The etiology of this febrile response is not well understood; possible mechanisms include noninfectious inflammatory activation, changes in thermoregulation, and acquired intrapartum infection. Intrapartum fever after epidural analgesia is associated with increased serum levels of inflammatory cytokines in the mother and fetus, but no mechanism in which epidural blockade might cause inflammation has been elucidated.[75] Thermoregulation may be altered because epidural analgesia leads to decreased sweating (by providing sympathetic blockade) and less hyperventilation due to pain in labor. Both sweating and hyperventilation would otherwise provide heat dissipation. Although infants of women randomized to epidural analgesia in one institution had a 1.5-fold increase (95% CI, 1.1 to 2) in neonatal sepsis evaluations, actual sepsis was extremely rare and did not differ between epidural and nonepidural groups.[76] Other institutions have not found an increase in sepsis evaluations, probably reflecting differences in neonatology practice styles and greater awareness of temperature increases associated with epidural analgesia.

Despite the lack of infectious morbidity, intrapartum exposure to hyperthermia may not be benign for the neonate. Animal study indicates that the presence of hyperthermia during an ischemic event increases susceptibility to hypoxic-ischemic insult. In addition, Impey and coworkers[77] reported a 10-fold higher risk for neonatal encephalopathy in term infants exposed to intrapartum fever, defined as an oral temperature greater than 37.5° C (OR, 10.8; 95% CI, 4 to 29.3). The absolute risk for encephalopathy in neonates born to febrile mothers was 2.1%. Finally, although the absolute risk is low, maternal temperature greater than 38° C is associated with 9.3-fold increased risk for cerebral palsy in term infants (95% CI, 2.7 to 31).[78] It is important to clarify that there is no evidence that epidural analgesia is associated with encephalopathy or cerebral palsy. Acetaminophen, the standard therapy used to ameliorate hyperthermia, is not effective in preventing fever secondary to epidural analgesia. High-dose maternal corticosteroids given to parturients with epidural analgesia block the febrile response but also substantially increase the risk for bacteremia in exposed babies.[79]

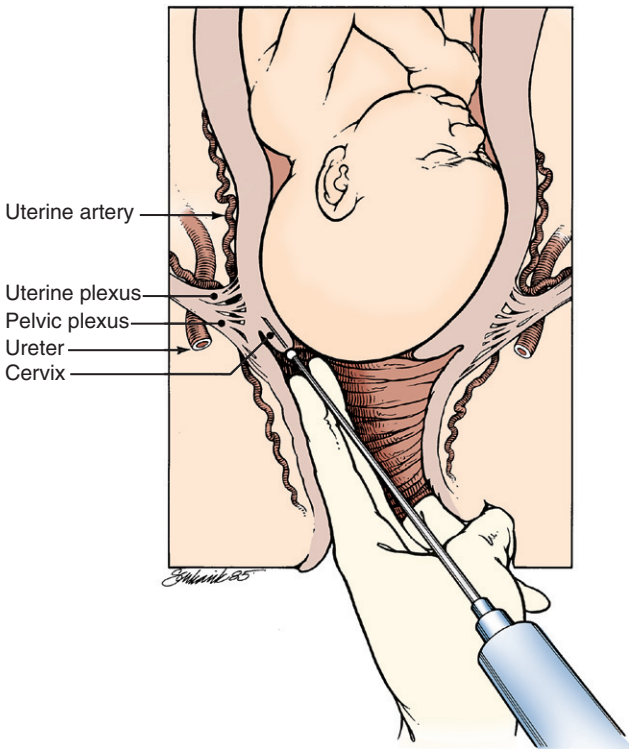

Figure 17-9. Technique of paracervical block. Schematic coronal section *(enlarged)* of lower portion of cervix and upper portion of vagina shows relation of needle to paracervical region. (Modified from Bonica JJ: Principles and Practice of Obstetric Analgesia and Anesthesia. Philadelphia, FA Davis, 1967, p 234.)

Paracervical Block

Paracervical block analgesia is a simple and effective procedure when performed properly (see Table 17-1). Commonly, 5 to 6 mL of a dilute solution of local anesthetic without epinephrine (e.g., 1% lidocaine or 1% or 2% 2-chloroprocaine) is injected into the mucosa of the cervix at the 3- and 9-o'clock positions (Figure 17-9). The duration of analgesia depends on the local anesthetic used. This technique has fallen out of favor owing to its association with the fetal bradycardia that follows in 2% to 70% of applications. Occurring within 2 to 10 minutes and persisting from 3 to 30 minutes, these bradycardias are usually benign. However, cases of fetal acidosis and death have been reported. A significant decrease in pH and a rise in base deficit occur only in those fetuses with bradycardia persisting more than 10 minutes.[80] **Paracervical block should be used cautiously at all times and should not be used at all in mothers with fetuses in either acute or chronic distress.**

There is no consensus regarding the mechanism of post-paracervical block bradycardia. High fetal blood concentrations of local anesthetic could occur if local anesthetic injected close to the uterine artery passed to the fetus. This theory is consistent with the finding that infants who suffer bradycardia frequently have higher local anesthetic

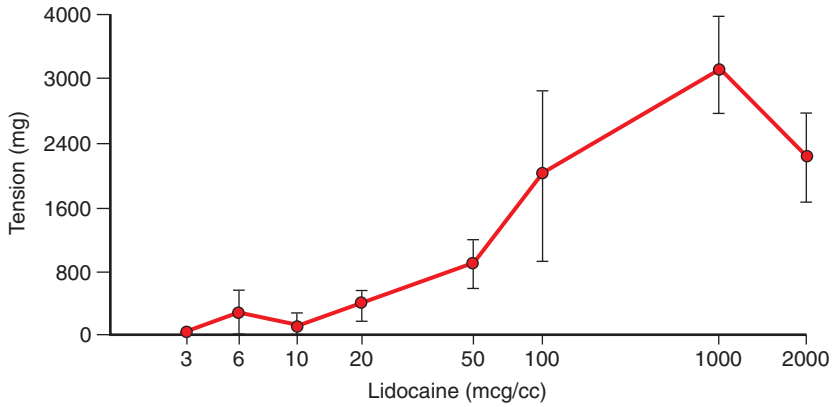

FIGURE 17-10. Dose-response curve of the pregnant human uterine artery to lidocaine hydrochloride (mean ± SEM; *N* = 9). (From Gibbs CP, Noel SC: Response of arterial segments from gravid human uterus to multiple concentrations of lignocaine. Br J Anaesth 45:409, 1977.)

concentrations than their mothers. Alternatively, bradycardia may result from uterine artery vasoconstriction secondary to a direct effect of the local anesthetic on the uterine artery (Figure 17-10).[81] The fetal electrocardiogram (ECG) pattern during one of these episodes suggests hypoxia, a finding that supports the uterine artery vasoconstriction theory.[81] Furthermore, the high concentrations of local anesthetic required to produce vasoconstriction during the administration of a paracervical block can be achieved close to the uterine artery (see Figure 17-10). A third theory is based on the possibility that local anesthetic injected directly into the uterine musculature increases uterine tone.

ANESTHESIA FOR VAGINAL DELIVERY

The goal of pain relief for vaginal delivery is to match the patient's wishes with the requirements of the delivery without subjecting either mother or fetus to unnecessary risk.

Local Anesthesia

In the form of perineal infiltration, local anesthesia is widely used and very safe. Spontaneous vaginal delivery, episiotomy, and perhaps outlet vacuum deliveries can be accomplished with this simple technique. Local anesthetic toxicity may occur if large amounts of local anesthetic are used or if an inadvertent intravascular injection occurs. Usually, 5 to 15 mL of 1% lidocaine suffices. There is rapid and significant transfer of lidocaine to the fetus after perineal infiltration. In 5 of 15 infants, the concentration of lidocaine at delivery was greater in the umbilical vein than in the mother (Table 17-5).

Pudendal Nerve Block

Pudendal nerve block is a minor regional block that also is reasonably effective and very safe. The obstetrician, using an Iowa trumpet and a 20-gauge needle, injects 5 to 10 mL of local anesthetic just below the ischial spine. Because the hemorrhoidal nerve may be aberrant in 50% of patients, some physicians prefer to inject a portion of the local anesthetic somewhat posterior to the spine (Figure 17-11). Although a transperineal approach to the ischial spine is possible, most prefer the transvaginal approach. One percent lidocaine or 2% 2-chloroprocaine can be used.

TABLE 17-5 LIDOCAINE CONCENTRATIONS AT DELIVERY IN MATERNAL PLASMA AND UMBILICAL CORD VEIN AFTER PERINEAL INFILTRATION

SAMPLE (*N* = 15)	CONCENTRATION (ng/mL)	
	Mean ± SD	Range
Maternal Plasma		
Peak concentration	648 ± 666	60-2400
At delivery	548 ± 468	33-1474
Umbilical cord vein	420 ± 406	45-1380
Fetal-to-maternal ratio*	1.32 ± 1.46	0.05-4.66

*Ratio of level in cord vein to level in maternal vein at delivery (mean of individual ratios, not ratio of means).

SD, Standard deviation.

Pudendal block is generally satisfactory for all spontaneous vaginal deliveries and episiotomies, and for some outlet or low operative vaginal deliveries, but it may not be sufficient for deliveries requiring additional manipulation. **The potential for local anesthetic toxicity is higher with pudendal block compared with perineal infiltration because of large vessels proximal to the injection site** (see Figure 17-11). Therefore, aspiration before injection is particularly important. When perineal and labial infiltration are required in addition to pudendal block, it is critically important to closely monitor the total amount of local anesthetic given.

Monitored Anesthesia Care with Sedation

For urgent or unanticipated instrumental deliveries, an anesthesiologist or nurse anesthetist may administer inhalation or intravenous analgesia while still maintaining protective laryngeal and cough reflexes. The obstetrician should add local infiltration or a pudendal block. The combined effects are additive and satisfactory for most operative vaginal deliveries, shoulder dystocias, and head entrapments. The anesthesiologist frequently questions the patient to determine the level of anesthesia and to ensure that deeper planes of anesthesia are avoided. Such precautions are important because if the patient becomes unconscious, all of the hazards associated with general

anesthesia are possible, including inadequate airway, hypoxia, and aspiration. Because continual assessment of the patient's state of consciousness is required and is sometimes difficult, only anesthesiologists or nurse anesthetists should administer inhalation analgesia. Furthermore, in the United States, this technique requires use of the anesthesia machine, misuse of which can prove disastrous. Most frequently, the anesthesiologist uses 50% nitrous oxide or, for intravenous analgesia, ketamine, 0.25 to 0.5 mg/kg. This latter agent may be particularly effective in the labor room when an anesthesia machine is not available, or for the patient who cannot or will not tolerate an anesthetic face mask. Inhalation or intravenous analgesia renders some patients amnesic of the event, a characteristic that may be undesirable.

Spinal (Subarachnoid) Block

A saddle block is a spinal block in which the level of anesthesia is limited to little more than the perineum. Spinal anesthesia is reasonably easy to perform and usually provides total pain relief in the blocked area. Therefore, spontaneous delivery, forceps delivery, perineal repairs, and more complicated deliveries can all be accomplished without pain for the mother. The patient's ability to push may be compromised somewhat by diminished motor strength as well as significant sensory block.

Usually, spinal anesthesia is achieved by injecting 25 to 50 mg hyperbaric lidocaine or 5 to 7.5 mg hyperbaric bupivacaine into the subarachnoid space through a 24- to 27-gauge spinal needle. It is preferable to use a pencil-point needle of the smallest possible gauge because these needles reduce the risk for spinal headache. Fentanyl, 10 to 25 mcg, may also be added to the spinal anesthetic. Because the solution is hyperbaric relative to cerebrospinal fluid, the most important determinant of anesthesia level is gravity. For example, the sitting position causes the level to fall toward the sacral nerve roots for a perineal block. Less controllable factors affecting spread include the Valsalva maneuver, coughing, and straining, any of which may cause the level to rise. Injecting the local anesthetic during a contraction may result in higher than expected levels of anesthesia and should be avoided.

Persons other than anesthesiologists sometimes administer spinal anesthesia, which is technically easy to perform. In such situations, it is important to remember that all hazards associated with major blocks are possible, including hypotension and "total spinal." **The person who administers spinal anesthesia must never leave the patient unattended without ensuring that another competent individual will assume responsibility for monitoring the blood pressure and level of anesthesia.** Usually, the level of the spinal block will be complete and fixed within 5 to 10 minutes, but it may continue to creep upward for 20 minutes or longer. Left uterine displacement should be maintained after the local anesthetic has been injected to maintain venous return and prevent excess hypotension.

Lumbar Epidural Anesthesia

Single-dose epidural anesthesia techniques are rarely used in modern obstetrical anesthesia practice. The relative difficulty, slow onset, and large amounts of local anesthetic required to block sacral nerves are significant disadvantages compared with spinal anesthesia. Usually, when these techniques are used, they are instituted during labor as continuous techniques and maintained or intensified for the delivery.

General Anesthesia

General anesthesia is rarely indicated for vaginal delivery. Airway management engenders risk; therefore, general anesthesia should not be used without a strong indication. An unanticipated breech presentation, shoulder dystocia, internal version, and extraction of a second twin or uterine inversion may represent rare indications for general anesthesia. General anesthesia may rarely be indicated for a difficult forceps delivery in a patient in whom major regional anesthesia is contraindicated. **When general anesthesia is indicated for vaginal delivery, the technique specific for cesarean delivery is used, including administration by experienced and competent personnel, rapid-sequence induction, and endotracheal intubation.** For breech delivery or delivery of a second twin, administration of a high concentration of a volatile halogenated agent (e.g., isoflurane, desflurane, or sevoflurane) may be used to effect uterine and perhaps cervical relaxation. Equipotent doses of any of these three agents will provide equivalent uterine relaxation.[82]

ANESTHESIA FOR CESAREAN DELIVERY

In the United States, general anesthesia is used for about 10% of cesarean births (depending on size of hospital), and spinal and epidural anesthetics are used for about 90% of these deliveries (Table 17-6).[1] Local anesthesia for cesarean delivery is possible, with the mother undergoing general anesthesia after delivery of the infant, but it is rarely used or taught anymore. Although general anesthesia may have increased risk for the mother, regional or general anesthesia results in similar fetal outcomes as ascertained by Apgar scores and blood gas measurements (Table 17-7).

TABLE 17-7 ELECTIVE CESAREAN SECTION—BLOOD GAS AND APGAR SCORES

*Data from James FM III, Crawford JS, Hopkinson R, et al: A comparison of general anesthesia and lumbar epidural analgesia for elective cesarean section. Anesth Analg 56:228, 1977.
†Data from Datta S, Brown WU: Acid-base status in diabetic mothers and their infants following general or spinal anesthesia for cesarean section. Anesthesiology 47:272, 1977.

Neurobehavioral testing that quantifies responses to certain stimuli in the early postpartum hours suggests that infants of mothers who receive regional anesthesia achieve somewhat higher scores than those whose mothers receive general anesthesia. The usefulness of neurobehavioral testing has been called into question because of poor interrater reliability. Neurobehavioral considerations do not weigh heavily in the choice of anesthesia or anesthetic agent; the choice can be based on the preferences of the mother, the obstetrician, and the anesthesiologist, as well as on the demands of the particular clinical situation.

Premedication

Premedication using sedative or opioid agents is usually omitted because these agents cross the placenta and can depress the fetus. Sedation should be unnecessary if the procedure is explained well and the patient is reassured.

Antacids

Use of a clear antacid is considered routine for all parturients before surgery. Additional aspiration prophylaxis using an H_2-receptor blocking agent and metoclopramide may be given to parturients with risk factors such as morbid obesity, diabetes mellitus, or a difficult airway, or those who have previously received opioids. As soon as it is known that the patient requires cesarean delivery, whether with regional or general anesthesia, 30 mL of a clear, nonparticulate antacid, such as 0.3 M sodium citrate, Bicitra, or Alka Seltzer, 2 tablets in 30 mL water, is administered to decrease gastric acidity and ameliorate the consequences of aspiration, should it occur. The chalky white particulate antacids are avoided because they can produce lung damage (Figure 17-12).[83]

Left Uterine Displacement

As during labor, the uterus may compress the inferior vena cava and the aorta during cesarean delivery; **aortocaval compression is detrimental to both mother and fetus.** The duration of anesthesia has little effect on neonatal acid-base status when left uterine displacement is practiced; however, when patients remain supine, Apgar scores decrease as time of anesthesia increases.[84]

ADVANTAGES AND DISADVANTAGES OF GENERAL ANESTHESIA FOR CESAREAN DELIVERY

- Advantages
  - Patient does not have to be awake during a major operation.
  - General anesthesia provides total pain relief.
  - Operating conditions are optimal.
  - The mother can be given 100% oxygen if needed.
- Disadvantages
  - Patients will not be awake during childbirth, but there is a small risk for undesirable awareness.
  - There is a slight risk for fetal depression immediately after birth.
  - Intubation causes hypertension and tachycardia, which may be particularly dangerous in severely preeclamptic patients.
  - Intubation can be difficult or impossible.
  - Aspiration of stomach contents is possible.

General Anesthesia

Balanced general anesthesia, referring to a combination of various agents, including barbiturates or other hypnotic agents to induce sleep, inhalation agents, opioids, and muscle relaxants as opposed to high concentrations of potent inhalation agents alone, is preferred for obstetrical applications (see box, Advantages and Disadvantages of General Anesthesia for Cesarean Delivery).

Failure to intubate and aspiration continue to cause anesthesia-related maternal mortality, and as a result, many anesthesiologists, obstetricians, and patients now prefer regional anesthesia over general anesthesia.[1] To understand how these complications may arise, the obstetrician should be aware of the sequence of events during general anesthesia.

Preoxygenation

Preoxygenation is especially important in pregnant patients who have decreased functional residual capacity and are more likely than nonpregnant patients to rapidly become hypoxemic if difficult intubation accompanied by apnea occurs. Before starting induction, 100% oxygen should be

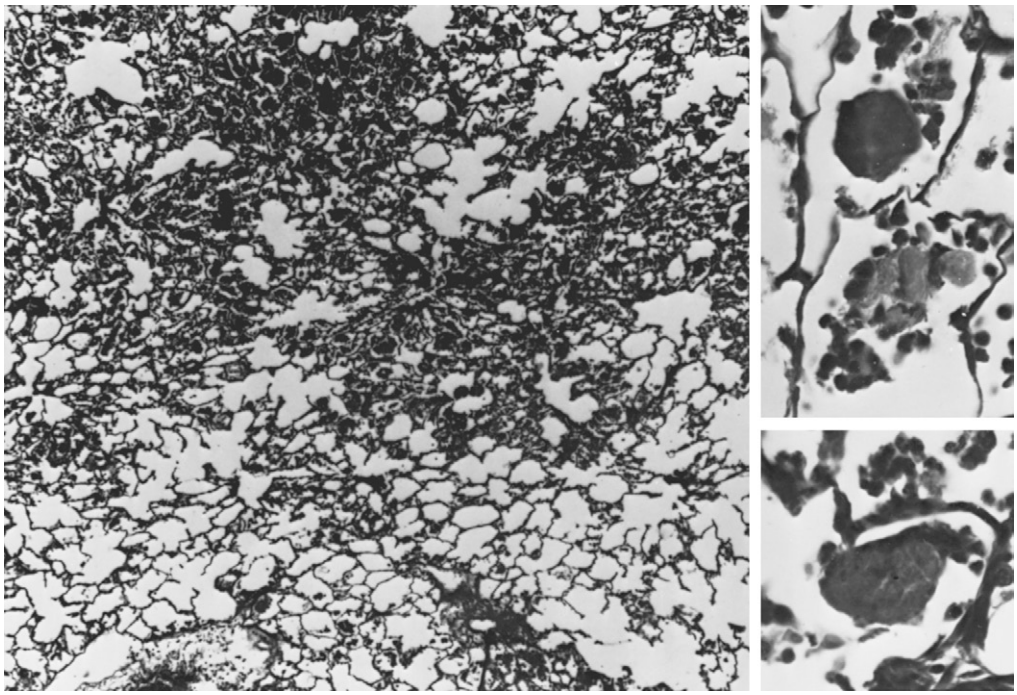

FIGURE 17-12. Lung after aspiration of particulate antacid. Note marked extensive inflammatory reaction. The alveoli are filled with polymorphonuclear leukocytes and macrophages in approximately equal numbers. *Insets at right* show large and small intra-alveolar particles surrounded by inflammatory cells (48 hours). Later, the reaction changed to an intra-alveolar cellular collection of clusters of large macrophages with abundant granular cytoplasm, in some of which were small amphophilic particles similar to those seen in the insets. No fibrosis or other inflammatory reaction was seen (28 days). (From Gibbs CP, Schwartz DJ, Wynne JW, et al: Antacid pulmonary aspiration in the dog. Anesthesiology 51:380, 1979.)

administered through a face mask for 2 to 3 minutes. In situations of dire emergency, four vital capacity breaths of 100% oxygen through a tight circle system will provide similar benefit.[85]

Induction

The anesthesiologist rapidly administers a short-acting induction agent to render the patient unconscious. An appropriate dose has little effect on the fetus. **Induction agents that may be used are thiopental, propofol,[86] etomidate,[87] and ketamine,[88] all of which are rapidly redistributed in the mother and fetus.** Women who receive ketamine for induction require less analgesic medications in the first 24 hours after their cesarean delivery compared with those who received thiopental.[89] Its antagonism of NMDA receptors may prevent central hypersensitization, providing preemptive analgesia.

Although obstetricians are often concerned about the induction-to-delivery interval (I-D) during general anesthesia, uterine incision-to-delivery interval (U-D) is more predictive of neonatal status.[84,90] With a prolonged I-D interval, there is fetal uptake of the inhaled anesthetic and depressed Apgar scores (i.e., sleepy babies), but fetal acid-base status is normal, and effective ventilation is all that is needed. Prolonged U-D intervals greater than 3 minutes lead to depressed Apgar scores with regional or general anesthesia, and they are associated with elevated fetal umbilical artery norepinephrine concentrations and associated fetal acidosis.[90]

Muscle Relaxants

Immediately after the induction agent, the anesthesiologist gives a muscle relaxant to facilitate intubation. Succinylcholine, a rapid-onset, short-acting muscle relaxant, remains the agent of choice in most patients.

Cricoid Pressure

In rapid-sequence induction, as the induction agent begins to take effect and the patient approaches unconsciousness, an assistant applies pressure to the cricoid cartilage, just below the thyroid cartilage, and does not release the pressure until an endotracheal tube is placed, its position verified by end-tidal carbon dioxide measurement, and the cuff on the tube inflated. **Pressure on the cricoid compresses the esophagus and is extremely important in preventing aspiration should regurgitation or vomiting occur.**

Intubation

In most cases, intubation proceeds smoothly. However, in approximately 1 in 238 obstetrical patients, it is difficult, delayed, or impossible. The incidence of failed intubation in obstetrical patients is about seven times more common than in patients in the general operating room (i.e., 1 in 230 to 280 in obstetrical patients versus 1 in 2230 in surgical patients).[91] When the delay is prolonged or the intubation impossible, **the critical factors include delivering oxygen to the now unconscious and paralyzed patient and preventing aspiration.**[92] Delay in intubation is associated with escalating aspiration risk. Therefore, it is particularly important during a difficult intubation that the person applying cricoid pressure not release that pressure until told to do so by the anesthesiologist.

The patient at risk for a difficult or impossible intubation can often be identified before surgery. Examination of the airway is a critical part of the preanesthetic evaluation. The anesthesiologist will assess (1) the ability to visualize

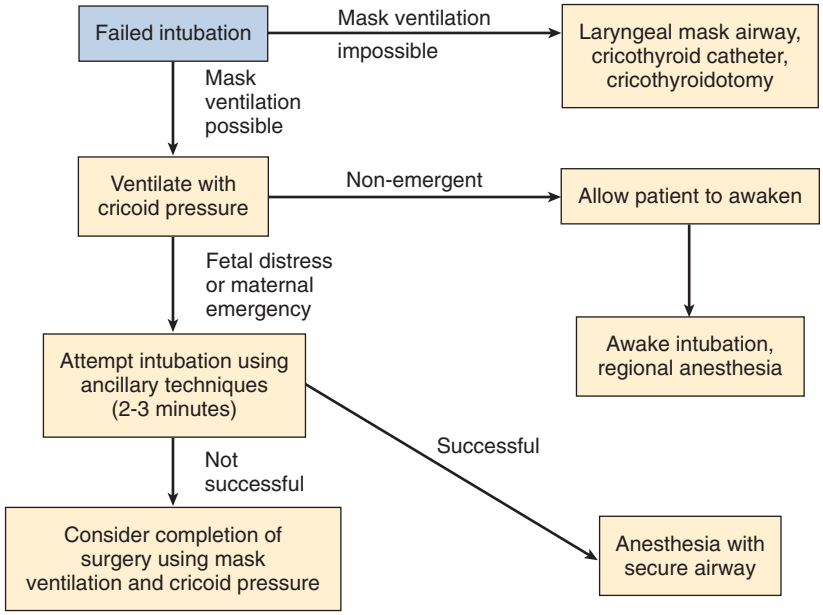

FIGURE 17-13. An algorithm for the management of failed intubation in the obstetrical patient.

oropharyngeal structures (Mallampati classification[93]); (2) range of motion of the neck; (3) presence of a receding mandible, which indicates the depth of the submandibular space; and (4) whether protruding maxillary incisors are present. **Obstetricians should be alert to the presence of obesity, severe edema, anatomic abnormalities of the face, neck, or spine, including trauma or surgery, abnormal dentition, difficulty opening the mouth, extremely short stature, short neck or arthritis of the neck, or goiter. When the obstetrician recognizes airway abnormalities, patients should be referred for an early preoperative evaluation by the anesthesiologist.**

Proper Tube Placement

Before the operation begins, the anesthesiologist must ensure that the endotracheal tube is properly positioned. End-tidal carbon dioxide analysis is the preferred method to confirm that the tube is within the trachea. Of course, the anesthesiologist will also confirm that breath sounds are bilateral and equal. The operation should not proceed until the airway is secure because the patient cannot be allowed to awaken after the abdomen is opened.

When intubation cannot be accomplished and cesarean delivery is not urgent, the decision to delay the operation and allow the mother to awaken is easy. However, if the operation is being done because of rapidly worsening fetal condition or maternal hemorrhage, allowing the mother to awaken may further jeopardize the fetus or mother. Rarely, in situations of dire fetal compromise, the anesthesiologist and obstetrician may jointly decide to proceed with cesarean delivery while the anesthesiologist provides oxygenation, ventilation, and anesthesia by face mask ventilation or laryngeal mask airway, with an additional person maintaining continuous cricoid pressure. In these emergent situations, it may be necessary to have additional trained personnel to provide assistance. After delivery, the obstetrician may need to obtain temporary hemostasis and then halt surgery while the anesthesiologist secures the airway by fiberoptics or other methods.

An algorithm for management of failed intubation in the obstetrical patient is shown in Figure 17-13. Nursing staff should also be familiar with the difficult airway algorithm in case they are called on to assist during an airway emergency. Equipment to manage the difficult airway must be immediately available in the labor and delivery suite.[3,94]

Nitrous Oxide and Oxygen

Once the endotracheal tube is in place, a 50:50 mixture of nitrous oxide and oxygen, which is safe for both mother and fetus, is added to provide analgesia and amnesia.

Volatile Halogenated Agent

In addition to nitrous oxide, a low concentration of a volatile halogenated agent (e.g., isoflurane, sevoflurane, or desflurane) is added to provide maternal amnesia and additional analgesia. These agents, in low concentrations, are not harmful to mother or fetus. **Uterine relaxation does not result from low concentrations of these agents, and bleeding should not be increased secondary to their addition.[82] Proceeding without a potent inhalation agent results in an unacceptably high incidence of maternal awareness and recall.** Even with the use of one of these agents, maternal awareness and recall occasionally occur. Therefore, it is important that all operating room personnel use discretion in conversation and conduct themselves as if the patient were awake.

Postdelivery

The concentration of nitrous oxide can usually be increased after delivery. In addition, the volatile halogenated agent is continued at a low concentration, and pain relief is supplemented with an opioid such as fentanyl or morphine. Other intravenous agents such as benzodiazepines may be added to ensure maternal amnesia. Oxytocin, 20 to 80 U/L,

is infused intravenously. Large bolus injections of oxytocin are avoided because they can cause a drop in systemic vascular resistance, hypotension, and tachycardia. **Maternal deaths have been reported following intravenous bolus oxytocin in the setting of hypovolemia or pulmonary hypertension.**[95]

Extubation

Because the patient can aspirate while awakening as well as during induction, extubation is not done until the patient is awake and can respond appropriately to commands. Coughing and bucking do not necessarily indicate that the patient is awake, merely that she is in the second stage—the excitement stage—of anesthesia. It is during this period of anesthesia that laryngospasm is most likely to occur should any foreign body, including the endotracheal tube or bits of stomach contents, stimulate the larynx. **The patient must therefore be awake and conscious, not merely active, before extubation.**

Aspiration

Aspiration is a serious and potentially fatal complication of general anesthesia and, therefore, deserves specific attention. In most instances, it can be prevented. When it cannot, the consequences depend in part on the volume and acidity of the aspirate. The conventional wisdom is that patients are at risk when their stomach contents are greater than 25 mL and when the pH of those contents is less than 2.5. Pregnant patients are at higher risk for aspiration. The enlarged uterus increases intra-abdominal pressure and thus intragastric pressure. The gastroesophageal sphincter is distorted by the enlarged uterus, making it less competent, and possibly explaining the high incidence of heartburn that occurs during pregnancy. Increased progesterone levels affect smooth muscle, delaying gastric emptying and relaxing the gastroesophageal sphincter. Gastrin, the hormone that increases both acidity and volume of gastric contents, is increased during pregnancy, and motilin, a hormone that speeds gastric emptying, is decreased during pregnancy. Labor itself delays gastric emptying, primarily when patients have received opioids.[96] Many patients undergo cesarean delivery after a prolonged labor, during which they may have received several doses of opioids.

The severity of lung damage and rates of morbidity after aspiration vary and depend on the type of material aspirated. Less acidic aspirates (pH >2.5) fill the alveoli, decreasing PaO_2 without a significant destructive or inflammatory effect. Aspirates with a pH of less than 2.5 cause hemorrhage, inflammatory exudates, and edema resulting in lower PaO_2. **Aspiration of partially digested food produces the most severe physiologic and histologic alterations.** PaO_2 decreases more than with any other type of aspiration, and lung damage is considerably more destructive (Table 17-8).

Although acidic stomach contents can be neutralized safely and effectively with clear antacids or an H_2-receptor antagonist, antacids cannot ameliorate the risks for aspiration after food intake. Aspiration of partially digested food causes significant hypoxia and lung damage, even at a pH level as high as 5.9. To decrease aspiration risk in cases of unplanned cesarean delivery, oral intake during labor should be limited to modest amounts of clear liquids or ice chips.[3]

TABLE 17-8 Arterial Blood Gas Tensions and pH of Dogs 30 Minutes After Aspiration of 2 mL/kg of Various Materials

Aspirate		Response		
Composition	pH	Po_2 (mm Hg)	Pco_2 (mm Hg)	pH
Saline	5.9	61	34	7.37
HCl	1.8	41	45	7.29

Neuraxial Anesthesia

If the fetal status permits and there are no maternal contraindications, regional anesthesia is preferred for cesarean delivery (see box, Advantages and Disadvantages of Regional Anesthesia). Contraindications to regional anesthesia include hemodynamically significant hemorrhage, infection at the site of needle insertion, coagulopathy, increased intracranial pressure caused by a mass lesion, patient refusal, and perhaps some forms of heart disease. Significant ongoing hemorrhage is a firm contraindication to regional anesthesia because the sympathetic blockade overrides compensatory vasoconstriction, potentially precipitating cardiovascular decompensation.

Advantages and Disadvantages of Regional Anesthesia

- Advantages
  - The patient is awake and can participate in the birth of her child.
  - There is little risk for drug depression or aspiration and no intubation difficulties.
  - Newborns generally have good neurobehavioral scores.
  - The father is more likely to be allowed in the operating room.
  - Postoperative pain control using neuraxial opioids may be superior to intravenous patient-controlled analgesia.
- Disadvantages
  - Patients may prefer not to be awake during major surgery.
  - A block that provides inadequate anesthesia may result.
  - Hypotension, perhaps the most common complication of regional anesthesia, occurs during 25% to 75% of spinal or epidural anesthetics.
  - Total spinal anesthesia may occur, necessitating airway management.
  - Local anesthetic toxicity may occur.
  - Although extremely rare, permanent neurologic sequelae may occur.
  - There are several contraindications (see text).

The use of regional anesthesia in patients with fetal compromise depends on the severity of fetal condition. **If the situation is severe and acute, do not delay delivery to perform a regional technique de novo. Ongoing acute fetal deterioration is usually an indication for general anesthesia.** However, a history or suspicion of difficult intubation should prompt performance of either awake intubation or regional anesthesia, despite the presence of fetal compromise, because of the risk for maternal death from unsuccessful intubation. Lesser degrees of fetal compromise may permit regional anesthesia. For example, if an epidural catheter has been placed earlier, a partial level of anesthesia already exists, and there is hemodynamic stability, extension of epidural anesthesia may be appropriate for cesarean delivery. The anesthesiologist may give additional local anesthetic while the urethral catheter is inserted and the abdomen is prepared and draped. Often, there will be satisfactory anesthesia when the surgeon is ready to make the skin incision. If not, the fetal heart rate pattern will dictate whether a delay is acceptable. When partial but inadequate epidural anesthesia results, one may consider supplemental local infiltration of local anesthetic, but most often general anesthesia will be indicated.

In cases in which the fetal heart rate tracing is not critical, de novo spinal or epidural anesthesia may be performed for cesarean delivery. In cases in which extension of existing epidural anesthesia is unsuccessful, spinal anesthesia should be placed with caution because the risk for high spinal anesthesia is increased.

In healthy patients, the choice between epidural, spinal, and CSE anesthesia primarily rests with the anesthesiologist. With the recent availability of small-gauge spinal needles with pencil-point tip design, the risk for headache is no different after spinal or epidural anesthesia. Most consider spinal block to be easier and quicker to perform, and most believe that the resulting anesthesia will be more solid and complete.[97] Perhaps the most significant advantage of spinal anesthesia is that it requires considerably less local anesthetic, and therefore, the potential for local anesthetic toxicity is reduced. Either technique is satisfactory, however, and should provide safe, effective anesthesia for mother, newborn, and obstetrician.

Postoperative Care

If spinal or epidural anesthesia is used for cesarean delivery, excellent postoperative analgesia can be obtained by addition of preservative-free morphine to the local anesthetic solution. The more lipid-soluble opioids, such as fentanyl or sufentanil, provide fast onset of analgesia with minimal side effects but have a short duration of 2 to 4 hours. They may be used postoperatively in combination with a local anesthetic in a continuous or patient-controlled epidural infusion to improve the quality of the block. In contrast, morphine is hydrophilic, which gives it a prolonged duration of up to 24 hours, and it can be given as a single dose at the time of cesarean delivery. Unfortunately, its water solubility gives it a long onset time and higher incidence of side effects. The most common side effects of spinal and epidural opioids are itching and nausea. Respiratory depression is a rare but serious complication. **Several studies have shown that spinal or epidural opioids provide superior pain relief compared with parenteral (intramuscular or intravenous PCA) opioids with a trend toward earlier hospital discharge and lower cost.**[3]

If general anesthesia was used or neuraxial opioids provide inadequate pain control, an intravenous PCA can be used for postoperative pain management. Morphine, hydromorphone (Dilaudid), and fentanyl have all been used successfully. When intravenous PCA is used, the pump settings include an incremental dose of 1 to 2 mg morphine, 0.2 to 0.4 mg hydromorphone, or 25 mcg fentanyl; a lockout interval of 6 to 10 minutes; and rarely, a basal or continuous infusion rate. Basal rates are rarely necessary for pain control and only increase maternal sedation and side effects. Using PCA provides better patient satisfaction by allowing her to control her pain medication.

The addition of nonsteroidal anti-inflammatory agents significantly improves pain scores with neuraxial morphine and reduces use of PCA opioids.[98] Intravenous ketorolac, rectal indomethacin, or oral ibuprofen can be used depending on the patient's ability to tolerate oral intake. Contraindications for nonsteroidal use include renal insufficiency or low urine output, use of gentamicin or similar drugs with renal toxicity, coagulopathy, and uterine atony. Although the package insert for ketorolac (Toradol) states that it is contraindicated for use in breastfeeding mothers, the American Academy of Pediatrics approves its use while women are breastfeeding.

In most cases, postoperative care is uneventful in obstetrical patients. However, **recent reports suggest that the postoperative period can be an important time for anesthetic-related maternal mortality.** In a state review of maternal deaths in Michigan from 1985 to 2003, 8 of 855 maternal deaths were anesthesia related and occurred during emergence or recovery from general anesthesia.[99] Hypoventilation or airway obstruction occurred in these cases, and obesity and African American race were factors associated with these deaths. Similar reports of anesthesia-related maternal mortality have emerged from the United Kingdom. During the time period from 2003 to 2005, there were six anesthesia-related maternal deaths.[41] Of those deaths, three were related to postoperative respiratory failure, and four of the patients had a body mass index greater than 35. These cases raise important questions about appropriate postanesthesia care unit management after general anesthesia for cesarean delivery, as well as the need for additional monitoring in obese patients at risk for obstructive sleep apnea. In a recent survey of obstetrical anesthesia recovery practices from obstetrical anesthesiology directors of North American academic institutions, 45% (28 of 62) of institutions had no specific postanesthesia recovery training for nursing staff providing postcesarean care for patients recovering from neuraxial or general anesthesia.[100] In addition, 43% (29 of 67) of respondents rated the recovery care provided to cesarean delivery patients as lower quality than care given to general surgical patients. Results from this survey suggest that in many cases, the level of care provided for postanesthesia recovery from cesarean delivery may not meet guidelines established by the ASA Task Force on Postanesthetic Care and the American Society of PeriAnesthesia Nurses. However, the most recent ASA Practice Guidelines for

Obstetric Anesthesia[3] emphasize that labor and delivery units should have the same staffing and equipment as surgical operating and recovery rooms to reduce risks associated with emergence after general anesthesia for cesarean delivery as well as to reduce the risk associated with obesity and obstructive sleep apnea.

KEY POINTS

- Analgesia during labor can reduce or prevent potentially adverse stress responses to the pain of labor.
- Parenteral opioids for labor analgesia work primarily by sedation and, except at high doses, result in minimal reduction of maternal pain. Side effects include nausea and respiratory depression in both the mother and newborn. The routine use of promethazine (Phenergan) in conjunction with opioids should be avoided.
- Placental transfer of a drug between mother and fetus is governed by the characteristics of the drug (including its size, lipid solubility, and ionization), maternal blood levels and uterine blood flow, placental circulation, and fetal circulation.
- Continuous regional analgesia is the most effective form of intrapartum pain relief currently available and has the flexibility to provide additional anesthesia for spontaneous or instrumental delivery, cesarean delivery, and postoperative pain control.
- Spinal opioids provide excellent analgesia during much of the first stage of labor, while decreasing or avoiding the risks for local anesthetic toxicity, high spinal anesthesia, and motor block. Most patients need additional analgesia later in labor and during the second stage.
- Side effects and complications of regional anesthesia include hypotension, local anesthetic toxicity, total spinal anesthesia, neurologic injury, and spinal headache. Personnel providing anesthesia must be available and competent to treat these problems.
- Epidural analgesia does not increase the rate of cesarean delivery but may increase oxytocin use and the rate of instrument-assisted vaginal deliveries. The duration of the second stage is increased by 15 to 30 minutes. Maternal-fetal factors and obstetrical management are the most important determinants of the cesarean delivery rate.
- Epidural analgesia is associated with an increased rate of maternal fever during labor. This does not alter the rate of documented neonatal sepsis. Other neonatal implications are unclear.
- General anesthesia is used for less than 5% of elective and roughly 25% of emergent cesarean deliveries. Although safe for the newborn, general anesthesia can be associated with failed intubation and aspiration, causes of anesthesia-related maternal mortality.
- Aspiration of gastric contents is most detrimental when food particles are present or the pH is less than 2.5; therefore, patients should be encouraged not to eat during labor, and acid-neutralizing medications should be used before operative deliveries.
- The use of regional anesthesia is not absolutely contraindicated in cases of non-reassuring fetal testing; the method of anesthesia should be chosen based on the degree of fetal compromise and maternal safety.

Relative Risk	RR

Near term or during labor, the fetus normally assumes a vertical orientation or lie and a cephalic presentation, with the flexed fetal vertex presenting to the pelvis (Figure 18-1). In about 5% of cases, however, deviation occurs from this normal lie, presentation, or flexed attitude; such deviation constitutes a fetal malpresentation. **The word "malpresentation" suggests the possibility of adverse consequences, and malpresentation is often associated with increased risk to both the mother and the fetus.** Malpresentation once led to a variety of maneuvers intended to facilitate vaginal delivery, and early in the twentieth century, such interventions included destructive operations leading, predictably, to fetal death. Later, manual or instrumental attempts to convert the malpresenting fetus to a more favorable orientation were devised. Internal podalic version followed by a complete breech extraction was once advocated as a solution to many malpresentation situations. However, internal podalic version along with most manipulative efforts to achieve vaginal delivery were associated with a high fetal or maternal morbidity or mortality rate and have been largely abandoned. **In contemporary practice, cesarean delivery has become the recommended alternative to manipulative vaginal techniques when normal progress toward vaginal delivery is not observed.**

This chapter examines malpresentations, possible etiologies, and the mechanics of labor and vaginal delivery unique to each situation.

CLINICAL CIRCUMSTANCES ASSOCIATED WITH MALPRESENTATION

Generally, factors associated with malpresentation include (1) diminished vertical polarity of the uterine cavity, (2) increased or decreased fetal mobility, (3) obstructed pelvic inlet, and (4) fetal malformation. The association of great parity with malpresentation is presumably related to laxity of maternal abdominal musculature and, therefore, loss of the normal vertical orientation of the uterine cavity. Placentation either high in the fundus or low in the pelvis (Figure 18-2) is another factor that diminishes the likelihood of a fetus assuming a longitudinal axis. Uterine myomata, intrauterine synechiae, and müllerian duct fusion abnormalities such as septate uterus or uterus didelphys are likewise associated with a higher than expected rate of malpresentation. Because both prematurity and polyhydramnios permit increased fetal mobility, there is a greater probability of a noncephalic presentation if labor or rupture of membranes occurs. Furthermore, preterm birth involves a fetus that is small relative to the maternal pelvis and may result in morbidity often secondary to prematurity. Pelvic engagement and descent with labor or rupture of membranes can occur despite malpresentation. In contrast, conditions such as aneuploidies, myotonic dystrophy, joint contractures from various etiologies, arthrogryposis, oligohydramnios, and fetal neurologic dysfunction that result in decreased fetal muscle tone, strength, or activity are also associated with an increased incidence of fetal malpresentation. Finally, the cephalopelvic disproportion associated with severe fetal hydrocephalus or with a contracted maternal pelvis may be

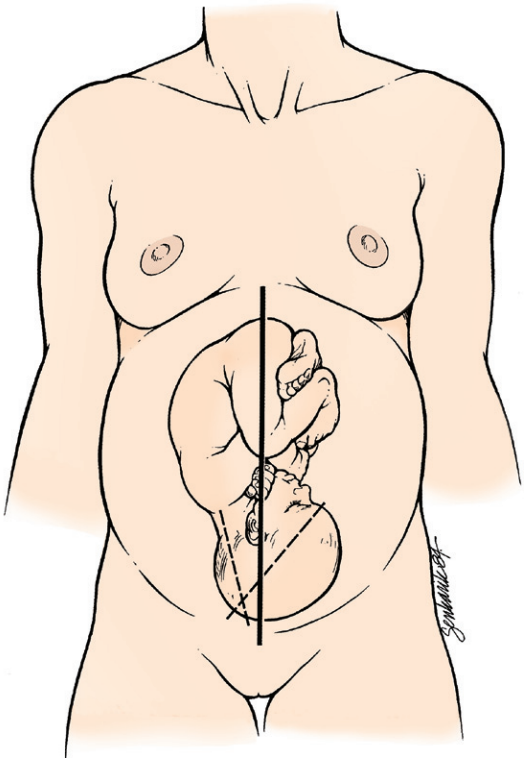

FIGURE 18-1. Frontal view of a fetus in a longitudinal lie with fetal vertex flexed on the neck.

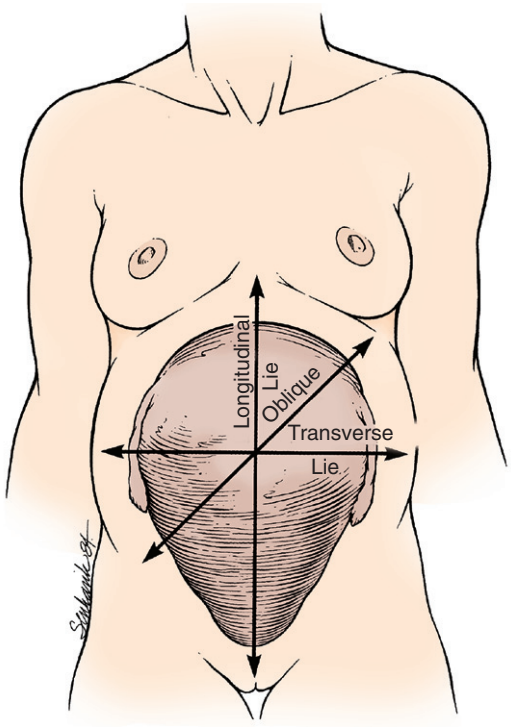

FIGURE 18-3. A fetus may occupy a longitudinal, oblique, or transverse axis, as illustrated by these vectors. The lie does not indicate whether the vertex or the breech is closest to the cervix.

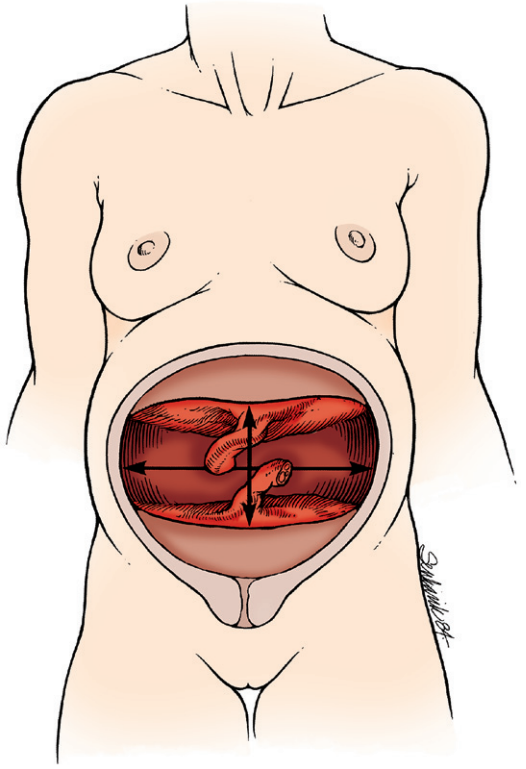

FIGURE 18-2. Either the high fundal or low implantation of the placenta illustrated here would normally be in the vertical orientation of the intrauterine cavity and increase the probability of a malpresentation.

implicated as an etiology of malpresentation because normal engagement of the fetal head is prevented.

ABNORMAL AXIAL LIE

The fetal "lie" indicates the orientation of the fetal spine relative to the spine of the mother. The normal fetal lie is longitudinal and by itself does not indicate whether the presentation is cephalic or breech. If the fetal spine or long axis crosses that of the mother, the fetus may be said to occupy a *transverse* or *oblique lie* (Figure 18-3), which may cause either an arm, a foot, or a shoulder to be the presenting part (Figure 18-4). The lie may be termed *unstable* if the fetal membranes are intact and there is great fetal mobility resulting in frequent changes of lie or presentation.

Abnormal fetal lie is diagnosed in approximately 1 in 300 cases, or 0.33% of pregnancies at term. Prematurity is often a factor, with abnormal lie reported to occur in about 2% of pregnancies at 32 weeks, or six times the rate found at term. Persistence of a transverse, oblique, or unstable lie beyond 37 weeks requires a systematic clinical assessment and a plan for management, because rupture of membranes without a fetal part filling the inlet of the pelvis imposes a high risk of cord prolapse, fetal compromise, and maternal morbidity if neglected.

Great parity, prematurity, contraction or deformity of the maternal pelvis, and abnormal placentation are the most commonly reported clinical factors associated with abnormal lie; however, often, none of these factors is present. In fact, any condition that alters the normal vertical polarity of the intrauterine cavity will predispose to abnormal lie.

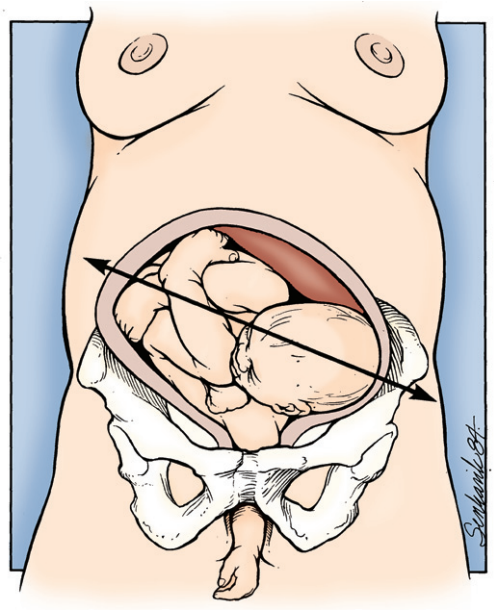

FIGURE 18-4. This fetus lies in an oblique axis with an arm prolapsing.

Diagnosis of the abnormal lie may be made by palpation or vaginal examination and verified by ultrasound. Routine use of Leopold's maneuvers may assist detection, but **Thorp and colleagues[1] found the sensitivity of Leopold's maneuvers for the detection of malpresentation to be only 28% and the positive predictive value only 24% compared with immediate ultrasound verification.** Others have observed prenatal detection in as few as 41% of cases before labor. Recently, adaptations have been made to the Leopold's maneuvers that may improve detection of abnormal lie or presentation. The Sharma modified Leopold's maneuver and the Sharma right and left lateral maneuvers in the original report have demonstrated improved diagnostic accuracy, detecting vertex presenting occipito-anterior (95% vs. 84.4%, $P = 0.04$) and posterior presentations (96.3% vs. 66.6%, $P = 0.00012$) and breech presentation correctly more often than Leopold's maneuvers.[2] These maneuvers employ the use of the forearms in addition to the hands and fingers. As with any abdominal palpation technique, limitations on accuracy are to be expected in the obese patient or a patient with uterine myomata. The ready availability of ultrasound in most clinical settings is of benefit, and its use can obviate the vagaries of the abdominal palpation techniques. In all situations, early diagnosis of malpresentation is of benefit. A reported fetal loss rate of 9.2% with an early diagnosis versus a loss rate of 27.5% with a delayed diagnosis indicates that early diagnosis improves fetal outcome.

Reported perinatal mortality rate for unstable or transverse lie (corrected for lethal malformations and extreme prematurity) varies from 3.9% to 24%, with maternal mortality as high as 10%. Maternal deaths are usually related to infection after premature rupture of membranes, hemorrhage secondary to abnormal placentation, complications of operative intervention for cephalopelvic disproportion, or traumatic delivery. Fetal loss of phenotypically and chromosomally normal gestations at ages considered to be viable is primarily associated with neglect, prolapsed cord, or traumatic delivery. **Cord prolapse occurs 20 times as often with abnormal axial lie as it does with a cephalic presentation.**

MANAGEMENT OF A SINGLETON GESTATION

Safe vaginal delivery of a fetus from an abnormal axial lie is not generally possible, so a search for the etiology of the malpresentation is indicated. A transverse/oblique or unstable lie late in the third trimester necessitates ultrasound examination to exclude a major fetal malformation and abnormal placentation. Fortunately, most cases of major fetal anomalies or abnormal placentation can now be diagnosed long before the third trimester. Elective hospitalization may permit observation and early recognition of cord prolapse, and provides proximity to immediate care. **Phelan and colleagues[3] reported 29 patients with transverse lie diagnosed at or beyond 37 weeks' gestation and managed expectantly. Eighty-three percent (24 of 29) spontaneously converted to breech (9 of 24) or vertex (15 of 24) before labor**; however, the overall cesarean delivery rate was 45%, and there were two cases of cord prolapse, one uterine rupture, and one neonatal death. Such outcomes suggest that active intervention at or beyond 37 weeks or after confirmation of fetal lung maturity may be of benefit. External cephalic version with subsequent induction of labor, if successful, might diminish the risk of adverse outcome.

In cases of an abnormal lie, the risk of fetal death varies with the obstetrical intervention. Fetal mortality should approach zero for cesarean birth but has been reported as high as 10% in older reports and between 25% and 90% when internal podalic version and breech extraction are performed. A mortality rate of 6% was reported for successful external version and vertex vaginal delivery in papers published more than 40 years ago. **External cephalic version in the case of abnormal lie is a reasonable alternative to both expectant management and elective cesarean delivery**. External cephalic version has been found to be safe and relatively efficacious.[4] External cephalic version is discussed to a greater extent later in this chapter.

If external version is unsuccessful or unavailable, if spontaneous rupture of membranes occurs, or if active labor has begun with an abnormal lie, cesarean delivery is the treatment of choice for the potentially viable infant. There is no place for internal podalic version and breech extraction in the management of transverse or oblique lie or unstable presentation in singleton pregnancies because of the unacceptably high rate of fetal and maternal complications.

A persistent abnormal axial lie, particularly if accompanied by ruptured membranes, also alters the choice of uterine incision at cesarean delivery. **Although a low cervical transverse (Kerr) incision has many surgical advantages, up to 25% of transverse incisions require vertical extension for delivery of an infant from an abnormal lie to allow access to and atraumatic delivery of the vertex entrapped in the muscular fundus.** Furthermore, the lower uterine segment is often poorly developed and insufficiently "broad" such that atraumatic delivery of the presenting part is nearly impossible. **Therefore, when managing a transverse or**

oblique lie with ruptured membranes or a poorly developed lower segment, a vertical incision (low vertical or classical) is more prudent. Intraoperative cephalic version may allow the use of a low transverse incision, but ruptured membranes or oligohydramnios makes this difficult. The use of uterine relaxing agents such as inhalational anesthetics or intravenous nitroglycerine may improve success of these maneuvers if the difficulty is attributable to a contracted uterine fundus.

DEFLECTION ATTITUDES

"Attitude" refers to the position of the fetal head in relation to the neck. The normal attitude of the fetal vertex during labor is one of full flexion on the neck, with the fetal chin against the upper chest. Deflexed attitudes include various degrees of deflection or even extension of the fetal head on the neck (Figure 18-5). Spontaneous conversion to a more normal, flexed attitude or further extension of an intermediate deflection to a fully extended position commonly occurs as labor progresses owing to resistance exerted by the bony pelvis and soft tissues. Although safe vaginal delivery is possible in many cases, experience indicates that cesarean delivery is the only appropriate alternative when arrest of progress is observed.

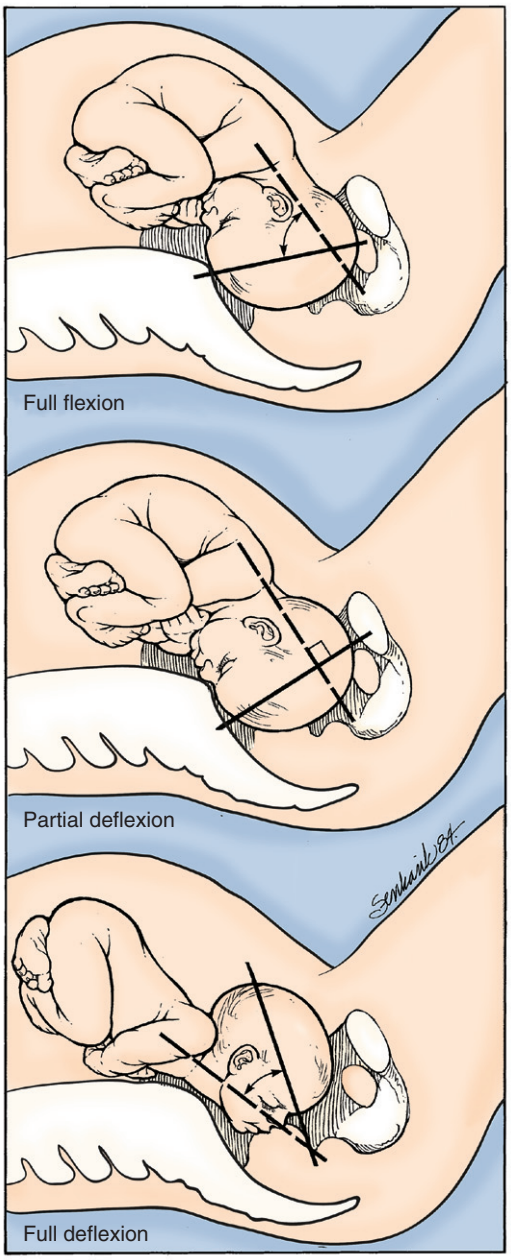

FIGURE 18-5. The normal "attitude" *(top view)* shows the fetal vertex flexed on the neck. Partial deflexion *(middle view)* shows the fetal vertex intermediate between flexion and extension. Full deflexion *(lower view)* shows the fetal vertex completely extended, with the face presenting.

FACE PRESENTATION

A face presentation is characterized by a longitudinal lie and full extension of the fetal head on the neck, with the occiput against the upper back (Figure 18-6). **The fetal chin (mentum) is chosen as the point of designation during vaginal examination.** For example, a fetus presenting by the face whose chin is in the right posterior quadrant of the maternal pelvis would be called a *right mentum posterior* (Figure 18-7). The reported incidence of face presentation ranges from 0.14% to 0.54%, averaging about 0.2%, or 1 in 500 live births overall.[5,6] Reported perinatal mortality rate, corrected for nonviable malformations and extreme prematurity, varies from 0.6% to 5%, averaging about 2% to 3%.

All clinical factors known to increase the general rate of malpresentation (see the accompanying box, Etiologic Factors in Malpresentation) have been implicated in face presentation; many infants with a face presentation have malformations. Anencephaly, for instance, is found in about one third of cases of face presentation. Fetal goiter as well as tumors of the soft tissues of the neck may also cause deflexion of the head. Frequently observed maternal factors include a contracted pelvis or cephalopelvic disproportion in 10% to 40% of cases. In a review of face presentation, Duff found that one of these etiologic factors was found in up to 90% of cases.[6]

Early recognition of the face presentation is important, and the diagnosis can be suspected anytime abdominal palpation finds the fetal cephalic prominence on the same side of the maternal abdomen as the fetal back (Figure 18-8); however, **face presentation is more often discovered by vaginal examination**. In practice, fewer than 1 in 20 infants with face presentation is diagnosed by abdominal examination. In fact, only half of these infants are found to have a face presentation by any means before the second stage of labor, and half of the remaining cases are undiagnosed until delivery. Perinatal mortality may be higher, however, with late diagnosis.

Mechanism of Labor

Knowledge of the early mechanism of labor for face presentation is incomplete. **Many infants with a face presentation probably begin labor in the less extended brow position**. With descent into the pelvis, the forces of labor press the fetus against maternal tissues; either flexion or full extension of the head on the spine then often occurs. **The labor of a face presentation must include engagement, descent,**

Etiologic Factors in Malpresentation

Maternal

- Great parity
- Pelvic tumors
- Pelvic contracture
- Uterine malformation

Fetal

- Prematurity
- Multiple gestation
- Hydramnios
- Macrosomia
- Hydrocephaly
- Trisomies
- Anencephaly
- Myotonic dystrophy
- Placenta previa

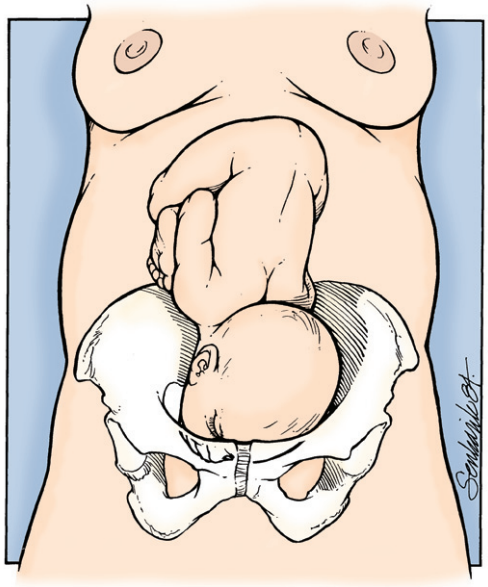

Figure 18-6. This fetus with the vertex completely extended on the neck enters the maternal pelvis in a face presentation. The cephalic prominence would be palpable on the same side of the maternal abdomen as the fetal spine.

