

Effect of Pregnancy on Epilepsy

It has been taught that between 30% and 50% of patients show an increase in seizure frequency during pregnancy. This was confirmed in the classic study of Knight and Rhind[5] of 153 pregnancies in 59 patients between 1953 and 1973. **In that study, 45% of patients showed an increase in seizure frequency during pregnancy, whereas 50% had no change and 4.8% experienced a decrease.** Anticonvulsant levels could not be readily measured until the mid-1970s. When this study was performed, anticonvulsant doses were usually only increased by physicians when patients had breakthrough seizures. An important finding from that study, however, was that patients with more frequent seizures tended to have exacerbations during pregnancy.[6] **In fact, virtually all patients who had more than one seizure each month experienced worsening of their epilepsy during pregnancy, whereas only about 25% of patients who had not had a seizure in over 9 months experienced exacerbation of epilepsy during pregnancy.**

With the introduction of new medications and the ability to monitor anticonvulsant levels, these absolute numbers are no longer true. The relationship, however, does remain. Patients with more frequent seizures tend to have exacerbations of seizures during pregnancy. In a large study by Schmidt and colleagues,[6] 63% of patients had no change or a decrease in seizure frequency during pregnancy, whereas only 37% of patients had an increase of seizures during pregnancy. Importantly, in 34 of the 50 patients who showed an increase in seizure frequency during pregnancy, the increase was associated with noncompliance with their drug regimen or sleep deprivation. Conversely, in 7 of the 18 pregnancies in which improvement of seizure frequency was shown, this was related to improved compliance with the drug regimen or a correction of sleep deprivation for the 9 months preceding pregnancy. In a study by Tanganelli and Regesta,[7] seizure frequency did not change or improved in 82.6% of pregnancies. Increases in seizure frequency were often due to noncompliance with medication regimens as well as frequent seizures in the preconception period. In contrast, Sabers and colleagues[8] summarized 151 pregnancies in 124 women with epilepsy between 1978 and 1992. They found that 21% of patients had exacerbations of their seizures during pregnancy and 71% were taking only one medication.[8] Lunardi and colleagues, via a series of interviews, examined the quality of life in women with epilepsy.[9] In this small study, pregnant women with epilepsy experienced no greater stress than those without epilepsy. However, when divided into different segments of gestation, those in late pregnancy showed more markers for stress than their nonpregnant counterparts. As stress is often associated with increased seizure frequency, the obstetrician should pay close attention to symptoms and medication dosing in late pregnancy.

In summary, we now have the means to monitor anticonvulsant levels in patients when necessary, and we have

the medications to control seizures. We also understand that sleep deprivation can be a catalyst for seizures. **With patient cooperation and close surveillance, seizure frequency should remain the same or even improve in most epileptic patients during pregnancy.**

Effects of Pregnancy on the Disposition of Anticonvulsant Medications

It is well known that the levels of anticonvulsant medications can change dramatically during pregnancy. They usually decrease in total concentration as pregnancy progresses. Many factors, including altered protein binding, delayed gastric emptying, nausea and vomiting, changes in plasma volume, and changes in the volume of distribution, can affect the levels of anticonvulsant medications. Also, the addition of increased folic acid to the vitamin regimen can decrease medication levels as folic acid is a cofactor in the metabolism of many of these medications.

Phenytoin use has greatly decreased over the past 10 years, but many patients have been taking it for years and continue its use. Landon and Kirkley[10] and Kochenour and colleagues[11] showed that the serum concentration of phenytoin tends to fall during pregnancy and rise again during the puerperium and postpartum periods. Several factors can account for this. In early gestation, patients often have nausea and vomiting. Phenytoin is usually administered on a once-daily basis. If the patient vomits the medication, the drug levels will be highly variable. Furthermore, an increase in calcium intake during pregnancy, as well as the use of antacids, leads to the formation of insoluble complexes with phenytoin, resulting in lower total drug levels. Also, with delayed gastric emptying in pregnancy, the time to peak drug level is lengthened. Phenytoin is inactivated in the liver. Its rate of conversion may increase greatly during pregnancy, because the activity of oxidative enzymes increases. This is due to increased progesterone levels, which induce enzyme activity. This may also be enhanced by increased folic acid, which serves as a cofactor in these metabolic processes. Outside of pregnancy, approximately 90% of phenytoin is protein bound. Plasma albumin levels decrease during pregnancy, whereas other protein levels may rise. This process causes changes in the total phenytoin level that do not necessarily reflect the free, active phenytoin concentrations. This effect is also enhanced by free fatty acids displacing phenytoin from albumin. In a study by Yerby and colleagues,[12] free levels of phenobarbital, carbamazepine, and phenytoin rose significantly throughout pregnancy while total levels fell. Therefore, the relationship observed in nonpregnant women between total drug and free or active drug is not maintained. Although we do not advocate the routine use of anticonvulsant levels during pregnancy, some patients need to have levels checked. These include patients with frequent seizures who may have questionable compliance. **In the case of phenytoin, free phenytoin levels should be measured.** If the patient has increased seizure activity, medication doses should be increased as long as the patient is not showing signs of toxicity. Likewise, if the medication level is low but the patient is seizure free, no adjustment in dosing is necessary.

Similar pharmacokinetic changes occur with the administration of phenobarbital and carbamazepine but to different degrees. It is extremely rare to find a patient who is taking phenobarbital today, but carbamazepine is widely used. Both of these drugs also show changes in protein binding and increased hepatic clearance during pregnancy. Infants born to the rare mother who has been taking a barbiturate during pregnancy may exhibit some withdrawal symptoms that begin about 1 week after birth and usually continue for up to 2 weeks. These symptoms usually involve minor irritability but may occasionally be more serious.

Carbamazepine also has an active metabolite, carbamazepine 10,11-epoxide. This metabolite can be measured, and this measurement can be clinically useful in many instances. **Carbamazepine is not as highly protein bound as phenytoin and, therefore, is not subject to as wide a fluctuation due to changes in protein levels.** Carbamazepine also induces its own metabolic enzymes in the liver, so the half-life changes as the dose increases.[11]

Lamotrigine is used with increased frequency today. It is being used more often as a "stand-alone" anticonvulsant. In addition, it is used in the treatment of patients with bipolar disorder. **Lamotrigine (Lamictal) clearance increases more than 50% during pregnancy. This effect occurs early in pregnancy and reverts quickly after delivery. Most patients require a higher dose to maintain therapeutic levels during pregnancy.** Concomitant use of carbamazepine may also increase lamotrigine requirements.

Although levetiracetam levels are not routinely checked, pregnancy may decrease the levels of this medication, requiring increased doses. Therefore, if a previously well-controlled patient begins having breakthrough seizures, levels of levetiracetam should be obtained. Pregnancy may have similar effects on the active oxcarbazepine metabolite, the monohydroxy derivative.

All anticonvulsants interfere with folic acid metabolism. Patients on anticonvulsants may actually become folic acid deficient and develop macrocytic anemia. Folic acid deficiency has been associated with neural tube defects (NTDs) and other congenital malformations. Because organogenesis occurs during the first weeks after conception, folic acid supplementation should be begun before pregnancy if possible. A dose of 4 mg daily is recommended. As previously stated, increasing folic acid ingestion may increase the activity of hepatic microsomal enzymes and thus the clearance of anticonvulsant medications. If anticonvulsant levels are being used, they should be checked frequently after folic acid therapy is implemented. Furthermore, therapy with phenytoin may result in increased metabolism of vitamin D, leading to decreased vitamin D levels. The patient should be reminded to take her prenatal vitamins, which include an adequate amount of vitamin D. In the occasional patient on long-term phenytoin, a vitamin D_3 level may be useful in guiding the amount of vitamin D the patient should take.

Neonatal hemorrhage, due to decreased vitamin K–dependent clotting factors (II, VII, IX, X), has been reported in infants born to mothers taking phenobarbital, phenytoin, and primidone. In one series,[13] 8 of 16 infants exposed to these medications had a cord blood coagulation pattern similar to that of a vitamin K deficiency. This occurred earlier than the customary hemorrhagic disease of the newborn. These infants responded to vitamin K

infusion. Bleyer and Skinner[14] reviewed a case of their own and 21 other cases of hemorrhagic disease following anticonvulsant therapy that have appeared in the literature. They reached similar conclusions that these cases are vitamin K–dependent clotting factor deficiencies and that, at birth, infants should be given 1 mg of vitamin K intramuscularly. **A more recent study did not find any increased risk of bleeding in the neonate if the infant received 1 mg of vitamin K intramuscularly (IM) at birth.**[15] This problem is rare today as most neonates are given vitamin K at birth and because phenobarbital and primidone are almost never used today and phenytoin use for epilepsy is greatly decreasing.

Effect of Epilepsy on Pregnancy

The majority of women with seizure disorders who become pregnant have an uneventful pregnancy with an excellent outcome. There appear, however, to be several pregnancy complications that are more prevalent in the mother with epilepsy than in the general population. In a review of all birth certificates for infants born in the state of Washington from 1980 to 1981, Yerby and coworkers[16] identified 200 births to mothers with seizure disorders. Although birth certificate studies are often limited, these researchers controlled for many variables including previous adverse pregnancy outcome and socioeconomic status. **They found that mothers with seizure disorders were 2.66 times more likely to have had a previous fetal death after 20 weeks' gestation than the control population.** Because of the retrospective nature of this study, the authors were unable to correlate this with intrauterine growth restriction (IUGR) or other fetal problems. This increased incidence of stillbirth is confirmed in other investigations.[5] It is unclear in any of these studies what type of fetal surveillance was used and if there were any predictors that these fetuses were at risk. With the increased use of ultrasound to identify IUGR, malformations, and oligohydramnios, many of the stillborn fetuses may have been identified as being at risk and might have undergone antepartum fetal testing and intervention before the fetal demise occurred. These studies also were not stratified by medications taken, dosages, drug levels, or seizure activity during pregnancy.

Hiilesmaa and colleagues,[17] in a study of 150 pregnant women with seizure disorders, found no difference in perinatal mortality rates between patients and controls. However, there were three third-trimester stillbirths in the epileptic group and two in the control group. **Yerby and colleagues[16] also found an increased incidence of preeclampsia in women with seizure disorders.** This finding has also been identified in other large retrospective studies.[5] In a Norwegian study, Borthen and colleagues[18] studied 205 epileptic women and found an increased risk of *severe* preeclampsia with an odds ratio (OR) of 5 and 95% confidence intervals (CIs) of 1.3 to 19.9. Even though this study can be criticized for the wide CI, the findings were statistically significant. It is the first such study to single out severe preeclampsia. Nonetheless, Hiilesmaa and colleagues[17] found no difference in the rate of preeclampsia between pregnant women with epilepsy and controls. Yerby and colleagues[16] also showed a 2.79-fold increase in low-birth-weight infants. In a carefully performed study in Italy, Mastroiacovo and coworkers[19] found that the mean birth weight in neonates born to women with epilepsy was 107 g lower than that of controls. The mean birth weight in the epilepsy group, however, still fell within the normal range for gestational age. The clinical significance of this finding, therefore, is questionable. When considering all commonly used anticonvulsants, this decrease in neonatal weight appeared to be more common in infants exposed in utero to phenobarbital, which is almost never used today.

Mastroiacovo and colleagues[19] also found a decrease in head circumference in infants of mothers with epilepsy. This effect was seen in both untreated women with epilepsy and those receiving medications. Although this change was statistically significant, the mean head circumferences of both study and control infants still fell within the normal range. These authors found no difference in neonatal length comparing groups of mothers with epilepsy and control populations. Hiilesmaa and colleagues[20] also found a decrease in head circumference in neonates born to women with epilepsy. This decrease was most marked in women taking carbamazepine both alone or in combination with phenobarbital. Again, the mean head circumferences, however, were still within the expected normal range.[20] In the follow-up of this study, head circumferences were still smaller at 18 months of age.

Along similar lines, Hvas and colleagues[21] compared pregnancy outcomes in 193 women with epilepsy with those of 24,094 women without epilepsy delivering between 1989 and 1997. They found that birth weight of infants born to women with epilepsy was 208 g less than those born to women without a seizure disorder. **The OR that a woman treated with epilepsy would give birth to an infant with IUGR was 1.9.** Head circumference and body length were also diminished in the infants born to women taking antiepileptic drugs. When smokers with and without epilepsy were compared, there was an increased risk of preterm birth in those who smoked. Battine and colleagues[22] examined anthropometrics in children born to women with epilepsy in Canada, Japan, and Italy. They found some distinct geographic differences in risk for decreased head circumference that may or may not be related to the drug regimen. The RR for small head circumference in infants exposed to more than one medication (polytherapy) was 2.7. A dose-dependent response for both head circumference and body weight was seen with the use of phenobarbital and primidone, both of which are rarely used today. The authors state that in addition to drug regimen, genetic, ethnic, and environmental effects should be taken into account when considering explanations for decreased head circumference and birth weight in infants born to women treated for epilepsy.

Hiilesmaa and colleagues[17,20] found no increase in pregnancy complications in women with epilepsy. They also observed no increase in preterm labor, bleeding, pregnancy-induced hypertension, operative vaginal delivery, or cesarean delivery rates. However, in a study from 1999 to 2006, Borthen and colleagues[18] did show an increase in labor induction and cesarean delivery in mothers being treated for seizure disorder. However, it is unknown whether the increase in induction led to the increase in cesarean deliveries.

Richmond and colleagues[23] showed increased rates of nonproteinuric hypertension, induction of labor, and fetal cardiovascular malformations in 414 women with epilepsy. Rates of other antenatal, intrapartum, and neonatal complications were similar to those in controls. They concluded that women with epilepsy are not at increased risk for obstetrical complications providing appropriate care is available.

Viinikainen[24] reviewed 179 pregnancies in women with epilepsy compared to controls. There were no significant differences in the incidences of preeclampsia, preterm labor, perinatal mortality, or low birth weight. The rate of small-for-gestational-age infants was significantly higher, and neonatal head circumferences were significantly smaller in women with epilepsy.

In summary, women with seizure disorders are at increased risk of IUGR and stillbirth. It also appears that infants born to mothers with seizure disorders, on average, are smaller than their control counterparts. Even though smaller, they are usually within the normal range for gestational age. Furthermore, the incidence of preeclampsia is probably higher in mothers with seizure disorders. **The vast majority of pregnancies, however, are uncomplicated with no increase in complications over the expected rate.** Nonetheless, because of these few potential problems, the obstetrician should be more surveillant for pregnancy-related complications in pregnant women with treated and untreated seizure disorders.

Effects of Anticonvulsant Medications on the Fetus

There is little doubt that anticonvulsant medications are associated with an increase in congenital malformations, but the magnitude of this risk and the association of certain anomalies with specific drugs remain debatable. Although there was some evidence for teratogenicity related to phenytoin in the 1960s, Hanson and Smith[25] identified a specific fetal hydantoin syndrome in 1975. They noted growth and performance delays, craniofacial abnormalities (including clefting), and limb anomalies (including hypoplasia of nails and distal phalanges). They first described this syndrome in five infants exposed to phenytoin in utero. Hanson and colleagues[26] later reported that 7% to 11% of infants exposed to phenytoin had this recognizable pattern of malformations. They furthermore found that 31% of exposed fetuses had some aspects of the syndrome. Yet in 1988 Gaily and colleagues[27] reported no evidence of the hydantoin syndrome in 82 women exposed in utero to phenytoin. Some of the patients had hypertelorism and hypoplasia of the distal phalanges, but none had the full hydantoin syndrome.

Since the original reports by Hanson and colleagues, many studies have reported congenital malformations in infants born to mothers taking both the traditional and newer anticonvulsant medications, particularly facial clefting, congenital heart disease, and NTDs.

The overall rate of anomalies is doubled, but the rate of NTDs with valproic acid is increased tenfold, from 1 to 2 per 1000 to 1% to 2%.[28] It remains of prime importance, however, to treat the patient with the medication that best controls her seizures.

It has been over three decades since Nakane and colleagues[29] published the first major, multi-institutional study investigating the teratogenicity of antiepileptic medications. This study, carried out between 1974 and 1977, examined 902 pregnancies in mothers with idiopathic epilepsy. The overall rate of congenital malformations was 7.2%. This included 8.7% in the mothers who received anticonvulsant medications during pregnancy and 1.9% in nonmedicated mothers. Looking only at live-born infants, 9.9% had malformations (11.5% in the medicated group and 2.3% in the nonmedicated group). Therefore, the incidence of malformations in mothers receiving anticonvulsant therapy was about five times that of the nonmedicated group. Interestingly, Canger and colleagues[30] began collecting data in Italy at the time Nakane's group completed their data collection. Canger and coworkers studied 517 women with epilepsy throughout pregnancy. They found a 9.7% rate of malformations, a proportion strikingly similar to that of Nakane.[29] The importance of this study was that it showed that the findings in Nakane's study were not due to something special in his geographic population but could be applied worldwide.

In Nakane's study,[29] the predominant malformations were cleft lip and palate (3.14%) and cardiovascular malformations (2.95%). Nakane's group also noted that as the number of anticonvulsant medications used in combination during pregnancy increased, the incidence of fetal malformations rose dramatically.[29] The malformation rate was less than 5% when one medication (monotherapy) was used and was greater than 20% when four medications were used. Of note, 537 patients were taking two or more medications, whereas 93 patients were taking only one medication. **This was the first study to show that the risk of anomalies was higher in those receiving polytherapy for epilepsy.**

Kaneko and colleagues[31] confirmed these findings. They performed a prospective study to determine primary factors responsible for the increased incidence of malformations in infants born to mothers being treated with anticonvulsants. They specifically looked at various drug combinations. The overall malformation rate was 14%. In the patients who were receiving a single medication, the malformation rate was 6.5%.[31] The malformation rate for those treated with multiple medications was 15.6%.

Kaneko and colleagues[32] subsequently published a follow-up study to detect malformations in infants exposed in utero to anticonvulsant medications. They compared these results with their previous investigation.[31] The first study examined infants born between 1978 and 1984, whereas the later study evaluated infants born between 1985 and 1989. Whereas 14% of infants had some malformation in the previous study, the malformation rate was only 6.3% in the second group.[32] Again, there was no relationship between the medication taken and the type of malformation found. The lower rate of malformations may be attributable to the increase in patients receiving monotherapy. In the earlier study, 16.1% of patients received a single medication, whereas 63.4% received a single medication in the later study. Jick and Terris[33] matched two nonexposed pregnant women to each of 297 pregnant women exposed to antiepileptic medication. The rate of anomalies in infants born to women with epilepsy was 3.4%,[33] a rate even lower than that found by Kaneko and colleagues in their 1992 study.[32] Nonetheless, Jick and

Terris found the RR for a woman on antiepileptic medications to give birth to an infant with an anomaly was 3.3.[33]

Most neurologists are treating patients with a single agent. **Now that blood levels of anticonvulsant medications can be easily measured, single medications can be given at higher doses to make certain that therapeutic levels are achieved.** This approach has lessened the need for multiple medications. Counseling is also more involved today because many patients are receiving the newer anticonvulsant medications with which we have less experience.

The same concept was verified in a study by Lindhout and colleagues.[34] They compared the pattern of malformations in the offspring of two cohorts of women with seizure disorders, one from 1972 to 1979 and one from 1980 to 1985. In the earlier cohort, 15 of 151 (10%) of live-born infants had at least one congenital anomaly. The most common anomalies were those most frequently reported for anticonvulsant medications: congenital heart defects, facial clefts, facial dysmorphism, and developmental delays. In the latter cohort, 13 of 172 infants (7.6%) exposed in utero to anticonvulsant medications had congenital malformations. The most frequent anomalies in this group were spinal defects and hypospadias. All of these anomalies were associated with maternal therapy with valproate, carbamazepine, or both. In the earlier cohort of patients, the mean number of drugs used during gestation was 2.2 compared with 1.7 in the later cohort. Whereas only 28% of women in the earlier cohort received only one medication, 47% of the women received monotherapy in the second group of patients. The lower overall rate of malformations in the latter cohort appeared to be due to the reduction in the number of pregnancies during which a combination of medications was used. It is also apparent in this study that neither the duration of maternal epilepsy nor maternal age was associated with malformations in the infants born to these mothers.

Dravet and colleagues[35] described the risk for malformations in the infants of 227 women participating in a prospective study between 1984 and 1988. There was a 7% malformation rate among infants born to mothers taking antiepileptic medications compared with 1.36% in the control group. Therefore, fetuses exposed in utero to anticonvulsants had an RR of 6.9 of being born with a congenital malformation. This is double the risk demonstrated by Jick and Terris.[33] In this study, the frequency of spina bifida was 17 times more than would be expected in the general population, and heart defects were 9.6 times greater than expected. Cleft lip with or without cleft palate was 8.4 times more frequent than expected in the general population. Using logistic regression, **these authors concluded that valproate and phenytoin were the two most teratogenic medications.**[35] This is important because, although phenytoin is less frequently used today, valproate is still commonly used. The cases of NTDs and congenital heart defects were studied carefully and could not be related to a familial disposition for these defects. As other studies have shown, there was a higher incidence of malformations in infants born to mothers receiving polytherapy (16%) than in those receiving monotherapy (6%). This relationship between the number of medications taken and the rate of malformations may not be as clear today, as most women taking multiple anticonvulsants are taking at least one of the newer medications. There are not a lot of data on malformations rates with combinations of these medications.

A study by Koch and colleagues,[36] however, showed no difference between the rate of malformations in mothers receiving polytherapy and mothers receiving a single medication. Furthermore, they found that the infants born to mothers with epilepsy, regardless of therapy, had only twice as many major malformations as infants born to the control population. The number of minor anomalies, however, was approximately three times greater in infants born to mothers receiving anticonvulsant medication than in the control group. **In the mothers receiving monotherapy, those taking valproate had the highest rate of minor malformations.**[36] In this study, there appeared to be a link between the dose of valproate and the rate of malformations.

Gaily and Granstrom[37] also investigated minor anomalies in children of mothers with epilepsy. These authors point out that many of the supposedly specific syndromes resulting from intrauterine exposure to certain medications have many common features. They argue that specific syndromes and their association with specific drugs, as well as the frequencies of these syndromes, have not been confirmed in epidemiologic studies. They found that many of the minor anomalies that are thought to be specific features of a medication appear to be genetically linked with epilepsy.[37] Indeed, this is in contrast to many of the other published studies. In this study only distal digital hypoplasia appeared to be a specific marker for phenytoin teratogenicity.

Yerby and colleagues[38] also looked prospectively at malformations in infants born to mothers with epilepsy. They further investigated whether pure folate deficiency might be responsible for the malformations. None of the women in their study had deficient folate levels. There was no difference in major malformations between patients and controls in this study. In fact, only 0.4 mg of folic acid supplementation is recommended preconception in a recent practice parameter update by the American Academy of Neurology. The infants born to mothers taking anticonvulsant medications, however, had a higher mean number of minor anomalies. They found no difference in the number of minor anomalies whether the child was exposed in utero to one anticonvulsant medication or to several.[38] The authors also confirm the great overlap in minor anomalies and various medications, further casting doubt on whether individual medications cause specific syndromes.[38]

Nulman and colleagues[39] examined 36 mother-child pairs exposed to carbamazepine, 34 pairs exposed to phenytoin, nine pairs of nonmedicated epileptic women, and matched each to nine mother-child pairs not exposed to teratogens. Minor anomalies were more common in offspring of mothers receiving either carbamazepine or phenytoin (RR 2.1).[39]

Valproate is still often used in in antiepileptic therapy as an anticonvulsant of choice because of its low side effect profile. It has, however, been reported to be associated with specific anomalies. DiLiberti and colleagues,[40] in 1984, reported a specific fetal valproate syndrome. This

was based on seven infants. They found a consistent facial phenotype in all seven children and other birth defects in four. This syndrome phenotype was confirmed by others. Jager-Roman and colleagues,[41] in 1986, reported fetal distress in 50% of 14 infants receiving valproate. Furthermore, 28% had low Apgar scores. They also found the same craniofacial defects as reported by DiLiberti and colleagues.[40] **Lindhout and Schmidt[42] confirmed the association between NTDs and valproate exposure in utero. They contend that there is a 1.5% risk of an infant being born with an NTD if the mother took valproate in the first trimester.** Lindhout and colleagues[43] also studied 34 cases of NTDs in mothers taking anticonvulsant medications. In 33 of the 34 cases, mothers were exposed to either valproate or carbamazepine. **Most of the cases of NTDs were lumbosacral. There was only one case of anencephaly. This implies that these medications have a predisposition to cause lumbosacral defects, because in the general population, spina bifida and anencephaly are equally distributed.** In only two cases were other major malformations found. The development of NTDs in these infants of mothers taking valproate also appeared to be a dose-dependent phenomenon. In a mouse model, valproate alters folic acid metabolism in embryos. This could account for the increased risk of NTDs in infants born to mothers who have taken valproate.

The U.K. registry[44] has reported a higher malformation rate with valproate, 5.9%, than with carbamazepine, 2.3%, and lamotrigine, 2.1%. In the North American registry, the RR of having an affected offspring for the valproate-exposed woman was 7.3.[45] Valproate is associated with major malformations other than NTDs (RR 3.77). The risk is dose dependent, beginning at 600 mg/day and becoming more prominent at 1000 mg/day.[46] Polytherapy including valproate carries more risk than any other polytherapy.[47] In summary, the pattern of physical abnormalities is related to the use of anticonvulsant drugs, rather than to epilepsy itself.[48]

In 1989, Jones and colleagues[49] reported a pattern of minor craniofacial defects, fingernail hypoplasia, and developmental delay in infants exposed in utero to carbamazepine. Others have shown that there is a 1% risk of spina bifida in infants of mothers taking carbamazepine. Carbamazepine increases the incidence of NTDs, cardiovascular and urinary tract anomalies, and cleft palate. Because this spectrum of defects (except spina bifida) is similar to that in the fetal hydantoin syndrome, Jones and colleagues[49] hypothesized that, because both drugs are metabolized through an arene oxide pathway, perhaps an epoxide intermediary is the teratogenic agent. Those fetuses with low levels of epoxide hydrolase are exposed to higher levels of epoxide intermediaries, and this may lead to an increase in malformations. Conversely, fetuses with high enzyme levels clear epoxides rapidly, minimizing exposure to the potential teratogens. Phenytoin, phenobarbital, and to a lesser extent carbamazepine are metabolized through this pathway. Much work in this area is being performed by researchers who believe that low levels of epoxide hydrolase activity may be the common link explaining why only certain fetuses exposed to anticonvulsant medications in utero develop congenital malformations.

The increased risk of delivery of a child with an NTD after first trimester exposure to carbamazepine and valproate continues to be studied using epilepsy registries. Jentink and colleagues[50] showed that there was a 3.3% risk of delivering a child with a congenital malformation after first trimester carbamazepine exposure, but this is significantly higher than in the general population in their study. However, that is not significantly higher than the background risk of malformations found in most populations. However, they showed an increased risk of spina bifida (OR 2.6 with 95% confidence level of 1.2 to 5.3).[50] They found this risk, however, to be significantly lower than the risk associated with first trimester valproate exposure.

Jentink and colleagues[51] showed that after valproate exposure, there was an increase in 6 of the 14 malformations investigated. The OR for spina bifida was 12.7 (95% CI 7.7 to 20.7). However, of particular interest, the OR for craniosynostosis was 6.8 with a CI of 1.8 to 18.8. Also the OR for cleft palate was 5.2 (95% CI 2.8 to 9.9). **This study confirms that valproate exposure, even as monotherapy in the first trimester, is associated with an increased risk of major congenital malformations.**[51]

New antiepileptic drugs have been approved and have been rapidly incorporated into clinical practice in the last decade. There is a need for these medications because 25% to 30% of epileptic patients are not adequately controlled by conventional therapies. These newer medications work at the level of neurotransmitters such as gamma-aminobutyric acid and also by blockade of sodium channels. **Table 46-2 lists these drugs, with their dosages, and describes other considerations in their use.** Gabapentin and pregabalin are also used in chronic pain,

TABLE 46-2 NEWER ANTIEPILEPTIC AGENTS

MEDICATION	USUAL DOSE (mg/day)	DOSES/ DAY	SPECIAL NOTES
Gabapentin	900-3600	3	Not enzyme inducer Antacids interfere
Lamotrigine	300-500	1 or 2	Rash in 11.2% Not enzyme inducer Half-life affected by meds
Topiramate	100-400	2	May interfere with OCs Moderate enzyme inducer
Tiagabine	8-56	2 or 4	Does not interfere with OCs Not enzyme inducer
Oxcarbazepine	600-2400	2	Moderate enzyme inducer
Levetiracetam	1000-3000	2	Not enzyme inducer
Zonisamide	400-600	2	Not enzyme inducer

OCs, Oral contraceptives.

mood stabilization, and neuropathies. Lamotrigine and oxcarbazepine are commonly used to treat bipolar disorder. Therefore, the obstetrician may encounter patients other than those with epilepsy on gabapentin. At present, there are limited data on its fetal effects in pregnancy. **Patients should be warned that we do not yet know enough about the effects of the drug on the developing fetus to appropriately counsel them. Nonetheless, if this medication is necessary to keep seizures under control, it should be used.**

Lamotrigine is an adjunctive therapy for the treatment of simple and complex seizures with and without secondary generalization. Approximately 10% of patients discontinue the medication because of a rash. Severe rashes such as Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported. The severe rashes have occurred with more frequency in pediatric patients. In one study, a rash necessitating discontinuation of therapy was found in only 2% of 11,316 treated patients.[52] **Cord blood levels of lamotrigine are equal to those of maternal serum. Also, the median milk/maternal plasma concentration ratio of 0.61 indicates that there are significant milk levels. In the lamotrigine pregnancy registry, of 595 exposures to date, 17 had major defects (2.9%), not significantly increased over the expected rate.[51] However, the American registry has reported an increased risk of nonsyndromic oral clefts.**

Topiramate, oxcarbazepine, and levetiracetam are also used as adjunctive therapies for epilepsy. All are effective. At this point there is limited information on the use of these medications in pregnancy. In March 2011, the FDA released an advisory that there was a 1.3% risk of oral clefts with the use of topiramate in pregnancy. This was based on findings from the North America Anti-Epilepsy Drug Registry. However, there has not yet been a major peer-reviewed publication with these data. **Molgaard-Nielsen and Hviid[53] reviewed 1532 infants who were exposed to lamotrigine, oxcarbazepine, topiramate, gabapentin, and levetiracetam in the first trimester.** They compared results with 836,263 infants that were not exposed to these medications. The rate of anomalies was 3.2% versus 2.4%, which gives an adjusted OR of 0.99. **They conclude that in Denmark these medications are not associated with an increased risk of malformations.**[53] In summary, the neurologist and obstetrician should work together and use whichever medications work best for the patient.

There has been much debate over whether epilepsy itself and the use of antiepileptic medications are associated with psychomotor delays or mental retardation. In the landmark study by Nelson and Ellenberg, an intelligence quotient (IQ) below 70 was seen in 65.2 per 1000 7-year-old children in the seizure group compared with 34 per 1000 in the age-matched control group, a statistically significant difference. Before generalizations can be made, many confounding factors must be evaluated, including other anomalies and social environment. In another review, none of the major antiepileptic medications appeared to carry special risk for mental retardation. However, polytherapy and inherited deviations in antiepileptic medication metabolism in the fetus may increase the risk for mental retardation. Other factors associated with maternal epilepsy such as seizures during pregnancy, inherited brain disorders, and a nonoptimal psychosocial environment can also affect a child's psychomotor development. These factors are hard to control in any study. In a report by Gaily and colleagues,[54] two of 48 (4.1%) infants of mothers with epilepsy had mental retardation, and two additional infants had borderline intelligence. The mean IQ of the infants exposed in utero to anticonvulsant medications was statistically lower than the control group. When these four children were excluded from the analysis, the difference in mean IQ disappeared.[54] **There was no increased risk of low intelligence attributable to fetal exposure either to antiepileptic medications below toxic levels or to brief maternal convulsions.** No particular medication appeared to be associated with a lower IQ. Social class also appeared to play a role in the differences in IQs in these patients.

Moore and colleagues[55] reviewed 57 infants with fetal anticonvulsant syndromes. Eighty-one percent reported behavioral problems, with hyperactivity being the most common (34%). Two or more autistic features were found in 34 (60%) of the 57 children. Four were diagnosed with autism and two with Asperberger's syndrome. Learning difficulties were found in 77% and speech delay in 81%. Gross and fine motor delays were identified in 60% and 42%, respectively. These percentages seem high, but it is important to remember that all of these children had already been identified as having an anticonvulsant syndrome. Meador and colleagues[56] showed that at age 3, infants with in utero exposure to valproate had a significantly lower IQ (92) when compared to exposures to carbamazepine (98), lamotrigine (101), and phenytoin (99). Even though all of these findings are statistically significant, it is unknown whether these findings are clinically significant.

In summary, there appears to be a small, undefined risk of a slightly lower IQ, psychomotor delay, and an increase in behavior problems in infants born to mothers with epilepsy. With the exception of valproate, it does not appear that any particular medication results in a higher risk of this outcome.[56]

Preconceptional Counseling for the Reproductive-Age Woman with a Seizure Disorder

Although it is not always possible, it is preferable to counsel the patient with epilepsy before she becomes pregnant. A detailed history should be taken to determine if there are any seizure disorders or congenital malformations in the family. The obstetrician must stress that the patient has greater than a 90% chance of having a successful pregnancy resulting in a normal newborn. A detailed history of medication use and seizure frequency should be obtained. The patient must be informed that if she has frequent seizures before conception, this pattern will probably continue. Furthermore, if she has frequent seizures, she should be encouraged to delay conception until control is better, even if this entails a change or an additional medication. The obstetrician must stress that controlling seizures is of primary importance and that the patient will need to take whatever medication or medications are necessary to achieve this goal throughout her pregnancy. **If the patient has had no seizures during the past 2 to 5 years, an attempt may be made to withdraw her from anticonvulsant medications.** This is usually done over a 1- to 3-month

period, slowly reducing the medication. Up to 50% of patients relapse and need to start their medications again. This withdrawal should be attempted only if the patient is completely seizure free for 2 years, has a normal electroencephalogram (EEG), and only with the help of a neurologist. During the period of withdrawal from medications, patients should refrain from driving.

It is best to have the patient taking a single medication during pregnancy. If the patient is on multiple medications, the patient can be changed to monotherapy over several months. The drug of choice for the specific type of epilepsy should be the one chosen for monotherapy. As the other medications are gradually withdrawn, levels of the remaining medication should be monitored to make certain that the level remains therapeutic. Many individuals do not believe that medication levels are useful. However, when withdrawing or changing medications, any additional data available can help the physician in making decisions. The patient should refrain from conceiving until seizures have been well controlled for several months on the single medication. **The patient must also be counseled that she should get adequate rest and sleep during pregnancy, because sleep deprivation is associated with increased seizure frequency.**

The most important point is to control maternal seizures with the least side effects to the mother and fetus. There may be some additional concern for using valproate in pregnancy due to the reported increased incidence of fetal distress and malformations, including NTDs. However, if valproate is the anticonvulsant that works best for the patient, it should be used with appropriate counseling and, in pregnancy, ultrasound to detect possible fetal anomalies should be performed at the appropriate gestational age. If valproate is selected, the total dose should be divided into three to four administrations daily to avoid high peak plasma levels. As described earlier, NTDs also occur with the use of carbamazepine. There is less information concerning the newer antiepileptic drugs and teratogenesis. If they need to be used for good seizure control, they should be implemented as part of the patient's therapy.

Folic acid supplementation should be begun before pregnancy. Folic acid supplementation may help to prevent NTDs, which have been seen most commonly with carbamazepine and valproate treatment but have been reported in women taking other anticonvulsants as well. Studies have shown that folic acid may decrease the incidence of NTDs in at-risk women.[11] It is important that this be implemented before pregnancy or very early in pregnancy, because open NTDs occur by the end of the fifth week of gestation. Furthermore, low folate levels have been associated with an increase in adverse pregnancy outcomes in women taking anticonvulsants.[57] Anticonvulsant levels should be checked frequently after implementing or increasing folic acid administration, because folate leads to lower anticonvulsant levels.[57] A daily dose of folic acid of 4 mg/day is recommended. Patients should also be encouraged to take their prenatal vitamins, which contain vitamin D. This is because anticonvulsants may interfere with the conversion of 25-hydroxycholecalciferol to 1-25-dihydroxycholecalciferol, the active form of vitamin D.

Mothers with idiopathic epilepsy often ask if their child will develop epilepsy. There is a surprising paucity of studies in this area. **Children of parents without seizures have a 0.5% to 1% risk of developing epilepsy. It appears that the infant born to a mother with a seizure disorder of unknown etiology has a four times greater chance of developing idiopathic epilepsy than the general population.** Furthermore, it appears that epilepsy in the father does not increase a child's risk of developing a seizure disorder. Many of the rare seizure disorders have a stronger genetic component.[54]

Care of the Patient During Pregnancy

Once the patient becomes pregnant, it is of the utmost importance to establish accurate gestational dating. This will prevent any confusion over fetal growth in later gestation. **The patient's anticonvulsant level should be followed as needed and dosages adjusted accordingly to keep the patient seizure free.** It is a common pitfall to monitor levels too frequently and adjust dosages in a likewise frequent manner. It is important to remember that it takes several half-lives for a medication to reach a steady state (Table 46-3). Drugs such as phenobarbital have extremely long half-lives, and the levels should not be checked too frequently. If levels are measured before the drug reaches a steady state and the dosage is increased, the patient will eventually become toxic from the medication. Drug levels should be drawn immediately before the next dose (trough levels) in order to assess if dosing is adequate. If the patient is showing signs of toxicity, a peak level may be obtained.