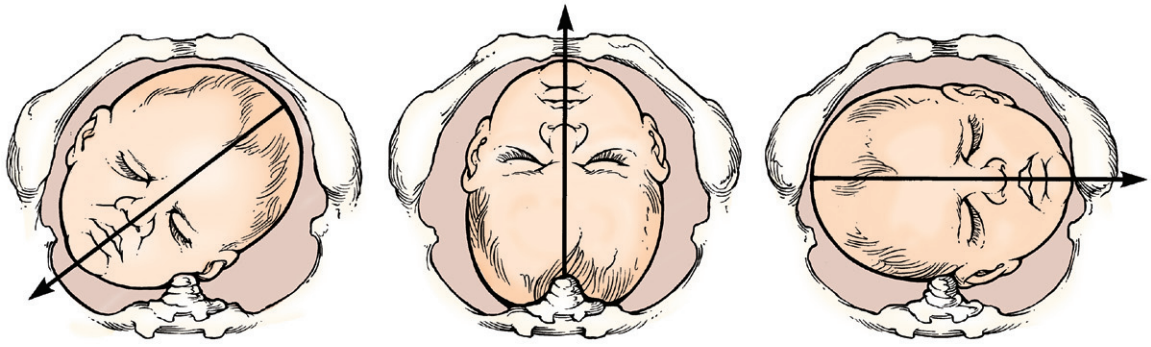

Figure 18-7. The point of designation from digital examination in the case of a face presentation is the fetal chin relative to the maternal pelvis. *Left,* Right mentum posterior *(RMP). Middle,* Mentum anterior *(MA). Right,* Left mentum transverse *(LMT).*

Figure 18-8. Palpation of the maternal abdomen in the case of a face presentation should find the fetal cephalic prominence on the side away from the fetal small parts instead of on the same side as in the case of a normally flexed fetal head.

internal rotation generally to a mentum anterior position, and delivery by flexion as the chin passes under the symphysis (Figure 18-9). However, flexion of the occiput may not always occur; delivery in the fully extended attitude may be common.

The prognosis for labor with a face presentation depends on the orientation of the fetal chin. At diagnosis, 60% to 80% of infants with a face presentation are mentum anterior,[6] 10% to 12% are mentum transverse,[7] and 20% to 25% are mentum posterior.[7] Almost all average-sized infants presenting mentum anterior with adequate pelvic dimensions will achieve spontaneous or easily assisted vaginal delivery. Furthermore, most mentum transverse infants will rotate to the mentum anterior position and deliver vaginally, and even 25% to 33% of mentum posterior infants will rotate and deliver vaginally in the mentum anterior position. In a review of 51 cases of persistent face presentation, Schwartz and colleagues[7] found that the mean birth weight of those infants in mentum posterior who did rotate and deliver vaginally was 3425 g, compared with 3792 g for those infants who did not rotate and deliver vaginally. **Persistence of mentum posterior with an infant of normal size, however, makes safe vaginal delivery less likely.** Overall, 70% to 80% of infants with face presentation can be delivered vaginally, either spontaneously or by low forceps, whereas 12% to 30% require cesarean delivery. Manual attempts to convert the face to a flexed attitude or to rotate a posterior position to a more favorable mentum anterior are rarely successful and increase both maternal and fetal risks.[5] Internal podalic version and breech extraction for face presentation historically are associated with unacceptably high fetal loss rates. Maternal deaths from uterine rupture and trauma have also been documented. Thus, contemporary management through spontaneous delivery or cesarean delivery are the preferred routes for maternal and fetal safety.[5]

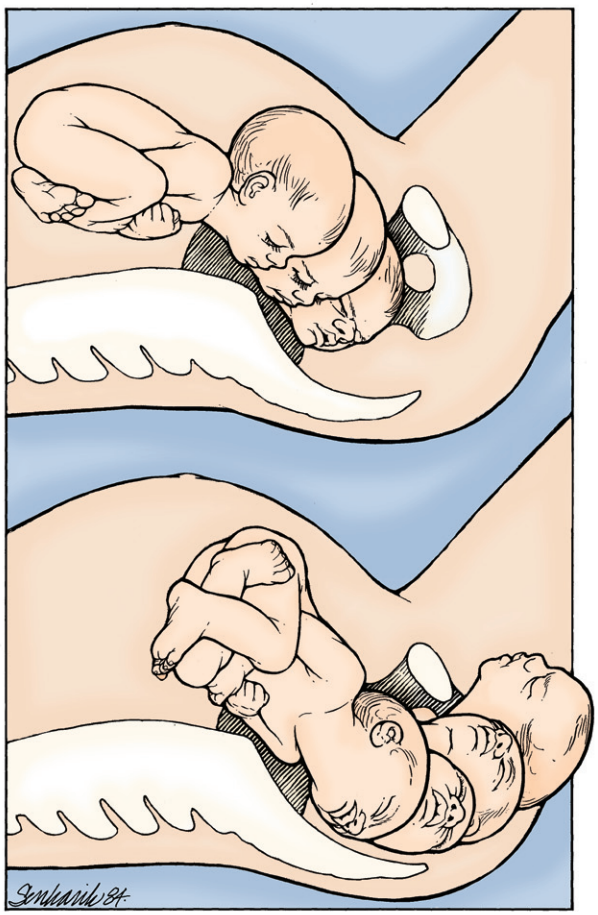

FIGURE 18-9. Engagement, descent, and internal rotation remain cardinal elements of vaginal delivery in the case of a face presentation, but successful vaginal delivery of a term-size fetus presenting a face generally requires delivery by flexion under the symphysis from a mentum anterior position, as illustrated here.

Prolonged labor is a common feature of face presentation and has been associated with an increased number of intrapartum deaths. Therefore, prompt attention to an arrested labor pattern is recommended. In the case of an average or small fetus, adequate pelvis, and hypotonic labor, oxytocin may be considered. No absolute contraindication to oxytocin augmentation of hypotonic labor in face presentations exists, but an arrest of progress despite adequate labor should call for cesarean delivery.

Worsening of the fetal condition in labor is common. **Salzmann and colleagues observed a 10-fold increase in fetal compromise with face presentation.** Several other observers have also found that abnormal fetal heart rate (FHR) patterns occur more often with face presentation.[5,6] Continuous intrapartum electronic FHR monitoring of a fetus with face presentation is considered mandatory, but extreme care must be exercised in the placement of an electrode, because ocular or cosmetic damage is possible. **If external Doppler heart rate monitoring is inadequate and an internal electrode is considered necessary, placement of the electrode on the fetal chin is often recommended.** Cesarean delivery is warranted if a non-reassuring heart rate pattern is identified, even if sufficient progress in labor is occurring.

Safe vaginal delivery may be accomplished in many cases of face presentation, and a trial of labor with careful monitoring of fetal condition and labor progress is not contraindicated unless macrosomia or a small maternal pelvis is identified. However, cesarean delivery has been reported in as many as 60% of cases of face presentation.[6] If cesarean delivery is warranted, care should be taken to flex the head gently both to accomplish elevation of the head through the hysterotomy incision, as well as to avoid potential nerve damage to the neonate. Forced flexion may also result in damage, especially with fetal goiter, or neck tumors.

Laryngeal and tracheal edema resulting from pressures of the birth process might require immediate nasotracheal intubation. Nuchal tumors or simple goiters, fetal anomalies that might have caused the malpresentation, require expert neonatal management.

BROW PRESENTATION

A fetus in a brow presentation occupies a longitudinal axis, with a partially deflexed cephalic attitude, midway between full flexion and full extension (Figure 18-10). **The frontal bones are the point of designation.** If the anterior fontanel is on the mother's left side, with the sagittal suture in the transverse pelvic axis, the fetus would be in a left frontum

transverse position (Figure 18-11). **The reported incidence of brow presentation varies widely, from 1 in 670 to 1 in 3433, averaging about 1 in 1500 deliveries**. Brow presentation is detected more often in early labor before flexion occurs to a normal attitude. Less frequently, further extension results in a face presentation.

Perinatal mortality rate corrected for lethal anomalies and very low birth weight varies from 1% to 8%.[8] In a study of 88,988 deliveries, corrected perinatal mortality rates for brow presentations depended on the mode of delivery, and a loss rate of 16%, the highest in this study, was associated with manipulative vaginal birth.

In general, factors that delay engagement are associated with persistent brow presentation. **Cephalopelvic disproportion, prematurity, and great parity are often found and have been implicated in more than 60% of cases of persistent brow presentation.**

Detection of a brow presentation by abdominal palpation is unusual in practice. More often, a brow presentation is detected on vaginal examination. As in the case of a face presentation, diagnosis in labor is more likely. Fewer than 50% of brow presentations are detected before the second stage of labor, with most of the remainder undiagnosed until delivery. **Frontum anterior is reportedly the most common position at diagnosis,** occurring about twice as often as either transverse or posterior positions. Although the initial position at diagnosis may be of limited prognostic value, the cesarean delivery rate is higher with frontum transverse or frontum posterior than with frontum anterior.

A persistent brow presentation requires engagement and descent of the largest (mento-occipital) diameter or profile of the fetal head. This process is possible only with a large pelvis or a small infant, or both. **However, most brow presentations convert spontaneously by flexion or further extension to either a vertex or a face presentation and are then managed accordingly.** The earlier the diagnosis is made, the more likely conversion will occur spontaneously. Fewer than half of fetuses with persistent brow presentations undergo spontaneous vaginal delivery, but in most cases, a trial of labor is not contraindicated.[8]

Prolonged labors have been observed in 33% to 50% of brow presentations, and secondary arrest is not uncommon. Forced conversion of the brow to a more favorable position with forceps is contraindicated, as are attempts at manual conversion. One unexpected cause of persistent brow presentation may be an open fetal mouth pressed against the vaginal wall, splinting the head and preventing either flexion or extension (Figure 18-12).

In most brow presentations, as with face presentations, minimal manipulation yields the best results if the FHR pattern remains reassuring. Expectant management may be justified only with a large pelvis, a small fetus, and adequate progress, according to one large study. If a brow presentation persists with a large baby, successful vaginal delivery is unlikely, and cesarean delivery may be most prudent.

Radiographic or computed tomographic (CT) pelvimetry might be considered helpful, but one report states that although 91% of cases with adequate pelvimetry converted to a vertex or a face and delivered vaginally, 20% with some form of pelvic contracture did also. Therefore, regardless of pelvic dimensions, consideration of a trial of labor with careful monitoring of maternal and fetal condition may be

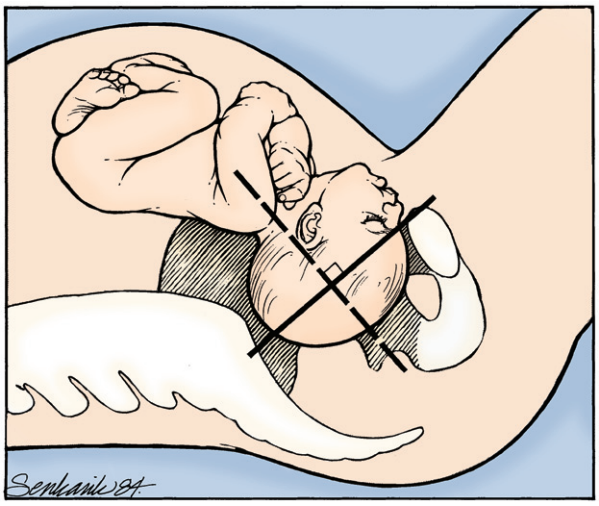

FIGURE 18-10. This fetus is a brow presentation in a frontum anterior position. The head is in an intermediate deflexion attitude.

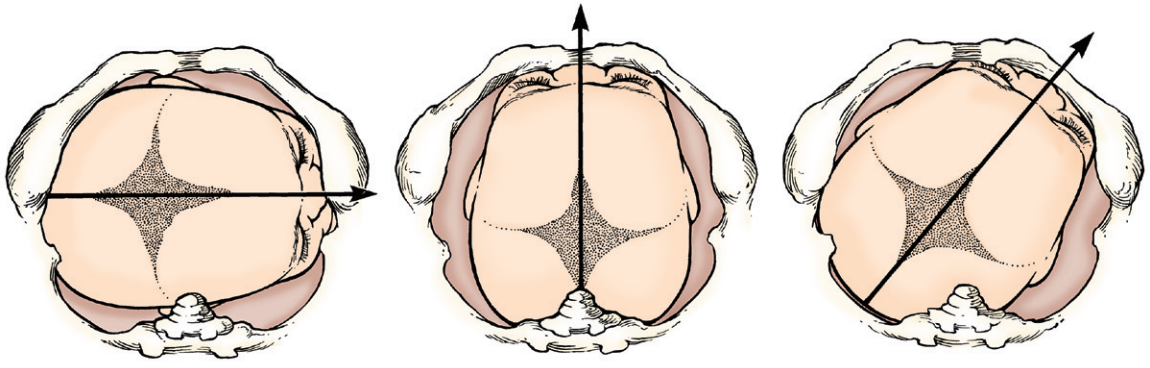

FIGURE 18-11. In brow presentation, the anterior fontanel (frontum) relative to the maternal pelvis is the point of designation. *Left,* Fetus in left frontum transverse *(LFT). Middle,* Frontum anterior *(FA). Right,* Left frontum anterior *(LFA).*

appropriate. As in the case of a face presentation, oxytocin may be used cautiously to correct hypotonic contractions, but prompt resumption of progress toward delivery should follow.

COMPOUND PRESENTATION

Whenever an extremity is found prolapsed beside the main presenting fetal part, the situation is referred to as a compound presentation (Figure 18-13). The reported incidence ranges from 1 in 377 to 1 in 1213 deliveries.[8] The combination of an upper extremity and the vertex is the most common.

This diagnosis should be suspected with any arrest of labor in the active phase or failure to engage during active labor. Diagnosis is made by vaginal examination by discovery of an irregular mobile tissue mass adjacent to the larger presenting part. Recognition late in labor is common, and as many as 50% of persisting compound presentations are not detected until the second stage. Delay in diagnosis may not be detrimental because it is likely that only the persistent cases require intervention.

Although maternal age, race, parity, and pelvic size have been associated with compound presentation, prematurity is the most consistent clinical finding. The very small premature fetus is at great risk of persistent compound presentation. In late pregnancy, external cephalic version of a fetus in breech position increases the risk of a compound presentation.

Older, uncontrolled studies report elevated perinatal mortality rates with a compound presentation, with an overall rate of 93 per 1000. Higher loss rates of 17% to 19%

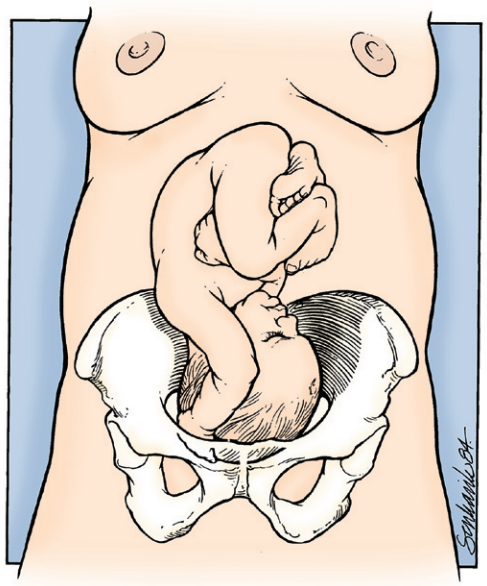

FIGURE 18-13. The compound presentation of an upper extremity and the vertex illustrated here most often spontaneously resolves with further labor and descent.

have been reported when the foot prolapses. As with other malpresentations, fetal risk is directly related to the method of management. A fetal mortality rate of 4.8% has been noted if no intervention is required compared with 14.4% with intervention other than cesarean delivery. A 30% fetal mortality rate has been observed with internal podalic version and breech extraction. These figures may

demonstrate selection bias because it is possible that more often the difficult cases were chosen for manipulative intervention. When intervention is necessary, cesarean delivery appears to be the only safe choice.

Fetal risk in compound presentation is specifically associated with birth trauma and cord prolapse. Cord prolapse occurs in 11% to 20% of cases, and it is the most frequent single complication of this malpresentation. Cord prolapse probably occurs because the compound extremity splints the larger presenting part, resulting in an irregular fetal aggregate that incompletely fills the pelvic inlet. In addition to the hypoxic risk of cord prolapse, common fetal morbidity includes neurologic and musculoskeletal damage to the involved extremity. Maternal risks include soft tissue damage and obstetrical laceration.

Despite these dangers, labor is not necessarily contraindicated with a compound presentation; however, the prolapsed extremity should not be manipulated. The accompanying extremity may retract as the major presenting part descends. Seventy-five percent of vertex/upper extremity combinations deliver spontaneously. Occult or undetected cord prolapse is possible, and, therefore, continuous electronic FHR monitoring is recommended.

The primary indications for surgical intervention are cord prolapse, non-reassuring fetal heart rate (FHR) patterns, and arrest of labor. **Cesarean delivery is the only appropriate clinical intervention for cord prolapse and non-reassuring FHR pattern, because both version extraction and repositioning the prolapsed extremity are associated with adverse outcome and are to be avoided.** From 2% to 25% of compound presentations require abdominal delivery. Protraction of the second stage of labor and dysfunctional labor patterns have been noted to occur more frequently with persistent compound presentation. As in other malpresentations, spontaneous resolution occurs more often and surgical intervention is less frequently necessary in those cases diagnosed early in labor. Small or premature fetuses are more likely to have persistent compound presentations but are also more likely to have a successful vaginal delivery. **Persistent compound presentation with parts other than the vertex and hand in combination in a term-sized infant has a poor prognosis for safe vaginal delivery, and cesarean delivery is usually necessary.** However, a simple compound presentation (e.g., hand) may be allowed to labor if progressing normally with reassuring fetal status.

BREECH PRESENTATION

The infant presenting as a breech occupies a longitudinal axis with the cephalic pole in the uterine fundus. This presentation occurs in 3% to 4% of labors overall, although it is found in 7% of pregnancies at 32 weeks and in 25% of pregnancies of less than 28 weeks' duration.[10] The three types of breech are noted in Table 18-1. The infant in the frank breech position is flexed at the hips with extended knees. The complete breech is flexed at both joints, and the footling breech has one or both hips partially or fully extended (Figure 18-14).

The diagnosis of breech presentation may be made by abdominal palpation or vaginal examination and confirmed by ultrasound. **Prematurity, fetal malformation, müllerian anomalies, and polar placentation are commonly observed causative factors.** High rates of breech presentation are noted in certain fetal genetic disorders, including trisomies 13, 18, and 21; Potter's syndrome; and myotonic dystrophy. Thus, conditions that alter fetal muscular tone

TABLE 18-1 BREECH CATEGORIES

TYPE	OVERALL PERCENT OF BREECHES	RISK (%) PROLAPSE	PREMATURE
Frank breech	48-73[13,14,51]	0.5[15]	38[14]
Complete	4.6-11.5[14,51]	4-6[15]	12[14]
Footling	12-38[14]	15-18[15]	50[14]

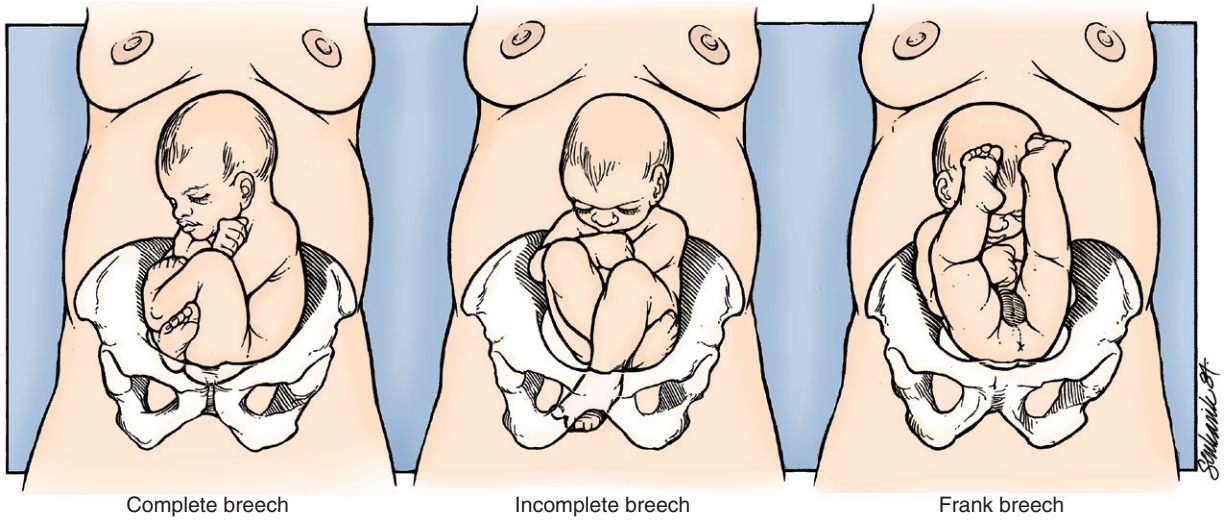

FIGURE 18-14. The complete breech is flexed at the hips and flexed at the knees. The incomplete breech shows incomplete deflexion of one or both knees or hips. The frank breech is flexed at the hips and extended at the knees.

and mobility such as increased and decreased amniotic fluid, for example, also increase the frequency of breech presentation.

Mechanism and Conduct of Labor and Vaginal Delivery

The two most important elements for the safe conduct of vaginal breech delivery are continuous electronic FHR monitoring and noninterference until spontaneous delivery of the breech to the umbilicus has occurred. Early in labor, the capability for immediate cesarean delivery should be established. Anesthesia should be available, the operating room readied, and appropriate informed consent obtained (discussed later). Two obstetricians should be in attendance, as well as a pediatric team. Appropriate training and experience with vaginal breech delivery are fundamental to success. The instrument table should be prepared in the customary manner, with the addition of Piper forceps and extra towels. There is no contraindication to epidural analgesia in labor; many even view epidural anesthesia as an asset in the control and conduct of the second stage.

The infant presenting in the frank breech position usually enters the pelvic inlet in one of the diagonal pelvic diameters (Figure 18-15). **Engagement has occurred when the bitrochanteric diameter of the fetus has progressed beyond the plane of the pelvic inlet, although by vaginal examination, the presenting part may be palpated only at –2 to –4 station (of 5).** As the breech descends and encounters the levator ani muscular sling, internal rotation usually occurs to bring the bitrochanteric diameter into the anteroposterior (AP) axis of the pelvis. **The point of designation in a breech labor is the fetal sacrum,** and, therefore, when the bitrochanteric diameter is in the AP axis of the pelvis, the fetal sacrum will lie in the transverse pelvic diameter (Figure 18-16).

If normal descent occurs, the breech will present at the outlet and begin to emerge, first as a sacrum transverse, then rotating to sacrum anterior. Crowning occurs when the bitrochanteric diameter passes under the pubic symphysis. An episiotomy may facilitate delivery but should be delayed until crowning begins. As the infant emerges, rotation begins, usually toward a sacrum anterior position. This direction of rotation may reflect the greater capacity

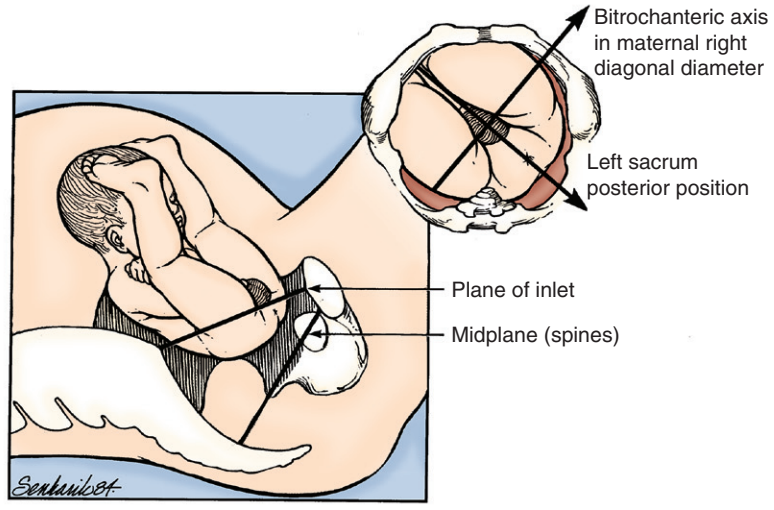

FIGURE 18-15. The breech typically enters the inlet with the bitrochanteric diameter aligned with one of the diagonal diameters, with the sacrum as the point of designation in the other diagonal diameter. This is a case of left sacrum posterior.

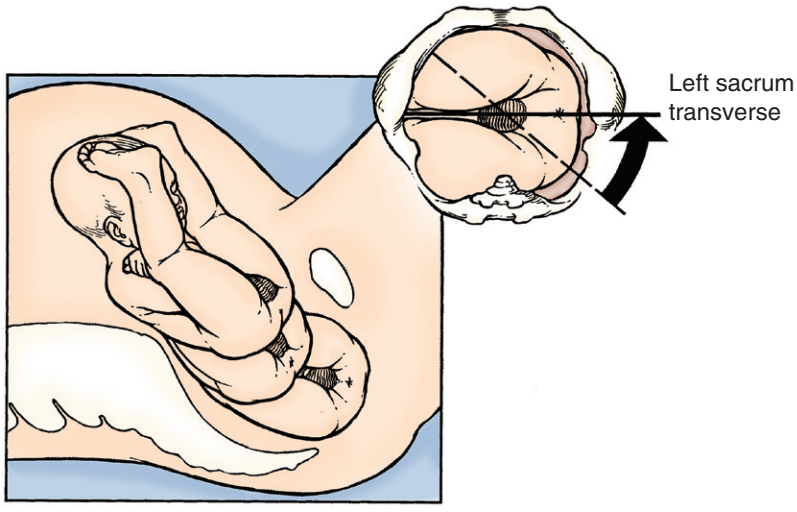

FIGURE 18-16. With labor and descent, the bitrochanteric diameter generally rotates toward the anteroposterior axis and the sacrum toward the transverse.

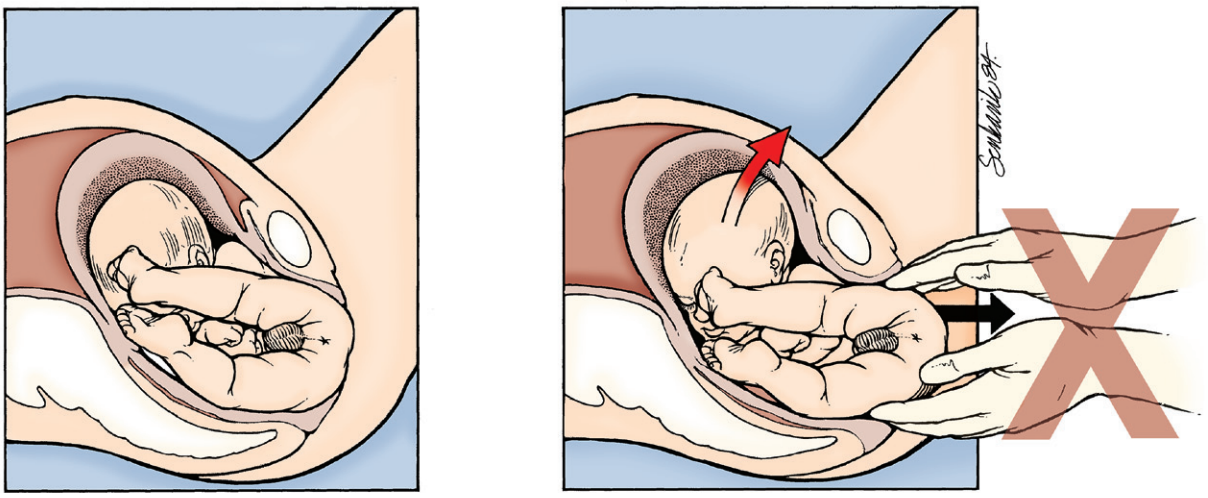

A Spontaneous expulsion

B Undesired deflexion

FIGURE 18-17. The fetus emerges spontaneously **(A),** whereas uterine contractions maintain cephalic flexion. Premature aggressive traction **(B)** encourages deflexion of the fetal vertex and increases the risk of head entrapment or nuchal arm entrapment.

of the hollow of the posterior pelvis to accept the fetal chest and small parts. It is important to emphasize that operator intervention is not yet needed or helpful other than possibly to perform the episiotomy if indicated and encourage maternal expulsive efforts.

Premature or aggressive assistance may adversely affect the delivery in at least two ways. **First, complete cervical dilation must be sustained for sufficient duration to retard retraction of the cervix and entrapment of the after-coming fetal head. Rushing the delivery of the trunk may result in cervical retraction. Second, the safe descent and delivery of the breech infant must be the result of uterine and maternal expulsive forces only, in order to maintain neck flexion. Any traction by the provider in an effort to speed delivery would encourage deflexion of the neck and result in the presentation of the larger occipitofrontal fetal cranial profile to the pelvic inlet** (Figure 18-17). Such an event could be catastrophic. **Rushed delivery also increases the risk of a nuchal arm,** with one or both arms trapped behind the head above the pelvic inlet. Entrapment of a nuchal arm makes safe vaginal delivery much more difficult, because it dramatically increases the aggregate size of delivering fetal parts that must egress vaginally. Safe breech delivery of an average-sized infant, therefore, depends predominantly on maternal expulsive forces, and patience, not traction, from the provider.

As the frank breech emerges further, the fetal thighs are typically flexed firmly against the fetal abdomen, often splinting and protecting the umbilicus and cord. The Pinard maneuver may be needed to facilitate delivery of the legs in a frank breech presentation. After the umbilicus has been reached, pressure is applied to the medial aspect of the knee, which causes flexion and subsequent delivery of the lower leg. Simultaneous to this, the fetal pelvis is rotated away from that side (Figure 18-18). This results in external rotation of the thigh at the hip, flexion of the knee, and delivery of one leg at a time. The dual movement of counterclockwise rotation of the fetal pelvis as the operator externally rotates the right thigh and clockwise rotation of the fetal pelvis as the operator externally rotates the fetal left thigh, is most effective in facilitating delivery. The fetal trunk is then wrapped with a towel to provide secure support of the body while further descent results from expulsive forces from the mother. The operator primarily facilitates the delivery of the fetus by guiding the body through the introitus. **The operator is not applying outward traction on the fetus that might result in deflexion of the fetal head or nuchal arm.**

When the scapulae appear at the introitus, the operator may slip a hand over the fetal shoulder from the back (Figure 18-19), follow the humerus, and, with movement from medial to lateral, sweep first one and then the other arm across the chest and out over the perineum. Gentle rotation of the fetal trunk counterclockwise assists delivery of the right arm, and clockwise rotation assists delivery of the left arm (turning the body "into" the arm). This accomplishes delivery of the arms by drawing them across the fetal chest in a fashion similar to that used for delivery of the legs (Figure 18-20). Once both arms have been delivered, if the vertex has remained flexed on the neck, the chin and face will appear at the outlet, and the airway may be cleared and suctioned (Figure 18-21).

With further maternal expulsive forces alone, spontaneous controlled delivery of the fetal head often occurs. **If not, delivery may be accomplished with a simple manual effort to maximize flexion of the vertex using pressure on the fetal maxilla (not mandible), the Mauriceau-Smellie-Veit maneuver, along with suprapubic pressure (Credé maneuver) and gentle downward traction** (Figure 18-22). Although maxillary pressure facilitates flexion, the main force effecting delivery remains the mother.

Alternatively, the operator may apply Piper forceps to the after-coming head. **The application requires *very slight* elevation of the fetal trunk by the assistant, while the operator kneels and applies the Piper forceps from underneath the fetus directly to the fetal head in the pelvis.** The position of the operator for applying the forceps is depicted in Figure 18-23, which also demonstrates how *excessive*

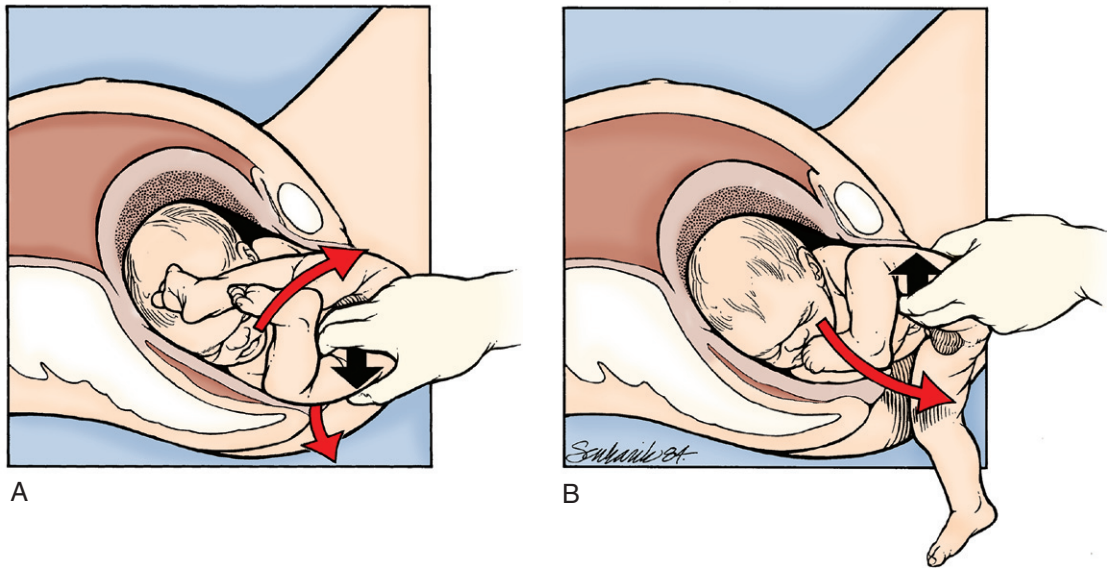

FIGURE 18-18. After spontaneous expulsion to the umbilicus, external rotation of each thigh **(A)** combined with opposite rotation of the fetal pelvis results in flexion of the knee and delivery of each leg **(B).**

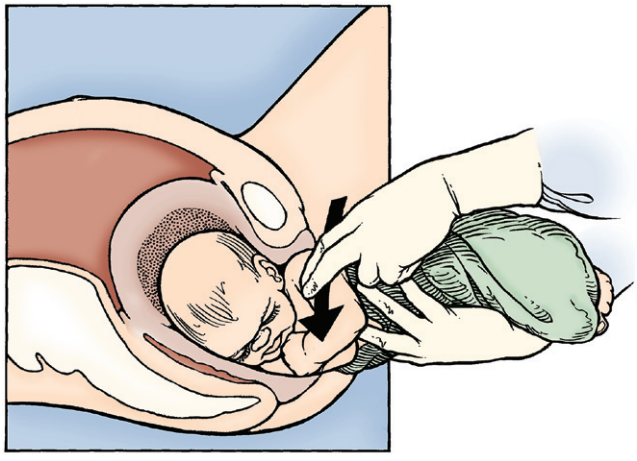

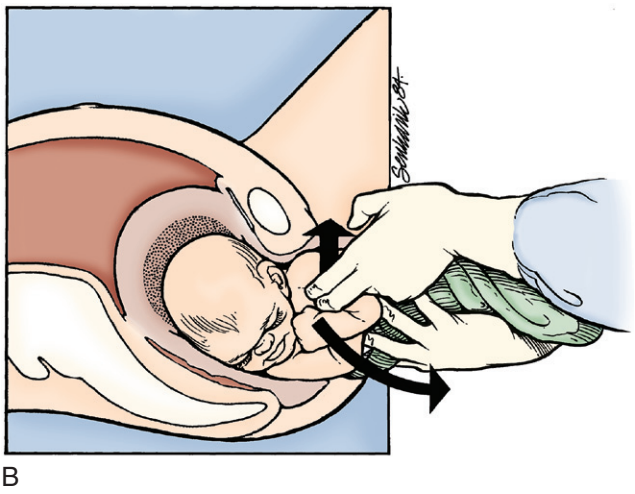

FIGURE 18-19. When the scapulae appear under the symphysis, the operator reaches over the left shoulder, sweeps the arm across the chest **(A),** and delivers the arm **(B).**

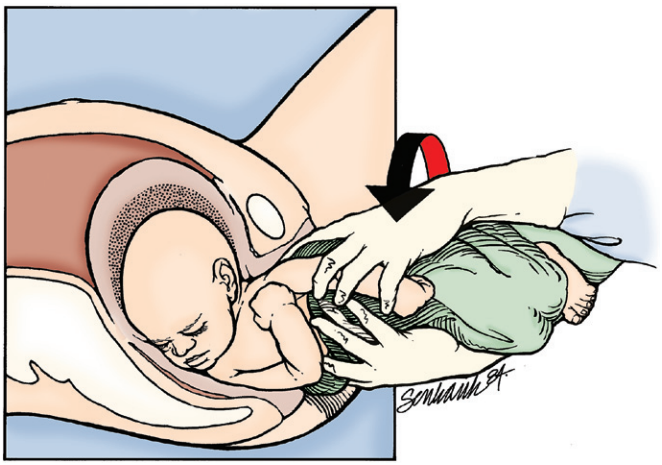

FIGURE 18-20. Gentle rotation of the shoulder girdle facilitates delivery of the right arm.

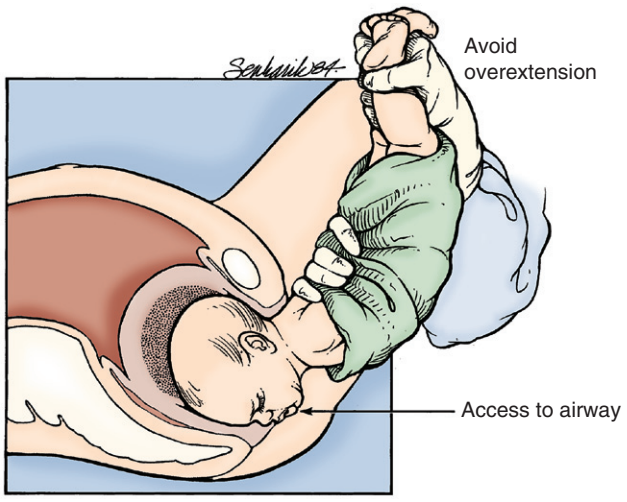

FIGURE 18-21. Following delivery of the arms, the fetus is wrapped in a towel for control and slightly elevated. The fetal face and airway may be visible over the perineum. Excessive elevation of the trunk is avoided.

elevation by the assistant may potentially cause harm to the neonate. Hyperextension of the fetal neck from excessive elevation of the fetal trunk, shown in Figure 18-23, should be avoided because of the potential for spinal cord injury.

Piper forceps are characterized by absence of pelvic curvature. This modification allows *direct* application to the fetal head and avoids conflict with the fetal body that would occur with the application of standard instruments from below. The forceps are inserted into the vagina from beneath the fetus. The blade to be placed on the maternal left is held by the handle in the operator's left hand and the blade inserted with the operator's right hand in the vagina along the left maternal sidewall and placed against the right fetal parietal bone. The handle of the right blade is then held in the operator's right hand and inserted by the left hand along the right maternal sidewall and placed against the left fetal parietal bone. Gentle downward traction on the forceps with the fetal trunk supported on the forceps shanks results in controlled delivery of the vertex (Figure 18-24). Forceps application controls the fetal head and prevents extension of the head on the neck. Application of Piper forceps to the after-coming head may be advisable both to ensure control of the delivery and to maintain optimal operator proficiency in anticipation of deliveries that may require their use.

Arrest of spontaneous progress in labor with adequate uterine contractions necessitates consideration of cesarean delivery. Any evidence of fetal compromise or sustained cord compression on the basis of continuous electronic fetal monitoring also requires consideration of cesarean delivery. Vaginal interventions directed at facilitating delivery of the breech that is complicated by an arrest of spontaneous progress are discouraged, because fetal and maternal morbidity and mortality are both greatly increased. However, if labor is deemed to be hypotonic by

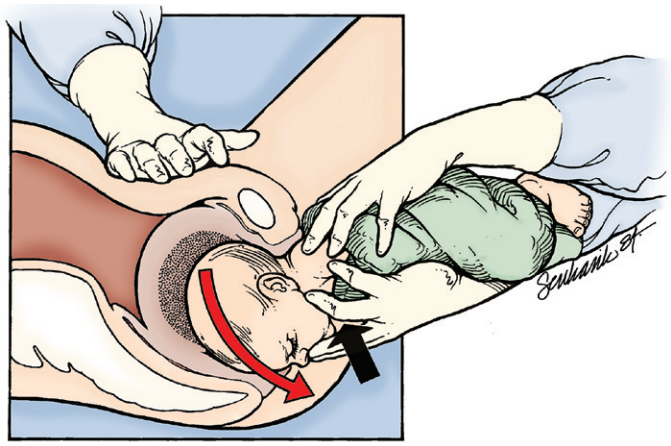

FIGURE 18-22. Cephalic flexion is maintained by pressure *(heavy arrow)* on the fetal maxilla (not mandible!). Often, delivery of the head is easily accomplished with continued expulsive forces from above and gentle downward traction.

FIGURE 18-23. Demonstration of *incorrect* assistance during the application of Piper forceps; the assistant hyperextends the fetal neck. Positioning as such increases the risk for neurologic injury.

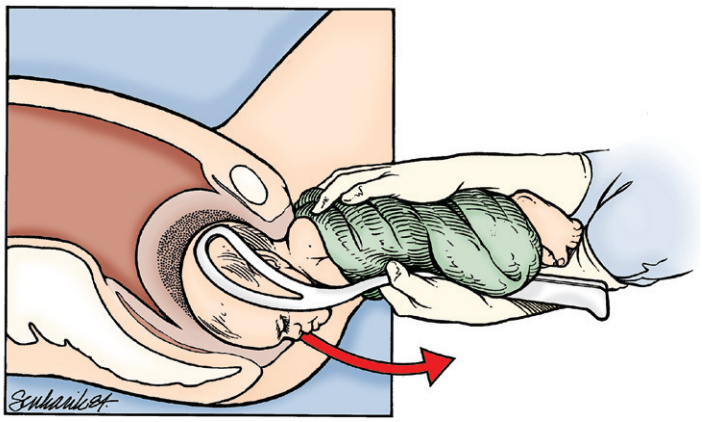

FIGURE 18-24. The fetus may be laid on the forceps and delivered with gentle downward traction, as illustrated here.

TABLE 18-2 INCIDENCE OF COMPLICATIONS SEEN WITH BREECH PRESENTATION

COMPLICATION	INCIDENCE
Intrapartum fetal death	Increased 16-fold[23]
Perinatal mortality	1.3%[20]
Intrapartum asphyxia	Increased 3.8-fold[31]
Cord prolapse	Increased 5- to 20-fold[14,15] 1.3%[20]
Birth trauma	Increased 13-fold[14] 1.4%[20]
Dystocia, difficulty delivering head	4.6%[20] to 8.8%[14]
Spinal cord injuries with extended head	21%
Major anomalies	6%-18%[31]
Prematurity	16%-33%[22,25]
Hyperextension of head	5%
Fetal heart rate abnormalities	15.2%[20]

From Zatuchni GI, Andros GJ: Prognostic index for vaginal delivery in breech presentation at term. Am J Obstet Gynecol 93:237, 1965.

internally monitored uterine pressures, oxytocin is not contraindicated.[11,12]

Mechanisms of descent and delivery of the incomplete and the complete breech are not unlike those used for the frank breech described earlier; at least one leg may not require attention. The risk of cord prolapse or entanglement is greater, and hence, the possibility of emergency cesarean delivery is increased. Furthermore, incomplete and complete breeches may not be as effective as cervical dilators as either the vertex or the larger aggregate profile of the thighs and buttocks of the frank breech. Thus, the risk of entrapment of the after-coming head is increased, and as a result, primary cesarean delivery is often advocated for nonfrank breech presentations. However, the randomized trial of Gimovsky and colleagues[13] found the vaginal delivery of the nonfrank breech to be reasonably safe as well.

Contemporary Management of the Term Breech

Debate has largely diminished about the proper management of the term breech. Much of the older data were derived from relatively few studies of varied methodologies, patient populations, and multiple retrospective cohort analyses, which are subject to bias. These reports indicated that the perinatal mortality rate for the vaginally delivered breech appears to be greater than for its cephalic counterpart, but much of the reported perinatal mortality rate associated with breech presentation was largely due to lethal anomalies and complications of prematurity, both of which are found more frequently among breech infants. Excluding anomalies and extreme prematurity, the corrected perinatal mortality reported by some investigators approached zero regardless of the method of delivery, whereas others find that even with exclusion of these factors, the term breech infant has been found to be at higher risk for birth trauma and asphyxia.[14] To date, only three randomized trials have been reported.[11,13] Although conclusions regarding safety of breech vaginal delivery from a fetal standpoint may continue to vary, the practical reality today is that intentional vaginal breech deliver is rare. A summary of some of the reported complications is listed in Table 18-2. Overall, consideration of a potential breech vaginal delivery must be mutually agreed on by the patient and the physician after a complete informed consent is obtained.

Further Discussion of Delivery for the Term Frank or Complete Breech

The cesarean delivery rate for breech presentation began to approach 90% in some centers in the mid-1970s without a consequent proportionate drop in perinatal mortality rate. Maternal mortality rate is clearly higher with cesarean delivery, ranging from 0.2% to 0.43%.[10] Maternal morbidity is also higher with abdominal delivery. Some institutions reported a 50% incidence of postcesarean maternal morbidity compared with as little as 5% with vaginal delivery.[10,13] In an attempt to balance both maternal and fetal risks, plans were proposed to select appropriate candidates for a trial of labor.

In 1965, Zatuchni and Andros retrospectively analyzed 182 breech births, of which 25 infants had poor outcomes.[16] Therefore, these investigators devised a score based on six clinical variables at the time of admission (Table 18-3) that identified those patients destined to manifest difficulties in labor for whom prompt and appropriate interventions could be made. The score used parity, gestational age, estimated weight, prior successful breech vaginal delivery, dilation, and station to ascertain likelihood of successful vaginal delivery. However, the parturient herself could increase the score by presenting later in labor; other factors that affect the score are less modifiable. At least three subsequent prospective studies applied the Zatuchni-Andros system and found it to be both sensitive and

accurate in selecting candidates for successful vaginal delivery.[17] **A Zatuchni-Andros score of less than 4 in these studies accurately predicted poor outcomes in patients with infants presenting as a breech.** Furthermore, in applying the scoring system, only 21% to 27% of patients failed to qualify for a trial of labor.[17] Previous breech delivery, one of the items scored in the Zatuchni-Andros system, has a significant odds ratio (OR) for recurrence of breech (4.32, 95% confidence interval [CI], 4.08 to 4.59) after one breech delivery, and up to 28.1 (95% CI, 12.2 to 64.8) after three. This study did not, however, control for recurrent causes of breech presentation such as uterine malformations and abnormal placentation.[18]

Because most reports of breech delivery are of level II to III evidence, their validity and, most important, universal applicability may be questioned. Many data were gathered before electronic FHR monitoring became commonplace. Until 2000, only one randomized trial (level I evidence) had examined term frank breech and method of delivery.[11] Improved perinatal survival had been reported for abdominally delivered breeches, and there is some evidence, although inconsistent, that the method of delivery may also have an impact on the quality of survival.[14] Functional neurologic defects were found by 2 years of age in 24% of breech infants born vaginally but only in 2.5% of those breech weight- and age-matched infants born by cesarean delivery.[19] However, in comparing 175 breech infants having a 94% cesarean delivery rate with 595 historical controls having a 22% rate of abdominal delivery, Green and colleagues[20] found no significant differences in outcome. Neurologic outcomes were reviewed for 239 of 348 infants delivered from breech position.[21] Examinations performed at 3 to 10 years of age showed no statistically significant neurologic differences between neonates delivered by vaginal breech versus matched vertex controls. Thus, these authors concluded that breech outcomes relate to degree of prematurity, maternal pregnancy complications, and fetal malformations, as well as birth trauma or asphyxia. A 2009 Norwegian study demonstrated that breech presentation *and* breech delivery are significant risk factors for cerebral palsy and a trend toward increasing risk for cerebral palsy among singletons born at term in breech by vaginal delivery (nearly fourfold). This adds to the body of literature that demonstrates that **breech presenting fetuses are already at increased risk for neurologic adversity, even when controlled for birth order, prematurity, smallness for gestational age, assisted reproduction, and sex, as well as route of delivery.**[22]

Pelvimetry is frequently employed when deciding to allow trial of labor in a breech presenting fetus. Clinical pelvimetry is an acceptable technique and can be used to determine the dimensions of the midpelvis and the outlet, and the inlet by way of surrogate measurement (the obstetrical conjugate). The reader is referred to the Intrapartum Care section in Chapter 13 on normal labor and delivery for discussion and demonstration of clinical pelvimetry. Radiographic pelvimetry has been included in the management of the breech presentation with little objective validation. Regardless, it is expected to predict successful vaginal delivery when adequate pelvic dimensions are present. There are at least four techniques for pelvimetry that are presently in common usage worldwide, including conventional plain film radiography using up to three films, CT with up to three views (lateral, AP, and axial slice), magnetic resonance imaging (MRI), and digital fluorography, not presently used in the United States. MRI is the only technique not associated with radiation exposure, and CT pelvimetry using a single lateral view results in the lowest exposure dose. Air gap technique with conventional radiography will lower the radiation dosage. **Current trends show a move toward the lower-dose CT techniques of up to three images.**

The clinician must possess the necessary training and experience to offer a patient with a persistent breech presentation a trial of labor. Furthermore, the relationship between the patient and the clinician should be well established and the discussions of risks and benefits must be objective and nondirective with accurate documentation of the discussion. If any of these factors are lacking, cesarean delivery becomes the safer choice. **However, even if a clinician has made the choice that he or she will never prospectively offer a patient with breech presentation a trial of labor, the burden of responsibility to know and understand the mechanism and management of a breech delivery is not relieved.** No one active in obstetrics will avoid the occasional emergency breech delivery. Regular review of principles, and practice with simulations using a mannequin and model pelvis with an experienced colleague, can increase the skills and improve the performance of anyone facing such an emergency. **A 2006 study of resident skill before and after simulation training showed universal improvement in technique and performance of key maneuvers required for vaginal delivery of a breech fetus when performed in mock emergency settings using a Noelle pelvic trainer.**[23] Maintenance of skill is particularly important as breech vaginal delivery becomes less frequently encountered in routine obstetrical practice (this is discussed in greater detail in regard to the Term Breech Trial).

Factors that affect the decision to deliver a breech vaginally or by cesarean section are listed in the accompanying box, Management of the Breech. The obvious implication of the dramatically diminished experience in training programs with vaginal breech delivery is that inexperience itself will constitute an indication for cesarean delivery. Certainly, in no case should a woman with an infant presenting as a breech be allowed to labor unless (1) anesthesia coverage is immediately available, (2) cesarean delivery can be undertaken promptly, (3) continuous FHR monitoring is used, and (4) the delivery is attended by a pediatrician and two obstetricians, of whom at least one is experienced with vaginal breech birth.

THE TERM BREECH TRIAL

One of the most influential publications of the last decade was the multicenter prospective study called the Term Breech Trial. The impetus for this investigation was a series of retrospective studies that demonstrated increased morbidity and mortality of neonates after vaginal breech delivery including neonatal intensive care unit admission, hyperbilirubinemia, bone fracture, intracranial hemorrhage, neonatal depression,[15] convulsions, and death.[24] Other studies, however, found that emergent cesarean

Management of the Breech

Trial of labor may be considered if
- Estimated fetal weight (EFW) = 2000 to 3800 g
- Frank breech
- Adequate pelvis
- Flexed fetal head
- Fetal monitoring
- Zatuchni-Andros score ≥4
- Rapid cesarean possible
- Good progress maintained in labor
- Experience and training available
- Informed consent possible

Cesarean delivery may be prudent if
- EFW <1500 or >4000 g
- Footling presentation
- Small pelvis
- Hyperextended fetal head
- Zatuchni-Andros score 4
- Absence of expertise
- Non-reassuring fetal heart rate pattern
- Arrest of progress

delivery was also associated with poor neonatal outcomes. Irion and colleagues[25] reported similarly poor neonatal outcomes from cesarean deliveries of 705 singleton breeches, and concluded that as a result of the increased *maternal* morbidity associated with cesarean birth, delivery of the breech by cesarean section was not firmly indicated. This opinion was supported by Brown and colleagues[12] in their prospective case series, noting that the corrected perinatal mortality rate did not differ for neonates weighing ≥1500 g.

In October 2000, the first results from the Term Breech Trial were published.[14] Overall, 2088 patients from 121 centers in 26 countries with varied national perinatal mortality statistics, according to the World Health Organization, were enrolled in the study, with random assignment of 1041 to the planned cesarean delivery group, and 1042 to the planned vaginal delivery group. The data were analyzed by the intention to treat method, and 941 of 1041 (90.4%) and 591 of 1042 (56.7%) delivered by their intended route of delivery, cesarean section and vaginal birth, respectively. Intrapartum events, including cord prolapse and FHR abnormalities, occurred at rates similar to prior studies. Maternal and fetal/neonatal short-term (immediate, 6 weeks, and 3 months) and long-term (2-year) outcome data were presented in this and subsequent reports. **For both countries with low and high perinatal mortality rates (PMRs), the occurrence of perinatal mortality, or serious neonatal morbidity (defined within the report) was significantly lower in the planned cesarean delivery group than the planned vaginal delivery group (relative risk [RR] = 0.33 [0.19 to 0.56], *P* <0.0001). In countries with an already low PMR, there was a proportionately greater risk reduction in PMR in the planned cesarean delivery.** The effects of operator experience and prolonged labor did not affect the direction of the risk reduction and marginally affected the amplitude. No differences existed in maternal mortality or serious maternal morbidity between the groups.[14]

The effects on the correlation between labor and delivery factors were assessed in a separate regression analysis, using only delivery mode in one regression, and only labor factors including all other variables, such as fetal monitoring, length of labor, and medications in the other. **Mode of delivery and birth weight were both significantly associated with adverse fetal outcome, without a significant degree of interaction of these variables. Essentially, smaller infants (less than 2800 g) were at greatest risk (OR 2.13 [1.2 to 3.8], *p* = 0.01).** Birth weights greater than 3500 g showed a trend toward more adverse outcomes, but the trend did not reach significance. The analysis of the labor data shows a "dose-response relationship between the progression of labor and the risk of adverse perinatal outcome," such that a prelabor cesarean delivery is associated with the lowest rates of adverse outcome compared with vaginal breech delivery.[26] Maternal outcomes at 3 months showed a reduced rate (RR = 0.62, 0.41 to 0.93) of urinary incontinence in the planned cesarean delivery group,[27] but 2 years after delivery, no differences in urinary incontinence or breastfeeding, medical, sexual, social, pain, or reproductive issues, as outlined in the text, existed.[28] Neonatal outcomes at 2 years showed no difference in mortality rates or neurodevelopmental delay between the planned cesarean section and planned vaginal delivery groups.[29] **Thus, the term breech trial can be summarized as follows: If a trial of labor is attempted and is successful, babies born by planned vaginal delivery have a small but significant risk of dying or sustaining a debilitating insult in the short term. If they survive, there is no difference in the mortality rate or in the presence of developmental delay when compared with those children born by planned cesarean delivery.**

The worldwide repercussions of the Term Breech Trial are still being realized. Eighty of the collaborating centers in 23 of 26 countries responded to a follow-up questionnaire regarding change in practice patterns after the results of the Term Breech Trial were published. A plurality stated that practice had changed (92.5%). Eighty five percent of respondents reported that an analysis of relative costs would not affect the continued implementation of a policy of planned cesarean delivery for the breech at term.[30]

A Dutch study examining the effects on delivery statistics and outcomes following the Term Breech Trial showed an increase in the cesarean delivery rate for the term breech from 50% to 80%, which was associated with a concomitant reduction in perinatal mortality rate from 0.35% to 0.18%.[31]

The total cesarean delivery rate in the United States in 2004 was 29.1% of all deliveries[32] and has increased substantially such that in 2007, the most recent year with complete statistics, the total cesarean rate was 31.8%, with 2008 preliminary data showing a further increase still. In 1978, the rate of cesarean deliveries in the United States was 24.4% of deliveries, with a drastic variation in rates in the intervening years. The 1981 National Institutes of Health Consensus Report found that 12% of cesarean deliveries in 1978 were performed for breech presentation and that this indication contributed 10% to 15% to the overall rise in the rate of cesarean births. At least a portion of the increase in cesarean delivery rates is a response to the perceived risk of morbidity and mortality associated with the breech presentation.[14,20] In the United States, the cesarean delivery rate for breech presentation increased from 11.6% to 79.1% between 1970 and 1985.[20,33]

Comparing the U.S. cesarean delivery rates from 1998 and 2002, before and after the Term Breech Trial's publication, one notes a marked increase in the rates for cesarean section: 21.2% of all live births in 1998, compared to 26.1% in 2002, and 29.1% in 2004. Rates of both primary and repeat cesarean deliveries increased. This may be in part because of the staggering number of multiple births and their related degree of prematurity, the relative reduction in vaginal birth after cesarean section,[34] and the self-fulfilling prophecy of lack of experience owing to increasing trends toward cesarean delivery for breech, leaving a void of experienced operators to perform breech vaginal deliveries (see Chapter 21). **The rates for cesarean delivery for breech presentation showed an increase over this period from 84.2% in 1998 compared with 86.9% in 2002, and remaining relatively stable in 2003 (85.1%).**[34] Although not as large a percentage increase as compared with the Netherlands, these trends are significant. The implications for future pregnancies have not been studied but may be implied by the trend toward decreasing attempts at vaginal birth after cesarean section: maternal morbidity and mortality rates are significantly increased with each subsequent cesarean birth.

Even though greater risks appear to face the breech infant, there remain many who believe that complete abandonment of vaginal delivery for the breech is not yet justified. The Term Breech Trial also has its detractors, who state inclusion of fetuses with estimated weights up to 4 kg and less than 2500 g, and procedural aberrations in labor assessment and adequacy (length of time permitted for first and second stage of labor, liberal use of induction and augmentation of labor), as well as worldwide differences in standards of obstetrical care and its providers make the trial's results not generalizable. No study is perfect in its methodology or results; the Term Breech Trial certainly adds to the body of literature on breech vaginal delivery but may not be the final answer to the question of the safety of vaginal breech delivery.

Special Clinical Circumstances and Risks: Preterm Breech, Hyperextended Head, Footling Breech

The various categories of breech presentation clearly demonstrate dissimilar risks, and management plans might vary among these situations. The premature breech, the breech with a hyperextended head, and the footling breech are categories that have high rates of fetal morbidity or mortality. Complications associated with incomplete dilatation and cephalic entrapment may be more frequent. For these three breech situations, in general, cesarean delivery appears to optimize fetal outcome and, therefore, is recommended.

Low birth weight (less than 2500 g) is a confounding factor in about one third of all breech presentations.[16] **Whereas the benefit of cesarean delivery for the breech infant weighing 1500 to 2500 g remains controversial,[12] some studies showed improved survival with abdominal delivery in the 1000 to 1500 g weight group.**[35] A multicenter study of long-term outcomes of vaginally delivered infants at 26 to 31 weeks' gestation found no differences in rates of death or developmental disability within 2 years of follow-up.[36] Traumatic morbidity is reportedly decreased in both weight groups by the use of cesarean delivery, including a lower rate of both intraventricular and periventricular hemorrhage. Although some advocate a trial of labor in the frank breech infant weighing over 1500 g, others recommend labor only when the infant exceeds 2000 g. There are proportionately fewer frank breech presentations in the low-birth-weight group. In fact, most infants weighing less than 1500 g and presenting as a breech are footling breeches. **Although most deaths in the very-low-birth-weight breech group are due to prematurity or lethal anomalies, cesarean delivery has been shown by some to decrease corrected perinatal mortality in this weight group compared with that in similar-sized vertex presentations.**[37] Other authors suggest that improved survival in these studies relates to improved neonatal care of the premature infant when compared with the outcomes of historical controls. However, when vaginal delivery of the preterm breech is chosen or is unavoidable, older studies demonstrated reduced fetal morbidity and mortality when conduction anesthesia and forceps for the delivery of the after-coming head are employed. Neither are commonplace in modern obstetrics.

Preterm premature rupture of the fetal membranes (PPROM) is associated with prematurity and chorioamnionitis, both of which have been found to be independent risk factors for the development of cerebral palsy (CP). PPROM is associated with a high rate of malpresentations because of prematurity and decreased amniotic fluid. Knowing the association of chorioamnionitis with periventricular leukomalacia (PVL), a lesion found to precede development of CP in the premature neonate, Baud and colleagues[38] correlated the mode of delivery with PVL, and subsequent CP in breech preterm deliveries. **The authors found that in the presence of chorioamnionitis, delivery by elective cesarean section was associated with a dramatic decrease in the incidence of PVL.**

Hyperextension of the fetal head during vaginal breech delivery has been consistently associated with a high (21%) risk of spinal cord injury. It is important to differentiate simple deflexion of the head from clear hyperextension, given that Ballas and colleagues demonstrated that simple deflexion carries no excess risk. Deflexion of the fetal vertex as opposed to hyperextension is similar to the relationships between the occipitofrontal cranial plane and the axis of the fetal cervical spine illustrated in Figure 18-5. Often, as labor progresses, spontaneous flexion will occur in response to fundal forces.

Finally, the footling breech carries a prohibitively high (16% to 19%) risk of cord prolapse during labor. In many cases, cord prolapse is manifest only late in labor, after commitment to vaginal delivery may have been made. Cord prolapse necessitates prompt cesarean delivery. Furthermore, the footling breech is a poor cervical dilator, and cephalic entrapment becomes more likely.