At approximately 16 weeks' gestation, the patient should undergo blood testing for maternal serum marker screening in an attempt to detect an NTD. This, coupled with ultrasonography, gives a more than 90% detection rate for open NTDs. If the patient is difficult to scan or if she wants to be even more certain that there is no NTD, amniocentesis can be undertaken. This should be considered if the patient is taking valproate or carbamazepine,

TABLE 46-3 ANTICONVULSANTS COMMONLY USED DURING PREGNANCY

DRUG	THERAPEUTIC LEVEL (mg/L)	USUAL NONPREGNANT DOSAGE	HALF-LIFE
Carbamazepine	4-10	600-1200 mg/day in three or divided doses (two doses if extended-release forms are used)	Initially 36 hr, chronic therapy 16 hr
Phenobarbital	15-40	90-180 mg/day in two or three divided doses	100 hr
Phenytoin	10-20, total; 1-2, free	300-500 mg/day in single or divided doses*	Average 24 hr
Primidone	5-15	750-1500 mg/day in three divided doses	8 hr
Valproic acid	50-100	550-2000 mg/day in three or divided doses	Average 13 hr
Ethosuximide	40-120	1000-2000 mg/day in two divided doses	60 hr

*If a total dose of more than 300 mg is needed, dividing the dose will result in a more stable serum concentration.

because these medications appear to carry almost the same risk as if the patient had a family history of an NTD.[42,43] At 18 to 22 weeks, the patient should undergo a comprehensive, targeted ultrasound examination by an experienced obstetrical sonographer to look for congenital malformations. A fetal echocardiogram can be obtained at 20 to 22 weeks to look for cardiac malformations, which are among the more common malformations in women taking any antiepileptic medications. If fetal echocardiography is not readily available, it is reassuring to remember that an adequate four-chamber view of the heart on ultrasound will identify 68% to 95% of major cardiac anomalies.[58]

As previously noted, there appears to be an increased risk for IUGR for fetuses exposed in utero to anticonvulsant medications. If the patient's weight gain and fundal growth appear appropriate, regular ultrasound examinations for fetal weight assessment are probably unnecessary. If, however, there is a question of poor fundal growth or if the patient's habitus precludes adequate assessment of this clinical parameter, serial ultrasonography for fetal weight can be performed.

In older and retrospective studies, there appears to be an increased risk of stillbirth in mothers taking anticonvulsant medications.[5,54] In a prospective study, however, this complication was not seen.[17] As previously noted, in the studies that showed an increase in stillbirths, factors such as IUGR or oligohydramnios were not prenatally identified. With modern surveillance and the more common use of ultrasonography, many of these risk factors can be detected before the fetus faces imminent risk. Nonstress testing, therefore, is not necessary in all mothers with seizure disorders. It should be limited to those who have other medical or obstetrical complications that place the patient at an increased risk for a stillbirth. There may be an increased risk of preterm contractions and possibly preterm labor in epileptic women exposed to anticonvulsant medications.[59]

The key to managing anticonvulsants in pregnancy is individualization of therapy, ideally with a single medication. Medication levels should be used as an adjunct to following symptoms. The physician should not treat levels alone. A brief seizure during pregnancy does not appear to be deleterious to the fetus.[19] It is best to use the lowest dose of a single medication possible that will keep the patient seizure free. This, however, must be individualized. For instance, if the patient usually experiences seizures during the day and drives, it is important to make certain that the patient remains seizure free. For this type of patient, drug dosages should be increased if levels fall. If, on the other hand, the patient only has brief partial complex seizures that do not generalize and occur only during her sleep, it is optimal to keep the medications at the lowest serum concentration that will keep her seizure free. An occasional seizure of this type would not harm either the patient or her fetus.

Labor and Delivery

Vaginal delivery is the route of choice for the mother with a seizure disorder. If the mother has frequent seizures brought on by the stress of labor, she may undergo cesarean delivery after stabilization. This, however, is rare. With the use of epidural analgesia, the stress of labor can be virtually obviated in the parturient with epilepsy. Furthermore, seizures during labor may cause transient fetal bradycardia.[17] The fetal heart rate should be given time to recover. If fetal bradycardia persists, one must assume fetal compromise or placental abruption and proceed with cesarean delivery.

Management of anticonvulsant medications during a prolonged labor presents a challenge. **During labor, oral absorption of medications is erratic and, if the patient vomits, almost negligible. Phenytoin and levetiracetam are available in intravenous preparations.** Fosphenytoin, although expensive, is available and makes the administration of intravenous phenytoin much easier. If the patient's phenytoin level is normal, the usual daily dose may be administered intravenously. The medication should only be mixed in normal saline and must be administered at a rate no faster than 50 mg/min. Fosphenytoin is easier to use, as it is less likely to cause a maternal arrhythmia. It is problematic if the patient is taking carbamazepine. This medication is not manufactured in a parenteral form, although extended-release forms are now used by many patients. Oral administration may be attempted, but if the patient has seizures or a preseizure aura, she may be loaded with a therapeutic dose of phenytoin to carry her through labor. The usual loading dose is 10 to 15 mg/kg administered intravenously at a rate no faster than 50 mg/min. This should be effective in controlling seizures. Short-active benzodiazepenes may also be used for acute seizures, but one must remember that they can cause early neonatal depression as well as maternal apnea. Prenatal diagnostic techniques cannot be expected to detect all malformations. Even if the infant appears to have no anomalies, an experienced clinician should be present at the delivery of the infant born to a mother taking anticonvulsant medications.

New Onset of Seizures in Pregnancy and the Puerperium

Occasionally, seizures are diagnosed for the first time during pregnancy. This may present a diagnostic dilemma (Table 46-4). If the seizures occur in the third trimester, they are eclampsia until proven otherwise and should be treated as such until the physician can perform a proper evaluation. The treatment of eclampsia is delivery, but the patient must first be stabilized. It is often difficult, however, to distinguish eclampsia from an epileptic seizure. The patient may be hypertensive initially after an epileptic seizure and may exhibit some myoglobinuria secondary to muscle breakdown, which will test as proteinuria on a routine urinalysis. The diagnosis becomes clearer over time, but in either case, rapid, thoughtful action must be undertaken. The first physician to attend a patient after a seizure may not be an obstetrician/gynecologist, and magnesium sulfate may not be started acutely. This should be remedied as soon as possible.

If the patient develops seizures for the first time at an earlier gestational age, she should be evaluated and started on the proper medication. The physician must look for acquired causes of seizures, including trauma, infection, metabolic disorders, space-occupying lesions, central nervous system (CNS) bleeding, and ingestion of drugs such as cocaine and amphetamines. When a seizure occurs,

TABLE 46-4 DIFFERENTIAL DIAGNOSIS OF PERIPARTUM SEIZURES

	BLOOD PRESSURE	PROTEINURIA	SEIZURES	TIMING	CSF	OTHER FEATURES
Eclampsia	+++	+++	+++	Third trimester	Early: RBC, 0-1000; protein, 50-150 mg/dL Late: grossly bloody	Platelets normal or ↓ RBC normal
Epilepsy	Normal	Normal to +	+++	Any trimester	Normal	Low anticonvulsant levels
Subarachnoid hemorrhage	+ to +++ (labile)	0 to +	+	Any trimester	Grossly bloody	
Thrombotic thrombocytopenic purpura	Normal to +++	++	++	Third trimester	RBC 0-100	Platelets ↓↓ RBC fragmented
Amniotic fluid embolus	Shock	–	+	Intrapartum	Normal	Hypoxia, cyanosis Platelets ↓↓ RBC normal Headache
Cerebral vein thrombosis	+	–	++	Postpartum	Normal (early)	Occasional pelvic phlebitis Oxytocin infusion rate >45 mU/min
Water intoxication	Normal	–	++	Intrapartum	Normal	Serum na <124 mEq/L
Pheochromocytoma	+++ (labile)	+	+	Any trimester	Normal	Neurofibromatosis
Autonomic stress syndrome of high paraplegics	+++ with labor pains	–	–	Intrapartum	Normal	Cardiac arrhythmia
Toxicity of local anesthetics	Variable	–	++	Intrapartum	Normal	

Modified from Donaldson JO: Peripartum convulsion. In Donaldson JO (ed): Neurology of Pregnancy. Philadelphia, WB Saunders, 1989, p 312.

the patient must be stabilized, and the physician must make certain that an adequate airway is established for the protection of both mother and fetus. The physician should also seek focal signs that may be more suggestive of a space-occupying lesion, CNS bleeding, or an abscess. Blood samples should be obtained for electrolytes, glucose, ionized calcium, magnesium, renal function studies, and toxicologic studies while intravenous access is being established. If the patient experienced a tonic-clonic seizure, and the attending physician believes that this is probably new-onset epilepsy, she should be started on the appropriate anticonvulsant medication while awaiting results of laboratory studies. If she is not in status epilepticus and is not obtunded, this medication may be given orally.

If the patient has recurrent generalized seizures, status epilepticus, immediate therapeutic action must be taken. The drug of choice is intravenous phenytoin or fosphenytoin, because they are highly effective, have a long duration of action, and have a low incidence of serious side effects. These medications should be administered in a loading dose of 15 to 20 mg/kg at a rate not exceeding 50 mg/min. Rapid infusion of phenytoin may cause transient hypotension and heart block. Therefore, if available, fosphenytoin is a better choice. If possible, the patient should be placed on a cardiac monitor while receiving a loading dose of phenytoin. Also, this medication must be given in a glucose-free solution to avoid precipitation. If phenytoin and fosphenytoin are unavailable, a benzodiazepine may be used as a first-line drug for status epilepticus. These drugs, however, cause respiratory depression, and the physician must have the ability to intubate the patient, if necessary, when these medications are used. If these measures are ineffective, an anesthesiologist and a neurologist should be immediately consulted if they are not already involved in the patient's care.

Any patient experiencing seizures for the first time during pregnancy without a known cause should undergo an EEG and intracranial imaging. In looking only at eclamptic patients, Sibai and colleagues[60] found that EEGs were initially abnormal in 75% of patients but normalized within 6 months in all women studied. Although this group found no uniform abnormalities on computed tomography (CT) in this series of eclamptic patients, they did find that 46% and 33% had some abnormal findings on magnetic resonance imaging (MRI) and CT, respectively. Most of the findings were nonspecific and were not helpful in diagnosis or treatment. If the physician is not certain that the patient has eclampsia, an imaging study should be part of the evaluation described previously.

Postpartum Period

The levels of anticonvulsant medications must be monitored frequently during the first few weeks postpartum, because they can rise rapidly. **If the patient's medication dosages were increased during pregnancy, they will need to be decreased rather rapidly after delivery to prepregnancy levels.** All of the major anticonvulsant medications cross into breast milk. The levels vary in breast milk from 18% to 79% of the plasma levels. The use of these medications, however, is not a contraindication to breastfeeding. Topiramate has been associated with neonatal weight loss and probably should not be used if the mother is breastfeeding.

All methods of contraception are available to women with idiopathic seizure disorders. The majority of women are able to take oral contraceptives without any adverse

side effects. Oral contraceptive failures are more common in women taking certain anticonvulsants, because some of the major anticonvulsant medications induce hepatic enzymes (cytochrome P 450), which metabolize estrogen faster. The enzyme-inducing drugs are phenytoin, carbamazepine, and phenobarbital. With topiramate and oxcarbazepine, the enzyme-inducing effects occur at higher doses, 200 mg and 1200 mg, respectively. This enzyme-inducing effect is not seen with lamotrigine, zonisamide, gabapentin, tiagabine, valproate, or levetiracetam (see Table 46-2).

In conclusion, the majority of women with idiopathic epilepsy have an uneventful pregnancy with an excellent outcome. To optimize neonatal outcome, the patient should take only one medication and, when possible, use the lowest dose effective in keeping her free of seizures. It is important, however, for the patient to realize that prevention of seizures is the most important goal during pregnancy. Simple interventions such as taking folic acid before conception, taking prenatal vitamins containing vitamin D, and giving the infant vitamin K at birth will help to optimize the outcome. There is an increase in congenital malformations in infants exposed to anticonvulsant medications in utero. The majority of infants exposed to these medications, however, will have no malformations. With modern techniques for prenatal diagnosis, including ultrasound and quadruple screening, many of these malformations can be detected early. The majority of women with epilepsy labor normally and have spontaneous vaginal deliveries. In short, with close cooperation and excellent communication among the obstetrician, neurologist, and pediatrician, the vast majority of these patients will have a safe pregnancy with an excellent outcome.

In 2009, the American Academy of Neurology, with some input from ACOG, made some recommendations to help guide physicians in caring for pregnant women with epilepsy.[61] **They recommend, if possible, avoiding valproate and polytherapy during the first trimester of pregnancy to help prevent anomalies. They recommend the avoidance of valproate and polytherapy throughout pregnancy to prevent reduced cognitive outcomes.** There is less evidence, but they feel that phenytoin and phenobarbital should be avoided because they may be associated with decreased cognitive outcomes. The offspring of women exposed to antiepileptic medication are probably at risk for being born small for gestational age and having a 1-minute Apgar score of less than 7.[61]

MIGRAINE

Headaches are extremely common in women, and the majority of migraine headaches occur in women of childbearing age. Migraines can be classified as those with aura (other neurologic signs and symptoms) and those without aura. Maggioni and colleagues[62] surveyed 430 women 3 days postpartum about their headache histories, and 126 (29.3%) were found to be primary headache sufferers. Of these patients, 81 suffered from migraine without aura, 12 suffered from migraine with aura, and 33 had tension-type headaches. Migraines are associated with vasodilation of the cerebral vasculature and last a variable amount of time. They are often accompanied by photosensitivity (and/or phonosensitivity) and nausea. Migraines with aura may be accompanied by sensations in the extremities and other lateralizing signs, sometimes making them difficult to distinguish from transient ischemic attacks. Migraines with these symptoms are often referred to as atypical migraines.

Migraine symptoms tend to improve during pregnancy. Maggioni and colleagues[62] found that 80% of patients experienced either complete remission or a 50% reduction in headaches during pregnancy. Improvement was more common after the first trimester. Others found that migraines disappeared during pregnancy in 67% of cases, or that 60% to 70% of women either go into remission or improve significantly, usually in the second and third trimesters. Migraine type does not seem to be a prognostic factor. Those with menstrual (catamenial) migraines showed the most improvement. However, 4% to 8% show significant worsening during pregnancy.

In 508 women with a history of migraine from the Collaborative Perinatal Project, patients with migraines smoked more heavily and had a longer smoking history than did their headache-free peers. They also found that in nonsmokers, migraine was often associated with allergies. In a study by Ertresveg and colleagues,[63] 58% of subjects with migraine reported having no headache during pregnancy. Transient neurologic symptoms were more common in patients with a history of migraine. Chen and Leviton[64] examined data from the large, prospective Collaborative Perinatal Project of 55,000 pregnancies. They found that less than 2% of women in the sample were considered to have migraines at their initial prenatal visit. Of the 484 (of 508) women with a complete data set, 17% experienced complete cessation of headache throughout pregnancy and an additional 62% had two or fewer headaches in the third trimester.[64] Only 21% of these women had no improvement in headache. They examined all available demographic and pregnancy factors and could find no factor that could be used to predict headache improvement during pregnancy.

Chancellor and colleagues[65] followed nine patients whose migraines first occurred during pregnancy at various gestational ages. They were followed for more than 4 years after pregnancy, and the prognosis for headache was excellent. Four of the nine patients developed complications of pregnancy, including preeclampsia in two. Maggioni's group found no increase in pregnancy complications in patients with migraine.[62] It is unknown if the headaches were caused by developing preeclampsia. It is important to rule out other significant complications of pregnancy before assigning a new diagnosis of migraine to a pregnant patient. Jacobson and Redman[66] reported a patient who actually lost consciousness during pregnancy because of a basilar migraine.

Using a nationwide population-based database in Taiwan, Chen and colleagues[67] identified 4911 women with migraines who delivered from 2001 to 2003. After adjusting for confounders, they found that there was an increased risk for low birth weight (OR 1.16), preterm birth (OR 1.24), cesarean delivery (OR 1.16), and preeclampsia (OR 1.34). Although these increases were not large, they were all statistically significant.[67] More research needs to

be undertaken to find out if these increases apply to different populations and if they are clinically significant.

Supportive therapy is recommended for patients who experience migraine attacks during gestation. Acetaminophen is initially recommended, and narcotic analgesics can be used as necessary. The use of nonsteroidal anti-inflammatory agents should be avoided, if possible, after 24 weeks' gestation, because when used for more than 48 hours, they can cause premature closure of the ductus arteriosus and/or oligohydramnios. When pain is severe, parenteral narcotics, prochlorperazine, and other antiemetic therapy may be used. These agents are often used in conjunction with diphenhydramine. **β-Blockers may be safely administered during pregnancy for prophylaxis,** and propranolol is probably safest. The calcium channel blockers used in the treatment of migraine can also be safely administered during gestation (see Chapter 8).

Ergotamine should be avoided during pregnancy. Previous reports have suggested that it may cause birth defects that have a vascular disruptive etiology. In addition, ergots are uterotonic and have an abortifacient potential.

Sumatriptan, a serotonin receptor agonist, is very successful in treating migraines. In a review by O'Quinn and colleagues,[68] there were no untoward effects in 76 first-trimester exposures to sumatriptan. Using logistic regression, Olesen and colleagues[69] compared 34 sumatriptan exposures with 89 migraine controls and 15,995 healthy women. They found that the risk of preterm birth was elevated (OR 6.3), as was the risk of IUGR.[69] They do state that they did not control for disease severity. A larger study by Kallen and colleagues[70] has not confirmed these findings. **In 658 infants whose mothers had used sumatriptan during pregnancy, there was no significant difference in prematurity or low birth weight.**[70] Hilaire and colleagues[71] found birth defects in 3% to 5% of infants exposed to sumatriptan in the first trimester, a rate not greater than expected.

Recent studies have demonstrated that sumatriptan can be used during pregnancy. Nezvalová-Henriksen and colleagues reviewed a large Norwegian database. They showed no increase in congenital anomalies (adjusted OR 1.0) or other adverse pregnancy outcomes. However, there was an increase in intrapartum bleeding (OR 1.5) and uterine atony (OR 1.4). Cunnington and coworkers[72] reviewed 479 first trimester exposures to sumatriptan and 50 to naratriptan. They observed an anomaly rate similar to the background population. However, this study had no control group. Evans and Lorber reviewed all available studies from 1990 through 2007 and also contacted the manufacturers of seven triptan medications. **They concluded that there are enough data to recommend the use of sumatriptan for treatment of migraine in the first trimester.** They also feel that naratriptan and rizatriptan are probably safe. Although these medications are acceptable for use in the second and third trimesters, there is little information regarding their use in late pregnancy. **Soldin and colleagues[73] confirm these findings and also stress that sumatriptan should be the triptan of choice as there are more data available concerning its use in pregnancy.** Table 46-5 lists some medications that can be used for treating migraines.

TABLE 46-5 DRUG THERAPY FOR MIGRAINE HEADACHES IN PREGNANCY

MEDICATION	CLASS	USE	DOSAGE	ROUTE OF ADMINISTRATION	SAFE FOR PREGNANCY?
Acetaminophen	Pain reliever	Acute pain	4 g/day maximum	PO or PR	Yes
Codeine	Narcotic	Acute pain	30-90 mg q3-4hr	PO	Yes
Nalbuphine	Narcotic agonist/ antagonist	Acute pain	5-10 mg q4-6hr	IV	Yes
Prochlorperazine	Phenothiazine	Nausea	5-25 mg q2-8hr depending on route	PO, PR, IM, IV	Yes
Promethazine	Phenothiazine	Nausea	12.5-50 mg q2-8hr depending on route	PO, PR, IM, IV	Yes
Butalbital (50 mg) Acetaminophen 325 mg, caffeine 40 mg	Sedative, pain reliever, vasoconstrictor	Acute migraine	2 tablets q4hr, not to exceed 6 tablets daily	PO	Yes
Isometheptene mucate (65 mg), dichloralphenazone (100 mg), acetaminophen (325 mg)	Vasoconstrictor, sedative, pain reliever	Acute migraine reliever	2 capsules immediately followed by 1 hourly for no more than 5 capsules in 12 hours	PO	Yes
Caffeine	Vasoconstrictor	Acute pain	500 mg in 50 mL IV solution—may repeat	PO or IV	Yes
Sumatriptan	Vasoconstrictor	Acute pain relief	300 mg/day po max 6 mg sq × 2/day max	PO or SQ	Yes
Nortriptyline	TCA	Prophylaxis	25-100 mg qhs	PO	Yes
Amitriptyline	TCA	Prophylaxis	50-150 mg qhs	PO	Yes
Propranolol	Beta-blocker	Prophylaxis	80-120 mg bid	PO	Small risk for IUGR
Gabapentin	Antiepileptic treatment	Prophylaxis	300-2400 mg daily	PO	Yes Caution for IUGR
Carbamazepine	Membrane stabilizer	Prophylaxis	Up to 1200 mg/day	PO in three divided doses	Risk of NTD, other anomalies

bid, Twice daily; *hs*, bedtime; *IM*, intramuscularly; *IUGR*, intrauterine growth restriction; *IV*, intravenously; *NTD*, neural tube defect; *PO*, orally; *PR*, per rectum; *qd*, daily; *SQ*, subcutaneous; *TCA*, tricyclic antidepressant.

Dietary factors may precipitate migraine attacks. Careful history may uncover foods that should be avoided, including foods containing monosodium glutamate, red wine, cured meats, and strong cheeses containing tyramine. Relative hypoglycemia and alcohol can also trigger migraine attacks. Many individuals have recommended, without supporting evidence, dietary supplements and vitamins for migraine prevention. Maizels and colleagues,[74] in a small study, demonstrated a possible role for riboflavin and magnesium in the prevention of migraines.

CEREBROVASCULAR DISEASES

Stroke is diagnosed in 34 per 100,000 deliveries, with 1.4 deaths per 100,000. The risk of stroke increases with age older than 35 years and in African American women. Zotto and colleagues[75] reviewed multiple worldwide databases and showed that there are varied incidences between 4 and 41 per 100,000 deliveries.[75] The highest risk was in patients with preeclampsia. **It can be categorized as ischemic (arterial occlusion), cerebral venous thrombosis, intracerebral hemorrhage, and subarachnoid hemorrhage.**

Arterial Occlusion

Twelve percent of arterial occlusions occur in women between the ages of 15 and 45 years, and approximately one third of these patients may be pregnant. In a study from India, 37% of patients affected with cerebrovascular disease were younger than 40 years of age, with a significant number of thromboses occurring during pregnancy and the puerperium.[76] Overall, the incidence of cerebral arterial occlusion in pregnancy is approximately 1 per 20,000 live births. The mortality rate for pregnant women with cerebral arterial occlusion is twice that of men and three times that of nonpregnant women. **Middle cerebral artery occlusion is most common during pregnancy, whereas internal carotid artery occlusion is observed most often in the puerperium.** Hemiplegia and dysphasia are frequent findings. Predisposing factors such as preeclampsia, chronic hypertension, or hypotensive episodes can be demonstrated in about one third of these patients. Brown and colleagues[77] investigated ischemic stroke in women recruited between 1992 and 1996 and again between 2001 and 2003. They found that preeclampsia was statistically associated with an increased risk of ischemic stroke (OR 1.59, 95% CI 1.00 to 2.52). Another interesting finding was that women with a history of preeclampsia were more likely to eventually experience a nonpregnancy-related ischemic stroke.[77] Cancer has been reported as an underlying etiology. Oral contraceptives also raise the risk of ischemic cerebrovascular disease. Perhaps because of their relative frequency in the general population, the factor V Leiden mutation and other hereditary thrombophilias may be a predisposing factor in many of these patients. Half of the pregnancy-related cases occur during the immediate postpartum period and the remainder during the second and third trimesters. Lidegaard[78] concluded that pregnancy was associated with an elevated OR of only 1.3 for cerebral thromboembolism. One woman had a documented partial obstruction of the left middle cerebral artery during the third trimester of pregnancy. Following delivery, her symptoms abated, and angiography 11 weeks later revealed complete resolution of the obstruction. Embolic stroke should also be considered. In one postpartum patient, a patent foramen ovale was discovered in association with anticardiolipin antibodies.

In cases of cerebral arterial occlusion, care must be taken to avoid increased intracranial pressure. If signs of increased intracranial pressure develop, parenteral dexamethasone should be administered. Osmotic diuresis can be used if needed. Supportive measures are also necessary, including close monitoring of electrolytes to detect inappropriate secretion of antidiuretic hormone. Successful thrombolytic therapy has been reported. **A neurologic team should be immediately consulted after the event, and probably low-dose aspirin therapy will be implemented.** Physical and rehabilitative therapy should be started as soon as possible. These patients can progress normally through pregnancy and deliver vaginally.

A case of maternal death from carotid artery thrombosis associated with the HELLP syndrome (hemolysis, elevated liver enzymes, and low platelet count) has been reported and also a case of cerebellar infarction. It was proposed that the infarction occurred because the patient experienced a rebound thrombocytosis leading to a hypercoagulable state. The importance of closely following patients with HELLP syndrome was stressed so that those who develop a reactive thrombocytosis can be monitored for signs and symptoms of CNS thrombosis.

Cerebral Vein Thrombosis

The chief symptoms in patients with cerebral vein thrombosis are headache, lethargy, and vomiting. Hemiplegia has a gradual onset, and seizure activity is common (see Table 46-4)**.** This disorder occurs most frequently during the immediate postpartum period and may be attributed to a hypercoagulable state. An incidence of 1 in 10,000 pregnancies was suggested in one study.[79] Vora and colleagues[80] reviewed 37,420 pregnancies in a Mumbai, India hospital between 2002 and 2006, and found a 0.1% incidence of thromboembolic phenomena. Of these phenomena, 10% were documented cortical vein thromboses confirming the incidence of 1 in 10,000 pregnancies.[80] In one case in which a blood patch failed to relieve an apparent spinal headache, the ultimate diagnosis was a cerebral vein thrombosis.

Many patients with cerebral vein thrombosis show signs of seizure activity, and prophylactic anticonvulsants should be considered after neurologic consultation. Many neurologists and neurosurgeons advocate expectant management and do not routinely use anticonvulsants. Anticoagulation should be implemented as recommended by neurologic colleagues.

Subarachnoid Hemorrhage

The rate of subarachnoid hemorrhage complicating pregnancy is approximately 1 per 10,400.[81] **Because cocaine abuse is rampant in society today, the incidence may rise, as the associated increase in vasospasm associated with this drug causes bleeding from preexisting berry aneurysms and arteriovenous (AV) malformations.** Most berry aneurysms are thought to be due to a congenital defect in the elastic and smooth muscle layers of cerebral blood vessels. They

are usually located in the vessels of the circle of Willis or those arising from it. Robinson and coworkers[82] evaluated 26 patients with spontaneous subarachnoid hemorrhage during pregnancy and found that approximately half were caused by berry aneurysms and half by AV malformations. They observed that AV malformations are more common in patients younger than 25 years of age and usually bleed before 20 weeks' gestation. Conversely, berry aneurysms occur in patients older than 30 years of age and usually bleed in the third trimester. Pregnancy appears to increase the risk of bleeding from an AV malformation. Stroke was hemorrhagic-arterial in 25 of 27 patients and thrombotic-arterial in two others. In the 24 patients being treated immediately before the stroke, systolic blood pressure (BP) was 160 mm Hg or higher in 96% and more than 155 mm Hg in 100%. In contrast, only 13% exhibited prestroke diastolic pressures of 110 mm Hg or higher. Only three patients received prestroke antihypertensive medications.

Diagnosis and Treatment

Any patient with localized signs of cerebral or meningeal irritation must be thoroughly evaluated. If the clinical examination dictates that further evaluation is necessary, MRI/magnetic resonance angiography or a CT scan should be performed. If necessary, contrast dyes may be used. Cerebral angiography can be safely used to pinpoint the origin of cerebral bleeding. Subarachnoid hemorrhages, whether caused by AV malformations or berry aneurysms, should be treated surgically, when possible. Surgery under hypothermia or hypotension appears to cause no adverse fetal effects. The fetal heart rate should be monitored. If fetal bradycardia occurs, BP should be raised sufficiently to normalize the fetal heart rate. Kawasaki and colleagues[83] report a case of cerebellar hemorrhage in a 32-week primigravida. She was treated conservatively until term and was delivered by elective cesarean section. Her surgery, which was delayed until after delivery, was successful. There was one case of combined cesarean delivery and clipping of an aneurysm.

If the patient has undergone corrective surgery for an aneurysm or AV malformation, she should be allowed to deliver vaginally. Because the Valsalva maneuver can increase intracranial pressure, epidural anesthesia is recommended. Moderate increases in BP do not cause spontaneous hemorrhage in nonpregnant patients with intracranial AV malformations. **If the aneurysm or AV malformation has not been surgically corrected, Robinson and colleagues[82] recommend elective cesarean delivery.** However, there are no data on which to base this decision. Therefore, the mode of delivery should be determined by the obstetrician after discussion about the individual case with neurologists, neurosurgeons, and anesthesiologists.

There are new, less invasive endovascular treatments for aneurysms and AV malformations, but there is virtually no published experience with these in pregnancy. Nonetheless, these procedures may pose less risk to the pregnancy than open neurologic surgeries. There are advantages of regional anesthesia in these patients. In one case a simultaneous cesarean delivery and ablation of a cerebral AV malformation were performed. Levy and Jaspan[84] have reviewed the anesthetic and obstetrical management of an untreated vascular anomaly that had bled earlier in pregnancy in a patient who developed severe preeclampsia.

Because pregnancy has a deleterious effect on AV malformations, those patients with inoperable lesions should be counseled about the dangers of future childbearing. The patient should be thoroughly evaluated before any recommendations are made for permanent sterilization.

Venous-venous (VV) malformations are low-pressure phenomena. Patients should progress to term and deliver vaginally without any hemorrhagic event or complications.

Women with a history of stroke have a low risk of recurrence during subsequent pregnancies, although the puerperium carries increased risk. A previous ischemic stroke is not a contraindication to a subsequent pregnancy. Studies have not addressed the role of prophylactic anticoagulation.

Reversible cerebral vasoconstriction syndrome can cause subarachnoid hemorrhage and can be confused with other causes. Thunderclap headaches occurring over a 1-week period are the hallmark symptom. Treatment with nimodipine appears to help the headaches.[85]

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is a demyelinating disease that attacks men and women equally. The onset of symptoms usually occurs between the ages of 20 and 40 years. In the United States, the disease is more common in those residing above 40 degrees north latitude. The prevalence for those living in the southern United States is 10 per 100,000, whereas it is approximately 50 per 100,000 in those living in the northern states. MS has no clear genetic predisposition.

The diagnosis of MS is often made years after the initial onset of sensory symptoms. The onset is usually subtle. Common presenting symptoms include weakness of one or both lower extremities, visual complaints, and loss of coordination. Because the disease primarily affects the white matter of the CNS, symptoms attributable to disruption of gray matter are uncommon. The disease is characterized by exacerbations and remissions. Less than one third of patients show steady progression of their disease after its onset. Because symptoms are subtle, it is often easy to attribute them to pregnancy. Many pregnant women complain of being more awkward or having some weakness. If these symptoms are persistent or progressive, they should not be ignored and the patient should be referred for neurologic consultation.

It is impossible to predict the long-range prognosis of a patient with MS. About half of patients are still able to work at their usual profession 10 years after the onset of the illness. After 20 years, however, only about one third remain employed. In a study of 185 women with MS, Weinshenker and colleagues[86] showed that there was no association between long-term disability and (1) total number of term pregnancies, (2) the timing of pregnancy relative to the onset of MS, or (3) the worsening of MS in relation to a pregnancy. The average life expectancy in patients with MS is also impossible to predict. Patients may live with the disease for more than 25 years.

The risk of onset of MS is reduced during gestation, whereas the risk of onset during the postpartum period is no different than for the nonpregnant state. There is a lower risk of onset of MS in parous than in nulliparous patients. Of 170 pregnant patients with MS studied by Millar and coworkers,[87] relapses occurred in only 45, the majority during the postpartum period. Birk and coinvestigators[88] carefully followed pregnancies in eight women with MS. None worsened during pregnancy. Six of the eight women, however, experienced relapses within the first 7 weeks after delivery. They also reported that there were differences in suppressor T-cell levels during pregnancy, but these were not predictive of changes in clinical disease. The lower rate of progression and exacerbation during pregnancy may be attributable to a pregnancy-induced shift from thymus helper (Th) 1 cytokines to Th 2 cytokines, which is reversed after delivery.

Frith and McLeod[89] studied 85 pregnancies and found no increased risk of relapse during pregnancy. They noted that most of the relapses that did occur during pregnancy took place in the third trimester, and also in the first 3 months postpartum. Nelson and colleagues[90] analyzed 191 pregnancies in women with nonprogressive MS. **The exacerbation rate during the 9-month postpartum period was 34%, three times that of the 9 months during pregnancy.** The rate was highest in the 3 months immediately following delivery and stabilized after 6 months postpartum. The exacerbation rates were the same in breastfeeding and nonbreastfeeding women. The average time to flare was also similar in both groups. **This study verifies that it is safe for women with MS to breastfeed their newborns. Breastfeeding does not protect from or cause MS exacerbations.** Relapse 1 year before pregnancy (HR = 1.5) and relapse during pregnancy (HR = 2.2) were the only factors that were related to postpartum relapse.

Bernardi and colleagues[91] showed a decreased risk of relapse during the 9 months of pregnancy and the first 6 months postpartum. In this study of 52 women, these researchers concluded that pregnancy, as a whole, is a protective event. Worthington and colleagues,[92] however, found more frequent relapses in the first 6 months postpartum, but not after that. Long-term prognosis was unaffected by pregnancy.

Verdru and colleagues[93] demonstrated that pregnancy delays the onset of long-term disability. As an index of progression, they used the length of time from onset of disease until wheelchair dependence. **In patients with at least one pregnancy after onset, the mean time to wheelchair dependence was 18.6 years compared with 12.5 years for other women.** In a study encompassing 12 European countries, Confavreux and colleagues[94] studied 269 pregnancies in 254 women with MS. They determined the relapse rate in each trimester using the Kuntzke Expanded Disability Status Scale with 0 as good function and 10 as very disabled. They found that the rate of relapse declined during pregnancy, especially in the third trimester. Relapses increased in the first 3 months postpartum before returning to prepregnancy rates. Neither breastfeeding nor epidural analgesia had an adverse effect on the rate of relapse or on the progression of disability.

Paraplegic patients with MS are more susceptible to urinary tract infections during pregnancy but may feel no symptoms. Therefore, they should be screened routinely. If the patient has become paraplegic or has lumbosacral lesions as a result of MS, there may be little pain associated with labor. It might be difficult therefore for the patient to discern when labor begins. Uterine contractions occur normally, but voluntary expulsive efforts may be hindered in the second stage of labor. Delivery by forceps or vacuum extraction therefore may be indicated. Women with MS who receive epidural anesthesia for vaginal delivery do not have a significantly higher incidence of postpartum exacerbation of their MS than those receiving only local anesthesia. In a recent study, van der Kop and coworkers[95] retrospectively analyzed 432 women with MS in British Columbia over an 11-year period ending in 2008, and compared them with 2975 controls. They looked at mode of delivery and neonatal outcomes. They found the mean just gestational age to be equivalent between the two groups. Furthermore, they found that the there was no difference between the assisted vaginal delivery rate (OR = 0.78) and the cesarean delivery rate (OR = 0.94).[95]

Corticosteroids and immunosuppressive agents are occasionally used to treat MS. There are many new agents used to treat the various symptoms and progressions of the disease. Their use in pregnancy has been limited, there are few data, and no controlled studies. **However, many are molecules that are too large to cross the placenta.**

For instance, natalizumab is a humanized monoclonal IgG4 antibody to human alpha-4 integrin. It works against many processes involved in human development. However, it is a large molecule that should not cross the placenta. Wehner and colleagues[96] looked at postnatal development in cynomolgus monkeys exposed to this medication. In the first cohort of monkeys, there was an increase in spontaneous abortions. However, the rate in the control group was very small (7%). In the second cohort studied, the spontaneous abortion rates were equivalent in both groups.[96] They found no adverse effects on the general health, survival, development, or immunologic structure or function of the newborn monkeys treated with natalizumab.

Hellwig and colleagues[97] report on 35 cases of accidental pregnancy in patients receiving natalizumab. Thirty-four of these pregnancies were followed prospectively. Twenty-nine pregnancies went to term, and there was only one anomaly, polydactyly. There were five spontaneous first trimester losses (14%) and one elective pregnancy termination.[97] **We know nothing about long-term effects, but in cases of MS relapse, natalizumab is a reasonable choice.** The patient, however, must be appropriately counseled.

Glatiramer is used to treat the frequency of relapses in those with relapsing remitting MS. It works by shifting the population of T cells from the pro-inflammatory Th1 to regulatory Th2 cells that suppress inflammation. Glatiramer is "Class B" as determined by the Food and Drug Administration. **Salminen and coworkers[98] prospectively followed 13 women who were exposed to glatiramer from preconception through pregnancy and the postpartum period. There were no congenital anomalies and treatment was well tolerated.** Fragoso and colleagues[99] retrospectively

evaluated 11 women who used glatiramer continuously for at least 7 months during pregnancy. Children were followed for at least 1 year after birth. There were no congenital anomalies, neonatal complications, or developmental abnormalities in the children. Postnatal MS relapse rates remained significantly lower than antenatal rates in these women.[99]

As with the aforementioned medications, there is a paucity of information concerning the use of interferon-beta therapy in pregnancy. Sandberg-Wollheim and colleagues[100] diligently dissected data on 1022 cases of interferon-beta exposure during pregnancy. In order to avoid bias, they only included outcomes for prospective data (n = 425). There were 324 normal term live births (76.2%) and 4 infants born with malformations (0.9%). There were four third trimester stillbirths (0.9%, 1 with anomalies), 5 ectopics, 49 (11.5%) first trimester spontaneous abortions, and 39 (9.2%) elective abortions. These results are not dissimilar to the general population. The authors believe that these data will help patients with MS who are planning pregnancy or become pregnant while taking interferon-beta.[100] Amato and colleagues[101] investigated first trimester exposure to interferon-beta. They compared these patients to those who were never treated or who discontinued treatment at least 4 weeks before conception. Of the 88 exposed fetuses, there was not an increase in spontaneous abortion, malformations, or developmental abnormalities over a median follow-up of 2.1 years.[101] There was an increased incidence of low birth weight and birth length. In summary, all these data are encouraging in that there are therapeutic options available to the woman with MS who becomes pregnant.

CARPAL TUNNEL SYNDROME

The medial border of the carpal tunnel consists of the pisiform and hamate bones, and its lateral border consists of the scaphoid and trapezium bones. They are covered on the palmar surface by the flexor retinaculum. The median nerve and flexor tendons pass through this carpal tunnel, which has little room for expansion. If the wrist is extremely flexed or extended, the volume of the carpal tunnel is reduced. In pregnancy, weight gain and edema can produce the carpal tunnel syndrome that results from compression of the median nerve. The association between carpal tunnel syndrome and pregnancy was first reported in 1957. Although many pregnant women complain of pain on the palmar surface of the hand, few actually have the true carpal tunnel syndrome. Stolp-Smith and colleagues[102] found that 50 of 14,579 (0.34%) pregnant patients presenting between 1987 and 1992 actually met criteria for carpal tunnel syndrome. **Commonly, the syndrome consists of pain, numbness, and tingling in the distribution of the median nerve in the hand and wrist. This includes the thumb, index finger, long finger, and radial side of the ring finger on the palmar aspect.** These symptoms/signs are often accompanied by dysesthetic wrist pain, loss of grip strength, and problems with dexterity. Compressing the median nerve and percussing the wrist and forearm with a reflex hammer, the Tinel maneuver, often exacerbates the pain. In severe cases, weakness and decreased motor function can occur. The definitive diagnosis is made by electromyography, but this test is often unnecessary.

McLennan and coworkers[103] studied 1216 consecutive pregnancies. Of these patients, 427 (35%) reported hand symptoms. Fewer than 20% of these 427 affected women described the classic carpal tunnel syndrome. No patient required operative intervention. Most symptoms were bilateral and commenced in the third trimester of pregnancy. **Ekman-Ordeberg and colleagues[104] found a 2.3% incidence of carpal tunnel syndrome in a prospective study of 2358 pregnancies. The syndrome appeared to be more common in primigravidas with generalized edema.** Increased weight gain during pregnancy also raises the risk.[103] Padua and colleagues[105] conducted a systematic literature review concerning carpal tunnel syndrome in pregnancy. Of the 214 studied reviewed, only 6 fulfilled their criteria for inclusion. Neurophysiologically confirmed carpal tunnel syndrome ranged from 7% to 43% of those who presented with symptoms in the 6 studies. Clinically diagnosed carpal tunnel syndrome ranged from 31% to 62%. Of note in 50% of cases, symptoms persisted for more than a year and in 30% symptoms were still present 3 years postpartum.

Conservative therapy with splinting of the wrist at night completely relieved symptoms in 46 of 56 patients.[106] Of the remaining 10 women, three required surgery before delivery. In Stolp-Smith's study,[102] symptoms began with equal frequency in all trimesters, but diagnosis was delayed until the third trimester in 50% of the patients. Only four patients required surgical intervention during gestation, and three additional patients required surgery postpartum. Wand[107] retrospectively studied 40 women with carpal tunnel syndrome developing in pregnancy and 18 women with carpal tunnel syndrome that occurred in the puerperium. He confirmed that the syndrome occurs most frequently in primigravidas older than 30 years of age. All cases that developed before delivery occurred during the third trimester and resolved within 2 weeks after delivery. In those cases developing during the puerperium in women who breastfed their infants, the symptoms lasted longer, a mean of 5.8 months. In another series, 27 women developed carpal tunnel syndrome during the puerperium. The condition was associated with breastfeeding in 24 of these women. Symptoms lasted an average of 6.5 months in the breastfeeding women. Only two of these patients required surgical decompression.

Supportive and conservative therapies are usually adequate for the treatment of carpal tunnel syndrome. Symptoms usually subside in the postpartum period as total body water returns to normal. Pain scores fall by half during the first week after delivery and by half again during the next week. The reduction in score is strongly correlated with loss of the weight gained during pregnancy. However, about half of the women with carpal tunnel syndrome during pregnancy still have some symptoms 1 year later, more commonly in those whose symptoms started early in pregnancy.

Splints placed on the dorsum of the hand, which keep the wrist in a neutral position and maximize the capacity of the carpal tunnel, often provide dramatic relief. Local injections of glucocorticoids may also be used in severe cases. Although diuretics may help to control the symptoms of

carpal tunnel syndrome over a short period of time, their use is not recommended because the symptoms return rather rapidly after the cessation of treatment.

Surgical correction of this syndrome should not be delayed in patients with deteriorating muscle tone and motor function. Even small changes can be documented by electromyography (EMG), which can be carried out safely during pregnancy. Decompression surgery for carpal tunnel syndrome is a simple procedure that can be safely carried out during pregnancy using local anesthesia, an axillary block, or a Bier block. With new endoscopic procedures, the procedure is even less invasive. Assmus and Hashemi[108] report 314 hands surgically treated during pregnancy or the puerperium for carpal tunnel syndrome. One hundred thirty-three cases were performed during pregnancy, most in the last trimester, including four who had both hands treated simultaneously, and 98% reported good or excellent results.[108] There were no complications, and local anesthesia was used in all cases. These authors recommend surgery if sensory loss is present or if motor latency is more than 5 msec. It is important to warn patients that carpal tunnel syndrome can persist for several years postpartum and can recur in future pregnancies.[105]

IDIOPATHIC INTRACRANIAL HYPERTENSION (PSEUDOTUMOR CEREBRI)

Idiopathic intracranial hypertension (IIH) may complicate as many as 1 in 870 births. It has been thought to be seen more frequently in pregnant women, particularly those who are obese. However, in a study by Ireland and colleagues[109] the incidences in pregnant women and in oral contraceptive users were no higher than in control groups. **More than 95% of these patients have headaches, and 15% have diplopia. Papilledema is found in virtually all patients.** In 12 women with 16 pregnancies complicated by IIH, 6 had mild and 6 had marked bilateral papilledema. There was decreased visual acuity in four of the patients. To establish the diagnosis, one must demonstrate elevated cerebrospinal fluid (CSF) pressure, normal CSF composition, and the absence of an intracranial mass on MRI or CT scan.[110]

The pathogenesis of this disorder is unknown, but CSF prolactin is markedly elevated. Prolactin appears to have an affinity for receptors in the choroid plexus, where CSF is produced. Prolactin has osmoregulatory functions and, therefore, may have a role in the increased CSF production found in IIH. Some believe that reduced CSF reabsorption is the etiology. Ahlskog and O'Neill[111] noted an association between the occurrence of IIH and the following conditions: corticosteroid therapy and its withdrawal, nalidixic acid therapy, nitrofurantoin therapy, tetracycline therapy, hypoparathyroidism, deficiencies or excesses of vitamin A, and iron deficiency anemia.

Pregnancy outcome appears to be unaffected by the illness.[110] **There is no increase in fetal wastage or congenital anomalies.** One case of IIH occurred in a 15-year-old primigravida following eclampsia, and it lasted for 3 weeks. IIH may occur in a pregnancy complicated by diabetes mellitus. **It is important to make the distinction between symptoms of IIH and visual impairment caused by diabetic retinopathy, because the treatments are different.** Thomas[112] described a case of ICH occurring in two consecutive pregnancies in a woman with hemoglobin SC. In both instances, symptoms resolved following delivery and both infants were born at term.

Most patients respond well to conservative management. **The main objectives of treatment are relief of pain and preservation of vision.** The patient should be followed closely with visual acuity and visual field determinations at intervals indicated by the clinical condition. In patients with mild disease, analgesics may be adequate. If pain persists, diuretics may be used. **Acetazolamide, a carbonic anhydrase inhibitor, will reduce CSF production in many patients.** Lee and colleagues[113] treated 12 patients with acetazolamide during pregnancy and there were no adverse fetal outcomes. They reviewed the English language literature and found nothing contradicting this assertion. The usual dose is 500 mg twice daily. In more difficult cases, prednisone in doses of 40 to 60 mg daily usually provides good results. Patients may be treated for 2 weeks, with the dose being tapered over the next month. Serial lumbar punctures to reduce CSF pressure are rarely necessary today. Surgical approaches are reserved for refractory patients in whom rapid visual deterioration occurs. The two most common procedures are optic nerve sheath fenestration and lumpoperitoneal shunt.

IIH is not an indication for cesarean delivery. A review of the literature reveals that 73% of the reported patients delivered vaginally. Cesarean delivery should be undertaken only for obstetrical indications. **Both epidural and spinal anesthesia, when expertly administered, can be safely used in patients with IIH.** Although there are no data to confirm this, the Valsalva maneuver, which can increase CSF pressure, should be minimized when possible. Therefore, the second stage of labor should be shortened by operative vaginal delivery if possible.

The recurrence rate for IIH appears to be between 10% and 12.3% in nonpregnant patients. Pregnancy does not appear to predispose to a recurrence.

KEY POINTS

- Idiopathic seizures affect approximately 1% of the general population and are the most frequent neurologic complication of pregnancy.
- Prepregnancy counseling is imperative in the patient with a seizure disorder, and preconceptional folic acid therapy, 4 mg daily, should be implemented in patients receiving anticonvulsants under the direction of an obstetrician and a neurologist.
- Those women with seizures occurring less than once each month will most likely have the best control of seizures during pregnancy.
- The anticonvulsant medication that best controls the patient's seizures should be used during pregnancy.
- Because of the changes in plasma volume, drug distribution, and metabolism that occur during

pregnancy, anticonvulsant levels should be checked and dosages adjusted when clinically indicated.

- Patients taking anticonvulsants have an increased risk of giving birth to an infant with both major and minor anomalies, but this risk is less than 10%. Therefore, the majority of patients with epilepsy give birth to healthy infants.
- Carbamazepine and valproate are associated with an increased risk of NTDs, as well as other anomalies.
- The pattern of physical abnormalities observed in the infants of patients taking anticonvulsants is related to the dose, type, and number of anticonvulsant drugs, rather than the epilepsy itself.
- Pregnancy does not hasten the onset of MS, and it decreases the onset of disability from MS. Exacerbations are decreased during pregnancy.
- Many of the newer MS medications may be acceptable for use during pregnancy. They do not appear to be associated with anomalies. The risk and benefits must be discussed with the patient. Elective abortion should not be strongly recommended to a patient who becomes pregnant while taking these medications.
- Carpal tunnel syndrome is common in pregnancy and usually responds to conservative splinting, glucocorticoid injection, or both. Surgery can be safely undertaken if indicated during pregnancy.

The juxtaposition of life and death can present numerous emotional and ethical conflicts to the patient, her family, and her physicians. The diagnosis of cancer for anyone is understandably frightening. To deal with cancer in the context of pregnancy is particularly burdensome, because the patient may have to balance competing maternal and fetal interests. On occasion, a pregnant woman may be required to make decisions affecting her life or longevity versus the life or well-being of her unborn. Cancer in pregnancy complicates the management of both the cancer and the pregnancy. Diagnostic and therapeutic interventions must carefully address the associated risks to both the patient and the fetus. Informed decisions require evaluation of a number of factors, and with counseling, these considerations are the foundation on which treatment decisions are made. There has been an evolution in the philosophy of care from one of total disregard of the pregnancy with frequent immediate termination to a more thoughtful approach in which management decisions consider both maternal and fetal outcomes so as to limit risk of death or morbidity to both.

It is estimated that approximately 20% to 30% of malignancies occur in women younger than age 45 years.[1] **Although cancer is the second most common cause of death for women in their reproductive years, only about 1 in 1000 pregnancies is complicated by cancer.**[2] Because there are no large prospective studies that address cancer treatment in pregnancy, physicians tend to base treatment strategies on small retrospective studies or anecdotal reports that occasionally present conflicting information.[1,2] A successful outcome is dependent on a cooperative multidisciplinary approach. The management plan must be formulated within a medical, moral, ethical, legal, and religious framework that is acceptable to the patient and guided by communication and educational resources of the health care team.

Delays in diagnosis of the cancer during pregnancy are common for various reasons, including the following: (1) many of the presenting symptoms of cancer are often attributed to the pregnancy; (2) many of the physiologic and anatomic alterations of pregnancy can compromise physical examination; (3) serum tumor markers, such as β-human chorionic gonadotropin (β-hCG), α-fetoprotein (AFP), and CA 125, are increased during pregnancy; and (4) our ability to optimally perform either imaging studies or invasive diagnostic procedures may be altered during pregnancy. Because the gestational age is significant when evaluating the risks of treatments, it is important to determine gestational age accurately. An early ultrasound evaluation may be useful to ensure accurate dating.

The malignancies most commonly encountered in the pregnant patient are breast cancer, cervical cancer, melanoma, ovarian cancer, thyroid cancer, leukemia, lymphoma, and colorectal cancer.[2] The frequencies of these diseases complicating pregnancy may increase secondary to the trend to delay childbearing, and age is the most potent

predictor of cancer. Before specific malignancies are discussed below, some general principles are reviewed.

CHEMOTHERAPY DURING PREGNANCY

Pharmacology of Chemotherapy During Pregnancy

Because pregnancy alters physiology, there is potential for altered pharmacokinetics associated with chemotherapy. Orally administered medications are subjected to altered gastrointestinal motility. Peak drug concentrations are decreased owing to the 50% expansion in plasma volume, producing a longer drug half-life unless there is a concurrent increase in metabolism or excretion. The increase in plasma proteins and fall in albumin may alter drug availability, and amniotic fluid may act as a pharmacologic third space, potentially increasing toxicity due to delayed metabolism and excretion. Hepatic oxidation and renal blood flow are both elevated during pregnancy and may influence the metabolism and excretion of most drugs.[3] However, because pharmacologic studies in the pregnant woman are lacking, we currently assume that initial drug dosages are similar to that given to the nonpregnant woman and adjustments to dose are based on toxicity on a course-by-course basis. Because most antineoplastic agents can be found in breast milk, breastfeeding is contraindicated.[3]

Drug Effects on the Fetus

All drugs undergo animal teratogenicity testing, and based on these results, the drugs are assigned risk categories (Table 47-1) by the U.S. Food and Drug Administration (FDA).[4] Based on this system, most chemotherapeutic agents are rated as C, D, or X. However, animal teratogenicity testing cannot always be reliably extrapolated to humans. For example, a drug (e.g., aspirin) may show teratogenic effects in animals and not affect humans. The opposite is also true and, as such, has serious potential to do harm; for example, a drug may show no animal teratogenicity (e.g., thalidomide) but cause serious human anomalies (see Chapter 8). Because detailed ultrasonography may fail to identify subtle anatomic but serious functional abnormalities before 20 weeks' gestation, patients should be appropriately counseled and may want to consider the option of pregnancy termination if first-trimester chemotherapy is planned or administered. **The risk of teratogenicity during the second and third trimesters is significantly reduced and is likely no different from that for pregnant woman who are not exposed to chemotherapy.**[3]

Although the literature addressing chemotherapy administration during pregnancy is somewhat limited and dated, literature reviews provide us with some information regarding the frequency of affected offspring.[3,5] Because antineoplastic agents are targeted for the rapidly dividing malignant cell, one would expect the exposed fetus to be particularly susceptible to serious toxicity. Clear documentation of such is not the case. Excluding the intentional use of abortifacients, it is difficult to clearly demonstrate that the use of chemotherapy results in an increase in the clinically recognized spontaneous abortion rate over the expected 15% to 20%. However, if continuation of the pregnancy is desired, chemotherapy is not advised in the first trimester due to an increased rate of major malformations, ranging from 10% to 17% with single agent therapy and up to 25% with combination chemotherapy.[5] Administration in the second and third trimester has been associated with intrauterine growth restriction, stillbirth, and low birthweight.[5-7] Maternal effects, such as chemotherapy-induced nausea and vomiting, may also affect fetal growth and birthweight.[8] Because early induction of labor or surgical delivery is often a component of the overall treatment plan, it has been difficult to identify premature birth as a specific result of the chemotherapy. Preterm delivery has been reported to occur in more than half of pregnancies associated with malignancies, with a majority being iatrogenically induced and associated with increased neonatal morbidity.[5] Therefore, the timing of delivery and consideration of delay of therapy, if early-stage disease, should be part of the treatment planning.

When chemotherapy is administered during the latter half of gestation, fetal organ toxicity has not been reported as a major problem, although neonatal myelosuppression and hearing loss have been reported.[5,9] Although second malignancies, impaired growth and development, intellectual impairment, and infertility have been reported after chemotherapy administration to children, the delayed effects of in utero exposure are less well documented.[5,9] Though little data is available, concerns regarding cognitive development have been evaluated and the outcomes are comparable to those not exposed to chemotherapy in utero. Growth and fertility outcomes have also been shown to be similar to those not exposed.[9]

TABLE 47-1 FDA Risk Categories for Drug Use During Pregnancy

CATEGORY	DEFINITION
A	Controlled studies have demonstrated no risk in first trimester, and the possibility of fetal harm appears remote.
B	*Either* animal studies have failed to identify a risk but there are no controlled studies in women, *or* animal studies have shown an adverse effect that was not confirmed.
C	*Either* animal studies have revealed adverse effects and there are no controlled studies in women, *or* studies in women and animals are not available. Use of drugs only if the potential benefit justifies the potential risks.
D	There is evidence of fetal risk, but the benefits may be acceptable despite the risk in either a life-threatening situation or a serious disease for which safer drugs are ineffective.
X	Studies in animals or humans have demonstrated fetal abnormalities and the risk of the drug clearly outweighs any possible benefit.

From Aviles A, Diaz-Maqueo JC, Talavera A, et al: Growth and development of children and mothers treated with chemotherapy during pregnancy: current status of 43 children. Am J Hematol 36:243, 1991.

Classification of Chemotherapy Agents

Antimetabolites

Historically, the antimetabolite aminopterin was used as an abortifacient, and in cases of failed abortion, the risk of fetal malformation was about 50%. Methotrexate has replaced aminopterin for chemotherapeutic purposes, and although similar types of anomalies occur, a lower overall

frequency (<10%) has been reported.[8] In the first trimester, methotrexate has been associated with skeletal and central nervous system (CNS) defects. Though no anomalies were reported in the second and third trimester, methotrexate was associated with low birthweight and neonatal myelosuppresion.[9] The use of low-dose methotrexate for systemic diseases (e.g., rheumatic disease and psoriasis) does not appear to produce teratogenicity.[10] In a prospective study, 5-fluorouracil, in combination with other agents, was well tolerated and resulted in no perinatal deaths.[8]

Alkylating Agents

The alkylating agents, such as cyclophosphamide and chlorambucil, are a commonly used group of drugs for the management of malignancies. Unfortunately, most of the alkylating agents have demonstrated some teratogenic potential when administered in the first trimester, including renal agenesis, ocular abnormalities, and cleft palate.[8] In the second and third trimester, alkylating agents have been shown to be acceptably safe.[1,9]

Antitumor Antibiotics

Even when administered in early pregnancy, antitumor antibiotics (doxorubicin, idarubicin, bleomycin, daunorubicin) appear to be associated with a low risk of teratogenicity. Doxorubicin has been associated with one case of multiple anomalies; however, the patient was receiving combination chemotherapy.[9] One potential reason for the low rate of anthracycline-associated teratogenicity is its questionable ability to cross the placenta.[11]

Vinca Alkaloids

Vincristine and vinblastine, although potent teratogens in animals, do not appear to be as teratogenic in humans.[8] In limited studies, vinca alkaloids were well tolerated in both early and later stages of pregnancy.[9]

Platinum Agents

Platinum agents have been used with relatively acceptable risks. Reports of normal outcomes have been reported; however, there are cases of intrauterine growth restriction as well. Case studies have reported hearing loss and ventriculomegaly in 2.7% of cases exposed to cisplatin.[1] One case of bilateral hearing loss was noted in a woman treated with carboplatin in the second trimester of pregnancy. However, the cause cannot be fully attributed to the platinum agent, as other causes of hearing loss were also present, including prematurity and administration of gentamycin in the neonatal period.[8]

Miscellaneous

Taxane chemotherapy is used in the treatment of malignant tumors of multiple sites, and experience with this class of drugs remains limited, although a few reports to date are favorable.[8,9]

Targeted Therapies

Despite the emerging role of targeted agents in cancer treatment, they have been used only inadvertently in pregnancy. Tratuzumab has been associated with oligohydraminos and its use is not recommended in pregnancy.[1] Rituximab has been associated with transient neonatal lymphopenia, and further studies are necessary to determine an accurate safety profile. Imatinib has been associated with low birthweight and premature delivery, whereas erlotinib has showed no adverse effects in one case. The antiangiogenic agents (bevacizumab, sunitinib, and sorafenib) are not recommended for use in pregnant women.[1]

National Registry

In 1984 the National Cancer Institute established a national registry for in utero exposure to chemotherapy.[12] The registry is currently located at the University of Oklahoma, under the direction of Dr. John J. Mulvihill (jmulvihill@ouhsc.edu). Through September 2006 the registry had summaries of 720 pregnancies. The rate of anomalies following first-trimester exposure was 19%, versus 6% after later exposure (and 3% in the general population). Of 422 pregnancies with third-trimester exposure, 66 (16%) of newborns had a functional abnormality, which was primarily myelosuppression occurring in a frequency related to time between last chemotherapy and delivery.

RADIATION THERAPY

Ionizing radiation is a known teratogen and the developing embryo is particularly sensitive to its effects. Doses higher than 0.20 Gray (Gy) are considered teratogenic. Effects during early pregnancy are typically lethal or result in congenital malformations. During late gestation, radiation may cause specific organ damage, such as mental retardation, skeletal anomalies, and ophthalmologic abnormalities. Reports have indicated that radiation exposure in utero increases the risk of malignancies, such as leukemia and other childhood tumors, particularly when exposure occurred in the first trimester.[1,9] It is important to remember that these data are conflicting and data is extrapolated from data from atomic catastrosphe.[9] Regardless, recommendations for radiation exposure in pregnancy should be less than 0.05 Gy.[1,9] Radiation therapy should be postponed until the postpartum period and consideration should be given to suitable alternative therapies, such as surgery or chemotherapy. If delay of therapy is not possible, termination of the pregnancy may be required.

SURGERY AND ANESTHESIA

Aspects of surgery are addressed later in the sections on specific cancers; first, some general principles should be considered. Although complications of surgery can threaten the fetus, extraperitoneal surgery is not related to spontaneous abortion or preterm labor. **Abdominal or pelvic surgery, if flexibility in timing exists, is best performed in the second trimester to limit the risk of first-trimester spontaneous abortion or preterm labor.** In the first trimester, progesterone therapy is indicated (weeks 7 to 12) following resection of the corpus luteum. Perioperative cautions include attention to the relative safety of all drugs administered. Fever secondary to either infection or atelectasis should be treated promptly, because it may be associated with fetal abnormalities.

There is no evidence that there are significant risks of anesthesia independent of coexisting disease.[13] In the

second and third trimesters, careful attention to positioning is required so as to avoid compression of the vena cava from the enlarged uterus. Use of local or regional anesthesia should be considered. Finally, continuous or intermittent fetal monitoring should be employed in cases in which extrauterine survival is possible.

PREGNANCY FOLLOWING CANCER TREATMENT

With improved survival rates for many childhood and adolescent malignancies, one must be prepared to offer prenatal counseling to the young woman who presents with a cancer history. Issues worthy of review and in need of clarification for the obstetrician and the patient are listed in the box, Counseling Issues for Pregnancy Following Cancer Treatment.

Counseling Issues for Pregnancy Following Cancer Treatment

1. What is the risk of recurrence of the malignancy?
2. If a recurrence was diagnosed, depending on the most likely sites, what would be the nature of the probable treatment? How would such treatment compromise both the patient and the fetus?
3. Will prior treatments—pelvic surgery, radiation to pelvis or abdomen, or chemotherapy—affect fertility or reproductive outcome?
4. Will the hormonal milieu of pregnancy adversely affect an estrogen receptor–positive tumor?

Previous abdominal irradiation for a Wilms' tumor appears to adversely affect the risk of pregnancy complications, including increased perinatal mortality, low birthweight, and abnormal pregnancy. In contrast, a review of pregnancies following treatment for Hodgkin's lymphoma revealed no increase in poor pregnancy outcome.[14] However, the rate of ovarian failure following the multiple drug combinations is greater than 50% in some reports.[15] Also, a combination of pelvic irradiation and chemotherapy for Hodgkin's disease results in an even higher rate of ovarian failure. Over recent years, a number of women with early cervical cancer have received fertility preservation surgery with radical trachelectomy and regional lymphadenectomy. The preliminary fertility and pregnancy outcomes have been favorable.[16]

Will pregnancy increase the risk of recurrence or accelerate recurrence? Even in women with estrogen receptor–positive breast cancer, there is no evidence that subsequent pregnancy adversely affects survival. In addition to the altered hormonal milieu, concern is also directed toward the potential for accelerated tumor activity associated with alterations in the pregnant patient's immune system. There are no data to support this concern. However, it has been recommended that after a cancer diagnosis, pregnancy should be delayed for at least 2 years (during which recurrence risk is highest).

CANCER DURING PREGNANCY

Breast Cancer

The predicted number of breast cancer cases in women in the United States for the year 2010 was 207,090, and the predicted number of related deaths was 39,840.[17] Though the lifetime risk of developing breast cancer is 1 in 8, the risk is 1 in 206 for women 40 years or younger. Each year, this results in approximately 7% to 15% of premenopausal breast cancers being diagnosed in women who are pregnant or lactating.[8,18] Although it has been predicted that there may be an increase in the frequency of breast cancer complicating pregnancy due to delayed childbearing, recent publications are consistent with a frequency of breast cancer concurrent with pregnancy of 1.3 per 10,000 live births.[1,2,8]

In general, the risk of breast cancer is directly related to the duration of ovarian function. Therefore, both early menarche and late menopause appear to increase the likelihood of developing breast cancer. However, interruption of the normal cyclic ovarian function by pregnancy appears protective. This apparent protective effect may be secondary to the normal hormonal milieu of pregnancy that produces epithelial proliferation, followed by marked differentiation and mitotic rest. Multiparous women, particularly those who breastfeed, have a lower risk of developing breast cancer than do nulliparous women. However, based on one study of almost 90,000 women, breastfeeding may not be an independent protective factor.[19] Paradoxically, carriers of BRCA1 and BRCA2 mutations may have an increased risk of developing breast cancer by having children.[20]

Diagnosis and Staging

Breast abnormalities should be evaluated in the same manner as if the patient were not pregnant. The most common presentation of breast cancer in pregnancy is a painless lump discovered by the patient. Because the breast changes become more pronounced in later pregnancy, it is important to perform a thorough breast examination at the initial visit. Despite the striking physiologic breast changes of pregnancy, including nipple enlargement and increases in glandular tissue resulting in engorgement and tenderness, a newly found breast mass should be evaluated promptly. Diagnostic delays, which may increase the risk of nodal involvement, are often attributed to physician reluctance to evaluate breast complaints or abnormal findings in pregnancy.[21] Although bilateral serosanguinous discharge may be normal in late pregnancy, masses require prompt and definitive evaluation. The lengths of delays in diagnosis of breast cancer in pregnancy are commonly 3 to 7 months or longer.[21,22] A case-control study from Princess Margaret Hospital suggested that pregnant patients are at higher risk of presenting with advanced disease because pregnancy impedes early detection.[23]

Less common presentations may include bloody nipple discharge, which should be evaluated with mammography and ultrasound.[18] In cases of mastitis or breast abscesses, or evaluation of breast edema or inflammation, a skin biopsy should be considered to evaluate for inflammatory breast cancer.

Mammography in pregnancy is controversial. Although the radiation exposure to the fetus is negligible, the hyperproliferative changes in the breast during pregnancy are characterized by increased tissue density, making interpretation more difficult.[9,18] Breast ultrasound has a high sensitivity and specificity and can distinguish between solid

and cystic masses, making it the preferred imaging modality for pregnant women. Magnetic resonance imaging (MRI), without gadolinium, has also been used; however, there is limited data on its accuracy in this population. Fine needle aspiration (FNA) of a mass for cytologic study may be used, but is often misleading due to changes in the breast during pregnancy. For breast masses, a core needle biopsy is the preferred method for histologic diagnosis.[9,21]

Before proceeding with treatment, staging should be undertaken. All draining lymph nodes should be evaluated. Sentinel lymph node biopsy techniques appear safe in pregnancy.[24] The contralateral breast must be carefully assessed. Laboratory tests should include baseline liver function tests and serum tumor markers, carcinoembryonic antigen (CEA), and CA 15-3. CA 15-3 appears to be a useful tumor marker for monitoring breast cancer in pregnancy.[25] A chest radiograph is indicated, and if the liver function tests are abnormal, the liver can be evaluated by ultrasound. If bone metastases are suspected, a bone scan can be performed in pregnancy. In a symptomatic patient, radiographs of the specific symptomatic bones are advised. However, in an asymptomatic patient with normal blood tests, because the yield is low, bone scanning is usually not performed.

Treatment

The treatment of breast carcinoma at any time is often overshadowed by psychological and emotional factors. Because of potential risks to the developing fetus, treatment decisions carry an additional burden. Therapy must be individualized in accordance with present knowledge and with the specific desires of the patient, and maternal treatment should adhere to standard recommendations.

Local Therapy

The usual criteria for breast-preserving therapy versus modified radical mastectomy pertain to the patient with breast cancer, stages I to III.[2,18] Though breast surgery can be safely performed in all trimesters with minimal fetal risks, the use of radiation is complicated by the presence of the pregnancy.[21,26] One publication presents a mathematical model suggesting that the risk of axillary metastases due to treatment delay is minimal and may be acceptable to some third-trimester patients with early breast cancer who prefer lumpectomy with radiation postpartum.[27] Consideration should be given to the delay of irradiation until after delivery. Experimental calculations suggest that a tumor dose of 5 Gy will expose the fetus to 0.010 to 0.015 Gy while the fetus is within the true pelvis. Later in pregnancy, parts of the fetus may receive as much as 0.200 Gy.[28] Because these levels exceed the upper limit of safety, alternative approaches should be considered. Reports have shown that in the late second or third trimester, delaying treatment without impacting maternal outcome may be reasonable.

Pregnancy Termination

Because early studies suggested more unfavorable outcomes in pregnant women, it was assumed that the hormonal changes of pregnancy contributed to rapid tumor growth. Therefore, therapeutic abortion was frequently advised. At present, a harmful effect of continuing pregnancy has not been demonstrated in most published series.[2] A series of 130 women with breast cancer diagnosed during pregnancy reported equivalent outcomes whether the pregnancy was terminated, spontaneous miscarriage occurred, or the pregnancy continued.[8] However, it is difficult to evaluate potential selection bias toward performing an abortion in patients with advanced disease. Because young women tend to have hormone receptor–negative tumors, it is difficult to make an argument, based on hormonal concerns, for either termination of pregnancy or oophorectomy as an adjunct to therapy.[18]

Chemotherapy

In general, women who present with either metastatic breast carcinoma or rapidly progressive inflammatory carcinoma should avoid any delays in therapy. Immediate initiation of chemotherapy is critical to providing the patient with inflammatory carcinoma with any chance for long-term survival. In the patient with a clinical indication for adjuvant chemotherapy other than inflammatory carcinoma, the delay of instituting chemotherapy and awaiting fetal pulmonary maturity should be considered in select third-trimester situations. Current literature shows that the use of cytotoxic agents for breast cancer in pregnancy is relatively safe, and includes the use of 5-fluorouracil, doxorubicin, cyclophosphamide, epirubicin, and taxanes.[21] Others concur with the use of chemotherapy in the second and third trimesters in the management of breast cancer.[18,29] Pregnancy is a contraindication to the use of tamoxifen due to the risk of adverse fetal outcomes, including oculoauriculovertebral dysplasia and ambiguous genitalia. Data regarding the safety of trastuzumab in pregnancy are limited, and currently it is not recommended due to reports of oligohydramios and deaths due to respiratory and renal failure.[21]

Prognosis

As with any malignant disease, prognosis best correlates with the anatomic extent of disease at the time of diagnosis. Outcomes in stage I and II disease are favorable, with survival rates approaching 86% to 100%; however, the presence and extent of nodal involvement is especially predictive of prognosis in both nonpregnant and pregnant patients.[8] Table 47-2 provides 5- and 10-year survival data by nodal status.[30-37] Although nodal status is of prognostic significance, the number of positive nodes is also important. In the pregnant patient, the 5-year survival rate is 82% for patients with three or fewer positive nodes, and 27% if greater than three nodes contain tumor.[36] Pregnancy, probably due to the associated delays in diagnosis, appears to increase the frequency of nodal disease, with 60% to 85% of patients exhibiting axillary nodal disease at diagnosis.[36]

Reports have demonstrated that up to 60% to 80% of breast cancer cases in the pregnant population are estrogen receptor negative and have a rate of HER2 positivity between 38% and 58%.[18] Additionally, breast tumors in pregnant women are more frequently reported to be larger, to be higher grade, and to have a higher rate of pathologic lymph node involvement compared to nonpregnant counterparts.[18] Thus, some reports concluded that breast cancer in pregnancy was associated with a worse prognosis.

TABLE 47-2 5- AND 10-YEAR SURVIVAL RATES, BY NODAL STATUS, OF PREGNANT OR LACTATING PATIENTS TREATED FOR BREAST CANCER

		OVERALL		NODE NEGATIVE		NODE POSITIVE	
Investigators	**No. of Patients**	**5-Yr (%)**	**10-Yr (%)**	**5-Yr (%)**	**10-Yr (%)**	**5-Yr (%)**	**10-Yr (%)**

Clark and Reid[35]							
Pregnant	121	—	22	—	35	—	22
Lactating	80	—	32	—	69	—	18
King et al.[36]	63	53	49	82	71	36	36
Petrek et al.[37]	56	61	45	82	77	47	25

However, these rates are histologically identical to the nonpregnant patient of similar age and, when controlled for age and stage, pregnancy does not seem to affect prognosis adversely.[23,37]

Subsequent Pregnancy

The risk of pregnancy after breast cancer has been a focus of a number of studies.[38,39] Although the consensus is that subsequent pregnancies do not adversely affect survival, there are recommendations regarding the timing of a subsequent pregnancy.[40] It is generally advised that women with node-negative disease wait for 2 to 3 years, and this interval should be extended to 5 years for patients with positive nodes. Others have advised that no delay is indicated for the patient with good prognostic disease who does not receive postoperative adjuvant chemotherapy.[40] It has been advised that patients should undergo a complete metastatic workup before a subsequent pregnancy.

Although no studies indicate that subsequent pregnancy adversely affects survival, the retrospective reports that suggest a potential favorable effect of subsequent pregnancy are too small to draw firm conclusions.[41] A trend toward better survival is also noted in patients who received adjuvant chemotherapy and subsequently became pregnant.[42]

Lactation and Breast Reconstruction

Lactation is possible in a small percentage of patients after breast-conserving therapy for early-stage breast cancer.[43] Lumpectomy using a radial incision rather than the cosmetically preferred circumareolar incision is less likely to disrupt ductal anatomy. Disruption of the ductal system may increase the rate of mastitis. Breastfeeding is contraindicated in women receiving chemotherapy, because significant levels of the drug can be found in breast milk.

Breast reconstruction with the use of autologous tissue has increased secondary to questions about the use of silicone-filled implants. The transverse rectus abdominis myocutaneous flap (TRAM) is one popular method of breast reconstruction. Because the donor site is a portion of the anterior abdominal wall, there is potential concern when the patient develops abdominal distention from pregnancy. In one case report and review of the literature, nine women who became pregnant following breast reconstruction experienced no problem with anterior abdominal wall integrity.[44] However, because data are limited, it may be best to address reconstruction in the postpartum period.

Lymphoma

Hodgkin's Lymphoma

Approximately 33,980 cases of lymphoma were expected to be diagnosed in women in the United States in the year 2010, and only about 11% of these would be Hodgkin's lymphoma (HL).[17] **Hodgkin's lymphoma is the second most commonly diagnosed cancer in women aged 15 to 29 years, and presents at a mean age of 32 years. It is therefore more commonly associated with pregnancy than non-Hodgkin's lymphoma (NHL), where the peak age incidence is 42 years.** Lymphomas complicate approximately 1 in 6000 pregnancies, and there are few large series to evaluate the many issues affecting these women. However, spontaneous abortion, stillbirth rates, and preterm births do not appear to be increased. Pregnancy does not appear to adversely affect the course of the disease.[45] **Termination of pregnancy should not be routinely advised.** Although some advocate therapeutic abortion for the patient with a first-trimester pregnancy and HL to allow complete staging, others limit therapeutic abortion to those women requiring infradiaphragmatic irradiation or those with systemic symptoms or visceral disease, which are best managed with multiagent chemotherapy.