Breech Second Twin

Approximately one third of all twin gestations present as vertex/breech (i.e., first twin is a vertex, and the second is a breech; see also Chapter 30, Multiple Gestations). The management alternatives in the case of the vertex/breech twin pregnancy in labor include cesarean delivery, vaginal delivery of the first twin and attempted external cephalic version of the second twin, or internal podalic version and

extraction of the second twin. Blickstein and colleagues compared the obstetrical outcomes of 39 cases of vertex/breech twins with the outcomes of 48 vertex/vertex twins. **Although the breech second twin had a higher incidence of low birth weight and a longer hospital stay, the authors found no basis for elective cesarean delivery in this clinical circumstance.** The outcomes of another study of 136 pairs of vertex/nonvertex twins weighing more than 1500 g allows us to conclude that breech extraction of the second twin appears to be a safe alternative to cesarean delivery.[39] Laros and Dattel[40] studied 206 twin pairs and likewise found no clear advantage to arbitrary cesarean delivery because of a specific presentation. **When comparing outcomes of 390 vaginally delivered second twins (207 delivered vertex; 183 delivered breech), with 95% of the breech deliveries being total breech extractions, it is noted that no significant differences existed between the vertex and breech infants, even when stratified by birth weight.**[41] These outcomes assume the skills and experience required to perform a successful breech extraction. Any clinician uncomfortable with the prospective delivery of a singleton breech, however, would be unwise to consider a breech extraction of a second twin.

Vaginal delivery followed by external version is a viable alternative, using ultrasound in the delivery room to directly visualize the fetus. Often there is a transient decrease in uterine activity after the delivery of the first infant, which can be used to advantage in the performance of a cephalic version. Description of experience with 30 malpositioned second twins (12 transverse and 18 breech) shows that version after birth of the first twin was successful in 11 of the 12 transverse infants and in 16 of the 18 breech infants.[42] These twins were all older than 35 weeks' gestation, with intact membranes of the second twin after delivery of the first, no evidence of anomalies, and normal amniotic fluid volume.

If internal podalic version/extraction of the second twin is to be performed, it can be facilitated by ultrasonic guidance. A hand is inserted into the uterus, both fetal feet are identified and grasped with membranes intact, and traction is applied to bring the feet into the pelvis and out the introitus, with maternal expulsive efforts remaining the major force in effecting descent of the fetus. Membranes are left intact until both feet are at the introitus. Once membranes are ruptured, the delivery is subsequently managed as a footling breech delivery. If the operator has difficulty identifying the fetal feet, intrapartum ultrasound may be of assistance.

During breech extraction, and perhaps more often with a breech extraction of a smaller twin, the fetal head can become entrapped in the cervix. In such cases, the operator's entire hand is placed in the uterus, the fetal head is cradled, and as the hand is withdrawn, the head is protected.[43] This splinting technique has also been used for the safe extraction of the breech head at the time of cesarean delivery. Head entrapment may also occur because of increased uterine tone, or contractions. **In this case, a uterine relaxing agent may be employed, with nitroglycerin (50 to 200 mcg intravenously) being one of the fastest acting, safest agents in appropriately selected patients.** Terbutaline, ritodrine, or inhalational anesthesia may also be used.

A small, prospective trial in the near-term gestation (greater than 35 weeks) found no difference in neonatal morbidity between vaginal delivery and cesarean birth of vertex/nonvertex twins. However, increased maternal morbidity with cesarean delivery was found. Again, safe vaginal delivery of the breech second twin by podalic version and extraction requires specific skills and experience.

External Cephalic Version

External cephalic version (ECV) is a third alternative to vaginal delivery or cesarean delivery for the breech fetus.[4,44] Many have found that ECV significantly reduces the incidence of breech presentation in labor and is associated with few complications such as cord compression or placental abruption.[4] Reported success with ECV varies from 60% to 75%, with a similar percentage of these remaining vertex at the time of labor.[4] Although many infants in breech presentation before 34 weeks will convert spontaneously to a cephalic presentation, the percentage that spontaneously convert decreases as term approaches. Repetitive external version applied weekly after 34 weeks in one report was successful in converting more than two thirds of cases and reducing their breech presentation rate by 50%. **In another randomized trial of ECV in low-risk pregnancies between 37 and 39 weeks, success was achieved in 68% of 25 cases in the version group, whereas only 4 of the 23 controls converted to a vertex spontaneously before labor.**[44] All of those in whom external version was successful presented in labor as a vertex.[44] In another prospective, controlled study of ECV performed weekly between 33 weeks and term, 48% of the study group were vertex in labor compared with only 26% of controls. Another experience with 112 patients demonstrated a 49% success rate with ECV. The cesarean delivery rate was 17% among those patients with successful ECV compared with 78% among those patients with an unsuccessful version attempt.

Outcomes of pregnancies after ECV prove that it is a safe and effective intervention.[4] **The overall success rate among investigators in the United States was 65%, with an average cesarean delivery rate of 37% among those undergoing an attempted version compared with 83% among controls.** Successful version was reported more often in parous than nulliparous women and more often between 37 and 39 weeks than after 40 weeks. Fetal complications include abruption, a non-reassuring FHR pattern, rupture of membranes, cord prolapse, spontaneous conversion back to breech, and fetomaternal hemorrhage. Maternal complications include a high rate of cesarean delivery (up to 64% in one study; twofold to fourfold risk in another), primarily for dystocia, despite successful conversion.[45]

Gentle constant pressure applied in a relaxed patient with frequent FHR assessments are elements of success stressed by all investigators.[44] Methodology varies, although the "forward roll" is more widely supported than the "back flip" (Figure 18-25).[44] The mechanical goal is to squeeze the fetal vertex gently out of the fundal area to the transverse and finally into the lower segment of the uterus.

A number of factors predict success of ECV with reliability. A study by Burgos and colleagues in 2010 demonstrated increased rates of successful ECV at approximately

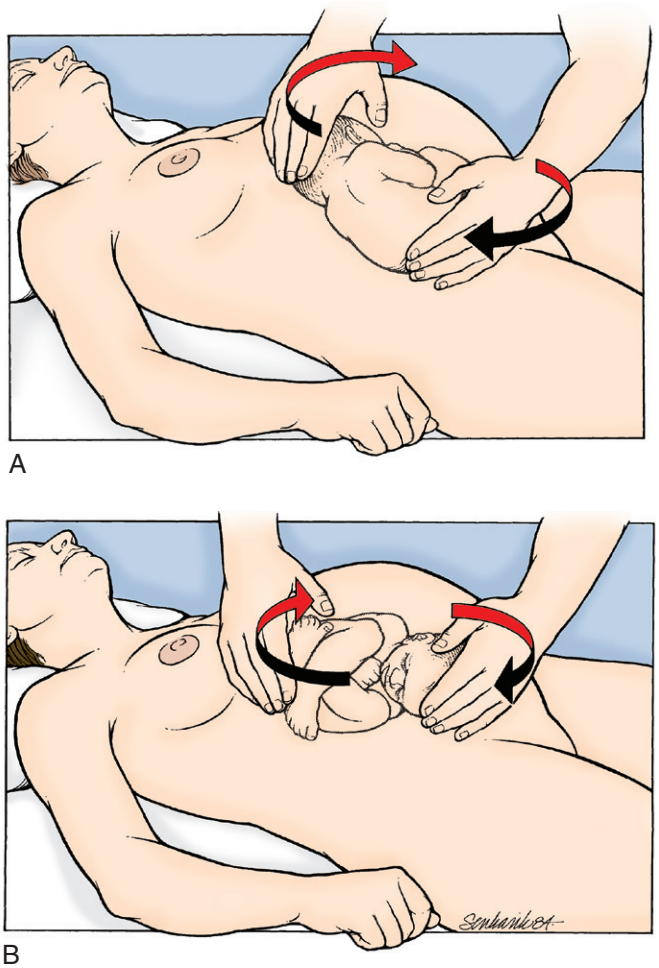

FIGURE 18-25. External cephalic version is accomplished by gently "squeezing" the fetus out of one area of the uterus and into another. Here, the "forward roll," often the most popular, is illustrated.

37 weeks' gestation with parity greater than 2 (OR 3.74; 95%CI 2.37 to 5.9), posterior placental location (OR 2.85; 1.87 to 4.36), and double footling breech as opposed to frank breech (2.77; 95%CI 1.16 to 6.62).[46] Complete breech also showed increased odds of success, but not to the extent that double footling did. Relative assessment of amniotic fluid was also made, and both "normal" and "abundant" fluid volumes showed improved successes. This study employed IV ritodrine, which is no longer available in the United States; therefore, these results may not be generalizable to our population, per se. Two recent studies showed improved successes when AFI exceeded 7 cm.[47,48] Tocolysis, regional anesthesia, and ultrasound during the procedure may also be helpful. Use of a number of tocolytics has been reported; however, considerable experience has been reported using intravenous ritodrine, which has been voluntarily pulled from the U.S. market by the manufacturer. Other agents used are hexoprenaline, salbutamol, nitroglycerin, and terbutaline (which now carries an FDA black box warning). A randomized trial of 103 nulliparous patients found success rates with subcutaneous terbutaline were 52% compared with 27% in the control group. No adverse maternal effects resulting from the drug were found.[49] A randomized trial of 58 patients at 37 to 41 weeks' gestation with breech presentation found no benefit from β-mimetic tocolysis, with success rates of approximately two thirds in each group. Factors associated with failure of version included obesity, deep pelvic engagement of the breech, oligohydramnios, and posterior positioning of the fetal back. The use of regional anesthesia for external cephalic version has also been controversial. Many believe that operators might apply excessive pressure to the maternal abdomen when epidural anesthesia is employed, which might make fetal compromise more likely, indicated by FHR decelerations and possibly related to placental abruption. However, a randomized trial of 69 women using epidural anesthesia demonstrated a better than twofold increase in success of the procedure when epidural was employed.[50] Disparate results are demonstrated when combined spinal-epidural analgesia or spinal anesthesia is employed. A randomized study of nulliparas undergoing ECV showed fourfold improvement in ECV success and reduced visual analog pain score when spinal anesthesia was used compared to no anesthetic.[51] Another randomized trial of combined spinal epidural at analgesic doses versus systemic opioids showed no difference in rates of ECV success.[52] This trial had low ECV success rates both overall (39%) and each arm (47% in CSE and 31% in opioid arms, respectively), and the utilization of 47 different physicians suggests the possibility of highly varied skill levels across providers. This trial specifically aimed to determine if analgesia as opposed to anesthesia improves success. It appear that the relationship of ECV success may be dose dependent where neuraxial anesthetic use is concerned, because other trials using anesthetic doses favor improved ECV success rates. A Cochrane database study of the effects of tocolysis, regional anesthesia, vibroacoustic stimulation, and transabdominal amnioinfusion for ECV was performed and reported in 2004. **Tocolysis reduced the failure rate of ECV (RR = 0.74, 95% CI, 0.64 to 0.87); the reduction of noncephalic presentations at birth did not reach significance, but the cesarean delivery rate was reduced (RR = 0.85, 95% CI, 0.72 to 0.99). Regional anesthesia also showed a reduced rate of cesarean sections and noncephalic presentations at birth in two out of five trials included. No other interventions improved success rates of ECV.**[53] Performing the version before term does not appear to significantly affect the likelihood of noncephalic presentations at term (RR = 1.02, 95% CI, 0.89 to 1.17); cesarean delivery (RR = 1.10, 95% CI, 0.78 to 1.54); low Apgar scores (RR = 0.81, 95% CI, 0.44 to 1.49); or perinatal mortality (RR = 1.19, 95% CI, 0.46 to 3.05).[54] Fetomaternal transfusion has been reported to occur in up to 6% of patients undergoing external version,[55] and thus, Rh-negative unsensitized women should receive Rh-immune globulin. Quantitation of fetomaternal hemorrhage with the Kleihauer-Betke or flow cytometry test will determine the number of ampules of Rh immune globulin to be administered.

In the case of the gravida with a previous cesarean delivery, ECV has also been controversial. Studies of limited sample size have concluded that ECV is safe for mother and fetus and results in increased vaginal delivery rates. Success rates of up to 82% in patients with a previous cesarean delivery have been reported.[56] Use of intravenous

ritodrine tocolysis in 11 patients with history of previous low cervical transverse cesarean section resulted in no uterine dehiscences found clinically or at the time of cesarean delivery.[57]

A 2009 study by Sela and colleagues that included a review of the world literature (of ≥36-week nonanomalous singleton fetuses; all were retrospective studies) found ECV success rates in multipara ranging between 65.8% and 100% (mean 76.6%) in patients with a single prior cesarean delivery.[58] Prior successful vaginal delivery was predictive of higher success rates for ECV overall, and no excess morbidity/mortality or asymptomatic scar dehiscence was noted in these patients. The largest study of complication rates from ECV included patients with a prior cesarean delivery but neither the success or complication rates for this subgroup was reported; descriptions of overall complications included no case of overt uterine rupture or scar dehiscence.[59] With the liberalization of recommendations for patients with two prior cesarean deliveries to attempt TOLAC (trial of labor after cesarean) with appropriate counseling, it would not be surprising to this author if the next edition of this text includes information on success rates for ECV in patients with two prior cesarean deliveries, given evidence of normal placentation.

Of interest are the recent trials employing moxibustion of acupoint BL 67 (Zhiyin; beside the outer corner of the fifth toenail) to resolve breech presentation, with and without acupuncture or percutaneous low-frequency electrical stimulation, also applied to the same acupoint. Moxibustion is a traditional Chinese method that uses the application of heat generated by the combustion of herbs to provide stimulation to accupoints. The particular herb used, *Artemisia vulgaris* (mugwort), is purported to work by stimulating fetal movements. Of 130 patients in the treatment group of one study, only one required cephalic version, whereas 24 of 130 in the controls group required this procedure. Seventy-five percent of the treatment group and 62% of the control group were cephalic at birth.[60] When acupuncture is used in conjunction with moxibustion, rates of spontaneous conversion approach 54% compared with the observed group (37%, $P = 0.01$).[61] Another study noted significantly higher spontaneous and moxibustion-induced correction rates of breech presentation: 74% versus 92.5%, respectively.[62] This study enrolled patients on average 4 weeks earlier than the prior study. No FHR abnormalities have been noted with the use of acupuncture and moxibustion in combination.[63] **A large meta-analysis from 2009 that included 1087 patients from studies comparing true moxibustion at BL67 alone or in combination with acupuncture, or postural measures to observation or postural methods alone, showed an improvement in the rate of cephalic version among the moxibustion group (72.5% vs. 53.2%; RR 1.36, 95%CI 1.17 to 1.58).** The increasing role of complementary and alternative medicine and traditional techniques in modern practice is only beginning to be realized, and remains to be further examined.

SHOULDER DYSTOCIA

Shoulder dystocia is diagnosed when, after delivery of the fetal head, further expulsion of the infant is prevented by impaction of the fetal shoulders within the maternal pelvis. Specific efforts are necessary to facilitate delivery (Figure 18-26).

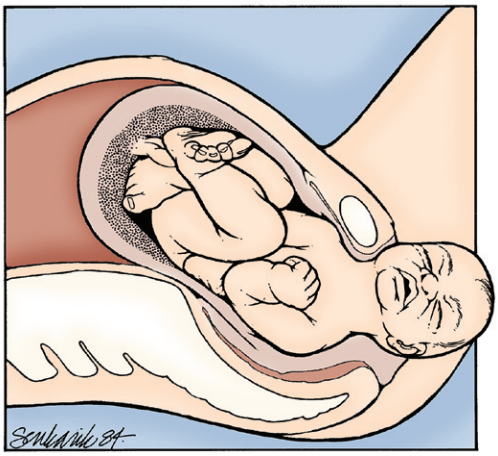

FIGURE 18-26. When delivery of the fetal head is not followed by delivery of the shoulders, the anterior shoulder has often become caught behind the symphysis, as illustrated here. The head may retract toward the perineum. Desperate traction on the fetal head is not likely to facilitate delivery and may lead to trauma.

Although a difficult shoulder dystocia occurs infrequently, one does not soon forget the experience. Often, but not always, at the end of a difficult labor, the fetal head may be delivered spontaneously or by forceps, but progresses no further. The fetal head appears to be drawn back with the chin close to the maternal perineum or thigh, creating difficulty suctioning the infant's mouth. As maternal expulsive efforts are encouraged, the fetal head becomes plethoric, and the danger to the infant is apparent if delivery cannot be promptly accomplished.

Shoulder dystocia has been reported in 0.15% to 1.7% of all vaginal deliveries,[64] but this number is highly variable based on lack of uniformity of definition. **Spong and colleagues have proposed employing the use of a "prolonged head to body delivery time (>60 seconds) and/or the necessitated use of ancillary obstetric measures" designed to facilitate delivery of the obstructed shoulder.**[65] **The >60-second interval is indicative of >2 standard deviations (SDs) above the mean for head to body delivery times in uncomplicated deliveries**. All investigators have documented increased perinatal morbidity and mortality rates with shoulder dystocia.[64] Mortality rate varies from 21 to 290 in 1000 when shoulder girdle impaction occurs, and neonatal morbidity has been reported to be immediately obvious in 20% of infants.[64] In reviewing 131 macrosomic infants, Boyd and colleagues[66] found that only half of all cases of brachial palsy occurring in macrosomic infants also carried a diagnosis of shoulder dystocia. Obviously, brachial palsy was noted in half of these cases without a clinical diagnosis of shoulder dystocia. Severe asphyxia was observed in 143 of 1000 births with shoulder dystocia compared with 14 of 1000 overall.[66] Fetal morbidity is not always immediately apparent. McCall[67] found that 28% of infants born with shoulder dystocia demonstrated some neuropsychiatric dysfunction at 5- to 10-year follow-up. Fewer than one half of these children had immediate morbidity. **The**

neonatal morbidity of greatest concern is brachial plexus injury, resulting from trauma to cervical nerve roots 5 and 6. Fortunately, most cases are transient, with full recovery observed in 90% to 95% of infants.[68]

Although shoulder dystocia has traditionally been strongly associated with macrosomia, up to half of cases of shoulder dystocia occur in neonates weighing less than 4000 g.[69,70] However, Acker and colleagues[68] found that the relative probability of shoulder dystocia in the 7% of infants weighing more than 4000 g was 11 times greater than the average, and in the 2% of infants weighing more than 4500 g it was 22 times greater. With macrosomia or continued fetal growth beyond term, the trunk and particularly the chest grow larger relative to the head. Chest circumference exceeds the head circumference in 80% of cases.[69] Arms also contribute to the greater dimensions of the upper body. **Macrosomia shows the strongest correlation with shoulder dystocia of any clinical factor and occurs more often with gestational diabetes and twice as often in prolonged pregnancies. Macrosomia is also associated with an abnormal 1-hour glucose screen and a nondiagnostic 3-hour glucose tolerance test. Other clinical factors associated with shoulder dystocia appear to be related to macrosomia as well and include maternal obesity,**[66,71] **previous birth of an infant weighing more than 4000 g,**[66,69,71] **diabetes mellitus,**[71] **prolonged second stage of labor,**[70,71] **prolonged deceleration phase (8 to 10 cm), instrumental midpelvic delivery, and previous shoulder dystocia, which has been found to have a recurrence risk of almost 14%.**[72] Increased maternal age and excess maternal weight gain have been found by some but not all investigators[66,71] to increase the risk of macrosomia and shoulder dystocia. Father's birth weight and adult size during young adulthood have also been found to correlate with fetal weight in addition to the traditional determinants.[70,74]

Macrosomia has been variously defined as a birth weight greater than either 4000 g or 4500 g.[64,66] Male predominance is routinely observed, and the condition is associated with the clinical features described earlier. **The two most common complications observed with macrosomia are postpartum hemorrhage and shoulder dystocia.**[71] Golditch and Kirkman[74] observed shoulder dystocia in 3% of deliveries of infants weighing between 4100 and 4500 g and in 8.2% of those weighing more than 4500 g. Benedetti and Gabbe[64] reported that fetal injury occurred in 47% of infants weighing more than 4000 g who were delivered from the midpelvis and had shoulder dystocia.

Clinical efforts to detect macrosomia prenatally could be helpful in anticipating problems with delivery of the shoulders. Such efforts, however, have been disappointing. Numerous sonographic markers have been assessed to determine their usefulness in predicting macrosomia. These include the estimation of fetal weight using a variety of fetal dimensions and the comparison of chest to head circumference. **Most recently, another biometric parameter, the fetal abdominal diameter–biparietal diameter difference (AD-BPD), was evaluated retrospectively both in diabetic and in nondiabetic women.**[75] **A difference of greater than or equal to 2.6 cm was found to predict shoulder dystocia with sensitivity and specificity of 100% and 46%, respectively, with positive and negative predictive values of 30% and 100%, respectively.** A similar study was performed in 2007 by Miller and colleagues.[76] Patients who experienced a dystocia birth were compared to a nondystocia group; all participants had a growth scan within the preceding 2 weeks. The dystocia group had an AD-BPD difference that was greater (2.9 vs. 1.97, $p = 0.0002$), and when the difference was ≥2.6 cm the risk of dystocia was 25% for unselected patients and 38.5% for patients with diabetes. Overall, an OR of 5.88 (95% CI 1.18 to 19.09) for presence of dystocia was noted in all patients and carried a sensitivity of 35.7% and a specificity of 91.4%. For diabetic patients, an OR of 7.19 (95% CI 1.58 to 32.67) and carried SE and SP of 55.5% and 85.2%.[76] **Furthermore, a fetal abdominal circumference of 35 cm or greater has been found to identify more then 90% of macrosomic infants.**[77] Both of these studies are retrospective and limited by difficulty measuring the fetal abdominal outline at advanced gestational age caused by acoustic shadowing. Parks and Ziel[71] found that of 110 macrosomic infants, the diagnosis was made prenatally in only 20%. The clinical estimate of birth weight was more than 3 lb in error in 6% of cases. **Numerous efforts in the literature repeatedly demonstrate the shortcomings of both clinical and ultrasonographic estimations of fetal weight and have concluded that the best estimation is a combination of the two.**

There is a growing trend to consider cesarean delivery of any infant with an estimated weight more than 4500 g or of any infant of a diabetic mother with an estimated weight more than 4000 g[70] to avoid birth trauma, particularly brachial plexus injury. Any consideration of elective abdominal delivery on the basis of estimated fetal weight alone, however, must consider the technical error of the method. **If 90% confidence is desired that the actual fetal weight is at least 4000 g, the sonographic estimate by most current methods must exceed 4600 g. This is a result of the expected methodologic error of ±10% (±1 SD).** Furthermore, the fetal vertex is often too deeply engaged in the pelvis to allow accurate measurement of head circumference. Estimated fetal weight should be only one of several factors considered in the management of the laboring patient. In the obese diabetic patient with an estimated fetal weight more than 4500 g and showing poor progress in labor, cesarean delivery may be the most prudent course. However, in most other cases, the risks of cesarean delivery to the mother, the accuracy of prediction of macrosomia, and the alternative of a carefully monitored trial of labor should be discussed. Gross and colleagues[78] carefully reviewed the clinical characteristics of 394 mothers delivering infants weighing more than 4000 g and concluded that although birth weight, prolonged deceleration phase, and length of second stage were all individually predictive, no prospective model adequately discriminated the infant destined to sustain trauma from shoulder dystocia from the infant not so destined. Taking this one step further, identifying macrosomic fetuses for the ultimate prevention of neurologic injury has been the subject of studies that report a significant increase in annual cost for routine cesarean deliveries for macrosomia in the nondiabetic population but improved ratios of cost per brachial plexus injury prevented per year in the diabetic population. **Ultrasound detection and elective cesarean delivery of the macrosomic infant of the nondiabetic mother has been predicted to result in $4.9 million of expenditure to prevent one**

permanent neurologic injury, whereas one maternal death would result from cesarean delivery for every 3.2 neonatal nerve injuries prevented.[78] Elective cesarean delivery for fetuses of diabetic mothers (both gestational and pregestational) has also been controversial. Langer and colleagues[79] found that 76% of shoulder dystocias could be prevented if a policy of elective cesarean delivery was instituted at an estimated weight of 4250 g, whereas Acker and colleagues[70] found that using a fetal weight threshold of 4000 g, 55% could be prevented in the diabetic population. Although many clinicians perform an elective cesarean delivery in a patient with diabetes mellitus and an estimated fetal weight of 4000 to 4500 g,[79] Keller and colleagues expressed concern about the inaccuracy of ultrasound estimation of fetal weight in the gestational diabetic population, with 50% of shoulder dystocias occurring in fetuses who weighed less than 4000 g.[80]

Using computer modeling, the forces applied to the fetal brachial plexus during dystocia delivery, and also with the addition of release maneuvers, were estimated by Grimm and colleagues[81] **All maneuvers resulted in less stretch to the brachial plexus than with standard lithotomy delivery alone. Delivering the posterior arm showed a 71% reduction in stretch applied to the anterior nerve plexus, and was the maneuver that required the least force to deliver the anterior arm.** In the past, however, it was believed that brachial plexus injury resulted primarily from operator-induced excess traction in the setting of shoulder dystocia. **Evidence now exists that plexus injuries may result from endogenous forces during the second stage of labor. Shoulder dystocia itself places the brachial plexus on stretch. Maternal endogenous forces may actually exceed clinician-applied exogenous forces as well.**[82] The occurrence of brachial plexus injury in the absence of shoulder dystocia has been described and attributed to in utero forces, such as the posterior shoulder impacting on the sacral promontory (although anterior injuries have been described as well), malpresentations,[83] and dysfunctional labor, mostly precipitate labor.[70] Interestingly, in neonates with brachial plexus injury without shoulder dystocia, there was a trend toward lower birth weight, more clavicular fractures, and longer persistence of the condition than their counterparts in the shoulder-dystocia-present group.[84]

The most effective preventive measure is to be familiar with the normal mechanism of labor and to be constantly prepared to deal with shoulder dystocia. Normally, after the delivery of the head, external rotation (restitution) occurs, returning the head to its natural perpendicular relationship to the shoulder girdle. The fetal sagittal suture is usually oblique to the AP diameter of the outlet, and the shoulders occupy the opposite oblique diameter of the inlet (Figure 18-27). As the shoulders descend in response to maternal pushing, the anterior shoulder emerges from its oblique axis under one of the pubic rami. However, if the anterior shoulder descends in the AP diameter of the outlet and the fetus is relatively large for the outlet, impaction behind the symphysis can occur, and further descent is blocked. Shoulder dystocia also occurs with an extremely rapid delivery of the head, as can occur with vacuum extraction or forceps or precipitous labor.

Successful treatment follows anticipation and preparation. Anticipation involves the prenatal suspicion of macrosomia by clinical and sonographic means. One must be aware of the clinical features that have been cited and consider a pregnancy at high risk for macrosomia and, therefore, for shoulder dystocia.

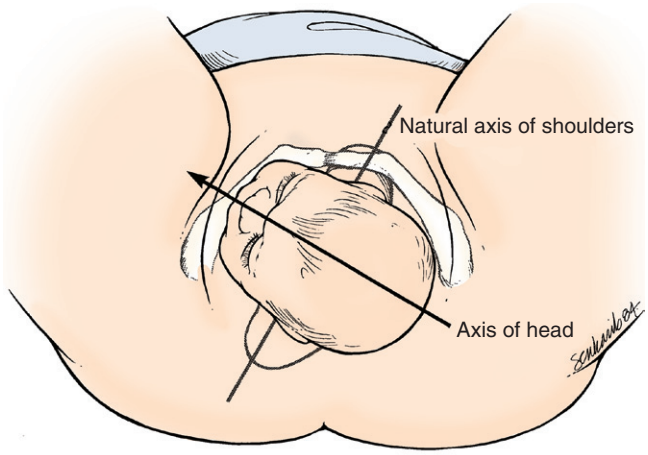

FIGURE 18-27. After delivery of the head, "restitution" results in the long axis of the head reassuming its normal orientation to the shoulders as seen here.

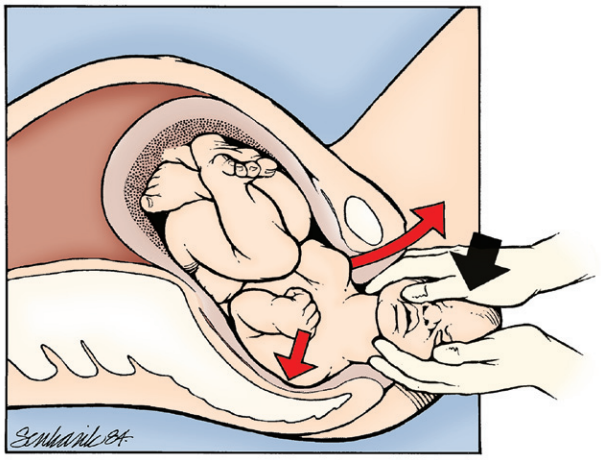

FIGURE 18-28. Gentle, symmetrical pressure on the head will move the posterior shoulder into the hollow of the sacrum and encourage delivery of the anterior shoulder. Care should be taken not to "pry" the anterior shoulder out asymmetrically, because this might lead to trauma to the anterior brachial plexus.

Such deliveries are best managed in a delivery room. Deliveries in bed increase the difficulty of reducing a shoulder dystocia because the bedding precludes fullest use of the posterior pelvis and outlet. Strong consideration for cesarean delivery is recommended when a prolonged second stage occurs in association with macrosomia.

Once a vaginal delivery has begun, the obstetrician must resist the temptation to rotate the head forcibly to a transverse axis. Maternal expulsive efforts should be used rather than traction. Gentle manual pressure on the fetal head inferiorly and posteriorly will push the posterior shoulder into the hollow of the sacrum, increasing the room for the anterior shoulder to pass under the pubis (Figure 18-28). This pressure is not outward traction and must be symmetrical. If the head is pressed asymmetrically, as if to

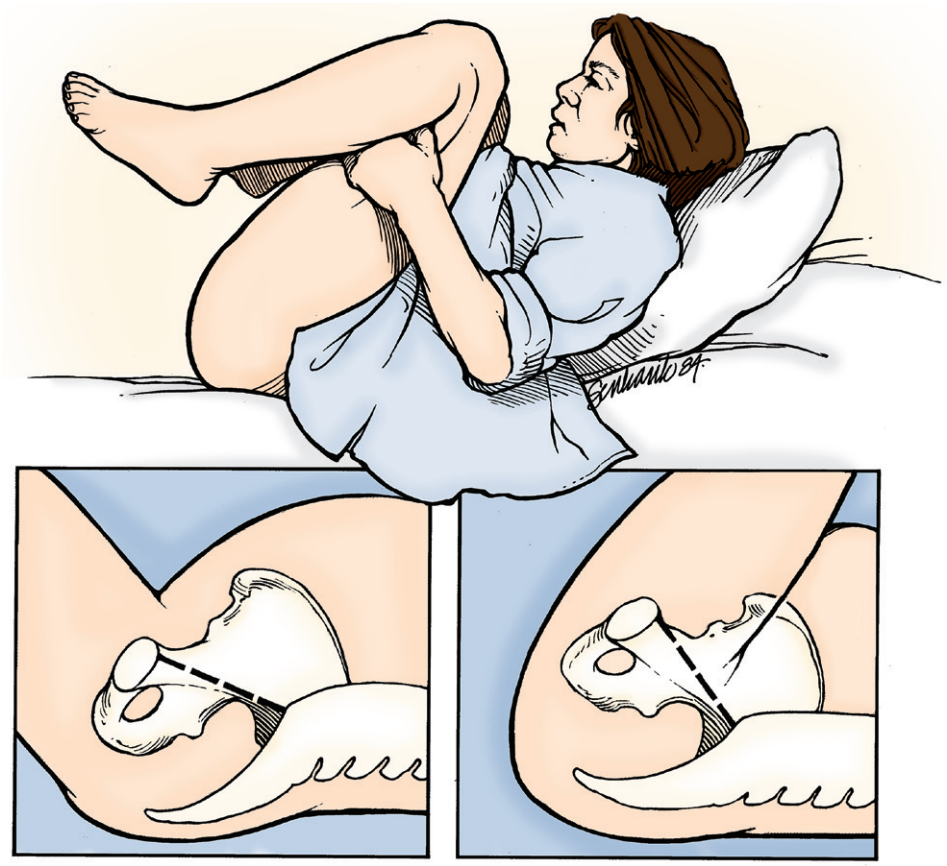

FIGURE 18-29. The least invasive maneuver to disimpact the shoulders is the McRoberts maneuver. Sharp ventral flexion of the maternal hips results in ventral rotation of the maternal pelvis and an increase in the useful size of the outlet.

"pry" the anterior shoulder out, brachial plexus injury is more likely.

If delivery is not accomplished, a deliberate, planned sequence of efforts should then be initiated. Pulling desperately on the fetal head is dangerous and should be avoided, and fundal expulsive efforts, including maternal pushing and fundal pressure, should be discontinued. Fundal pressure applied before disimpaction or rotation of the shoulders will not facilitate delivery and may be counterproductive in that it may increase the degree of impaction of the shoulder.

The McRoberts maneuver[85] is a simple, logical, and usually successful measure to promote delivery of the shoulders. **The McRoberts maneuver involves hyperflexion of maternal legs on the maternal abdomen that results in flattening of the lumbar spine and ventral rotation of the maternal pelvis and symphysis** (Figure 18-29). This maneuver may increase the useful size of the posterior outlet, resulting in easier disimpaction of the anterior shoulder. Gonik and colleagues[86] showed that the McRoberts maneuver significantly reduces shoulder extraction forces, brachial plexus stretching, and likelihood of clavicular fracture. In a retrospective review of shoulder dystocia, Gherman and colleagues[87] found that the McRoberts maneuver was the only step required in 42% of 236 cases. **When shoulder dystocia occurs because of failure of the bisacromial diameter to engage, the Walcher position, which entails dropping the maternal legs down toward the floor with concurrent suprapubic pressure in a dorsal-caudal direction, has been advocated. Only then, while constant suprapubic pressure is being maintained, should the parturient be placed in the McRoberts position; this may allow for the disimpaction of the fetal shoulder from the symphysis by increasing the AP diameter of the inlet before increasing the outlet.** Additionally, the "all fours," or Gaskin maneuver, which differs from the knee-chest position, may relieve the dystocia.[88] Use of this maneuver is reasonable only in the setting of a mobile parturient with no significant motor blockade from regional anesthetic, and a stable and wide surface on which to assume this position in order to avoid the potential for injury during transition to this position.

If the shoulders remain undelivered, often only moderate suprapubic pressure is required to disimpact the anterior shoulder and allow delivery. If this is not effective, **the operator's hand may be passed behind the occiput into the vagina, and the anterior shoulder may be pushed forward to the oblique,** after which, with maternal efforts and gentle posterior pressure, delivery should occur (Figure 18-30). **Alternatively, the posterior shoulder may be rotated forward, through a 180-degree arc, and passed under the pubic ramus as in turning a screw (Wood's screw maneuver). As the posterior shoulder rotates anteriorly, delivery will often occur.**[89]

Many authorities have advocated delivery of the posterior arm (Barnum's maneuver; Jacquemier's maneuver)

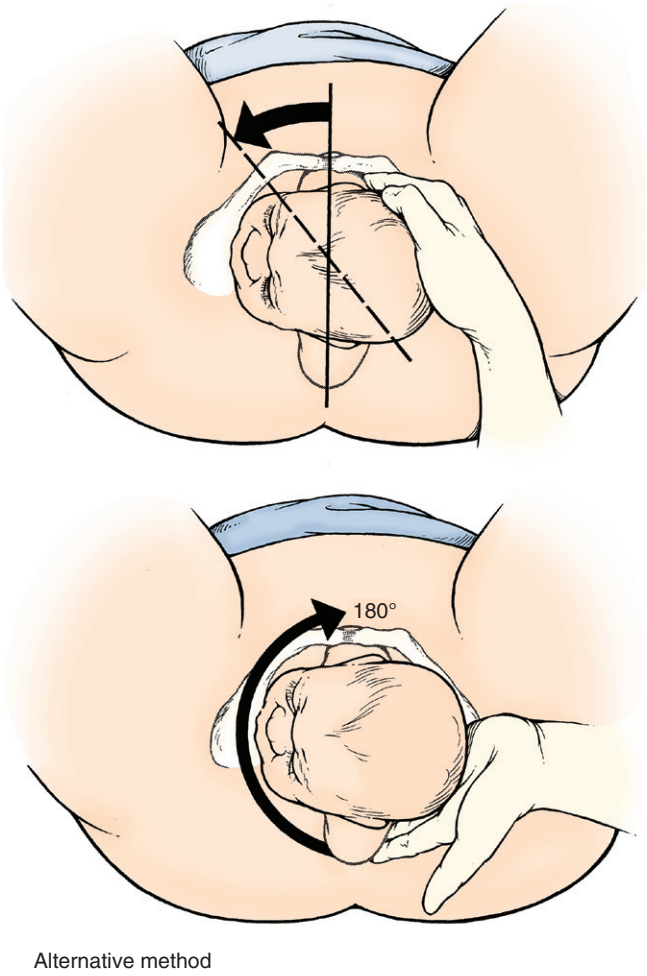

FIGURE 18-30. Rotation of the anterior shoulder forward through a small arc or the posterior shoulder forward through a larger one will often lead to descent and delivery of the shoulders. Forward rotation is preferred, because it tends to compress and diminish the size of the shoulder girdle, whereas backward rotation would open the shoulder girdle and increase the size.

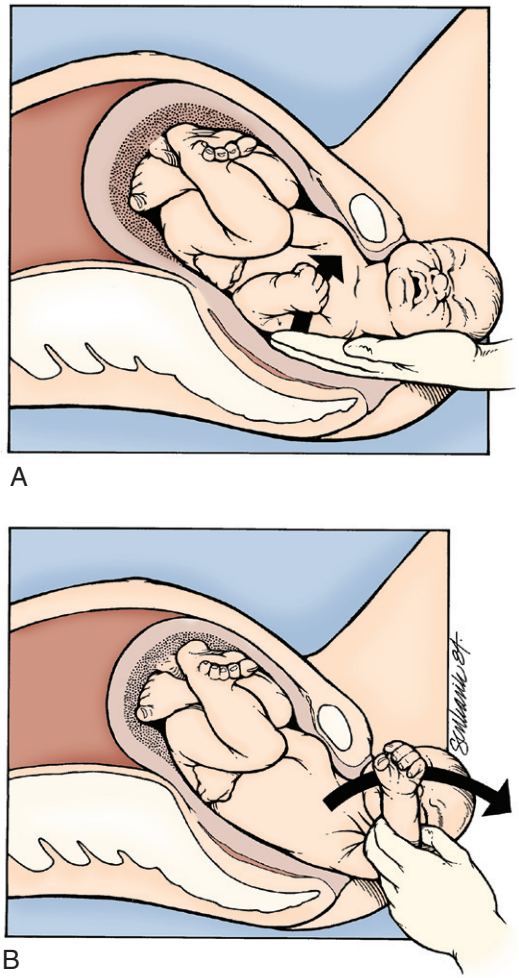

FIGURE 18-31. The operator here inserts a hand and sweeps the posterior arm across the chest and over the perineum. Care should be taken to distribute the pressure evenly across the humerus to avoid unnecessary fracture.

and shoulder should the aforementioned methods fail. The operator's hand is passed into the vagina, following the posterior arm of the fetus to the elbow. The arm is flexed and swept out over the chest and the perineum (Figure 18-31). In some cases, delivery will now occur without further manipulation. In others, rotation of the trunk, bringing the freed posterior arm anteriorly, is required.[69] **These maneuvers are highly likely to fracture the clavicle (up to 25%), humerus (up to 15%), or both, or they may result in transient or permanent nerve injury in up to approximately 9% of cases.**[89] Overall, similar rates of bone fracture were noted when any type of manipulation was performed to accomplish delivery of an impacted fetal shoulder.[90] Deliberate fracture of the clavicle is possible and will facilitate delivery by diminishing the rigidity and size of the shoulder girdle. It is best if the pressure is exerted in a direction away from the lung to avoid puncture. Sharp instrumental transection of the clavicle is not recommended, because lung puncture is common with such a method, and infection of the bone through the open wound is a serious possible complication.

Maneuvers to prevent shoulder dystocia have been evaluated in two separate studies: one compared McRoberts position and suprapubic pressure to no intervention,[91] and the other examined the use of lithotomy versus McRoberts position.[92] In the first study, head to body delivery times did not differ significantly. The "prophylactic" group had greater numbers of subjects who required cesarean delivery, and, when these were included in the analysis, results strongly favored use of prophylactic measures for reducing incidence of shoulder dystocia (RR = 0.33, 95% CI, 0.12 to 0.86). A greater number of patients required additional maneuvers to relieve the shoulder dystocia in the control group. Additionally, no differences were noted in NICU admissions or birth injuries. This study does not support routine use of these maneuvers in cases of suspected shoulder dystocia. The study by Poggi and colleagues[92] compared the traditional lithotomy position to McRoberts position, and additionally evaluated the forces required to release the shoulder with force-sensing gloves. The study concluded that peak forces and force rates did not differ between groups. The head to body delivery time was longer by 4 seconds in the prophylactic group, which was

statistically significant. There were similar numbers of actual shoulder dystocias (one per group) encountered in each arm. **In summary, it is unclear whether the use of prophylactic measures in patients at risk for shoulder dystocia are of benefit.**

The Gaskin's maneuver (all-fours maneuver) has been described and used with varying degrees of penetration into physician practice, but is commonly used for shoulder dystocia management in the modern practice of midwifery.[93] A survey of physicians in the middle Tennessee area found that only 8% of practitioners knew of the all-fours maneuver.[94] **The procedure involves moving the parturient onto hands and knees and then effecting delivery.** The purported mechanism of action is an expansion at the sacroiliac joints, which can increase the sagittal diameter of the pelvic outlet by 1 to 2 cm.[95] Change of maternal position may help to disimpact the shoulders, and gravitational forces push the posterior shoulder anteriorly, allowing it to bypass the sacral promontory. This maneuver has not been tested prospectively or comparatively to the traditional shoulder-dystocia-relieving maneuvers, and may be impractical for some patients. Reports of 82 consecutive cases of shoulder dystocia managed with the all-fours maneuver showed no increased maternal or neonatal morbidity or mortality, with only one case of humerus fracture noted in a fetus whose weight exceeded 4500 g. Mean diagnosis to delivery time was 2.3 minutes ±1 minute (SD).[96] Delivery in all fours requires a stable surface, generally, not a narrow OR table, and a fully mobile patient. Fetal monitors and intravenous lines may hinder the patient's mobility and neuraxial anesthesia, with concomitant motor blockade, may reduce strength, making this maneuver unsafe in some situations.

Two techniques rarely used in the United States for the management of shoulder dystocia are vaginal replacement of the fetal head with cesarean delivery (Zavanelli maneuver) and subcutaneous symphysiotomy. Sandberg[97] reviewed the Zavanelli maneuver for both the vertex- and breech-presenting undeliverable fetuses. Cephalic replacement was successful in 84 of 92 vertex-presenting fetuses, and in 11 of 11 breech-presenting fetuses, podalic replacement was successful. Maternal risks included soft tissue trauma and sepsis, but the fetal risks were described as "minimal," with no fetal injuries attributed to the maneuver; this may be misleading because of the presence of a multitude of etiologies for permanent injury or death, likely from attempts at disimpaction, prolonged delivery time, and hypoxia.[97] O'Leary and Cuva[98] described 35 cases, 31 of which were considered successful and one of which needed a hysterotomy incision to allow manual disimpaction of the fetal shoulders and facilitate vaginal delivery when the fetal head could not be replaced into the vagina from below.

Subcutaneous symphysiotomy has been practiced in remote areas of the world for many years as an expedient alternative to cesarean delivery with very good results.[99] In a case series of three symphysiotomies, the procedure was used as a last resort and was associated with the death of all three neonates because of hypoxic complications. The procedure was concluded to be safe and effective as long as attention is paid to the three main points in the procedure: lateral support of the legs, partial sharp dissection of the symphysis, and displacement of the urethra to the side with an indwelling urinary catheter.[100] **However, neither cephalic replacement nor symphysiotomy has been widely or often used in obstetrical practice in the United States. Attempted implementation of either method by the inexperienced practitioner before the trial of more conventional remedies may increase risk to the child, the mother, and the clinician.**

In summary, shoulder dystocia is not precisely predictable but may be anticipated in the case of a variety of predisposing clinical conditions. Shoulder dystocia will, in most cases, respond to any or all of several prudent interventions. The specific method used to disimpact the shoulder is probably not as critical as the practice of a careful, methodical approach to the problem and the avoidance of desperate, potentially traumatic or asymmetric traction. The maneuvers used should be carefully described in the delivery note. There may not be any complication of labor and delivery when forethought is used to achieve a successful outcome with shoulder dystocia.

KEY POINTS

- The "fetal lie" indicates the orientation of the fetal spine relative to that of the mother. Normal fetal lie is longitudinal and by itself does not connote whether the presentation is cephalic or breech.
- Cord prolapse occurs 20 times as often with an abnormal axial lie as it does with a cephalic presentation.
- Fetal malformations are observed in more than half of infants with a face presentation.
- Fetal malpresentation requires timely diagnostic exclusion of major fetal or uterine malformations and/or abnormal placentation.
- With few exceptions, a closely monitored labor and vaginal delivery is a safe possibility with most malpresentations. However, cesarean delivery is the only acceptable alternative if normal progress toward spontaneous vaginal delivery is not observed.
- External cephalic version of the infant in breech presentation near term is a safe and often successful management option. Use of tocolytics and epidural anesthesia may improve success.
- Appropriate training and experience is a prerequisite to the safe vaginal delivery of selected infants in breech presentation.
- Simple compound presentation may be permitted a trial of labor as long as labor progresses normally with reassuring fetal status. Compression or reduction of the fetal part may result in damage, however.
- Shoulder dystocia cannot be precisely predicted or prevented but is often associated with macrosomia, maternal obesity, gestational diabetes, and a prolonged pregnancy.
- The clinician must be prepared to deal with shoulder dystocia at every vaginal delivery with a deliberate, controlled sequence of interventions.

KEY ABBREVIATIONS

Fresh Frozen Plasma	FFP
Packed Red Blood Cells	PRBCs

Obstetrical hemorrhage is one of the leading causes of maternal morbidity and mortality throughout the world. Not only is hemorrhage the leading reason for an obstetrical admission to the intensive care unit, it is responsible for 17% to 25% of all pregnancy-related deaths.[1,2] Because of this significant contribution to maternal morbidity and mortality, it is critical for the obstetrician to have a thorough understanding of the hemodynamic changes that accompany pregnancy and the maternal adaptations that occur with excessive blood loss.

PREGNANCY-RELATED HEMODYNAMIC CHANGES

Pregnancy is associated with four significant hemodynamic changes. The first of these changes is **plasma volume expansion.** The average singleton pregnancy has a 40% to 50% increase in plasma volume by the 30th week of gestation. This increase in plasma volume is accompanied by an **increase in red blood cell mass**. With appropriate substrate availability, red blood cell mass can be expected to increase 20% to 30% by the end of pregnancy. **Maternal cardiac output rises** with normal pregnancy owing to both increased stroke volume and heart rate. Consensus exists that the average rise in cardiac output is 30% to 50% above nonpregnant levels, with the peak occurring in the early third trimester. **Systemic vascular resistance falls** in parallel with this rise in cardiac output and blood volume expansion. Finally, **fibrinogen and the majority of procoagulant blood factors (II, VII, VIII, IX, and X) increase** during pregnancy.[3] These four physiologic changes are protective of maternal hemodynamic status and, thus, allow for further physiologic adaptations that accompany obstetrical hemorrhage.

PHYSIOLOGIC ADAPTATION TO HEMORRHAGE

During pregnancy and the puerperium, a **defined sequence of physiologic adaptations takes place with hemorrhage** (Figure 19-1). When 10% of the circulatory blood volume is lost, vasoconstriction occurs in both the arterial and venous compartments in order to maintain blood pressure and preserve blood flow to essential organs. As blood loss reaches 20% or more of the total blood volume, increases in systemic vascular resistance can no longer compensate for the lost intravascular volume and blood pressure decreases. Cardiac output falls in parallel because of a loss in preload, resulting in poor end-organ perfusion. If the intravascular volume is not appropriately replaced, cardiogenic shock will ensue.

In severe preeclampsia, these physiologic adaptations are altered. Unlike in most pregnant patients, the protective mechanism of blood volume expansion is diminished with severe preeclampsia. It is estimated that plasma volume expansion is 9% lower in preeclamptic patients.[4] In addition, because of the significant vasoconstriction that accompanies preeclampsia, blood loss in these patients may be underestimated because blood pressure is often maintained in the normotensive range despite significant hemorrhage. Finally, with preeclampsia, oliguria may not be as reliable an indicator of poor end-organ perfusion secondary to hemorrhage because reduced urine output is typically a manifestation of the severity of the hypertensive disorder.

CLASSIFICATION OF HEMORRHAGE

A standard classification for acute blood loss is illustrated in Table 19-1. **Understanding the physiologic responses that accompany varying degrees of volume deficit can assist the clinician when caring for hemorrhaging patients.** Determination of the hemorrhage class reflects the volume deficit, which may not be the same as volume loss. **The average 60-kg pregnant woman maintains a blood volume of 6000 mL by 30 weeks of gestation.**

Class 1 hemorrhage corresponds to approximately 1000 mL of blood loss. This blood loss correlates to a **15% volume deficit.** Women with this amount of volume deficit exhibit mild physiologic changes of dizziness and palpitations, owing to the hemodynamic adaptations that accompany pregnancy.

Class 2 hemorrhage is characterized by 1500 mL of blood loss, or a 20% to 25% volume deficit. Early physical changes that occur during this hemorrhage class include **tachycardia and tachypnea**. Although tachycardia is usually recognized as a compensatory mechanism to increase cardiac output, the significance of tachypnea is unclear and often unappreciated clinically. Tachypnea can represent a sign of impending clinical decompensation.

Narrowing of the pulse pressure is another sign of class 2 hemorrhage. The pulse pressure represents the difference between the systolic and diastolic blood pressures. Systolic blood pressure is a good representation of stroke volume and β_1 stimulation. Diastolic blood pressure is a reflection of systemic vasoconstriction. Therefore, the pulse pressure represents the interrelationship between these entities. With a class 2 volume deficit, the sympathoadrenal system is activated, resulting in a diversion of blood away from nonvital organs (skin, muscle, and kidney) and a redistribution of the circulation to vital body organs, including the brain and heart. The end result is increased vasoconstriction, increased diastolic blood pressure, maintenance of systolic blood pressure, and a narrowing of the pulse pressure. With greater narrowing of the pulse pressure, more compensatory vasoconstriction is occurring to accommodate for a loss in stroke volume.

A final physiologic response of class 2 hemorrhage is **orthostatic hypotension.** Although blood pressure comparisons can be made in the supine, sitting, and standing positions to document this response, a practical approach is to assess the time needed to refill a blanched hypothenar area on the patient's hand. Typically, a patient with normal volume status can reperfuse this area within 1 to 2 seconds after pressure is applied. A patient with class 2 hemorrhage and orthostatic hypotension will have significant reperfusion delay.

Class 3 hemorrhage is defined as a blood loss of 2000 mL and corresponds to a volume deficit of 30% to 35%. Within this hemorrhage class, the physiologic responses noted in class 2 hemorrhage are exaggerated. Patients demonstrate **significant tachycardia** (120 to 160 beats/minute), **tachypnea** (30 to 50 breaths/minute), **overt hypotension, restlessness, pallor, and cool extremities.**

Class 4 hemorrhage is characterized by more than 2500 mL of blood loss. This amount of blood loss exceeds **40% of the patient's total blood volume.** The clinical manifestations of this volume deficit include **absent distal pulses, cardiogenic shock, air hunger, and oliguria or anuria.** When a large hemorrhage occurs, renal blood flow is reduced and redirected from the outer renal cortex to the juxtamedullary region. In this region, increased water and sodium absorption occur, resulting in less urine volume, lower urinary sodium concentration, and increased urine osmolarity. A urine sodium concentration less than 10 to 20 mEq/L or a urine-to-serum osmolar ratio greater than 2 indicates significantly reduced renal perfusion in the face of hemorrhage.

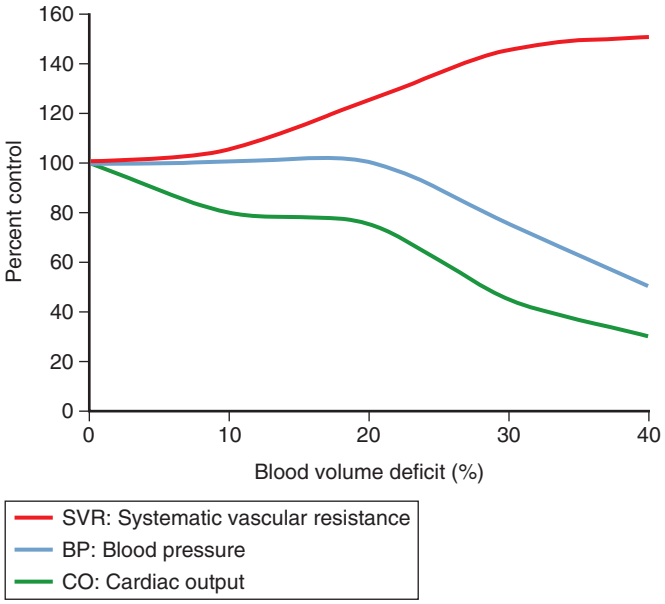

FIGURE 19-1. Relationships among systemic vascular resistance, blood pressure, and cardiac output in the face of progressive blood volume deficit.

ANTEPARTUM HEMORRHAGE

Placental Abruption

Definition and Pathogenesis

Placental abruption, or abruptio placenta, refers to the premature separation of a normally implanted placenta from the uterus. Typically, defective maternal vessels in the decidua basalis rupture and cause the separation. On rare occasions, the separation may be caused by a disruption of the fetal-placental vessels.[5] These damaged vessels cause bleeding, which results in a decidual hematoma that may

TABLE 19-1 HEMORRHAGE CLASSIFICATION AND PHYSIOLOGIC RESPONSE

HEMORRHAGE CLASS	ACUTE BLOOD LOSS	PERCENTAGE LOST	PHYSIOLOGIC RESPONSE
1	1000 mL	15	Dizziness, palpitations, minimal blood pressure change
2	1500 mL	20-25	Tachycardia, tachypnea, sweating, weakness, narrowed pulse pressure
3	2000 mL	30-35	Significant tachycardia and tachypnea, restlessness, pallor, cool extremities
4	≥2500 mL	40	Cardiogenic shock, air hunger, oliguria or anuria

Modified from Baker R: Hemorrhage in obstetrics. Obstet Gynecol Annu 6:295, 1977; and Bonnar J: Massive obstetric haemorrhage. Baillieres Best Pract Res Clin Obstet Gynaecol 14:1-18, 2000.

lead to placental separation, destruction of placental tissue, and a loss of maternal-fetal surface area for nutrient and gas exchange.

Placental abruption is often the result of both acute and chronic processes. Thrombin, which is released in response to decidual hemorrhage or hypoxia, appears to play an active role in the pathogenesis of placental abruption.[6] Thrombin acts as a direct uterotonic, enhances the action of matrix metalloproteinases, upregulates apoptosis genes, and increases the expression of inflammatory cytokines.[6,7] These thrombin-mediated events initiate a cyclic pathway of vascular disruption, hemorrhage, inflammation, contractions, and rupture of membranes.[5]

Incidence

The overall incidence of placental abruption is 1 in 100 births; however, a range of 1 in 75 to 1 in 226 deliveries has been reported.[5,8] The range in incidence likely reflects variable criteria for diagnosis as well as an increased recognition in recent years of milder forms of abruption. **About one third of all antepartum bleeding can be attributed to placental abruption.[8] Placental abruption peaks at 24 to 26 weeks of gestation.**[5] The incidence has risen in the United States because of increased rates of gestational diabetes mellitus, preterm labor, and umbilical cord abnormalities.[9]

Clinical Manifestations

Several factors determine the clinical manifestations of placental abruption. These factors include the temporal nature of the abruption (acute versus chronic), the clinical presentation (overt versus concealed), and the **severity**.[5] An acute, overt abruption typically presents with vaginal bleeding, abdominal pain, and uterine contractions. As the placental separation worsens, uterine tenderness, tachysystole, non-reassuring fetal heart rate patterns, and fetal death may occur.[10] **The amount of vaginal bleeding correlates poorly with the extent of placental separation and its potential for fetal compromise. In fact, concealed abruption occurs in 10% to 20% of cases.**[11] With severe abruptions, more than 50% of the placental surface area separates.[5] In these scenarios, maternal compromise in the form of consumptive coagulopathy may result from the triggering of the clotting cascade by hemorrhage and extensive thrombin deposition.[10,12]

Chronic abruption may be insidious in its presentation and is often associated with ischemic placental disease.[13] Typically, these cases present with intermittent, light vaginal bleeding and evidence of chronic placental inflammation and dysfunction, such as oligohydramnios, fetal growth restriction, preterm labor, premature preterm rupture of membranes, and preeclampsia.[14]

Risk Factors

Although the exact etiology of placental abruption is unclear, a variety of risk factors have been identified (Table 19-2).

Increasing Parity and Maternal Age

Several studies have noted a **higher incidence of placental abruption with increasing parity**.[15] Among primigravid women, the frequency of placental abruption is less than 1%; however, 2.5% of grand multiparas experience placental abruption. Theories suggest that damaged endometrium, impaired decidualization, and aberrant vasculature may have causal roles with increasing parity or age.

Maternal age is often cited as an associated risk factor for placental abruption. Although a 15-year population-based study in Norway was able to demonstrate a strong relationship between maternal age and placental abruption for all levels of parity, others studies suggest that there is no increased risk for placental abruption among older women when parity and hypertensive disease are excluded.

Cigarette Smoking

Cigarette smoking is associated with a significantly increased incidence of placental abruption and fetal death.[15,16] There appears to be a dose-response relationship with the number of cigarettes smoked and the risks for placental abruption and fetal loss.[17] Compared with nonsmokers, smokers have a 40% increased risk for fetal death from placental abruption with each pack of cigarettes smoked.[15] In addition, smoking and hypertensive disease appear to have an additive effect on placental abruption.[16] Proposed etiologies include placental hypoperfusion with resulting decidual ischemia and necrosis.

Cocaine Abuse

Cocaine abuse in the third trimester has been associated with as high as a 10% placental abruption rate.[18] The pathogenesis appears to be related to cocaine-induced vasospasm with subsequent decidual ischemia, reflex vasodilation, and vascular disruption within the placental bed.[5]

Trauma

Blunt or penetrating trauma to the gravid abdomen has been associated with placental abruption. After a **minor trauma,** the risk for placental abruption is between **1% and 5%,** whereas the risk may be as high as **50% after severe injury.**[19] The two most common causes of maternal trauma are motor vehicle crashes and domestic abuse. With motor vehicle crashes, uterine stretch, direct penetration, and placental shearing from acceleration-deceleration forces are the primary etiologies of trauma-related placental abruption.

Maternal Hypertension

Maternal hypertension is the most consistently identified risk factor for placental abruption.[13,15,16] This relationship

Table 19-2 Placental Abruption Risk Factors

Increasing parity and/or maternal age
Cigarette smoking
Cocaine abuse
Trauma
Maternal hypertension
Preterm premature rupture of membranes
Rapid uterine decompression associated with multiple gestation and polyhydramnios
Inherited or acquired thrombophilia
Uterine malformations or fibroids
Placental abnormalities or ischemia
Prior abruption

has been noted with both chronic and pregnancy-related hypertension. Compared with normotensive women, hypertensive women have a fivefold increased risk for placental abruption. This relationship is most strongly associated with fetal death due to placental abruption, in which 40% to 50% of cases have underlying hypertensive disease.[20] Unfortunately, antihypertensive therapy does not reduce the risk for placental abruption in women with chronic hypertension.[21]

Preterm Premature Rupture of Membranes

Placental abruption occurs in 2% to 5% of pregnancies with preterm premature rupture of membranes.[14,22] Intrauterine infection and oligohydramnios significantly increase the risk for placental abruption, and non-reassuring fetal heart rate patterns occur in nearly half of these pregnancies.[14]

It is unclear whether placental abruption is the cause or consequence of preterm premature rupture of membranes.[5] Hemorrhage and associated thrombin generation may stimulate cytokine and protease production, resulting in membrane rupture. Alternatively, the cytokine-protease cascade that follows ruptured membranes may cause damage to the decidual vasculature, predisposing the placenta to an abruption.

Rapid Uterine Decompression Associated with Multiple Gestation and Polyhydramnios

Rapid decompression of an overdistended uterus can cause placental abruption. This may occur in the setting of multiple gestations or with polyhydramnios. Compared with singletons, twins have been reported to have nearly a threefold increased risk for placental abruption.[23] Although the exact timing of placental abruption in multiple gestations is difficult to ascertain, it has been attributed to rapid decompression of the uterus after the delivery of the first twin. Likewise, rapid loss of amniotic fluid in pregnancies complicated by polyhydramnios has been implicated in placental abruption. This can occur with spontaneous rupture of membranes or may follow therapeutic amniocentesis.

Thrombophilia

Inherited and acquired thrombophilias have been implicated as risk factors for placental abruption.[24] The thrombophilias most commonly cited include factor V Leiden mutation, prothrombin G20210A mutation, antithrombin deficiency, protein C deficiency, protein S deficiency, hyperhomocysteinemia due to thermolabile methylene tetrahydrofolate reductase mutation (C677T), hypofibrinogenemia or dysfibrinogenemia, and antiphospholipid antibody syndrome. There appears to be a dose-response increase in the risk for placental abruption with increasing numbers or combinations of thrombophilias.[25]

Uterine and Placental Factors

Placental implantation over a uterine malformation (e.g., septum) **or fibroid can be associated with abruption.**[26] In addition, abnormal placental formation (e.g., circumvallate placenta) or chronic ischemia associated with preeclampsia and fetal growth restriction have been implicated in placental abruption.[16,25]

Prior Abruption

A previous abruption is associated with a risk for recurrence between 5% and 17%. After two consecutive abruptions, the recurrence risk rises to 25%. In the largest series of placental abruption with resultant fetal death, the recurrence rate of repeat placental abruption with fetal demise was 11%.