Women with HL frequently present with enlarged cervical or axillary lymph nodes. The diagnosis is established by biopsy of the suspicious nodes. The presence of systemic symptoms, such as night sweats, pruritus, or weight loss, suggests more extensive disease. In a series of 17 women diagnosed with HL during pregnancy, the average time of diagnosis was 22 weeks of gestation and systemic symptoms were uncommon.[45] Two histologic variants, nodular sclerosis and lymphocyte predominant, have a better prognosis than mixed-cellularity and lymphocyte-depleted tumors. Nodular sclerosis type has been reported in approximately 75% of the cases diagnosed during pregnancy.[45] Clinical staging for lymphoma requires systemic evaluation by history, laboratory findings, bone marrow, and radiographic imaging. Clinical treatment and staging are individualized. Although pathologic staging for HL in the nonpregnant patient may involve laparotomy and splenectomy, these are not generally performed in pregnancy. The routine evaluation for HL during pregnancy includes

TABLE 47-3 STAGING CLASSIFICATION OF HODGKIN'S DISEASE*

STAGE	DESCRIPTION
I	Involvement of a single lymph node region (I) or of a single extralymphatic organ site (I_E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ site and of one or more lymph node regions on the same side of the diaphragm (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which also may be accompanied by localized involvement of an extralymphatic organ or site (III_E), of the spleen (III_S), or of both (III_{SE})
IV	Diffuse or disseminated involvement of an extralymphatic organ with or without localized lymph node involvement (liver, bone marrow, lung, skin)

*Symptoms of unexplained fever, night sweats, and unexplained weight loss of 10% of normal body weight result in classification of patients as B; absence of these symptoms is denoted as A.

a single anterior/posterior view chest x-ray, liver function tests, serum creatinine clearance, complete blood count, erythrocyte sedimentation rate, and bone marrow biopsy. **Evaluation of the abdomen is compromised by the gravid uterus, and MRI is preferred, because it can accurately assess nodes, liver, and spleen.** Chest tomography or computed tomographic (CT) scan of the mediastinum may be necessary to evaluate nodal enlargement in the chest. Isotope scans of the liver and bone are best avoided during pregnancy. A single-shot lymphangiogram results in an exposure of less than 1 cGy to the fetus and is probably safe after the first trimester, but has become less available and may have limited accuracy.[46] Ultrasonography is safe and may provide useful information.

Disease stage (Table 47-3) is the most important factor in treatment planning and prognosis. The survival rate for early-stage HL exceeds 90%, whereas patients with disseminated nodal disease have a 5-year survival rate of about 50%. As expected, patients with stage IV disease have poor survival rates. Radiation therapy is the mainstay of treatment for early-stage HL, and combination chemotherapy is employed for the treatment of advanced-stage disease with organ involvement. **Most investigators agree that treatment should not be withheld during pregnancy except in early-stage disease, particularly if the diagnosis is made in late gestation.**

Radiotherapy to the supradiaphragmatic regions may be performed with abdominal shielding after the first trimester. When this approach is chosen, irradiation should be delayed until after the first trimester, total fetal dose should be limited to 10 cGy or less, and the goal is partial therapy with completion therapy after delivery. Thomas and Peckham reported three cases of mantle field irradiation with abdominal shielding for supradiaphragmatic disease. The estimated radiation exposures to the fetus for these patients at 10, 15, and 16 weeks were 2.5, 4.4, and 10.4 cGy, respectively.[46] Although these pregnancies went to term with apparent normal outcomes, long-term follow-up on these infants was not presented. Spontaneous abortion has been reported with an estimated first-trimester fetal dose of 9 cGy secondary to scatter from delivering 4400 cGy to the chest of a patient receiving treatment for a recurrence.[47] In general, if the estimated exposure to a first-trimester fetus is expected to exceed 10 cGy or if combination chemotherapy is planned for the first trimester, therapeutic abortion should be considered because of an increased risk of fetal malformations.[48] Asymptomatic early-stage disease presenting in the second half of pregnancy may be followed closely while preparations are made for early delivery.[47] The use of corticosteroids and single-agent chemotherapy has been proposed for the patient with systemic symptoms.

Subdiaphragmatic or advanced disease requires chemotherapy. ABVD (doxorubicin, bleomycin, vinblastine, dacarbazine) is considered the standard-of-care regimen, with MOPP (mechloretamine, vincristine, procarbazine, prednisone) also reported with the second most frequency.[49] Because many of these chemotherapeutic agents are known teratogens, such treatment is best avoided in the first trimester. A recent systematic review found 42 pregnancies in which HL was treated with chemotherapy.[50] Seventeen were exposed to chemotherapy in the first trimester, resulting in six congenital anomalies and three spontaneous abortions. Similar treatments should also be approached with caution later in pregnancy, although most case reports have documented only intrauterine growth restriction and neonatal neutropenia as complications. The aforementioned systematic review found normal pregnancy outcomes in women treated after the first trimester, with the exception of a single third-trimester intrauterine fetal demise (IUFD). Long-term follow-up toxicity studies are lacking.

Following therapy for HL, it has been suggested that pregnancy planning should take into consideration that about 80% of recurrences manifest within 2 years. Treatments for HL may compromise the reproductive potential of young patients.[15,51] As reflected in Figure 47-1, ovarian failure is more likely to occur in older patients, even if treated with fewer courses of chemotherapy.[51] Early studies reported normal ovarian function in only 12% of women following therapy for HL. Combined treatment with radiation and chemotherapy lead to the highest risk of ovarian failure. **More recent series have shown the pregnancy rate among reproductive-age HL survivors to be similar to the normal female population.**[52] Regimen changes that have occurred since the earlier reports include improved pelvic shielding during primary irradiation, ovarian transposition when pelvic radiation is required, and the more frequent use of the ABVD regimen instead of MOPP. Whereas combined oral contraceptives have been advocated to preserve ovarian function, there is no evidence of efficacy. Depending on their availability, new reproductive technologies, including oocyte donation and embryo cryopreservation, can be considered for select situations.

Patients who become pregnant after treatment for HL do not demonstrate increased adverse perinatal outcomes such as fetal wastage, preterm birth, and birth defects when compared with sibling controls.[53] Although fetal anomalies have occurred after treatment for HL, chromosomal abnormalities or a new gene mutation have not been diagnosed.[51] The absence of a repetitive pattern of malformations makes it difficult to imply a causal relationship

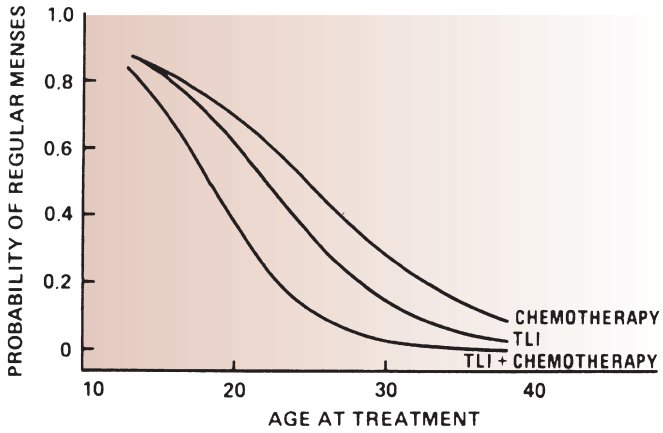

FIGURE 47-1. Probability of regular menses after chemotherapy, total lymphoid irradiation (TLI), and TLI and chemotherapy in patients with Hodgkin's disease. The synergistic effect is more apparent in younger women. (From Horning SJ, Hoppe RT, Kaplan HS: Female reproduction after treatment for Hodgkin's disease. N Engl J Med 304:1377, 1981.)

between any birth defects observed and previous therapy for Hodgkin's disease.

General recommendations, therefore, include delaying therapy until at least the second trimester due to the increased first-trimester fetal risk. **After the first trimester, therapy should not be delayed for patients with symptomatic, subdiaphragmatic or progressive HL.** Treatment options include supradiaphragmatic radiation therapy for early-stage disease, and combination chemotherapy for bulky, subdiaphragmatic, progressive, or advanced disease. Radiation fields should be tailored to limit fetal dose, and a maximal fetal dose calculation should be performed prior to treatment. Pregnant women with HL should be managed by a maternal-fetal medicine specialist, and whether pregnancy termination should be pursued will depend on the clinical situation.

Non-Hodgkin's Lymphoma

Non-Hodgkin's lymphoma (NHL) occurs at a mean age of 42 years and, therefore, is reported less frequently than Hodgkin's lymphoma in association with pregnancy. **In general, NHL is more likely to complicate pregnancy because more patients have an aggressive histology and advanced-stage disease.** Indolent lymphomas are less common in younger patients and are rarely described in pregnancy. Up to 70% of NHL in pregnancy is diffuse large B-cell lymphoma.[54] Burkitt's lymphoma is usually rapidly progressive and may involve the breast and ovary. Lymphoma of the breast has a particularly poor prognosis, and it has been speculated that there may be a hormonal influence on this malignancy in pregnant patients.

A recent systematic review identified 75 women with NHL treated with systemic therapy in pregnancy.[50] CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) is the most widely used regimen for aggressive NHL, and CHOP or CHOP-B (plus bleomycin) was the most common regimen in the above series. Overall, CHOP/CHOP-B did not have a clear adverse effect on pregnancy outcomes. Approximately 25% of these patients received chemotherapy in the first trimester, with no congenital anomalies reported. Two miscarriages were reported in patients treated with non–CHOP-based regimens. In patients treated after the first trimester, there was one IUFD and one stillborn infant, both with non-CHOP-based regimens, as well as a 33-week infant with transient leukopenia. The anti-CD20 antibody rituximab was incorporated into the regimen of seven patients. Adverse events in these seven infants included one episode of transient pulmonary insufficiency, and one episode of premature B-cell depletion that resolved at 12 weeks.[55]

Adult T-cell leukemia/lymphoma, caused by the human T-cell lymphotropic virus type I, is found in Japan, the Caribbean, and the southern United States. The virus is present in familial clusters and is transmitted by sexual intercourse, blood transfusions, and breast milk. Infants seroconvert between 12 and 19 months of age at a rate of 20% to 25%.[56]

Acute Leukemia

Although the incidence of leukemia in pregnancy is not specifically known, it is estimated to occur in fewer than 1 in 75,000 pregnancies. **Acute leukemia represents about 90% of leukemias coexisting with pregnancy.** Acute myeloid leukemia (AML) accounts for about 60% and acute lymphoblastic leukemia (ALL) for about 30% of cases. More than three fourths of the cases are diagnosed after the first trimester.[11] The prognosis for acute leukemia in pregnancy is guarded.[57] Although there is no evidence that pregnancy adversely affects the prognosis of acute leukemia, a study in 1988 reported a median survival of 27.5 months in a nonpregnant population.[58] However, the differences in patients and the varied treatments preclude any reliable comparison.[59] Optimal care of the pregnant patient with acute leukemia necessitates a team effort and is best achieved in a cancer referral center.

The diagnosis of acute leukemia is rarely difficult. The signs and symptoms of anemia, granulocytopenia, and thrombocytopenia, including fatigue, fever, infection, and easy bleeding or petechiae, usually prompt a complete blood count. A normal or elevated white blood cell count (WBC) is present in up to 90% of patients with ALL. A WBC in excess of 50,000 is found in only one fourth of patients. In contrast, patients with acute nonlymphocytic leukemia (ANLL) may present with markedly elevated WBC, although one third present with leukopenia. The diagnosis of leukemia should be confirmed by bone marrow biopsy and aspirate. The biopsy material is usually hypercellular with leukemic cells. The smear of the aspirate reveals decreased erythocyte and granulocytic precursors as well as megakaryocytes. Leukemic cells comprise greater than half of the marrow's cellular elements in most patients. The morphology of the marrow and the peripheral leukemic cells help to distinguish between lymphocytic and nonlymphocytic leukemias. This latter group includes acute myelocytic (granulocytic), promyelocytic, monocytic, and myelomonocytic leukemias and erythroleukemia. Acute myelocytic leukemia is the most common form of ANLL. Patients who develop ANLL as a result of previous chemotherapy have a particularly poor response to treatment.

There are numerous reports of successful pregnancies in patients aggressively treated with combination

chemotherapy for acute leukemia. Acute leukemia and its therapy are associated with an increase in stillbirths (approximately 15%), prematurity (approximately 50%), and fetal growth restriction.[59] In 1988 and 1991 reports by Aviles and colleagues showed no serious long-term effects of in utero exposure to chemotherapy.[60] The first report included 17 children, aged 4 to 22, whose mothers received treatment for acute leukemia.[60] In the second report, 43 children who were born to mothers with a variety of hematologic malignancies were examined at 3 to 19 years of age.[60] In both studies, greater than 40% of the cases involved exposure during the first trimester. Anthracyclines (daunorubicin, idarubicin, doxorubicin) are important components of acute leukemia therapy; daunorubicin and idarubicin in particular are associated with a high rate of congenital defects. Although doxorubicin is no longer generally included in leukemia induction regimens, it appears to have comparable efficacy and a more favorable side-effect profile in pregnancy.[61] In patients with breast cancer treated during pregnancy, doxorubicin has been used effectively with a favorable toxicity profile.[8] It may be rational to favor doxorubicin for anthracycline-based regimens in pregnancy.

If the mother is exposed to cytotoxic drugs within 1 month of delivery, the newborn should be monitored closely for evidence of granulocytopenia or thrombocytopenia.

Chronic Leukemia

Chronic leukemia accounts for approximately 10% of cases of leukemia during pregnancy, with the majority of these being patients with chronic myelocytic leukemia (CML).[59] Chronic lymphocytic leukemia has a median age of onset of about 60 years, making cases during pregnancy rare. The median age of patients with CML is 35 years. CML is characterized by excessive production of mature myeloid cell elements, with granulocyte counts averaging 200,000/dL. Most patients have thrombocytosis and a mild normochromic normocytic anemia. Platelet function is often abnormal, although hemorrhage is usually limited to patients with marked thrombocytopenia. CML tends to be indolent, and normal hematopoiesis is only mildly affected in the early stages of disease. Therefore, delay of aggressive treatment is more feasible than with acute leukemia. Unless complications such as severe systemic symptoms, autoimmune hemolytic anemia, recurrent infection, or symptomatic lymphatic enlargement occur, treatment for chronic leukemia should be withheld until after delivery. Therapy, when necessary, has included prednisone and an alkylating agent such as chlorambucil or cyclophosphamide. High-dose steroids alone may be used to treat autoimmune hemolytic anemia. Targeting the BCR/ABL fusion gene with imatinib, however, has caused a shift in the treatment paradigm for this disease. Due to the high rate of teratogenicity, however, imatinib is not labeled for use in pregnancy. Currently, the median survival time for CML is more than 60 months, with survivals up to 10 years common.

Often, the diagnosis of CML antedates the pregnancy. **Although pregnancy does not appear to affect CML adversely, therapy does increase the frequency of preterm birth and low birthweight.** Information about contemporary management and prognosis is scarce secondary to the fact that few recent cases of CML during pregnancy have been reported. There are reports of CML treatment with leukapheresis during pregnancy. This treatment appears to be both safe and effective. Leukapheresis results in improvement of blood counts, systemic symptoms, and splenomegaly. This treatment, although costly and involved, has less risk of teratogenesis than cytotoxic treatments.[57,62] Although allogeneic stem cell transplants offer the highest cure rates, such therapy is hazardous during pregnancy. Interferon (IFN) therapy has been reported in a limited number of pregnancies with good outcomes. In 2001 the FDA gave accelerated approval to imatinib mesylate (Gleevec), a synthetic inhibitor of the BCR/ABL kinase, STI571, for (1) treatment of patients in the chronic phase after failure of IFN therapy, (2) accelerated phase, and (3) blast crisis. This drug carries a category D warning in pregnancy.[63] Pye and colleagues reported the largest clinical report on the safety of imatinib in pregnancy in 2008.[64] A total of 180 pregnant women were exposed to imatinib (80% CML), but after excluding patients with unknown outcomes and those who underwent therapeutic abortion, 55 patients were remaining for evaluation. While 40 women delivered live infants without anomalies, there were eight spontaneous abortions and seven congenital anomalies (plus one termination for anomaly). **Although flawed by the limited data available in this series, it does appear that early exposure to imatinib is associated with a high rate of congenital anomalies and miscarriage.** Imatinib therapy initiated in the second and third trimester may not add significant additional risk, but better outcome data are necessary to determine.

Hairy cell leukemia during pregnancy is rare, with only six reported cases. A predilection for men and the older age groups is the reason for the infrequency. IFN treatment has been used in two cases with no adverse fetal effects.[62]

Melanoma

The incidence of malignant melanoma is increasing in the childbearing years, with reports of melanoma ranging from 1% to 3.3% in pregnant or lactating women and accounting for 8% of malignancies diagnosed in gestation.[1,2,65] The understanding of the natural history of melanoma has been advanced by the identification of prognostic variables.[65] Prognostic features of the primary tumor include tumor thickness, ulceration, and body location.[66] The methods used to describe the depth of invasion for melanoma are depicted in Figure 47-2.

A topic of continued debate is whether pregnancy exerts a negative effect on the course of malignant melanoma. Reports have suggested that melanoma arising during pregnancy is associated with an aggressive clinical course, more likely to be diagnosed at an advanced stage, and associated with a shorter disease-free interval.[9,65,66] Although many studies suggest that melanoma developing during pregnancy is more likely to appear in locations associated with a poor prognosis,[67-70] others show no increase in poor prognostic location of lesions in the pregnant patient and comparable survival outcomes to nonpregnant cohorts.[65,66]

The World Health Organization (WHO) 1991 study examined the relevant prognostic features of melanoma in

the childbearing years and in pregnancy.[67] This report suggested that patients who were diagnosed during pregnancy had tumors demonstrating significantly greater tumor thickness, which has been confirmed by other studies as well (Tables 47-4 and 47-5).[67-69] However, after correcting for tumor thickness, survival rates were similar. Other investigators have found no difference in lesion thickness in pregnancy.[70] The issue remains unsettled, and explanations for the increased tumor thickness in pregnancy include hormonal stimulation, growth factor stimulation, immunologic alterations of pregnancy, and delays in diagnosis, secondary to pigmentation changes during pregnancy.[69] Once diagnosis is suspected, biopsy is recommended. Wide surgical excision with appropriate margins remains the most effective modality for the treatment of melanoma. For patients with stage I or II tumors, the standard surgical excision with margins appropriate for tumor thickness should be performed. Lymph node dissection is undertaken in the patient with regional disease, and more recently, sentinel node evaluation and biopsy has been used successfully.[9] Because adjuvant chemotherapy is experimental and has not demonstrated improved survival, it is not recommended for the pregnant patient because of the potential risk to the fetus. Because chemotherapy results in a clinical response, usually of short duration, it is usually most appropriate to plan for early delivery in cases of disseminated disease presenting late in pregnancy.

Despite rare reports of regression after delivery, no studies support any therapeutic benefit associated with therapeutic abortion.[71] However, given the aggressive nature of the current therapies available for metastatic disease, it is appropriate to consider termination when managing advanced disease presenting in the first trimester.[71]

The patient who has undergone apparent successful treatment for a malignant melanoma may express concern about the safety of a future pregnancy. No adverse impact on recurrence or survival has been identified in most studies addressing this issue.[67] However, the timing of subsequent pregnancy deserves some consideration. The probability of survival of a specific cancer should be evaluated based on the known prognostic variables. The 5-year survival rate for the patient with a melanoma less than 1.5 mm thick is 90%. For a tumor of intermediate thickness (1.5 to 4 mm), the 5-year survival rate is 50% to 75%, and for a more deeply invasive tumor, survival is less than

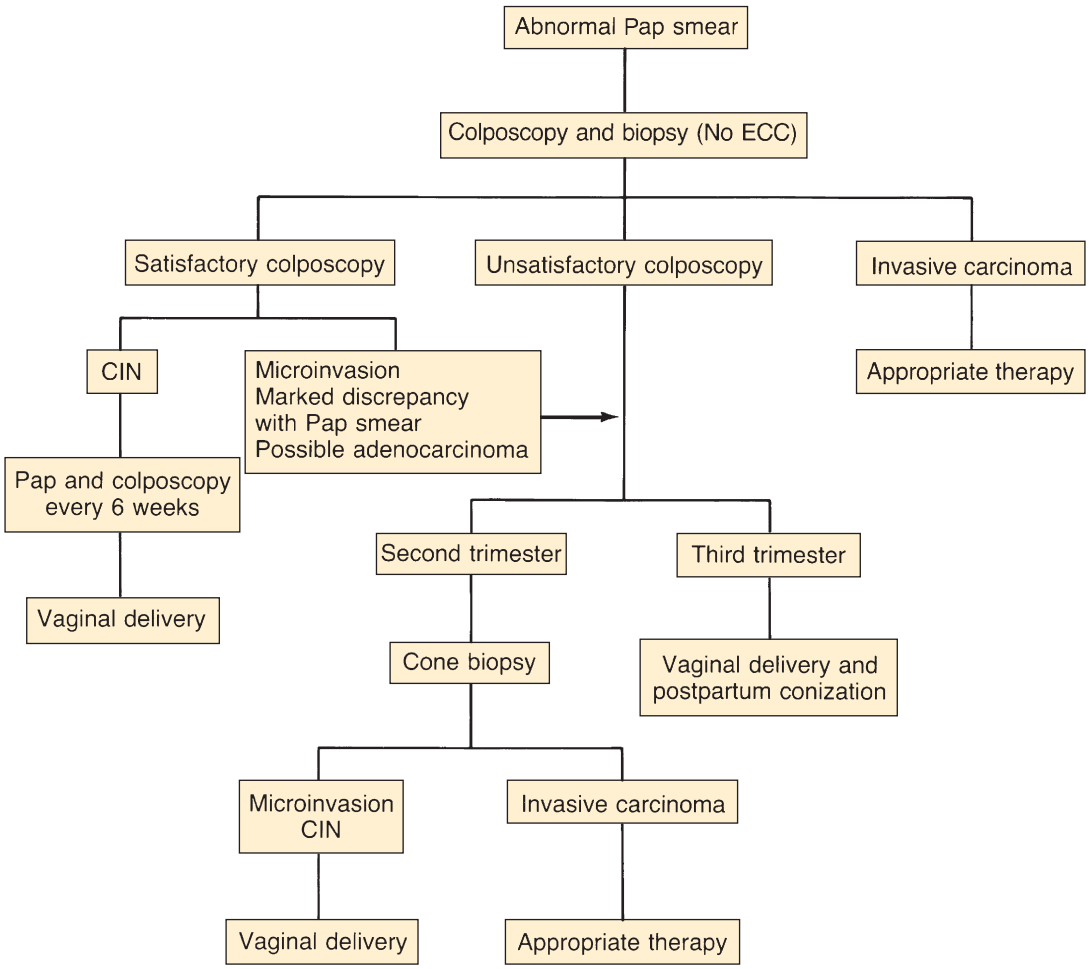

FIGURE 47-3. Suggested protocol for evaluation of abnormal cervical cytology in pregnancy. *ECC,* Endocervical curettage; *CIN,* cervical intraepithelial neoplasia. (From Hacker NF, Berek JS, Lagasse LD, et al: Carcinoma of the cervix associated with pregnancy. Obstet Gynecol 59:735, 1982.)

50%. Although some report that approximately 60% to 70% of patients develop their recurrence within 2 years and 80% to 90% within 5 years, the WHO study claimed that 83% of recurrences develop within the first 2 years.[71] Based on this information, it is generally recommended that patients wait 2 to 3 years before attempting another pregnancy, especially with nodal disease.[67] Furthermore, the use of hormonal agents, such as oral contraceptives, has not been demonstrated to adversely affect previously treated melanoma and recommendations for their use should be individualized.[72]

Cervical Cancer

Cervical cancer is the most common gynecologic malignancy associated with pregnancy, occurring in approximately 1 per 2200 pregnancies, and approximately 3%, or 1 in 34 cases, of all invasive cervical cancers occur during pregnancy.[1,2] Though it is the only cancer whose screening is part of the prenatal evaluation, the true incidence is difficult to ascertain due to the reporting biases associated with the reports originating from large referral centers. Also, various reports may include patients who have preinvasive lesions as well as those who are diagnosed in the postpartum period.

The initial obstetrical visit should include visualization of the cervix and cervical cytology, including an endocervical brush. The general principles of screening for cervical neoplasia apply during pregnancy. If the cervix appears friable, cervical cytology alone may not be sufficient to alert the physician to the presence of a malignant tumor. False-negative cervical cytology is at increased risk in pregnancy owing to excess mucus and bleeding from cervical eversion. Therefore, it is necessary to obtain a biopsy to ensure that tissue friability is not secondary to tumor. Also, an ulcerative or exophytic lesion must have histologic sampling performed. Although approximately one third of pregnant patients with cervical cancer are asymptomatic at the time of diagnosis, the most common symptoms are vaginal bleeding or discharge. Though these complaints are common and usually attributed to pregnancy-related conditions, it is important to evaluate for the possibility of neoplastic disease of the lower genital tract in pregnant women with these symptoms.

Cervical cytology suggestive of a squamous intraepithelial lesion or a report of atypical glandular cells during pregnancy requires appropriate clinical evaluation (Figure 47-3). Colposcopy during pregnancy is usually enhanced by the physiologic eversion of the lower endocervical canal.

However, vascular changes and redundant vagina may alter or obscure normal visualization, rendering interpretation difficult, and referral to a gynecologic oncologist may be appropriate. During pregnancy, failure to visualize the entire transformation zone and squamocolumnar junction is uncommon. Although endocervical curettage is not generally recommended during pregnancy, lesions involving the lower endocervical canal can often be directly visualized and biopsied. Whereas the pregnant cervix is hypervascular, serious hemorrhage from an outpatient biopsy is uncommon, and the risk of bleeding is offset by the risk of missing an early invasive cancer. Following a colposcopy evaluation with appropriate tissue sampling, most patients with preinvasive lesions can be followed with repeat colposcopy at 6- to 8-week intervals to delivery.[73]

Patients with cervical neoplasia will require a careful and complete colposcopic evaluation 6 weeks postpartum. Cone biopsy during pregnancy, when necessary, should ideally be performed during the second trimester to reduce the risks of first-trimester abortion and rupture of membranes or premature labor in the third trimester.[74] Complications from conization of the pregnant cervix are common. Therapeutic conization for intraepithelial squamous lesions is contraindicated during pregnancy. Diagnostic cone biopsy in pregnancy is reserved for patients whose colposcopic-directed biopsy has shown superficial invasion (suspect microinvasion) or in other situations in which an invasive lesion is suspected but cannot be confirmed by biopsy. When a cone biopsy is necessary during pregnancy, one should keep in mind the anatomic alteration of the cervix secondary to pregnancy. A shallow disk-like cone is usually satisfactory to clarify the diagnosis with a minimum of morbidity. It should be kept in mind that patients who have had a conization during pregnancy are at higher risk for residual disease. Therefore, close follow-up is essential.

Considering the routine practice of performing cervical cytology in early pregnancy, one would expect there to be a preponderance of early-stage disease diagnosed in the first trimester. Surprisingly, this is not the situation. The diagnosis of cervical cancer is commonly made postpartum rather than during pregnancy, and although stage IB disease is the most common stage found, all stages are represented in significant numbers. Both patient and physician factors, including lack of prenatal care, failure to obtain cervical cytology or to biopsy gross cervical abnormalities, false-negative cytology, and failure to evaluate abnormal cytology or vaginal bleeding properly, contribute to the delays in diagnosis.

Following the diagnosis of invasive cervical cancer, a staging evaluation is indicated. The standard cervical staging is clinical and usually based on the results of physical examination, cystoscopy, proctoscopy, chest radiograph, and intravenous pyelogram. A CT scan or, in some centers, lymphangiography is often performed to identify lymph node metastasis; however, in the pregnant patient, the standard staging evaluation is modified. The chest radiograph is performed with abdominal shielding. Sonography is used to detect hydronephrosis and, if additional retroperitoneal imaging is desired for the evaluation of lymphadenopathy, consideration should be given to employing MRI because it does not involve ionizing radiation.

Microinvasion

In patients with a microinvasive squamous carcinoma with negative margins on cone biopsy, consideration can be given to conservative management until delivery. The risk of occult metastatic disease is predominantly dependent on two pathologic features: (1) the depth of invasion and (2) the presence or absence of lymph-vascular space involvement.[75] Whether the cone biopsy can be considered sufficient long-term therapy or whether a postpartum hysterectomy with or without lymphadenectomy should be performed is also based on the detailed analysis of the pathologic features of the cone biopsy. In these cases, consultation with a gynecologic oncologist is appropriate.

Invasive, Early-Stage Disease

Because the definitive treatment of invasive cervical cancer is not compatible with continuation of pregnancy, the clinical question that must be addressed is when to proceed with delivery so that therapy can be completed. Considering this requirement, treatment options will be influenced by gestational age, tumor stage and metastatic evaluation, and maternal desires and expectations regarding the pregnancy. The management of early invasive cervical cancer (stages IA2, IB, and IIA) in the young patient is usually by radical hysterectomy, pelvic lymphadenectomy, and aortic lymph node sampling.[76,77] The primary advantage of this treatment approach over radiation therapy for these patients is preservation of ovarian function. For the woman with a high probability of having a poor prognostic lesion and, therefore, requiring postoperative irradiation, consideration can be given to performing a unilateral or bilateral oophoropexy at the time of the hysterectomy. The ovarian suspension should be intraperitoneal, because retroperitoneal placement seems to predispose to subsequent ovarian cyst formation. In the first trimester, this surgery is usually carried out with the fetus in utero. In the third trimester, the radical hysterectomy and pelvic +/– para-aortic lymphadenectomy are performed after completion of a high classic cesarean delivery. Delays in therapeutic intervention have not been reported to increase recurrence rates for patients with small-volume stage I disease.[76] Although the pelvic vessels are large, the dissection is enhanced by more easily defined tissue planes.[77]

Second-trimester situations are more problematic. Studies have supported delay in management of early-stage disease until after fetal viability in women diagnosed after 20 weeks' gestation.[76] Other reports have suggested the administration of one to three cycles of platinum-based chemotherapy, allowing an additional 7 to 15 weeks of fetal maturation. In one study, maturation from 26 to 27 weeks' gestation compared with 34 to 35 weeks increased neonatal survival from 67% to 97%.[78] The neoadjuvant chemotherapy approach (chemotherapy before either surgery or irradiation) has been reported in nine cases of cervical cancer diagnosed during pregnancy. Three patients, all with advanced disease, ultimately died of disease, but all neonatal outcomes were normal.[79] Certainly in terms of general fetal salvage and outcome, the risk of extreme prematurity would far outweigh the risk of the chemotherapy exposure. Although this management of second-trimester cervical cancer presentations seems logical, there is scant information about this treatment approach. In cases diagnosed

remote from fetal maturity, between 20 and 30 weeks of gestation, assessment of nodal involvement should be considered and will dictate further recommendations for management.[79]

Invasive, Locally Advanced Disease

The management of the patient with more advanced, local disease is based on treatment with chemotherapy and irradiation, both external beam to treat the regional nodes and shrink the central tumor and brachytherapy to complete the delivery of a tumoricidal dose to the cervix and adjacent tissues.[79] Coordinating a chemoradiation treatment plan for pregnant patients with stage IIB, stage III, and stage IVA is challenging. The patient with a first-trimester pregnancy can usually be treated in the standard fashion with initiation of chemotherapy and external therapy to the pelvis or extended field, as dictated by standard treatment guidelines. Most of these patients proceed to abort spontaneously within 2 to 5 weeks of initiating the radiation. Patients in the late first trimester are least likely to abort spontaneously, and it may be necessary to perform a uterine evacuation on the completion of external therapy in some patients. Following either spontaneous abortion or uterine evacuation, the brachytherapy component of the radiation therapy can proceed in the standard fashion. Patients in either their second or third trimester should have a high classic cesarean delivery before starting standard chemotherapy and irradiation. Again, it would seem appropriate to strongly consider neoadjuvant chemotherapy for this group of patients, especially the patient with a second-trimester or early third-trimester presentation, when the opportunity for further fetal maturation can be provided.

Invasive, Distant Metastasis

Metastatic disease to extrapelvic sites carries a poor prognosis. Although a select few patients with aortic node metastasis may receive curative therapy, it is unlikely for the patient with pulmonary metastasis, bone metastasis, or supraclavicular lymph node metastasis to be cured. Personal patient choices and ethical considerations are the major factors guiding treatment in these situations.

Small cell neuroendocrine tumors of the cervix associated with pregnancy are rare. Neoadjuvant or adjuvant chemotherapy with cisplatin, etoposide, and doxorubicin is recommended, and long-term survivors have been reported.[80] These tumors are considered to be histologically aggressive, and pregnancy preservation is not recommended. However, each case should be individualized.[79,80]

Method of Delivery

Controversy continues to surround the issue of the method of delivery for the term patient with cervical cancer. It seems heroic and unjustifiably risky to encourage vaginal delivery of a patient with a large, firm, barrel-shaped tumor or a large friable and hemorrhagic exophytic tumor. However, many small-volume stage IB, IIA, and early IIB tumors are potential candidates for vaginal delivery. Whether vaginal delivery promotes systemic dissemination of tumor cells is unknown, although the general opinion is that survival rates are not influenced by the mode of delivery.

Although systemic tumor dissemination secondary to vaginal delivery has not been documented, there are reports of episiotomy implants for both squamous carcinoma and adenocarcinoma following vaginal delivery.[81] Episiotomy implants are sufficiently rare that the risk should not be a determining factor for a given patient. However, the episiotomy should be carefully followed in a cervical cancer patient who delivers vaginally. Episiotomy nodules in these patients must be promptly evaluated by biopsy, because an early diagnosis may permit curative therapy.[81] Diagnostic delays secondary to suspicion of the nodules representing stitch abscess should be avoided.

Survival

Although some authors have suggested that the survival of patients with cervical cancer associated with pregnancy is compromised, most reports indicate that the prognosis is not altered.[75-78]

Ovarian Cancer

Although adnexal masses are often observed in pregnancy, only 2% to 5% are malignant ovarian tumors.[82] Ovarian cancer occurs in approximately 1 in 18,000 to 1 in 56,000 pregnancies.[82] With the increased use of diagnostic ultrasound, ovarian cysts and neoplasms are more frequently encountered in early pregnancy.[82,83] Ultrasonic features that are associated with an increased risk of malignancy include the presence of excrescences/papillary structures, irregular borders, septations/complex appearance, and presence of ascites, and these features should prompt further evaluation.[83]

Whereas the three major categories of ovarian tumors (epithelial, including borderline tumors, germ cell, and sex-cord stromal) occur during pregnancy, the majority of cases are diagnosed in early stages, resulting in favorable outcomes.[82] Germ cell tumors account for 30% to 50% (Figure 47-4), 37.5% to 50% are epithelial tumors, and the remainder are sex-cord stromal tumors or metastatic tumors to the

FIGURE 47-4. Dysgerminoma, the most common malignant ovarian neoplasm found in pregnancy, characterized by a lobulated solid gross appearance. (From Copeland LJ: Gestational trophoblastic neoplasia. *In* Copeland LJ [ed]: Textbook of Gynecology, ed 2. Philadelphia, WB Saunders, 2000, p 1391.)

ovary.[82] This distribution is undoubtedly skewed by the reporting bias associated with rare tumors. Characteristic of epithelial tumors in young patients who are not pregnant, the majority of epithelial ovarian tumors complicating pregnancy are of low grade (grade 1 or low malignant potential) or early stage, and not uncommonly these tumors are both low grade and stage I.

Management of the adnexal mass in pregnancy is controversial. The risks of surgical intervention may favor a conservative approach.[82,83] Serial sonograms may be of some value in determining the nature and biologic potential of the tumor. A number of opposing risks require consideration before following a conservative approach. The risk of greatest concern is that a delay of surgical intervention could permit a malignant ovarian tumor to spread, resulting in a decreased opportunity for cure. However, considering the rarity of advanced-stage poorly differentiated epithelial tumors in this age group, this risk is relatively small. Although ovarian tumors may be the cause of obstructed labor, this is uncommon.[82] Skilled sonographic examination is essential to determining the potential for malignancy based on size and imaging characteristics. Serial sonographic evaluations will also identify the rare tumor that remains in the pelvis as the gestation progresses. Because most ovarian masses relocate to the abdomen as the pregnancy advances, other explanations should be considered for persistent pelvic masses, including pelvic kidney, uterine fibroids, and colorectal or bladder tumors.

There does appear to be an increased probability that an adnexal mass during pregnancy will undergo torsion or rupture, and surgical intervention for these events is associated with higher fetal loss than an elective procedure.[84] Prompt surgical exploration is also performed for the mass associated with ascites or when there is evidence of metastatic disease. Because surgical exploration during pregnancy is associated with an increase in pregnancy loss and neonatal morbidity, it is ideal to delay surgical intervention until term or after delivery. However, if intervention is required during pregnancy, surgery should be performed after 16 weeks of gestation to reduce the risk of spontaneous abortion and allow the resolution of functional cysts.[84]

When a malignant ovarian tumor is encountered at laparotomy, surgical intervention should be similar to that for the nonpregnant patient. If the patient is preterm and the tumor appears confined to one ovary, consideration should be given to limiting the staging to removal of the involved ovary, cytologic washings, omentectomy, pelvic and paraaortic lymph node dissection, and a thorough manual exploration of the abdomen and pelvis.[85] The potential benefit of more extensive staging may be offset by higher pregnancy loss or neonatal morbidity. Before surgery, a comprehensive discussion with the patient should guide the extent of surgery if metastatic disease, especially a high-grade epithelial lesion, is encountered. Depending on the gestational age and the patient's desires, limited surgery followed by chemotherapy and additional extirpative surgery following delivery may be offered in select cases.[85]

Preoperative serum tumor markers are of limited value during pregnancy secondary to the physiologic increases in β-hCG, AFP, and CA 125. Kobayashi and colleagues have reported the mean CA 125 level during the first trimester is 72 units/mL and then normalizes during the second trimester.[86] However, following diagnostic confirmation of a malignant ovarian tumor, the appropriate serum markers may be useful to monitor the course of the disease.

Virilizing ovarian tumors during pregnancy are most commonly secondary to theca-lutein cysts, and their evaluation and management should be conservative. These benign exaggerated physiologic "tumors" may redevelop with subsequent pregnancies.[82,83]

Postoperative Adjuvant Therapy

Postoperative adjuvant therapy should follow the treatment guidelines for the nonpregnant patient. Though it may be reasonable for patients with low-risk, low-stage tumors to have adjuvant therapy delayed until after delivery, patients with advanced epithelial tumors should receive combination chemotherapy. Until 1995 the standard therapy was a platinum agent and an alkylating agent, which were well tolerated in pregnancy. With the superior effectiveness of the combination of a platinum agent and paclitaxel, these agents offer the patient a better survival. There are few reports that suggests tolerability of this regimen when used in the second and third trimester, including favorable case reports on the treatment of stage III serous ovarian carcinoma with postoperative platinum-based chemotherapy.[85] There also have been a number of favorable treatment outcomes reported in patients who have malignant germ cell tumors and are pregnant.[87]

Young and colleagues reviewed their collective experience with stromal ovarian tumors in pregnancy.[88] One third of the patients presented with tumor rupture. Despite reports of successful use of bleomycin, etoposide, and platinum in pregnancy, the role of adjuvant chemotherapy for stromal tumors is complex and controversial, and consultation with a gynecologic oncologist is recommended.

Vulvar and Vaginal Cancer

Because vulvar and vaginal cancers usually occur after age 40, the diagnosis of either disease concurrent with pregnancy is rare. Fewer than 30 cases of vulvar carcinoma diagnosed and treated during pregnancy have been reported.[85,89]

Vulvar carcinoma in pregnancy is usually stage I or II disease. The diagnosis is based on biopsy, and neither pregnancy nor the young age of a patient should discourage the biopsy of a vulvar mass. Because verrucous squamous carcinoma tends to be misdiagnosed as condyloma, it is important to inform the pathologist of the clinical characteristics of unusually large or aggressive condyloma-like lesions. Surgical management is similar to that used in the nonpregnant patient, with the preference being to perform surgery in the second trimester to avoid the fetal risks of exposure to anesthesia in the first trimester and the maternal risks associated with operating on the hypervascular vulva in the third trimester. If vulvar carcinoma is diagnosed after 36 weeks' gestation, treatment is generally deferred until the postpartum period.[85] The surgical management of vulvar carcinoma is trending to more conservative procedures.[85] Vaginal delivery has been reported following surgical resection of vulvar cancers during pregnancy.[85]

Vaginal carcinoma is less common than vulvar carcinoma. The same limitations apply to vaginal cancer as apply to locally advanced cervical cancer in pregnancy. The cornerstone of treatment is irradiation therapy. Clear cell adenocarcinoma of the vagina has been reported in 16 pregnant patients, and 13 were long-term survivors.[90]

Endometrial Cancer

Approximately 35 cases of endometrial cancer associated with pregnancy have been reported in the literature. Although more than half of these cases were diagnosed in the first trimester, abnormal bleeding later in pregnancy or postpartum may be the presenting symptom of this tumor. Only about 30% of these cases are associated with a viable fetus.[91] Fortunately, a majority of cases of endometrial cancer in pregnancy are diagnosed with stage I disease (88%) and grade 1 tumors (80%). With a thorough evaluation excluding metastatic disease and extensive counseling, these patients may be candidates for conservative treatment with hormonal manipulation, repeat endometrial evaluation, and modifications of risk factors, in order to preserve fertility.[91]

Gastrointestinal Cancers

Upper Gastrointestinal Cancers

The diagnostic delay in detecting pregnancy-related upper gastrointestinal (GI) cancers is often attributable to the frequency and duration of GI symptoms in pregnancy. In the United States, stomach cancer is rarely diagnosed in women during the reproductive years. During pregnancy, persistent severe upper GI symptoms are best evaluated by gastroduodenoscopy rather than radiologic studies. Because curative resection of localized stomach cancer is possible in only approximately 30% of patients, it is imperative that treatment not be delayed.

Malignant hepatic tumors are rare during the reproductive years. Hepatocellular tumors detected during pregnancy should be resected, because the maternal and fetal mortality associated with subcapsular hemorrhage and liver rupture during pregnancy is high. Elevated steroid levels may predispose the tumor to rupture during pregnancy. There is no increase in the vascularity of the liver during pregnancy. In patients with unresectable hepatomas, therapeutic abortion can be considered to decrease the risk of subsequent rupture and bleeding.

Colon and Rectal Cancer

The incidence of colon cancer during pregnancy is about 1 in 13,000 live-born deliveries.[92] Colorectal carcinoma is usually found in women beyond childbearing age, with only 8% of patients diagnosed before age 40.

Because pregnancy is often accompanied by constipation and exacerbations of hemorrhoids and anal fissures, the symptoms of colorectal carcinoma, namely, rectal bleeding, constipation, pain, and backache, tend to be attributed to the pregnancy, and diagnostic delay is common. **The majority of colorectal carcinomas during pregnancy are rectal and palpable on rectal examination, in contrast to more proximal lesions found in the nonpregnant patient (Table 47-6).**[92] Patients with unexplained hypochromic microcytic anemia should be evaluated with stool guaiac testing. If a colorectal lesion is suspected, endoscopic methods of evaluation are preferred to radiologic imaging studies. Unfortunately, most cases of colorectal cancer are not diagnosed until late pregnancy or at the time of delivery. Delays in diagnosis are probably responsible for a higher likelihood of advanced-stage colorectal cancer in pregnancy and an associated poor prognosis. The hormonal effect of pregnancy on tumor development is unknown. A report by Woods and colleagues suggests that colorectal carcinoma in pregnancy adversely affects the pregnancy.[92] Only 78% of their cases resulted in healthy live-born infants.

TABLE 47-6 Distribution of Colon and Rectal Carcinomas in Nonpregnant and Pregnant Populations

PATIENT GROUP	TOTAL	COLON	RECTUM
General population	1704	1244 (73%)	460 (27%)
Age under 40 years	186	127 (68%)	59 (32%)
Pregnant	244	41 (17%)	203 (83%)

From Medich DS, Fazio VW: Hemorrhoids, anal fissure, and carcinoma of the colon, rectum, and anus during pregnancy. Surg Clin North Am 75:77, 1995.

Management of colon cancer is determined by gestational age at diagnosis and tumor stage. During the first half of pregnancy, colon resection with anastomosis is indicated for colon or appendiceal cancers.[93] Abdominoperineal resection or low anterior resection has been accomplished up to 20 weeks' gestation without disturbing the gravid uterus. In some cases, access to the rectum may not be possible without a hysterectomy or uterine evacuation.

In late pregnancy, a diverting colostomy may be necessary to relieve a colonic obstruction and allow the development of fetal maturity before instituting definitive therapy. Some patients with a diagnosis after 20 weeks may opt to continue the pregnancy to fetal viability. Vaginal delivery is planned unless the tumor is obstructing the pelvis or is located on the anterior rectum. If cesarean delivery is performed, tumor resection can be accomplished immediately. Neoadjuvant chemotherapy or radiation therapy for colorectal carcinoma in the pregnant patient has not demonstrated sufficient response to risk fetal exposure.

There are two reports of pregnant patients with metastatic colorectal cancer treated with combination chemotherapy.[94] Both received FOLFOX6 (oxaliplatin, 5-FU, leucovorin). After diagnosis at 20 and 23 weeks' gestation, they were treated and delivered at 33 and 31 weeks, respectively. Normal development was reported at 1 and 3 years.

In one report, the stage-specific survival rates for pregnant patients with rectal cancer were 83%, 27%, and 0% for stages B, C, and D, respectively.[95] The corresponding survival rates for the same stages of colon cancer were 75%, 33%, and 0%. No Dukes' A classification rectal or colon cancer was reported, consistent with the frequency of diagnostic delays.[95]

Urinary Tract Cancers

Fewer than 50 cases of renal cell carcinoma and fewer than 10 cases of bladder cancer have been reported during pregnancy. Urethral carcinoma during pregnancy is also rare.

The hallmark of urinary tract cancers is hematuria. The initial evaluation of hematuria in pregnancy should be urethrocystoscopy, urinary cytology, and renal ultrasonography. The primary therapy for renal cell carcinoma is surgery, and the survival rate for localized disease may exceed 50%. Although preoperative arterial embolization may facilitate surgery on hypervascular tumors, improved survival rates have not been conclusively demonstrated. Adjuvant radiotherapy or chemotherapy tends to have minimal impact on long-term outcomes.

Transitional carcinoma of the bladder can be managed by local fulguration or resection if it is well differentiated and superficial. Less-differentiated, deeply invasive, and recurrent tumors may require a partial or complete cystectomy. Treatment of urethral carcinoma varies with the size and location. Distal urethral tumors are usually treated with excision and interstitial brachytherapy implants.

CENTRAL NERVOUS SYSTEM TUMORS

The spectrum of CNS tumors found in pregnant patients is similar to that of the nonpregnant patient. In pregnancy, 32% of brain tumors are gliomas, 29% meningiomas, 15% acoustic neuromas, and the other 24% are divided among other more rare subtypes. Spinal tumors account for only one eighth of the central nervous system tumors. Vertebral hemangiomas comprise 61% of the spinal tumors and 18% of meningiomas. Unfortunately, the presenting symptoms of headache and nausea and vomiting are often attributed to normal complaints of pregnancy, and delays in diagnosis result. Meningiomas, pituitary adenomas, acoustic neuromas, and vertebral hemangiomas may demonstrate rapid enlargement during pregnancy. This may be secondary to fluid retention, increase in blood volume, or hormonal stimulation. MRI is the preferred imaging technique used to diagnose intracranial neoplasms.

Because painful contractions and pushing increase intracranial pressure, it is recommended that labor be as pain free as possible, and the second stage of labor should be assisted with forceps to reduce the risk of herniation. The anesthetic management of labor and delivery for patients with intracranial neoplasms has been reviewed by Finfer.[95]

Whereas high-grade glial tumors should undergo prompt diagnosis and treatment, low-grade glial tumors such as astrocytomas and oligodendrogliomas do not usually require immediate intervention. Adjuvant cranial radiotherapy with abdominal shielding should be considered for patients with high-grade tumors. Adjuvant chemotherapy is not usually effective and, therefore, should probably be delayed until after delivery. A single series of six patients with malignant gliomas treated during pregnancy has been reported.[96] Three patients received procarbazine, lomustine, and vincristine, and three received temozolomide; all were unintentionally exposed during the first 4 weeks of pregnancy. Chemotherapy was stopped in all cases, and all patients delivered without immediate or remote fetal adverse events.

Successful surgical removal of a variety of CNS tumors has been reported.[95,96] Corticosteroids are recommended to reduce the surrounding edema of intracranial masses.

Bromocriptine may be used during pregnancy if a prolactin-secreting adenoma enlarges, causing symptoms. The safety of this medication is supported by a report of no adverse fetal effects in more than 1400 pregnancies following first-trimester exposure.

MISCELLANEOUS TUMORS

Similar to the management for small cell neuroendocrine tumors of the cervix,[80] neuroendocrine tumors or neuroblastomas of other primary sites tend to demonstrate excellent response to surgery or chemotherapy. Pheochromocytoma during pregnancy is rare and may mimic hypertensive disorders of pregnancy (see Chapter 41).

FETAL-PLACENTAL METASTASIS

Metastatic spread of a maternal primary tumor to the placenta or fetus is rare. In general, the biologically aggressive spectrum of malignancies seem to carry the highest risk for fetal metastases. One review identified 45 cases of placental metastases and seven cases of fetal metastases.[97] **Malignant melanoma is the most frequently reported tumor metastatic to the placenta.** Hematologic malignancies are the second most common tumor to spread to the placenta. Placental and fetal dissemination of lymphomas, leukemias, lung cancer, and CNS tumors have been reported.[97,98] Choriocarcinoma metastatic to a fetus usually results in death within a few months of age.[99] Therefore, in pregnant women with a concurrent malignancy, in addition to notifying the neonatology service, a thorough visual and histologic inspection of the placenta is recommended to assess for metastatic disease.[99]

GESTATIONAL TROPHOBLASTIC DISEASE AND PREGNANCY-RELATED ISSUES

It is uncommon for a normal viable pregnancy to be complicated by gestational trophoblastic disease (GTD). A comprehensive summary of the evaluation and management of the complete spectrum of GTD is beyond the scope of this chapter. However, the aspects of GTD related to the general obstetric and postpartum care are reviewed.

Hydatidiform Mole (Complete Mole)

The incidence of hydatidiform mole has great geographic variability. In the United States it occurs in approximately 1 in 1000 to 1 in 1500 pregnancies. The two clinical risk factors that carry the highest risk of a molar pregnancy are (1) the extremes of the reproductive years (age 50 or older carries a relative risk of over 500) and (2) the history of a prior hydatidiform mole (the risk for development of a second molar pregnancy is 1% to 2%, and the risk of a third after two is approximately 25%).[100,101] Patients with these risk factors should have an ultrasound evaluation of uterine contents in the first trimester. Although historically approximately 50% of patients were not diagnosed with a molar pregnancy before vaginal expulsion of molar tissue, currently in developed countries, most patients are diagnosed either by ultrasound while asymptomatic or by ultrasound for the evaluation of vaginal spotting or cramping

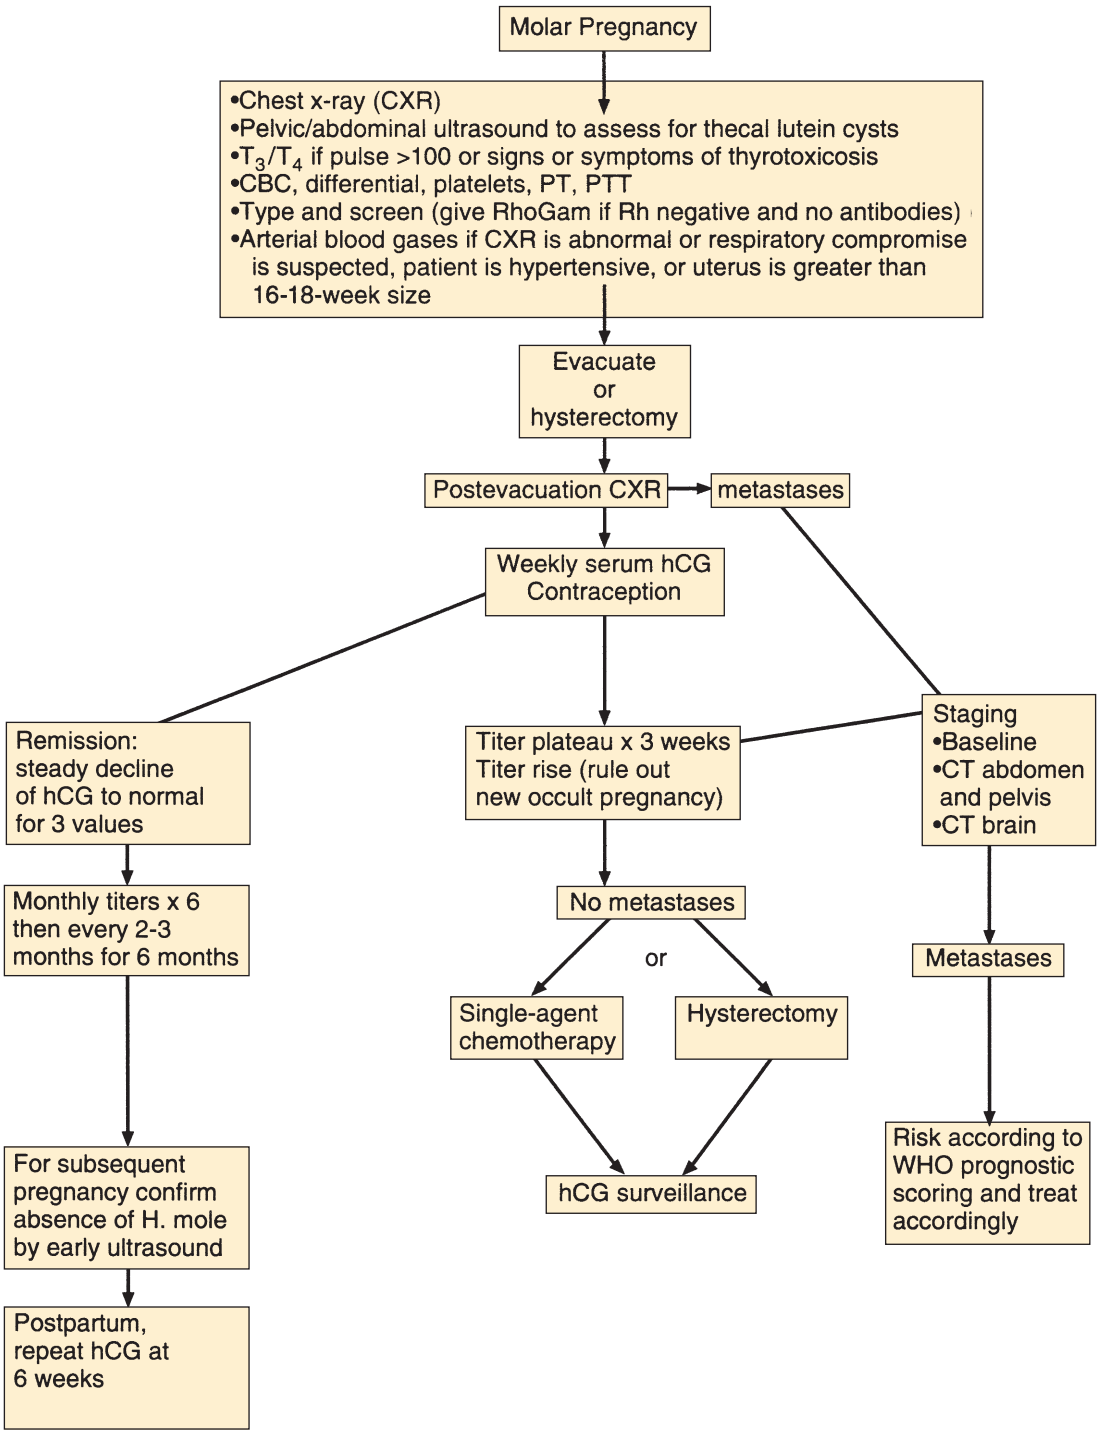

FIGURE 47-5. Algorithm for the management of molar pregnancy. (From Copeland LJ: Gestational trophoblastic neoplasia. *In* Copeland LJ [ed]: Textbook of Gynecology, ed 2. Philadelphia, WB Saunders, 2000, p 1414.)

symptoms. Approximately 95% of complete hydatidiform moles have a 46,XX paternal homologous chromosomal pattern.

The safest technique of evacuating a hydatidiform mole is with the suction aspiration technique. Oxytocin should not be initiated until the patient is in the operating room and evacuation is imminent in order to minimize the risk of embolization of trophoblastic tissue. The alternative management for the elderly patient who requests concurrent sterilization is hysterectomy. Following either evacuation or hysterectomy, weekly β-hCG is drawn until the hCG titer is within normal limits for 3 weeks. The titers are then observed at monthly intervals for 6 to 12 months. Figure 47-5 illustrates an algorithm for molar pregnancy management.[102]

For the patient with a complete molar pregnancy, the risk of requiring chemotherapy for persistent GTD is approximately 20%. Clinical features that increase this risk include

delayed hemorrhage, excessive uterine enlargement, theca-lutein cysts, serum hCG greater than 100,000 mIU/mL, and maternal age older than 40. It is important not to misinterpret a rising β-hCG due to a new intervening pregnancy as persistent GTD, because intervention with chemotherapy would be a significant risk to a new gestation, inducing either abortion or possible teratogenic defects.

Invasive Mole (Chorioadenoma Destruens)

Because invasion of the myometrium by molar tissue is clinically occult, it is difficult to assess the true incidence, and it is estimated to be between 5% and 10%. The clinical hallmark of an invasive mole is hemorrhage, which can be severe, and either vaginal or intraperitoneal.

Partial Hydatidiform Mole

Most partial moles have a triploid (paternally inherited, diandric, triploidies) karyotype, and the next most common are tetraploidies. A minority of partial moles exhibit a mosaic or partially diploid karyotype. Karyotype analysis of the accompanying fetus is important in planning therapeutic intervention. A partial mole associated with a nonviable fetal chromosomal abnormality requires either mechanical or medically induced uterine evacuation (Figure 47-6).[102] In the presence of an abundance of hydropic tissue, there is always the concern that trophoblastic tissue embolization may occur during uterine contractions induced to evacuate molar tissue. The management of a patient with sonographic findings suggestive of a diagnosis of a partial mole is particularly challenging if the karyotype analysis of the fetus is diploid, especially if the diagnosis is made in the second or third trimester. When a normal karyotype exists, it is appropriate to consider diagnostic possibilities other than partial mole, such as a twin gestation—one normal developing fetus and one molar pregnancy. Also, degenerative changes (hydropic villi), retroplacental hematomas, placental abnormalities (chorioangiomas), degenerative uterine myomas, and aborted tissue, sometimes referred to as a "transitional mole," may lead to imaging abnormalities that are difficult to interpret.

Approximately 2% to 6% of patients develop persistent GTD after a partial molar pregnancy.[103] Therefore, because choriocarcinoma can follow a true partial mole, these patients require the same postevacuation surveillance and management as the patient with a complete mole, with a follow-up of at least 6 months.[104]

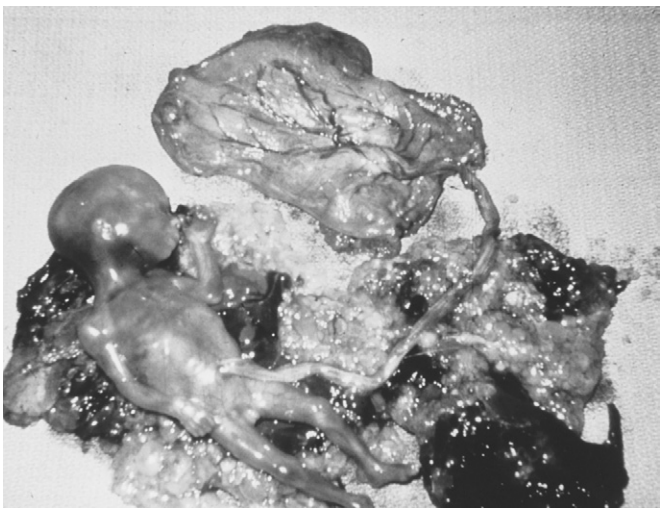

FIGURE 47-6. Partial mole with dead fetus of abnormal karyotype. (From Copeland LJ: Gestational trophoblastic neoplasia. *In* Copeland LJ [ed]: Textbook of Gynecology, ed 2. Philadelphia, WB Saunders, 2000, p 1416.)

Placental Site Trophoblastic Tumor

Less than 1% of all patients with GTD have placental site trophoblastic tumor. Although this tumor usually presents with abnormal vaginal bleeding following a term pregnancy, it can also be a sequela to a molar pregnancy or abortion. The postpartum presentation is characterized by a slightly enlarged uterus, persistent bleeding or, occasionally, amenorrhea, and a slightly elevated β-hCG level. **The β-hCG may not reliably reflect disease progression.** The histologic diagnosis may be obtained by uterine curettage, possibly hysteroscopically directed. Because this disease tends to metastasize late and be somewhat resistant to chemotherapy, surgical excision (hysterectomy) should be considered. If the patient is desirous of future childbearing, management considerations that have been reported with some success include systemic chemotherapy, regional infusion chemotherapy, uterine curettage, and local excision of tumor by hysterotomy and uterine reconstruction.[105]

Choriocarcinoma

Choriocarcinoma develops in approximately 1 in every 40,000 term pregnancies, and this clinical presentation represents about one fourth of all cases of choriocarcinoma. The other cases follow molar disease or an abortion (spontaneous, therapeutic, or ectopic). GTD following a term pregnancy is always either choriocarcinoma or a placental site trophoblastic tumor, assuming a singleton pregnancy.

Choriocarcinoma is notorious for masquerading as other diseases. This is secondary to hemorrhagic metastases producing symptoms such as hematuria, hemoptysis, hematemesis, hematochezia, stroke, or vaginal bleeding. The common sites for metastatic disease are listed in Table 47-7. The diagnosis of choriocarcinoma is based on history, imaging studies, and a serum β-hCG level.

TABLE 47-7 COMMON SITES FOR METASTATIC CHORIOCARCINOMA*

SITE	PERCENT
Lung	60-95
Vagina	40-50
Vulva/cervix	10-15
Brain	5-15
Liver	5-15
Kidney	0-5
Spleen	0-5
Gastrointestinal	0-5

From Copeland LJ: Gestational trophoblastic neoplasia. *In* Copeland LJ (ed): Textbook of Gynecology, ed 2. Philadelphia, WB Saunders, 2000, p 1391.

*Frequencies vary, depending on whether data are based on autopsy studies or are obtained from pretreatment imaging.

Histologic confirmation is neither necessary for the diagnosis nor a prerequisite to initiate therapy. Again, it is necessary to exclude the presence of a new gestation as the source of a rising β-hCG level before extensive diagnostic imaging or therapeutic intervention. **It is also important to rule out phantom β-hCG production if the clinical scenario warrants, such as situations with low titers and no histologic or convincing imaging evidence of GTD.**

The complexities of the general treatment approach or treatment for special situations is beyond the scope of this chapter. It is recommended that the reader refer to a gynecology or gynecologic oncology resource for discussions of the therapeutic subtleties and pitfalls. Choriocarcinoma should be managed by a gynecologic oncologist, preferably one with a special interest in the disease.

KEY POINTS

- Because many of the common complaints of pregnancy are also early symptoms of metastatic cancer, pregnant women with cancer are at risk for delays in diagnosis and therapeutic intervention.
- The safest interval for most cancer therapies in pregnancy is the second and third trimesters, thereby avoiding induction of teratogenic risks or miscarriage in the first trimester. For most malignancies diagnosed during the second trimester, chemotherapy should be undertaken as indicated because fetal risk is generally lower than the risk of delaying treatment or proceeding with preterm delivery.
- Antimetabolites and alkylating agents present the greatest hazard to the developing fetus.
- Diagnostic delays of breast cancer in pregnancy are often attributed to physician reluctance to properly evaluate breast complaints or abnormal findings in pregnancy.
- Treatment for Hodgkin's disease may compromise the reproductive potential, and combined treatment with irradiation and chemotherapy provides the highest risk of ovarian failure.
- If a mother is exposed to cytotoxic drugs within 1 month of delivery, the newborn should be monitored closely for evidence of granulocytopenia or thrombocytopenia.
- The effect of pregnancy on the clinical course of melanoma has been the subject of debate. When corrected for tumor thickness, pregnancy does not appear to be an independent prognostic variable for survival.
- After stratifying for stage and age, patients with pregnancy-associated cervical carcinoma have survival rates similar to the nonpregnant patient.
- Because most malignant ovarian tumors found in pregnancy are either germ cell tumors or low-grade, early-stage epithelial tumors, the therapeutic plan will usually permit continuation of the pregnancy and preservation of fertility.
- Although rare, most colorectal carcinomas in pregnancy are detectable on rectal examination, underscoring the need for a rectal examination at the patient's first prenatal visit.
- Phantom β-hCG should be ruled out in patients suspected of having gestational trophoblastic disease when not documented by other clear clinical evidence (histology, imaging, and clinical history), especially when β-hCG titers are low.

Ultraviolet Light B	UVB

This chapter reviews both the physiologic skin changes induced by pregnancy and the following categories of skin problems that can occur during pregnancy:

- Preexisting skin diseases and tumors
- Diagnosis and treatment of melanoma
- Pruritus
- Specific dermatoses of pregnancy

Common skin conditions that are discussed in the text are defined (Table 48-1).

PHYSIOLOGIC SKIN CHANGES INDUCED BY PREGNANCY

The human skin undergoes substantial changes during pregnancy induced by the combined effect of endocrine, metabolic, mechanical, and blood flow alterations. **Physiologic changes, while they may prompt cosmetic complaints, are not associated with risks to the mother or fetus and can be expected to resolve or improve postpartum** (Table 48-2).[1-3]

Pigmentary Changes

Mild forms of localized or generalized hyperpigmentation occur to some extent in up to 90% of pregnant women and are most noticeable in the areolae, nipples, genital skin, axillae and inner thighs. Familiar examples include the darkening of the *linea alba (linea nigra)* and periareolar skin. Melasma *(chloasma or "mask of pregnancy")* refers to the facial hyperpigmentation reported in up to 70% of pregnant women.[2] Hyperpigmented, symmetric, poorly demarcated patches are commonly seen on the malar areas (malar pattern) and are often distributed over the entire central face (centrofacial pattern) (Figure 48-1). In 16% of cases, hyperpigmentation occurs on the ramus of the mandible (mandibular pattern).[4,5] Melasma results from melanin deposition in the epidermis (70%), dermal macrophages (10 to 15%), or both (20%). It is likely secondary to the hormonal changes of gestation with increased expression of alpha-melanocyte-stimulating hormone. Melasma typically is exacerbated by exposure to ultraviolet and visible light.[5,6] Hyperpigmentation is often more pronounced in brunettes and women with more melanocytes than in women with lighter baseline skin tone; the use of a broad-spectrum sunscreen with high sun protection factor during pregnancy may decrease the severity of hyperpigmentation.

Melasma usually resolves postpartum but may recur in subsequent pregnancies or with the use of oral contraceptives.[4] Troublesome persistent melasma can be treated postpartum with topical hydroquinone 2% to 4% and sunscreen, with or without a topical retinoid and mild topical steroid.[7] Despite treatment postpartum melasma persists in approximately 30% of patients, especially in women with the dermal or mixed subtypes in which the deeper level of pigmentation results in decreased efficacy of topical agents. Combination therapies including laser treatment[8,9] and chemical peels[10] may be effective in resistant cases. There have been no reports of adverse fetal

TABLE 48-1 COMMON SKIN CHANGES AND DISEASES WITH BRIEF DESCRIPTIONS

Pseudoacanthosis nigricans	Hyperpigmentation of the skin folds and neck mimicking acanthosis nigricans
Dermal melanocytosis	Clusters of melanocytes abnormally located in the dermis and resulting in ill-defined bluish-gray patches
Vulvar melanosis	Irregularly distributed patches of pigmentation on the vulva
Verrucous areolar hyperpigmentation	Pigmented wartlike papules on the areolae
Miliaria	Sweat retention reflecting obstruction of eccrine sweat ducts
Hyperhidrosis	Skin disorder characterized by increased sweat secretion
Dyshidrosis	Recurrent vesicular eruption of palms and soles
Fox-Fordyce disease	Chronic pruritic disorder of the apocrine glands characterized by blockage of the apocrine duct and sweat retention
Onycholysis	Detachment of nail plate from nail bed
Subungual hyperkeratosis	Deposition of keratinous material on the distal nail beds
Palmoplantar pompholyx eczema	See dyshidrosis above (synonyms)
Acne conglobata	Variant of acne vulgaris characterized by severe eruptive nodulocystic lesions without systemic manifestations
Pemphigus vulgaris	Autoimmune bullous disorder of the skin and oral mucosa produced by antidesmoglein-3 antibodies that cause intraepidermal acantholysis
Pemphigus vegetans	Variant of pemphigus vulgaris characterized by pustules that form fungoid vegetations or papillomatous proliferations
Pemphigus foliaceus	Autoimmune bullous skin disorder produced by antidesmoglein-3 antibodies that cause subcorneal acantholysis
Spitz nevi	Seen predominantly in children or young adults and characterized by prominent epithelioid and/or spindled melanocytes that can have atypical features

effects from laser skin treatment during pregnancy. Most laser experts agree that laser radiation does not penetrate through the skin into deeper soft tissues and, therefore, should not affect the fetus or the placenta. Still, because of potential liability issues, most dermatologists and plastic surgeons prefer not to perform laser procedures during gestation.

Uncommon pigmentary patterns, such as pseudoacanthosis nigricans,[11] dermal melanocytosis, vulvar melanosis and verrucous areolar hyperpigmentation can also be seen in pregnancy (see Table 48-2).[12] Postinflammatory hyperpigmentation secondary to specific dermatoses of pregnancy (see section "Specific Dermatoses of Pregnancy") is also common in women with more highly pigmented skin types.

Vascular Changes

As a result of the combination of rising estrogen levels and increased blood volume in pregnancy, blood flow to the skin increases (4 to 16 times in the first 2 months of

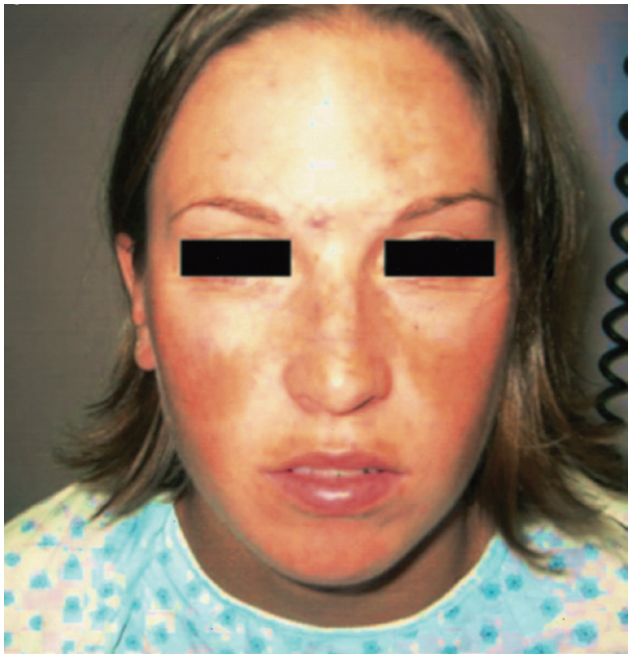

FIGURE 48-1. Centrofacial type of melasma involving the cheeks, nose, upper lip, and forehead.

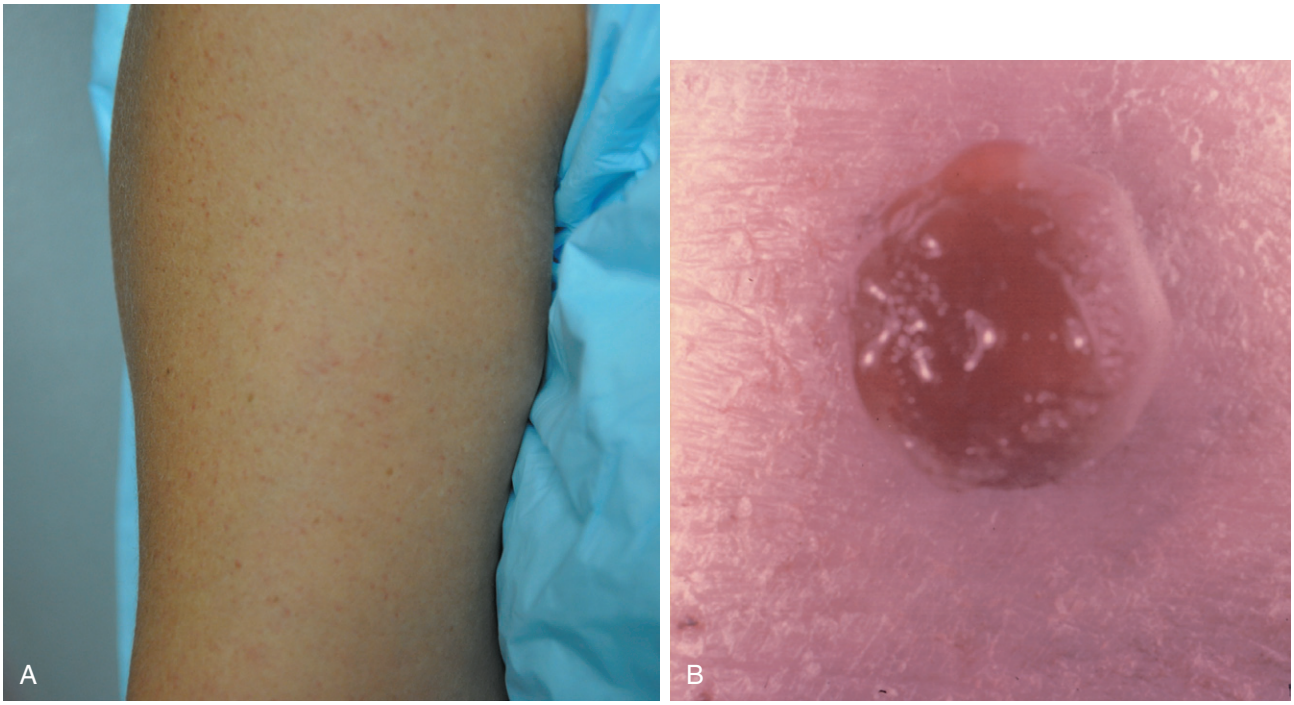

FIGURE 48-2. **A,** Numerous telangiectasias and spider angiomas on the arm of a pregnant female. **B,** Pyogenic granuloma of pregnancy *(granuloma gravidarum),* a benign vascular proliferation, is typically seen as a nodule on the gingivae and is shown here at a less common extramucosal site.

pregnancy and doubles again during the third month) resulting in significant vascular sequelae (see Table 48-2). Spider nevi (spider angiomas) and telangiectasias develop in approximately two thirds of Caucasian women and 10% of African American women between the second and fifth months of pregnancy, and usually resolve within 3 months postpartum[1,4] (Figure 48-2*A*). Approximately 10% of women have persistent spider nevi; treatment with electrodessication or pulsed dye laser is effective in women who find these cosmetically troubling.