Diagnosis

Placental abruption is primarily a clinical diagnosis that is supported by radiographic, laboratory, and pathologic studies. Any patient with findings of vaginal bleeding, preterm labor, abdominal pain, or trauma should prompt an investigation of placental abruption.[5]

Radiology

Although early studies evaluating the use of **ultrasound** for the diagnosis of placental abruption identified less than 2% of cases, recent advances in imaging and its interpretation have improved detection rates. Early hemorrhage is typically hyperechoic or isoechoic, whereas resolving hematomas are hypoechoic within 1 week and sonolucent within 2 weeks of the abruption. Acute hemorrhage may be misinterpreted as a thickened placenta or fibroid.

Ultrasound can identify **three predominant locations for placental abruption.** These are **subchorionic** (between the placenta and the membranes), **retroplacental** (between the placenta and the myometrium), and **preplacental** (between the placenta and the amniotic fluid). Figure 19-2 illustrates the classification of hematomas in and around the placenta. Figure 19-3 demonstrates a sonographic representation of a subchorionic abruption.

The location and extent of the placental abruption identified on ultrasound examination is of clinical significance. **Retroplacental hematomas are associated with a worse prognosis for fetal survival than subchorionic hemorrhage.** The size of the hemorrhage is also predictive of fetal survival. Large retroplacental hemorrhages (>60 mL) are associated with a 50% or greater fetal mortality, whereas similarly sized subchorionic hemorrhages are associated with a 10% mortality risk.[26]

Magnetic resonance imaging (MRI) has been used successfully for diagnosing placental abruption when sonography is equivocal.

Laboratory Findings

Few laboratory studies assist in the diagnosis of placental abruption. **Hypofibrinogenemia and evidence of consumptive coagulopathy are supportive of a severe abruption**; however, clinical correlation is necessary.

Abnormal serum markers early in pregnancy, such as an unexplained elevated maternal serum α-fetoprotein (MSAFP) and human chorionic gonadotropin (hCG), have been associated with an increased risk for subsequent placental abruption.[5,27]

Pathologic Studies

Macroscopic inspection of the placenta may demonstrate adherent clot and depression of the placental surface. Fresh or acute placental abruptions may not have any identifiable evidence on pathologic examination.

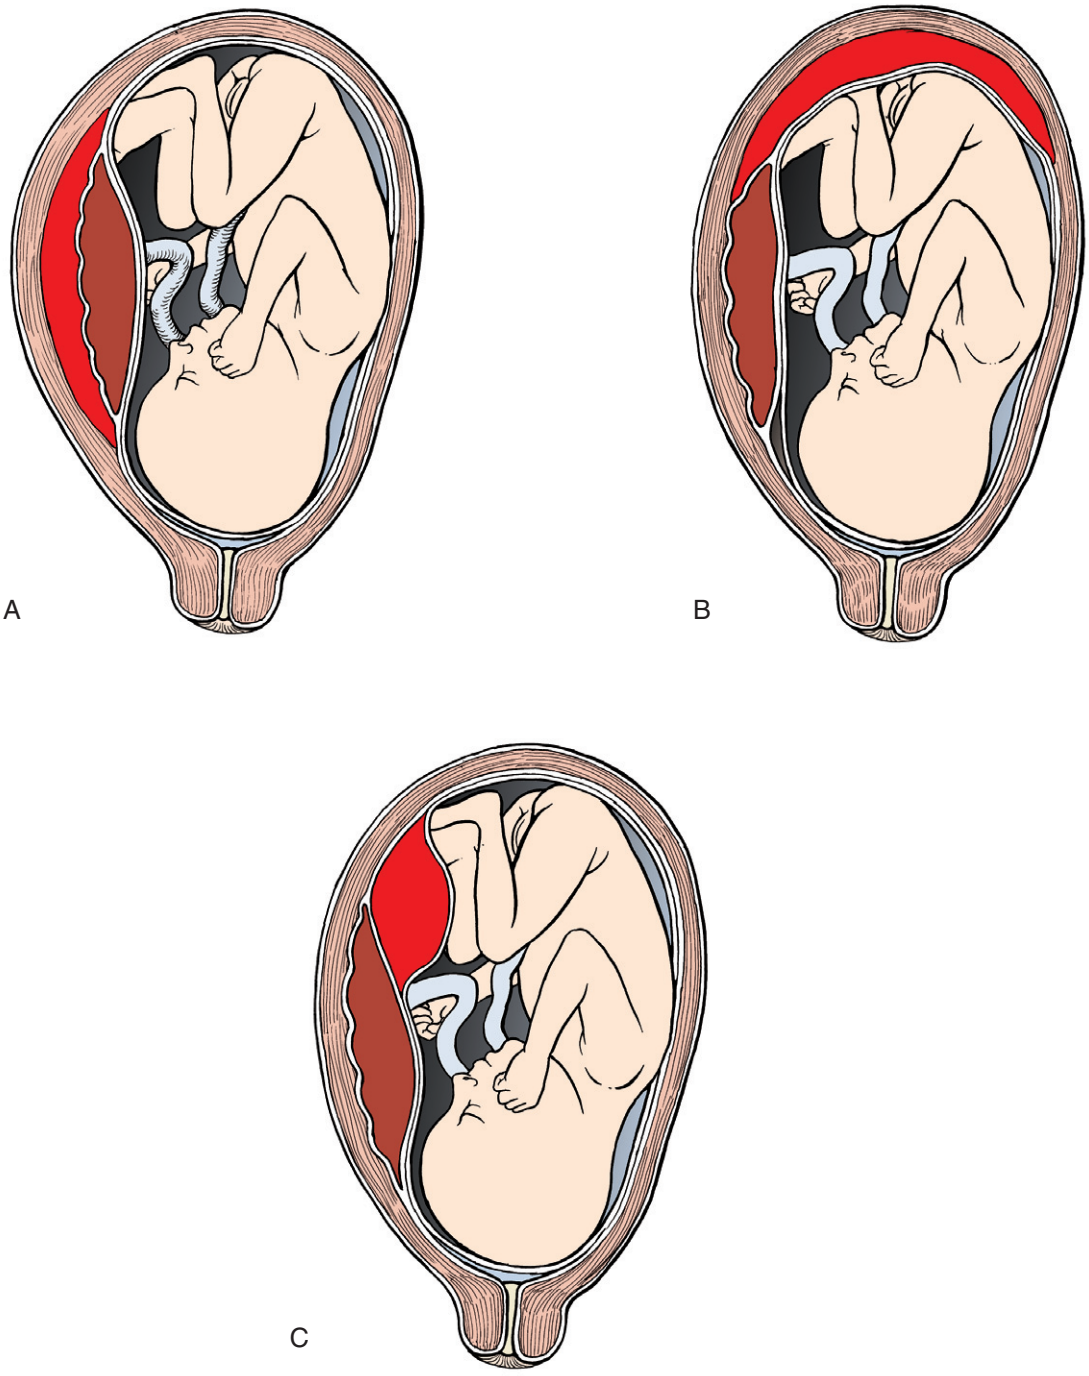

FIGURE 19-2. Drawings demonstrating the classification system of placental abruption. **A,** Retroplacental abruption: the *bright red area* represents a blood collection behind the placenta *(dark red)*. **B,** Subchorionic abruption: the *bright red area* represents subchorionic bleeding, which is observed to dissect along the chorion. **C,** Preplacental abruption: the *bright red area* represents a blood collection anterior to the placenta within the amnion and chorion (subamniotic). Management

Both maternal and fetal complications may occur with placental abruption. Maternal complications include blood loss, consumptive coagulopathy, need for transfusion, end-organ damage, and death. Fetal complications include intrauterine growth restriction, oligohydramnios, hypoxemia, prematurity, and death.[12,28] Although maternal complications are related to the severity of the abruption, fetal complications are due to the severity and timing of the hemorrhage.[11] Nearly half of all placental abruptions will result in delivery at less than 37 weeks' gestation. Gestational age at the time of presentation is an important

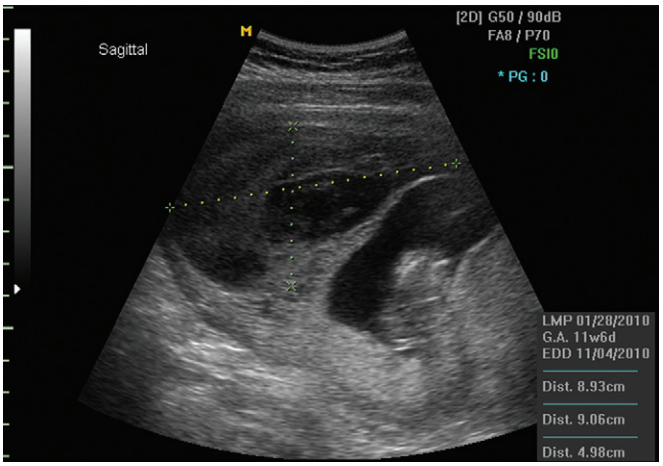

FIGURE 19-3. Ultrasonic image of a subchorionic abruption. (Courtesy K. Francois.)

prognostic factor. In patients presenting at less than 20 weeks, 82% can be expected to have a term delivery despite evidence of placental abruption. However, if the presentation occurs after 20 weeks' gestation, only 27% will deliver at term.

Management of placental abruption depends on the severity, gestational age, and maternal-fetal status. Once the diagnosis of placental abruption has been made, precautions should be taken to anticipate the possible life-threatening consequences for both mother and fetus. These precautions include baseline **laboratory assessment** (hemoglobin, hematocrit, platelet count, type and screen, fibrinogen, and coagulation studies), **appropriate intravenous access** (large-bore catheter), **availability of blood products, continuous fetal heart rate and contraction monitoring, and communication with operating room and neonatal personnel.**

Small placental abruptions remote from term may be managed expectantly in the hospital. A trial of tocolysis for documented preterm labor and administration of antenatal corticosteroid therapy can be considered if maternal-fetal status is stable.[29] Reported series of expectant management in preterm gestations with placental abruption have shown a significant prolongation of the pregnancy (>1 week) in more than 50% of patients without adverse maternal or fetal outcomes.[30] In a large series of preterm patients who presented with placental abruption and received tocolysis, about one third delivered within 48 hours of admission, one third delivered within 7 days, and one third delivered greater than 1 week from initial presentation. There were no cases of intrauterine demise in women presenting with a live fetus.[31] Although these results are encouraging, the clinician must always keep in mind that placental abruption can result in both maternal and fetal morbidity. Any attempt to arrest preterm labor in a known or suspected placental abruption must be weighed against the likelihood of neonatal survival and morbidity, the severity of the abruption, and the safety of the mother.

Women presenting at or near term with a placental abruption should undergo delivery. Induction or augmentation of labor is not contraindicated in the setting of an abruption; however, close surveillance for any evidence of maternal or fetal compromise is advised. Continuous fetal heart rate monitoring is recommended because 60% of fetuses may exhibit non-reassuring intrapartum heart rate patterns. Intrauterine pressure catheters and fetal scalp electrodes can assist the clinician during the intrapartum course. Intrauterine pressure catheter monitoring can demonstrate elevated uterine resting tone, which may be associated with deficits in uterine blood flow and fetal oxygenation. Maternal hemodynamic and clotting parameters must be followed closely in order to detect signs of evolving coagulopathy. **Although vaginal delivery is generally preferable, operative delivery is often necessary owing to fetal or maternal decompensation.** When cesarean delivery is needed, a decision-to-delivery time of less than 20 minutes from a fetal bradycardic episode results in better outcomes than a 30-minute interval.[32] A Couvelaire uterus, characterized by extravasation of blood into the myometrium, may be noted in some cases and is often associated with significant uterine atony. Administration of uterotonic therapy usually improves the condition. Hysterectomy should be reserved for cases of atony and hemorrhage unresponsive to conventional uterotonic therapies and replacement of blood products.

The management of women with consumptive coagulopathy and fetal demise requires a thorough knowledge of the natural history of severe placental abruption. More than four decades ago, Pritchard and Brekken noted several clinically important and relevant observations, including the following: (1) about 40% of patients with placental abruption and fetal demise will demonstrate signs of consumptive coagulopathy; (2) within 8 hours of initial symptoms, hypofibrinogenemia will be present; (3) severe hypofibrinogenemia will not recover without blood product replacement; and (4) the time course for recovery from hypofibrinogenemia is roughly 10 mg/dL per hour after delivery of the fetus and placenta.[33]

When managing patients with severe placental abruptions and fetal demise, maintenance of maternal volume status and replacement of blood products is essential. Although operative delivery may appear to lead to the most rapid resolution of the problem, it may pose significant risk to the patient. Unless the consumptive coagulopathy is corrected, surgery can result in uncontrollable bleeding and increased need for hysterectomy. The uterus does not need to be evacuated before coagulation status can be restored. Blood product replacement and delayed delivery until hematologic parameters have improved are generally associated with good maternal outcomes.

Neonatal Outcome

Placental abruption is associated with increased perinatal morbidity and mortality. When compared with normal pregnancies, pregnancies complicated by abruption have a **tenfold increased risk for perinatal death.**[28] A case-control study has also shown a **greater risk for adverse long-term neurobehavioral outcomes** in infants delivered after placental abruption.[34] Neonates at risk for abnormal outcomes had higher incidences of abnormal fetal heart rate tracings (45%) and emergency cesarean deliveries (53%) compared with controls (10% and 10%, respectively). Finally, **periventricular leukomalacia and sudden infant death syndrome**

are more common in newborns delivered after placental abruptions.[35]

Placenta Previa

Definition and Pathogenesis

Placenta previa is defined as the presence of placental tissue over or adjacent to the cervical os. Traditionally, three variations of placenta previa were recognized: complete, partial, and marginal. Although complete placenta previa referred to the total coverage of the cervical os by placental tissue, the differences between partial (placental edge at the cervical os) and marginal (placental edge near the cervical os) were often subtle and varied by the timing and method of diagnosis. In more recent years, improved ultrasound technology and precision have allowed for more accurate assessments of the placental location in relation to the cervical os. With this in mind, **contemporary classification of placenta previa consists of two variations: *placenta previa,* in which the cervical os is covered by placental tissue, and *marginal placenta previa,* in which the placenta lies within 2 cm of the cervical os but does not cover it.** Low-lying placenta has also been described. Within the literature, a variety of definitions have been ascribed to a low-lying placenta, including an apparent second-trimester placenta previa, a placenta that lies within the lower uterine segment, and a placental edge that lies within 2 to 3 cm of the cervical os. Although not true placenta previa, low-lying placentas are associated with increased risks for bleeding and other adverse pregnancy events.[36]

Incidence

The overall reported incidence of placenta previa at delivery is 4 in 1000 deliveries.[37] In the second trimester, placenta previa may be found in 4% to 6% of pregnancies.[38] The term *placental migration* has been used to explain this "resolution" of placenta previa that is noted near term. Two theories have been suggested to account for this phenomenon. The first hypothesis proposes that as the pregnancy advances, the stationary lower placental edge relocates away from the cervical os with the development of the lower uterine segment. Indeed the lower uterine segment has been noted to increase from 0.5 cm at 20 weeks to more than 5 cm at term.[39] The second hypothesis suggests that trophotropism, or the growth of trophoblastic tissue away from the cervical os toward the fundus, results in resolution of the placenta previa.

Clinical Manifestations

Placenta previa typically presents as painless vaginal bleeding in the second or third trimester. Between 70% and 80% of patients with placenta previa will have at least one bleeding episode.[38,40] About 10% to 20% of patients present with uterine contractions before bleeding, and fewer than 10% remain asymptomatic.[38,40] Of patients with bleeding, one third will present before 30 weeks' gestation, **one third between 30 and 36 weeks' gestation, and one third after 36 weeks' gestation.[38,40]** Patients with early-onset bleeding (<30 weeks' gestation) have the greatest risk for blood transfusion and associated perinatal morbidity and mortality. The bleeding is believed to occur from disruption of placental blood vessels in association with the development and thinning out of the lower uterine segment.

Multiple gestations
Male fetal gender
Previous placenta previa
Prior curettage
Prior cesarean delivery

Risk Factors

Several risk factors for placenta previa have been noted (Table 19-3). Additionally, some reports have documented a higher association of fetal malpresentation, preterm premature rupture of membranes, intrauterine growth restriction, congenital anomalies, and amniotic fluid embolism with placenta previa.[38,41]

Increasing Parity, Maternal Age, and Maternal Race

Studies have reported **more cases of placenta previa with increasing parity**. Grand multiparas have been reported to have a 5% risk for placenta previa compared with 0.2% among nulliparous women.[39] **Maternal age also seems to influence the occurrence of placenta previa.** Women older than 35 years of age have more than a fourfold increased risk for placenta previa, and women older than 40 years of age have a ninefold greater risk.[42] **Maternal race has been associated with placenta previa.** In a large population-based cohort, the rate of placenta previa among white, black, and other races was 3.3, 3, and 4.5 per 1000 births, respectively.[43] Asian women appear to have the highest rates of placenta previa.

Cigarette Smoking and Residence at Higher Elevation

Cigarette smoking has been associated with as high as a threefold increased risk for previa formation.[44,45] Likewise, **residence at higher elevations may contribute to previa development.[38]** The need for increased placental surface area secondary to decreased uteroplacental oxygenation may contribute to these associations.

Multiple Gestations and Male Fetal Gender

Controversy exists regarding an increased risk for placenta previa with multiple gestations. Although some studies have shown a higher incidence of placenta previa among twins, others have not documented a significantly increased risk.[23,45,46] There is a consistently **higher proportion of male offspring in women with placenta previa.[44]** This association is unexplained; however, two theories suggest larger placental sizes among male fetuses and delayed implantation of the male blastocyst in the lower uterine segment.

Previous Placenta Previa

Having had a previous placenta previa increases the risk for the development of another previa in a subsequent pregnancy. This association has been reported to be as high as an eightfold relative risk.[47] The exact etiology for this increased risk is unclear but may be attributed to a genetic predisposition for the phenomenon.

Prior Curettage and Prior Cesarean Delivery

Prior uterine surgery has been associated with placenta previa formation. Although a history of curettage has a slightly elevated previa risk (1.3 relative risk), prior cesarean delivery is a significant risk factor.[48] **In the pregnancy following a cesarean delivery, the risk for placenta previa has been reported to be between 1% and 4%.**[48,49] There is a **linear increase in placenta previa risk with the number of prior cesarean deliveries.** Placenta previa occurs in 0.9% of women with one prior cesarean delivery, 1.7% of women with two prior cesarean deliveries, and 3% of those with three or more cesarean deliveries.[50] In patients with four or more cesarean deliveries, the risk for placenta previa has been reported as high as 10%.[49] Endometrial scarring is thought to be the etiologic factor for this increased risk.

Diagnosis

The timing of the diagnosis of placenta previa has undergone significant change in the past three decades. Painless third-trimester bleeding was a common presentation for placenta previa in the past, whereas **most cases of placenta previa are now detected antenatally with ultrasound** before the onset of significant bleeding.

Radiology

Transabdominal and transvaginal ultrasound provide the best means for diagnosing placenta previa. Although transabdominal ultrasound can detect at least 95% of placenta previa cases, transvaginal ultrasound has a reported diagnostic accuracy approaching 100%.[51] Typically, a combined approach can be used in which transabdominal ultrasound is employed as the initial diagnostic modality followed by transvaginal ultrasound for uncertain cases. Of note, good images can be obtained using transvaginal ultrasound without the probe contacting the cervix (Figure 19-4). Also, translabial ultrasound can be used to assist in the diagnosis if reservation exists regarding the use of a transvaginal probe.

If placenta previa is diagnosed in the midtrimester, repeat sonography should be obtained in the early third trimester. More than 90% of the cases of placenta previa diagnosed in the midtrimester resolve by term. The potential for placenta previa resolution is dependent on the timing of the diagnosis, the extent over the cervical os, and the location. For example, one study of 714 women with an ultrasound diagnosis of placenta previa noted that the earlier the diagnosis in the pregnancy, the more likely for the previa to resolve by term (Table 19-4).[52] In addition, complete placenta previa diagnosed in the second trimester will persist into the third trimester in 26% of cases, whereas marginal placenta previa will persist in only 2.5% of cases.[53] Finally, anterior placenta previa is less likely to migrate away from the cervical os than posterior locations.

Occasionally, MRI is used to diagnose placenta previa. MRI is particularly helpful with posterior placenta previa identification and assessment of invasive placentation (see later).

Management

General management principles for patients with placenta previa in the third trimester include serial ultrasounds to assess placental location and fetal growth, avoidance of cervical examinations and coitus, activity restrictions, counseling regarding labor symptoms and vaginal bleeding, dietary and nutrient supplementation to avoid maternal anemia, and early medical attention if any vaginal bleeding occurs.[1]

Outpatient Management

Asymptomatic patients with placenta previa or patients with a history of a small bleed that has resolved for greater than 7 days are potential candidates for outpatient management. Several studies have documented the safety, efficacy, and cost savings of outpatient versus inpatient

management in such cases.[54] **Candidates for outpatient management must be highly compliant, live within 20 minutes from the hospital, have 24-hour emergency transportation to the hospital, and verbalize a thorough understanding of the risks associated with placenta previa and outpatient management.**

Expectant Management of Preterm Patients

Patients with placenta previa who present preterm with vaginal bleeding require hospitalization and immediate evaluation to assess maternal-fetal stability. In at least 50% of women who present with a symptomatic previa, delivery can be delayed for more than 4 weeks, including patients with initial bleeding episodes greater than 500 mL.[38,40,54]

In order to optimize maternal-fetal outcome, **patients should initially be managed in a labor and delivery unit with continuous fetal heart rate and contraction monitoring. Large-bore intravenous access and baseline laboratory studies** (hemoglobin, hematocrit, platelet count, blood type and screen, and coagulation studies) should be obtained. **If the patient is less than 34 weeks' gestation, administration of antenatal corticosteroids should be undertaken** as well as an assessment of the facility's emergency resources for both the mother and the neonate. In some cases, maternal transport and consultation with a maternal-fetal medicine specialist and a neonatologist may be warranted. **Finally, tocolysis can be employed if the vaginal bleeding is preceded by or associated with uterine contractions.** Magnesium sulfate and β-mimetic therapy have both been shown to be efficacious; however, some authorities recommend magnesium sulfate as a first-line agent given its reduced potential for hemodynamic-related side effects.[55]

Once stabilized, patients can be maintained on hospitalized bed rest and expectantly managed. Minimizing maternal anemia by employing blood conservation techniques is recommended. Although some patients may require transfusion, many patients can be supplemented with iron replacement (oral or intravenous), vitamin C to enhance oral iron absorption, and B vitamins. Erythropoietin may be used in selected cases to hasten red cell formation. Lastly, autologous donation may be considered in patients with hemoglobin concentrations greater than 11 g/dL.[56]

Although maternal hemorrhage is of utmost concern, **fetal blood can also be lost during the process of placental separation. Rh immune globulin (RhoGAM) should be given to all Rh-negative, unsensitized women with third-trimester bleeding from placenta previa.** A Kleihauer-Betke preparation of maternal blood should be considered. Occasionally, a fetomaternal hemorrhage of greater than 30 mL occurs, necessitating additional doses of RhoGAM. One study noted that 35% of infants whose mothers received an antepartum transfusion were also anemic and required a transfusion after delivery.[38]

Delivery

Cesarean delivery is indicated for all patients with sonographic evidence of placenta previa. In women with a low-lying placenta in which the placental edge is clearly greater than 2 to 3 cm from the cervical os, vaginal delivery may be considered; however, precautions should be made for the possibility of an emergent cesarean delivery with labor.

The timing of delivery depends on clinical circumstances. Any patient with persistent hemorrhage mandates delivery regardless of gestational age. **For asymptomatic patients with placenta previa, delivery is typically recommended by 37 weeks' gestation** with documented fetal lung maturity or after administration of antenatal corticosteroids.[54]

When performing a cesarean delivery for placenta previa, the surgeon should be aware of the potential for rapid blood loss during the delivery process. Patients should have blood products cross-matched and readily available for delivery, including packed red blood cells and fresh-frozen plasma, with or without pooled platelets. In addition, before incising the lower uterine segment, the surgeon should assess the vascularity of this region. Although a low transverse incision is not contraindicated in patients with placenta previa, performing a vertical uterine incision may be preferable in selected cases. This is particularly true with an anterior placenta previa. Ideally, the placenta should not be disrupted when entering the uterus. If disruption occurs, expedited delivery is essential. Once the fetus has been removed from the uterus, the cord blood should be "milked" to the fetus to avoid immediate neonatal hypovolemia and anemia. Given the potential for invasive placentation, the physician should allow the placenta to spontaneously deliver. If it does not separate easily, precautions should be taken for dealing with a placenta accreta (see below). Once the placenta separates, bleeding is controlled by the contraction of uterine myometrial fibers around the spiral arterioles. Because the lower uterine segment often contracts poorly, significant bleeding can occur from the placental implantation site. Aggressive uterotonic therapy, surgical intervention, or tamponade techniques, or a combination of these, should be undertaken to rapidly control the bleeding.

Associated Conditions

Placenta Accreta

Definition and Pathogenesis

Placenta accreta represents the abnormal attachment of the placenta to the uterine lining due to an absence of the decidua basalis and an incomplete development of the fibrinoid layer. Variations of placenta accreta include placenta increta and placenta percreta, in which the placenta extends to and through the uterine myometrium, respectively (Figure 19-5).

Incidence and Risk Factors

The overall incidence of placenta accreta or one of its variations ranges from 1 in 533 to 1 in 2510 deliveries.[57] Based on histologic diagnosis, placenta accreta is the most common form of invasive placentation (79%) followed by placenta increta (14%) and placenta percreta (7%), respectively.[57] **The two most significant risk factors for placenta accreta are placenta previa and prior cesarean delivery.** The risk for placenta accreta in patients with placenta previa and an unscarred uterus is approximately 3%.[49] This risk dramatically increases with one or more cesarean deliveries (Table 19-5). Even without a placenta previa, placenta accreta is more common with a prior cesarean delivery.[50]

Other risk factors that have been reported include increasing **parity and maternal age, submucosal uterine fibroids, prior uterine surgery, and endometrial defects.**

Contrary to placenta previa, **female fetal gender is more common with invasive placentation.**[58]

CLINICAL MANIFESTATIONS

The clinical manifestations are similar to those of placenta previa. **Hematuria can be feature of placenta percreta with bladder invasion.**

DIAGNOSIS

In the past, placenta accreta was usually diagnosed intrapartum by the difficult or incomplete removal of the placenta and associated postpartum hemorrhage. Today with advanced **radiographic technology, the diagnosis can be made antenatally.** In fact, prenatal diagnosis has been shown to improve maternal outcomes, resulting in lower blood loss and transfusion requirements.[59]

RADIOLOGY

Ultrasound is the best radiographic modality for the diagnosis of placenta accreta. Findings that are suggestive of placenta accreta include a loss of the normal hypoechoic retroplacental-myometrial zone, thinning and disruption of the uterine serosa–bladder interface, focal exophytic masses within the placenta, and numerous intraplacental vascular lacunae (Figure 19-6).[60] With experienced sonographers, the diagnostic sensitivity and specificity approach 85% to 90%.[60] Color Doppler ultrasound is also useful as an adjunctive tool in diagnosing placenta accreta.[61] Specific color Doppler findings that differentiate placenta accreta from normal placentation include diffuse and focal intraparenchymal placental lacunar blood flow, hypervascularity of the bladder and uterine serosa, prominent subplacental venous complexes, and loss of subplacental Doppler vascular signals. Finally, color-flow mapping studies suggest that a myometrial thickness less than 1 mm with large intraplacental venous lakes is highly predictive of invasive placentation (sensitivity, 100%; specificity, 72%; positive predictive value, 72%; and negative predictive value, 100%).[62]

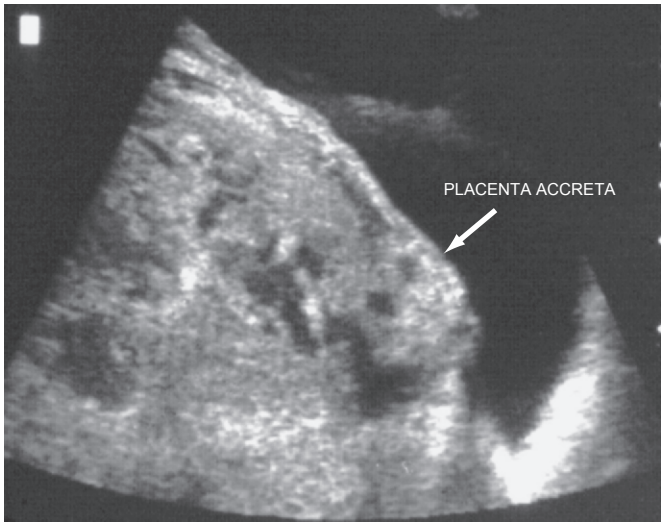

FIGURE 19-6. Ultrasonic image of focal placenta accreta. *Arrow* identifies an area at the uterine placental interface that demonstrates a loss of the normal hypoechoic zone, thinning and disruption of the uterine serosa-bladder interface, and a focal exophytic mass within the placenta.

MRI can be used in conjunction with sonography to assess abnormal placental invasion. Situations in which MRI has been particularly helpful include equivocal ultrasound findings, posterior placental location, and determination of the extent of placental invasion within surrounding tissue, such as the parametrium and bladder.[63] In one series of 300 patients with ultrasound-detected placenta accreta, MRI was able to characterize the level and extent of the placenta invasion with an accuracy of greater than 97%.[64]

LABORATORY FINDINGS

Placenta accreta has also been associated with unexplained elevations in MSAFP concentration.[65]

PATHOLOGIC STUDIES

Placenta accreta is confirmed by the pathologic evaluation of a hysterectomy specimen. Histologic evaluation demonstrates placental villi within the uterine myometrium. In focal accreta cases in which the uterus is not removed, curettage specimens may show myometrial cells adherent to the placenta.

MANAGEMENT

Because of its associated risk for massive postpartum hemorrhage, **placenta accreta accounts for most peripartum hysterectomies.**[38,66] **A multidisciplinary team approach is the most ideal way to manage these cases.** Preoperative

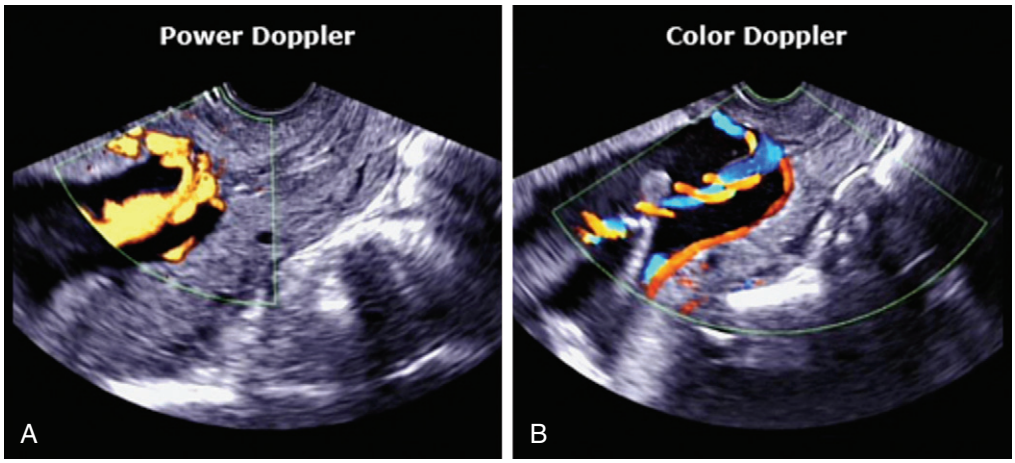

FIGURE 19-7. Transvaginal ultrasound images showing vasa previa and velamentous cord. The placenta is posterior with an anterior succenturiate lobe. (From Lockwood CJ, Russo-Steiglitz K: Vasa previa and velamentous umbilical cord. Available at http://www.uptodate.com. Accessed August 2010.)

assessments by **blood conservation teams, anesthesiologists, advanced pelvic surgeons, and urologists** (especially for a suspected placenta percreta) are recommended. The delivery should occur at a facility that is prepared to manage significant obstetrical hemorrhage. **Adequate intravenous access with two large-bore catheters and ample blood product availability are mandatory.** When performing the surgery, it is recommended that the **uterus be incised above the placental attachment site and the placenta left in situ after clamping the cord because disruption of the implantation site may result in rapid blood loss.** Adjuvant use of aortic or internal iliac artery balloon occlusion catheters, or both, with postsurgical embolization may be considered.[67]

When future fertility is desired, a variety of uterine conservation techniques may be attempted. These techniques include delayed manual removal of the placenta, wedge resection or oversewing of the placental implantation site, tamponade of the lower uterine segment, curettage, uterine artery embolization, and administration of methotrexate. Although each of these techniques has reported success, they are also associated with potential complications, including delayed hemorrhage, infection, fistula formation, subsequent surgery, and uterine necrosis.[68] Data are limited regarding future reproduction in patients treated conservatively for invasive placentation. In a case series of 35 women treated conservatively for placenta accreta, 12 of 14 women desiring future pregnancy were successful in conceiving; however, 5 women had pregnancies that ended in spontaneous abortion, 4 delivered preterm, and 2 had recurrent placenta accreta.[69]

Vasa Previa

Definition and Pathogenesis

Vasa previa is defined as the presence of fetal vessels over the cervical os. Typically, these fetal vessels lack protection from Wharton's jelly and are prone to rupture and compression. When the vessels rupture, the fetus is at high risk for exsanguination. There are **two variations of vasa previa: (1) velamentous cord insertion; and (2) fetal vessels running between a bilobed or succenturiate-lobed placenta.**

Incidence and Risk Factors

The overall incidence of vasa previa is 1 in 2500 deliveries; however, data have shown a range from 1 in 2000 to 1 in 5000 deliveries.[70] **Reported risk factors for vasa previa include bilobed, succenturiate-lobed, and low-lying placentas; pregnancies resulting from assisted reproductive technology; multiple gestations; history of second-trimester placenta previa, and vaginal bleeding.**[70,71]

Clinical Manifestations

Vasa previa usually presents after rupture of membranes with the acute onset of vaginal bleeding from a lacerated fetal vessel. If immediate intervention is not provided, fetal bradycardia and subsequent death occur.

Diagnosis

In the past, vasa previa was usually detected by palpation of the fetal vessels within the membranes during labor or with the acute onset of vaginal bleeding and subsequent fetal bradycardia and/or death after membrane rupture. Today with widespread use of **ultrasound and color-flow Doppler imaging, most cases are diagnosed antenatally.**[72] Transabdominal, transvaginal, and translabial approaches have been used. **The diagnosis is confirmed by documenting umbilical vessels over the cervical os using color-flow Doppler imaging** (Figure 19-7).[73]

Management

When diagnosed antenatally, vasa previa should be managed similarly to placenta previa. Some authorities have recommended hospitalization in the third trimester with administration of antenatal corticosteroids, serial antepartum testing, and cesarean delivery by 36 weeks' gestation.[71,74] If an intrapartum diagnosis of vasa previa is made, expeditious delivery is needed. Immediate neonatal blood transfusion is often required in these circumstances. **The importance of antenatal detection was emphasized in a large series based on data from the Vasa Previa Foundation. The overall perinatal mortality rate was 36%, but the neonatal survival was 97% in cases diagnosed antenatally compared with 44% in those diagnosed intrapartum.**[74]

POSTPARTUM HEMORRHAGE

Postpartum hemorrhage is an obstetrical emergency that complicates between 1 in 100 and 1 in 20 deliveries.[75] It is a major cause of maternal morbidity and mortality. Obstetricians need to have a clear understanding of normal delivery-related blood loss in order to efficiently recognize postpartum hemorrhage.

Normal Blood Loss and Postpartum Hemorrhage

Normal delivery-related blood loss depends on the type of delivery. Based on objective data, the mean blood losses for a vaginal delivery, cesarean delivery, and cesarean hysterectomy are 500 mL, 1000 mL, and 1500 mL, respectively.[76] These values are often underestimated and unappreciated clinically owing to the significant blood volume expansion that accompanies normal pregnancy.

Postpartum hemorrhage has been variably defined in the literature. Definitions have included subjective assessments greater than the standard norms, a 10% decline in hematocrit, and the need for a blood transfusion. A more practical definition is delivery-related blood loss that is excessive in nature and results in a symptomatic patient or signs of hypovolemia.

Postpartum Hemorrhage Etiologies

The etiologies of postpartum hemorrhage can be categorized as primary (or early), those occurring within 24 hours of delivery, and secondary (or late), those occurring from 24 hours until 6 weeks after delivery. Table 19-6 lists the most common causes of primary and secondary postpartum hemorrhage. Because primary postpartum hemorrhage is more common than secondary, the remainder of this discussion focuses on its causes and management (Figure 19-8).

Uterine Atony

Definition and Pathogenesis

Uterine atony, or the inability of the uterine myometrium to contract effectively, is the most common cause of primary postpartum hemorrhage. At term, blood flow through the

Table 19-6 Etiologies of Postpartum Hemorrhage

Early	Uterine atony
	Lower genital tract lacerations (perineal, vaginal, cervical, periclitoral, periurethral, rectal)

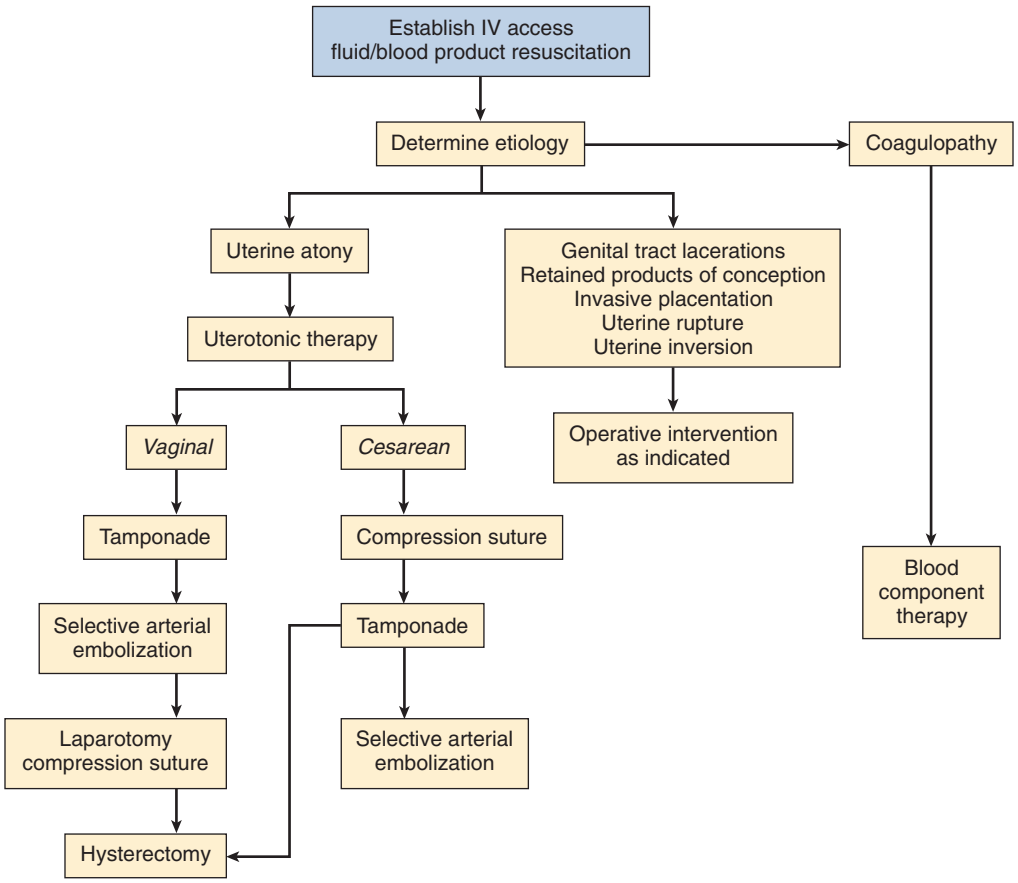

Figure 19-8. Management of postpartum hemorrhage.

placental site averages 600 mL/minute. After placental delivery, the uterus controls bleeding by contracting its myometrial fibers in a tourniquet fashion around the spiral arterioles. If inadequate uterine contraction occurs, rapid blood loss can ensue.

Incidence and Risk Factors

Uterine atony complicates 1 in 20 deliveries and is responsible for 80% of postpartum hemorrhages.[77] **Risk factors** for uterine atony include uterine overdistention (multiple gestation, polyhydramnios, fetal macrosomia), **labor induction, rapid or prolonged labor, grand multiparity, uterine infection, uterine inversion, retained products of conception, placenta previa, and use of uterine-relaxing agents** (tocolytic therapy, halogenated anesthetics, nitroglycerin).

Clinical Manifestations and Diagnosis

Uterine atony is diagnosed clinically by rapid uterine bleeding associated with a lack of myometrial tone and an absence of other etiologies for postpartum hemorrhage. Typically, bimanual palpation of the uterus confirms the diagnosis.

Prevention and Management

By recognizing risk factors for uterine atony and quickly initiating a treatment cascade, the clinician can minimize blood loss. Two preventive methods for atonic postpartum hemorrhage are active management of the third stage of labor and spontaneous placental separation after cesarean delivery. Active management of the third stage of labor includes early cord clamping, controlled cord traction, uterine massage, and administration of uterotonic therapy before placental separation. A systematic review of five randomized controlled trials comparing active to expectant management of the third stage of labor showed significant reductions in maternal blood loss, postpartum hemorrhage, prolonged third stage of labor, and the need for additional uterotonic therapies.[78] Controversy exists regarding the timing of uterotonic administration. Although some studies suggest that giving uterotonic therapy before delivery of the placenta results in less blood loss and fewer postpartum transfusions, other trials have found no significant differences in these outcomes.[79] Spontaneous separation of the placenta during cesarean delivery is also associated with reduced blood loss. In one controlled study, spontaneous placental separation reduced blood loss by 30% and postpartum endometritis sevenfold compared with manual removal.[80]

If preventive measures are unsuccessful, medical management for uterine atony should be initiated. This treatment includes bimanual uterine massage and uterotonic therapy.

Bimanual Uterine Massage

Figure 19-9 demonstrates the proper technique for **bimanual uterine massage.** To provide effective massage, the **uterus should be compressed between the external fundally placed hand and the internal intravaginal hand.** Care must be taken to avoid aggressive massage that can injure the large vessels of the broad ligament.

Uterotonic Therapy

Uterotonic medications represent the mainstay of drug therapy for postpartum hemorrhage secondary to uterine atony. Table 19-7 lists available uterotonic agents with

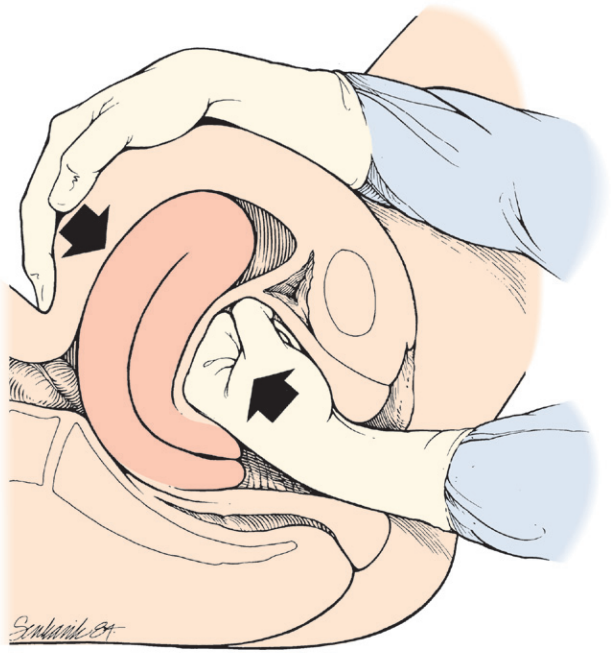

Figure 19-9. Bimanual uterine massage.

Table 19-7 Uterotonic Therapy

Agent	Dose	Route	Dosing Interval	Side Effects	Contraindications
Oxytocin (Pitocin)	10-80 U in 1000 mL crystalloid solution	First line: IV Second line: IM or IU	Continuous	Nausea, emesis, water intoxication	None
Misoprostol (Cytotec)	200-1000 mcg	First line: PR Second line: PO or SL	Single dose	Nausea, emesis, diarrhea, fever, chills	None
Methylergonovine (Methergine)	0.2 mg	First line: IM Second line: IU or PO	Every 2 to 4 hr	Hypertension, hypotension, nausea, emesis	Hypertension, preeclampsia
Prostaglandin $F_{2\alpha}$ (Hemabate)	0.25 mg	First line: IM Second line: IU	Every 15 to 90 min (maximum of 8 doses)	Nausea, emesis, diarrhea, flushing, chills	Active cardiac, pulmonary, renal, or hepatic disease
Prostaglandin E_2 (Dinoprostone)	20 mg	PR	Every 2 hr	Nausea, emesis, diarrhea, fever, chills, headache	Hypotension

IM, Intramuscular; *IU*, intrauterine; *IV*, intravenous; *PO*, per oral; *PR*, per rectum; *SL*, sublingual.

their dosages, side effects, and contraindications. **Oxytocin** (Pitocin) is usually given as a first-line agent. Intravenous therapy is the preferred route of administration, but intramuscular and intrauterine dosing is possible. Initial treatment starts with 10 to 20 U of oxytocin in 1000 mL of crystalloid solution. Higher doses (80 units in 1000 mL) have proved safe and efficacious, with a 20% reduction in the need for additional uterotonic therapy compared with standard dosing.[81]

When oxytocin fails to produce adequate uterine tone, second-line therapy must be initiated. Currently, a variety of other uterotonic agents are available for use. The choice of a second-line agent depends on its side-effect profile as well as its contraindications. **Misoprostol (Cytotec), a synthetic prostaglandin E_1 analog,** is a safe, inexpensive, and efficacious uterotonic medication. It has been used for both the prevention and treatment of postpartum hemorrhage.[82] Misoprostol is attractive as a second-line agent in that it has multiple administration routes that can be combined. Although higher doses (600 to 1000 mcg) have traditionally been used rectally, the sublingual route allows for lower dosing (400 mcg) with higher bioavailability.[82] Although helpful in some settings, **methylergonovine (Methergine)** has limited usefulness in the acute postpartum hemorrhage because of its relatively long half-life and its potential for worsening hypertension in patients with preexisting disease. **Prostaglandins** are highly effective uterotonic agents. Both natural and synthetic prostaglandin formulations are available. Intramuscular and intrauterine administration of **prostaglandin $F_{2\alpha}$ (Hemabate)** can be used for control of atony. Recurrent doses (0.25 mg) may be administered as often as every 15 minutes to a maximum of eight doses (2 mg). It is important to note that asthma is a strong contraindication to its use because of its bronchoconstrictive properties. Finally, **prostaglandin E_2 (dinoprostone)** is a naturally occurring oxytocic that can dramatically improve uterine tone; however, it has an unfavorable side-effect profile (fever, chills, nausea, emesis, diarrhea, headaches) that often precludes its use.

When atony is due to tocolytic drugs that have impaired calcium entry into the cell (magnesium sulfate, nifedipine), calcium gluconate should be considered as an adjuvant therapy. Given as an intravenous push, one ampule (1 g) of calcium gluconate can effectively improve uterine tone and resolve bleeding due to atony.

If pharmacologic methods fail to control atony-related hemorrhage, alternative measures must be undertaken. These include uterine tamponade, selective arterial embolization, and surgical intervention.

Uterine Tamponade

Uterine packing is a safe, simple, and effective way to control postpartum hemorrhage by providing tamponade to the bleeding uterine surface.[83] Although packing techniques vary, a few basic principles should be followed. The pack should be made of long, continuous gauze (Kerlix) rather than multiple small sponges. Placement of the gauze within a sterile plastic bag or glove can ease removal of the pack. When packing the uterus, placement should begin at the fundus and progress downward in a side-to-side fashion to avoid dead space for blood accumulation.[77] Transurethral Foley catheter placement and prophylactic antibiotic use should be considered to prevent urinary retention and infection, respectively. Finally, prolonged packing should be avoided (not more than 12 to 24 hours), and close attention to the patient's vital signs and blood indices should be paid while the pack is in place in order to minimize unrecognized ongoing bleeding.

In recent years, **intrauterine tamponade balloons** have replaced traditional uterine packing. Multiple balloon types have been employed, including the **Bakri SOS (Surgical Obstetric Silicone) balloon** and the **BT-Cath balloon**. Both devices were developed specifically for postpartum hemorrhage management. The Bakri SOS balloon (Cook Women's Health, Bloomington, IN; Figure 19-10) consists of a silicone balloon attached to a catheter. The catheter is inserted into the uterus either manually or under ultrasound guidance, and the silicone balloon is subsequently inflated with sterile saline (maximum of 500 mL). Once inflated, the balloon should adapt to the uterine configuration and provide tamponade to the endometrial surface. The intraluminal catheter allows drainage from within the uterus, allowing for ongoing assessment of blood loss.[84] Proper placement of the balloon is essential to provide adequate tamponade (Figure 19-11). The BT-Cath is a silicone balloon shaped like an inverted pear. Similar to the Bakri balloon, this tamponade balloon has a double-lumen catheter that allows saline filling of the balloon as well as drainage of blood from within the uterus.

The Glenveigh *ebb* Complete Tamponade System is a new postpartum tamponade balloon (Figure 19-12). Developed by maternal-fetal specialists, this system incorporates both intrauterine and intravaginal tamponade. Both balloons are made of strong yet malleable polyurethane, allowing for better conformation to the uterine and vaginal shapes. In addition, the uterine balloon can be rapidly inflated from a saline bag to a larger volume of 750 mL for circumstances in which the smaller balloons are inadequate (such as multiple gestations). Finally, like the other balloons, this system has a drainage port to assess for ongoing bleeding; however, unlike the others, it also has an infusion port to irrigate the uterus.

Selective Arterial Embolization

Selective arterial embolization is an increasingly common therapeutic option for hemodynamically stable patients with postpartum hemorrhage. The procedure can be performed alone or after failed surgical intervention.[85] Pelvic angiography is used to visualize bleeding vessels, and Gelfoam (gelatin) pledgets are placed into the vessels for occlusion. **Cumulative success rates of 90% to 95% have been reported.**[85]

Selective arterial embolization has several advantages over surgical intervention. First, it allows for selective occlusion of bleeding vessels. This can be extremely valuable in circumstances of aberrant pelvic vasculature, such as uterine arteriovenous malformations. Second, the uterus and potential future fertility are preserved. Cases series have reported successful pregnancies after pelvic embolization.[85] Finally, the procedure has minimal morbidity, enables the physician to forego or delay surgical intervention, and can be performed in coagulopathic patients, allowing more time for blood and clotting factor replacement. Procedure-related complications occur in 3% to 6%

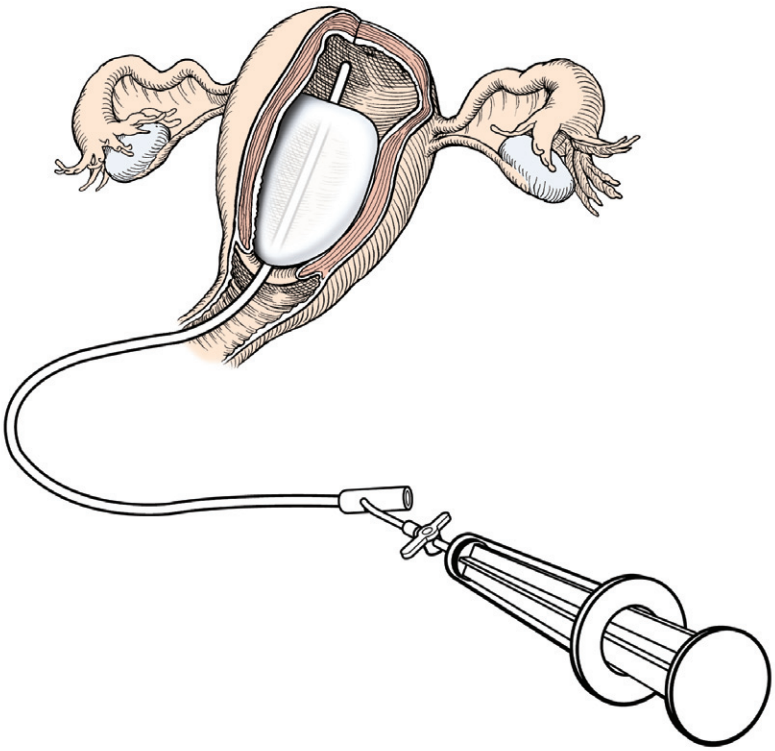

FIGURE 19-10. The Bakri SOS Tamponade Balloon. (Courtesy Cook Women's Health.)

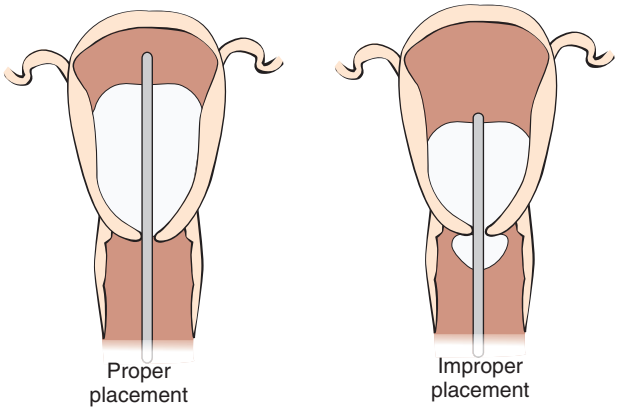

FIGURE 19-11. Proper placement of the Bakri SOS Tamponade Balloon.

FIGURE 19-12. The Glenveigh *ebb* Complete Tamponade System. (Courtesy Glenveigh Medical, LLC.)

of cases.[85] Reported complications include postembolization fever, infection, ischemic pain, vascular perforation, and tissue necrosis. A relative disadvantage of the procedure is its limited availability. Timely coordination of services between the obstetrical team and interventional radiology is necessary to provide this treatment option.

Surgical Intervention

When uterine atony is unresponsive to conservative management, surgical intervention by laparotomy is necessary. Possible interventions include arterial ligation, uterine compression sutures, and hysterectomy.

The goal of arterial ligation is to decrease uterine perfusion and subsequent bleeding. Success rates have varied from 40% to 95% in the literature depending on which vessels are ligated.[86] Arterial ligation may be performed on the ascending uterine arteries, the utero-ovarian arteries, the infundibulopelvic ligament vessels, and the hypogastric arteries. Because hypogastric arterial ligation can be technically challenging and time-consuming, it is not advised as a first-line technique unless the surgeon is extremely skilled

in performing the procedure. Instead, a stepwise progression of uterine vessel ligation is recommended.

Nearly 45 years ago, O'Leary described a technique of bilateral uterine artery ligation for control of postpartum hemorrhage.[87] Today, it is still considered the best initial ligation technique given its ease in performance and the accessibility of the uterine artery. To perform the procedure, the ascending uterine artery should be located at the border of the upper and lower uterine segment. Absorbable suture is passed through the uterine myometrium at the level of the lower uterine segment and laterally around the uterine vessels through the broad ligament. The suture is then tied to compress the vessels against the uterine wall (Figure 19-13). Because the suture is placed fairly high in the lower uterine segment, the ureter is not in jeopardy, and the bladder does not need to be mobilized. Unilateral artery ligation will control hemorrhage in 10% to 15% of cases, whereas bilateral ligation will control an additional 75%.[88]

If bleeding persists, the utero-ovarian and infundibulopelvic vessels should be ligated. The utero-ovarian arteries can be ligated similarly to what has been described for the ascending uterine vessels. If this measure is unsuccessful, interruption of the infundibulopelvic vessels can be undertaken. Although the ovarian blood supply may be decreased with an infundibulopelvic vessel ligation, successful pregnancy has been reported.[89]

Bakri has described a newer technique for bilateral uterine artery ligation in combination with tamponade balloon placement (Figure 19-14).[90] The procedure, termed **Bilateral Looped Uterine Vessels Sutures** (B-LUVS), incorporates looped absorbable sutures bilaterally through the myometrium around the uterine vessels from the lower segment up to the corneal region. Once the sutures are tied, a Bakri SOS balloon is placed within the uterine cavity to provide tamponade. A small series has had 100% success with this combined ligation-tamponade approach.[90]

In addition to arterial ligation, **uterine compression sutures** have been described for atony control. Several techniques have evolved over the past decade, including the **B-Lynch suture, Hayman vertical sutures, Pereira transverse and vertical sutures, and multiple square sutures.**[91-93]

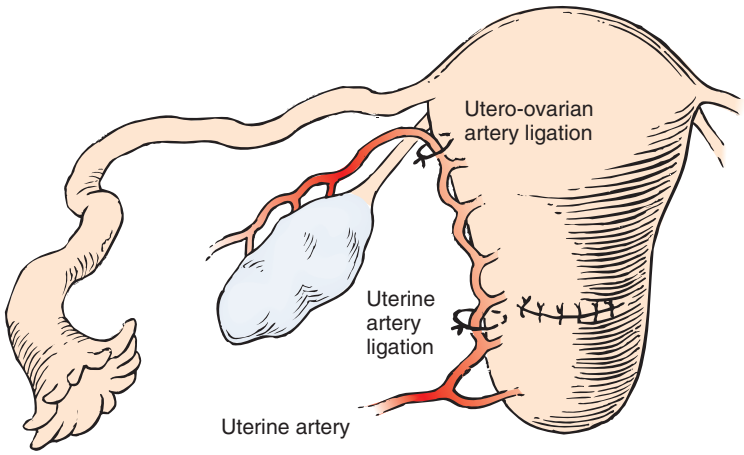

FIGURE 19-13. Uterine artery ligation.

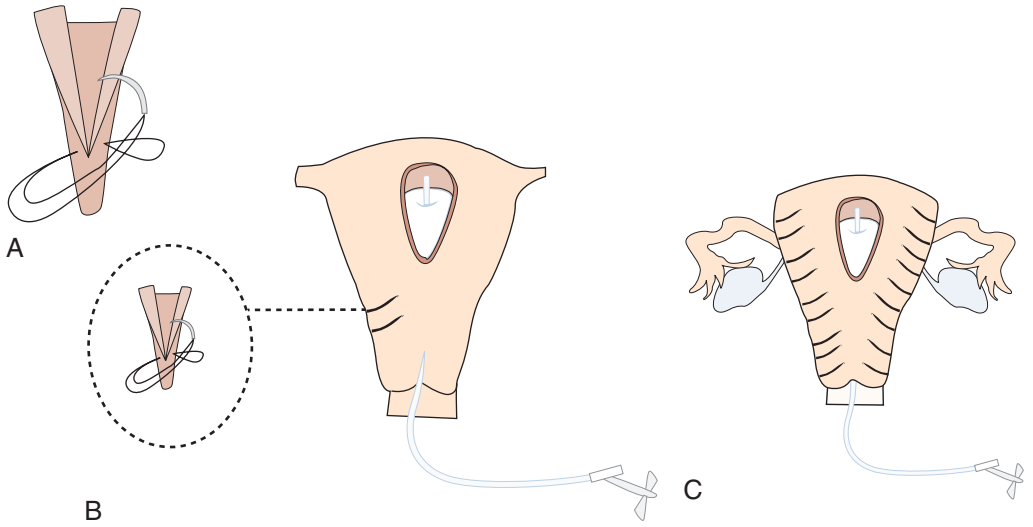

FIGURE 19-14. B-LUVS: Bilateral Looped Uterine Vessels Sutures. (Modified from Bakri YN, Wilkenson JP: Use of intrauterine balloon catheters for control of uterine hemorrhage. Available at http://www.uptodate.com. Accessed September 2010.)

To place a compression suture, the patient should lie in the dorsal lithotomy position so that an assessment of vaginal bleeding can occur. Large absorbable suture is typically anchored within the uterine myometrium both anteriorly and posteriorly. It is passed in a continuous or intermittent fashion around or through the external surface of the uterus and tied firmly so that adequate uterine compression occurs. Figures 19-15 to 19-18 demonstrate proper placements of these sutures. Like arterial ligation, uterine compression sutures can be combined with tamponade balloons for refractory bleeding. The "uterine sandwich" technique refers to placement of a B-Lynch suture followed by a Bakri SOS balloon within the uterine cavity.[94] Typically, the tamponade balloon is inflated to a lesser degree (median volume of 100 mL) in these scenarios. Small series have demonstrated 100% success for this combined approach.[94]

The final surgical intervention for refractory bleeding due to atony is hysterectomy. Hysterectomy provides definitive therapy. Because blood loss may be severe, it is often prudent to modify the surgical approach by using the "clamp-cut-drop" technique or performing a supracervical hysterectomy (Figure 19-19), or both.[95] These considerations are especially important when the patient is hemodynamically unstable.