Palmar erythema, likely secondary to capillary engorgement, is also very common, occurring in up to 70% of Caucasian and 30% of African American women. While varicosities of the distal leg veins and hemorrhodial veins develop in more than 40% of women, thrombosis within these superficial varicosities occurs infrequently (<10%). Nonpitting edema can be seen on the ankles (70%) and face (50%) and is most pronounced in the early months of gestation. Varicosities may regress postpartum but usually not completely; varicosities are likely to recur in subsequent pregnancies.

Gum hyperemia and gingivitis are common and frequently result in mild bleeding from the gums during routine oral hygiene. This is most prominent during the third trimester and resolves postpartum. Good dental hygiene will minimize symptoms. Periodontal disease has been associated with adverse pregnancy outcomes and so women without a recent dental examination should be referred.[13]

The pyogenic granuloma of pregnancy (*granuloma gravidarum* or pregnancy epulis) is a benign proliferation of capillaries that usually occurs in the gingiva but can occasionally be identified on the lip or extramucosal sites (Figure 48-2*B*). Pyogenic granulomas commonly appear between the second and fifth months of pregnancy and affect up to 2% of pregnancies.[4] Presenting as a vascular, deep-red or purple, exuberant, often pedunculated nodule between the teeth or on the buccal or lingual surface of the marginal gingival, a pyogenic granuloma may be more likely after mucosal trauma. Spontaneous shrinkage of the tumor usually occurs postpartum, and most cases do not require treatment. Surgical excision or electrosurgical destruction should be reserved for cases complicated by excessive bleeding or severe discomfort.

Connective Tissue Changes

***Striae gravidarum* (*striae distensae* or "stretch marks") develop in up to 90% of Caucasians between the sixth and seventh months of gestation** and less commonly in Asians and African Americans.[4] Risk factors include younger maternal age, excessive pregnancy weight gain, and concomitant use of corticosteroids; however genetic susceptibility likely plays a key role. Striae are most prominent on the abdomen, breasts, buttocks, groin and axillae; while usually asymptomatic, a proportion of patients complain of mild to moderate pruritus. The treatment of striae gravidarum is a challenge; at present there is no optimal treatment. The erythema (red color) of early striae responds well to various pulsed-dye lasers or intense pulsed light. The red color tends to become pale over time (with or without treatment), but the atrophic lines never disappear completely and do not respond to laser treatment. Topical tretinoin 0.1% cream has been shown to improve the appearance of the striae (decreased their length by 20%) and is occasionally used in combination with topical glycolic acid (up to 20%) in an effort to increase elastin content

of the affected areas.[14] Nevertheless, tretinoin can be very irritating to the skin and does not make striae completely disappear. No topical therapy prevents or affects the course of striae. They are less apparent postpartum but may never disappear.

Skin tags *(molluscum fibrosum gravidarum)* present as 1- to 5-mm fleshy, pedunculated, exophytic growths on the neck, axillae, inframammary region or groin, and usually appear during the later months of gestation. Treatment can be postponed until completion of the pregnancy as lesions may regress postpartum. Cryotherapy with liquid nitrogen or shave removal is effective for persistent or enlarging lesions. Skin tags do not have malignant potential, and treatment is unnecessary unless inflammation or ulceration develops.

Glandular Changes

Increased eccrine function has been reported during pregnancy and may account for the increased prevalence of miliaria, hyperhidrosis, and dyshidrosis.[4,12] **Conversely, apocrine activity may decrease** during gestation contributing to the decreased prevalence of Fox-Fordyce disease and possibly hidradenitis suppurativa in pregnancy.[2] Changes in sebaceous function are variable, and the effects of pregnancy on acne vulgaris are unpredictable. Treatment for acne vulgaris during pregnancy is discussed below. During pregnancy, the sebaceous glands on the areolae enlarge *(Montgomery's glands or tubercles)*.

Hair and Nail Changes

Most pregnant women develop mild hirsutism affecting their face, trunk and extremities that commonly regresses within 6 months postpartum. In addition, **postpartum hair shedding *(telogen effluvium)* may be noted as a greater proportion of hairs enter the telogen phase,** and this can cause distress (Figure 48-3). The severity of *telogen effluvium* varies considerably, and the hair loss becomes noticeable when more than 40% to 50% of hairs become affected. Recovery is spontaneous, and there are no effective treatments. Patients can be counseled that hair thinning usually resolves within 1 to 5 months but that complete resolution may occasionally take up to 15 months.[1,4] Frontoparietal hair recession and diffuse hair thinning in the later months of pregnancy have been noted in some women. Nail changes can be seen as early as the first trimester of gestation. These changes include brittleness, onycholysis, subungual hyperkeratosis, and transverse grooving. There is no specific treatment for nail changes during pregnancy, and most are expected to resolve postpartum. An attempt should be made to eliminate external sensitizers, such as nail polish removers, and infections. The nails should be kept short if they are brittle or prone to onycholysis.[6]

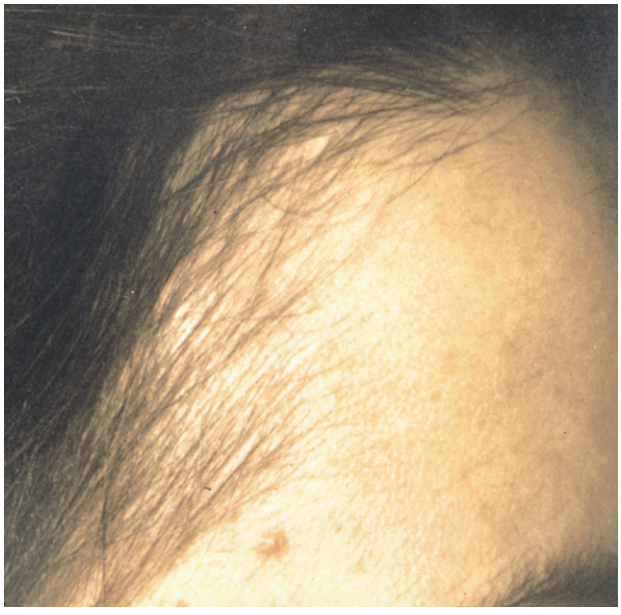

FIGURE 48-3. *Telogen effluvium* that develops within 5 months postpartum typically presents with temporal recession and hair thinning.

PREEXISTING SKIN DISEASES AND TUMORS AFFECTED BY PREGNANCY

Pregnancy can aggravate or, less often, improve many skin conditions and primary skin tumors.[15] Diseases that may improve during pregnancy include atopic eczema, acne, some subtypes of psoriasis, Fox-Fordyce disease, hidradenitis suppurativa, linear IgA dermatosis, sarcoidosis and autoimmune progesterone dermatitis (see Table 48-1).

Atopic Eczema and Dermatitis

Atopic dermatitis (AD) (atopic eczema) is a very common skin condition and is often exacerbated by pregnancy, although remission has been noted in up to 24% of cases.[16] Two large studies, using diagnostic criteria established in pediatric populations, indicated a high prevalence of AD in gestation, including "new AD" (AD presenting during gestation for the first time); however, the true prevalence may be revised as the criteria for gestational AD are refined.[16-20] Risk factors include a history of prior atopy (27%), family history of atopy (50%), and offspring with infantile AD (19%). Other risk factors for AD include African American or Asian race and tobacco use.[21,22] The prevalence of intrinsic ("nonallergic") versus extrinsic (IgE-associated) type of AD[23] during gestation is unknown, although a small study showed that intrinsic AD that is more affected by pregnancy.[24]

Most patients present with lesions in the flexural surfaces of the extremities, occasionally with concomitant lesions on the trunk. Less common presentations are palmoplantar pompholyx eczema, follicular and facial eczema. Eczematous lesions can develop bacterial or viral (i.e. *eczema herpeticum* secondary to herpes simplex virus) superinfection in pregnancy; treatment with dicloxacillin or a first-generation cephalosporin should be used as necessary in these cases. *Eczema herpeticum* should be promptly treated with intravenous acyclovir in order to minimize maternal and fetal risks.

AD is not associated with an increased risk of adverse fetal outcomes. The effects of breastfeeding and maternal food antigen avoidance during pregnancy on AD in the offspring are controversial. Treatment for gestational exacerbations of AD is primarily symptomatic. Using a moisturizer and low- to mid-potent topical steroid is the first-line treatment. Systemic antihistamines, such as

chlorpheniramine or diphenhydramine, can also be used as necessary for relief of pruritus. A short course of oral steroids may be required for severe AD. Ultraviolet light B (UVB) is a safe second-line treatment for eczema in pregnancy. There is less experience with the newer topical immunomodulators (pimecrolimus, tacrolimus).[25] Although their bioavailability is limited (<5%) and no pattern of anomalies has been reported after exposure to these drugs in utero, several infants have had neonatal hyperkalemia.[26] Therefore, these immunomodulators should be used as third-line treatment for refractory AD that has not responded to UVB. If systemic agents are needed for refractory AD, cyclosporine is the safest option.

The course of gestational AD in the postpartum period has not been studied. Irritant hand dermatitis and nipple eczema are often seen postpartum.[1] Irritant hand dermatitis is treated with emollients and hand protection. Nipple eczema can evolve into painful fissures and be complicated with bacterial superinfection, most commonly with *Staphylococcus aureus*. Superinfected nipple eczema should be treated with a topical steroid combined with a topical or systemic antibiotic.

Acne Vulgaris

The effects of pregnancy on acne vulgaris are unpredictable. **In one study, pregnancy affected acne in approximately 70% of women, with 41% reporting improvement and 29% worsening with pregnancy.**[27] Two patients had improvement and exacerbations with two different pregnancies. Some patients may develop acne for the first time during pregnancy or in the postpartum period ("postgestational acne"). Comedonal acne should be treated with topical keratolytic agents, such as benzoyl peroxide, whereas inflammatory acne should be treated with azelaic acid, topical erythromycin, topical clindamycin, or oral erythromycin base. Although first trimester use of topical tretinoin has not been associated with an increased rate of malformations in controlled studies, the number of reported exposures is too small to exclude a small increased risk. A theoretical concern remains as the percutaneous absorption is 5 to 30% and use of tretinoin is not recommended during pregnancy (see Chapter 8).

Other Inflammatory Skin Conditions

Recurrent flares of urticaria may worsen in pregnancy. Of interest, these flares show common features with hereditary angioedema and may have been exacerbated in the past by oral contraceptive use or prior to menses. Chronic plaque psoriasis may develop for the first time during pregnancy. **Women with existing chronic psoriasis can be counseled that between 40% and 63% of women have symptomatic improvement, compared to only 14% of women with symptomatic deterioration**; postpartum flares are common (80%).[28] Topical steroids and topical calcipotriene are relatively safe treatment options for localized psoriasis in pregnancy.[29] For severe psoriasis that has not responded to topical medications, UVB and/or a short course of cyclosporine are considered second-line treatment options.

Autoimmune Progesterone Dermatitis

Autoimmune progesterone dermatitis is caused by hypersensitivity to progesterone through autoimmune or nonimmune mechanisms. Although this rare dermatosis can take various forms (urticarial, papular, vesicular or pustular) the hallmark is recurrent cyclic lesions that usually appear during the luteal phase of the menstrual cycle. Limited information is available regarding the effects of pregnancy on autoimmune progesterone dermatitis. Case series report instances of both improvement and exacerbation.[30] Increased cortisol levels and/or the gradual increase in the sex hormone levels during pregnancy with subsequent hormonal desensitization in some patients are both possible mechanisms for observed improvement. Diagnosis is based on either an immediate local urticarial reaction or more frequently a delayed hypersensitivity reaction following intradermal challenge with synthetic progesterone. Intramuscular administration of progesterone should be avoided in these patients as it has been associated with angioedema. Circulating antibodies to progesterone or the *corpus luteum* have been detected by indirect immunofluorescence in several patients. The sensitivity of this test seems to be lower than that of the intradermal progesterone challenge; therefore, these antibodies are not widely used to confirm this diagnosis. No specific therapy for the condition during pregnancy has been proposed. Autoimmune estrogen dermatitis has also been reported in a patient presenting with urticaria in early pregnancy.[31]

Impetigo Herpetiformis

Impetigo herpetiformis is a rare variant of generalized pustular psoriasis that develops primarily during pregnancy, often in association with hypocalcemia[32] **or low serum levels of vitamin D.**[33] Although familial occurrence has been reported, more commonly a personal or family history of psoriasis is absent. The eruption usually develops in the third trimester but can also start in earlier trimesters and postpartum. While the overwhelming majority of cases resolve postpartum, persistent cases have been reported, and can be associated with oral contraceptive use.[34] Various infections during pregnancy may also trigger a flare of pustular psoriasis in a genetically predisposed individual.[35]

Impetigo herpetiformis is characterized by numerous grouped discrete sterile pustules at the periphery of erythematous patches (Figure 48-4*A*). Lesions typically originate in the major flexures (axillae, inframammary areas, groin, and gluteal fold) and progress onto the trunk, usually sparing the face, hands, and feet. Painful mucosal erosions may also develop. Onycholysis or complete nail shedding secondary to subungual lesions has been reported. Constitutional symptoms are common including fever, malaise, diarrhea, and vomiting with resultant dehydration. Rarely patients develop complications secondary to hypocalcemia including tetany, convulsions, and delirium. Common laboratory findings are leukocytosis and elevated erythrocyte sedimentation rate; rarer perturbations include hypocalcemia, decreased serum vitamin D levels, and signs of hypoparathyroidism. Historically reported maternal risks, such as tetany, seizures, delirium, and death from cardiac or renal failure or septicemia are uncommon. Fetal risks, such as stillbirth, neonatal birth, and fetal abnormalities secondary to placental insufficiency,[33] have been reported even when the condition was well controlled.[36] While maternal

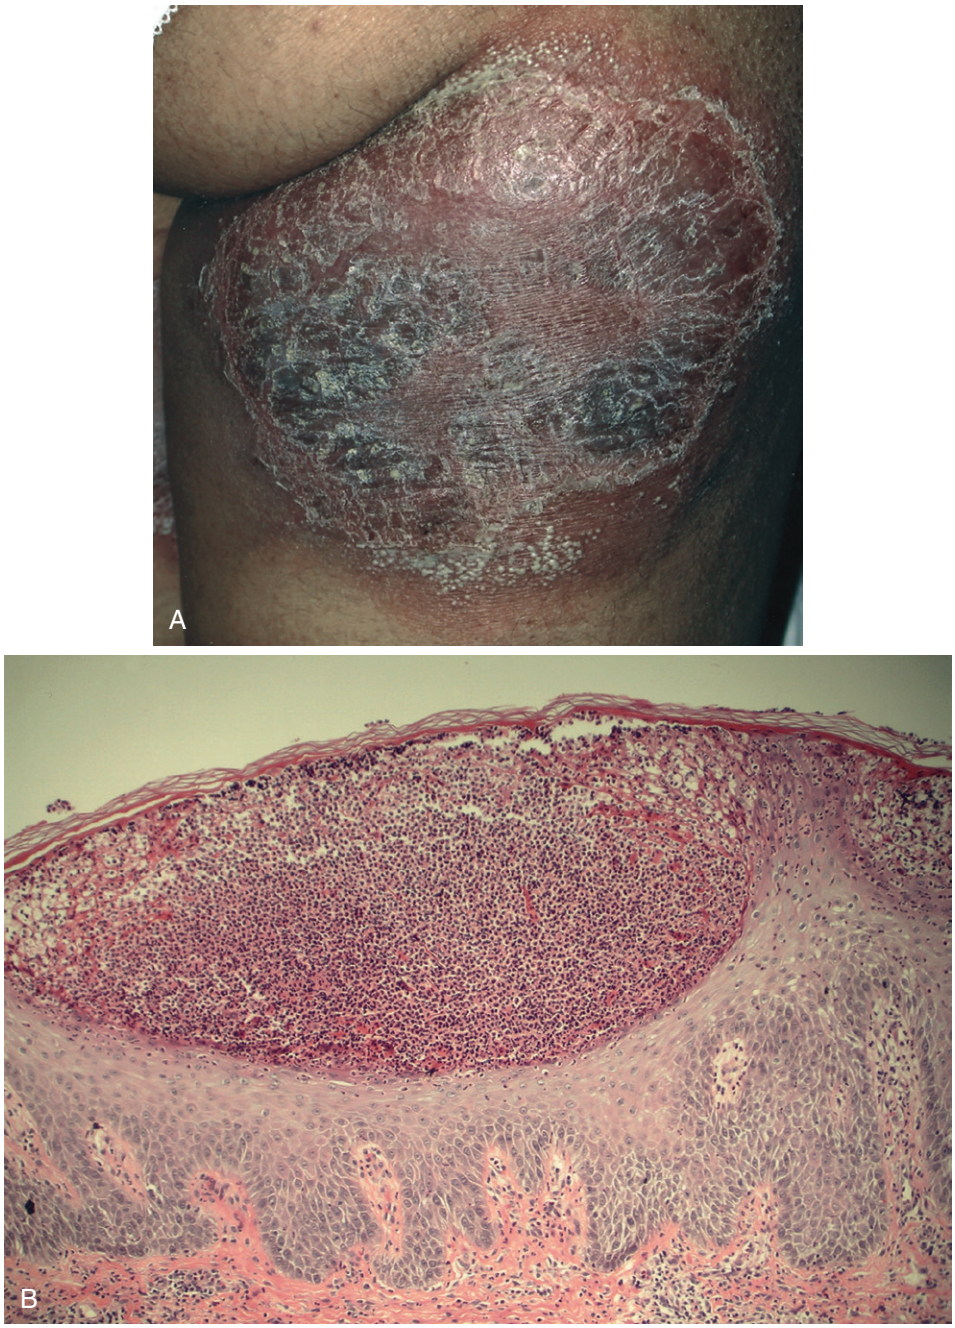

FIGURE 48-4. **A,** Impetigo herpetiformis: discrete grouped sterile pustules at the periphery of an erythematous crusted plaque. **B,** Histopathology of impetigo herpetiformis shows the characteristic spongiform pustule of Kogoj, which is formed of neutrophils in the uppermost portion of the spinous layer (hematoxylin-eosin stain). (Photograph courtesy Aleksandr Itkin, MD.)

prognosis is excellent with early diagnosis, aggressive treatment, and supportive care, an increased risk of perinatal mortality may persist despite maternal treatment.[37] The risk is difficult to quantify as it is based on sparse case reports that span decades. Intensive fetal monitoring should be considered until the mother is stabilized. After acute treatment the appropriate degree of fetal surveillance is not known, however periodic assessment of fetal well being is likely prudent after viability.

Definite diagnosis of impetigo herpetiformis is based on histopathology that shows typical features of pustular psoriasis (see Figure 48-4*B*). Direct and indirect skin immunofluorescence is negative. Systemic steroids are first-line therapy for impetigo herpetiformis; 20 to 40 mg/day of prednisone is usually effective. Cases of pustular psoriasis exacerbated by pregnancy have been treated with cyclosporine.[37] Calcium and vitamin D replacement therapy should be undertaken if necessary, and can lead to remission of the eruption.[25] Systemic antibiotics should be administered if bacterial superinfection is suspected. Postinflammatory hyperpigmentation may develop, but scarring is usually absent. Impetigo herpetiformis has been treated postpartum with oral steroids, oral retinoids[38] or photochemotherapy (psoralen with ultraviolet light A

[PUVA])[39] as single agents or in combination. Resistant cases can be treated with a combination of PUVA and clofazimine or methotrexate.

Cutaneous Manifestations of Autoimmune Disorders

Cutaneous lesions may be prominent in some individuals affected by autoimmune disorders, and these patients often have questions regarding how pregnancy will affect the appearance of these lesions. The cutaneous manifestations of chronic discoid lupus are not affected by pregnancy. Cutaneous flares of systemic lupus erythematosus can usually be managed with oral steroid treatment. Dermatomyositis/polymyositis may show exacerbation of the characteristic heliotrope rash in approximately half of affected individuals.[40] The cutaneous progression of scleroderma is not significantly altered by pregnancy, and symptoms of Raynaud's phenomenon may improve. Pregnant women with limited skin disease do significantly better than those with diffuse scleroderma.[41] The medical and obstetric management of pregnancies complicated by collagen vascular disease is discussed in detail in Chapter 44.

Bullous Disorders

Bullous dermatologic disorders develop secondary to autoantibodies that target constituents of the skin and/or oral mucosa. **Pemphigus vulgaris,[42] vegetans or foliaceus may develop or worsen during pregnancy** whereas linear IgA disease may improve.[43] In more than 50% of cases of pemphigus vulgaris, lesions may initially appear within the oral cavity. Diffuse skin involvement with multiple flaccid vesicles follows, with confluence of vesicles forming large eroded areas. Skin biopsy with immunofluorescence studies are needed for a definitive diagnosis. Biopsy for routine histopathology and immunofluorescence is indicated in patients with new-onset lesions, most critically to differentiate pemphigus from herpes gestationis (see section IV below). In cases of pemphigus, fetal and neonatal skin lesions can occur secondary to transplacental transfer of IgG antibodies but resolve spontaneously within 2 to 3 weeks after birth. Pemphigus should be treated with oral corticosteroids, and high doses may be required. A recent study of 49 pregnancies complicated by pemphigus vulgaris showed 12% perinatal mortality. Forty-five percent of live neonates had pemphigus lesions at birth.[44] Increased fetal surveillance is prudent in pregnancies affected by active pemphigus, although the effectiveness of this surveillance in preventing morbidity and fetal loss is not known.

Acrodermatitis enteropathica is a rare autosomal recessive disorder of zinc deficiency characterized by dermatitis, diarrhea, and alopecia. Vesiculobullous and/or eczematous skin lesions can develop on the extremities and periorificial sites, such as the mouth, perianal, and genital areas. The disease usually flares early in gestation[45] as serum zinc levels decrease, but may also flare with oral contraceptives.

Skin Tumors

Most skin neoplasms that present or enlarge during pregnancy (pyogenic granuloma, hemangioma, hemangioendothelioma, glomus tumor, glomangioma, dermatofibroma, dermatofibrosarcoma protuberans, leiomyoma, keloid, desmoid tumor and neurofibroma) are benign. **Melanocytic nevi may develop, enlarge or darken during pregnancy but these changes seem to be less dramatic than previously thought.** A mild degree of histopathologic atypia has been reported in a few studies. Pennoyer et al[46] compared photographs of moles taken during the first trimester and again in the third trimester. Only 3% of nevi enlarged during pregnancy, and another 3% regressed. In contrast, dysplastic nevi in women with familial dysplastic nevus syndrome do have a tendency to increase in size and undergo color change during pregnancy.[47] Spitz nevi, another class of common pigmented benign neoplasms, may also increase in size or erupt during pregnancy.[48] Studies that used dermoscopy showed that the pigment network of nevi becomes thicker and more prominent, and the globules darker during pregnancy; these features, however, return to their original condition within 1 year after delivery.[49] Any suspicious pigmented skin lesion should prompt a dermatologic referral. The "ABCDE" clinical criteria for pigmented lesions are helpful in determining which lesions are of higher malignant potential: Asymmetry, Border irregularity, Color variegation, Diameter greater than 6 mm, and Evolution (i.e. an enlarging or otherwise changing lesion).[50] Seborrheic keratoses are also common and may enlarge or darken during gestation. None of these benign lesions require treatment during pregnancy; the pregnant woman should be reassured that these changes are benign and may improve postpartum.

Malignant Melanoma

Malignant melanoma accounts for approximately 8% of malignant tumors during pregnancy with an overall incidence of approximately 2.8 cases per 1000 births.[51] Melanomas that develop during pregnancy are thicker than melanomas in non-pregnant women[52] possibly due to a delayed diagnosis because of a shared misconception by the patient and/or her physician that darkening and changing of a nevus is normal in pregnancy. Despite initial concerns, **several epidemiologic studies evaluating the effect of pregnancy status at diagnosis suggest that the 5-year survival rate is not affected after controlling for confounding factors.**[53-55] In the largest study to date,[55] Lens compared 185 women diagnosed with melanoma during pregnancy with over 5000 women of childbearing age who developed melanoma while not pregnant. Pregnancy status at the time of diagnosis was associated with a hazard ratio for death of 1.08 (95% CI 0.0-1.9). **The major prognostic determinants of survival in pregnant women with localized melanoma are tumor thickness (Breslow scale) and ulceration status**,[56] with level of invasion only significant in women with tumors more than 1 mm in thickness.

Surgery is the treatment of choice in patients presenting with early melanoma in pregnancy.[57] Sentinel lymph node biopsy using a combination of isosulfan blue dye and tenetium should be performed as indicated and is not contraindicated in pregnancy.[58] For pregnant women with advanced disease, the prognosis, risks, and benefits of systemic therapy should be discussed. The decision to administer systemic therapy should be determined based on the gestational age at presentation with consideration given to the potential consequence of delayed treatment

on ultimate survival. In early gestation, the option of termination of pregnancy should also be considered. Melanoma is the most common type of malignancy to metastasize to the placenta and fetus, representing 31% of such metastases.[59] However, it should be emphasized that placental and/or fetal metastases are extraordinarily rare (27 cases) and that even in the setting of placental metastasis, fetal metastasis only occurs in 17% of cases. Histologic evaluation of the placenta should be performed because of the association between melanoma and placental metastasis. The presence of placental metastases is associated with widespread disease and dismal maternal survival. The role of systemic therapy in preventing metastases to the placenta and fetus has not been adequately studied.

There are currently no standard guidelines for patients who desire to become pregnant after the diagnosis and treatment of melanoma, although in a recent study pregnancy subsequent to a diagnosis of melanoma was associated with nonsignificant decrease in mortality.[55] Similarly, most studies did not show an increased risk of melanoma recurrence with oral contraceptive or hormone replacement therapy use.[60,61] In most cases, melanoma cell lines lack type I estrogen receptors.[62,63] In contrast, there appears to be some evidence for an inhibitory effect of estrogens on melanoma cell lines through type II estrogen receptors.[61] These findings may indicate a protective effect of female gender on the prognosis of melanoma.[64,65] The primary reason to delay pregnancy following a recent diagnosis of melanoma is the time-dependent risk of tumor recurrence and subsequent maternal mortality. Patients should be counseled on a case-by-case basis depending primarily on risk of recurrence, taking into account the thickness of their original tumor and other prognostic factors. Women with a significant risk of recurrence may want to delay pregnancy until they can be assured of a low recurrence risk. In women with a thin tumor with a low risk of recurrence, no delay may be necessary.

PRURITUS IN PREGNANCY

Itching is the most common dermatologic symptom of pregnancy. Mild pruritus attributed to pregnancy *(pruritus gravidarum)* is common, occurring most frequently over the abdomen. Pruritus has been reported in up to 17% of pregnancies,[66] but a more recent report suggests that significant pruritus requiring a more thorough evaluation occurs in only 1.6% of patients.[67] **A broad differential diagnosis needs to be considered; the constellation of clinical and laboratory findings will help establish a diagnosis and guide management decisions.** Pruritic skin diseases that are not specifically related to pregnancy, such as AD and scabies, should be considered. In cases of pruritus without eruption, systemic diseases are more likely. Intrahepatic cholestasis of pregnancy (ICP) is a common etiology (see Chapter 45 for diagnosis and management); however other conditions such as lymphoma, liver, renal, and thyroid disease should be considered.[12] In the patient with pruritus and skin lesions other than excoriations, referral to a dermatologist for evaluation of a specific dermatosis of pregnancy (see section "Specific Dermatoses of Pregnancy") is appropriate unless a clear etiologic agent for a systemic or topical allergic reaction can be elucidated.

SPECIFIC DERMATOSES OF PREGNANCY

Specific dermatoses of pregnancy refer to a group of skin diseases that are encountered predominantly during or immediately following pregnancy and **include only those skin diseases which result directly from the state of gestation or the products of conception.**[16] Included in this definition are: herpes gestationis (HG), pruritic urticarial papules and plaques of pregnancy (PUPPP), prurigo of pregnancy (PP), and pruritic folliculitis of pregnancy (PFP) (Table 48-3). A recent reclassification[17] that included ICP in the specific dermatoses of pregnancy and grouped AD, PP, and PFP under "atopic eruption of pregnancy" has been debated.[18]

Herpes (Pemphigoid) Gestationis

HG is a rare autoimmune skin disease affecting between 1 in 7,000 and 1 in 50,000 pregnancies.[20] While HG and bullous pemphigoid recognize the same antigen[68] and share certain features, HG is confined to pregnant women or women affected by gestational trophoblastic disease. Some authors[69] have suggested that exposure to paternal antigens may play a critical role in disease initiation but "skip pregnancies" while having the same partner have been reported and would argue against this association. Of interest, expression of the HG antigen in the placenta begins in the midtrimester correlating with the timing of clinical symptoms. The antibody that incites the pathology in HG belongs to the IgG1 subclass and recognizes the NC16A2 (MCW-1) epitope in the noncollagenous domain (NC16A) of the transmembrane 180-kd antigen (bullous pemphigoid antigen 2).[70] HG primarily affects Caucasians with only scattered case reports in African Americans[71]; this observation is consistent with the association between HG and the human leukocyte antigens (HLA) DR3 (61%-80%), DR4 (52%), or both (43%-50%), which are less frequent in the African American population.

Clinically, **HG usually presents in the second or third trimester of pregnancy, with extremely pruritic urticarial lesions that typically begin on the abdomen and trunk, commonly involving the umbilicus** (Figure 48-5*A*). These urticarial plaques rapidly progress to widespread bullous lesions (Figure 48-5*B*) that may affect the palms and soles but rarely the face and mucous membranes. Tense bullous lesions arise in both inflamed and clinically normal skin and usually heal without scarring. Up to 25% of cases can present in the postpartum period, although these may represent recrudescences of previously undiagnosed mild HG. The most important clinical and laboratory features of HG are summarized in Table 48-3.

Although the differential diagnosis of HG includes drug eruption, erythema multiforme and allergic contact dermatitis, the most common diagnosis to exclude is the far more common pruritic papules and plaques of pregnancy (PUPPP, see below). PUPPP can manifest with urticarial and/or vesicular lesions almost indistinguishable from those of HG, although PUPPP classically begins in the abdominal striae and spares the umbilicus. Definitive diagnosis should be based on immunofluorescence of perilesional skin demonstrating the hallmark finding of HG, linear C3 deposition along the basement membrane zone.[1]

TABLE 48-3 OVERVIEW OF SPECIFIC DERMATOSES OF PREGNANCY

	PREVALENCE (UNITED STATES)	CLINICAL DATA	LESION MORPHOLOGY AND DISTRIBUTION	IMPORTANT LABORATORY FINDINGS	FETAL RISKS
Herpes gestationis (HG)	1:50,000	Second or third trimester or postpartum Flare at delivery (75%) Resolution postpartum +++ recurrence in future pregnancies	Abdominal urticarial lesions progress into a generalized bullous eruption	Skin immunofluorescence shows linear deposition of C3 along basement membrane	Neonatal HG Small-for-gestational age infants Preterm delivery
Pruritic urticarial papules and plaques of pregnancy (PUPPP)	1:130 to 1:300	Third trimester or postpartum Primigravidas Resolution postpartum Association with multiple gestation No recurrence in future pregnancies	Polymorphous eruption starts in the abdominal striae and shows periumbilical sparing	None	None
Prurigo of pregnancy (PP)	1:300 to 1:450	Second or third trimester Resolution postpartum + recurrence in future pregnancies	Grouped excoriated papules over the extensor extremities and occasionally abdomen	None	None
Pruritic folliculitis of pregnancy (PFP)	Approximately 30 cases	Second or third trimester Resolution postpartum ± recurrence in future pregnancies	Follicular papules and pustules	Biopsy: sterile folliculitis	None

Modified from Kroumpouzos, G, Cohen LM: Specific dermatoses of pregnancy: an evidence-based systematic review. Am J Obstet Gynecol 18:1083, 2003.

In addition, skin histopathology shows a spongiotic epidermis, marked papillary dermal edema, and an eosinophilic infiltrate. Serum antibody titers with conventional indirect immunofluorescence do not correlate with the course of disease but parallel disease activity when BP-180 NC16A-ELISA was used.[72]

Oral corticosteroids remain the cornerstone of treatment in HG. The majority of patients will respond rapidly to relatively low-dose treatment with prednisone (20 to 40 mg/day). In resistant cases, doses as high as 180 mg/day have been tried. Once new blister formation has been suppressed, prednisone should be tapered to 5 to 10 mg/day. Typically, up to 75% of patients will experience spontaneously resolution or improvement in the late third trimester and steroid treatment can often be discontinued. However, since HG typically flares at delivery or within the days following delivery, steroid doses can be increased in anticipation. A subset of patients will have persistent HG or recurrent flares lasting weeks or months. Patients at risk for prolonged or chronic HG tend to be older with higher parity, more widespread lesions and a history of HG in prior pregnancies.[73] Oral contraceptive use has been implicated in postpartum flares; 20% to 50% of patients using oral contraceptives within 6 months of delivery have associated flares. This association should be considered when counseling patients on their contraceptive options. Breast feeding was associated with a significantly shorter duration of active lesions in one study,[74] but this has been debated. HG recurs in 95% of future pregnancies, and lesions may be more severe, appear earlier in gestation, and persist longer postpartum. Treatment for chronic, recalcitrant HG is generally unsatisfactory, although case reports have described successful treatment with plasmapheresis, immunoapheresis, chemical oophorectomy with goserelin, ritodrine, rituximab, high-dose intravenous immunoglobulin combined with cyclosporine or other immunosuppressant medications, and minocycline or doxycycline combined with nicotinamide, immunosuppressive and anti-inflammatory agents, such as cyclophosphamide, azathioprine, rituximab, pyridoxine, sulfapyridine, gold, methotrexate or dapsone, have been used postpartum in refractory cases with some success but their use is limited to nonlactating patients.[20]

The maternal effects of HG are largely limited to symptomatic pruritus and a small risk of lesion superinfection. An association between HG and Grave's disease has been reported and HG[75] is an indication for performing both immediate and periodic screening tests of thyroid function. **An association with small-for-gestational age infants and preterm delivery has been reported** but the effect of HG on the fetus remains difficult to estimate from the small study cohorts due to the rarity of the disease. The largest cohort to date compared fetal outcome between the affected and unaffected pregnancies of 74 women; a 16% versus 2% rate of delivery at less than 32 weeks complicated pregnancies with active HG.[76] Mild placental insufficiency has been postulated as a mechanism; therefore sonographic evaluation of fetal interval growth and third-trimester fetal surveillance is appropriate. Finally**, approximately 5% to 10% of neonates will manifest bullous skin lesions (neonatal HG) secondary to passive transplacental transfer of HG antibody.**[77] Parents should be reassured that these lesions will resolve spontaneously without scarring over a period of a few weeks as the maternal antibodies clear from the infant's blood. However, parents should be counseled about the signs and symptoms of

bacterial superinfection so that timely treatment can prevent progression to systemic infection.

Pruritic Urticarial Papules and Plaques of Pregnancy

PUPPP, also known as "polymorphic eruption of pregnancy," is the most common specific dermatosis of pregnancy, affecting between 1 in 130 and 1 in 300 pregnancies. It occurs classically in primigravidas in the mid to late third trimester, and has been associated with a slight predominance of male babies (55%).[20,78,79] **Lesions typically begin in the abdominal striae and spare the periumbilical region** (Figure 48-6*A*).[1,80] PUPPP can be difficult to characterize as the eruption is polymorphous and can include urticarial and occasionally vesicular, purpuric, polycyclic or targetoid lesions, reminiscent of erythema multiforme or herpes gestationis (Figure 48-6*B*).[79] Although lesions can spread over the trunk and extremities they usually spare the palms and soles, and involvement of the face is very unusual. Generalized PUPPP may resemble a toxic erythema or atopic dermatitis (Figure 48-6*C*).