Genital Tract Lacerations

Definition and Pathogenesis

Genital tract lacerations may occur with both vaginal and cesarean deliveries. These lacerations involve the maternal

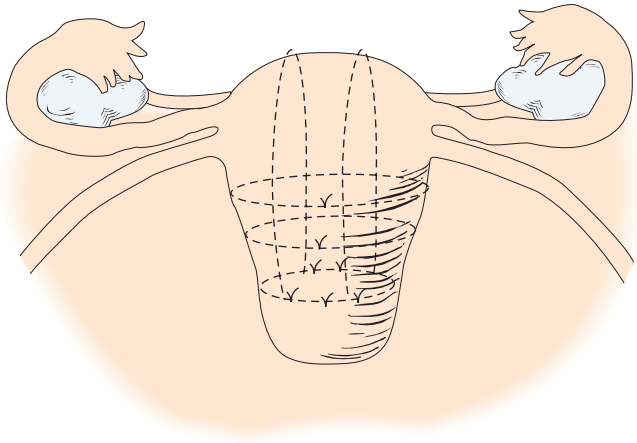

FIGURE 19-17. Pereira transverse and vertical sutures. (Modified from Jacobs AJ: Management of postpartum hemorrhage at cesarean delivery. Available at http://www.uptodate.com. Accessed September 2010.)

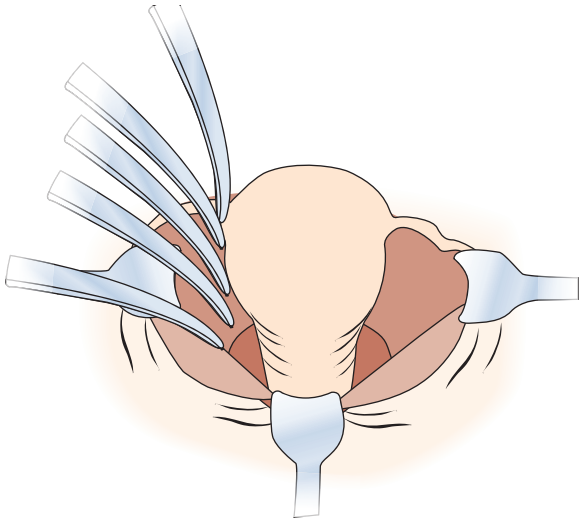

FIGURE 19-19. "Clamp-cut-drop" technique for hysterectomy. The vascular pedicles are clamped and divided. The pedicles are ligated after the hemorrhage is controlled. (Modified from Wright JD, Bonanno C, Shah M, et al: Peripartum hysterectomy. Obstet Gynecol 116:429, 2010.)

soft tissue structures and can be associated with large hematomas and rapid blood loss if unrecognized. **The most common lower genital tract lacerations are perineal, vulvar, vaginal, and cervical. Upper genital tract lacerations are typically associated with broad ligament and retroperitoneal hematomas.**

Incidence and Risk Factors

Although it is difficult to ascertain their exact incidence, **genital tract lacerations are the second leading cause of postpartum hemorrhage. Risk factors** include instrumented **vaginal delivery, fetal malpresentation, fetal macrosomia, episiotomy, precipitous delivery, prior cerclage placement, Dührssen incisions, and shoulder dystocia.**

Clinical Manifestations and Diagnosis

A genitourinary tract laceration should be suspected if bleeding persists after delivery despite adequate uterine tone. Occasionally, the bleeding may be masked because of its location, that is, the broad ligament. In these circumstances, large amounts of blood loss may occur in an unrecognized hematoma. Pain and hemodynamic instability are often the primary presenting symptoms.

For diagnosis, it is best to evaluate the lower genital tract starting superiorly at the cervix and progressing inferiorly to the vagina, perineum, and vulva. Adequate exposure and retraction are essential to diagnosing many of these lacerations.

Management

Once a genital tract laceration is diagnosed, management depends on its severity and location. Lacerations of the cervix and vaginal fornices are often difficult to repair owing to their position. In these circumstances, relocation to an operating room for better pain relief, pelvic relaxation, and visualization are recommended. For cervical lacerations, it is important to secure the apex of the tear because this is often a major source of bleeding.

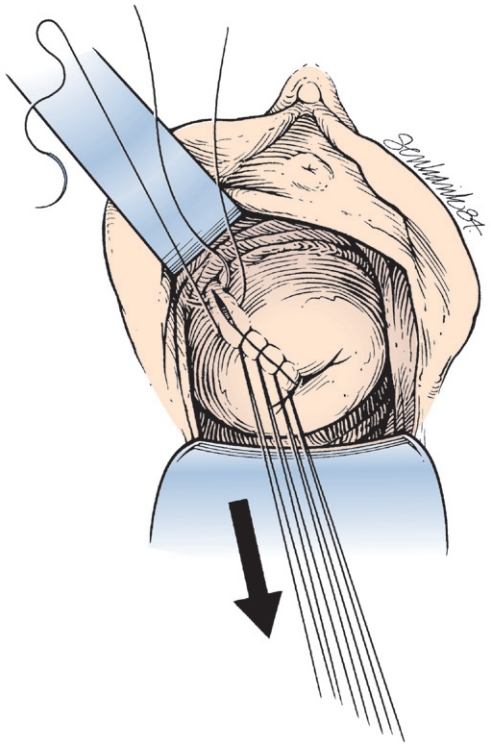

FIGURE 19-20. Repair of a cervical laceration, beginning at the proximal part of the laceration and using traction on the previous sutures to aid in exposure of the distal defect.

Unfortunately, exposure of this angle can be difficult. A helpful technique for these scenarios is to start suturing the laceration at its proximal end, thereby using the suture for traction to expose the more distal portion of the cervix until the apex is in view (Figure 19-20).

Perineal repairs are the most common types of genital tract lacerations. Figures 19-21 to 19-23 illustrate second-, third-, and fourth-degree perineal lacerations and techniques for their repair. If the laceration is adjacent to the urethra or bowel, the use of additional instrumentation (e.g., transurethral catheter) can protect uninjured organs and allow for more efficient repair.

On occasion, a blood vessel laceration may lead to the formation of a pelvic hematoma in the lower or upper genital tract. The three most common locations for a pelvic hematoma are vulvar, vaginal, and retroperitoneal.

Vulvar Hematoma

Vulvar hematomas usually result from lacerated vessels in the superficial fascia of the anterior or posterior pelvic triangle. Blood loss is tamponaded by Colles fascia, the urogenital diaphragm, and anal fascia (Figure 19-24). Because of these fascial boundaries, the mass will extend to the skin, and a visible hematoma results (Figure 19-25).

Surgical drainage is the primary treatment for vulvar hematomas. A wide linear incision through the skin is recommended. Typically, the bleeding is due to multiple small vessels; hence, vessel ligation is not possible. Once the hematoma is evacuated, the dead space should be closed in layers with absorbable suture and a sterile pressure dressing applied. A transurethral Foley catheter should be placed until significant tissue edema subsides.

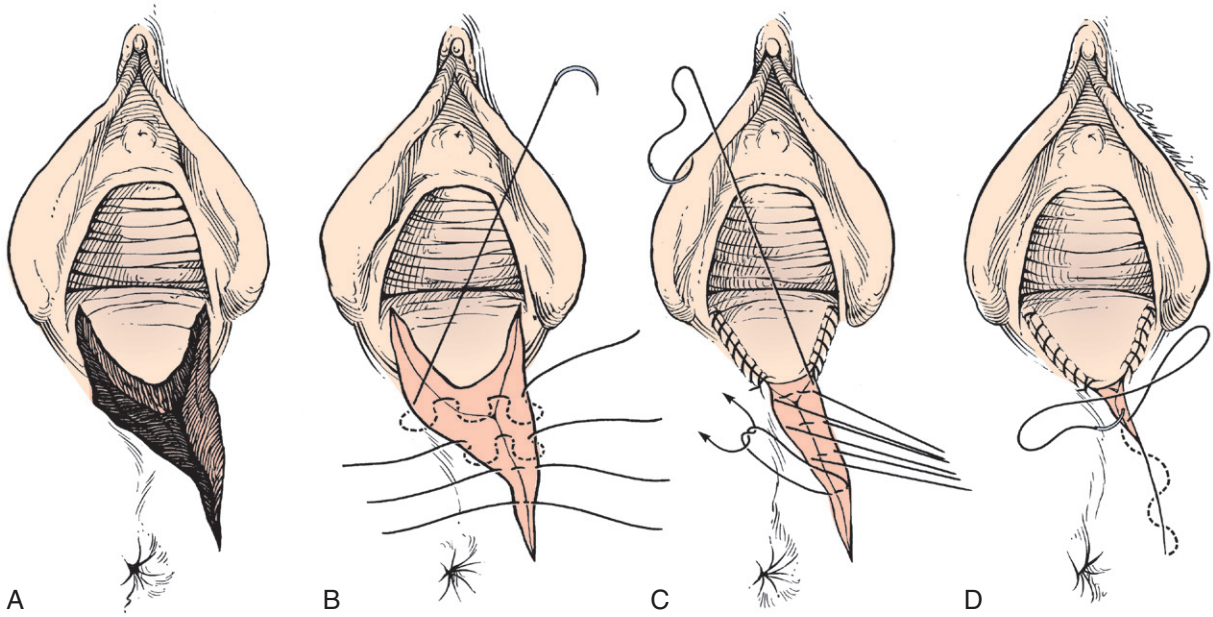

FIGURE 19-21. Repair of a second-degree laceration. A first-degree laceration involves the fourchet, the perineal skin, and the vaginal mucous membrane. A second-degree laceration also includes the muscles of the perineal body. The rectal sphincter remains intact.

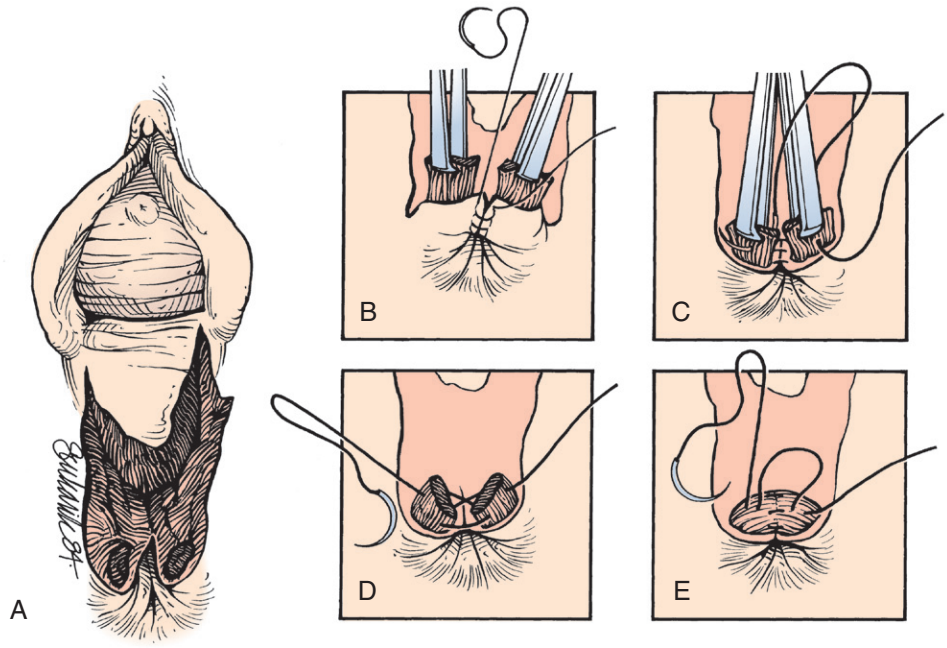

FIGURE 19-22. Repair of the sphincter after a third-degree laceration. A third-degree laceration not only extends through the skin, mucous membrane, and perineal body but also includes the anal sphincter. Interrupted figure-of-eight sutures should be placed in the capsule of the sphincter muscle.

Vaginal Hematoma

Vaginal hematomas result from delivery-related soft tissue damage. These hematomas accumulate above the pelvic diaphragm (Figure 19-26). Occasionally, these hematomas protrude in the vaginal-rectal area. Like vulvar hematomas, vaginal hematomas are due to multiple small vessel lacerations. Depending on the extent of the hemorrhage, **vaginal hematomas may or may not require surgical drainage.** Small, nonexpanding hematomas are often best managed expectantly. Larger, expanding hematomas require surgical intervention. Unlike vulvar hematomas, the incision of a vaginal hematoma does not require closing; rather a vaginal pack or tamponade device should be placed on the raw edges. If bleeding persists, **selective arterial embolization may be considered.**

Retroperitoneal Hematoma

Although infrequent, **retroperitoneal hematomas are the most serious and life threatening.** The early symptoms of a retroperitoneal hematoma are often subtle, with the

hematoma being unrecognized until the patient is hemodynamically unstable from massive hemorrhage. **These hematomas usually occur after a vessel laceration from the hypogastric arterial tree** (Figure 19-27). Such lacerations may result from instrumented vaginal delivery, inadequate hemostasis of the uterine arteries at the time of cesarean delivery, or uterine rupture during a trial of labor after cesarean delivery. **Treatment of a retroperitoneal hematoma typically involves surgical exploration, hematoma evacuation, and arterial ligation. In some situations, selective arterial embolization may be used as a primary or adjunctive treatment.**

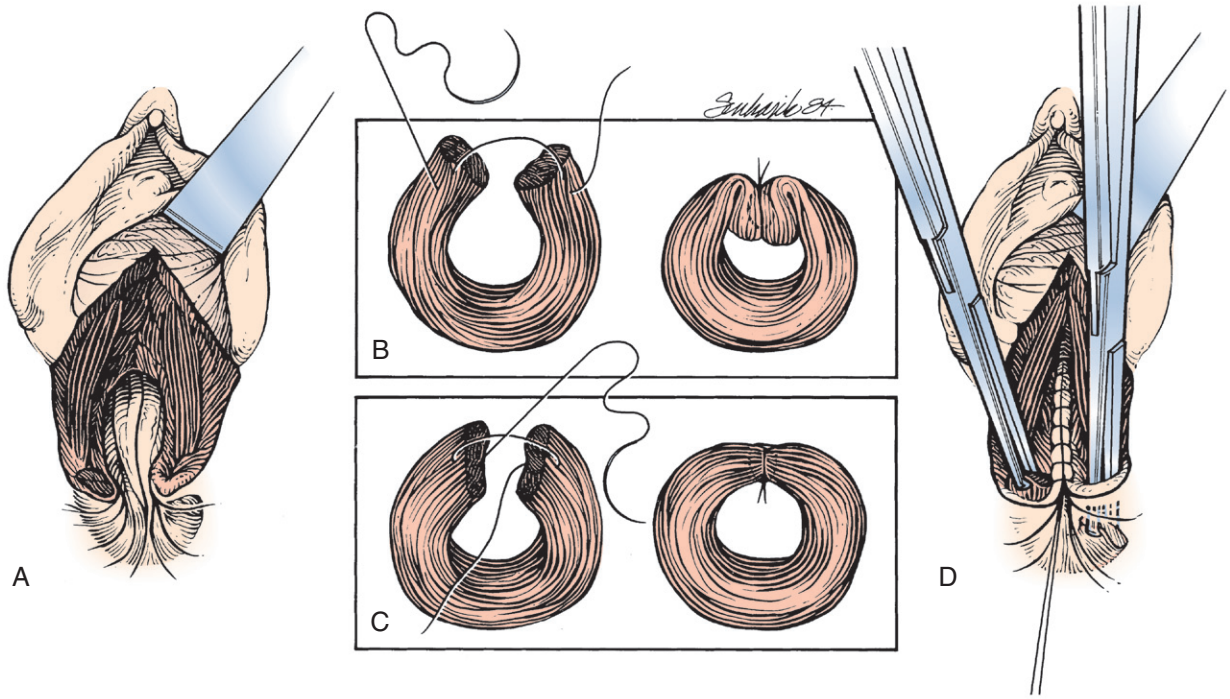

FIGURE 19-23. Repair of a fourth-degree laceration. This laceration extends through the rectal mucosa. **A,** The extent of this laceration is shown, with a segment of the rectum exposed. **B,** Approximation of the rectal submucosa. This is the most commonly recommended method for repair. **C,** Alternative method of approximating the rectal mucosa in which the knots are actually buried inside the rectal lumen. **D,** After closure of the rectal submucosa, an additional layer of running sutures may be placed. The rectal sphincter is then repaired.

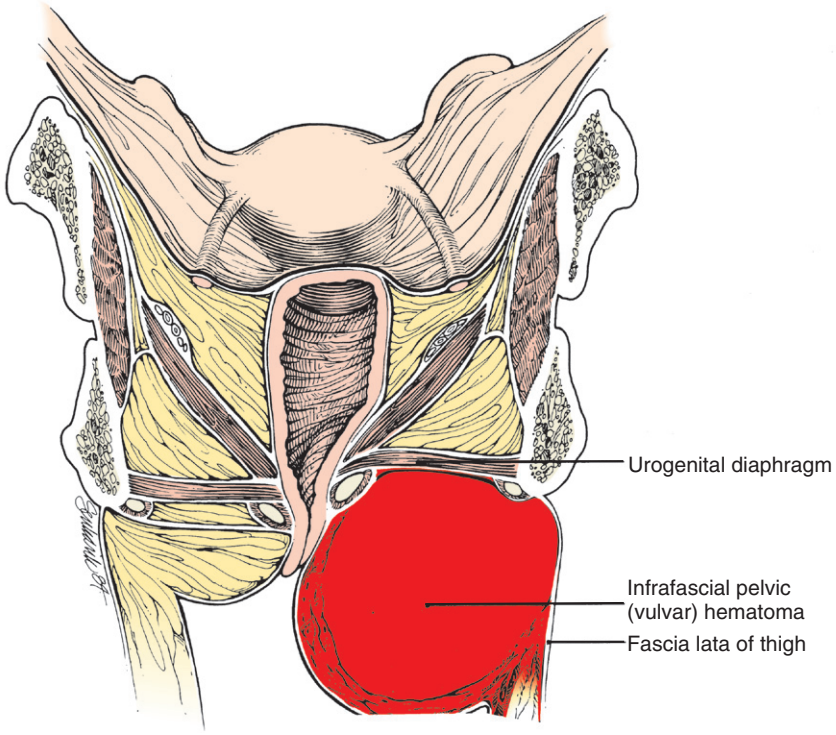

FIGURE 19-24. Vulvar hematoma fascial boundaries.

Retained Products of Conception

Definition and Pathogenesis

Retained products of conception, namely placental tissue and amniotic membranes, can inhibit the uterus from adequate contraction and result in hemorrhage. The diagnosis is made when there has not been spontaneous expulsion of the tissue within 30 to 60 minutes of delivery.[96]

Incidence and Risk Factors

Retained products of conception complicate 1 in 100 to 1 in 200 deliveries. Risk factors include midtrimester delivery, chorioamnionitis, and accessory placental lobes.

Clinical Manifestations and Diagnosis

Retained products of conception typically present with uterine bleeding and associated atony. To assess the uterus for retained products of conception, the uterine cavity needs to be explored. Manual exploration is not only diagnostic but also often therapeutic (Figure 19-28). By wrapping the examination hand with moist gauze, removal of retained placental fragments and amniotic membranes can be facilitated. If manual access to the uterine cavity is difficult or limited owing to maternal body habitus or inadequate pain relief, **transabdominal or transvaginal ultrasound may be used to determine whether retained placental fragments are present.**

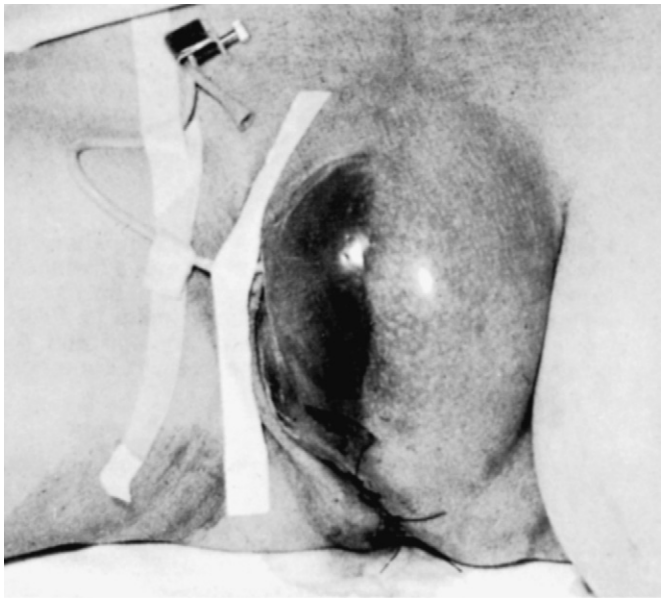

Figure 19-25. Large vulvar hematoma.

Management

Once a diagnosis of retained products of conception is made, removal must be undertaken. Therapeutic options include **manual extraction,** as noted previously, or **uterine curettage.** Nitroglycerin (50 to 200 mcg intravenous) has been used effectively to assist with manual placental extraction.[97] Nitroglycerin provides rapid uterine relaxation to assist with removal of the retained tissue. Uterine curettage may be performed in a delivery room; however, excessive bleeding mandates that an operating room be used for the procedure. Either a large Banjo curette or vacuum suction curette can be employed. Transabdominal ultrasound guidance is helpful in determining that tissue evacuation is complete.

Pharmacologic options for retained products of conception include intraumbilical vein oxytocin injection and Misoprostol (Cytotec). Although initial studies of intraumbilical vein oxytocin injection were promising, larger systematic reviews and meta-analyses have shown no significant reduction in need for manual placental extraction.[98] Misoprostol administration (800 mcg), on the other hand, demonstrated a significant reduction in need for manual placental removal compared with intraumbilical vein oxytocin and saline injections.[99]

Uterine Rupture

Definition and Pathogenesis

Uterine rupture refers to the complete nonsurgical disruption of all uterine layers (endometrium, myometrium, and

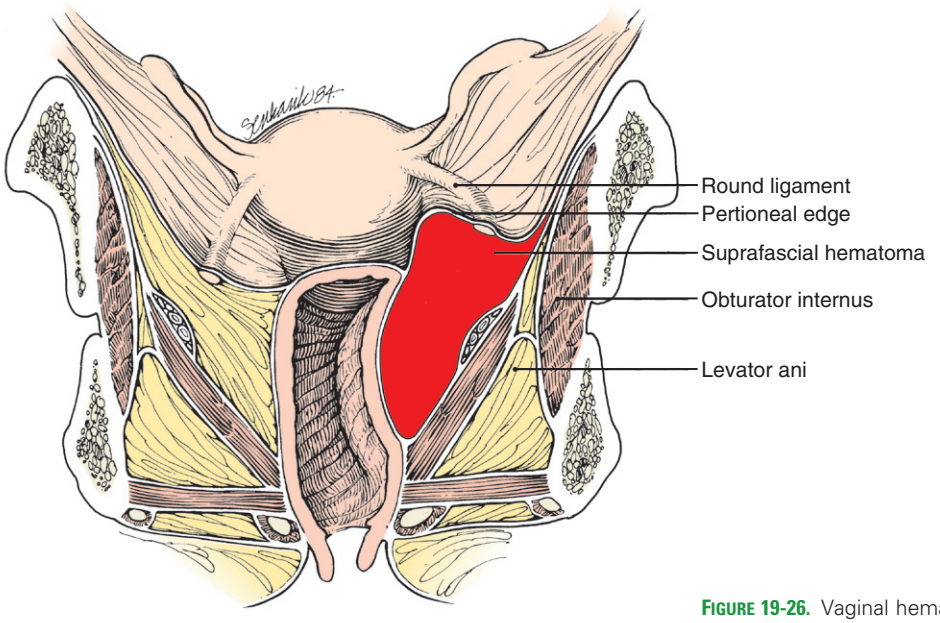

Figure 19-26. Vaginal hematoma.

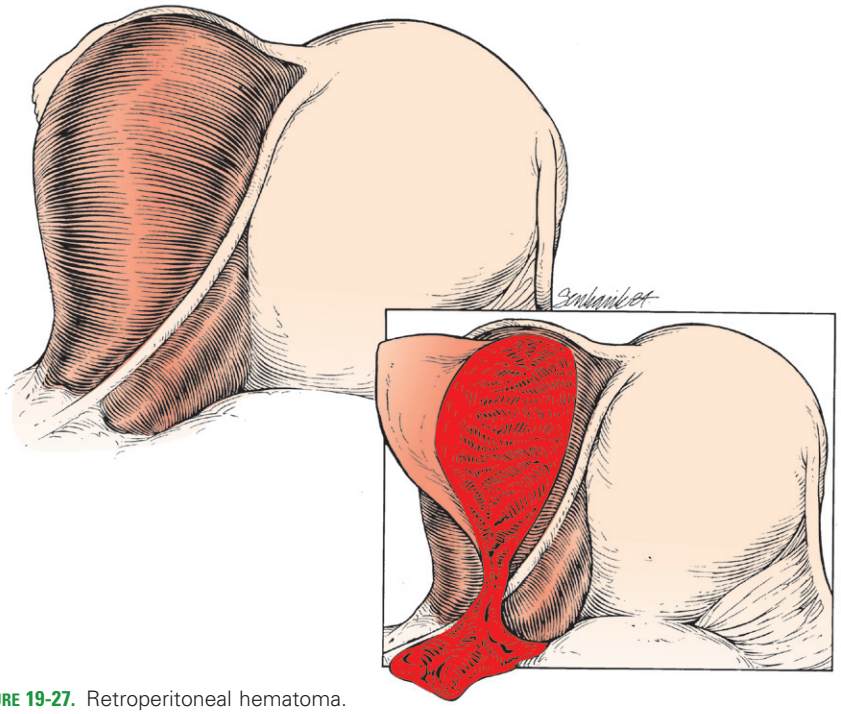

FIGURE 19-27. Retroperitoneal hematoma.

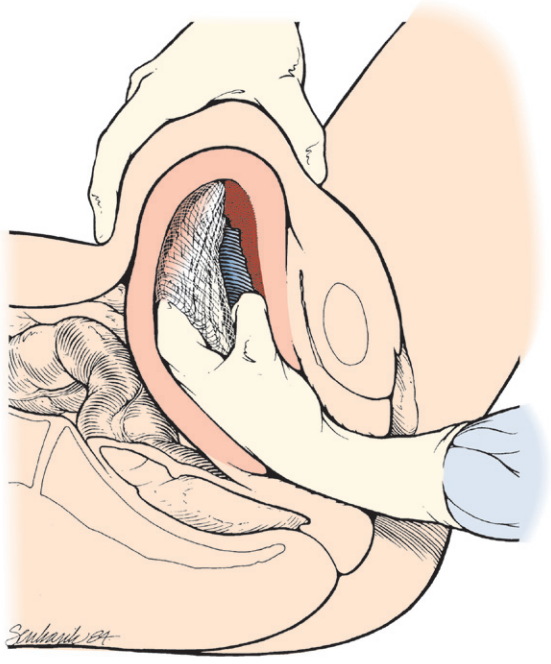

FIGURE 19-28. Manual uterine exploration.

serosa). The severity of hemorrhage and maternal-fetal morbidity depends on the extent of the rupture. A large rupture may be associated with massive hemorrhage and extrusion of the fetus or placenta into the maternal abdomen, whereas a small rupture may have minimal bleeding and insignificant maternal-fetal consequences. The terms *uterine dehiscence* and *incomplete uterine rupture* are often used to describe the latter type of disruption.

TABLE 19-8 RISK FOR UTERINE RUPTURE BASED ON INCISION OF PRIOR CESAREAN DELIVERY

INCISION OF PRIOR CESAREAN DELIVERY	UTERINE RUPTURE RISK (%)
Classical	4-9
T-shaped	4-9
Low vertical	1-7
Low transverse	0.5-2

From Welischar J, Quirk JG: Trail of labor after cesarean delivery. Available at http://www.uptodate.com. Accessed September 2010.

INCIDENCE AND RISK FACTORS

The overall incidence of uterine rupture is 1 in 2000 deliveries. Uterine rupture is most common in women with a scarred uterus, including prior cesarean delivery and myomectomy. The location of the previous hysterotomy affects the uterine rupture risk. For prior cesarean deliveries, the risk of uterine rupture is illustrated in Table 19-8.

While **multiple risk factors** have been associated with uterine rupture, no single or combination of factors is able to reliably predict all cases.[100] Despite this, consistent data demonstrate strong associations for trial of labor after cesarean delivery and one or more of the following: **multiple prior cesarean deliveries, no previous vaginal delivery, induced or augmented labor, term gestation, thin uterine scar identified by ultrasound, multiple gestation, fetal macrosomia, post–cesarean delivery infection, single layer closure of hysterotomy incision, and short interpregnancy interval.**[101] Other reported risk factors include increasing **maternal age, multiparity, fetal malpresentation, uterine manipulation** (e.g., internal podalic version), **mid- to high-operative vaginal delivery, congenital uterine malformations, Ehlers-Danlos syndrome, invasive placentation, and trauma.**[102]

Clinical Manifestations and Diagnosis

Uterine rupture is associated with both fetal and maternal clinical manifestations. Fetal bradycardia with or without preceding variable or late decelerations is the most common clinical manifestation of symptomatic uterine rupture, occurring in 33% to 70% of cases.[103] In some circumstances, a **loss of fetal station in labor** may occur. **Maternal clinical manifestations** are variable and may include **acute vaginal bleeding, constant abdominal pain or uterine tenderness, change in uterine shape, cessation of contractions, hematuria** (if extension into the bladder has occurred), and **signs of hemodynamic instability.**

Uterine rupture is suspected clinically but confirmed surgically. Laparotomy will demonstrate complete disruption of the uterine wall, with bleeding and partial or complete extravasation of the fetus into the maternal abdomen.

Management

Once the fetus and placenta are delivered, the **site of rupture should be assessed to determine whether it can be repaired. If feasible, the rupture can be repaired in multiple layers with absorbable suture.** Hysterectomy should be reserved for cases of massive hemorrhage, irreparable uterine defects, or maternal hemodynamic instability.

Maternal and Neonatal Outcomes

Although maternal mortality is uncommon with a uterine rupture, **significant morbidity** can occur. The most comprehensive review of trial of labor after cesarean delivery found **increased risks for blood transfusion, hysterectomy, and genitourinary injury.**[104] With regard to perinatal outcome, **increased rates of low 5-minute Apgar scores (<5), umbilical artery pH less than 7.0, admission to the neonatal intensive care unit, hypoxic-ischemic encephalopathy, and neonatal death** have been documented.[105]

Uterine Inversion

Definition and Pathogenesis

Uterine inversion refers to the collapse of the fundus into the uterine cavity. Uterine inversion is classified by degree and timing. With regard to degree, uterine inversion may be incomplete, complete, or prolapsed. Incomplete uterine inversion represents a partial extrusion of the fundus into the uterine cavity. With complete uterine inversion, the internal lining of the fundus crosses through the cervical os, forming a rounded mass in the vagina with no palpable fundus abdominally. Prolapsed uterine inversion refers to the entire uterus prolapsing through the cervix with the fundus passing out of the vaginal introitus. Uterine inversion timing is classified as **acute (≤24 hours of delivery), subacute (>24 hours postpartum), or chronic (>1 month postpartum)**.

The two most commonly proposed etiologies for uterine inversion include excessive umbilical cord traction with a fundally attached placenta and fundal pressure in the setting of a relaxed uterus. However, a causal relationship between active management of the third stage of labor and uterine inversion remains unproved.[106]

Incidence and Risk Factors

Uterine inversion is a rare event, complicating about 1 in 2000 to 1 in 23,000 deliveries.[107] Proposed **risk factors** for uterine inversion include **uterine overdistention, fetal macrosomia, rapid labor, congenital uterine malformations, invasive placentation, short umbilical cord, use of uterine-relaxing agents, nulliparity, manual placental extraction, and Ehlers-Danlos syndrome.**

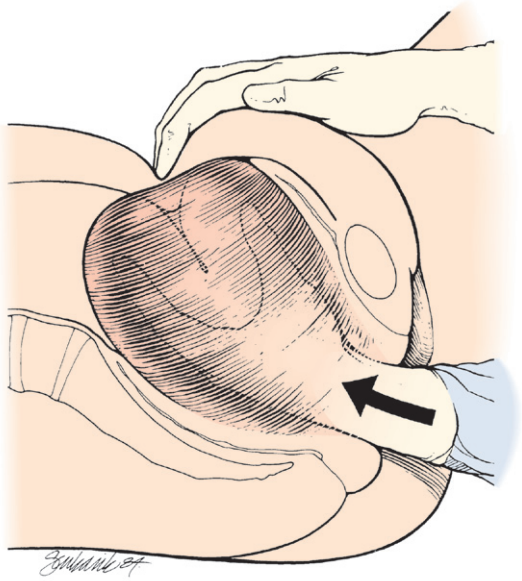

Figure 19-29. Manual replacement of uterine inversion.

Clinical Manifestations and Diagnosis

Uterine inversion should be suspected with the **sudden onset of brisk vaginal bleeding in association with the inability to palpate the fundus abdominally and maternal hemodynamic instability.** It may occur before or after placental detachment. The diagnosis is made clinically with bimanual examination, during which the uterine fundus is palpated in the lower uterine segment or within the vagina. Sonography can be used to confirm the diagnosis if the clinical examination is unclear.[108]

Management

Once diagnosed, uterine inversion requires rapid intervention in order to restore maternal hemodynamic stability and control hemorrhage. Maternal fluid resuscitation through a large-bore intravenous catheter is recommended. The uterus must be replaced to its proper orientation to resolve the hemorrhage. This is best accomplished in an operating room with the assistance of an anesthesiologist. The uterus and cervix should initially be relaxed with nitroglycerin (50 to 500 mcg), a tocolytic agent (magnesium sulfate or β-mimetic), or a halogenated anesthetic.[109] Once relaxed, gentle manual pressure is applied to the uterine fundus in order to return it to its proper abdominal location (Figure 19-29). Uterotonic therapy should then be given to assist with uterine contraction and prevent recurrence of the inversion.

If manual repositioning is unsuccessful, other options include hydrostatic reduction and surgical correction. With hydrostatic reduction, warmed sterile saline is infused into the vagina. The physician's hand or a Silastic ventouse cup is used as a fluid retainer in order to generate intravaginal hydrostatic pressure and resultant correction of the

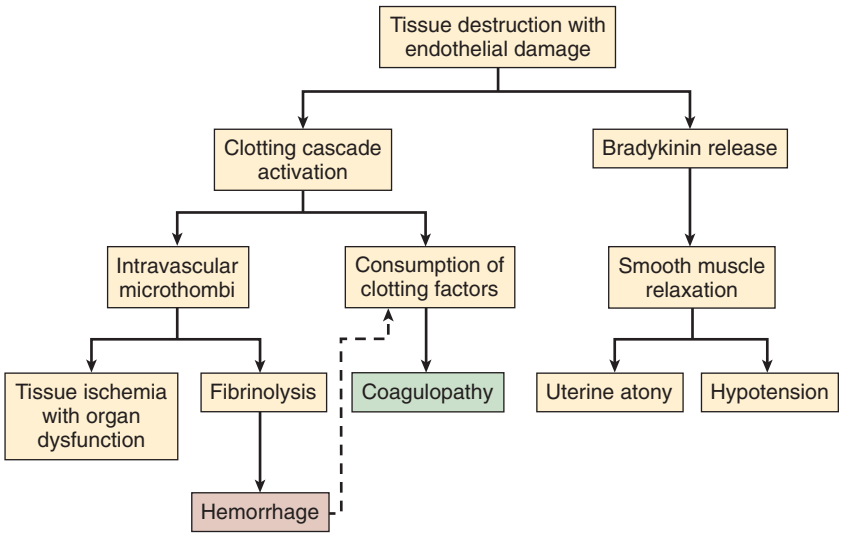

FIGURE 19-30. Pathophysiology and clinical manifestations of consumptive coagulopathy.

inversion.[110] Surgical options include the Huntington and Haultain procedures, laparoscopic-assisted repositioning, and cervical incisions with manual uterine repositioning.[111] The Huntington procedure involves a laparotomy with serial clamping and upward traction of the round ligaments to restore the uterus to its proper position. If this technique fails, the Haultain procedure, which uses a vertical incision within the inversion and manual repositioning of the fundus, can be attempted. As with manual repositioning, uterotonic therapy should be administered immediately after uterine replacement.

Coagulopathy

Definition and Pathogenesis

Coagulopathy represents an imbalance between the clotting and fibrinolytic systems. This imbalance may be hereditary or acquired in origin. Hereditary coagulopathies are relatively rare and have variable etiologies. Although **acquired coagulopathy** can be due to iatrogenic causes, such as anticoagulant administration, it is **usually the result of clotting factor consumption.** Figure 19-30 demonstrates the pathophysiology of consumptive coagulopathy and its association with hemorrhage.

Incidence and Risk Factors

The overall incidence of coagulopathy in the obstetrical population has not been reported; however, several **risk factors** have been documented. These include **massive antepartum or postpartum hemorrhage, sepsis, severe preeclampsia, HELLP syndrome, amniotic fluid embolism, fetal demise, placental abruption, septic abortion, and acute fatty liver of pregnancy.**

Clinical Manifestations and Diagnosis

The primary clinical manifestations of consumptive coagulopathy include bleeding, hypotension out of proportion to blood loss, microangiopathic hemolytic anemia, acute lung injury, acute renal failure, and ischemic end-organ tissue damage.

Consumptive coagulopathy is a clinical diagnosis that is confirmed with laboratory data, such as thrombocytopenia, hemolytic changes on the peripheral blood smear, decreased fibrinogen, elevated fibrin degradation products, and prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT). When timely laboratory assessment is unavailable, drawing 5 mL of maternal blood into an empty red-topped tube and observing for clot formation provide the clinician with a rough estimate of the degree of existing coagulopathy. If a clot is not visible within 6 minutes or forms and lyses within 30 minutes, the fibrinogen level is usually less than 150 mg/dL.

Management

The most important factor in the successful treatment of coagulopathy is identifying and correcting the underlying etiology. For most obstetrical causes, **delivery of the fetus initiates resolution of the coagulopathy.** In addition, rapid replacement of blood products and clotting factors should occur simultaneously. The patient should have **two large-bore intravenous catheters for fluid and blood component therapy. Laboratory studies should be drawn serially every 4 hours until resolution** of the coagulopathy is evident. The obstetrician should attempt to achieve a hematocrit greater than 21%, a platelet count greater than 50,000/mm^3, a fibrinogen level greater than 100 mg/dL, and PT and aPTT less than 1.5 times control. It also is important to maintain adequate oxygenation and normothermia. Finally, adjuvant therapies, such as vitamin K, recombinant activated factor VIIa, fibrinogen concentrate, and hemostatic agents, should be considered.

Vitamin K

Factors II, VII, IX, and X are vitamin K–dependent clotting factors. In consumptive coagulopathy, these clotting factors are consumed. Administration of vitamin K (5 to 10 mg) by the subcutaneous, intramuscular, or intravenous routes can assist with endogenous replenishment of these procoagulants.

Recombinant Activated Factor VIIa

Factor VII is a precursor for the extrinsic clotting cascade. When massive procoagulant factor consumption occurs, factor replacement is necessary. **Human recombinant factor VIIa has been used successfully in cases of consumptive**

coagulopathy attributed to postpartum hemorrhage. The dosage of this intravenous therapy has ranged from 16.7 to 120 mcg/kg.[112] Important advantages of this therapy are its rapid bioavailability and reversal of coagulopathy (10 to 40 minutes); however, disadvantages include a relatively short half life (2 hours), cost (approximately $1 per 1 mcg), and thromboembolism risk. Recombinant activated factor VIIa should be considered in cases of refractory coagulopathy or when blood component replacement is delayed.

Fibrinogen Concentrate

Human fibrinogen concentrate (RiaStap) has recently been approved by the U.S. Food and Drug Administration. This intravenous therapy has been used successfully in Europe for the treatment of massive hemorrhage due to consumptive coagulopathy (trauma, surgery, gastrointestinal hemorrhage) and congenital fibrinogen deficiency.[113]

Hemostatic Agents

A variety of topical hemostatic agents are available for control of coagulopathic surface bleeding. These agents have different clotting factors and mechanisms of action. Examples include fibrin sealants (e.g., Tisseal), hemostatic matrices (e.g., Floseal), and Gelfoam. These agents may be used alone or in combination.

Fluid Resuscitation and Transfusion

All obstetricians will encounter antepartum and postpartum hemorrhage. In most instances, **fluid resuscitation and blood component therapy is life-saving.** Therefore, every physician should have a thorough understanding of appropriate volume and transfusion therapy, alternative treatment options, and their risks.

Volume Resuscitation

Initial management of a hemorrhaging patient requires appropriate volume resuscitation. Two large-bore intravenous catheters are recommended. **Warmed crystalloid solution in a 3:1 ratio to the estimated blood loss should be rapidly infused.** Goals of therapy are to prevent hypotension (systolic blood pressure >90 mm Hg) and maintain urine output (at least 30 mL/hr). If the hemorrhage is easily controlled, this may be the only volume resuscitation needed. The patient should have serial assessments of her vital signs and hematologic profiles to confirm hemodynamic stability.

Colloid Solutions

Colloid solutions contain larger particles, called *colloids*, which are less permeable across vascular membranes. These solutions provide a greater increase in colloid oncotic pressure and plasma volume; however, they are more expensive than crystalloids and may be associated with anaphylactoid reactions. Examples of colloid solutions include albumin, hetastarch, and dextran.

Blood Component Therapy

Whole Blood

Whole blood contains red cells, clotting factors, and platelets. Whole blood is rarely used in modern obstetrics because of its many disadvantages, including a short storage life (24 hours), large volume (500 mL per unit), and potential for hypercalcemia.

Packed Red Blood Cells

Packed red blood cells (PRBCs) are the most appropriate therapy for patients requiring red blood cell replacement due to hemorrhage. They are the only blood product to provide oxygen-carrying capacity. **Each PRBC unit contains approximately 300 mL of volume: 250 mL red blood cells and 50 mL of plasma. In a 70-kg patient, one unit of PRBCs will raise the hemoglobin by 1 g/dL and the hematocrit by 3%.** Transfusion of PRBCs should be considered in any gravida with hemoglobin less than 8 g/dL or with active hemorrhage and associated coagulopathy.

Platelet Concentrates

Platelets are separated from whole blood and stored in plasma. Because 1 U of platelets provides an increase of only approximately 7500/mm^3, platelet concentrates of 6 to 10 U need to be transfused. Platelet concentrates can be derived from multiple donors or single donors. The single donor concentrates are preferred because they expose the patient to fewer potential antigenic and immunologic risks. Transfusion of a single donor platelet concentrate will increase the circulating platelet count by 30,000 to 60,000/mm^3. Because sensitization can occur, it is important for platelets to be ABO and Rh specific. **Transfusion of platelets should be considered when the platelet count is less than 20,000/mm^3 after a vaginal delivery or less than 50,000/mm^3 after a cesarean delivery, or if there is evidence of coagulopathy.**

Fresh-Frozen Plasma

Fresh-frozen plasma (FFP) is plasma that is extracted from whole blood. FFP primarily contains fibrinogen, antithrombin, and clotting factors V, XI, XII. Transfusing FFP not only assists with coagulation but also provides the patient with volume resuscitation because **each unit contains approximately 250 mL.** Typically, fibrinogen levels are used to monitor a patient's response to FFP. Each unit of **FFP should raise the fibrinogen level by 5 to 10 mg/dL.** FFP does not need to be ABO or Rh compatible. FFP should be considered for hemorrhaging patients with evidence of consumptive coagulopathy, coagulopathic liver disease, or warfarin reversal.

Cryoprecipitate

Cryoprecipitate is the precipitate that results from thawed FFP. It is rich in fibrinogen, von Willebrand factor, factor VIII, and factor XIII. Like FFP, **cryoprecipitate can be measured clinically by the fibrinogen response, which should increase by 5 to 10 mg/dL per unit. Unlike FFP, each unit of cryoprecipitate provides minimal volume (10 to 15 mL),** so it is an ineffective agent for volume resuscitation. Cryoprecipitate is indicated for patients with coagulopathy and concerns of volume overload, hypofibrinogenemia, factor VIII deficiency, and von Willebrand disease.

Table 19-9 contains a summary of the available blood component therapies.

Transfusion Protocols

In the past, no consensus existed regarding the optimal ratio of blood product replacement. Newer data from trauma, military, and hospital-based protocols suggests that more aggressive replacement of coagulation factors with

TABLE 19-9 BLOOD COMPONENT THERAPY

PRODUCT	CONTENTS	VOLUME	ANTICIPATED EFFECT (PER UNIT)
Whole blood	All components	500 mL	*Used only in emergencies*
Packed red blood cells	Red blood cells	300 mL	Increase hemoglobin by 1 g/dL Increase hematocrit by 3%
Platelets (single donor pooled)	Platelets	300 mL (6 U)	Increase platelet count by 30,000-60,000/mm^3
Fresh-frozen plasma	All clotting factors	250 mL	Increase fibrinogen by 5-10 mg/dL
Cryoprecipitate	Fibrinogen, von Willebrand factor, factors VIII and XIII	10-15 mL	Increase fibrinogen by 5-10 mg/dL

PRBCs improves outcomes and survival.[114-116] A variety of protocols have been recommended. **Two of the most common are 1 U of PRBCs to 1 U of FFP to 1 U of platelets (1:1:1) and 6 U of PRBCs to 4 U of FFP to 1 U of pooled platelets (6:4:1).**[114,115]

TRANSFUSION RISKS AND REACTIONS

METABOLIC ABNORMALITIES AND HYPOTHERMIA

When PRBCs are stored, leakage of potassium and ammonia can occur into the plasma. This may result in hyperkalemia and high ammonia concentrations in patients requiring massive transfusion. In addition, because most PRBCs units are stored with a calcium-chelating agent, hypocalcemia may occur. Serial assessments of metabolic profiles and ionized calcium levels can assist the clinician in managing these changes.

In addition to metabolic abnormalities, hypothermia may complicate the clinical course of massive transfusion and result in cardiac arrhythmias. Hypothermia can be prevented by warming PRBC units before transfusion and by providing alternative heating devices to the patient (e.g., "bear-hugger" anesthesia warmer).

IMMUNOLOGIC REACTIONS

Transfusions introduce interactions between inherited or acquired antibodies and the foreign antigens of the transfused blood products. The most common immunologic reactions are febrile nonhemolytic transfusion reactions and urticarial reactions. Transfusion of leukoreduced blood products has been proposed to decrease the frequency of these reactions; however, supportive data have been inconsistent.[117] Rare immunologic complications include acute or delayed hemolytic transfusion reactions, anaphylaxis, posttransfusion purpura, and graft-versus-host disease.

INFECTION RISKS

All blood products have the potential to transmit viral and bacterial infections. Although transmission rates have substantially decreased in the past decade, they are still a potential risk that must be disclosed when a transfusion is needed. Table 19-10 lists current transfusion-related infection risks.[118]

ACUTE LUNG INJURY

Acute lung injury complicates 1 in 2000 transfusions.[119] This complication is characterized by acute respiratory distress, hypoxemia, hypotension, fever, and pulmonary edema. Symptoms can be mild or severe, and resolution is usually complete within 96 hours. Three etiologies have been proposed, including antileukocyte antibodies, granulocyte priming, and a combination of the two. Treatment consists of supportive care with oxygen administration and diuresis.

TABLE 19-10 TRANSFUSION-RELATED INFECTIONS RISKS

INFECTION	TRANSMISSION RISK
HIV-1, HIV-2	1 in 1.5-2.1 million
Hepatitis B	1 in 205,000-355,000
Hepatitis C	1 in 1.1-1.9 million
HTLV I and II	1 in 2 million
Bacterial contamination	
• Red blood cells	1 in 30,000
• Platelets	1 in 5000

HIV, Human immunodeficiency virus; *HTLV*, human T-cell lymphotropic virus.

Blood Conservation Approaches

Autologous Donation and Transfusion

Autologous donation and transfusion refers to the collection and reinfusion of the patient's own red blood cells. Although it is unreasonable to have all pregnant individuals consider autologous donation, patients at high risk for transfusion (e.g., placenta previa or accreta) may be good candidates. Guidelines for autologous donation are as follows: minimal predonation hemoglobin of 11 g/dL, first donation within 6 weeks of anticipated delivery due to PRBC storage life of 42 days, weekly interval between donations, and no donation within 2 weeks of anticipated delivery.[120]

Autologous transfusion should be used selectively. Not only is it significantly more expensive than homologous transfusion, but also the risks for bacterial contamination and subsequent homologous transfusion are not completely eliminated.

Acute Normovolemic Hemodilution

Acute normovolemic hemodilution refers to a blood conservation technique in which blood is removed from a patient immediately before surgery, the patient is given crystalloid or colloid solution to maintain normovolemia during surgery, and then the blood is reinfused to the patient after surgery. The goal is for more dilute blood loss at the time of surgery. Acute normovolemic hemodilution can be considered for patients with good initial hemoglobin concentrations who are expected to have a blood loss of at least 1000 mL during surgery (e.g., patients with suspected placenta accreta).

Intraoperative and Postoperative Blood Salvage

***Blood salvage* refers to collecting the patient's blood during or after surgery, filtering the blood, and then reinfusing the red cells back to the patient. Cell Saver technology is the most widely used blood salvage system.** In the past, theoretical concerns regarding the risks for infection and amniotic fluid embolism limited the use of blood salvage technology in obstetrics; however, **several small studies have documented its safety and effectivenes.**[121] Blood salvage has many advantages over homologous transfusion. Not only does it eliminate the risk for infectious disease transmission, alloimmunization, and immunologic transfusion reactions, but it also can rapidly provide the patient with red cells (1 U in a 3-minute interval).

Alternative Oxygen Carriers

Because some patients refuse to accept blood products (e.g., Jehovah's Witness patients) or are unable to be transfused owing to a lack of compatible blood, new oxygen carriers are being developed and have promise as alternatives to transfusion therapy. The two primary products are hemoglobin-based oxygen carriers and perfluorocarbons. Hemoglobin-based oxygen carriers use hemoglobin from animals, outdated human blood, or recombinant technology. The hemoglobin is separated from the red cell stroma and undergoes multiple filtration and polymerization processes before use. Perfluorocarbons are inert compounds that can dissolve gases, including oxygen. Both products have high oxygen-carrying capacities and have been used in phase III trials for elective surgery and in patients with hemorrhagic shock.

Hemorrhage Prevention and Protocols

Because obstetrical hemorrhage is such a widespread problem, it is important for institutions to develop standardized management protocols and conduct hemorrhage drills.[122] The California Maternal Quality Care Collaborative and related efforts in New York have developed best practice approaches that can be adopted by other institutions. The use of obstetrical rapid response teams and massive transfusion protocols is vital to program success.

KEY POINTS

- Hemorrhage is a major cause of obstetrical morbidity and mortality throughout the world and is the leading reason for obstetrical intensive care unit admissions.
- Understanding the hemodynamic changes of pregnancy and the physiologic responses that occur with hemorrhage assists in appropriate management. Clinicians should recognize the four classes of hemorrhage in order to allow for intervention.
- Placental abruption is diagnosed primarily by clinical findings and confirmed by radiographic, laboratory, and pathologic studies. Management of placental abruption is dependent on the severity, gestational age, and maternal-fetal status.
- Placenta previa is typically diagnosed with sonography. Placenta previa remote from term can be expectantly managed. Outpatient management is possible in selected cases.
- Placenta previa in association with a prior cesarean delivery is a major risk factor for placenta accreta. Additional radiographic surveillance should be attempted in these cases to provide antenatal diagnosis of placenta accreta.
- Placenta accreta is best managed with a multidisciplinary approach, including blood conservation teams, anesthesiologists, advanced pelvic surgeons, and urologists.
- Antenatal detection of vasa previa is possible with sonography and significantly improves perinatal outcomes.
- Postpartum hemorrhage complicates 1 in 100 to 1 in 20 deliveries. Every obstetrician needs to have a thorough understanding of normal delivery-related blood loss in order to recognize postpartum hemorrhage.
- Management of uterine atony should follow a rapidly initiated sequenced protocol, including bimanual massage, uterotonic therapy, uterine tamponade, selective arterial embolization, and surgical intervention.
- Coagulopathy mandates treatment of the initiating event and rapid replacement of consumed blood products. Transfusion of blood components should not be delayed, and replacement protocols should be followed.
- Blood conservation approaches should be considered if clinically appropriate.
- Standardized obstetrical hemorrhage management protocols and drills improve outcomes.

DEFINITIONS

Cesarean section has classically been defined as delivery of a fetus through a surgically created incision in the anterior uterine wall. Because cesarean and section both refer to an incision, some prefer the terms *cesarean delivery* and *cesarean birth* to describe the procedure. *Primary cesarean* is the "first-time" operation, whereas *repeat cesarean* refers to the operation done after a prior cesarean. This chapter reviews the history, incidence, indications, techniques, and complications of cesarean delivery.

HISTORY OF CESAREAN DELIVERY

Cesarean delivery has been described since ancient times, and there is evidence from both early Western and non-Western societies of this surgical procedure being performed. The evolution of the term "cesarean" has been debated over time. Although this term was originally believed to have been derived from the birth of Julius Caesar, it is unlikely that his mother, Aurelia, would have survived the operation. Her knowledge of her son's invasion of Europe many years later indicates that she survived childbirth. In Caesar's time, surgical delivery was reserved for cases when the mother was dead or dying. Roman law under Numa Pompilius first ("Lex Regia"), then renamed after Caesar ("Lex Cesarea"), specified surgical removal of the fetus before burial of deceased pregnant women. Religious edicts required separate burial for the infant and mother. The term cesarean may also refer to being cut open because the Latin verb *caedare* means to cut. Cesarean operation was the preferred term before the 1598 publication of Guillimeau, who introduced the term "section."

Although sporadic reports of heroic life-saving efforts through cesarean childbirth existed for hundreds of years, it was not until the later part of the 19th century that the operation began to be established as part of obstetrical practice. This coincided with the gradual transition of childbirth as primarily a midwife-attended event, often in rural settings, to an urban hospital experience. The wide emergence of hospitals laid the foundation for establishing obstetrics as a hospital-based specialty. As new methods for anesthesia emerged, cesarean delivery for obstructed labor gained popularity over destructive procedures such as craniotomy accompanying difficult vaginal births. Despite the dangers that still existed with cesarean delivery, the operation was viewed as preferable to a difficult high forceps delivery, which was associated with fetal injury and deep pelvic lacerations. Whereas refinements in anesthesia techniques allowed the operation to be performed, mortality rates remained very high, with sepsis and peritonitis as leading causes of postoperative deaths. Primitive surgical techniques and lack of antisepsis clearly contributed to such outcomes. Surgeons attempted to complete the operation without closing the uterus, fearing that the suture material itself would promote infection and that the uterus would best heal by intention. As a result, women were placed at risk for both hemorrhage and infection.

In 1876, Eduardo Porro advocated hysterectomy with cesarean delivery in order to control bleeding and to prevent postoperative infection. Shortly thereafter, surgeons gained experience with internal suturing because silver wire stitches were developed by the gynecologist J. Marion Sims. Sims had perfected the use of these sutures in the treatment of vesicovaginal fistulas resulting from obstructed labors.

As gynecologic surgeons performed more cesarean deliveries and the outcomes improved, greater attention was placed on technique, including the site of uterine incision. Between 1880 and 1925, surgeons began employing transverse incisions of the uterus. It was noted that such incisions reduced the rate of infection and the risk for rupture with subsequent pregnancies. However, owing to the risk for peritonitis, extraperitoneal cesarean was advocated by Frank (1907) and Latzko (1909) and was popularized by Beck (1919) in the United States.

The introduction of penicillin in 1940 dramatically reduced the risks for infection associated with childbirth. As antibiotic therapy emerged, the need for extraperitoneal dissection and incision diminished. The low cervical incision introduced by Munro Kerr (1926) became further established as the technique of choice. As technology, including improved anesthesia, developed and the medical management of pregnancy and childbirth accelerated, cesarean delivery became more commonplace in obstetrics. Given its current safety and effectiveness, a liberalized approach to using cesarean childbirth has emerged in the United States over the past 40 years.

INCIDENCE

Trends in Cesarean Delivery Rates

The cesarean delivery rate describes the proportion of women undergoing cesarean delivery of all women giving birth during a specific time period. The cesarean delivery rate may be further subdivided into the primary and the repeat cesarean delivery rates, both as a proportion of the entire obstetrical population. **Cesarean delivery rates have risen in the United States in a dramatic fashion from less than 5% in the 1960s to 32.8% by 2008. Among the reasons for this increase are (1) continued increase in primary cesarean deliveries for dystocia, failed induction, and abnormal presentation; (2) an increase in the proportion of women with obesity, diabetes mellitus, and multiple gestation, which predispose to cesarean delivery; (3) increased practice of cesarean delivery on request; and (4) limited use of trial of labor after cesarean (TOLAC) delivery owing to both safety and medicolegal concerns** (Table 20-1).

A recent increase in international cesarean delivery rates has also been documented, with some countries with cesarean rates in the 40% (e.g., Italy), or even higher (e.g., Brasil), range.

Given the discrepancy in cesarean delivery rates between the United States and other countries without a perceivable benefit in neonatal outcomes, health policy groups have critically evaluated this issue, including its cause and possible solutions. Twenty-five years ago, the National Institutes of Health (NIH) established a task force on cesarean childbirth and sponsored a consensus development conference on this subject. It was recognized that almost all of the increase in cesarean section rates was due to increased repeat operations and primary cesarean deliveries for dystocia and fetal distress (see Table 20-1). With expanding indications for cesarean delivery, and little enthusiasm for vaginal birth after cesarean delivery (VBAC) before 1980, it was obvious that prior cesarean delivery had emerged as a major indication. Dystocia was also being diagnosed more frequently through the 1970s and 1980s, along with a parallel decline in operative vaginal delivery rates. Not surprisingly, the increased cesarean delivery rates in the United States compared with other countries can be explained almost entirely by cephalopelvic disproportion and repeat cesarean delivery as the dominant indications for the operation.

Fear of litigation is also recognized as liberalizing the indications for cesarean section, particularly with respect to labor management and the diagnosis of non-reassuring fetal heart rate (FHR) patterns. The widespread use of intrapartum electronic FHR monitoring has been cited

TABLE 20-1 FACTORS RESPONSIBLE FOR INCREASED CESAREAN DELIVERY RATES

Obstetrical Factors
Increased primary cesarean delivery rate
Failed induction and increased use of induction of labor
Decreased use of operative vaginal delivery
Increased macrosomia and cesarean delivery for macrosomia
Decline in vaginal breech delivery
Increased repeat cesarean delivery rate
Decreased use of vaginal birth after cesarean delivery
Maternal Factors
Increased proportion of women older than 35 years
Increased proportion of nulliparous women
Increased primary cesarean deliveries on maternal request
Physician Factors
Malpractice litigation concerns

as a factor in increasing the diagnosis of non-reassuring FHR and thus cesarean delivery. The NIH task force recommended that both dystocia and repeat cesarean deliveries clearly required further study and institution of strategies to reduce their contribution to the overall rise in cesarean delivery. This recommendation was appealing in that these two categories contributed greatly to the rise in cesarean section, and they represent indications that would likely be amenable to a reduction since physician practice patterns clearly influence these categories of cesarean delivery.

Cesarean delivery accounts for more than 1 million major operations performed annually in the United States.[1] It is the most common major surgical procedure undertaken today. **Following efforts championed by institutions and payers to reduce the cesarean section rate, between 1988 and 1996, the overall cesarean delivery rate in the United States fell from 24.7% to a nadir of 20.7%. This decline can be largely attributed to the increased practice of TOLAC after prior cesarean birth. However, over the past decade, cesarean rates have steadily climbed and exceed those of the late 1980s. This rise is reflected by an increase in the primary cesarean rate and a steep drop in the rate of vaginal births after previous cesarean deliveries. VBAC rates plummeted from a peak of 28.3% in 1996 to 9.2% in 2004** (Figure 20-1).

The rise in cesarean section rates has prompted increased interest in the indications, complications, and techniques involved with this procedure. Despite clear documentation of the prevalence of cesarean section, there is remarkably little prospectively gathered information concerning a variety of issues related to abdominal delivery. The overwhelming economic burden of cesarean birth on health care delivery continues to focus efforts on strategies aimed at reducing cesarean delivery rates. Because cesarean section carries with it a risk for uncommon complications such as maternal mortality and more often observed infectious complications extending the mother's length of stay in the hospital, cesarean section data continue to be employed as an indicator to reflect overall quality of care for obstetrical services. The appropriate use of a TOLAC in women with a prior cesarean section has also been a focus for providers and payers of obstetrical care.

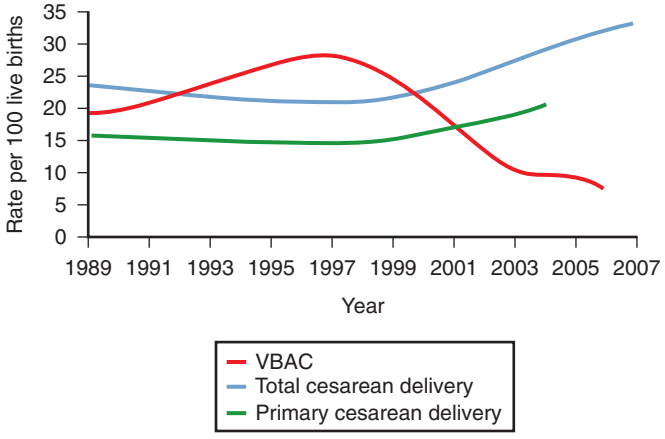

FIGURE 20-1. Total and primary cesarean rate and vaginal birth after previous cesarean (VBAC): United States, 1989 to 2006. (Data from National Center for Health Statistics: Births: final data for 2005. National Vital Statistics Report 57[7], 2009.)