Skin histopathology is often nonspecific, showing spongiotic dermatitis with variable numbers of eosinophils. In contrast to HG, immunofluorescence studies and serologic tests are typically negative. IgE elevation (uncontrolled) was reported in 28% of PUPPP cases in a recent study[81] but the significance and specificity of IgE elevations in pregnancy remain unclear.[18] The high prevalence (55%) of personal and/or family history of atopy[81] has not been confirmed by other studies. The pathogenesis of PUPPP has not been established, but the immunohistologic profile (T helper lymphocytes, dermal dendritic cells, and epidermal Langerhans cells)[82] suggests a delayed hypersensitivity reaction to an unknown antigen. Some authors have proposed that rapid abdominal wall distention in primigravidas may trigger an inflammatory process; this has been supported by the association between PUPPP and multiple-gestation pregnancy, excess maternal weight gain, and

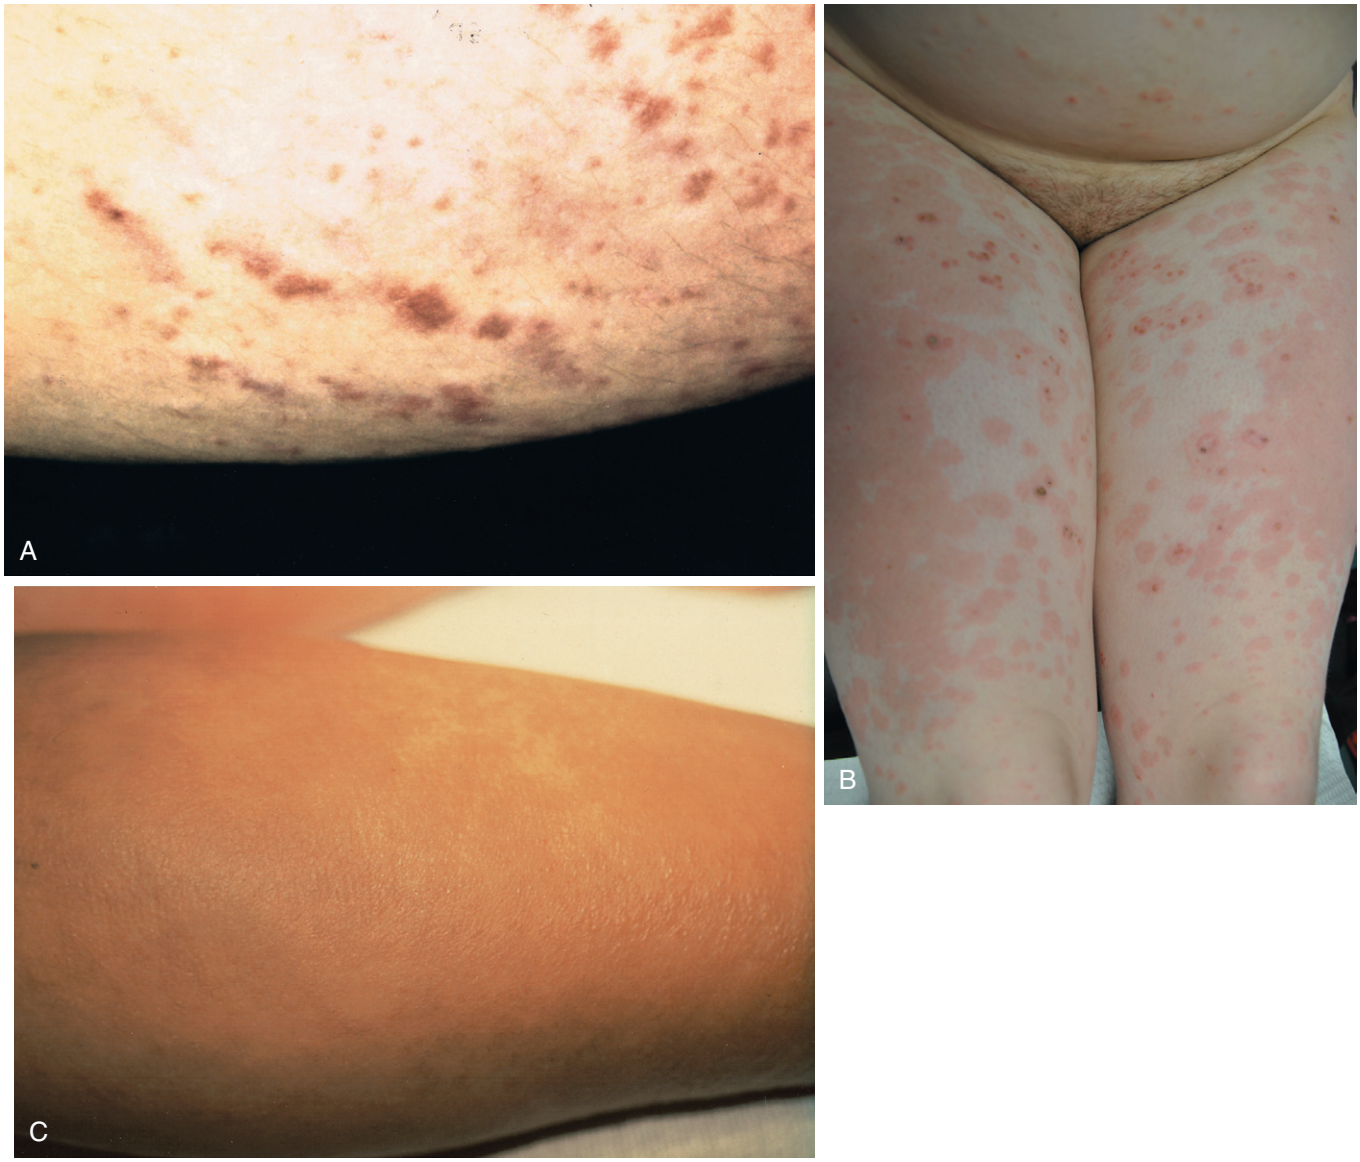

FIGURE 48-6. A, Pruritic urticarial papules and plaques of pregnancy (PUPPP) include urticarial lesions that typically start in the abdominal striae. **B,** Vesicular lesions superimposed on urticarial plaques and targetoid lesions reminiscent of erythema multiforme or herpes gestationis. **C,** Widespread PUPPP may resemble a toxic erythema or atopic dermatitis. (Photograph courtesy Helen Raynham, MD.)

fetal macrosomia.[83,84] **A meta-analysis revealed a 10-fold higher prevalence of multiple gestation in pregnancies affected by PUPPP.**[80] Multiple-gestation pregnancy is associated with higher estrogen/progesterone levels, and progesterone has been shown to aggravate the inflammatory process at the tissue level. Interestingly, increased progesterone receptor levels have been detected in skin lesions of PUPPP.[85] Finally, fetal DNA has been detected in PUPPP lesions[86]; still, the importance of microchimerism in the pathogenesis of PUPPP remains uncertain.

PUPPP is not associated with adverse maternal or fetal outcomes. The association with cesarean section in two recent studies needs to be clarified.[87] The goal of therapy is the relief of maternal discomfort. Mild PUPPP can be treated with antipruritic topical medications, topical steroids, and oral antihistamines. In cases of severe itching a short course of oral prednisone may be necessary. UVB has been used anecdotally.[80]

Prurigo of Pregnancy

PP affects between 1 in 300 and 1 in 450 pregnancies. It manifests itself with grouped excoriated or crusted pruritic papules over the extensor surfaces of the extremities, and occasionally on the trunk and elsewhere[1] (see Table 48-3). The condition lacks pathognomonic histopathologic features, and skin immunofluorescence is negative. Serologic tests may show elevated IgE levels.[16] Early reports[88] of a dismal fetal outcome in patients with PP have not been confirmed by subsequent studies, and **PP has not been associated with increased maternal risk.** PP should be differentiated from pruritic dermatoses unrelated to pregnancy, other specific dermatoses of pregnancy, drug eruptions, arthropod bites, and infestations such as scabies. PP is treated with moderately potent topical steroids, if necessary intralesional or under occlusion, and oral antihistamines.[80] A short course of oral steroid is rarely required.

FIGURE 48-7. Pruritic folliculitis of pregnancy: discrete follicular erythematous or pigmented papules on the abdomen.

PP has been associated with a family history of ICP (see Chapter 45). It has been proposed that PP and ICP are closely related conditions, distinguished only by the absence of primary lesions in ICP.[16] These authors reported an association with a personal or family history of AD and elevation of serum IgE (uncontrolled), and suggested that PP may be the result of ICP in women with an atopic predisposition. A reclassification of PP under "atopic eruption of pregnancy" by the same group[17] has been debated[18] because there has been no history of AD or established atopic background in some PP patients and several PP patients fulfill only minor criteria of atopy.[17] Furthermore, the association with atopy has not been confirmed by other groups, and the importance of mild serum IgE elevations in pregnancy has been controversial.[18,20]

Pruritic Folliculitis of Pregnancy

PFP is a rare specific dermatosis of pregnancy the exact prevalence of which remains unknown (see Table 48-3). Approximately 30 cases have been reported.[20] **PFP presents with pruritic follicular erythematous papules and pustules that affect primarily the trunk** (Figure 48-7).[89] PFP resolves spontaneously at delivery or postpartum, but may recur in subsequent pregnancies.[67] The histopathology is that of folliculitis and special stains for microorganisms are negative. Skin immunofluorescence studies and serology are negative. The differential diagnosis of PFP includes an infectious folliculitis and specific dermatoses of pregnancy. An infectious folliculitis can be ruled out with stains for microorganisms and cultures from the pustular lesions. PFP was associated with decreased birth weight and a male to female ratio of 2:1 in one study.[16] Preterm delivery was reported in one case but no other maternal or fetal risks have been noted.

The pregnant patient should be reassured that **PFP resolves postpartum and has not been associated with substantial risks for the fetus.** PFP has been treated with low- or mid-potent topical steroids, benzoyl peroxide, and UVB.[90] The etiology of PFP remains unknown. Increased serum androgen levels in PFP or association with ICP have been reported but were probably coincidental. It has been postulated that PFP may be a form of hormonally induced acne, based on clinical similarities with the acne that develops after the administration of systemic steroids or progestogens.[91] Other authors[67] have considered PFP to be a variant of PUPPP based on reports of follicular lesions in some PUPPP patients. Nevertheless, the clinical presentation and histopathology of PFP differ overall from those of PUPPP. An association with *Pityrosporum* has been debated.[92] A reclassification[17] of PFP under "atopic eruption of pregnancy" on the basis of personal and family history of eczema in a patient with PFP has been debated[18] because, among other factors, history of atopy has not been reported in other PFP cases. Further studies will be required to define whether PFP is a distinct specific dermatosis of pregnancy.

KEY POINTS

- With the physiologic skin changes of pregnancy, there are no risks for the mother or fetus. The changes should be expected to resolve postpartum.
- Preexisting melanocytic nevi may show mild changes in pregnancy but no increased risk for malignant transformation.
- Preexisting skin disorders are more likely to worsen than improve in pregnancy; atopic dermatitis (eczema) is the most common dermatosis in pregnancy.
- Prognosis of melanoma is not adversely affected by pregnancy.
- Pruritus occurs in up to 3% to 14% of pregnancies. A constellation of clinical and laboratory findings is crucial to establishing etiology.
- Impetigo herpetiformis (pustular psoriasis of pregnancy) is often associated with reduced

calcium or vitamin D. There are serious maternal and fetal risks with this disease.

- Herpes gestationis typically flares at delivery. Treatment is with oral steroids. Fetal risks, such as small-for-gestational-age infants, preterm delivery, and neonatal herpes gestationis, have been associated with this disease.
- PUPPP starts in the abdominal striae and spares the periumbilical area. There is an association with multiple-gestation pregnancy, but there are no maternal or fetal risks.
- Prurigo and pruritic folliculitis of pregnancy carry no maternal or fetal risks.

Maternal and perinatal infections represent common complications of the peripartum interval. In many industrialized nations, the role of sexually transmitted pathogens is declining in its relative contribution to infections in women; however, in the United States and developing nations, the epidemic persists. Many of these pathogens are either proved or presumed to play an integral role in infectious morbidities of pregnancy and the neonatal period, and thus, understanding the social, economic, and pathophysiologic burden is essential. Indeed, as our ability to readily screen the population as a whole for the most prevalent or malignant of these infectious agents (e.g., chlamydia, gonorrhea, and syphilis) has improved, epidemiologic statistics have provided evidence for their implied role in preterm labor, preterm premature rupture of the membranes, intrauterine growth restriction, neonatal conjunctivitis, neonatal pneumonia, and congenital syphilis. Thus, a greater understanding of the role of these prevalent pathogens in mediating disease pathogenesis has mandated that the obstetrician be well versed in the identification and management of these organisms. In this chapter, we review current trends in epidemiology, diagnosis, treatment, and prevention.

EPIDEMIOLOGY

The two most valuable sources of incidence and prevalence data on the sexually transmitted pathogens are provided by the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO). The CDC reports sexually transmitted disease (STD) estimates for the United States using reported cases and

estimates after accounting for underreporting. The Institute of Medicine (IOM) provides WHO estimates on worldwide incidences and prevalence of the four curable sexually transmitted infections (chlamydia, gonorrhea, syphilis, and *Trichomonas*). **Overall, the WHO places annual estimates of worldwide incidence at 89.1 million new cases of chlamydia infection, 62.6 million new cases of gonorrhea, and 12.2 million new cases of syphilis among persons aged 15 to 49 years.** In addition, epidemiologic studies have revealed a number of basic truths regarding STDs: (1) sexually active adolescents have the highest rates of STDs of any age group[1]; (2) gender differences are observed in the transmission of the most prevalent STDs, with more efficient transmission from men to women; (3) curable STDs (i.e., not human immunodeficiency virus [HIV], human papillomavirus [HPV], or chronic recurrent herpes simplex virus) are associated with more serious long-term consequences in women than in men; (4) having one or more STDs predisposes an individual to acquisition and transmission of other STDs; (5) STDs in developing nations are both hyperendemic and epidemic; and (6) there exists marked racial disparity.

Chlamydia

Genital tract chlamydial infections are generally ascribed to *Chlamydia trachomatis* and account for the most prevalent reported infectious disease in the United States annually. More than 1.2 million cases are reported to the CDC annually, with an actual presumed number of new cases (accounting for estimates of underreporting) of 3 million annually.[1] **These infections present unique problems for public health control programs because 50% to 70% of infections in women are clinically silent.** Unrecognized and untreated, the bacteria may remain infectious in the host for months and be readily transmitted to sex partners. Furthermore, most reported infections occur in the 15- to 24-year-old age group, individuals who do not partake in preventive health care programs. Estimates on worldwide exposure approximate that 90 million new cases of *C. trachomatis* infection occur on an annual basis, accounting for a rising majority of perinatal and neonatal complications.[2-5] Of note, a primary goal of *Healthy People 2010* is the elimination of racial disparities among multiple sexually transmitted pathogens. An assessment of the racial disparities of nationally notifiable disease for the year 2002 revealed a nearly 10-fold increase rate for chlamydia in blacks compared with whites (805.9 versus 90.2 per 100,000).[6]

The cost of treatment, prevention, and management of complications of chlamydial infections is estimated at $2.4 billion in health care costs annually.[3-5] Taken together, these factors have resulted in the endorsement of a nationwide broad-based screening program by both the CDC and IOM. Specific recommendations regarding population-based screening and prevention programs are reviewed later in this chapter.

Gonorrhea

The reported incidence of *Neisseria gonorrhoeae* infection is just over 300,000 cases in the United States annually.[1] However, the actual number of reported cases may be underrepresented by as much as 40%, yielding a U.S. estimate of 700,000 cases annually.[7] In contrast to chlamydia, the worldwide prevalence of gonorrhea may be significantly less than that observed in the United States, as supported by epidemiologic data from Canada and Western Europe.[8]

Historically, review of trends in incidence of reported gonorrhea in the United States from 1941 to 1997 reveal peak increases among both men and women in the interval around World War II (WWII), and again in 1975, peaking at 473 cases per 100,000.[7] The steady decline since 1975 has been accompanied by three interesting observations. First, the male-to-female ratio of reported cases has declined from a high of 3:1 to its current gender equivalence of 1:1.[7] Second, racial disparity is noted, with a 24-fold higher rate among blacks compared with whites (570.4 versus 23.6 per 100,000).[6] **Third, the single greatest determinant of gonorrhea incidence since 1975 is age: annual reported cases are twice as high in adolescents (aged 15 to 19 years) than in women aged 20 to 24 years.**[8,9]

Syphilis

Historically, syphilis has long been recognized as a chronic systemic infectious process secondary to infection with the spirochete *Treponema pallidum*. Throughout the centuries, epidemics of syphilis have been periodically reported. In the United States, the observed incidence of primary and secondary syphilis initially mirrored that of gonorrhea (reflecting the principle that epidemiologic synergy among the STDs occurs), with a rising peak during and shortly after WWII to 76 per 100,000 population to its reported nadir of 4 per 100,000 in 1955 to 1957.[10] Since the mid-1950s, recurrent epidemics have occurred, the most recent in 1985 to 1990, with a peak incidence of 23.5 cases per 100,000.[11] **Beginning in 2001 syphilis has increased each year to 13,997 cases in 2009.**[1]

Of concern are observations from both the WHO and CDC that the prevalence of syphilis in both the United States and developing nations has fluctuated over the past two decades. Again noted are elements of racial disparity, with a disproportionate number of cases in blacks compared with whites (9.4 versus 1.1 per 100,000),[6] as well as gender disparity, with a predilection in women aged 15 to 24 years.[7]

Congenital Syphilis

As might be expected, the trend toward increasing prevalence in reproductive-aged women is accompanied by fluctuations in the incidence of congenital syphilis. Thus, there existed an epidemic of congenital syphilis from 1986 to 1992.[10] Fortunately, 2002 congenital syphilis surveillance data from the CDC report that provisional cases are at 348 per 100,000 births.[1] Of concern, however, is the observation that the rates of congenital syphilis remain disproportionately high in black and southern U.S. populations.[1,6,7] In their most recent report, the CDC summarized 2002 congenital syphilis surveillance data, which indicated that congenital syphilis rates decreased among all racial and ethnic minority populations, as well as in all regions of the United States, except the Northeast. Thus, rates of congenital syphilis per 100,000 live-born infants were determined from U.S. natality data and demonstrated a 21.1% decrease, from 14.2 to 11.2 cases per 100,000 live births, reflecting that primary and secondary syphilis rates

among reproductive-aged women declined 35.3%, from 1.7 to 1.1 cases per 100,000 women.[12] The rate of congenital syphilis fell 50.6% among American Indian/Alaska Native infants, 22.4% among Hispanic infants, 21.4% among Asian/Pacific Islander infants, and 19.8% among non-Hispanic black infants; the rate remained unchanged among non-Hispanic white infants.[12] **Of concern is a recent rise in the number of congenital syphilis cases from 339 in 2005 to 437 in 2008 according to the CDC.**[1]

Review of the data involved in recent trends in congenital syphilis demonstrate one of the successes of STD prevention and therapy and is worth mentioning at this juncture. To summarize the report of the CDC,[12] among the 451 cases of congenital syphilis reported in 2002, a total of 333 (73.8%) occurred because the mother had no documented treatment or received inadequate treatment of syphilis before or during pregnancy; **many of these cases occurred among infants born to women who had no prenatal care or no documented prenatal care.** In 63 (14.0%) cases, the mother was treated adequately but did not have an adequate serologic response to therapy, and the infant was evaluated inadequately for congenital disease. In 39 (8.6%) cases, the mother was treated adequately but did not have an adequate serologic response to therapy, and the infant's evaluation revealed laboratory or clinical signs of congenital syphilis. A total of 16 (3.6%) cases were reported for other reasons. In 288 (63.9%) of the cases reported in 2002, the mother received prenatal care; the mother did not receive prenatal care in 130 (28.8%) cases; and no information on prenatal care was reported for 33 (7.3%) cases. When examined for trimester of pregnancy in which prenatal care occurred, in 86 instances care was initiated during the first trimester of pregnancy, 93 during the second trimester, and 59 during the third trimester. A total of 18 (30.5%) mothers who initiated prenatal care during the third trimester did so less than 30 days before delivery. In 2002, among those infants with congenital syphilis, 18 (4.0%) were stillborn, and 8 (1.8%) died within 30 days of delivery. Taken together, these findings highlight that decreases in incidence of congenital syphilis closely parallel decreases in prevalence of primary and secondary syphilis among women, and interventions designed to prevent, detect, and treat syphilis among women of reproductive age have likely played an important role in the eventual decline of congenital disease. Indeed, following the epidemic of 1985 to 1990, efforts to eliminate syphilis were initiated with the implementation of a "National Plan to Eliminate Syphilis" in 1998.[13] Elimination efforts initially focused on syphilis among racial and ethnic minority populations and persons living in the South and employed the following three methods: enhanced screening of women at high risk for acquiring syphilis; increased provider awareness, education, and training regarding syphilis; and increased awareness of the disease among communities with high rates of infection. However, it is important to note that although the incidence of congenital syphilis decreased with the implementation of the aforementioned initiative, most congenital syphilis cases reported were preventable.[9,12,13]

PATHOGENESIS

Endocervical Infections

Chlamydia and gonorrhea are the sexually transmitted pathogens generally associated with endocervical infections and have been noted to bear resemblance in their profile of observed maternal and perinatal clinical syndromes.[14,15] Although they are common in their association with increased cervical discharge, they are unique in almost every other aspect of their pathogenesis.

Chlamydia

Species of *Chlamydia* were initially serotyped according to their biologic and biochemical properties, and a greater than 95% homology in their 16s ribosomal ribonucleic acid (RNA) sequences was observed. Subsequent molecular analyses led to the reclassification of some *Chlamydia psittaci* strains as *Chlamydia pneumoniae*, a human pathogen, and *Chlamydia pecorum*, a pathogen of ruminants. Nevertheless, of the four species of chlamydiae (*C. trachomatis*, *psittaci*, *pneumoniae*, and *pecorum*), only *C. trachomatis* and *C. pneumoniae* claim primates as their endogenous hosts. Each of the species bears multiple strains based on serotype, which, in turn, are associated with distinct clinical entities. These are as summarized in Table 49-1.

Chlamydiae are obligate intracellular bacteria that grow in eukaryotic epithelial cells, and they employ a growth cycle unique to that from all other pathogens. During the

TABLE 49-1 SPECTRUM OF HUMAN AND MAMMALIAN DISEASES CAUSED BY *CHLAMYDIAE* SEROTYPES

SPECIES SEROTYPE	ACUTE DISEASES	CLINICAL SEQUELAE
Chlamydia trachomatis	Conjunctivitis	Trachoma

Ewes		

1970s, the infectivity and growth cycle of chlamydiae was initially characterized.[16-20] Known to specifically infect the cuboidal or nonciliated columnar epithelial cells common to the endocervix, urethra, and conjunctiva, this growth cycle involves infection of a susceptible host cell through a receptor-specific phagocytic process. This phagocytic process involves chlamydiae *elementary bodies* (EBs) binding to the host cell through a heparin sulfate–like molecule to glycosaminoglycan receptors, and these subsequently are phagocytosed into cytoplasmic vacuoles termed *phagosomes*.[21] In this fashion, chlamydiae may be considered to have a unique biphasic life cycle with dimorphic forms that are functionally and morphologically distinct. Once endocytosed, the EB differentiates into a larger pleomorphic form called the *reticulate body* (RB), which replicates by binary fission. The chlamydiae remain in the phagosome throughout their growth cycle, presumptively as an acquired means of escaping host lysosomes.[18-21] The endosome is transported to the distal region of the Golgi apparatus and incorporates host-derived sphingolipids into the inclusion membrane. Thus, it appears that chlamydiae are able to intercept host vesicular traffic bound for the plasma membrane to sequester lipids and possibly other host substances synthesized in the Golgi. Subversion of host vesicular traffic may represent a dual advantage for chlamydiae in obtaining materials from the host for its metabolism as well as in modifying the inclusion membrane to evade lysosomal fusion and immune detection.

Because chlamydiae depend on their host cell for the generation of adenosine triphosphate (ATP), they require viable cells for survival.[22] Chlamydiae are incapable of de novo nucleotide biosynthesis and thus are dependent on host nucleotide pools. In this manner, one may consider this unique pathogen to be virus like. On the other hand, chlamydiae resemble a bacterial pathogen in that they contain both DNA and RNA, have a modified rigid cell wall with a lipopolysaccharide similar to that in the outer membrane of gram-negative bacteria (albeit lacking the intervening peptidoglycan layer), and multiply by binary fission.[18-22]

Some interesting insights into the interaction of chlamydiae and its host immune system have emerged in the past decade. These new observations include the extensive but unexpected polymorphism of the major outer membrane protein (MOMP), the evidence for genetic susceptibility to disease, and the association of antibody response to the 60-kDa heat shock protein (CHSP60) with the development of adverse sequelae following ocular and genital infections. By way of summary, MOMP is a major target for protective host immune responses, such as neutralizing antibodies and possibly protective T-cell responses.[23,24] The basis for MOMP antigenic variation is allelic polymorphism at the omp-1 locus, and immune selection appears to be occurring in host populations frequently exposed to *C. trachomatis*.[25] Combined with the observations that there appears to be a clear genetic susceptibility to disease, because only a subset of infected persons appear to have long-term complications after acute or repeated chlamydial infections, it is now believed that chronic immune activation plays a role in propagating clinical disease.[26] Thus, susceptibility to chlamydial pelvic inflammatory disease in a study of sex workers in Nairobi, Kenya has been associated with an HLA class I allele, HLA-A31.[27,28] Similarly, allelic variation in the class II allele (DQ) have been shown to be positively associated with *C. trachomatis* tubal infertility.[29,30]

In addition to host genotype playing a role in determining the severity of chlamydia-mediated disease, aberrations in humoral immunity also appear to modulate clinical disease. Antibody response to a 57-kDa chlamydial protein was initially observed more frequently in women with tubal infertility than in controls.[15,26] This protein was subsequently identified as a heat shock protein of the GroEL family of stress proteins. The association between antibody response to CHSP60 and pelvic inflammatory disease, ectopic pregnancy, tubal infertility, and trachoma has been subsequently observed in a number of population-based serotype studies.[15,16] Suffice it to say, although it remains unclear whether antibody to CHSP60 is causally involved in chlamydial immunopathogenesis or is merely a marker of persistent chlamydial infection, in cells persistently infected with *C. trachomatis*, the constitutive expression of CHSP60 may provide continued antigenic stimulation for the CHSP60 antibody response observed in persons with long-term sequelae. Moreover, observed immunopathology may also result from aberrations in self-tolerance mediated by shared and similar epitopes between CHSP60 and endogenous HSP60, which, in turn, results in a classic immune cascade resulting in tissue damage.

Gonorrhea

In contrast to chlamydiae species, the pathogenesis of *N. gonorrhoeae* and human disease is more straightforward and reflects classic bacterial pathogenesis. *N. gonorrhoeae* is a gram-negative diplococcus for which humans are the only natural hosts. Like the other endocervical infectious pathogens, gonorrhea also bears a predilection for the columnar epithelium, which lines the mucous membranes of the anogenital tract.[7,31] Gonococcal pathogens adhere to these mucosal cells through attachment of pili and other surface proteins, resulting in the release of lipopolysaccharide, which likely instigates mucosal damage. Following adherence, *N. gonorrhoeae* is pinocytosed and thereby transported into epithelial cells. Unlike chlamydiae, the gonococcus does not replicate in the phagosome and, hence, evades lysosomal degradation. **Rather, gonococci persist in the host by virtue of their ability to alter the host environment.** In sum, multiple structures of *N. gonorrhoeae* enable pathogenesis by a variety of immune evasive mechanisms, including immunoglobulin A (IgA) proteases, iron repression, and cell-adherence mechanisms.[7,31]

Systemic Infection

Syphilis is a chronic disease caused by the spirochete *Treponema* subspecies *pallidum*. *T. pallidum* belongs to the order Spirochaetales, characterized by slender, nonflagellated, flexuous, tightly spiraled protozoa-like organisms. Motility is attained by the flexuous bending of this long slender body. This motility is responsible for the attainment of access through disrupted integument (mostly mucous membranous) primarily during sexual contact. This anaerobic and obligate human parasite is acquired by 50% of individuals having sexual contact with an infected partner.[7] Following mucosal invasion, an incubation period

of about 1 week to 3 months ensues until the chancre appears, heralding primary infection. The chancre arises at the point of entry by the spirochetes. The chancre is a broad-based, typically nontender ulcerated lesion that gives a characteristic "woody" or "rubbery" feel on palpation. It is seldom secondarily infected, and it resolves without medical treatment in 3 to 6 weeks. The organism then hematogenously spreads through the body during the period in which the immune system has responded, about 4 to 10 weeks.[7] Secondary syphilis is characterized by a generalized maculopapular eruption, constitutional symptoms, major organ involvement, and lymphadenopathy. Like the other major organ systems, the central nervous system (CNS) is invaded in about 40% of individuals during this hematogenous phase.[32,33] Secondary syphilis resolves over 2 to 6 weeks as the patient enters the latent phase of the disease.[7] The latent phase is divided into early latent (<1 year) and late latent (>1 year) disease in which no symptoms or signs of clinical disease are noted. If left untreated, progress to tertiary disease with cardiovascular system, CNS, and musculoskeletal system involvement occurs. The organism has an affinity for the arterioles, and the inflammatory response that follows results in obliterative endarteritis.[34] Subsequent end-organ destruction then occurs. In immunocompromised individuals (e.g., immune-suppressive medications, HIV infection), the progression to tertiary disease, especially CNS, is known to occur early after the onset of disease. **Congenital infection results from transplacental migration of the organism to the fetus. Congenital disease occurs with all stages of maternal infection as well as at any gestational age.**[35] Past theories of a placental impasse during the first half of gestation were disproved by pathologic examination of infected first-trimester abortuses and by the demonstration of living organisms in amniotic fluid obtained by amniocentesis in the early second trimester.[35,36] It is now believed that transplacental infection must be close to 100% during the early stages of maternal disease because of the known hematogenous spread, with lower rates of transmission, falling to 10%, as bacteremia abates with the subsequent mounting of the maternal immunologic response during late latent disease.[37-39] Like chlamydia, *T. pallidum* invades the host and evades the host defense mechanisms while being completely dependent on the host for survival. It lacks the fundamental biosynthetic machinery to create complex molecules and fatty acids.[40,41] The ability to evade the host defense mechanisms stems from its basic construct of an inner membrane with few integral membrane proteins protruding through the surface gaining exposure through the outer membrane.[42] Berman concluded that this construct "may provide some understanding of how the organism elicits such a vigorous inflammatory and immunological response, but manages to evade immunological clearance, although a paucity of surface proteins means that its surface presents few targets for a host immune response."[43] Of paramount importance in the pathogenesis of fetal disease is knowledge of fetal immunologic development. Disease early in gestation incites little response because the immune system functions little until midgestation. Following this period, the fetus is able to mount a vigorous response with marked endarteritis and end-organ involvement. Characteristics of subsequent fetal damage and loss are covered further in the section on diagnosis.

DIAGNOSIS

Chlamydia and Gonorrhea

In women, the gold standard for diagnosis of gonorrhea infection requires isolation of the organism by culture. Traditionally, specimens are streaked on a selective (Thayer-Martin or Martin-Lewis) or nonselective (chocolate agar) medium. Inoculated media are incubated at 35° to 36.5° C in an atmosphere supplemented with 5% CO_2 and examined at 24-hour intervals for 72 hours. Subsequent diagnosis is made by identification of the organism with growth on this selective media, with a Gram stain and oxidase test on colonies identifying gram-negative, oxidase-positive diplococci morphology. A confirmed laboratory diagnosis of *N. gonorrhoeae* cannot be made on the basis of these tests alone. A presumptive test result is sufficient to initiate antimicrobial therapy, but additional tests must be performed to confirm the identity of an isolate as *N. gonorrhoeae*. Culture isolation is also suitable for non–genital tract specimens. Using selective media is necessary if the anatomic source of the specimen normally contains other bacterial species. Given ongoing concerns by the CDC regarding resistant species,[44] all gonorrhea cases in the United States are confirmed by culture to allow for antimicrobial susceptibility testing. In women, a single endocervical culture on selective media detects 80% to 90% of uncomplicated gonorrhea.[31,44] Thus, it is recommended that for optimal yield, two consecutive endocervical specimens or a combination of an endocervical and rectal-vaginal swab should be obtained.[7]

The advantages of gonorrheal culture are high sensitivity and specificity, low cost, suitability for use with different types of specimens, and the ability to retain the isolate for additional testing. The major disadvantage of culture for *N. gonorrhoeae* is that specimens must be transported under conditions adequate to maintain the viability of organisms. Another disadvantage is that a minimum of 24 to 72 hours is required from specimen collection to the report of a presumptive culture result.[44]

Because curative antibiotic therapies for chlamydial infections are available and inexpensive, early diagnosis is an essential component of management and prevention. Historically, isolation of chlamydia in cell culture had been the traditional method for laboratory diagnosis and has remained the gold standard in diagnoses because of its specificity. However, culture requires expensive equipment, technical expertise, and stringent transport conditions to preserve specimen viability. **Thus, chlamydial culture is being replaced by antigen-detection methods, such as enzyme immunoassay (EIA) and direct fluorescence assay (DFA), which have less demanding transport requirements and can provide results on the same day.** Assays are typically based on the capture of the chlamydial lipopolysaccharide using monoclonal or polyclonal antibodies linked to a solid-phase support. Early problems with low specificity because of cross-reactivity between the chlamydial lipopolysaccharide (LPS) and that of other gram-negative bacteria have been largely overcome by confirmation with DFA or a blocking antibody assay.

A substantial number of EIA tests have been marketed for detecting *C. trachomatis* infection. By contrast, the performance and cost characteristics of EIA tests for *N. gonorrhoeae* infection have not made them competitive with culture.[44] *C. trachomatis* EIA tests detect chlamydial LPS with a monoclonal or polyclonal antibody that has been labeled with an enzyme. The enzyme converts a colorless substrate into a colored product, which is detected by a spectrophotometer. Specimens can be stored and transported without refrigeration and should be processed within the time indicated by the manufacturer.

The DFA procedure identifies either the MOMP or LPS as its antigen, and staining consists of coincubation with a fluorescein-labeled monoclonal antibody that binds to *C. trachomatis* elementary bodies. DFA with a *C. trachomatis*–specific anti-MOMP monoclonal antibody is considered to be highly specific. Similar to EIAs, DFA is not appropriate as a diagnostic test for the direct detection of *N. gonorrhoeae* in clinical specimens.[44]

Nucleic acid–based hybridization probes and nucleic acid amplification tests (NAATs) based on polymerase chain reaction (PCR), ligase chain reaction, and transcription-mediated amplification technology are now commercially available.[16,44] The common characteristic among NAATs is that they are designed to amplify nucleic acid sequences that are specific for the organism being detected and thus do not require viable organisms. The increased sensitivity of NAATs is attributable to their ability to produce a positive signal from as little as a single copy of the target DNA or RNA. Most commercial NAATs have been cleared by the U.S. Food and Drug Administration to detect *C. trachomatis* and *N. gonorrhoeae* in endocervical swabs from women, urethral swabs from men, and urine from both men and women.[44] The ability of NAATs to detect *C. trachomatis* and *N. gonorrhoeae* without a pelvic examination is a key advantage of NAATs, and this ability facilitates screening men and women in other nontraditional screening venues. A disadvantage of NAATs is that specimens can contain amplification inhibitors that result in false-negative results.

In addition to the NAATs, nucleic acid hybridization assays are now available to detect *C. trachomatis* or *N. gonorrhoeae*. Both the PACE and Hybrid Capture assays can detect *C. trachomatis* or *N. gonorrhoeae* in a single specimen. In the Gen-Probe hybridization assays, a DNA probe that is complementary to a specific sequence of *C. trachomatis* or *N. gonorrhoeae* ribosomal RNA hybridizes with any complementary ribosomal RNA that is present in the specimen.[44] RNA hybridization probes in the Digene assay are specific for DNA sequences of *C. trachomatis* and *N. gonorrhoeae*, including both genomic DNA and cryptic plasmid DNA.[44] One of the advantages of the nucleic acid hybridization tests is the ability to store and transport specimens for up to 7 days at ambient temperatures.

Duplex testing for the simultaneous detection of chlamydial and gonococcal DNA from a single specimen is also commercially available in some markets.[44] However, it bears mention that inherent in the increased sensitivity of these molecular techniques is the potential for false-positive results due to cross-contamination between specimens as well as contamination from equipment, reagents, and supplies.

Serology screening has no or limited value in testing for uncomplicated genital *C. trachomatis* infection and should not be used for screening because previous chlamydial infection frequently elicits long-lasting antibodies that cannot be easily distinguished from the antibodies produced in a current infection. A serologic screening or diagnostic assay is not available for *N. gonorrhoeae*.

Syphilis

The ability to diagnose infection with the organism *T. pallidum* has been problematic for two primary reasons. The first is the failure of the organism, as of yet, to be cultured on an artificial medium. The second lies in the long-recognized tendency of clinical manifestations to mimic or imitate a variety of other diseases. Reports continue to surface touting the difficulty with which syphilis is recognized at any stage.[45] Although the primary genital lesion of syphilis, the chancre, is commonly recognized by affected males, women more often than not fail to identify this lesion. As reviewed earlier in this chapter, the chancre is a painless, sharply demarcated, woody-based (induration), 1- to 2-cm erosion of the mucosal surface at the site of the organism's entrance. It occurs typically without constitutional symptoms and is seldom secondarily infected. Examination of the serous exudates from the chancre under dark-field microscopy definitively diagnoses the condition by identification of the flexuous (spiraled) bodied organism. Unfortunately, dark-field microscopy lacks sensitivity, owing in part to specimen collection technique. The lesion must be abraded with a gauze sponge or cotton-tip application until bleeding ensues. The lesion is then squeezed to express clear serum, which is pressed onto a microscope slide. Direct fluorescent-antibody tests have the advantage that they can be performed on slides that are air-dried as well as on stored paraffin-embedded tissue.[46] PCR has increased the sensitivity for detection in samples obtained from genital lesions, cerebrospinal fluid (CSF), amniotic fluid, serum, and paraffin-embedded tissue.[47] Great difficulty in the diagnosis of syphilis lies in the fact that primary syphilis often goes unrecognized by the infected individual, as eluded to earlier.