Monitoring Cesarean Delivery Rates

It is not possible to determine an optimal cesarean delivery rate because an "ideal" rate must be a function of multiple clinical factors that vary in each population and are influenced by the level of obstetrical care provided. Further complicating this issue is the absence of complete and accurate data that focus on both maternal and infant outcomes. Thus, although cesarean delivery rates can be considered a measure of a specific health care process (mode of delivery), these rates are not outcome measures because they do not indicate whether cesarean or vaginal birth results in optimal perinatal outcomes. Maternal and perinatal morbidity and mortality should be the outcomes most monitored to ensure best quality of care. Higher cesarean delivery rates have been associated with better perinatal outcomes in several studies. So, instead of setting goals or limits for overall cesarean delivery rates, it is most important to monitor maternal and perinatal health outcomes. We would all agree with a 0% or 100% cesarean delivery rate if either of these were associated with the lowest incidences of complications for mother or baby. The optimal cesarean delivery rate in the early 21st century is in between these extremes and depends on the population.

Despite little consensus regarding the best mode of delivery for many complicated pregnancies, third-party payers and institutions continue to rely on expert opinion concerning optimal cesarean delivery rates without the benefit of risk stratification. It follows that institutions involved in tertiary obstetrical care thus managing a large number of preterm deliveries and maternal complications of pregnancy should have higher cesarean rates than primary care facilities. Several models have been developed to provide risk-adjusted cesarean delivery rates. Use of hospital billing information consisting of International Classification of Diseases codes is a common methodology; however, important information such as parity and other demographics are lacking with this approach. In contrast, Leiberman and colleagues employed a case-mix system, which stratified women according to parity, prior cesarean delivery, presentation, gestational age, and the presence of medical conditions precluding a TOLAC. In their study, the crude cesarean delivery rate was higher for hospital-based practice physicians (24.4%) than for community-based practitioners (21.5%). However, the proportion of women falling into categories conferring a high risk for cesarean delivery was twice as high for the hospital-based practice. Standardizing the case mix resulted in an overall cesarean rate of 20.1% for the hospital-based physicians.

In 2000, the American College of Obstetricians and Gynecologists (ACOG) developed a simple formula to help institutions and physicians assess their risk-adjusted cesarean delivery rates.[1] Two populations were targeted that included (1) nulliparous women with a singleton vertex gestation at 37 weeks or greater without other complications; and (2) women with one prior low-transverse cesarean delivery, delivering a single vertex fetus at 37 weeks or greater without other complications. The use of these simple case-mix adjusted rates should make comparative evaluation of cesarean delivery rates and their

comparison to maternal and perinatal outcomes more meaningful. As data become more unified and methodologically sound, the quality of obstetrical care can be better assessed.

Using raw and risk-adjusted data, institutions have sought to reduce cesarean birth rates through quality improvement initiatives. Myers and Gleicher successfully reduced overall cesarean rates from 17.5% to 11.9% after developing guidelines in concert with a comprehensive data collection process and intensive feedback to physicians. Outliers were identified and subjected to "one-on-one" reviews of their individual practices. Other successful programs aimed at lowering cesarean rates have also relied on the combination of providing quality data and counseling to physicians who become invested in changing their practice pattern.[1] **The 2000 ACOG report on evaluation of cesarean delivery concludes with two major observations:**

1. **Improved residency or postresidency training in operative (forceps or vacuum-assisted) vaginal delivery is recommended to foster better understanding of the use of these techniques and the normal progression of labor. Surveys show that operative vaginal delivery is less than 15% among ACOG Fellows and residents in the United States, yet safe use of these techniques may help reduce the cesarean delivery rate** (see Chapter 15).
2. **Certain management practices may affect cesarean delivery rates, so institutions and physicians should consider some changes if their cesarean delivery rates are believed to be too high. The continuous presence of nurses or other trained individuals who provide comfort and support to women in labor may lead to lower rates. In addition, 24-hour dedicated in-house obstetrical coverage by hospitals and practice groups may help reduce cesarean delivery rates.**

INDICATIONS FOR CESAREAN DELIVERY

Indications for cesarean delivery can be divided in maternal-fetal, fetal, and maternal. The most common current indications are, in order of frequency, failure to progress (also called *cephalopelvic disproportion*, or *dystocia*) (about 30%), prior cesarean (i.e., repeat cesarean) (30%), non-reassuring FHR patterns (10%), and fetal malpresentation (10%) (Table 20-2).

TABLE 20-2 COMMON INDICATIONS FOR CESAREAN DELIVERY

Maternal-Fetal
Cephalopelvic disproportion
Placental abruption
Placenta previa
Repeat cesarean delivery
Cesarean delivery on maternal request
Maternal
Specific cardiac disease (e.g., Marfan syndrome, unstable coronary artery disease)
Specific respiratory disease (e.g., Guillain-Barré syndrome)
Conditions associated with increased intracranial pressure
Mechanical obstruction of the lower uterine segment (tumors, fibroids)
Mechanical vulvar obstruction (e.g. extensive condylomata)
Fetal
Non-reassuring fetal status
Breech or transverse lie
Maternal herpes
Congenital anomalies

Maternal-Fetal Indications

Most cesarean deliveries are performed for conditions that might pose a threat to both mother and fetus if vaginal delivery occurred. Placenta previa and placental abruption with the potential for hemorrhage are clear examples. Dystocia presents a risk for both direct fetal and maternal trauma. It may also compromise fetal oxygenation and metabolic status. **Cephalopelvic disproportion (CPD) is a diagnosis that is generally made on a relative basis after a trial of sufficient labor, often with oxytocin augmentation. The criteria for CPD remain subjective, and at present, norms for progress during labor have been challenged.** Although failure to make sufficient progress in the active phase of labor has been attributed to deficiencies in uterine activity ("power"), large baby ("passenger"), and unfavorable maternal pelvis ("passage"), the failure to progress may also be the potential of varying physician approaches to the management of labor itself. **The proper length of time for an adequate TOLAC with oxytocin stimulation in protraction disorders is undefined, with most practitioners allowing "a few hours." Because it has been shown that oxytocin has not been employed at all in many cesarean deliveries performed for dystocia, it can be concluded that inadequate trials of oxytocin stimulation may be a significant factor in the performance of some unnecessary cesarean deliveries.**

Blumenthal and colleagues found a large difference between the incidence of dystocia in public and private patients and concluded that the difference probably resulted from differences in criteria used for the two groups. However, they were unable to determine whether the difference resulted from excessive intervention in the private group or from less than optimal intervention in the public groups. Haynes de Regt and colleagues similarly demonstrated an overall cesarean section rate of 17.1% in nonprivate versus 21.4% in private patients. In this study, private patients giving birth to their first child were significantly more likely than clinic patients to undergo cesarean delivery if dystocia, malpresentation, or fetal distress were diagnosed. Unfortunately, this large retrospective study could not provide detailed information concerning criteria used to diagnose both dystocia and suspected fetal compromise.

Understanding that physician characteristics may affect cesarean delivery rates, Berkowitz and colleagues analyzed 6327 deliveries performed by 48 different practitioners between 1983 and 1985. Although no significant differences were found according to gender or practice setting of the physicians, older, more experienced physicians performed significantly fewer cesarean sections for dystocia and a higher percentage of forceps deliveries for breech extractions. This finding is of great interest inasmuch as Frigoletto and coworkers noted that between 30% and 40% of primary cesarean deliveries at both Brigham and Women's Hospital and Northwestern University are performed during the second stage of labor, in contrast to

less than 5% at the National Maternity Hospital in Dublin. These findings may provide insight into potential strategies to further reduce cesarean deliveries performed for dystocia.

Fetal Indications

Fetal indications are primarily recognized by non-reassuring FHR testing with the potential for long-term consequences of metabolic acidosis. Somewhere between 1% and 3% of women undergo cesarean section for a non-reassuring FHR pattern. The diagnosis of *fetal distress* (a term ACOG prefers to avoid) has been cited as the third leading cause for the rise in cesarean birth over the past several decades. It is noteworthy that no apparent reduction in the frequency of cerebral palsy has accompanied this rise and has led to challenging the benefit of continuous electronic fetal monitoring and associated increases in the cesarean delivery rate. Haverkamp and colleagues first noted that cesarean delivery is more often performed for labor abnormalities in women who undergo continuous fetal monitoring compared with controls. This finding is of particular interest considering a more recent randomized trial involving the use of continuous fetal pulse oximetry during labor. Whereas women monitored with this device demonstrated a 50% reduction in the number of cesarean deliveries for non-reassuring fetal status compared with continuous FHR monitoring, the overall cesarean delivery rates between study groups was not different. The women monitored with fetal pulse oximetry had an increased rate of cesarean delivery for dystocia.

Other fetal indications for cesarean delivery include risk for transmission of infection or potential for fetal trauma. Examples of these categories would include active maternal herpes infection and breech delivery, in which head entrapment is a possibility. By the mid-1990s, the cesarean delivery rate for breech presentation had reached nearly 85% in the United States, and following current recommendations from ACOG, it will likely rise further. Excessive fetal size or suspected macrosomia has been increasingly designated as an indication for cesarean delivery, yet little data exist to support this approach in the nondiabetic woman. Fetuses with certain birth defects such as hydrocephalus with macrocephaly and neural tube defects have traditionally undergone cesarean delivery, yet insufficient data exist to make this an absolute indication. Similarly, few data exist to suggest a benefit for cesarean delivery with fetal abdominal wall defects, such as omphalocele and gastroschisis.

Maternal Indications

Maternal indications for cesarean delivery are relatively few and can be considered as medical or mechanical in nature (see Table 20-2). Most of these indications are not based on evidence from randomized trials. Although somewhat debatable, certain maternal cardiac conditions such as unstable ischemic coronary artery disease and a dilated aortic root with Marfan syndrome have been considered indications for cesarean section. These diagnoses may pose a risk for deterioration of maternal condition with the stress of labor. Serious respiratory disease requiring assisted ventilation and conditions resulting in altered mental status might also mandate cesarean delivery. Central nervous system abnormalities in which increased intracranial pressure such as accompanies the second stage of labor would be undesirable have also led some to recommend cesarean section.

Alterations in the capacity of the maternal pelvis can be indications for cesarean delivery. Mechanical vaginal obstruction due to pelvic masses such as lower segment myomata or ovarian neoplasm are examples. Finally, women with massive condylomata may require cesarean section as well.

Cesarean Delivery on Maternal Request

As cesarean delivery has become safer, women have occasionally voiced their wish for a cesarean without a medical indication with their obstetrician. This clinical scenario has been recently called "cesarean delivery on maternal request." **The lack of specificity of the term "elective" suggests the most reasonable and prudent course of action is to not use it, but rather to document the specific indication (whether medical or nonmedical) for the intervention or procedure (i.e., cesarean delivery on maternal request).** At times, physicians have also advocated cesarean as the preferred mode of delivery, even in the absence of accepted indications as described previously. We would term this scenario "cesarean delivery on physician request."

Feldman and Freiman first proposed cesarean delivery to prevent fetal morbidity and mortality associated with intrapartum events. In their 1985 publication, the fetal benefits of "elective" cesarean were weighed against the increased risk for maternal mortality with cesarean section. The increasing safety of cesarean delivery over the next 20 years and emergence of improved data concerning benefits and risks has rekindled interest in this subject. In 2000, Harer endorsed cesarean delivery, citing better infant outcomes compared with vaginal birth as well as lower rates of pelvic floor injury.

The decision to plan a cesarean or a vaginal birth should be based on the best literature available comparing these choices. Cases in which cesarean (or vaginal) delivery is indicated for accepted indications as described previously should be excluded from this comparison. The NIH and ACOG have carefully reviewed the literature on this topic.[2,3] NIH and ACOG reported that there is no high-quality evidence to compare planned cesarean to planned vaginal delivery because there are no randomized studies for most women—those with a singleton gestation in vertex presentation at term. Moderate-quality evidence shows that planned cesarean is associated with less postpartum hemorrhage, more mild neonatal respiratory morbidity, longer maternal hospital stay, and possibly greater complications in subsequent pregnancies[2,3] (Table 20-3). **Cesarean delivery on maternal request is not recommended for women desiring several children because there is a direct association with an increasing number of cesarean deliveries and increasing life-threatening complications such as placenta previa, placenta accreta, and the need for cesarean hysterectomy.**[3] Cesarean delivery on maternal request is unfortunately performed at times because of maternal fear of excessive pain. Fear of childbirth is present in about 3% to 8% of women. These women should be reassured of adequate maternal pain

TABLE 20-3 RISKS AND BENEFITS OF CESAREAN DELIVERY ON MATERNAL REQUEST (OR WITHOUT MEDICAL INDICATIONS)

Potential Benefits
Reduction in perinatal morbidity and mortality
Elimination of intrapartum events associated with perinatal asphyxia
Reduction in traumatic birth injuries
Reduction in stillbirth beyond 39 weeks' gestation
Possible protective effect against pelvic floor dysfunction
Less postpartum hemorrhage
Potential Risks
Increased short-term maternal morbidity
Increased endometritis, transfusion, venous thrombosis rates
Increased length of stay and longer recovery time
Increased short-term neonatal morbidity
Increased mild neonatal respiratory morbidity
Increased long-term maternal and neonatal morbidity
Increased risk for placenta accreta, hysterectomy with subsequent cesarean deliveries

relief in labor and directly reassured and counseled regarding TOLAC.

All remaining comparisons, discussed later, are based on weak evidence and should not decisively sway clinical decisions. Perinatal mortality has been reported to be several times lower with a planned cesarean delivery compared with labor and vaginal birth. Additionally, hypoxic-ischemic encephalopathy (HIE) of the newborn related to intrapartum events, including abruption, cord prolapse, and progressive asphyxia, may occur in approximately 1 in 3000 to 5000 births. Many of these cases presumably would be prevented by planned cesarean delivery, as would unexplained stillbirths occurring beyond 39 weeks' gestation. Traumatic birth injuries, including intracranial hemorrhage, fractures, and brachial plexus injury, are reduced with cesarean delivery as well.

Increased maternal risks attributed to vaginal delivery include urinary and fetal incontinence, pelvic prolapse, and sexual dysfunction. The precise contribution of vaginal delivery versus pregnancy and labor to these complications has been difficult to ascertain. In a survey of 2000 women, Wilson and colleagues reported a prevalence of incontinence of 24.5% following vaginal delivery compared with 5.2% after cesarean section. In primiparous women, cesarean delivery significantly reduced the risk for incontinence (relative risk [RR] = 0.2) compared with vaginal birth. However, these authors noted that in women with more than three cesarean deliveries, no difference was noted compared with rates in women delivered vaginally. In a Norwegian study of 15,000 women, Rortveit reported a 10.1% rate of incontinence in nulliparous women, 15.9% in those having cesarean section, and 21% in the vaginal delivery group. These authors concluded that pregnancy itself can cause pelvic floor damage and that cesarean delivery may not be completely protective. MacLennan's survey of 3000 women also supports an increased risk for prolapse with all methods of delivery. The author concluded that pregnancy, more than mode of delivery, appeared to contribute to long-term pelvic floor damage. Nonetheless, Minkoff and Chervenak assert that a policy of prophylactic cesarean delivery might reduce the risk for significant urinary incontinence from 10% to 5%.

The maternal risks of cesarean delivery have been considered marginal compared with those of vaginal delivery. Rates of maternal mortality (excluding indicated cesarean deliveries) are comparable to vaginal delivery. Sachs and colleagues reported a cesarean mortality rate of 22.3 per 100,000 compared with 10.9 per 100,000 for vaginal delivery; however, the rates were comparable excluding medical complications. A British survey reported one death in 78,000 cesarean deliveries, which was lower than the rate for vaginal births. In contrast, a population-based 7-year study (1992 to 1998) revealed cesarean section to be associated with a fourfold increased risk for maternal death, when controlling for various pregnancy complications.

Cesarean delivery does increase maternal morbidity. The rate of endometritis (3.0%) versus vaginal birth (0.4%) is increased, yet one study indicates comparable rates of postpartum hemorrhage, transfusion, and deep venous thrombosis (DVT). Other reports confirm increased risks for these morbidities with cesarean section, including major complication rates as high as 4.5%. **Cesarean delivery also presents a risk for future placental abnormalities, including placenta previa and placenta accreta. These risks increase with the increasing number of cesarean deliveries performed for each woman and are substantial with more than three operations. Thus, the decision to undergo cesarean delivery on request must include thoughtful consideration of future childbearing plans.**

When a cesarean delivery is performed without accepted indications, but for either maternal or physician request, it should be performed at 39 weeks.[2-4] After appropriate counseling, if the woman still insists on cesarean delivery on maternal request, implementing the woman's request is ethically permissible. Less than 10% of women prefer a cesarean delivery based solely on their request.

TECHNIQUE OF CESAREAN SECTION

Because more than 500,000 cesarean deliveries are performed in the United States every year, and about 20 million worldwide, it extremely important to adhere to the safest, most effective technique that is associated with the lowest perinatal and maternal complications. Each aspect of cesarean delivery should be evaluated individually, optimally by randomized trials, because it is impossible to evaluate the benefit of a technical aspect if this is studied together with others. Proper universal surgical precautions aimed at preventing blood loss and infections should be employed. Preferred technical aspects of cesarean delivery are shown in Table 20-4.

Prophylactic Pre-cesarean Interventions, Including Antibiotics and Thromboprophylaxis

Prophylactic antibiotics are of clear benefit in reducing the frequency of postcesarean endomyometritis and wound infection in both laboring and nonlaboring cesarean delivery.[5] Timing, agents, and dose of prophylactic antibiotics have been extensively studied.[6]

Prophylactic antibiotics should be given, if possible, about 30 minutes before skin incision for cesarean.[7] The preferred agent for prophylaxis is either ampicillin or a

TABLE 20-4 EVIDENCE-BASED RECOMMENDATIONS FOR CESAREAN DELIVERY TECHNIQUES

- No preoperative hair removal; or clipping or depilatory creams on the day of surgery or the preceding day (no shaving)
- No specific antiseptic for preoperative bathing
- Antibiotic prophylaxis with ampicillin or a first-generation cephalosporin 30 minutes before skin incision (one dose)
- Spinal and epidural anesthesia preferred to general anesthesia
- Chlorhexidine-alcohol for skin preparation
- Transverse lower abdominal wall opening using Pfannenstiel or Joel-Cohen-based methods
- Mostly blunt dissection of subcutaneous fat layer
- Low-transverse uterine incision initially done with scalpel
- Blunt uterine incision expansion, with cephalad-caudad traction
- Spontaneous placental removal with cord traction
- Extra-abdominal (exteriorization) or intra-abdominal repair of the uterus
- Uterine closure with single-layer continuous locking suture has short-term benefits. However, the evidence from observational studies of an increased risk for scar rupture favors the use of double-layer closure pending evidence on this outcome from randomized trials.
- Nonclosure of both peritoneal layers
- Closure of the subcutaneous tissues when the thickness is ≥2 cm.
- No routine drainage of the subcutaneous tissues
- Closure of skin with staples (leave in at least 4 days) or sutures

(Modified from Berghella V, Baxter JK, Chauhan SP: Evidence-based surgery for cesarean delivery. Am J Obstet Gynecol 193:107, 2005.)

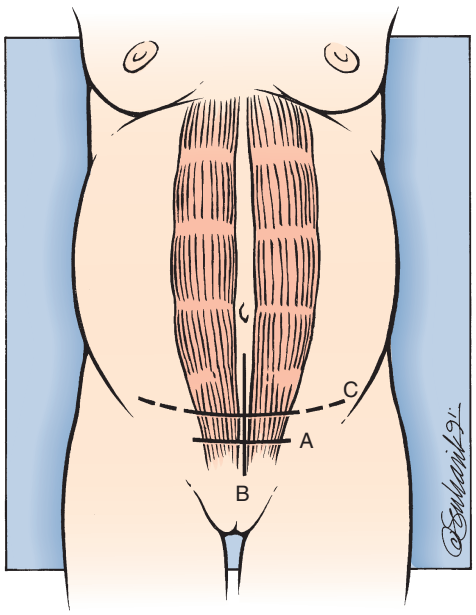

FIGURE 20-2. The obstetrician most commonly uses the Pfannenstiel abdominal incision for cesarean **(A)**. Other, much less common incisions are midline **(B)** and Maylard **(C)** incisions. *Hatched lines* indicate possible extension. (Modified from Baker C, Shingleton HM: Incisions. Clin Obstet Gynecol 31:701, 1988.)

first-generation cephalosporin (e.g., cefazolin).[6] For women with an anaphylactic allergic reaction to penicillin, either metronidazole or clindamycin and gentamicin can be used. There is no apparent advantage to more broad-spectrum antibiotic prophylaxis (e.g., azithromycin or metronidazole[8,9]), except perhaps for women who do not get antibiotic prophylaxis before cesarean delivery, high-risk populations, and use of drugs effective against *Ureaplasma urealiticum*.[10] Single-dose therapy is as effective as multidose therapy[11,12] and is therefore preferred.

For women with clinical chorioamnionitis, treatment with combination antibiotic therapy (e.g., UNASYN, ampicillin sodium/sulbactam sodium) supplants the need for prophylaxis. This therapy should be instituted promptly before delivery and continued until the patient exhibits a clinical response.

Because venous thromboembolism (VTE) is the leading cause of maternal mortality in developed countries, and cesarean delivery increases this risk, thromboprophylaxis should be considered in all cesarean deliveries. There is an insufficient number of women randomized to either heparin or no heparin to assess its safety and efficacy.[13] Mechanical prophylaxis, with graduated compression stockings or a pneumatic compression device during and after cesarean delivery until ambulation is restarted, is suggested. Women with additional risk factors (e.g., morbid obesity, prior VTE, immobility) may benefit from medical thromboprophylaxis (e.g., with prophylactic heparin after cesarean).

Lateral tilt of about 15 degrees elevating the mother's right side; left lateral tilt, head-up, or head-down position; and the use of wedges and cushions, flexion of the table, and a mechanical displacer have been insufficiently studied to provide any strong recommendation for clinical use.[14]

Vaginal irrigation with chlorhexidine has not been associated with a decrease in maternal or neonatal infections.[15]

Site Preparation

Preparation of the skin is performed to reduce the risk for wound infection by decreasing the amount of skin flora and contaminants at the incision site. Hair does not have to be removed from the operative site. Removal with a razor may actually increase the risk for infection by breaks in the skin allowing entry of bacteria. For this reason, some advocate clipping of the hair before surgery.[16] Only enough hair should be removed to allow good approximation of skin edges.

Incision site preparation is accomplished in the operating room through application of a surgical scrub. Cesarean delivery wounds are considered to be clean contaminated. Chlorhexidine-alcohol scrub is the scrub we use because it has been associated with a lower incidence of wound infections compared with povidone-iodine scrub.[17]

Drapes should not be adhesive because adhesive drapes have been associated with higher rate of wound infections compared with nonadhesive drapes.[18,19]

Abdominal Incision Type and Dissection

In general, universally accepted good surgical techniques, aimed at avoiding excessive blood loss and tissue trauma, should be employed.[20] The use of blunt needles during a cesarean delivery is associated with a decrease in rate of surgeon glove perforation, but also a decrease in the surgeon's satisfaction, compared with sharp needles.[21]

The surgeon has a choice of a transverse or vertical skin incision, with the transverse Pfannenstiel being the most common incision type in the United States (Figure 20-2). **Factors that influence the type of incision include the urgency of the delivery, prior incision type, and the potential need to explore the upper abdomen for nonobstetrical pathology. Although some prefer a vertical incision in**

emergent situations, a Pfannenstiel incision actually adds only 1 minute extra operative time in primary and 2 minutes in repeat cesareans, differences that are not associated with improved neonatal outcomes.[22] The skin incision used in the previous procedure is usually repeated in most cesarean deliveries. Transverse incisions are more cosmetic and less painful than vertical incisions. The authors prefer a transverse Pfannenstiel incision for more than 90% of their cesarean deliveries. Studies reporting benefits of the Joel-Cohen incision include multiple aspects of the cesarean technique, not just the skin incision. As stated previously, studies evaluating multiple technical features of the cesarean delivery together are not clinically helpful.[23] When a transverse skin incision is employed, it is made about 3 cm above the symphysis in the midline and extended laterally in a slightly curvilinear manner. The length of the incision should be based on the estimated fetal size. At term, it usually should be about 15 cm, or the length of an Allis clamp. Site of the incision, either below or above the pannus, or either vertical or transverse, has not been sufficiently studied in obese individuals to provide an evidence-based recommendation.

Occasionally, a transverse incision of the rectus sheath and muscles (Maylard incision) is necessary for proper exposure and room to deliver the fetus. In these cases, only the medial half of the muscle is incised to avoid lacerating the deep epigastric vessels. Complete transection of the rectus muscles is the Cherney incision, which requires identification of the epigastric vessels and ligation bilaterally.

The subcutaneous tissue can then be bluntly pushed away to identify the underlying fascia. In repeat operations, sharp dissection of the subcutaneous adipose tissue may be required. The fascia is incised and dissected or bluntly extended in a curvilinear manner bilaterally. It should be tented with the surgeon's forceps to separate it from the underlying muscle and to identify perforating vessels, which require ligation or coagulation. Curvilinear extension is essential because direct transverse extension often leads to inadvertent muscle incisions and bleeding.

Once the fascial incision is completed, the fascia is then grasped in the midline bilaterally and is separated from the underlying rectus muscles superiorly and inferiorly by blunt and sharp dissection from the median raphe.

The rectus muscles can be separated bluntly in the midline to reveal the posterior rectus sheath and peritoneum, which can also be entered bluntly with fingers, to avoid trauma to underlying bowel. The point of entry should be as superior as possible to avoid bladder injury, particularly in repeat operations in which the bladder may be adherent superiorly.

Uterine Incision and Delivery of the Fetus

Following full entry into the peritoneal cavity, the surgeons should palpate the uterus for fetal presentation and alignment, and then place a bladder retractor to expose the lower uterine segment. The uterus is often dextrorotated, and its position must be appreciated to plan the incision site. The safety and efficacy of using special retractors, especially in obese women, has been insufficiently studied.

Creation of a bladder flap versus a direct uterine incision above the bladder fold has been compared in a randomized trial of 102 women. Bladder flap development was associated with a longer incision to delivery interval and total operating time and a greater fall in maternal hemoglobin.[24] Given these findings, we generally do not develop a bladder flap at cesarean delivery. Should the obstetrician elect to create a bladder flap, the vesicouterine serosa is picked up with smooth forceps and is incised in the midline with Metzenbaum scissors. The incision is carried out laterally in a curvilinear manner. The vesicouterine fold is then tented with forceps or a pair of hemostats, which allows direct visualization as the bladder flap is bluntly created using the index and middle fingers of the surgeon's hand. Sharp dissection may be necessary, particularly in repeat operations. The surgeon then bluntly sweeps out laterally on each side to allow just enough room for insertion of the bladder blade. A Richardson retractor is then inserted laterally, and continuous suction is made available for preparation of the uterine incision.

A low-transverse uterine incision is employed in more than 90% of cases (Figure 20-3). **It is preferred to a vertical incision because it is associated with less blood loss, is easier to perform and repair, and provides for the option of subsequent TOLAC because the rate of subsequent rupture is lower than with incisions incorporating the upper uterine segment.**

In cases of a low-transverse incision, the incision is begun at least 2 cm above the bladder margin. Suction is applied. Tamponade with sponges superiorly and inferiorly can be performed if considerable bleeding is encountered. This technique allows better visualization and minimizes the chance of fetal laceration. The incision is extended laterally and superiorly at the angles by blunt spreading using the index fingers. Two randomized trials have compared blunt versus sharp extension of the uterine incision. Sharp extension is associated with increased blood loss and carries with it the potential risk for cutting the umbilical cord or direct fetal injury.[25,26] Blunt uterine incision extension can be done preferably with cephaladcaudad traction because transverse expansion is associated with more unintended extension and blood loss.[27] As per the skin and the fascial incisions, adequate exposure for an easy extraction of the fetus should be obtained. At term, this is usually more than 15 cm.

A vertical uterine incision, now rarely performed (Table 20-5), is either low (involving mostly low uterine segment) or classic (involving upper uterine segment) and should have clear indications. **A vertical uterine incision may need to be performed if the lower uterine segment is poorly developed (e.g., at 24 to 25 weeks), if the fetus is in a back-down transverse lie, in most cases of a complete anterior placenta previa, or if there are leiomyomas obstructing the lower segment.** Other, even less common indications may include certain fetal abnormalities such as massive hydrocephalus or a very large sacrococcygeal teratoma. The disadvantages of a classic incision are its tendency for greater adhesion formation and a greater risk for uterine rupture with subsequent pregnancy. The low-vertical incision depends on the downward displacement of the bladder to confine the incision to the true lower segment (Figure 20-4). The incision is begun as inferiorly as possible and

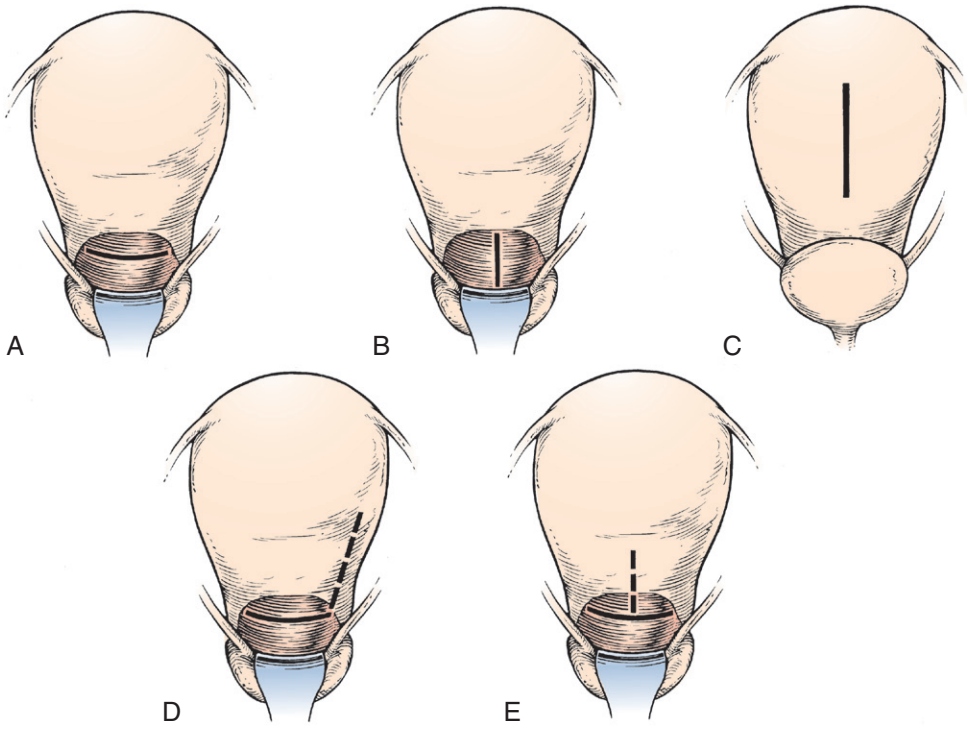

FIGURE 20-3. Uterine incisions for cesarean delivery. **A,** Low transverse incision (performed in >90% of cesarean deliveries). The bladder can be retracted downward as needed, and the incision is made in the lower uterine segment, curving gently upward. If the lower segment is poorly developed, the incision can also curve sharply upward at each end to avoid extending into the ascending branches of the uterine arteries. **B,** Low-vertical incision. The incision is made vertically in the lower uterine segment after reflecting the bladder, avoiding extension into the bladder below. If more room is needed, the incision can be extended upward into the upper uterine segment. **C,** Classic incision. The incision is entirely within the upper uterine segment and can be at the level shown or in the fundus. **D,** J incision. If more room is needed when an initial transverse incision has been made, either end of the incision can be extended upward into the upper uterine segment and parallel to the ascending branch of the uterine artery. **E,** T incision. More room can be obtained in a transverse incision by an upward midline extension into the upper uterine segment.

TABLE 20-5 POTENTIAL INDICATIONS FOR VERTICAL UTERINE INCISION

- Underdeveloped lower uterine segment
- Breech or transverse lie with undeveloped lower uterine segment
- Inability to develop bladder flap with repeat cesarean delivery
- Lower segment anterior myoma
- Anterior placenta previa

extended cephalad with fingers or bandage scissors. If the thick myometrium of the upper segment is incised, the incision becomes a classic one and should be described as such in the operative report.

Extraction of the Fetus

Once an adequate uterine incision has been completed, the fetal head is extracted by elevation and flexion using the operator's hand as a fulcrum. Adequate fundal pressure by the assistant is often critical to obtain delivery. If the head is not easily delivered, the uterine incision (or skin or abdomen incisions) may be extended. Rarely, a T-incision will be made to facilitate delivery**. In cases in which the vertex is wedged in the maternal pelvis, usually in advanced second-stage arrest, reverse breech extraction ("pull" method) has been associated with shorter operating time, less extension of the uterine incision, and postpartum endometritis compared with vaginal displacement of the presenting part upward,**[28] but the evidence is insufficient to make a strong recommendation. Vacuum extraction or short Simpson forceps should in general be avoided because they are rarely necessary if the previously mentioned steps are taken.

Following delivery, the cord is clamped and cut, and the infant is passed from the field to the pediatric team.

Placental Extraction and Uterine Repair

Following delivery of the infant, intravenous oxytocin is started as a drip (at least 20 U/L). One randomized trial has reported benefit from using 80 versus 20 U/L.

Removal of the placenta by spontaneous expulsion with gentle cord traction has been shown by several randomized trials to be associated with less blood loss and a lower rate of endometritis than by manual extraction.[29-31] **Therefore, spontaneous expulsion with gentle cord traction and uterine massage should be performed for delivery of the placenta.**

The uterine repair may be greatly facilitated by lifting the fundus and delivering the uterus through the abdominal incision. Uterine exteriorization facilitates better visualization of the extent of the incision to be repaired as well as the adnexa. There is no significant increased risk for blood loss, infection, hypotension, or nausea and vomiting with exteriorization of the uterus compared with intra-abdominal repair, as shown by a meta-analysis of 11 trials.[32]

Bleeding along the incision line is temporarily controlled by using ring clamps because they are less traumatic than

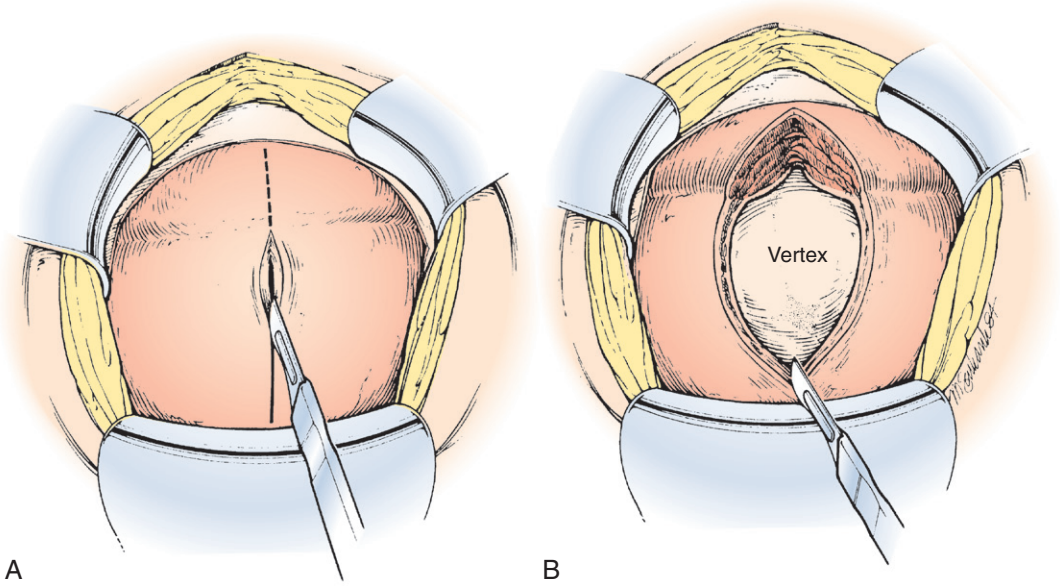

FIGURE 20-4. Low-vertical incision. **A,** Ideally, a vertical incision is contained entirely in the lower uterine segment. **B,** Extension into the upper uterine segment, either inadvertently or by choice, is common.

other instruments. The uterus is then manually curetted with a moistened sponge, and all placental fragments or membranes are teased away from the uterine wall. Routine cervical dilation is not necessary, even if the patient has not labored and the cervix is not dilated, because it is not associated with any benefit.[33]

The uterine incision should be well inspected before closure. Any inferior extensions of the incision should be visualized and repaired separately before closure.

The first layer of uterine closure is always performed. Continuous suturing is associated with less operating time and reduced blood loss compared with interrupted sutures.[34] **The locking of the primary layer of closure facilitates hemostasis, but may not be necessary if the incision is fairly hemostatic before closure. Size 1-0 or 0-0 synthetic suture is employed. Full-thickness repair, including the endometrial layer, is associated with improved healing as checked by ultrasound 6 weeks after cesarean.**[35,36]

The lower uterine incision may be closed with either a single or a double layer of sutures (Figure 20-5). Single-layer closure is associated with a statistically significant but clinically small reduction in mean blood loss, duration of the operative procedure, and presence of postoperative pain compared with double-layer closure.[36] There is controversy about whether an increased risk for subsequent uterine rupture accompanies the single-layer closure technique. (see later). In women who receive a tubal ligation at the time of cesarean delivery, we perform a single-layer closure. Otherwise, we prefer a double-layer closure; however, this practice is not based on level I evidence.

A vertical uterine incision generally requires at least a double-layer, and often a triple-layer, closure technique (Figure 20-6).

The uterine incision is carefully inspected for hemostasis before returning it to the peritoneal cavity. Individual bleeding points are cauterized or ligated using as little suture material as possible. The adnexa are inspected.

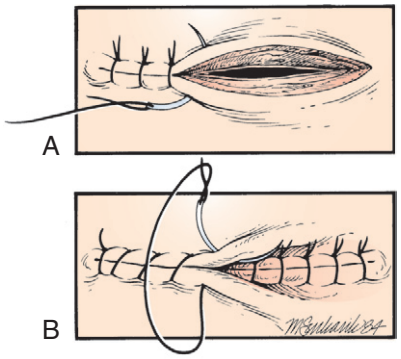

FIGURE 20-5. Closure of low-transverse incision. **A,** The first layer can be either continuous (recommended) or interrupted. A continuous locking suture is less desirable, despite its reputed hemostatic abilities, because it may interfere with incision vasculature and, hence, with healing and scar formation. **B,** A second inverted layer is created by using a continuous Lembert or Cushing stitch. Inclusion of too much tissue produces a bulky mass that may delay involution and interfere with healing.

Tubal ligation is performed, if so desired. Following return of the uterus inside the pelvis, sponge and needle counts are then performed before abdominal closure. Intra-abdominal irrigation does not reduce intrapartum or postpartum maternal morbidity.[37]

Abdominal Closure

The parietal and visceral peritoneum are not reapproximated because spontaneous closure will occur within days, and nonclosure is associated with less operative time, less fever, and less need for analgesia compared with closure.[38]

There are no trials evaluating technical aspects of fascial closure at cesarean. The rectus fascia is usually closed with a continuous nonlocking technique, but some prefer interrupted sutures. A suture with good tensile strength

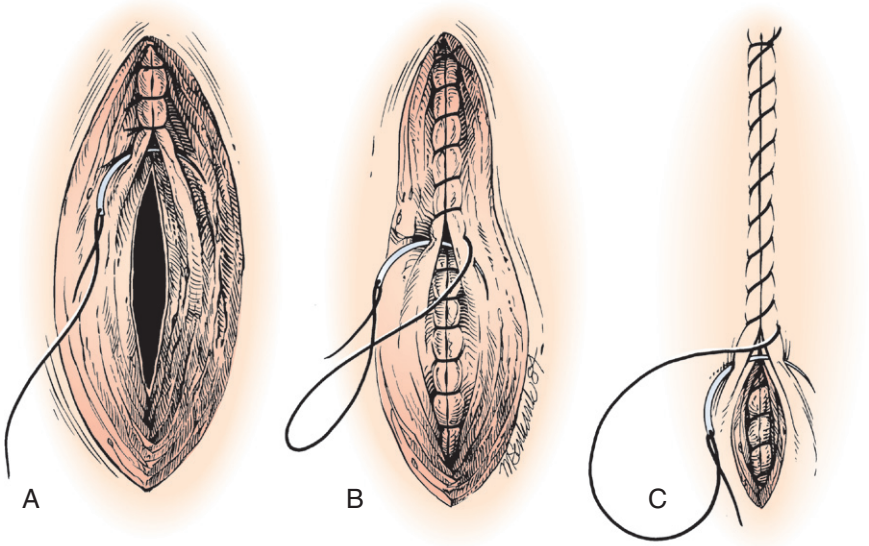

FIGURE 20-6. Repair of a classic incision. Three-layer closure of a classic incision, including inversion of the serosal layer to discourage adhesion formation. The knot at the superior end of the incision of the second layer can be buried by medial to lateral placement of the suture from within the depth of the incision and subsequent lateral to medial reentry on the opposing side with resultant knot placement within the incision.

and relatively delayed absorption is preferred. Synthetic braided or monofilament sutures are best to use. In most instances, a running continuous monofilament propylene suture will suffice for a transverse incision. **In closing the fascia, placement of sutures should be at a minimum 1.5 cm from the margin of the incision. Sutures are placed at about 1-cm intervals. In most cases of wound disruption, the suture remains intact but has cut through the fascia as a result of placement too close to the cut margin.** Patients at risk for wound disruption may benefit from either the Smead-Jones technique or interrupted figure-of-eight suturing, both employing delayed absorption suture material such as monofilament polyglycolic acid. The Smead-Jones closure technique is preferred for vertical incisions in high-risk cases (Figure 20-7). A suture with either far-near or near-far placement that passes through the lateral side of the anterior rectus fascia and adjacent subcutaneous adipose tissue and then crosses the midline of the incision to pick up the medial edge of the rectus fascia, then catches the near side of the opposite rectus sheath before returning to the far margin of the opposite rectus sheath and subcutaneous fat, accomplishes this technique.

The subcutaneous tissue is closed if it will facilitate skin closure or if the fat thickness is at least 2 cm. Closure of the subcutaneous tissue with sutures is associated with less wound complications such as a hematoma, seroma, wound infection, or wound separation compared with no closure.[39]

Closure is more beneficial than drainage in these cases. In fact, routine prophylactic wound drainage is not associated with benefits and should therefore not be performed.[40] When hemostasis is not adequate either intra-abdominally or subcutaneously, drains can be used, but there are no level I data assessing their effectiveness.

The skin is closed with either a staple device or a subcuticular closure for transverse incisions. There is insufficient evidence to recommend one skin closure over the other. Staples, as long as they are left in for at least 4 days, appear to be associated with shorter operating times, with no significant differences in pain or cosmesis.[41-43]

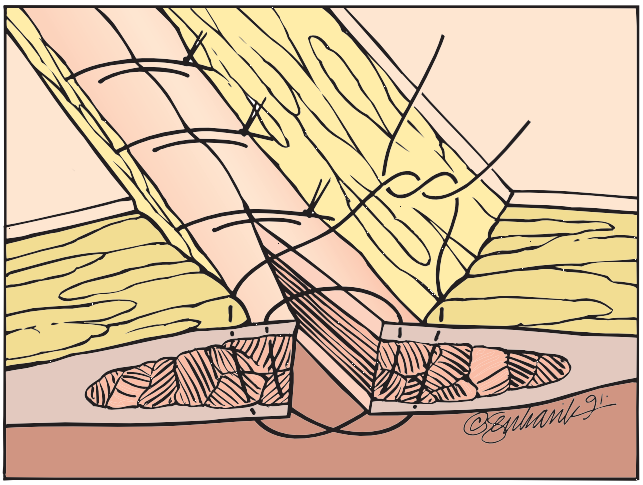

FIGURE 20-7. Modification of far-near, near-far Smead-Jones suture. Suture passes deeply through lateral side of anterior rectus fascia and adjacent fat, crosses the midline of the incision to pick up the medial edge of the rectus fascia, then catches the near side of the opposite rectus sheath, and, finally, returns to the far margin of the opposite rectus sheath and subcutaneous fat. (Modified from American College of Obstetricians and Gynecologists: Prolog. In Gynecologic Oncology and Surgery. Washington, DC, ACOG, 1991, p 187.)

COMPLICATIONS OF CESAREAN DELIVERY

Intraoperative Complications

Women undergoing cesarean delivery are at risk for several intraoperative complications, including hemorrhage and injury to adjacent organs. Injury to the bowel, bladder, and ureters is uncommon; however, the obstetrician must be familiar with management of these problems. The key element is to recognize and define the extent of these injuries and to promptly institute repair. Consultation with a urologist, general surgeon, or gynecologic oncologist may be necessary depending on the skill level of the obstetrician and the complexity of the injury encountered.

Uterine Lacerations

Lacerations of the uterine incision most commonly involve extension of a low-transverse incision following arrest of descent in the second stage or with delivery of a large fetus. **Most lacerations are myometrial extensions and can be closed with a running locking suture independently or in conjunction with closure of the primary uterine incision. High lateral extensions may require unilateral ascending uterine artery branch ligation.** In cases that extend laterally and inferiorly, care must be taken to avoid ureteral injury. On occasion, if the extension involves bleeding into the broad ligament, opening this space and identifying the ureters before suture placement may be helpful. On rare occasions, retrograde ureteral stent placement may be necessary. Opening the dome of the bladder is the preferred technique for retrograde stent placement.

Bladder Injury

Minor injury to the bladder from vigorous retraction and bruising with resultant hematuria is common. More significant injury such as a bladder dome laceration is infrequent but can occur on entering the peritoneum, particularly with multiple repeat operations. Bladder injury is also encountered with development of the bladder flap in cases in which scarring increases adherence to the lower anterior uterine wall. This is another reason that we do not routinely perform a bladder flap. If the bladder is very adherent and tacked high, it may be advisable to proceed with a vertical uterine incision to avoid bladder disruption.

Bladder dome lacerations are generally repaired with a double-layer closure technique employing 2-0 or 3-0 vicryl suture. The mucosa may be avoided with closure, although this is not imperative. If there is any question regarding possible trigone or ureteral injury before repair, intravenous indigo carmine is administered, and the ureteral orifices are visualized for dye spillage. Retrograde filling of the bladder with sterile milk may be useful following closure to ensure its integrity. Continuous Foley drainage should be accomplished for several days following repair of a bladder injury.

Ureteral Injury

Ureteral injury has been reported to occur in about 1 in 1000 cesarean deliveries. The frequency of injury increases with cesarean hysterectomy. **Most ureteral injuries follow attempts to control bleeding from lateral extensions into the broad ligament. As described previously, opening the broad ligament before suture placement may reduce the risk for this complication.** If the integrity of the ureter is in doubt, intravenous indigo carmine can be administered, with visualization of spillage in the bladder by cystoscope (usually performed by a urologic consultant). The ureteral orifices are visualized for dye spillage, signifying ureteral patency. If ureteral injury is recognized postoperatively, cystoscopy with stent placement or nephrostomy with radiologic imaging may define the extent of injury and help in planning appropriate management.

Gastrointestinal Tract Injury

Bowel injury during cesarean section is rare. Most cases involve incidental enterotomy on entering the abdomen for a repeat laparotomy, especially if scissors or scalpel are used. This is another reason why we employ blunt dissection, with fingers, for peritoneal entry. Defects in the bowel serosa are closed with interrupted suture of fine silk using an atraumatic needle. If the lumen of the small bowel is lacerated, closure is accomplished in two layers. A 3-0 absorbable suture is preferred for the mucosa, followed by interrupted silk sutures for the serosa.

Large defects of the small bowel or injuries of the colon generally require consultation with a general surgeon or gynecologic oncologist. Small defects may be closed primarily; however, large defects with fecal contamination may require a temporary colostomy. Broad-spectrum antibiotic coverage is recommended for such cases, which must include administration of an aminoglycoside in addition to metronidazole or clindamycin.

Uterine Atony

A more complete review of the management of uterine atony is found in Chapter 19. Uterine atony can be controlled in most cases by a combination of uterine massage and uterotonic agents. Intravenous oxytocin in dosages up to 80 U/L running wide open is attempted initially. If this fails to result in uterine contraction, either methergonovine maleate (Methergine), 0.2 mg administered intramuscularly, or 0.25 mg of 15-methylprostaglandin F2 alpha (Hemabate), is administered intramuscularly or directly into the myometrium. Several successive doses of Hemabate every 10 to 15 minutes may be tried (up to 1 mg) if necessary. Most individuals respond to one or two doses. Misoprostol, up to 1000 mcg per rectum, can be administered. Packing or use of a uterine balloon is also effective in these cases, if medical management is not fully effective. Medical management is successful, if employed correctly and promptly, in most cases of uterine atony.

In the rare cases in which nonsurgical management does not control bleeding, a surgical approach should be employed. The initial surgical approach is bilateral ascending uterine artery branch ligation, especially if future fertility is desired. If this fails, hypogastric artery ligation or hysterectomy may be undertaken (Figure 20-8). Hypogastric artery ligation is effective in less than 50% of cases.

Placenta Accreta

Placenta accreta has increased in frequency with rising cesarean delivery rates, and in some series of cesarean hysterectomy, placenta accreta is the most common indication. The risk for placenta accreta increases with each repeat cesarean delivery and is substantially increased by the presence of placenta previa (see Chapter 19).[44]

Focal placenta accreta may be managed by oversewing the implantation site with figure-of-eight absorbable sutures. However, hemostasis must be ensured. If the lower segment continues to bleed, it should be packed tightly to reduce blood loss while proceeding with hysterectomy. **In cases of total placenta previa with clinically apparent placenta accreta, it is advisable to leave the placenta attached while proceeding with hysterectomy.** This approach may lower blood loss considerably. Most cases of placenta accreta with previa require total hysterectomy because of placental attachment to the relatively hypocontractile lower uterine segment.

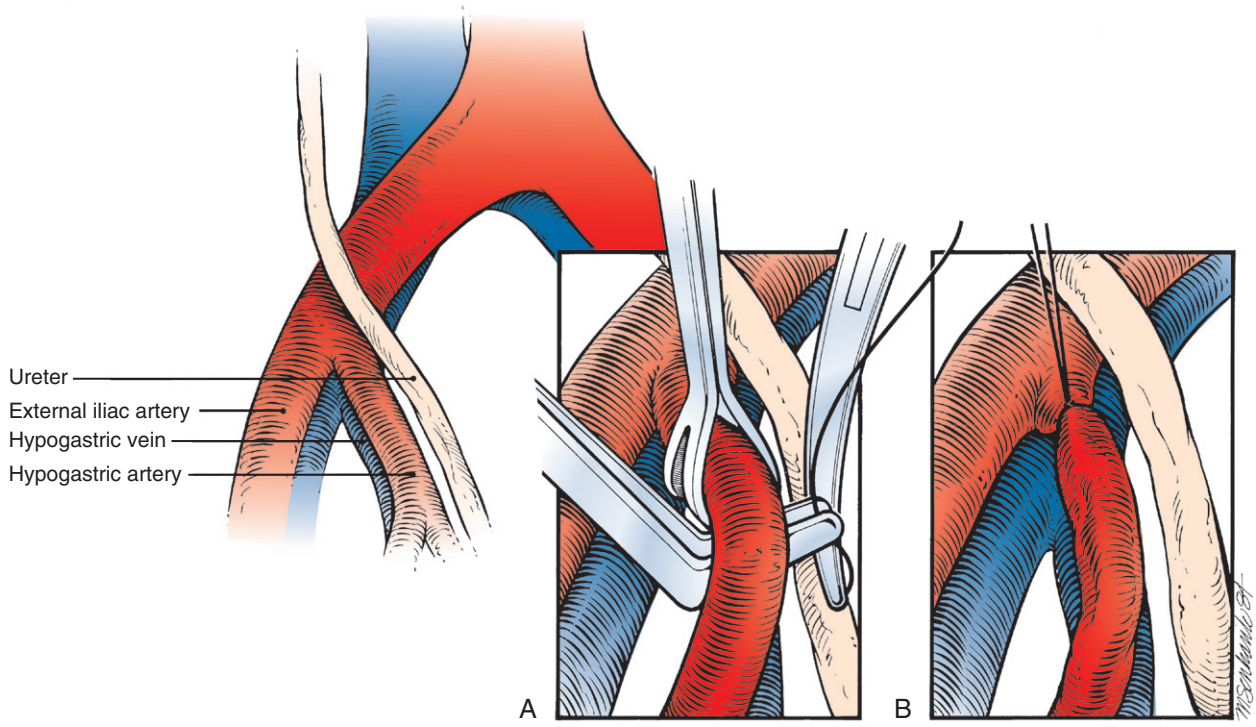

FIGURE 20-8. Hypogastric artery ligation. Approach to the hypogastric artery through the peritoneum, parallel and just lateral to the ovarian vessels, exposing the interior surface of the posterior layer of the broad ligament. The ureter will be found attached to the medial leaf of the broad ligament. The bifurcation of the common iliac artery into its external and internal (hypogastric) branches is exposed by blunt dissection of the loose overlying areolar tissues. Identification of these structures is essential. **A** and **B,** To avoid traumatizing the underlying hypogastric vein, the hypogastric artery is elevated by means of a Babcock clamp before passing an angled clamp to catch a free tie. (Modified from Breen J, Cregori CA, Kindierski JA: Hemorrhage in Gynecologic Surgery. Hagerstown, MD, Harper & Row, 1981, p 438.)

Maternal Mortality

The attributable maternal death rate has ranged from 6 to 22 per 100,000. In a study of 250,000 deliveries, Lilford and colleagues[45] reported the RR for maternal death from cesarean delivery compared with vaginal birth to be about seven-fold higher when preexisting medical conditions were excluded. In contrast, Lydon-Rochelle noted similar rates of maternal death among women delivered by cesarean section versus vaginal birth when adjusting for maternal age and the presence of severe preeclampsia.[46]

Anesthesia-related morbidity and mortality have been substantially reduced through the expanded use of regional anesthesia and the employment of awake intubation for patients requiring general anesthesia who may have a difficult airway for standard intubation.

Maternal Postoperative Morbidity

Endomyometritis

Postcesarean endomyometritis remains the most common complication of cesarean delivery. Its frequency, with the use of appropriate prophylactic antibiotics as described previously, is usually less than 5%,[9,10] much reduced from preantibiotic times. Prolonged labor, rupture of membranes, and lower socioeconomic status appear to be the factors that most influence the rate of this complication.

Most cases of endomyometritis arise from ascending infection from cervicovaginal flora. Infections past the deepest part of the uterine incision may extend to the uterine musculature and, if not adequately treated, may produce peritonitis, abscess, and septic phlebitis. Using antibiotic prophylaxis, pelvic abscesses are rare, developing in 0.47% of cases following the diagnosis of chorioamnionitis compared with only 0.1% if fever was not observed during labor.

The diagnosis of postpartum endomyometritis is based on fever (100.4° F or more) with either fundal tenderness or foul-smelling discharge, in the absence of any other source. The presence of chorioamnionitis, prolonged labor, and ruptured membranes should prompt early treatment in suspected cases. The utility of endometrial cultures is limited owing to contamination with vaginal flora and the fact that therapy is rarely guided by these results. Treatment is primarily based on clinical findings, including uterine tenderness and fever.

Parenteral antibiotics employing a regimen directed against possible anaerobic infection are the preferred therapeutic agents. A regimen of clindamycin and an aminoglycoside such as gentamicin is associated with better safety and efficacy compared with other regimens. An alternative is a single-agent penicillin-based regimen using β-lactamase inhibition to allow for anaerobic coverage (e.g., ampicillin and sulbactam). These antibiotics should be continued until at least 24 hours after the patient has defervesced. Once uncomplicated endometritis has clinically improved with intravenous therapy, oral therapy is not needed.

For women who fail to respond to antibiotic therapy over 2 to 3 days, an alternative source for the fever such as a wound infection, deep abscess, hematoma, or septic pelvic thrombophlebitis should be considered. On

occasion, mastitis may produce significant temperature elevations (Figures 20-9 and 20-10).

Wound Infection

Wound infection complicates about 1% to 5% of cesarean deliveries.[5] **Most cesarean section wounds are considered clean contaminated owing to the interface with the lower reproductive tract. Emergent cesarean deliveries and those associated with chorioamnionitis are considered contaminated and have higher wound infection rates.**

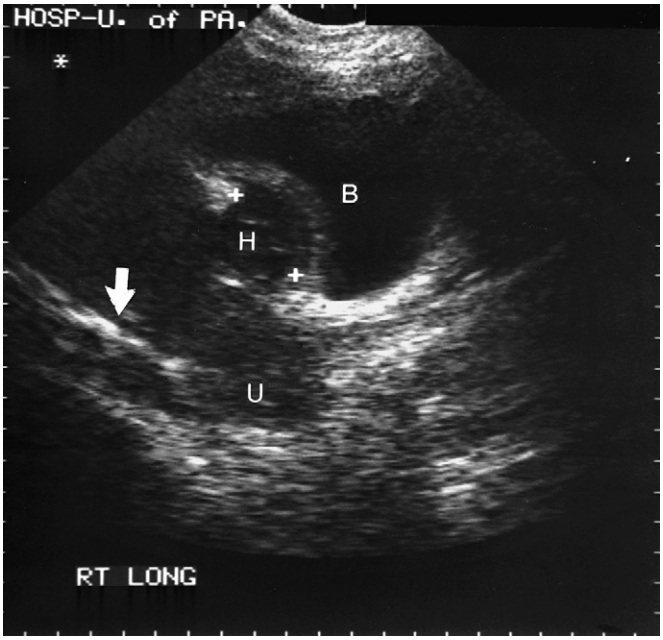

Figure 20-9. Ultrasound of infected bladder flap hematoma marked by cursors (+). The patient presented about 1 week after cesarean delivery with fever. She responded to antibiotics. Note that the full bladder *(B)* enhances visualization of the hematoma *(H)*. The *arrow* designates the endometrial cavity of the uterus *(U)*.

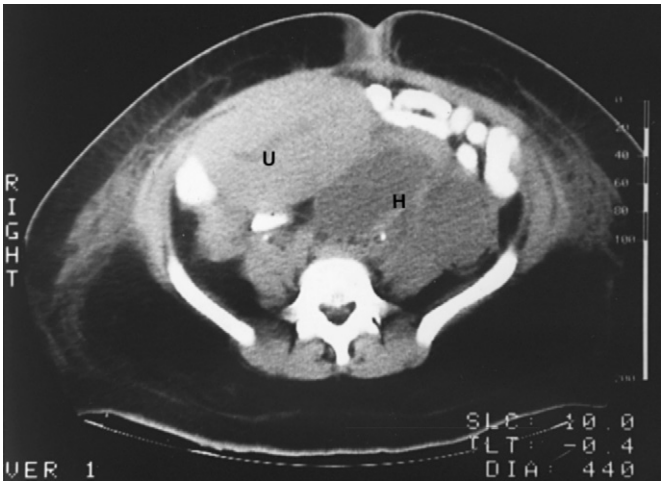

Figure 20-10. Computed tomography scan of pelvis 6 days after a cesarean section showing left-sided broad ligament hematoma *(H)*. The uterus *(U)* is displaced to the right. The patient responded to antibiotics. (Courtesy of Dr. Michael Blumenfeld, Department of Obstetrics and Gynecology, Ohio State University, Columbus, OH.)

The diagnosis of wound infection is usually straightforward in patients who present with tenderness, erythema, or discharge. Early wound infection (first 2 postoperative days) is often a result of streptococcal infection, whereas later wound infection is generally caused by overgrowth of staphylococcus or a mixed aerobic-anaerobic infection.

Wound discharge may be sent for culture before instituting therapy. The infected portion of the wound should be opened, inspected, irrigated, and débrided as necessary. In most cases, this alone will suffice for therapy. A wound abscess may require drainage (Figure 20-11). Antibiotic coverage, which is rarely necessary for simple wound infections, should be instituted promptly for advanced serious wound disruptions. Wound closure once the infection has resolved can be accomplished either surgically or by secondary intention. Reclosure of disrupted laparotomy wounds is successful in more than 80% of patients, is safe, and decreases healing times compared with healing by secondary intention.

Extreme wound discoloration, extensive infection, discoloration, gangrene, bullae, or anesthesia of the surrounding tissue should prompt consideration of necrotizing fasciitis. Necrotizing fasciitis has been reported to develop in 1 in 2500 of women undergoing primary cesarean delivery and is a surgical, life-threatening emergency. In these cases, the wound should be débrided under general

Figure 20-11. Magnetic resonance imaging (MRI) scan of abdominal wall abscess. This patient presented 1 week after a cesarean delivery with fever and an abdominal mass. The differential diagnosis included an intraperitoneal infection with extension or a wound abscess. This MRI shows a wound abscess *(A)* above fascia that extended to the abdominal wall *(arrow)*. The abscess responded to drainage and antibiotics.

anesthesia. Examination of histologic specimens may aid in the diagnosis of necrotizing infection. In such cases, all nonviable tissue should be removed, and consultation with an experienced surgeon is recommended. Antibiotic coverage, which is rarely necessary for simple wound infections, should be instituted promptly for advanced serious wound disruptions.

Thromboembolic Disease

VTE occurs more commonly during pregnancy secondary to higher levels of clotting factors and venous stasis (see Chapter 43) and is the leading cause of maternal death in developed countries. Risk factors are also the puerperal period, cesarean delivery, immobility, obesity, advanced age, and parity. The incidence of DVT was reported at 0.17% and that of pulmonary embolism (PE) at 0.12% in women undergoing cesarean birth.

The diagnosis of DVT is suggested by the presence of unilateral leg pain and swelling. A significant difference in the calf or thigh diameter may be present; however, error with this measurement is possible. The presence of Homans sign (pain with foot dorsiflexion) is often observed if the calf is involved. Many cases of DVT present as PE, particularly in the postoperative patient. Tachypnea, dyspnea, tachycardia, and pleuritic pain are the classic symptoms, with cough and specific pulmonary auscultatory findings less common.

If DVT is suggested, Doppler studies may be useful for proximal disease but are less sensitive for calf thrombosis. Impedance plethysmography is also helpful in detecting proximal disease, but it is of limited value in the diagnosis of pelvic thrombosis. If DVT is highly suspected and the previous studies are inconclusive, a venogram should be obtained.

The workup for suspected PE includes an arterial blood gas and chest film followed by a ventilation-perfusion study or spiral computed tomography (CT) study. Oxygen should be administered and heparin begun if a clinical PE appears likely. An indeterminate perfusion scan requires pulmonary angiography to establish or rule out the diagnosis of PE.

Septic Pelvic Thrombophlebitis

Probably less than 1% of women with endomyometritis develop septic pelvic thrombophlebitis; however, accurate figures for the frequency of this condition in current practice are lacking.

Septic pelvic thrombophlebitis is most often a diagnosis of exclusion established in refractory cases of women being treated for endomyometritis. A pelvic CT scan may aid in the diagnosis, although the sensitivity and specificity of this technique are clearly difficult to establish. In practice, a febrile patient who has undergone cesarean delivery and fails to respond to appropriate broad coverage antibiotic therapy for suspected uterine infection for several days, usually more than 5 to 7 days, may be started on full-dose heparin therapy, which is continued for several days following a clinical response. Long-term anticoagulation is not prescribed. Patients with septic pelvic phlebitis may present with spiking nocturnal fever and chills. However, these findings may be absent, and a persistent febrile state may be all that is present. In cases in which there is no response to anticoagulation therapy, imaging studies including pelvic CT are indicated to rule out an abscess or hematoma.

VAGINAL BIRTH AFTER CESAREAN DELIVERY

Trends

In a recent review of contemporary cesarean delivery practice in the United States, Zhang and colleagues concluded that primary emphasis should be placed on reducing cesarean section for dystocia and repeat operations because these two indications have increased the rate of cesarean section far beyond any other indications.[47] The modest decline in cesarean delivery observed to a nadir of 21% in 1996 was largely due to an increased TOLAC rate in women with a prior cesarean section. However, at the present time, only 8.5% of women with a prior cesarean delivery undergo a TOLAC in the United States. **It has been suggested that about two thirds of women with a prior cesarean delivery are actually candidates for a TOLAC. Thus, most repeat operations are influenced by physician discretion and patient choice.** A comparison of TOLAC rates between the United States and several European nations where TOLAC rates vary between 50% and 70% indicates significant underuse of TOLAC in this country. Given this information and the fact that 8% to 10% of the obstetrical population has had a previous cesarean delivery, more widespread use of TOLAC continues to have the potential to decrease the overall cesarean section rate.

The evolution in management of the woman with a prior cesarean delivery can be traced through several ACOG documents and key studies over the past 25 years. In 1988, ACOG published "Guidelines for Vaginal Delivery after a Previous Cesarean Birth," recommending VBAC-TOLAC as it became clear that this procedure was safe and did not appear to be associated with excess perinatal morbidity compared with repeat cesarean delivery. They recommended that each hospital develop its own protocol for the management of VBAC patients and that women with one prior low-transverse cesarean section should be counseled and encouraged to attempt labor in the absence of a contraindication such as a prior classic incision. This recommendation was supported by several large case series attesting to the safety and effectiveness of TOLAC. With this information, VBAC rates reached a peak of 28.3%. Some third-party payers and managed care organizations began to mandate a TOLAC for women with a prior cesarean delivery. Physicians, feeling institutional pressure to lower cesarean section rates, began to offer a TOLAC liberally and likely included less-than-optimal candidates. With the rise in VBAC experience, a number of reports appeared in the literature suggesting a possible increase in uterine rupture and its maternal and fetal consequences. Sachs and colleagues[48] reported a tripling of the incidence of uterine rupture in Massachusetts from 1985 to 1995. Further descriptions of uterine rupture with hysterectomy and adverse perinatal outcomes, including fetal death and neonatal brain injury, set the stage for the precipitous decline in VBAC during the past 15 years.[49,50]

In 1999, ACOG issued a practice bulletin that acknowledged the apparent statistically small but significant risks of uterine rupture with poor outcomes for both women and their infants. It was also recognized that such adverse events during a TOLAC may lead to malpractice suits.[51] ACOG thus recommended that TOLAC be conducted in settings in which a physician capable of performing a cesarean be "immediately available" and institutions be equipped to respond to emergencies such as uterine rupture. The language in the 1999 document also suggested that instead of "encouraging" TOLAC, women with prior low-transverse cesareans should be "offered" TOLAC. A more conservative approach to TOLAC then followed with recognition of the need to reevaluate VBAC recommendations.[52] Nonetheless, the 1999 practice bulletin and the 2004 version consistently conclude that most women with one previous cesarean delivery with a low-transverse incision are candidates for VBAC and should be counseled about VBAC and offered a TOLAC.[52] The 2004 practice bulletin added that insufficient data existed to provide counseling for patients presenting with a prior low-vertical incision, multiple gestation, breech presentation, or an estimated fetal weight greater than 4000 g.

In response to a growing body of evidence indicating restriction to a women's access to VBAC-TOLAC, despite two recent large-scale contemporary multicenter studies attesting to the relative safety of VBAC-TOLAC, the NIH held a consensus development conference concerning VBAC in 2010. The panel concluded that trial of labor is a reasonable birth option for many women with previous cesarean delivery. The panel also found that existing practice guidelines and the medical liability climate were restricting access to VBAC-TOLAC and that these factors need to be addressed.[53] A specific concern raised was the low level of evidence for the requirement for "immediately available" surgical and anesthesia personnel in existing guidelines and the need to reassess this recommendation with reference to other obstetrical complications of comparable risk given limited physician and nursing resources.

Several months later, in 2010, ACOG issued an updated practice bulletin concerning VBAC.[54] The ACOG acknowledged a background of limited access to TOLAC-VBAC evolving over time as well as recommendation by the NIH panel to facilitate access. In doing so, while again recommending that TOLAC-VBAC be undertaken in facilities with staff immediately available to provide emergency care, ACOG recognized that resources for immediate cesarean may not be available in smaller institutions. In such cases, the decision to offer and pursue VBAC-TOLAC should be carefully considered by patients and their health care providers. It is recommended that the best alternative may be to refer patients to a facility with available resources.[54]

Candidates for Trial of Labor After Cesarean

Most women who have had a low-transverse uterine incision with a prior cesarean delivery and have no contraindications to vaginal birth can be considered candidates for a TOLAC. **The following are selection criteria suggested by ACOG[54] for identifying candidates for VBAC:**

- **One or two previous low-transverse cesarean deliveries**
- **Clinically adequate pelvis**
- **No other uterine scars or previous rupture**
- **Physicians immediately available throughout active labor capable of monitoring labor and performing an emergency cesarean delivery**

Additionally, several retrospective studies indicate that it may be reasonable to offer a TOLAC to women in other clinical situations. These would include macrosomia, gestation beyond 40 weeks, previous low-vertical incision, unknown uterine scar type, and twin gestation.

A TOLAC is contraindicated in women at high risk for uterine rupture. **A TOLAC should not be attempted in the following circumstances:**

- **Previous classical or T-shaped incision, or extensive transfundal uterine surgery**
- **Previous uterine rupture**
- **Medical or obstetrical complications that preclude vaginal delivery**

CPD, Cephalopelvic disproportion; *FTP*, failure to progress; *NRFWB*, nonreassuring fetal well-being.

Success Rates for Trial of Labor After Cesarean

The overall success rate for VBAC appears to be in the 60% to 80% range according to published reports.[54] At the peak of VBAC experience with high TOLAC rates, success was observed in only 60% of cases. More selective criteria resulting in TOLAC rates in the 30% range have yielded a higher number of vaginal births, 70% to 75%.[55,56] Predictors of successful TOLAC are well described. The prior indication for cesarean delivery clearly affects the likelihood of successful VBAC. A history of prior vaginal birth or a non-recurring condition such as a breech or nonreassuring fetal testing is associated with the highest success rates for VBAC (Table 20-6). Grobman and colleagues[57] have developed a nomogram for predicting VBAC (Figure 20-12). The prediction model is based on a multivariable logistic regression, including the variables of maternal age, body mass index, ethnicity, prior vaginal delivery, the occurrences of a VBAC, and a potential recurrent indication for the cesarean delivery. After analyzing the model with cross-validation techniques, it was found to be accurate and discriminating. Several factors have been studied that influence success, and these are summarized in the following sections.

Maternal Demographics

Race, age, body mass index, and insurance status have all been demonstrated to affect the success of TOLAC.[55] In

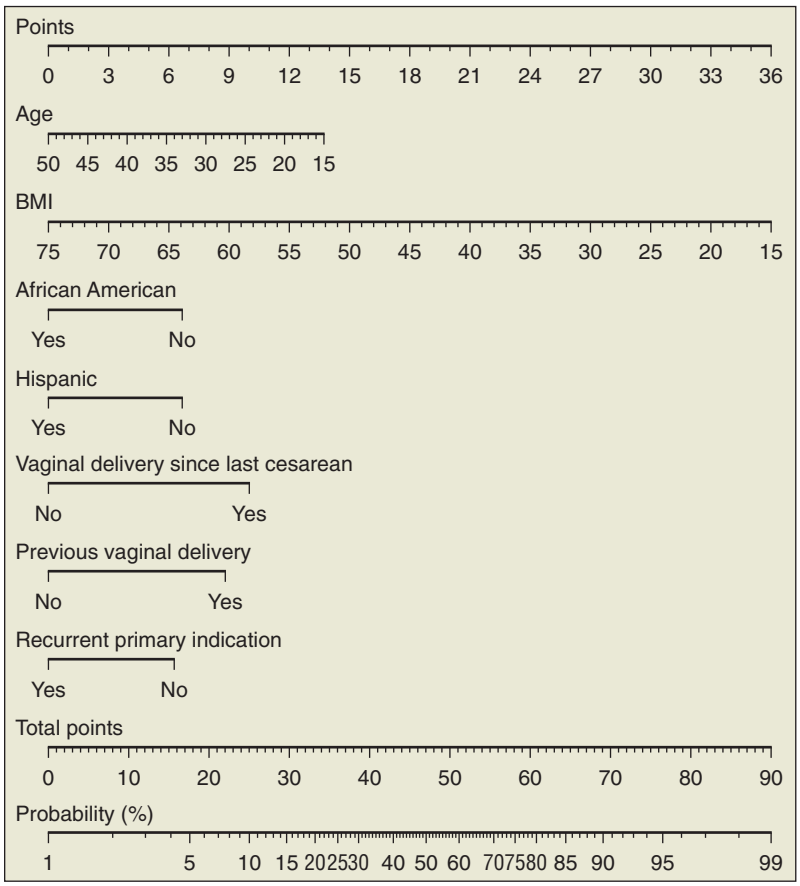

FIGURE 20-12. Graphic nomogram used to predict probability of vaginal birth after cesarean delivery (VBAC). The nomogram is used by locating each patient characteristic and finding the number of points on the upper most scale, to which that characteristic corresponds. The sum of total points predicts the probability of VBAC on the lower scale. (Modified from Grobman WA, Lai Y, Landon MB, et al: For the National Institute of Child Health and Human Development [NICHD] Maternal Fetal Medicine Units Network [MFMU]. Development of a normogram for prediction of vaginal birth after cesarean delivery. Obstet Gynecol 109:806-812, 2007.)

a multicenter study of 14,529 term pregnancies undergoing TOLAC, white women had a 78% success rate compared with 70% in nonwhite women.[55] Obese women are more likely to fail a TOLAC, as are women older than age 40 years.[55] Conflicting data exist with regard to payer status.[55]

Prior Indication for Cesarean Delivery

Success rates for women whose first cesarean delivery was performed for a non-recurring indication (breech, non-reassuring fetal well-being) are similar to vaginal delivery rates for nulliparous women. Prior cesarean delivery for a breech presentation is associated with the highest reported success rate of 89%.[55] In contrast, prior operative delivery for cephalopelvic disproportion or failure to progress is associated with success rates ranging from 50% to 67%.

Prior Vaginal Delivery

Prior vaginal delivery, including prior successful VBAC, can be considered the greatest predictor for successful TOLAC.[55] In one series, prior vaginal delivery had an 87% success rate compared with a 61% success in women without a prior vaginal delivery. Caughey and colleagues reported that for patients with a prior VBAC, the success rate is 93%, compared with 85% in women with a vaginal delivery before their cesarean birth but who had not had a successful VBAC.[58] Mercer and colleagues[59] have noted that success rate increases from 87.6% with one prior vaginal delivery to 90.0% in those with two prior successful attempts.

Birthweight

Increased birthweight is associated with a lower likelihood of a successful VBAC.[56] Birthweight greater than 4000 g in particular is associated with a significantly higher risk for failed VBAC.[56] However, 60% to 70% of women who attempt VBAC with a macrosomic fetus are successful. Peaceman and colleagues[60] reported a 34% success rate when the second pregnancy birthweight exceeded the first by 500 g and the prior indication was dystocia, compared with a 64% success rate with other prior indications.

Labor Status and Cervical Examinations

Both labor status and cervical examination on admission influence the success of a TOLAC. Flamm and colleagues reported an 86% success rate in women presenting with cervical dilation greater than 4 cm. Conversely, the VBAC success rate drops to 67% if the cervical examination is less than 4 cm on admission.[61]

Not surprisingly, women who undergo induction of labor are at higher risk for repeat cesarean delivery compared with those who enter spontaneous labor.[55,62] The National Institute of Child Health and Human Development (NICHD) Maternal-Fetal Medical Units (MFMU) Cesarean Registry reported a 67.4% success rate in women undergoing induction versus 80.5% in those entering spontaneous labor. In a study of 429 women undergoing induction with a prior cesarean delivery, Grinstead and Grobman[63] reported an overall 78% success rate. These authors noted several factors in addition to past obstetrical history, including indication for induction and the need

TABLE 20-7 Success Rates for Trial of Labor After Cesarean with Two Prior Cesarean Deliveries

STUDY	NO. OF SUBJECTS	SUCCESS RATE (%)
Miller et al., 1994[66]	2936	75.3
Caughey et al., 1999[65]	134	62.0
Macones et al., 2005[68]	1082	74.6
Landon et al., 2006[67]	876	67.0

for cervical ripening as determinants of VBAC success.[63] Grobman and colleagues[62] have also reported a VBAC success rate of 83% in 1208 women with a prior cesarean delivery and prior vaginal delivery undergoing induction of labor.

Previous Incision Type

Previous incision type cannot be ascertained in certain patients, which may challenge the obstetrician. It appears that women with an unknown scar have VBAC success rates similar to those of women with documented prior low-transverse incisions.[55] Similarly, women with previous low-vertical incisions do not appear to have lower VBAC success rates.[64]

Multiple Prior Cesarean Deliveries

Women with more than one prior cesarean delivery have been demonstrated to consistently have a lower likelihood of achieving VBAC[65-67] (Table 20-7). Caughey and colleagues reported a 75% success rate for women with one prior cesarean delivery compared with 62% in women with two prior operations.[65] In contrast, a larger multicenter study of 13,617 women undergoing a TOLAC revealed a 75.5% success rate for women with two prior cesarean deliveries, which was not statistically different from the 75% success rate in women with one prior operation.[68]

RISKS OF VAGINAL BIRTH AFTER CESAREAN DELIVERY–TRIAL OF LABOR

Uterine Rupture

The principal risk associated with VBAC-TOLAC is uterine rupture. This complication is directly attributable to attempted VBAC because symptomatic rupture is rarely observed in planned repeat operations.[69,70] **It is important to differentiate between uterine rupture and uterine scar dehiscence. This distinction is clinically relevant because dehiscence most often represents an occult scar separation observed at laparotomy in women with a prior cesarean section.** The serosa of the uterus is intact, and hemorrhage with its potential for fetal and maternal sequelae is absent. In contrast, uterine rupture is a through-and-through disruption of all uterine layers, with consequences of hemorrhage, non-reassuring fetal status, stillbirth and significant maternal morbidity, and the potential for mortality. Terminology, definitions, and ascertainment for uterine rupture vary significantly in the existing VBAC literature.[71] A review of four observational studies reported the risks of symptomatic uterine rupture in the TOLAC group and elective repeat cesarean group to be 0.47% (95% CI, 0.28% to 0.77%) and 0.026% (95% CI, 0.009% to 0.082%), respectively.[72] The large multicenter prospective observational MFMU Network Study reported a 0.69% incidence, with 124 symptomatic ruptures occurring in 17,898 women undergoing a TOLAC.[73]

TABLE 20-8 Risk for Uterine Rupture with Trial of Labor After Cesarean

PRIOR INCISION TYPE	RUPTURE RATE (%)
Low transverse	0.5-1.0
Low-vertical	0.8-1.1
Classic or T	4-9

The rate of uterine rupture depends on both the type and location of the previous uterine incision (Table 20-8).[74] Uterine rupture rates are highest with a previous classical or T-shaped incision, with a range reported between 4% and 9%. The risk for rupture with a previous low-vertical incision has been difficult to estimate owing to imprecision with the diagnosis and the uncommon use of this incision type. Naif and colleagues reported a 1.1% risk for rupture in 174 women with a prior low-vertical scar undergoing TOLAC, whereas Shipp reported a 0.8% (3 of 377) risk for rupture with a prior low-vertical incision. On the basis of these two studies, the authors concluded that women with a prior low-vertical uterine incision are not at increased risk for rupture compared with women with prior low-transverse incisions.

Women with an unknown type of scar do not appear to be at increased risk for uterine rupture. Among 3206 women with an unknown scar in the MFMU Network report, uterine rupture occurred in 0.5% of the trials of labor.[73]

The most serious sequelae of uterine rupture include perinatal death, HIE, and hysterectomy. Citing six deaths in 74 uterine ruptures among 11 studies, Guise and colleagues[75] calculated 0.14 additional perinatal deaths per 1000 trials of labor. This figure is remarkably similar to that from the NICHD MFMU Network study, in which there were two neonatal deaths among 124 ruptures, for an overall rate of rupture related perinatal death of 0.11 per 1000 TOLACs.[73] An all-inclusive review of 880 maternal uterine ruptures in studies of varying quality during a 20-year period showed 40 perinatal deaths in 91,039 trials of labor, for a rate of 0.4 per 1000[74] (Table 20-9).

Perinatal hypoxic brain injury is recognized as an underreported adverse outcome related to uterine rupture. Perinatal asphyxia has been poorly defined in VBAC studies, and variables such as cord blood gas levels and Apgar scores are reported in only a fraction of cases. Landon and colleagues[73] found a significant increase in the rate of HIE related to uterine rupture among the offspring of women who underwent a TOLAC at term compared with the children of women who underwent an planned repeat cesarean delivery (0.46 per 1000 trials of labor versus no cases, respectively). In 114 cases of uterine rupture at term, seven (6.2%) infants sustained HIE, and two of these infants died in the neonatal period (Table 20-10).

Modified from Landon MB, Hauth JC, Leveno KJ, et al, for the National Institute of Child Health and Human Development Maternal-Fetal Medicine Units Network: Maternal and perinatal outcomes associated with a trial of labor after prior cesarean section. N Engl J Med 351:2581, 2004.

Maternal hysterectomy may be a complication of uterine rupture, if the defect cannot be repaired or is associated with uncontrollable hemorrhage. In five studies reporting on hysterectomies related to rupture, seven cases occurred in 60 symptomatic ruptures (13%; range, 4% to 27%), indicating that 3.4 per 10,000 women electing a TOLAC sustain a rupture that necessitates hysterectomy.[71] The NICHD MFMU Network study included 5 of 124 (4%) cases requiring hysterectomy in which the uterus could not be repaired following rupture.[73] Guise and colleagues have reported no significant difference in the risk for hysterectomy in women with a prior cesarean attempting TOLAC compared with those undergoing planned repeat cesareans.[72]

Risk Factors for Uterine Rupture

Rates of uterine rupture vary significantly depending on a variety of associated risk factors. In addition to the type of uterine scar, characteristics of the obstetrical history, including number of prior cesarean deliveries, prior vaginal delivery, interdelivery interval, and uterine closure technique, have been reported to affect the risk for uterine rupture. Similarly, factors related to labor management, including induction and the use of oxytocin augmentation, have been studied.

Number of Prior Cesarean Deliveries

In a large single-center study of more than 1000 women with multiple prior cesarean deliveries undergoing a TOLAC, Miller and colleagues[66] reported uterine rupture in 1.7% of women with two or more previous cesarean deliveries compared with a frequency of 0.6% in those with one prior operation (odds ratio [OR], 3.06; 95% confidence interval [CI], 1.95 to 4.79). Interestingly, the risk for uterine rupture was not increased further for women with three prior cesarean deliveries. Caughey and colleagues[65] conducted a smaller study of 134 women with two prior cesarean deliveries and controlled for labor characteristics as well as obstetrical history. These authors reported a rate of uterine rupture of 3.7% among these 134 women compared to 0.8% in the 3757 women with one previous scar (OR, 4.5; 95% CI, 1.18 to 11.5). The risk was 4.8 times greater for these women after multivariate analysis. Macones and colleagues[68] reported a rate of uterine rupture of 20 of 1082 (1.8%) women with two prior cesarean deliveries compared with 113 of 12,535 (0.9%) women with one prior operation (adjusted OR, 2.3; 95% CI, 1.37 to 3.85). A recently published meta-analysis also suggested a nearly threefold increased risk for uterine rupture with two previous cesarean deliveries.[76] In contrast, Landon's analysis from the MFMU Network Cesarean Registry found no significant difference in rupture rates in women with one prior cesarean (115 of 16,916 [0.7%] versus multiple prior cesareans [9 of 975 (0.9%)].[67] **It thus appears that if multiple prior cesarean section is associated with an increased risk for uterine rupture, the magnitude of any additional risk is fairly small** (Table 20-11). **ACOG considers it reasonable to offer TOLAC to women with two prior cesareans and to counsel such women based on the combination of other factors that affect their probability of achieving a successful VBAC.** There are limited data available concerning the risk for women undergoing TOLAC with more than two previous cesarean deliveries.

TABLE 20-11 Risk for Uterine Rupture Following Multiple Prior Cesarean Deliveries

STUDY	RUPTURE RATE			
	N	Single Prior (%)	Multiple Prior (%)	RR (CI)
Miller et al., 1994[66]	3728	0.6	1.7	3.1 (1.9-4.8)
Caughey et al., 1999[65]	134	0.8	3.7	4.5 (1.2-11.5)
Macones et al., 2005[68]	1082	0.9	1.8	2.3 (1.4-3.9)
Landon et al., 2006[67]	975	0.7	0.9	1.4 (0.7-2.7)

CI, Confidence interval; *N*, number of women with multiple prior cesarean sections attempting vaginal birth after cesarean; *RR*, relative risk.

Prior Vaginal Delivery

Prior vaginal delivery appears to be protective against uterine rupture following TOLAC. In a study of 3783 women undergoing a TOLAC, Zelop and colleagues[77] noted that the rate of uterine rupture among women with a prior vaginal birth was 0.2% (2 of 1021) compared with 1.1% (30 of 2762) among women with no prior vaginal deliveries. After controlling for demographic differences and labor characteristics, women having one or more vaginal deliveries had a rate of uterine rupture that was one fifth that of women without prior vaginal birth (OR, 0.2; 95% CI, 0.04 to 0.8). A similar protective effect of prior vaginal birth has been reported in two large multicenter studies.[67,78] There is

currently no information about whether a history of successful VBAC is also protective against uterine rupture.

Uterine Closure Technique

Over the past 15 years, the single-layer closure technique has gained popularity because it has appeared to be associated with shorter operating time and comparable short-term complications compared with the traditional two-layer technique. In a randomized trial, Chapman and colleagues[79] compared the incidence of uterine rupture in 145 women who received either one- or two-layer closure at their primary cesarean delivery. Following TOLAC, no cases of uterine rupture were found in either group; however, the study is underpowered to detect a potential difference. A large observational cohort study identified an approximate fourfold increased rate of rupture following single-closure technique when compared with previous double-layer closure.[80] This study included detailed review of operative reports in which the rate of rupture was 15 of 489 (3.1%) with single-layer closure versus 8 of 1491 (0.5%) with a previous double-layer closure. Finally, in a recent case-control study, the same authors[81] suggested an increased risk for uterine rupture with a single-layer closure (OR, 2.69; 95% CI, 1.57 to 5.28) compared with a two-layer closure. In the absence of randomized controlled studies, it remains unclear whether the single-layer closure technique increases the risk for rupture.

Interpregnancy Interval

Three studies have addressed whether a short interpregnancy interval may be associated with an increased risk for uterine rupture with a TOLAC. Shipp and colleagues reported an incidence of rupture of 2.3% (7 of 311) in women with an interdelivery interval less than 18 months compared with 1.1% (22 of 2098) with a longer interdelivery interval. After controlling for demographic characteristics and oxytocin use, women with a shorter interpregnancy interval were three times more likely to experience uterine rupture. In a study of 1185 women undergoing a TOLAC, Huang and colleagues found no increased risk for uterine rupture with an interdelivery interval of less than 18 months. Using a multivariate approach, Bujold and associates have reported an interdelivery interval of less than 24 months to be associated with an almost threefold increased risk for uterine rupture. In this study, the rate of rupture was 2.8% in women with a short interval versus 0.9% in women with greater than 2 years since the prior cesarean birth.

Induction of Labor

Induction of labor may be associated with an increased risk for uterine rupture.[82,83] In a population-based retrospective cohort analysis, Lydon-Rochelle and colleagues[82] reported a rate of uterine rupture of 24 of 2326 (1.0%) for women undergoing induction compared with 56 of 10,789 (0.5%) in women with the spontaneous onset of labor. In the prospective MFMU Network cohort analysis, Landon and coworkers noted the risk for uterine rupture to be elevated nearly threefold (OR, 2.86; 95% CI, 1.75 to 4.67) with induction in 48 of 4708 (1.0%) versus spontaneous labor in 24 of 6685 (0.4%).[73] A secondary analysis of 11,778 women from this study with one prior low-transverse cesarean showed an increase in uterine rupture in women undergoing induction who had no prior vaginal delivery (1.5% vs 0.8%).[62] In controlling for various potential confounders, Zelop and colleagues[77] compared the risk for uterine rupture in women undergoing labor induction with oxytocin versus spontaneous labor. Induction of labor with oxytocin was found to be associated with a 4.6-fold increased risk for uterine rupture (rupture rate of 2% versus 0.7%). Most recently, Dekker and colleagues reported a risk for rupture with induction using oxytocin alone of 0.54% compared with 0.15% for those women attempting VBAC in spontaneous labor. Compared with spontaneous labor, risks were increased three to five times for any type of induction.[83] Despite these analyses, **it remains unclear whether induction causes uterine rupture or whether an associated risk factor is present** (Table 20-12). **There are also conflicting data concerning whether various induction methods increase the risk for uterine rupture.** Lydon-Rochelle's[82] study suggested an increased risk for uterine rupture with the use of prostaglandins for labor induction. Uterine rupture was noted in 15 of 1960 (0.8%) women induced without prostaglandins compared with 9 of 366 (2.5%) women induced with prostaglandin. Unfortunately, these authors could not determine which specific prostaglandin agent was used. In Dekker's study,[83] the risk for rupture with oxytocin alone was 0.54% compared with 0.68% with prostaglandins and 0.88% when the combined agents were used.

Neither Landon nor Macones confirmed the findings of Lydon-Rochelle of an increased risk for rupture associated with the use of prostaglandin agents alone for induction.[73,78] Macones did report an increased risk for rupture in women undergoing induction only if they received both prostaglandins *and* oxytocin.[78] The methodology in this study did allow the authors to distinguish between induction methods. In contrast, this was not possible in Lydon-Rochelle's report, which relied on procedure codes for the use of prostaglandins that did not exclude the concomitant use of oxytocin. Interestingly, in the MFMU Network Study, there were no cases of uterine rupture when prostaglandin alone was used for induction, including 52 cases

TABLE 20-12 Risk for Uterine Rupture after Labor Induction

	STUDY		
	Lydon-Rochelle et al., 2001[82]	**Landon et al., 2004[73]**	**Dekker et al., 2010[83]**
All inductions	24/2326 (1.0)	48/4708 (1.0)	16/1867 (0.9)
Spontaneous	56/10,789 (0.5)	24/6685 (0.4)	16/8221 (0.2)
Prostaglandins	9/366 (2.5)	0/227 (0.0)	4/586 (0.7)
Prostaglandin + and oxytocin	—	13/926 (1.4)	4/226 (1.8)

in which misoprostol was used.[73] The safety of this medication, which is popular for cervical ripening and labor induction (see Chapter 14), has been challenged for women attempting VBAC. Plaut reported a uterine rupture rate of 5.6% (5 of 89) in women receiving misoprostol for labor induction. However, as in other series, it is unclear whether these women received oxytocin as well. The timing (delay) of uterine rupture in relation to misoprostol administration also calls into question cause and effect. Following several case reports of uterine rupture with misoprostol use, Wing and colleagues[84] conducted a randomized trial of intravaginal misoprostol versus oxytocin in women attempting VBAC. Seventeen women received misoprostol and 21 oxytocin. The study was stopped prematurely because two emergency cesarean deliveries were performed with uterine disruption in patients receiving misoprostol. Unfortunately, many VBAC studies fail to specify the prostaglandin used for labor induction. In the largest report of woman receiving prostaglandins for labor induction attempting VBAC, Smith and colleagues[85] reported a 0.87% risk for uterine rupture among 4475 women receiving unspecified prostaglandins compared with 0.29% in 4429 cases not receiving this class of medication. Although the relative risk associated with prostaglandin use was elevated, clearly the absolute risk for rupture was impressively low in this series. **At present, based on limited data, ACOG suggests avoiding sequential use of prostaglandin E_2 and oxytocin in women undergoing TOLAC.** This recommendation has thus limited options for induction in women undergoing TOLAC to primarily oxytocin or mechanical methods with or without oxytocin. At present, the use of mechanical methods, such as Foley catheters, indicate relative safety.

Labor Augmentation

Excessive use of oxytocin may be associated with uterine rupture, and careful labor augmentation should be practiced in women attempting TOLAC. A meta-analysis concluded that oxytocin use does not appear to influence the risk for a dehiscence or uterine rupture. In a case-control study, Leung and colleagues reported an OR of 2.7 for uterine rupture in women receiving oxytocin augmentation. Dysfunctional labor, including arrest disorders, actually increased the risk sevenfold and, thus, may be the primary factor responsible for rupture. In contrast to Leung's data, Zelop[77] found that labor augmentation with oxytocin did not significantly increase the risk for rupture. **Cahill and colleagues[86] have reported that a dose-response relationship exists between maximal oxytocin dose and the risk for rupture compared with women who attempt VBAC with no oxytocin exposure.** A limitation of this report is that it includes both women undergoing induction and those receiving oxytocin augmentation. At their maximal dose of oxytocin (>20 mU/minute), these authors noted the risk for uterine rupture to be 2.07%. In a follow-up study, these authors considered the association of maximum oxytocin exposure and risk for uterine rupture by estimated time to event in their analysis.[87] Their previous analysis suggested an approximate 1% attributable risk for rupture at higher oxytocin doses; however, the more recent report estimated the attributable risks to be 2.9% and 3.6% for doses greater than 20 and 30 mU/minute, respectively. **From these data, large doses of oxytocin should be used with caution in women undergoing TOLAC, and an upper limit of 20 mU/minute seems reasonable.**

Sonographic Evaluation of the Uterine Scar

To better identify women at risk for uterine rupture undergoing TOLAC, the thickness of the lower uterine segment (LUS) has been assessed with ultrasound. Bujold and colleages[88] conducted a prospective study of 125 women with previous cesarean undergoing TOLAC who received sonographic measurement of the LUS before labor. There were only three cases of uterine rupture; however, receiver operative curve analysis showed that full thickness of less than 2.3 mm was the optimal cutoff for the prediction of uterine rupture (3 of 33 vs. 0 of 92; $P = .02$). The rate of uterine rupture (9.1%) reported is significantly greater than previously cited risk factors and, thus, if confirmed in additional studies, may identify a subgroup of women at sufficiently high risk to advise against TOLAC. Limitations of Bujold's study include the small number of ruptures as well as the fact that most women with an LUS of less than 2 mm did not undergo TOLAC. This later fact suggests that practice patterns have been established that may limit further investigation concerning the utility of ultrasound to predict uterine rupture.[87]

Other Risks Associated with Vaginal Birth After Cesarean Delivery–Trial of Labor

In the absence of randomized controlled trials, there are limited data to inform women and health care providers about adverse outcomes associated with a TOLAC. Meta-analysis of these data have been criticized owing to lack of comparability between women undergoing a TOLAC and those having a planned repeat cesarean delivery.[70]

It has generally been accepted that vaginal delivery is associated with lower morbidity and mortality rates than is cesarean delivery. In contrast to Mozurkevich's meta-analysis of 15 studies, Landon and colleagues found an increased risk for both postpartum endometritis and the need for blood transfusion in women undergoing a TOLAC compared with planned repeat cesarean delivery without labor[70,73] (Table 20-13). However, the exclusion of women who presented in early labor who subsequently underwent repeat operation may have lowered the risk for complications in the planned repeat cesarean group. Nonetheless, most of the excess adverse events accompanying a TOLAC are attributable to the failure group of women who require a repeat cesarean operation[89] (Table 20-14).

An increased risk for maternal mortality accompanying all cases of cesarean delivery has been extrapolated to women undergoing a planned repeat operation versus a planned TOLAC, although the data to support this suggestion are limited. The infrequency of maternal death, confounding variables such as maternal disease, and the classification of a planned or nonplanned procedure, complicate comparisons of mortality. Maternal death attributable to uterine rupture is exceedingly rare.[49] The MFMU Cesarean Registry study found that maternal deaths were not significantly more common with planned

repeat cesarean delivery. However, the study was not powered to detect a difference between this group and women attempting VBAC.[73] Guise and colleagues evaluated 24 maternal deaths among 402,833 patients with prior a cesarean delivery and noted the overall risk for maternal death associated with TOLAC is significantly lower (RR, 0.33; 95% CI, 0.13 to 0.88) than with repeat operation.[72]

Management of Vaginal Birth After Cesarean Delivery–Trial of Labor

The management of labor in women undergoing a TOLAC is primarily based on opinion. Women attempting VBAC should be encouraged to contact their health care provider promptly when labor or ruptured membranes occur. Continuous electronic fetal monitoring is prudent, although the need for intrauterine pressure catheter monitoring is controversial. **Studies that have examined FHR patterns before uterine rupture consistently report that nonreassuring signs, particularly significant variable decelerations or bradycardia, are the most common finding accompanying uterine rupture.**[90,91] Leung analyzed FHR and contraction patterns in association with 78 cases of uterine rupture. Prolonged decelerations (FHR <90 beats/minute exceeding 1 minute without return to baseline) occurred in 55 of 78 cases (71%) of uterine rupture. Prolonged deceleration was also noted in 36 of 36 cases (100%) in which the fetus was extruded from the uterus.

Despite the presence of adequate personnel to conduct an emergency cesarean delivery, prompt intervention does not always prevent fetal neurologic injury or death.[92] It appears that a non-reassuring FHR pattern occurring before uterine rupture identified cases in which the amount of time necessary to deliver an intact fetus is limited (Figure 20-13). In Leung's study, significant neonatal morbidity occurred when 18 minutes or longer elapsed between the onset of FHR deceleration and delivery. In cases in which prolonged deceleration was preceded by severe variable or late decelerations, fetal injury was noted as early as 10 minutes from the onset of a prolonged deceleration. In contrast to Leung's findings, Bujold and Gauthier[93] reported that less than 18 minutes elapsed between prolonged decelerations and delivery in two of three neonates diagnosed with HIE in 23 cases of uterine rupture.

TOLAC is not a contraindication to the use of epidural analgesia and does not appear to affect success rates.[55] Epidural analgesia also does not mask the signs and symptoms of uterine rupture. The role of oxytocin augmentation in uterine rupture has been discussed previously. Most studies, again, do not support a marked increased risk for associated uterine rupture with modest doses of oxytocin employed.[94] In a case-control study, Goetzel and colleagues[94] reported no association between uterine rupture and oxytocin-dosing intervals, total dose used, and the mean duration of oxytocin administration.

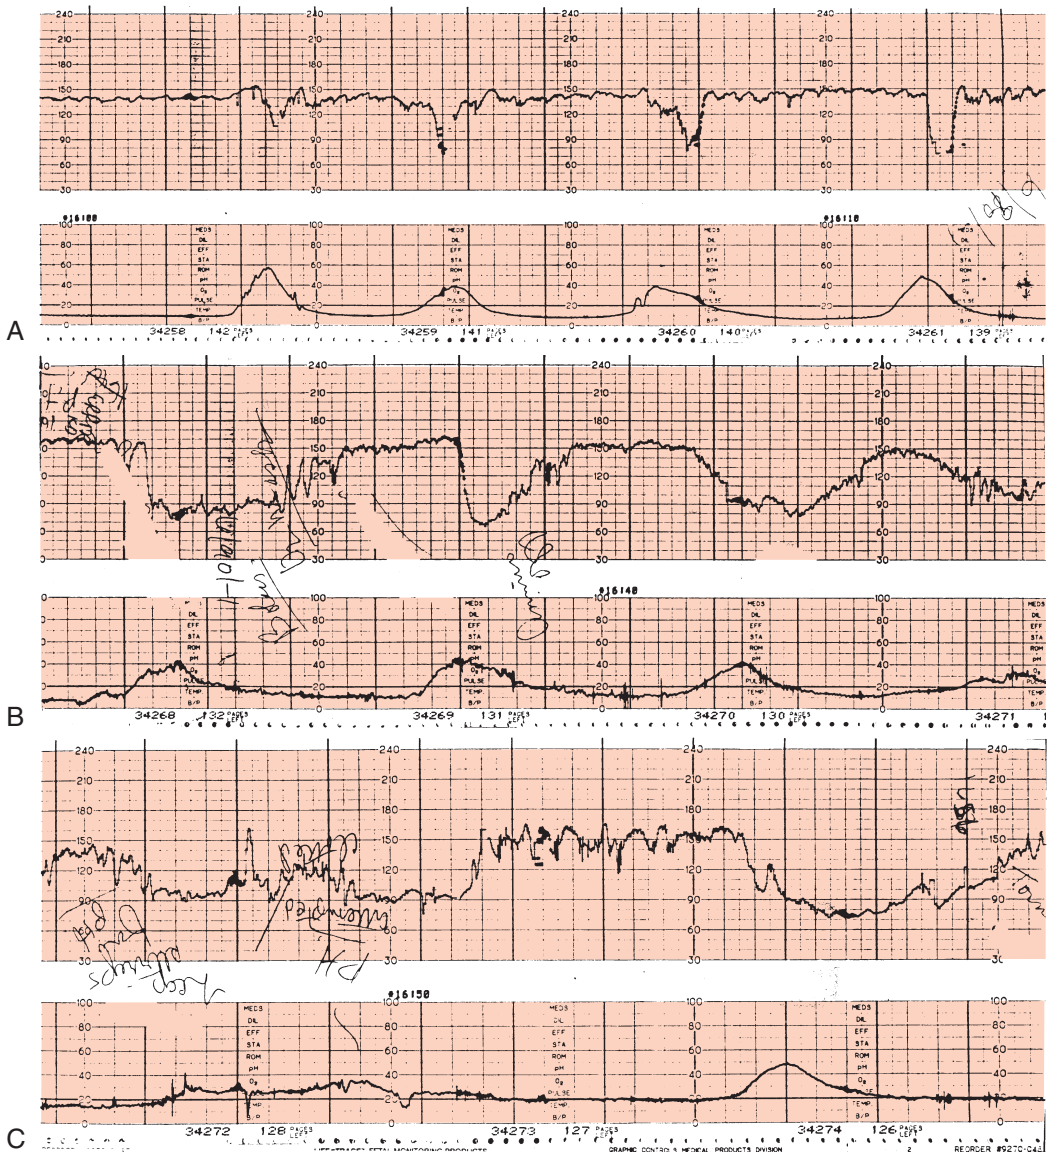

FIGURE 20-13. **A,** The patient is a 37-year-old gravida 7 para 3 Ab3 woman at 41 weeks' gestation who presented for induction of labor. She had had two prior vaginal deliveries, but her last baby was born at 33 weeks by low-transverse cesarean section for nonimmune hydrops caused by a cardiac malformation. The patient's induction was begun with prostaglandin gel. Her cervix changed from fingertip dilated, 50% effaced, to 1-cm dilated, 70% effaced with a cephalic presentation at –2 station. Oxytocin was then begun at 1 mU/minute. The patient progressed well, and epidural anesthesia was administered at 4 to 5 cm dilation, 90% effaced, and 0 station. The patient was at 6 cm dilation with a tracing demonstrating normal heart rate variability and variable decelerations. **B,** Thirty minutes after the above tracing was recorded, the fetal heart rate pattern changed to severe variable decelerations. **C,** The tracing then demonstrated prolonged decelerations at 90 beats/minute. The patient was taken to the operating room for an emergency cesarean delivery. Uterine rupture had occurred along the site of the previous uterine incision. A female fetus weighting 3200 g with Apgar scores of 7 and 8 was delivered. The umbilical arterial pH was 7.17 and the venous pH 7.22. The uterine incision had not extended and was easily closed. The baby did well.

The conduct of vaginal delivery itself is not altered by a history of prior cesarean birth. Most obstetricians do not routinely explore the uterus in order to detect asymptomatic scar dehiscences because these generally heal well. However, excessive vaginal bleeding or maternal hypotension should be promptly evaluated, including assessment for possible uterine rupture. Of 124 cases of uterine rupture accompanying 17,898 trials of labor, 14 (11%) were identified following vaginal delivery.[73]

Counseling for Vaginal Birth After Cesarean Delivery–Trial of Labor

Because uterine rupture may be a catastrophic event, ACOG continues to recommend that VBAC should only be attempted in institutions equipped to respond to emergencies, with physicians immediately available to provide emergency care. Thus, both in-house obstetrical and obstetrical anesthesia coverage are necessary to comply with this recommendation. ACOG recognizes that referral

- Increased length of stay and recovery
- Increased risks for abnormal placentation and hemorrhage with successive cesarean operations

may be required if a facility has inadequate resources to offer VBAC-TOLAC.[54]

A pregnant woman with a previous cesarean delivery is at risk for both maternal and perinatal complications whether undergoing TOLAC or choosing a planned repeat operation. Complications of both procedures should be discussed, and an attempt should be made to include an individualized risk assessment for both uterine rupture and the likelihood of successful VBAC (Table 20-15). For example, a woman who might require induction of labor may be at a slight increased risk for uterine rupture and is also less likely to achieve vaginal delivery. Future childbearing and the risks for multiple cesarean deliveries, including the risks for placenta previa and placenta accreta, should be considered as well (Table 20-16).

It is essential to make every effort possible to obtain records of the prior cesarean delivery in order to ascertain previous uterine incision type. This is particularly relevant to cases of prior preterm breech delivery in which a vertical uterine incision or a low-transverse incision in an undeveloped lower uterine segment might preclude a TOLAC. If previous uterine incision type is unknown, the implications of this missing information should be discussed as well.

Following complete informed consent detailing the risks and benefits for the individual woman, the delivery plan should be formulated by both the patient and physician. It is inappropriate to mandate VBAC-TOLAC because many women desire a planned repeat operation after thorough counseling. However, **VBAC-TOLAC should continue to remain an option for most women with a prior cesarean delivery, particularly when one considers the low absolute risks accompanying TOLAC. The attributable risk for a serious adverse perinatal outcome (perinatal death or HIE) at term appears to be about 1 in 2000 trials of labor. Combining an independent risk for hysterectomy attributable to uterine rupture at term with the risk for newborn HIE indicates the chance of one of these adverse events occurring to be about 1 in 1250 cases.**

The decision to elect a TOLAC may also increase the risk for perinatal death and HIE unrelated to uterine rupture. For women awaiting spontaneous labor beyond 39 weeks, there is a small possibility of unexplained stillbirth that might be avoidable with a scheduled repeat operation. A risk for fetal hypoxia and its sequelae may also accompany labor events unrelated to the uterine scar. In the MFMU Network Study, five cases of non-rupture-related HIE occurred in term infants in the TOLAC group compared with none in the planned repeat cesarean population.[73]

CESAREAN HYSTERECTOMY

Cesarean hysterectomy refers to the removal of the uterus at the time of a planned or unplanned cesarean delivery. The reported incidence of cesarean hysterectomy is 5 to 8 per 1000 cesarean deliveries.[95] Postpartum hysterectomy encompasses both cesarean hysterectomy and removal of the uterus following vaginal delivery. Cesarean section precedes postpartum hysterectomy in 73% of cases.[96] A systematic review of 981 emergency postpartum hysterectomies for uncontrolled hemorrhage indicated prior cesarean delivery in 449 cases. In this series, maternal death occurred in 26 (2.6%) of these postpartum hysterectomies.[96]

Substantial morbidity also accompanies peripartum hysterectomy compared with nonobstetrical hysterectomy.[97] Rates of bladder injury (9% vs. 1%), ureteral injury (0.7% vs. 0.1%), reoperation (4% vs. 0.5%), postoperative hemorrhage (5% vs. 2%), wound complications (10% vs. 3%), and VTE (1% vs. 0.7%) are all higher in women undergoing peripartum hysterectomy.[97] Wright and colleagues have demonstrated a lower incidence of perioperative morbidity with intensive care as well as mortality among women undergoing peripartum hysterectomy at high-volume hospitals compared with smaller institutions.[98] These authors concluded that, given the resources required to manage patients with placenta accreta and the improved outcomes at high-volume centers, women at high risk or those with suspected accreta should be referred to tertiary centers for delivery.

In most cases of hysterectomy following vaginal birth, the indication for the procedure is uterine atony with uncontrolled hemorrhage that has failed to respond to conservative measures (see Chapter 19). In contrast, placenta accreta has emerged as the most common indication for postcesarean hysterectomy (Table 20-17). In a series of 186 cesarean hysterectomies, 38% were performed for placenta accreta, whereas 35% had atony as the primary indication. Of the 71 placenta accreta cases, 82% accompanied a repeat cesarean delivery.[95] **There appears to be a trend of increasing cesarean hysterectomy as a result of an increased frequency of prior cesarean birth, itself a risk factor for placenta accreta. Nearly 25% of women with placenta previa and prior cesarean delivery develop placenta accreta, which in most cases requires a hysterectomy to control bleeding.**[99] With two or more prior cesarean deliveries and an existing placenta previa, the risk for cesarean hysterectomy ranges from 30% to 50%. Although placenta accreta itself poses a risk for peripartum hysterectomy, its association with prior uterine scarring, such as a cesarean delivery incision, is responsible for the about 50- to 100-fold increased risk for hysterectomy following cesarean section compared with

TABLE 20-17 INDICATIONS FOR CESAREAN HYSTERECTOMY

INDICATION	OVERALL NUMBER (*n* = 186)*	PRIMARY CESAREAN DELIVERIES*	REPEAT CESAREAN DELIVERIES (*n* = 106)

vaginal delivery. A history of prior cesarean section is now present in 57% to 67% of women undergoing a peripartum hysterectomy.[97]

Most cesarean hysterectomies are emergent procedures performed to control hemorrhage when conservative measures have failed. Occasionally, cesarean hysterectomy is planned for the treatment of cervical cancer or large myomas. The most common indications for emergency cesarean hysterectomy are placenta accreta, uterine atony, and uterine rupture. In Shellhaas and colleagues' series from the MFMU Network, these accounted for more than 75% of the procedures.[95]

Before the introduction of effective oxytocics such as prostaglandin $F_{2\alpha}$, uterine atony was the most common indication for cesarean hysterectomy. Today, improved oxytocics have reduced uterine atony as an indication. However, the rising rate of cesarean delivery has increased the frequency of abnormal placentation that has resulted in placenta accreta becoming the most common indication for cesarean hysterectomy. In two reports from Los Angeles County–University of Southern California Medical Center over an 18-year period, placenta accreta accounted for 30% of peripartum hysterectomies initially and later was associated with 45% of procedures.[99] The frequency of atony associated with peripartum hysterectomy fell from 43% to 20% from 1978 to 1990.[99]

In the previously mentioned series, uterine rupture was responsible for 11% to 13% of peripartum hysterectomies. In most cases of symptomatic rupture, the uterus can be preserved if so desired. The decision to proceed with hysterectomy ultimately depends on the ability to satisfactorily repair the uterus with hemostasis as well as the patients' wishes for future childbearing. Small dehiscences discovered at cesarean delivery or following successful VBAC are generally not indications for cesarean hysterectomy.

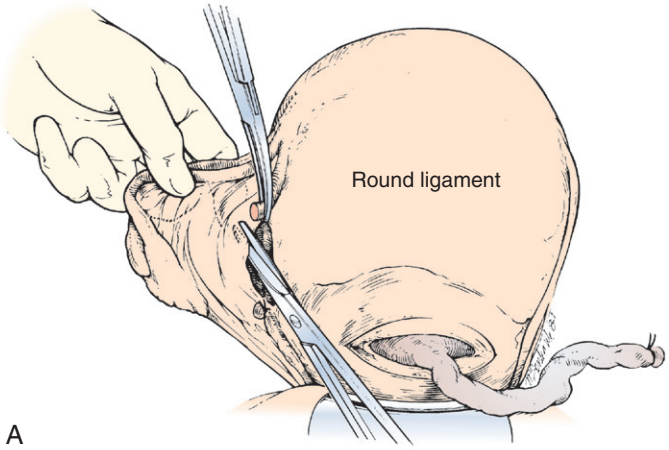
Technique and Complications

A peripartum hysterectomy, including cesarean hysterectomy, may be subtotal (supracervical) or total depending on the clinical circumstances. **In most planned procedures, a total hysterectomy is performed, whereas a subtotal hysterectomy may be preferable in cases in which emergency surgery is necessary for life-threatening hemorrhage and dissection of the cervix is difficult. Subtotal hysterectomy is a faster procedure and has been suggested in unstable patients.**

Subtotal hysterectomy is more likely to be performed in cases of atony. In one series of 30 cases of peripartum hysterectomy for atony, a subtotal procedure was accomplished in 77% of patients. Subtotal hysterectomy is less often performed in cases of placenta previa or accreta because lower uterine segment bleeding with these conditions often requires a total hysterectomy to control hemorrhage. In Shellhaas' series of 186 procedures, 66% were total hysterectomies.[95]

The operative technique for cesarean hysterectomy consists of the same general surgical considerations for the procedure performed in the nonpregnant individual. Specific considerations include adequate inferior displacement of the bladder if possible before the hysterectomy because taking the bladder down may be difficult following uterine incision and delivery of the infant. Additionally, care must be taken to avoid bladder and ureteral injury, which appears to be relatively common with peripartum hysterectomy. Cystotomy has been reported to occur in up to 5% to 9% of cases, although many of these represent intentional procedures.[98] Ureteral injury is observed in 1 in 200 operations. The ureter is particularly vulnerable to injury if broad ligament bleeding occurs and lateral clamping is necessary to control this. If ureteral injury is suspected, the dome of the bladder may be incised, and retrograde stenting of the ureter is performed. Intravenous injection of indigo carmine may also be useful in identifying a ureteral injury or detecting a suspected ligature.

The sequence of maneuvers for hysterectomy is not different from the procedure in the nonpregnant state. As mentioned previously, efforts to displace the bladder inferiorly before delivery are advised. Following delivery and removal of the placenta, the uterine incision is frequently reapproximated, or attention is given to securing hemostasis by ligating the uteroovarian anastomosis bilaterally. The bladder should be inspected and mobilized by blunt and sharp dissection. In cases of accreta or percreta with bladder involvement, creation of a bladder flap is not advised. Intentional cystotomy may be performed to determine the extent of placental involvement. In most cesarean hysterectomies, the ovaries are left, although the adnexa in the pregnant state are vulnerable to hematoma formation, which may necessitate salpingo-oophorectomy. The avascular portion of the broad ligaments is incised, and the uterine vessels are identified, clamped, and suture-ligated (Figures 20-14 and 20-15). Clamps are placed tightly along the lateral aspect of the uterus to prevent injury to the ureter and hematoma formation. At this point, the decision is often made whether to proceed with subtotal versus total hysterectomy. In most instances, a total procedure is performed unless the patient is unstable, and bleeding can be adequately controlled by the subtotal approach. If the cervix is amputated, it is closed with figure-of-eight sutures and reperitonealization may or may not be performed (Figure 20-16). If total hysterectomy is to be accomplished, after further consideration, the cervical stump is elevated with traction and is separated from the cardinal and uterosacral ligaments by clamping and



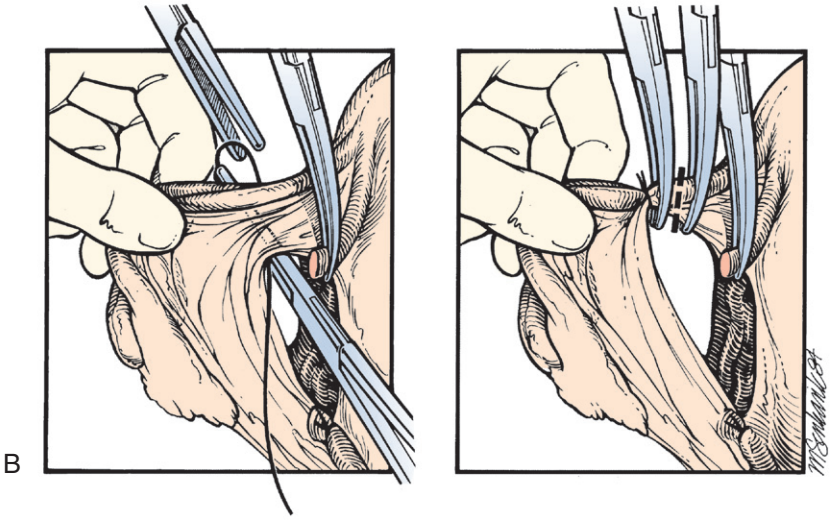


FIGURE 20-14. Cesarean hysterectomy. **A,** After extending the bladder flap, each round ligament is cut and ligated. The posterior leaf of the broad ligament can be opened for a short distance, taking care to incise only the surface layer. The avascular space beneath the utero-ovarian ligament may be opened by blunt finger dissection to isolate the adnexal pedicle. **B,** A free tie is passed through the avascular space and firmly tied. The advantage of this tie is to secure the vessels within the pedicle before it is cut *(right)*. The adnexal pedicle is doubly clamped and cut. In addition, a transfixing suture will then be placed around the pedicle.

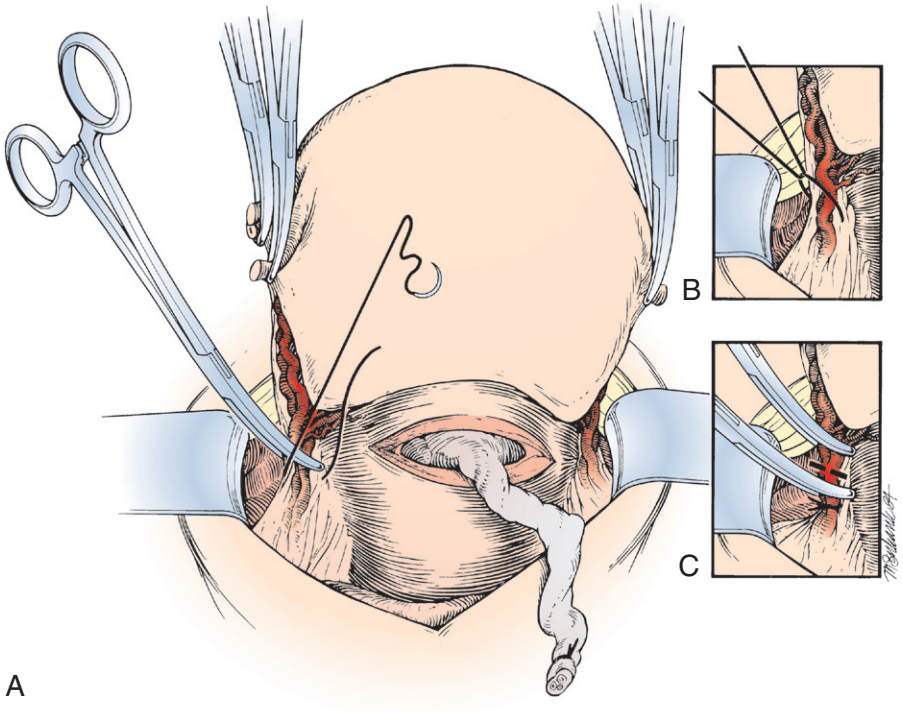

FIGURE 20-15. **A,** The ascending branches of the uterine artery are clamped and cut, and a suture is placed just below the tip of the clamp and immediately next to the uterine wall. **B,** After removing the clamp, the suture is tied, thus securing the vessels before they are cut. **C,** The pedicle is regrasped just above the tie and then doubly ligated.

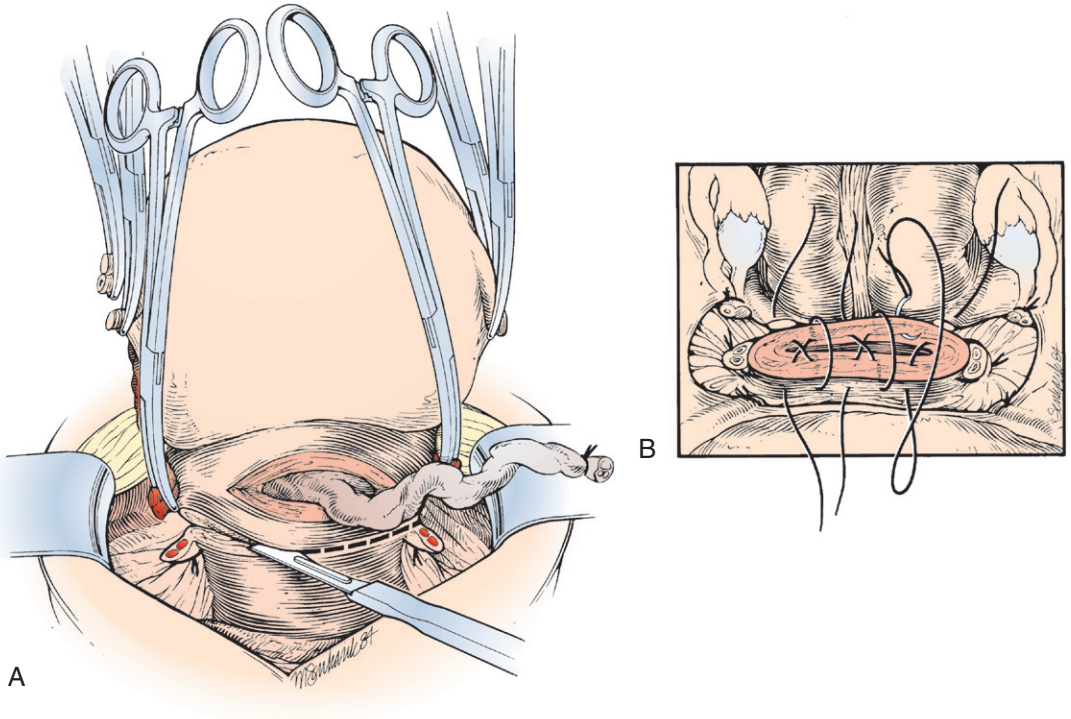

FIGURE 20-16. Subtotal hysterectomy. **A,** The cervix is incised just below the level of the ligated pedicles of the uterine arteries, amputating the uterine corpus from its cervical stump. **B,** The cervical stump may be closed with several interrupted figure-of-eight sutures; reperitonealization is then accomplished as in a total hysterectomy.

ligature (Figure 20-17). The vagina is then entered anteriorly or at the lateral angle above a curved clamp. An effort should be made to be certain the cervix is completely removed, although in cases following labor, this may be difficult. Similarly, excess portions of the superior vagina should not be excised. In order to minimize these complications, some surgeons prefer to insert a finger through an incision in the lower uterine segment to identify the cervicovaginal junction before excision of the cervix (Figure 20-18). The vaginal cuff is supported by approximation to the cardinal and uterosacral ligament pedicles (Figures 20-19 and 20-20). The cuff may be left open or closed in with interrupted or running locking continuous sutures (Figure 20-21). If significant bleeding is a concern, the cuff is better left open for dependent drainage or placement of a drain. Reperitonealization has become less favored and has been replaced by many with fixation of the ovarian pedicles to the round ligaments, to reduce the chance of adhesion to the vaginal cuff (Figure 20-22).