Because most individuals infected with *T. pallidum* are in the asymptomatic latent phase of the disease, serologic testing is the primary means of diagnosis. Historically, reliance has been placed on two nonspecific antibody tests: the rapid plasma reagin (RPR) and the Venereal Disease Research Laboratories (VDRL) tests. Both pregnant and nonpregnant women are primarily screened using one of these two tests. **In an effort to reduce the incidence of congenital syphilis, the WHO and the CDC recommend at a minimum screening all pregnant women in the first trimester.**[48,49] It would be ideal if pregnant women were additionally screened at the start of the third trimester to enhance the detection of newly acquired infection after first-trimester screening as well as reinfection.[50] If prenatal screening is not available, then screening at the time of delivery should be performed.[46] Once appropriately treated, most individuals (pregnant or not) lose reactivity to these nontreponemal serologic tests.[49] **Confirmation that the infection is indeed due to *T. pallidum* is made by the *Treponema*-specific microhemagglutination–*Treponema pallidum* (MHA-TP) and fluorescent treponemal antibody**

absorbed (FTA-ABS) tests. For most individuals, the MHA-TP and FTA-ABS tests remain positive lifelong.[51] False-positive reactions occur with both nonspecific antibody tests (RPR, VDRL) because of viral infections and autoimmune disease. Although most HIV-infected individuals exhibit normal serologic testing, occasionally one encounters patients with expressed lesion exudates or biopsy-proven disease, and serologic testing is negative.[51] The following recommendations for diagnosing syphilis in HIV-infected individuals have been made by the CDC.[52] First, individuals with HIV should be screened for syphilis, and all sexually active individuals with syphilis should be screened for HIV. If clinical examination and findings suggest syphilis in the presence of negative serologic testing, then DFA for *T. pallidum* staining of lesion exudates and biopsy or dark-field microscopic examination should be performed. In these individuals, all laboratories should titrate the nontreponemal tests (RPR, VDRL) to the exact final end point to better guide response to therapy. Finally, neurosyphilis must be entertained as a diagnosis in the HIV-infected individuals and appropriate consultations obtained to better interpret serologic results. Neurosyphilis is diagnosed in non–HIV-infected and HIV-infected patients by examination of CSF through spinal tap.

Spinal tap and examination of CSF is not currently recommended in non–HIV-infected individuals who have early asymptomatic syphilis.[49] Individuals in whom CSF testing should be considered include those with neurologic or ophthalmologic symptoms, active tertiary disease, or treatment failure and HIV-positive individuals.[49]

Nonimmune fetal hydrops, polyhydramnios, and intrauterine fetal demise have long been associated with congenital syphilis. Recent reports confirm the constellation of nonimmune hydrops (ascites, pleural effusion, scalp or skin edema), hepatomegaly, polyhydramnios, and placentomegaly as markers for congenital syphilis.[53,54] Hollier and colleagues prospectively identified and followed 24 women with untreated syphilis to better define the pathophysiology of fetal disease.[55] Ultrasound examination with amniocentesis and funipuncture was performed. Maternal treatment was with benzathine penicillin G given intramuscularly (IM) as per current CDC guidelines (Table 49-2). Six women had primary, 12 secondary, and 6 early latent disease. Ultrasound examination was abnormal in 16 (66%) of the 24 fetuses. Thirteen of these fetuses had hepatomegaly, 3 had hepatomegaly and ascites, and 1 had nonimmune hydrops. Increased placental thickness was seen in 17 (71%) and hydramnios in only 1 fetus with abnormal ultrasound. Sixteen (66%) of these fetuses had either congenital syphilis or *T. pallidum* identified in the amniotic fluid specimens. Maternal stage of disease (primary, secondary, early latent) correlated with fetal infection rates of 50%, 67%, and 83%, respectively. γ-Glutamyl transpeptidase was elevated in 79% of fetuses compared with aspartate aminotransferase elevation in only 58% of cases. The authors recommend ultrasound examination as an important tool in the diagnosis and management of the syphilis-infected gravida and her unborn child. The authors conclude that the pathophysiologic disease process begins with hepatic and placental involvement, followed by amniotic fluid infection and the development of hematologic abnormalities. The intrauterine fetal demise of 1 of the 24 fetuses serves as a chilling reminder of the severity of devastation following infection with this relatively simple organism.

TABLE 49-2 RECOMMENDED TREATMENT REGIMENS* FOR *TREPONEMA PALLIDUM* INFECTIONS

Primary, Secondary, Early Latent Disease
Benzathine penicillin G, 2.4 million U IM as a single dose
Children: 50,000 U/kg IM (maximum, 2.4 million U) as a single dose
Late Latent and Latent Disease of Unknown Duration
Benzathine penicillin G, 2.4 million U IM weekly for 3 doses (7.2 million U total)
Children: 50,000 U/kg IM weekly for 3 doses (maximum, 150,000 U/kg or 7.2 million U)
Penicillin Allergy (Documented)
Pregnancy: desensitization and penicillin therapy as above
Nonpregnant:
• Doxycycline, 100 mg PO twice daily for 2 weeks, or tetracycline, 500 mg PO four times a day for 2 weeks†
• Ceftriaxone, 1 g IM or IV daily for 8-10 days†
• Azithromycin, 2 g PO as a single dose†
Tertiary Disease
Neurosyphilis: aqueous crystalline penicillin G, 18-24 million U IV daily (3-4 million U every 4 hours or continuous infusion) for 10-14 days
Alternative: procaine penicillin, 2.4 million U IM once daily, with probenecid, 500 mg PO four times a day for 10-14 days
No neurosyphilis: benzathine penicillin G, 2.4 million U IM weekly for 3 weeks (7.2 million U total)

From Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2006. MMWR Morb Mortal Wkly Rep 55:1, 2006.

*The Centers for Disease Control and Prevention recommend penicillin as the treatment of choice in individuals with syphilis.

†Efficacy data are limited.

TABLE 49-3 RECOMMENDED TREATMENT REGIMENS* FOR *CHLAMYDIA TRACHOMATIS* INFECTIONS

Recommended Regimen
Azithromycin, 1 g orally in a single dose, *or*
Doxycycline, 100 mg orally twice a day for 7 days
Alternative Regimens
Erythromycin base, 500 mg orally four times a day for 7 days, *or*
Erythromycin ethylsuccinate, 800 mg orally four times a day for 7 days, *or*
Ofloxacin, 300 mg orally twice a day for 7 days, *or*
Levofloxacin, 500 mg orally for 7 days

Modified from the Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2002. MMWR Morb Mortal Wkly Rep 51:1, 2002.

*The Centers for Disease Control and Prevention recommend treating persons with a positive sensitive nucleic acid amplification chlamydia test. Although tetracycline and doxycycline have the greatest activity against *Chlamydia trachomatis*, these drugs should not be used in pregnancy because of their enamel effects. Owing to gastrointestinal side effects with erythromycin, azithromycin is the drug of choice in pregnancy.

TREATMENT

Chlamydia

The recommended treatment regimen for uncomplicated genital chlamydia infection has remained unchanged since 1998. **The CDC recommends either azithromycin, 1 g in a single oral dose, or doxycycline, 100 mg orally twice a day for 7 days** (Table 49-3). Although the results of clinical trials indicate that azithromycin and doxycycline are equally efficacious, single-dose treatment maximizes compliance.[56] To minimize transmission and reinfection,

patients should be instructed to abstain from sexual intercourse for 7 days after single-dose therapy or until completion of a 7-day regimen and should also be instructed to abstain from sexual intercourse until all of their sex partners have been treated. Longitudinal studies of chlamydia-infected adolescent female patients demonstrate a high risk for chlamydia reinfection and other STD infections within a few months of initial diagnosis. Because of the high incidence of chlamydia infection that can occur in the months following a treated infection, CDC guidelines suggest that providers consider the repeat screening of chlamydia-infected female patients 3 to 4 months after treatment.

Gonorrhea

Although uncomplicated genital gonorrhea infections can be treated with single-dose therapy, there are fewer oral treatment options compared with efficacious therapy in chlamydial infections (Table 49-4). Moreover, recent emergence of quinolone-resistant *N. gonorrhoeae* in California, Hawaii, Asia, and the Pacific Islands has led to the generalized recommendation that these agents should not be used to treat gonorrhea infections acquired in these areas or in areas with an increased prevalence of quinolone resistance.[44] The CDC recommendations became somewhat complicated in July 2002, when Wyeth Pharmaceuticals (Collegeville, PA) discontinued cefixime. In the absence of cefixime, the primary recommended treatment option for gonorrhea in Hawaii and California is ceftriaxone.[44] In addition, because of the risk for coinfectivity with *N. gonorrhoeae* and *C. trachomatis*, the CDC recommends empirically treating patients with positive gonorrhea test results for both gonorrhea and chlamydia.[44]

In 2007 the Gonococcal Isolate Surveillance Project (GISP) found 27% of *N. gonorrhoeae* infections were resistant to penicillin, tetracycline, ciprofloxacin, or a combination of these antibiotics. In 2009, a CDC Working Group for Cephalosporin-Resistant Gonorrhea Outbreak Response Plan was convened to address the growing resistance to these antibiotics by *N. gonorrhoeae*.[57] The CDC in their *Morbidity and Mortality Weekly Report* dated May 13, 2011 reviewed five cases of urethral gonorrhea with high mean inhibitory capacities (9.1%) of azithromycin representing 10% of those treated for *N. gonorrhoeae* in San Diego County August to October 2009.[58] In this monograph they reinforce the 2010 STD Treatment Guidelines recommending dual therapy with 250 mg ceftriaxone and either 1 g of azithromycin orally or 100 mg of doxycycline twice daily for 7 days for uncomplicated urogenital, rectal, and pharyngeal gonorrhea. The CDC does not recommend azithromycin as monotherapy in the treatment of gonorrhea. If azithromycin is prescribed because of cephalosporin allergy, a 2-g oral dose is recommended, with a test of cure performed 1 week after treatment. Culture is recommended, and if not available, a NAAT should be performed. If the NAAT is positive, a culture should be obtained.

TABLE 49-4 RECOMMENDED TREATMENT REGIMEN* FOR UNCOMPLICATED GENITAL *NEISSERIA GONORRHOEAE* INFECTIONS

Ceftriaxone, 250 mg IM in a single dose, *plus*
Azithromycin, 1 g orally in a single dose, *or*
Doxycycline, 100 mg orally twice a day for 7 days

Modified from the Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2002. MMWR Morb Mortal Wkly Rep 51:1, 2002.

*The Centers for Disease Control and Prevention recommend treating persons with a positive gonorrhea test result for both gonorrhea and chlamydia unless a negative result has been obtained with a sensitive nucleic acid amplification chlamydia test.

Syphilis

It was not long after the introduction of penicillin about the time of WWII that it became recognized as the primary antimicrobial for the treatment of syphilis. **Penicillin has been effective in the treatment of disease and in the prevention of disease progression in both nonpregnant and pregnant women as well as in the prevention and treatment of congenital syphilis** (see Table 49-2).[49,56] CDC 2006 treatment guidelines recommend benzathine penicillin G, 2.4 million U IM as a single dose, for primary, secondary, and early latent syphilis in both pregnant and nonpregnant women.[51] Likewise, children are treated with benzathine penicillin G, 50,000 U/kg IM (maximum dose, 2.4 million U as a single dose). Late latent syphilis and latent syphilis of unknown duration are treated with 2.4 million U IM benzathine penicillin G weekly for three doses (7.2 million U total).[49] Children, in turn, are treated with 50,000 U/kg weekly for 3 doses (150,000 U/kg or 7.2 million U maximum) for late latent and latent syphilis of unknown duration.

Individuals with documented allergies to penicillin present a particular treatment problem. Treatment recommendations differ as to whether the individual is pregnant or not. For early disease in nonpregnant women, doxycycline, 100 mg by mouth (PO) twice daily for 2 weeks (tetracycline, 500 mg four times daily) has been used with little available data. Alternatively, ceftriaxone, 1 g IM or intravenously (IV) daily for 8 to 10 days, or azithromycin, 2 g PO as a single dose may be effective. These alternatives should not be considered in individuals who are HIV positive, noncompliant, or pregnant. These aforementioned individuals should undergo penicillin desensitization and penicillin therapy.

Therapy for tertiary syphilis is dependent on the presence or absence of neurosyphilis. Provided CSF examination is negative, individuals are treated with benzathine penicillin G, 2.4 million U IM weekly for 3 weeks (7.2 million U total).[49] If neurosyphilis has been diagnosed, then aqueous crystalline penicillin G, 18 to 24 million U IV daily (3 to 4 million U every 4 hours or continuous infusion) for 10 to 14 days is given. An alternative therapy in compliant individuals is procaine penicillin, 2.4 million U IM once daily, with probenecid, 500 mg orally four times a day for 10 to 14 days. Follow-up CSF evaluation is recommended to assess response to therapy. Attempts at targeted mass treatment for syphilis in populations at risk to reduce outbreaks and ultimately congenital syphilis have met with failure.[59]

The implementation of appropriate screening and treatment of pregnant women should theoretically result in the elimination of congenital syphilis.[37,43] Unfortunately, children continue to be born with increased prematurity, low birthweight, hepatomegaly, and cutaneous and bone

lesions in developed as well as developing nations.[48] Almost 90% of stillbirths attributed to congenital syphilis occur among women who are never treated or inappropriately treated.[60] Alexander and colleagues examined the CDC guidelines for the treatment of maternal syphilis among 340 gravidas and found better than 95% success for all stages of clinical disease in preventing congenital disease.[61] Sheffield and associates[62] evaluated 43 women who received antepartum therapy with treatment failure. Her work revealed that preterm delivery (<36 weeks), short interval between treatment and delivery, higher VDRL titer at time of treatment and delivery, and early stage of maternal disease were associated with treatment failure. The optimal management (transplacental vs. neonatal) of the fetus with severe or advanced clinical disease remains unknown and requires consultation with experienced clinicians.[63]

KEY POINTS

- Sexually active adolescents have higher rates of sexually transmitted diseases than any other age groups.
- Marked racial disparity exists in the rates of chlamydia, gonorrhea, and syphilis, with the highest rates found among minority populations.
- Transmission and long-term sequelae of sexually transmitted diseases are greater in women than in men.
- Much of the end-organ damage seen with sexually transmitted disease is a result of the host's immune response and to a lesser extent is due to the invading organism itself.
- Even though *Treponema pallidum* and *Chlamydia trachomatis* lack the biosynthetic machinery necessary for life and thus are dependent on the host, they are masters at evading the host's immune system.
- Most cases of congenital syphilis in the United States should be preventable.
- *Neisseria gonorrhoeae* is a gram-negative diplococcus for which humans are the only natural hosts.
- Given concerns for antibiotic resistance, all cases of gonorrhea in the United States are confirmed by culture to allow susceptibility testing.
- Serologic testing for uncomplicated genital *C. trachomatis* infection has little or no value because previous infection elicits long-lasting antibody response.
- Penicillin is the antimicrobial of choice in treating syphilis among pregnant women and reducing the incidence of congenital syphilis.

Viruses have been identified in virtually all living organisms. They are among the simplest of living organisms, yet they have significantly shaped our history and remain an important causative factor for infectious disease. Viruses are obligate intracellular parasites, utilizing the host cell's structural and functional components for replication, while exhibiting remarkably diverse strategies for gene expression and replication. Viral infection ranges from asymptomatic and/or subclinical to overwhelming and highly lethal, with findings such as meningoencephalitis or hemorrhagic fever with shock. The duration of viral infection is also highly variable; many viruses are limited to acute infection, whereas some viruses can establish chronic and/or latent infection. Latent viruses can reactivate their gene expression many years after acute infection. Retroviruses can integrate into the host cell genome; and some viruses have demonstrated oncogenic potential.

Virus particles contain nucleic acid and structural proteins which together are referred to as a nucleocapsid. Viral nucleic acid is composed of either deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), which may be single or double stranded. Viral genomes can be linear or circular, existing in multiple segments or as a single segment. Viral genome size ranges from two genes in parvovirus B19 to more than 200 genes in cytomegalovirus. Some viruses have lipid bilayer envelopes external to the nucleocapsid; these envelopes are derived from the host cell and contain viral proteins. Herpesviruses have an additional layer, called a tegument, between the nucleocapsid and envelope.

Viruses are classified by the International Committee on Taxonomy of Viruses into Orders, Families, Subfamilies, Genera, and Species. Classification is based on morphology, nucleic acid type, the presence or absence of an envelope, genome replication strategy, and homology to other identified viruses.

Infection is typically initiated by the virus binding to a specific host cell receptor. These receptors are normally functional host cell membrane proteins, but are also recognized by a viral protein ligand within the viral envelope or nucleocapsid. The viral protein and cellular receptor interaction defines, in part, the host-range of the virus; limiting infection to cells displaying the appropriate receptor. Virus then penetrates the host cell via translocation of the virion across the plasma membrane, involving endocytosis or fusion of the viral envelope with the cell membrane. The virus then uncoats its nucleic acid for replication, ultimately leading to viral gene expression and replication. This may occur in either the cytoplasm or nucleus of the cell and may involve integration into the host genome, in the case of retroviruses. Intracellular assembly of progeny virions occurs, followed by release of newly formed virions by cell lysis or by budding from the cell surface, in the case of most enveloped viruses.

Despite their inability to replicate independently, viruses play an important role in infectious disease. For productive infection to occur, viruses must enter cells, replicate their genome, and release infectious virions. The inability of a virus to complete any of these required steps results in a "nonproductive infection"; by default most viruses alter the structure and/or function of the host cell. Viral pathogenesis does not require productive infection and is mediated via several mechanisms. These include direct effects on infected host cells, which may result in cell death via lysis or apoptosis. Infected cells can also be killed by antiviral antibody and complement or by cell-mediated immune mechanisms. In addition, some viral genomes encode oncogenes that can mediate transformation of infected host cells. Viral proteins can also affect the function of uninfected cells, including the immune system. Finally, the host immune response to viral infection encompasses both local and systemic effects via activation of immune cells, the induction of an adaptive immune response, and the release of cytokines, chemokines, and antibodies. Thus the immune response contributes to or causes the signs and symptoms associated with viral infections, including fever, rash, arthralgias, and myalgias. The outcome of viral infection is dependent on host factors including immune status, age, nutritional status, and genetic background. Genetic factors can alter susceptibility to viral infection, the immune response generated following infection, and the long-term consequences of viral infection.

This chapter discusses many of the viral infections relevant to pregnancy (i.e., those that can have significant impact on maternal health and/or pregnancy outcome). The virology, epidemiology, diagnosis, clinical manifestations, management during pregnancy, and impact on the fetus/neonate are detailed for the viruses listed in Table 50-1.

HUMAN IMMUNODEFICIENCY VIRUS

Virology

Human immunodeficiency virus (HIV) is a member of the Retroviridae family, which is characterized by spherical, enveloped viruses. The virus envelope surrounds an icosahedral capsid containing the viral genome, consisting of

TABLE 50-1 SUMMARY OF ETIOLOGY, DIAGNOSIS, AND MANAGEMENT OF MAJOR PERINATAL VIRAL INFECTIONS

	COMPLICATIONS		DIAGNOSIS		TREATMENT/MANAGEMENT	
Virus	**Maternal**	**Fetal/ Neonatal**	**Maternal**	**Fetal/ Neonatal**	**Maternal**	**Fetal/Neonatal**
HIV	Opportunistic infection	Perinatal infection	Antibody detection	PCR	Combination ART*	ART to prevent perinatal transmission*
Influenza	Pneumonia, increased maternal mortality	N/A	RIPT screening, RT-PCR or immunofluorescence for diagnosis	N/A	Osteltamivir for prophylaxis and treatment, supportive care, vaccinate annually	None
Parvovirus B19	Rare	Anemia/hydrops/ death	PCR or antibody detection	PCR, ultrasound for anemia	Supportive care	Intrauterine transfusion for severe anemia
Rubeola measles	Otitis media, pneumonia, encephalitis	Abortion, preterm delivery	RT-PCR or antibody detection	N/A	Supportive care, prevention- vaccinate prior to pregnancy	N/A
Rubella	Rare	Congenital infection	Antibody detection or RT-PCR	RT-PCR, ultrasound for congenital rubella syndrome	Supportive care, prevention- vaccinate prior to pregnancy	Consider pregnancy termination for fetus with CRS*
CMV	Chorioretinitis	Congenital infection	PCR	PCR, ultrasound for detection of sequelae	Ganciclovir for severe infection	Consider pregnancy termination for infected fetus with primary maternal infection*
HSV	Disseminated infection, primarily in immunocompromised patients	Neonatal infection, intrauterine infection is extremely rare	Examination, PCR, antibody detection	Examination, PCR, antibody detection	Antiviral Tx for infection and prophylaxis against recurrent outbreaks*	Cesarean delivery when mother has active genital lesions
Varicella	Pneumonia, encephalitis, zoster	Congenital or perinatal infection	History, PCR, antibody detection	Ultrasound	VZIG, antivirals for prophylaxis and/or treatment	VZIG, antivirals for prophylaxis and/or treatment
Hepatitis A	Rare	None	RT-PCR or antibody detection	N/A	Supportive care, prevention- hepatitis A vaccine	Immune globulin to neonate if mother acutely infected at delivery
Hepatitis B	Chronic liver disease	Neonatal infection	Surface antigen detection, PCR	N/A	Supportive care, prevention- hepatitis B vaccine, HBIg for exposed, susceptible individuals	HBIg+ hepatitis B vaccine immediately following delivery
Hepatitis C	Chronic liver disease	Neonatal infection	ELISA screen followed by RIBA, PCR	N/A	Supportive care	None
Hepatitis D	Chronic liver disease	Neonatal infection	Antigen and antibody detection		Supportive care	HBIg+ hepatitis B vaccine immediately following delivery
Hepatitis E	Increased mortality	Neonatal infection	RT-PCR, antibody detection	N/A	Supportive care	None

two identical pieces of positive sense, single-stranded RNA, about 9.2 kb long. HIV has three main genes: gag, pol, and env, which are surrounded by long terminal repeat (LTR) regions, and a total of nine genes. The gag gene encodes the precursor for the virion capsid proteins, which include the full-length p55 polyprotein precursor and its cleavage products: p17 matrix, p24 capsid, p9 nucleocapsid, and p7. The pol gene encodes the precursor polyprotein for several viral enzymes including protease, reverse transcriptase, RNase H, and integrase. The env gene encodes the envelope glycoprotein (gp160), which is cleaved to the surface unit (gp120) and the transmembrane protein (gp41) that is necessary for fusion. Retroviruses are unique because the viral genome is transcribed into DNA via the viral enzyme reverse transcriptase, followed by integration into the host cell genome via the viral enzyme integrase. HIV also has the capacity to become latent within quiescent infected cells, making eradication of the virus thus far impossible.

The HIV envelope glycoprotein (gp120) is a ligand for CD4, the cellular HIV receptor; thus HIV predominantly infects $CD4^+$ cells, including T cells, monocytes, and macrophages. Coreceptors required for viral entry and infection have also been identified. The two primary HIV coreceptors are the chemokine receptors CXCR4 and CCR5.[1] New infections almost always occur with an HIV strain utilizing the CCR5 coreceptor,[2] potentially reflecting viral fitness. Individuals homozygous for a 32-base pair deletion within the CCR5 gene are much less likely to become HIV-infected, even following significant exposure; moreover, some CCR5 polymorphisms correlate with disease progression of HIV in perinatally infected children and adults.[3,4]

Epidemiology

The CDC estimates that more than 1 million people in the United States are HIV infected, with 21% of infected individuals undiagnosed (or unaware of their infection).[5] Approximately 56,300 Americans are diagnosed with HIV infection annually; women account for 27% of new HIV infections and 25% of existing infections. Women typically acquire their HIV infection by heterosexual contact. Caucasian women have the highest percentage of HIV infections attributable to injection drug use (24%), whereas injection drug use accounts for 15% of HIV infections in Hispanic/Latinas and 13% in African American women. African American women have an HIV incidence rate approximately 15 times greater than that of Caucasian women and almost 4 times that of Hispanic women. Factors associated with an increased prevalence of HIV infection (and HIV transmission risk) include the following: a high number of sexual contacts, high-risk sexual exposure, receptive anal intercourse, sexual contact with an uncircumcised male, intravenous (IV) drug and/or crack cocaine use, residing in the "inner city," and the presence of other STDs, particularly those which cause genital ulcers (herpes, syphilis, chancroid).[6]

HIV infection is limited to humans and chimpanzees and most infections in the United States are caused by HIV-1. HIV-1 is divided into three groups: M, N, and O. More than 95% of HIV-1 infections are caused by group M, which is divided into subtypes (or clades) A to K. The predominant type of HIV within the United States is clade B, whereas other clades predominate in other regions of the world. HIV-2, a related strain of HIV, is endemic in Africa, Portugal, and France and appears to have a lower vertical transmission rate compared to HIV-1.[7] Much less is known about the treatment of these related viruses given their prevalence in areas of the world where antiretroviral (ARV) treatment is not readily available.

Screening, Diagnosis, and Staging

Chronic HIV infection is diagnosed via detection of virus-specific antibody; diagnostic algorithms employ an initial screening assay followed by an antigen-specific confirmatory assay. The most commonly utilized serologic screen is the enzyme-linked immunosorbent assay (ELISA), which is highly sensitive, inexpensive, and well suited for large sample numbers. Positive ELISAs are repeated for verification, followed by Western blot confirmation or immunofluorescent antibody assay. The Western blot identifies antibodies recognizing specific viral antigens and is considered positive when any two of the following three antigens are identified: p24 (capsid), gp41 (envelope), and gp120/160 (envelope). Most serologic tests in use detect either HIV-1– or HIV-2–specific antibodies, and several salivary and/or rapid blood tests are available with efficacy comparable to ELISA.[8] Patients with early, acute HIV infection may not yet have detectable HIV-specific antibodies; therefore HIV viral load determination should be used for diagnosing acute HIV infection.[9] Any patient suspected of having the acute retroviral syndrome should have a repeat viral load and serologic assessment in 2 weeks. Although clinicians in the United States infrequently encounter patients infected with HIV-2 or a non–clade-B HIV-1 subtype, accurate diagnosis and plasma HIV RNA (viral load) assessment require assays capable of detecting the virus carried by the patient. Thus, consultation with an expert familiar with "atypical" HIV infection is warranted when caring for patients with an indeterminate HIV diagnosis and untreated patients with an undetectable viral load, particularly if HIV infection was acquired outside the United States or there is possible HIV-2 or nonclade-B HIV-1 infection.

Given the increasing prevalence of HIV infection and studies demonstrating that identification and early ARV treatment of HIV-infected pregnant women most effectively prevents perinatal HIV transmission, both the American Congress of Obstetricians and Gynecologists (ACOG) and the CDC recommend an "opt out" approach ensuring routine HIV screening for all pregnant women, ideally performed at the first prenatal visit. The CDC also advocates for repeat testing in the third trimester, citing its cost effectiveness even in areas of low prevalence.[10] A second HIV test in the third trimester is recommended for women at increased risk of HIV infection and women living in areas of elevated HIV incidence including residents of Alabama, Connecticut, Delaware, the District of Columbia, Florida, Georgia, Illinois, Louisiana, Maryland, Massachusetts, Mississippi, Nevada, New Jersey, New York, North Carolina, Pennsylvania, Puerto Rico, Rhode Island, South Carolina, Tennessee, Texas, and Virginia, as well as women receiving health care in facilities in which

TABLE 50-2 STAGES OF HIV INFECTION

CDC STAGE	CD4+ T-LYMPHOCYTE COUNT AND PERCENTAGES
Stage 1 (HIV infection)	CD4+ T-lymphocyte count of ≥500 cells/μL or % of ≥29
Stage 2 (HIV infection)	CD4+ T-lymphocyte count of 200-499 cells/μL or % of 14-29
Stage 3 (AIDS)	CD4+ T-lymphocyte count of <200 cells/μL or % of <14

prenatal screening identifies at least one HIV-infected pregnant woman per 1000 women screened.[10]

Clinical Manifestations and Staging

The clinical presentation of HIV infection and/or acquired immunodeficiency syndrome (AIDS) depends on when infection occurred and whether there is a resulting immunodeficiency. Following exposure and primary infection, 50% to 70% of individuals infected with HIV develop the acute retroviral syndrome. At this time patients may have "mononucleosis-like" symptoms, including fever, rigors, pharyngitis, arthralgias, myalgias, maculopapular rash, urticaria, abdominal cramps, diarrhea, headache, and lymphocytic meningitis. The acute phase of infection usually occurs 4 to 6 weeks following HIV exposure and can last several weeks; however, it is uncommon for individuals to be diagnosed during acute infection. Following primary HIV infection, patients enter the latent phase of illness, which can last approximately 5 to 10 years in untreated patients and comprises stages 1 and 2 of infection (Table 50-2). During this asymptomatic phase of infection, in the absence of antiretroviral therapy (ART) there is chronic immune activation and progressive destruction of lymphatic tissue.[11] If untreated, most patients will develop stage 3 infection, AIDS, typically including one or more of the conditions listed in the box, AIDS-Defining Conditions in Adults.

AIDS-DEFINING CONDITIONS IN ADULTS

Candidiasis of bronchi, trachea, or lungs
Candidiasis of esophagus*
Cervical cancer, invasive†
Coccidioidomycosis, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary
Cryptosporidiosis, chronic intestinal (>1 month's duration)
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age >1 month
Cytomegalovirus retinitis (with loss of vision)*
Encephalopathy, HIV related
Herpes simplex: chronic ulcers (>1 month's duration) or bronchitis, pneumonitis, or esophagitis (onset at age >1 month)
Histoplasmosis, disseminated or extrapulmonary
Isosporiasis, chronic intestinal (>1 month's duration)
Kaposi sarcoma*
Lymphoid interstitial pneumonia or pulmonary lymphoid hyperplasia complex*
Lymphoma, Burkitt's (or equivalent term)
Lymphoma, immunoblastic (or equivalent term)
Lymphoma, primary, of brain
Mycobacterium avium complex or *Mycobacterium kansasii,* disseminated or extrapulmonary*
Mycobacterium tuberculosis of any site, pulmonary,*† disseminated,* or extrapulmonary*
Mycobacterium, other species or unidentified species, disseminated,* or extrapulmonary*
Pneumocystis jirovecii pneumonia*
Pneumonia, recurrent*†
Progressive multifocal leukoencephalopathy
Salmonella septicemia, recurrent
Toxoplasmosis of brain, onset at age >1 month*
Wasting syndrome attributed to HIV

*Condition that might be diagnosed presumptively.
†Only among adults and adolescents 13 years or older. (CDC: 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. MMWR 41[No. RR-17], 1992.)

Management During Pregnancy

Initial Evaluation

Beyond the standard initial antenatal assessment for all pregnant women, including a first trimester ultrasound to confirm gestational age, evaluation of an HIV-infected pregnant woman should include a status assessment as described in the box, Assessment of HIV Disease Status. Viral loads are typically determined using the Roche COBAS Amplicor Monitor, using reverse transcriptase polymerase chain reaction (RT-PCR) technology.[12] If the patient's HIV viral load is undetectable in the absence of treatment, retesting and/or using an alternative assay is recommended (bDNA signal amplification or a NASBA-based technique).[13] Some patients may have an undetectable viral load; however, the patient could be infected with a non–clade B HIV-1 isolate or HIV-2. None of the previously mentioned assays detect HIV-2 plasma RNA. Consultation with an infectious disease physician with experience in the management of HIV disease can be helpful in these cases or when the woman's genotype and phenotype assay demonstrate significant resistance to ART. Following complete evaluation, recommendations for a plan of HIV-related medical care, including antepartum, intrapartum, and postpartum care, should be provided, taking into account issues described in the following sections.

Ethical Considerations

Patients should be offered ART based on the same principles used for nonpregnant individuals, taking into account pregnancy-specific maternal or fetal safety issues. When caring for HIV-infected pregnant women, there are two separate but related goals: (1) treatment of maternal infection and (2) chemoprophylaxis to reduce the risk of perinatal HIV transmission. Providers caring for HIV-infected women may encounter patients declining to start or continue ART. For guidance, the author supports the recommendations of the Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission.[14] In summary, the provider is responsible for providing information to enable the woman to make an informed choice regarding this and other medical recommendations (including elective cesarean delivery). Coercive and punitive policies potentially undermine trust and

Assessment of HIV Disease Status

1. HIV History Review:
   a. Duration of HIV infection, transmission route (if known), prior HIV-related illnesses and hospitalizations (including opportunistic infections), and immunization history.
   b. Prior and/or ongoing use, duration, and tolerance of ARV, including whether treatment was given for maternal benefit, and/or to prevent perinatal HIV transmission, and history of adherence issues.
   c. Outcome of HIV-affected pregnancies.
   d. Past CD4 cell counts and plasma HIV viral loads (plasma HIV RNA copy number/mL of plasma) and their relationship to ARV, and results of prior and current HIV ARV drug-resistance studies.
   e. Immunization/infection/serology status with attention to hepatitis B, hepatitis C, tuberculosis, and pneumococcus.
2. Laboratory Assessment:
   a. CD4 count and HIV viral load.
   b. ARV drug-resistance studies (genotype preferred), indicated prior to starting or modifying ARV regimens in patients with HIV RNA levels above the threshold for resistance testing (e.g., >500 to 1000 copies/mL).
   c. Baseline complete blood cell count with platelets, renal and liver function testing.
   d. Serologic assessment as indicated by history.
   e. HLA-B*5701 testing, if abacavir use is anticipated.
   f. In PPD positive patients, a chest x-ray should be performed to rule out active pulmonary disease.
   g. If CD4 count is <200, serology for cytomegalovirus and *Toxoplasma gondii.*
   h. If abnormal Pap smear—HPV testing and colposcopy as indicated.

the provider/patient relationship. Results can include the discontinuation of prenatal care or refusal (or failure) to disclose her HIV status to other health care providers, preventing the adoption of behaviors to enhance maternal and fetal well-being. Out of respect for patient autonomy, we consider it unethical to consider punitive actions against a patient secondary to her decisions regarding her HIV treatment or disclosure of her HIV status. Moreover, disclosure carries risks ranging from discrimination to intimate partner violence, making it critical to respect the patient's decision. Clinicians should be aware of local legal requirements regarding confidentiality and disclosure of HIV-related health information.

Treatment of HIV Infection During Pregnancy

Historically, the PACTG 076 study first showed that ART reduces perinatal HIV transmission.[15] This randomized, placebo-controlled study included treatment naïve, HIV-infected women with a CD4 count above 200/mm^3 beyond the first trimester of pregnancy. Treatment included prenatal oral zidovudine (AZT), IV AZT during labor, and following delivery infants within the treatment arm received oral AZT for 6 weeks; randomization was ethical secondary to the unknown safety (within pregnancy) and efficacy of AZT at the time the study was initiated. Interim data analysis revealed a substantially reduced risk of vertical HIV transmission (8.3% vs. 25.5% in placebo arm); subsequent studies have confirmed the efficacy of oral AZT and other nucleoside analog drugs in preventing perinatal HIV transmission.

Combination care with at least three drugs from at least two classes of ARV is the standard of care for HIV infection in the United States. Considerations include the following: timing of therapy initiation, dosing changes secondary to pregnancy-associated physiologic changes, side effects, drug interactions, teratogenicity, comorbidities, convenience and adherence potential, the results of genotypic resistance testing, and the pharmacokinetics and toxicity of transplacentally transferred drugs. Regimens containing antepartum and intrapartum maternal treatment and postpartum infant treatment provide the best protection against perinatal HIV transmission. This three-part regimen is superior to regimens not containing all three components. Maternal ART should be started as soon as feasible, following review of ARV resistance panel results, preferably prior to the second trimester. The European National Study of HIV in Pregnancy and Childhood demonstrated that with longer duration of antenatal ARV prophylaxis (starting prior to 28 weeks' gestation), each additional week of therapy corresponds to a 10% reduced risk of HIV transmission after adjusting for viral load, mode of delivery, and sex of the infant.[16] Moreover, expanding infant postexposure prophylaxis does not fully substitute for the protective effect of increased maternal ART duration. Women with undetectable viral loads should also receive combination ART because their risk of perinatal transmission is 9.8% if untreated.[17] ART-treated women who become pregnant should continue their medications; if a component of their regimen is contraindicated in pregnancy the regimen should be altered without therapy interruption. If pregnancy-associated vomiting interferes with ongoing adherence to therapy, antiemetics should be aggressively used prior to discontinuing therapy.

The most commonly used ARTs in pregnancy are described in Table 50-3; classes include nucleoside (and nucleotide) reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), and protease inhibitors (PIs). The ideal regimen demonstrates durable virologic suppression with immunologic and clinical improvement, is well tolerated with a simple dosage regimen, and has been shown to be effective in pregnancy in terms of reducing perinatal HIV transmission. ARV drug combinations used today are more convenient and better tolerated than previously utilized regimens, resulting in greater efficacy and improved adherence. Up-to-date U.S. treatment recommendations are available at www.AIDSinfo.nih.gov, and the National Perinatal HIV Hotline (1-888-448-8765) provides free clinical consultation on all aspects of perinatal HIV care.[14]

Nucleoside Reverse Transcriptase Inhibitors

These drugs are used within combination regimens, usually including two NRTIs with either an NNRTI or a PI. Lamivudine (3TC) and AZT are preferred agents; together they comprise the dual-NRTI backbone recommended in pregnancy secondary to extensive experience. AZT should be included in pregnancy-based regimens whenever possible, because of its proven efficacy in

TABLE 50-3 COMMONLY USED ANTIRETROVIRAL DRUGS IN PREGNANCY[14]

ARV DRUG DOSAGE RECOMMENDATIONS	FDA PREGNANCY CATEGORY	ANIMAL STUDIES CARCINOGEN/ TERATOGEN	PHARMACOKINETICS IN PREGNANCY	CONCERNS IN PREGNANCY	RECOMMENDED USE IN PREGNANCY
NRTIs					
Preferred Agents					
Lamivudine (3TC) (Epivir) • 150 mg BID or 300 mg once daily	C	*Carcinogen:* Negative *Teratogen:* Negative	Pharmacokinetics not significantly altered in pregnancy; no change in dose indicated. High placental transfer to fetus.	No evidence of human teratogenicity (1.5-fold increase in birth defects ruled out). Well-tolerated, short-term safety demonstrated for mother and infant. If HBV co-infected, possible HBV flare if drug is stopped postpartum.	Because of extensive experience, 3TC and ZDV are the recommended dual NRTI backbone for pregnant women. Has antiviral activity against HBV.