The principal complications of cesarean hysterectomy are urologic injury, as discussed earlier, and hemorrhage. The average blood loss varies, with an excess of 500 to 1000 mL beyond a routine cesarean delivery. The frequency of transfusion has been reported to be 75%[95] (Table 20-18). In many cases, the indication for hysterectomy is hemorrhage itself with a large preexisting blood loss before commencing the hysterectomy. Febrile morbidity is common, particularly with an unplanned cesarean hysterectomy, with infection rates of 25% to 30% observed, despite prophylactic antibiotic administration.[99] With the friability of pelvic tissues, as well as the indications for

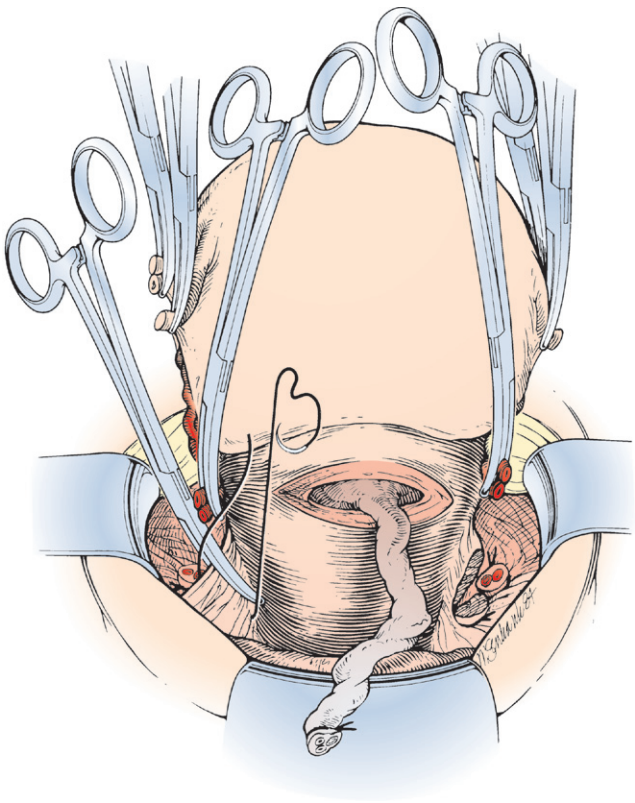

FIGURE 20-17. The cardinal ligaments are clamped at their point of insertion, cut, and singly ligated. Because these structures are hypertrophied, several bites may be necessary. Some physicians clamp, cut, and ligate the uterosacral ligaments separately.

hysterectomy often resulting in coagulopathy, postsurgical bleeding is observed with increased frequency following peripartum hysterectomy. Reexploration has been reported in 2% to 4% of cases.[95,98]

TUBAL STERILIZATION

Surgical approach to tubal sterilization is influenced by whether the procedure is being performed on a postpartum or on an interval basis. Advantages to the postpartum approach include the use of one anesthesia for labor, delivery, and sterilization and only one hospitalization. Tubal ligations after vaginal delivery are performed through a minilaparotomy incision at the level of the uterine fundus, usually subumbilically. The same surgical techniques are applied if tubal ligation is performed at the time of cesarean section.

Modified Pomeroy

The method of tubal occlusion used by Pomeroy was described in 1930, and it is the most popular means of postpartum tubal ligation because of its simplicity. The Pomeroy technique as originally described included grasping the fallopian tube at its midportion, creating a small knuckle, and then ligating the loop of tube with a double strand of catgut suture. It is critical that the fallopian tube be conclusively identified. Visualizing the fimbriated

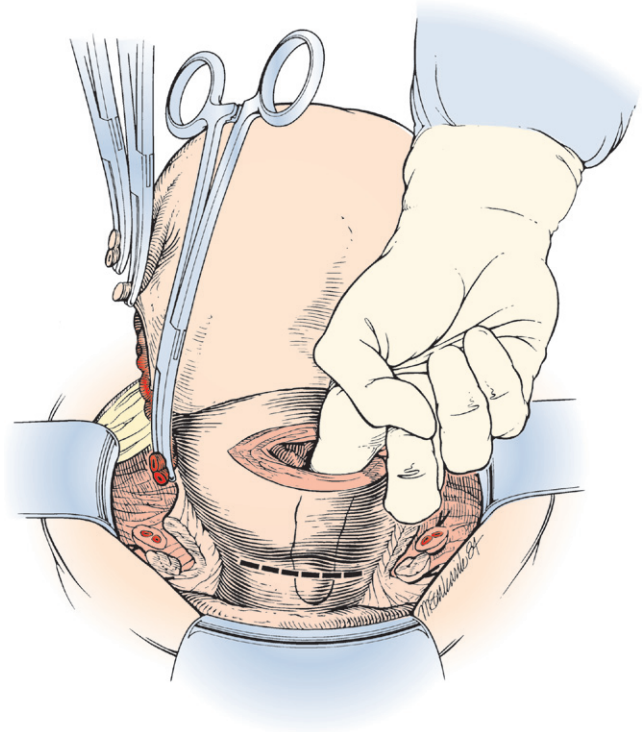

FIGURE 20-18. Because the cervix is elongated, it may be useful to insert an index finger through the cervical canal to demarcate the vaginal incision and to ensure complete removal of the cervix and avoid unnecessary removal of vaginal length.

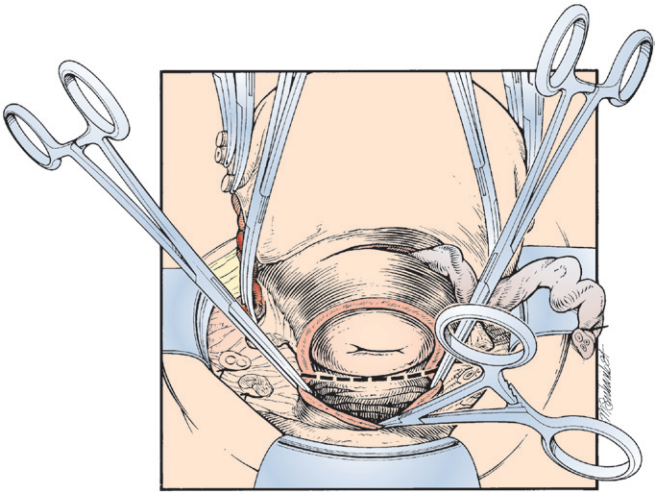

FIGURE 20-19. The vagina is circumferentially incised at its cervical attachment and grasped with four clamps.

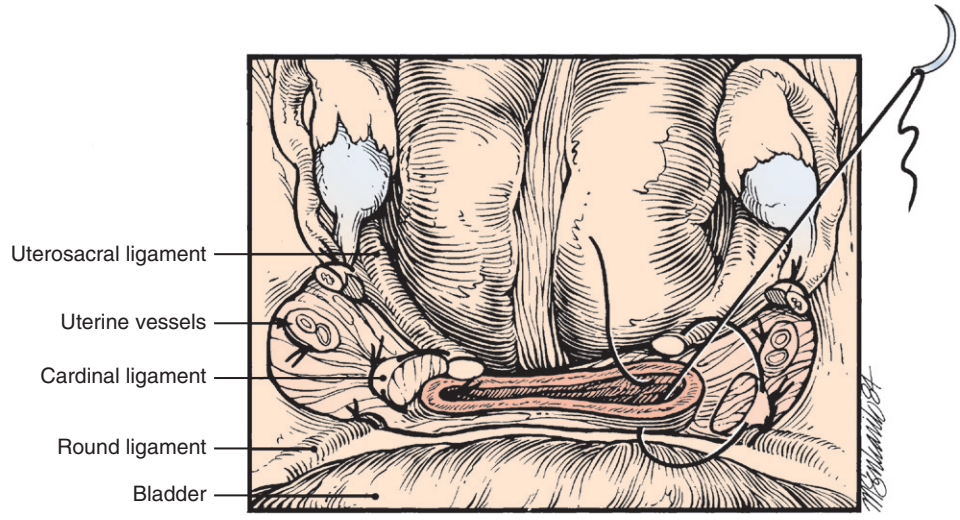

FIGURE 20-20. The angles of the vaginal cuff are closed with sutures to include the cardinal and uterosacral ligaments, thus providing fascial support to the vaginal vault. A simple loop suture is commonly used at this location to reduce the likelihood of breakage during the state of postoperative edema.

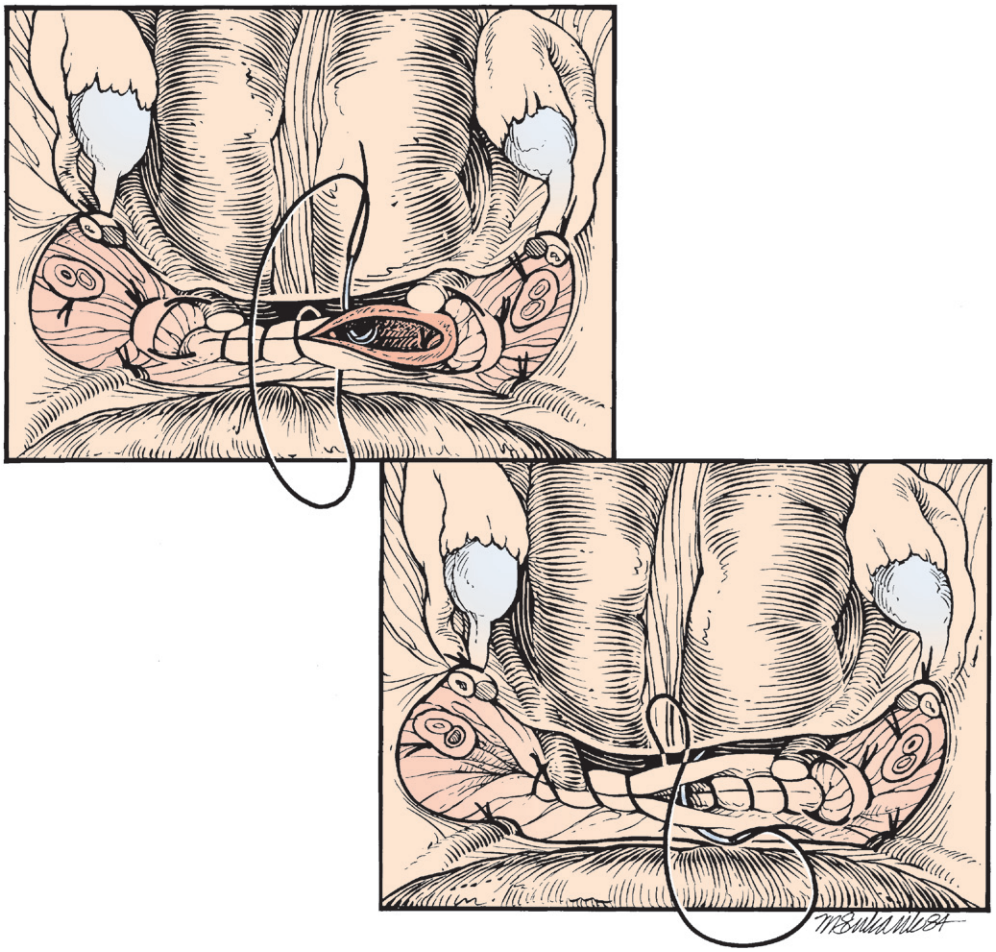

FIGURE 20-21. There are a number of methods of closing the vaginal cuff. Illustrated is a two-layer closure. The first layer closes the vagina, and the second layer closes the endopelvic fascia. Many operators prefer to leave the cuff "open" by using one continuous suture that circles the cuff, approximating the cut edge to its surrounding fascia.

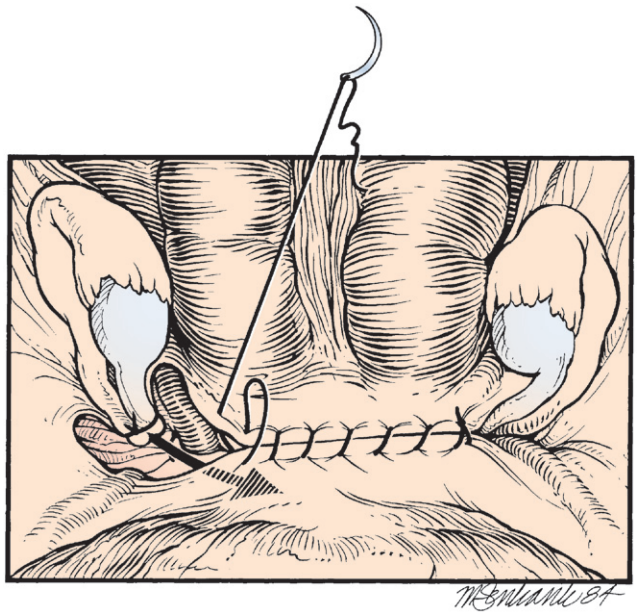

FIGURE 20-22. The bladder flap is closed with a continuous suture that inverts the pedicles of the round ligaments and adnexa. Note that these structures have not been attached to the vaginal cuff.

portion of the tube and identifying the round ligament as a separate structure can accomplish this. Absorbable sutures are used so that the tubal ends will separate quickly after surgery, leaving a gap between the proximal and distal ends. In performing the procedure, care should be taken to make the loop of fallopian tube sufficient in size to ensure that complete transection of the tubal lumen will occur. After the loop of fallopian tube is ligated, the mesosalpinx of the ligated loop should be perforated using scissors, and the knuckle of the tube is transected (Figure 20-23). It is important not to resect the fallopian tube so close to the suture that the remaining portion of the fallopian tube slips out of the ligature and causes delayed bleeding.

The Parkland Procedure

The Parkland procedure was designed to avoid close approximation of the cut ends of the fallopian tube accompanying the Pomeroy procedure. An avascular segment of midposition mesosalpinx is identified. A hemostat or coagulation can be used to create an opening. The freed fallopian tube is then ligated proximally and distally with the intervening segment being excised and submitted for pathologic examination. The proximal ligated end of the tube may be left free or can be buried in the mesosalpinx (Figure 20-24).

The Irving Procedure

Irving first reported his sterilization technique in 1924, with a modification in 1950. In the modified procedure, a window is created in the mesosalpinx and the fallopian tube is doubly ligated as in the Parkland procedure. The fallopian tube is then transected about 4 cm from the uterotubal portion; the two free ends of the ligation stitch on the proximal tubal segment are held long. The proximal portion of the fallopian tube is dissected free from the

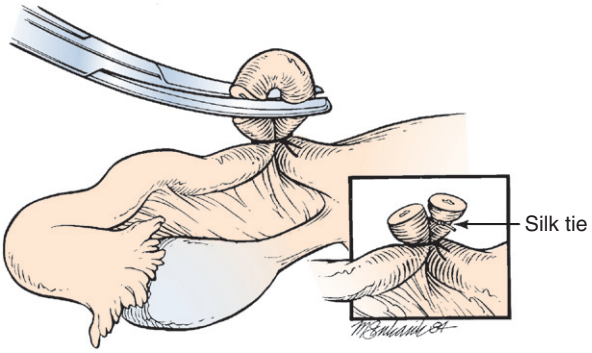

FIGURE 20-23. Pomeroy sterilization. A knuckle of tube is ligated with absorbable suture, and a small segment is being excised. Note that the ligation is performed at a site that will favor reanastomosis, should that become desirable. Some surgeons place an extra tie of nonabsorbable suture around the proximal stump as added protection against recanalization.

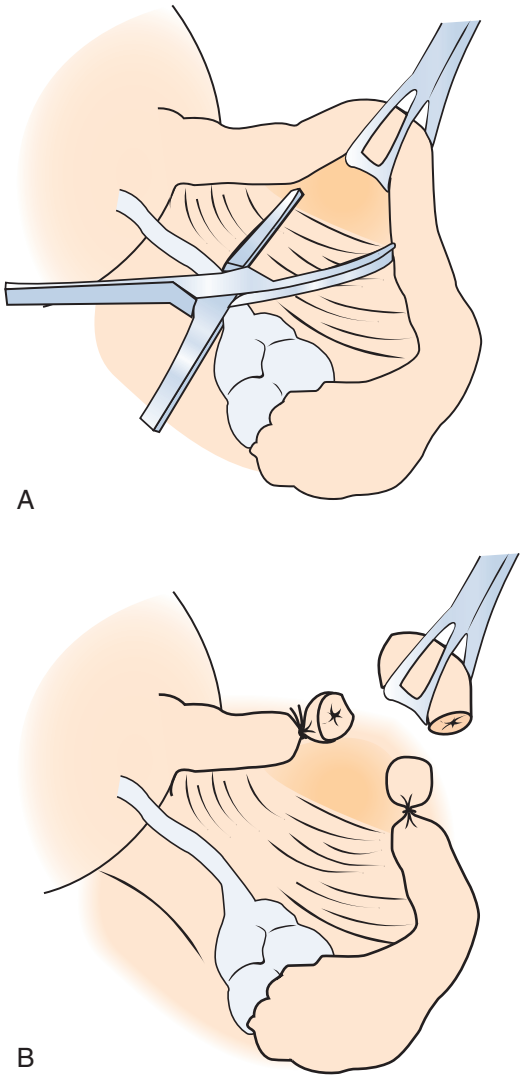

FIGURE 20-24. Parkland tubal ligation. The avascular mesosalpinx is opened by blunt dissection. A 2-cm midsegment of tube is ligated with 0-0 chromic suture and divided between the sutures. (Modified from Cunningham FG, Leveno KJ, Bloom SL, et al [eds]: Williams Obstetrics, 22nd ed. New York, McGraw-Hill, 2005.)

mesosalpinx and then buried into an incision in the myometrium of the posterior uterine wall, near the uterotubal junction. This is accomplished by first creating a tunnel about 2 cm in length with a mosquito clamp in the uterine wall. The two free ends of the ligation stitch on the proximal tubal segment are then brought deep into the myometrial tunnel and are brought out through the uterine serosa. Traction is then placed on the sutures to draw the proximal tubal stump into the myometrial tunnel; tying the free sutures fixes the tube in that location. No treatment of the distal tubal stump is necessary, but some choose to bury the segment in the mesosalpinx (Figure 20-25). Although this technique is slightly more complicated than the others, it has the lowest failure rate.

The Uchida Procedure

In this sterilization procedure, the muscular portion of the fallopian tube is separated from its serosal cover and grasped about 6 to 7 cm from the uterotubal junction. Saline solution is injected subserosally, and the serosa is then incised. The muscular portion of the fallopian tube is grasped with a clamp and divided. The serosa over the proximal tubal segment is bluntly dissected toward the uterus, exposing about 5 cm of the proximal tubal segment. The tube is then ligated with chromic suture near the uterotubal junction, and about 5 cm of the tube is resected. The shortened proximal tubal stump is allowed to retract into the mesosalpinx. The serosa around the opening in the mesosalpinx is sutured in a pursestring with a fine absorbable stitch; when the suture is tied, the mesosalpinx is gathered around the distal tubal segment (Figure 20-26). Some surgeons choose to excise only 1 cm of fallopian tube rather than the recommended 5 cm in case the patient wishes to have a tubal reanastomosis in the future.

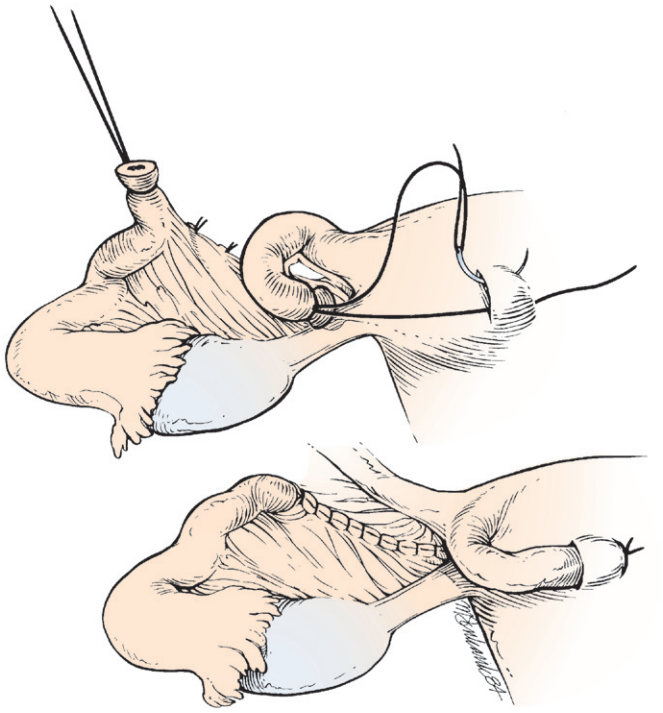

FIGURE 20-25. Irving sterilization. The tube is transected 3 to 4 cm from its insertion, and a short tunnel is created by means of a sharp-nosed hemostat in either the anterior or posterior uterine wall. The cut end of the tube can then be buried in the tunnel and, if necessary, further secured by an interrupted suture at the opening of the tunnel. The distal cut end is buried between the leaves of the broad ligament.

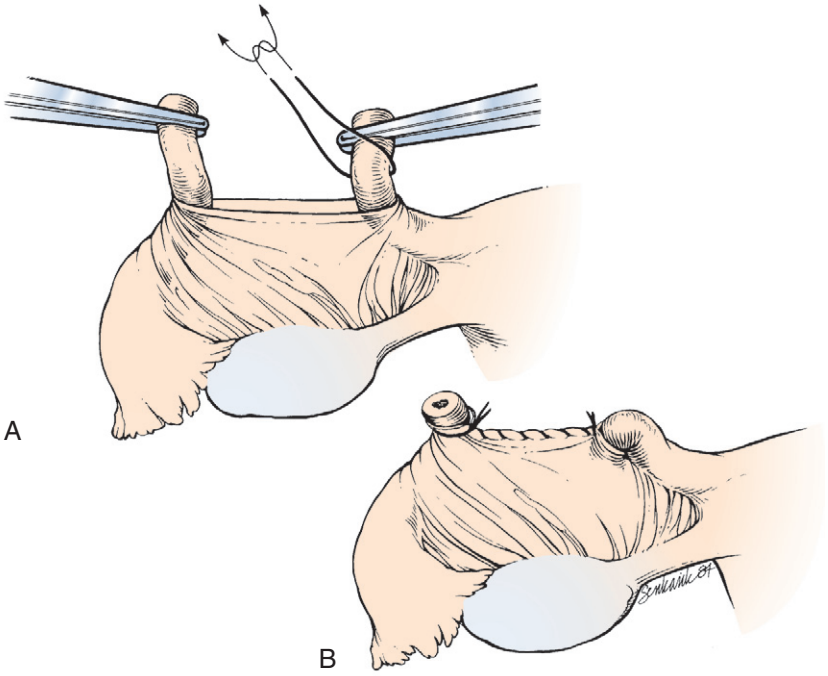

FIGURE 20-26. Uchida sterilization. The leaves of the broad ligament and peritubal peritoneum are infiltrated with saline so that the tube can be easily isolated from these structures, divided **(A)**, and ligated **(B)**. The broad ligament is then closed, burying the proximal stump between the leaves and including the distal stump in the line of closure.

KEY POINTS

- In 1970, the cesarean delivery rate was about 5%. By 2008, it had reached 32.8%, the highest rate ever recorded in the United States. VBAC rates have plummeted from a peak of 28.3% in 1996 to 8.5% in 2008.
- Factors that have contributed to the rise in cesarean deliveries during the past decade include (1) continued increase in primary cesarean deliveries for dystocia, failed induction, and abnormal presentation; (2) an increase in the proportion of women with obesity, diabetes mellitus, and multiple gestation; (3) increased use of planned cesarean delivery to preserve pelvic floor function; and (4) limited use of TOLAC after cesarean delivery because of both safety and medicolegal concerns.
- Mechanical prophylaxis with graduated compression stockings or a pneumatic compression device during and after cesarean delivery should be considered.
- Single-dose, preoperative prophylactic antibiotics are of clear benefit in reducing the frequency of postcesarean endomyometritis and wound infection.
- A low-transverse uterine incision is performed in more than 90% of cesarean deliveries. A vertical uterine incision may rarely be performed for cesarean delivery if the lower uterine segment is poorly developed or if the fetus is in a back-down transverse lie.
- Sharp uterine extension appears to be associated with increased blood loss as well as the potential risk for cutting the umbilical cord or direct fetal injury.
- Several randomized trials have demonstrated greater blood loss and a higher rate of endometritis with manual extraction of the placenta at cesarean delivery. Thus, spontaneous expulsion of the placenta with gentle cord traction is preferred.
- When closing the abdomen after a cesarean delivery, the subcutaneous tissue is closed if its thickness exceeds 2 cm. This approach reduces the risk for wound disruption by 34% in women with excessive subcutaneous fat.
- The risk for uterine rupture in a TOLAC depends greatly on the previous uterine incision, ranging from 0.5% to 1.0% with a prior low-transverse cesarean delivery to 4% to 9% with a prior classic or T-incision.
- Misoprostol should not be used in women attempting VBAC. Oxytocin use may marginally increase the risk for uterine rupture in women undergoing a TOLAC. Therefore, judicious stimulation of labor should be used in these patients.
- A non-reassuring FHR pattern, particularly significant variable decelerations or bradycardia, is the most common finding accompanying uterine rupture.

KEY ABBREVIATIONS

Appropriate for Gestational Age	AGA
Central Nervous System	CNS
Chronic Lung Disease	CLD
Computed Tomography	CT
Cyclic Adenosine Monophosphate	cAMP
Dipalmitoylphosphatidylcholine	DPPC
Docohexanoic Acid	DHA
Functional Residual Capacity	FRC
Glucose-6-Phosphate Dehydrogenase	G6PD
Group B Streptococcus	GBS
Hyaline Membrane Disease	HMD
Human Immunodeficiency Virus	HIV
Idiopathic Thrombocytopenic Purpura	ITP
Inferior Vena Cava	IVC
Insulin-like Growth Factor-1	IGF-1
Intrauterine Growth Restriction	IUGR
Large for Gestational Age	LGA
Magnetic Resonance Imaging	MRI
Meconium Aspiration Syndrome	MAS
Necrotizing Enterocolitis	NEC
Periventricular/Intraventricular Hemorrhage	PVH/IVH
Periventricular Leukomalacia	PVL
Persistent Pulmonary Hypertension of the Newborn	PPHN
Pulmonary Vascular Resistance	PVR
Rapid Eye Movement Sleep	REM
Respiratory Distress Syndrome	RDS
Small for Gestational Age	SGA
Surfactant Protein	SP
Thyroid-releasing Hormone	TRH
Thyroid-stimulating Hormone	TSH
Uridine Diphosphoglucuronosyl Transferase	UDPGT
Vascular Endothelial Growth Factor	VEGF

The first 4 weeks of an infant's life, the neonatal period, are marked by the highest mortality rate in all of childhood. The greatest risk occurs during the first several days after birth. Critical to survival during this period is the infant's ability to adapt successfully to extrauterine life. During the early hours after birth, the newborn must assume responsibility for thermoregulation, metabolic homeostasis, and respiratory gas exchange, as well as undergo the conversion from fetal to postnatal circulatory pathways. This chapter reviews the physiology of a successful transition as well as the implications of circumstances that disrupt this process. Implicit in these considerations is the understanding that the newborn

reflects the sum total of its genetic and environmental past as well as any minor or major insults to which it was subjected during gestation and parturition. The period of neonatal adaptation is then most meaningfully viewed as continuous with fetal life.

CARDIOPULMONARY TRANSITION

Pulmonary Development

Lung development and maturation require a carefully regulated interaction of anatomic, physiologic, and biochemical processes. The outcome of these events provides an organ with adequate surface area, sufficient vascularization, and the metabolic capability to sustain oxygenation and ventilation during the neonatal period. Five stages of morphologic lung development have been identified in the human fetus[1]:

1. Embryonic period: 3 to 7 weeks postconception
2. Pseudoglandular period: 5th to 17th weeks
3. Canalicular period: 16th to 26th weeks
4. Saccular period: 24th to 38th weeks
5. Alveolar period: 36 weeks to 2 years after birth

The lung arises as a ventral diverticulum from the foregut during the fourth week of gestation. During the ensuing weeks, branching of the diverticulum occurs, leading to a tree of narrow tubes with thick epithelial walls composed of columnar-type cells. Molecular mechanisms involved in lung development include expression of transcription factors that are important for specification of the foregut endoderm, endogenous secretion of polypeptides that are important for pattern formation, growth and differentiation factors critical to cell development, and involvement of external signals such as retinoic acid. By 16 weeks, the conducting portion of the tracheobronchial tree up to and including terminal bronchioles has been established. The vasculature derived from the pulmonary circulation develops concurrently with the conducting airways, and by 16 weeks, preacinar blood vessels are formed. The canalicular stage is characterized by differentiation of the airways, with widening of the airways and thinning of epithelium. In addition, primitive respiratory bronchioles begin to form, marking the start of the gas-exchanging portion of the lung. Vascular proliferation continues, along with a relative decrease in mesenchyme, bringing the vessels closer to the airway epithelium. The saccular stage is marked by the development of the gas-exchanging portion of the tracheobronchial tree (acinus) composed of respiratory bronchioles, alveolar ducts, terminal saccules, and finally, alveoli. During this stage, the pulmonary vessels continue to proliferate with the airways and surround the developing air sacs. The final phase of prenatal lung development (alveolar) is marked by the formation of thin secondary alveolar septae and the remodeling of the capillary bed.

Throughout these periods mesenchymal and epithelial cell cross-talk directs the normal processes of lung alveolarization and vascularization.[2] Several million alveoli will form before birth, which emphasizes the importance of the last few weeks of pregnancy to pulmonary adaptation. Postnatal lung growth is characterized by generation of alveoli. At birth, there are approximately 50 million airspaces, and by 8 years of age, there are 300 million.[1]

The critical determinants of extrauterine survival are the formation of the thin air-blood barrier and production of surfactant. By the time of birth, the epithelial lining of the gas-exchanging surface is thin and continuous with two alveolar cell types (types I and II). Type I cells are thin and contain few subcellular organelles, whereas type II cells contain subcellular organelles that aid in the production of surfactant (Figure 21-1). Surfactant lipids and surfactant protein B and C are secreted by exocytosis as lamellar bodies and unravel into tubular myelin. The other surfactant proteins (A and D) are secreted independently of the lamellar bodies. Tubular myelin is a loose lattice of phospholipids and surfactant-specific proteins. The surface active component of surfactant then adsorbs at the alveolar interface between air and water in a monolayer. With repetitive expansion and compression of the surface monolayer, material is extruded that is either cleared by alveolar macrophages through endocytic pathways or taken up by the type II cell for recycling back into lamellar bodies.[3]

Because of the development of high surface forces along the respiratory epithelium when breathing begins, the availability of surfactants in terminal airspaces is critical to postnatal lung function. Just as surface tension acts to reduce the size of a bubble in water, so, too, it acts to reduce lung inflation, promoting atelectasis. This is described by the LaPlace relationship, which states that the pressure, P, within a sphere is directly proportional to surface tension, T, and inversely proportional to the radius of curvature, r (Figure 21-2). Surfactant has the physical property of variable surface tension dependent on the degree of surface area compression. In other words, as the radius of the alveolus decreases, surfactant serves to reduce surface tension, preventing collapse of the alveolus. If this property is extrapolated to the lung, smaller alveoli will remain stable because of lower surface tension than larger alveoli. This feature is emphasized in Figure 21-3, which compares pressure-volume curves from surfactant-deficient and surfactant-treated preterm rabbits. Surfactant deficiency is characterized by high opening pressure, low maximal lung volume, and lack of deflation stability at low pressures.

Natural surfactant contains mostly lipids, phospholipids specifically, and some protein (Figure 21-4).[3] Approximately half of the protein is specific for surfactant. The principal classes of phospholipids are:

- Saturated phosphatidylcholine compounds (the surface tension-reducing component of surfactant), 45% (more than 80% of which is dipalmitoylphosphatidylcholine [DPPC])
- Unsaturated phosphatidylcholine compounds, 25%
- Phosphatidylglycerol, phosphatidylinositol, and phosphatidylethanolamine, 10%.

Saturated phosphatidylcholine is found in lung tissue of the human fetus earlier in gestation than in other species. Surfactant is released from storage pools into fetal lung fluid at a basal rate during late gestation and is stimulated by labor and the initiation of air breathing. Four unique surfactant-associated proteins have been identified. All are synthesized and secreted by type II alveolar cells. Surfactant protein (SP)-A functions cooperatively with the other surfactant proteins and lipids to enhance the biophysical activity of surfactant, but its most

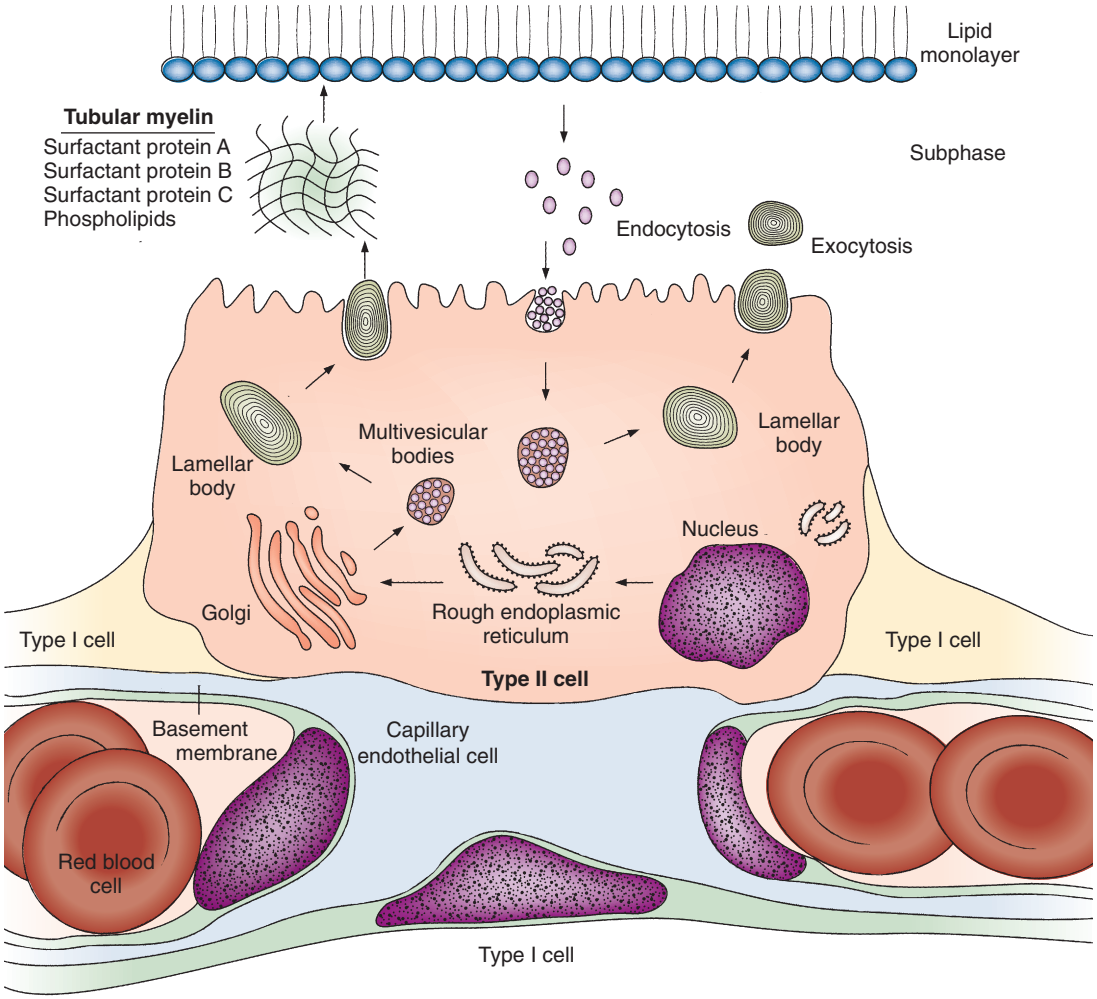

FIGURE 21-1. Metabolism of surfactant. Surfactant phospholipids are synthesized in the endoplasmic reticulum, transported through the Golgi apparatus to multivesicular bodies, and finally packaged in lamellar bodies. After lamellar body exocytosis, phospholipids are organized into tubular myelin before aligning in a monolayer at the air-fluid interface in the alveolus. Surfactant phospholipids and proteins are taken up by type II cells and either catabolized or reused. Surfactant proteins are synthesized in polyribosomes, modified in endoplasmic reticulum, Golgi apparatus, and multivesicular bodies. (Modified from Whitsett JA, Pryhuber GS, Rice WR, et al: Acute respiratory disorders. *In* Avery GB, Fletcher MA, MacDonald MG [eds]: Neonatology: Pathophysiology and Management of the Newborn, 5th ed. Philadelphia, Lippincott Williams & Wilkins, 1999, p 485.)

important role is in innate host defense of the lung. SP-B and SP-C are lipophilic proteins that facilitate the adsorption and spreading of lipid to form the surfactant monolayer. SP-B deficiencies are associated with neonatal pulmonary complications and death, whereas SP-C deficiencies are associated with interstitial lung disease presenting at a more variable age. SP-D plays a role in the regulation of surfactant lipid homeostasis, inflammatory responses, and host defense mechanisms.[3]

Several hormones and growth factors contribute to the regulation of pulmonary phospholipid metabolism and lung maturation: glucocorticoids, thyroid hormone, thyrotropin-releasing hormone, retinoic acid, epidermal growth factor, and others. **Glucocorticoids are the most important and are used clinically to augment the synthesis of surfactant and accelerate morphologic development.**[4] Pregnant women with anticipated preterm delivery have received corticosteroid treatment since 1972. Numerous controlled trials have since been performed. Based on a meta-analysis, a significant reduction of about 50% in the incidence of respiratory distress syndrome (RDS) is seen in infants born to mothers who received antenatal corticosteroids.[5] In secondary analysis, a 70% reduction in RDS was seen among babies born between 24 hours and 7 days after corticosteroid administration. In addition, evidence suggests a reduction in mortality and RDS even with treatment started less than 24 hours before delivery. Although most babies in the trials were between 30 and 34 weeks' gestation, clear reduction in RDS was evident when the population of babies less than 31 weeks was examined, and given the impact on neonatal morbidity and mortality, prenatal steroid use can be recommended in pregnancies as early as 23 weeks' gestation.[6] Gender and race do not influence the protective effect of corticosteroids. In the

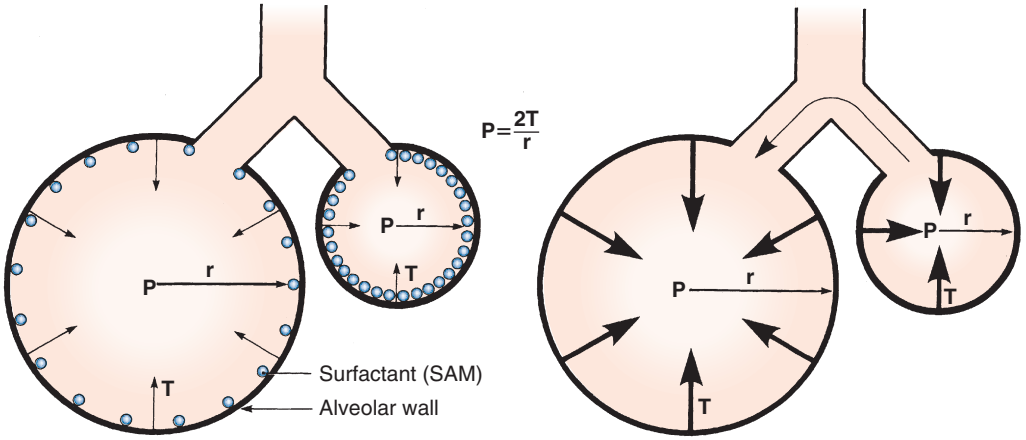

FIGURE 21-2. LaPlace's law. The pressure, *P,* within a sphere is directly proportional to surface tension, *T,* and inversely proportional to the radius of curvature, *r.* In the normal lung, as alveolar size decreases, surface tension is reduced because of the presence of surfactant. This serves to decrease the collapsing pressure that needs to be opposed and maintains equal pressures in the small and large interconnected alveoli. (Modified from Netter FH: The Ciba Collection of Medical Illustrations. The Respiratory System, Vol 7. Summit, NJ, Ciba-Geigy, 1979.)

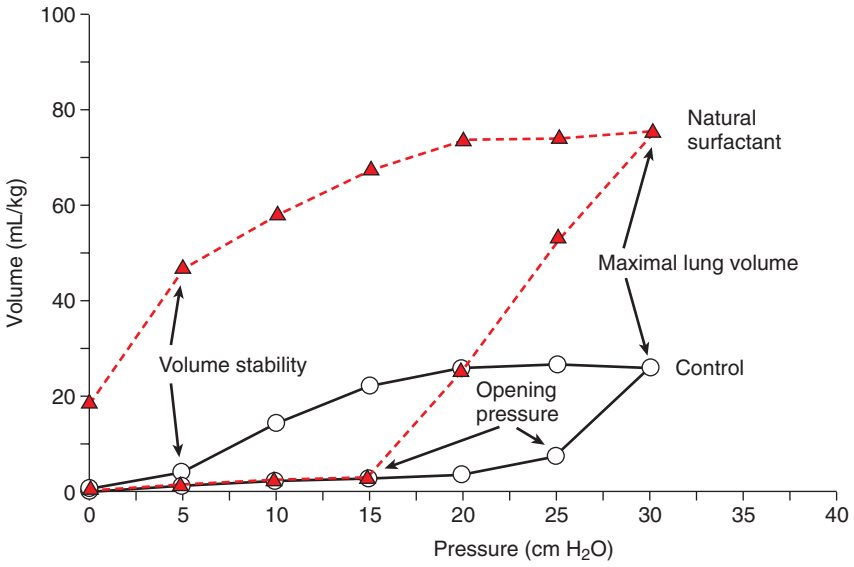

FIGURE 21-3. Pressure-volume relationships for the inflation and deflation of surfactant-deficient and surfactant-treated preterm rabbit lungs. Surfactant deficiency is indicated by high opening pressure, low maximal volume at a distending pressure of 30 cm of water, and the lack of deflation stability at low pressures on deflation. (Modified from Jobe AH: Lung development and maturation. *In* Fanaroff AA, Martin RJ [eds]: Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant, 7th ed. St. Louis, Mosby, 2002, p 973.)

population of patients with preterm premature rupture of the membranes, antenatal corticosteroids also reduce the frequency of RDS.

Corticosteroids also accelerate maturation of other organs in the developing fetus, including cardiovascular, gastrointestinal, and central nervous system (CNS). Corticosteroid therapy reduces the chances of both periventricular-intraventricular hemorrhage (PVH/IVH) and necrotizing enterocolitis (NEC).[5] The significant reductions in serious neonatal morbidity are also reflected in a reduction in the risk of early neonatal mortality. The short-term beneficial effects of antenatal corticosteroids are enhanced by reassuring reports about long-term outcome. The children of mothers treated with antenatal corticosteroids show no lag in intellectual or motor development, no increase in learning disabilities or behavioral disturbances, and no effect on growth compared with untreated infants.[7,8]

Since the advent of antenatal steroids for the prevention of RDS, other therapies have been introduced that decrease mortality and morbidity. Surfactant replacement therapy to treat specifically the surfactant deficiency that is the cause of RDS has been shown to decrease mortality and the severity of RDS.[9] The effects of antenatal corticosteroids and postnatal surfactant appear to be additive in terms of decreasing the severity of and mortality caused by RDS.[10]

The First Breaths

A critical step in the transition from intrauterine to extrauterine life is the conversion of the lung from a fluid-filled organ to one capable of gas exchange. This requires

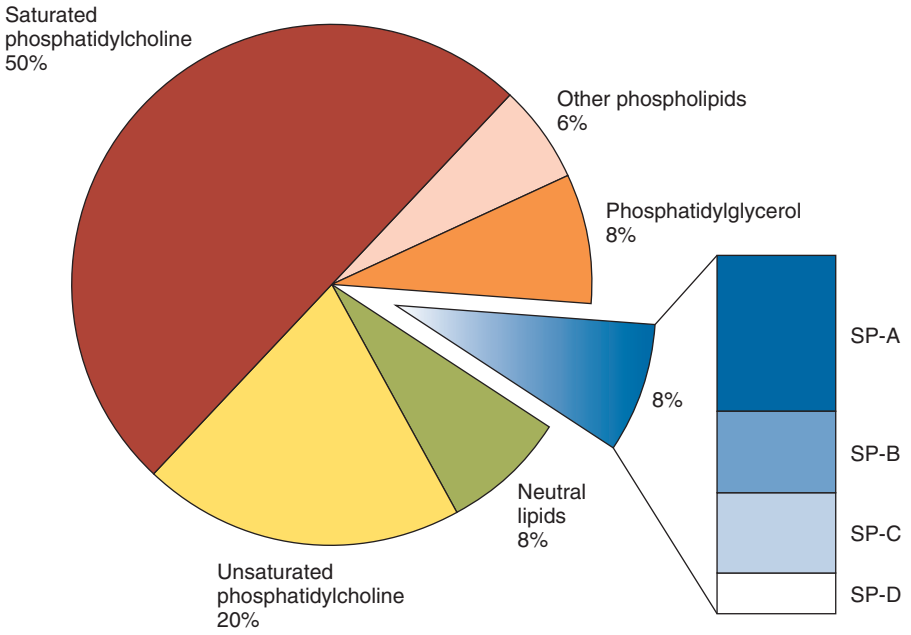

FIGURE 21-4. Composition of pulmonary surfactant. *SP,* Surfactant protein. (Modified from Jobe AH: Lung development and maturation. *In* Fanaroff AA, Martin RJ [eds]: Neonatal-Perinatal Medicine: Diseases of the Fetus and Infant, 7th ed. St Louis, Mosby, 2002, p 973.)

aeration of the lungs, establishment of an adequate pulmonary circulation, ventilation of the aerated parenchyma, and diffusion of oxygen and carbon dioxide through the alveolar-capillary membranes. This process has its origins in utero as fetal breathing.

Fetal Breathing

Fetal respiratory activity is initially detectable at 11 weeks. The most prevalent pattern is rapid, small-amplitude movements (60 to 90 per minute) present 60% to 80% of the time. Less commonly, irregular low-amplitude movements interspersed with slower larger amplitude movements are seen.[11] Initially, fetal breathing was thought to depend on behavioral influences. However, subsequent work has shown responses to chemical stimuli and other agents. Acute hypercapnea stimulates breathing. Hypoxia abolishes fetal breathing, whereas an increase in oxygen tension to levels above 200 mm Hg induces continuous fetal breathing. Although peripheral and central chemoreflexes as well as vagal afferent reflexes can be demonstrated in the fetus, their role in spontaneous fetal breathing appears minimal. The role of fetal breathing in the continuum from fetal to neonatal life is still not completely understood. Fetal respiratory activity is probably essential to the development of chest wall muscles (including diaphragm) and serves as a regulator of lung fluid volume and thus lung growth.

The mechanism responsible for the transition from intermittent fetal to continuous neonatal breathing is unknown. Prostaglandins may be involved as well as other factors surrounding birth, including blood gas changes and various sensory stimuli. Another possibility is the "release" from a placental inhibitory factor that is removed after cord occlusion.

Mechanics of the First Breath

With its first breaths, the neonate must overcome several forces resisting lung expansion: (1) viscosity of fetal lung fluid, (2) resistance provided by lung tissue itself, and (3) the forces of surface tension at the air-liquid interface.[12-14] Viscosity of fetal lung fluid is a major factor as the neonate attempts to displace fluid present in the large airways. As the passage of air moves toward small airways and alveoli, surface tension becomes more important. Resistance to expansion by the lung tissue itself is less significant. The process begins as the infant passes through the birth canal. The intrathoracic pressure caused by vaginal squeeze is up to 200 cm H_2O. With delivery of the head, approximately 5 to 28 mL of tracheal fluid is expressed. Subsequent delivery of the thorax causes an elastic recoil of the chest. With this recoil, a small passive inspiration (no more than 2 mL) occurs. This is accompanied by glossopharyngeal forcing of some air into the proximal airways (frog breathing) and the introduction of some blood into pulmonary capillaries. This pulmonary vascular pressure may have a role in producing initial continuous surfaces throughout the small airways of the lung into which surfactant can deploy.

The initial breath is characteristically a short inspiration, followed by a more prolonged expiration (Figure 21-5).[13] The initial breath begins with no air volume and no transpulmonary pressure gradient. Considerable negative intrathoracic pressure during inspiration is provided by diaphragmatic contraction and chest wall expansion. An opening pressure of about 25 cm H_2O usually is necessary to overcome surface tension in the smaller airways and alveoli before air begins to enter. The volume of this first breath varies between 30 and 67 mL and correlates with intrathoracic pressure. The expiratory phase is prolonged, because the infant's expiration is opposed by intermittent closure at the pharyngolaryngeal level with the generation of large positive intrathoracic pressure. This pressure serves to aid both in maintenance of a functional residual capacity (FRC) and with fluid removal from the air sacs. The residual volume after this first breath ranges between 4 and 30 mL, averaging 16 to 20 mL. There are really no

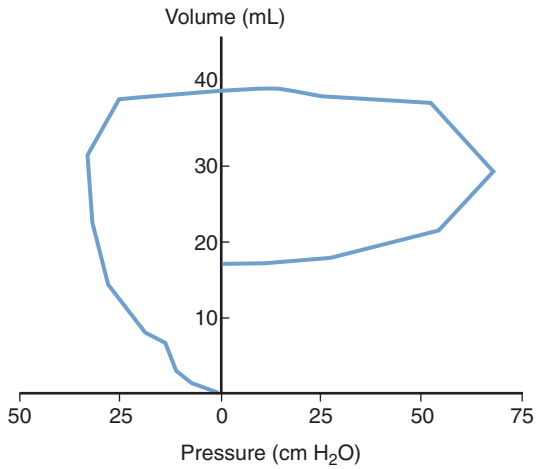

FIGURE 21-5. Pressure-volume loop of the first breath. Air enters the lung as soon as intrathoracic pressure falls and expiratory pressure greatly exceeds inspiratory pressure. (Modified from Milner AD, Vyas H: Lung expansion at birth. J Pediatr 101:879, 1982.)

TABLE 21-1 PRESSURES IN THE PERINATAL CIRCULATION

	FETAL (mm Hg)	NEONATAL (mm Hg)
Right atrium	4	5
Right ventricle	65/10	40/5
Pulmonary artery	65/40	40/25
Left atrium	3	7
Left ventricle	60/7	70/10
Aorta	60/40	70/45

Modified from Nelson NM: Respiration and circulation after birth, *In* Smith CA, Nelson NM (eds): The Physiology of the Newborn Infant, 4th ed. Springfield, IL, Charles C Thomas, 1976, p 117.

major systematic differences among the first three breaths, demonstrating similar pressure patterns of decreasing magnitude. The FRC rapidly increases with the first several breaths and then more gradually. By 30 minutes of age, most infants attain a normal FRC with uniform lung expansion. The presence of functional surfactant is instrumental in the accumulation of an FRC.

In utero, alveoli are open and stable at nearly neonatal lung volume because they are filled with fetal lung liquid, probably produced by ultrafiltration of pulmonary capillary blood as well as by secretion by alveolar cells. Transepithelial chloride secretion appears to be a major factor responsible for the production of luminal liquid in the fetal lung. **Normal expansion and aeration of the neonatal lung is dependent on removal of fetal lung liquid. Liquid is removed by a combination of mechanical drainage and absorption across the lung epithelium.[15] This process begins before a normal term birth because of decreased fluid secretion and increased absorption. Once labor is initiated, there is a reversal of liquid flow across the lung epithelium.** Active transcellular sodium absorption drives liquid from the lumen to interstitial space, where it is drained through the pulmonary circulation and lymphatics.[16] In normal circumstances, the process is complete within 2 hours of birth. Cesarean-delivered infants without benefit of labor and premature infants have delayed lung fluid clearance. In both groups, the prenatal decrease in lung water does not occur. In addition, in the premature neonate, fluid clearance is diminished by increased alveolar surface tension, increased left atrial pressure, and hypoproteinemia.

Circulatory Transition

The circulation in the fetus (Figure 21-6) has been studied in a variety of species using several techniques (see Chapter 2).[17,18] Umbilical venous blood, returning from the placenta, has a P_{O_2} of about 30 to 35 mm Hg. Because of the left-shifted fetal hemoglobin oxyhemoglobin disassociation curve, this corresponds to a saturation of 80% to 90%. About 60% of this blood perfuses the liver (mainly to the middle and left lobes) and ultimately enters the inferior vena cava (IVC) through the hepatic veins. The remainder (40% midgestation; 20% at term) bypasses the hepatic circulation through the ductus venosus and empties directly into the IVC. Because of streaming in the IVC, the more oxygenated blood from the ductus venosus and left hepatic vein, as it enters the heart, is deflected by the crista dividens through the foramen ovale to the left atrium. The remainder of left atrial blood is the small amount of venous return from the pulmonary circulation. The less oxygenated IVC blood from the lower body, renal, mesenteric, and right hepatic veins, streams across the tricuspid valve to the right ventricle. Almost all the return from the superior vena cava (SVC) and the coronary sinus passes through the tricuspid valve to the right ventricle, with only 2% to 3% crossing the foramen ovale. In the near-term fetus, the combined ventricular output is about 450 mL/kg/min; two thirds from the right ventricle and one third from the left ventricle. The blood in the left ventricle has a P_{O_2} of 25 to 28 mm Hg (saturation of 60%) and is distributed to the coronary circulation, brain, head, and upper extremities, with the remainder (10% of combined output) passing into the descending aorta. The major portion of the right ventricular output (60% of combined output) is carried by the ductus arteriosus to the descending aorta, with only 7% of combined output going to the lungs. Thus, 70% of combined output passes through the descending aorta, with a P_{O_2} of 20 to 23 mm Hg (saturation of 55%) to supply the abdominal viscera and lower extremities. Forty-five percent of combined output goes through the umbilical arteries to the placenta. Thus, blood of a higher P_{O_2} supplies the critical coronary and cerebral circulations, and umbilical venous blood is diverted to where oxygenation is critical.

The diversion of right ventricular output away from the lungs through the ductus arteriosus is caused by the very high pulmonary vascular resistance (PVR) in the fetus. This high PVR is maintained by multiple mechanisms. With advancing gestational age, an increase in the number of small pulmonary vessels occurs that increases the cross-sectional area of the pulmonary vasculature. This contributes to the gradual decline in PVR that begins during later gestation (Figure 21-7). With delivery, a variety of factors interact to decrease PVR acutely including mechanical ventilation, increased oxygen tension, and the production of endothelium-derived relaxing factor or nitric oxide.[19]

With the increase in pulmonary flow, left atrial return increases with a rise in left atrial pressure (Table 21-1). In addition, with the removal of the placenta, IVC return to

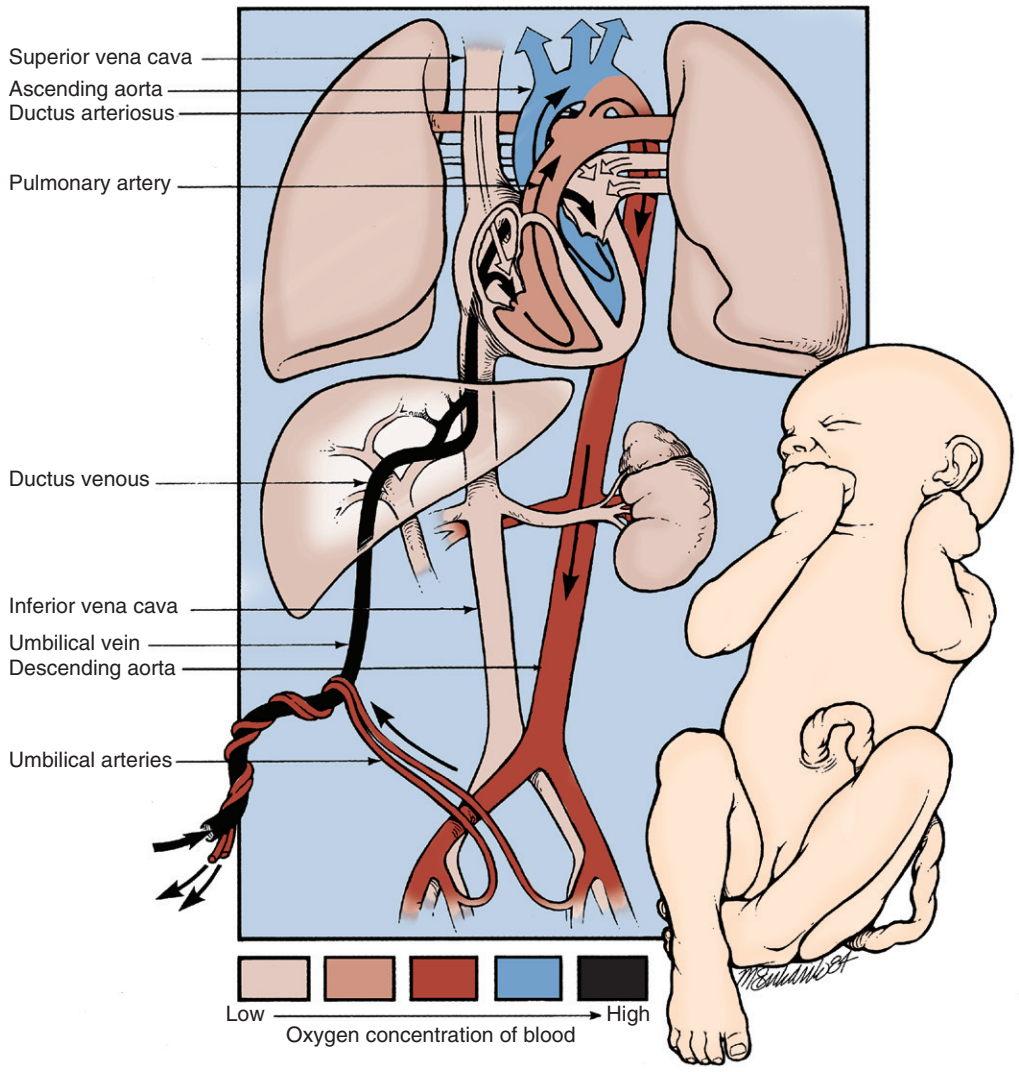

FIGURE 21-6. The fetal circulation.

the right atrium is diminished. The foramen ovale is a flap valve, and when left atrial pressure increases over that on the right side, the opening is functionally closed. It is still possible to demonstrate patency with insignificant right-to-left shunts in the first 12 hours of life in a human neonate, but in a 7- to 12-day newborn, such a shunt is rarely seen. Anatomic closure is not complete for a longer time.

With occlusion of the umbilical cord, the low-resistance placental circulation is interrupted, causing an increase in systemic pressure. This, coupled with the decrease in PVR, serves to reverse the shunt through the ductus arteriosus to a predominantly left-to-right shunt. By 15 hours of age, shunting in either direction is physiologically insignificant. Although functionally closed by 4 days of age, the ductus arteriosus is not anatomically occluded for 1 month. The role of an increased oxygen environment and prostaglandin metabolism in ductal closure is well established. Ductal closure occurs in two phases: constriction and anatomic occlusion. Initially, the muscular wall constricts, followed by permanent closure achieved by endothelial destruction, subintimal proliferation, and connective tissue formation.[20] The ductus venosus is functionally occluded shortly after the umbilical circulation is interrupted.

ABNORMALITIES OF CARDIOPULMONARY TRANSITION

Birth Asphyxia

Even normal infants may experience some limitation of oxygenation (asphyxia) during the birth process. A variety of circumstances can exaggerate this problem, resulting in respiratory depression in the infant, including (1) acute interruption of umbilical blood flow, as occurs during cord compression; (2) premature placental separation; (3) maternal hypotension or hypoxia; (4) any of the above-mentioned problems superimposed on chronic uteroplacental insufficiency; and (5) failure to execute a proper resuscitation. Other contributing factors include anesthetics and analgesics used in the mother, mode and difficulty of delivery, maternal health, and prematurity.

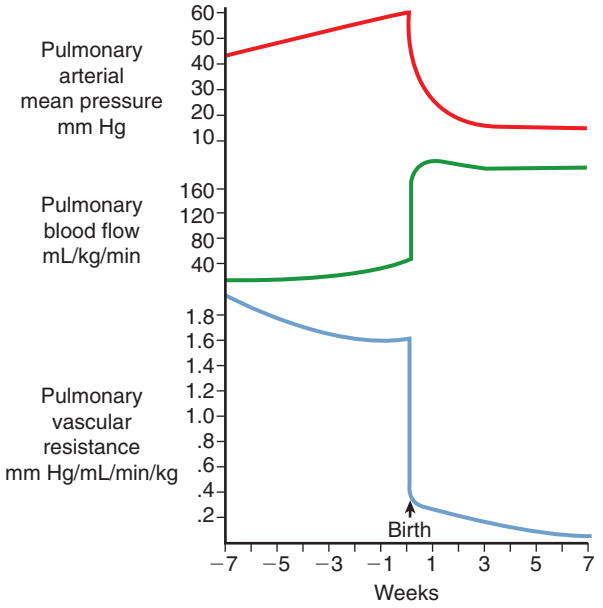

FIGURE 21-7. Representative changes in pulmonary hemodynamics during transition from the late-term fetal circulation to the neonatal circulation. (Modified from Rudolph AM: Fetal circulation and cardiovascular adjustments after birth. *In* Rudolph CD, Rudolph AM, Hostetter MK, et al [eds]: Rudolph's Pediatrics, 21st ed. New York, McGraw-Hill, 2003, p 1749.)

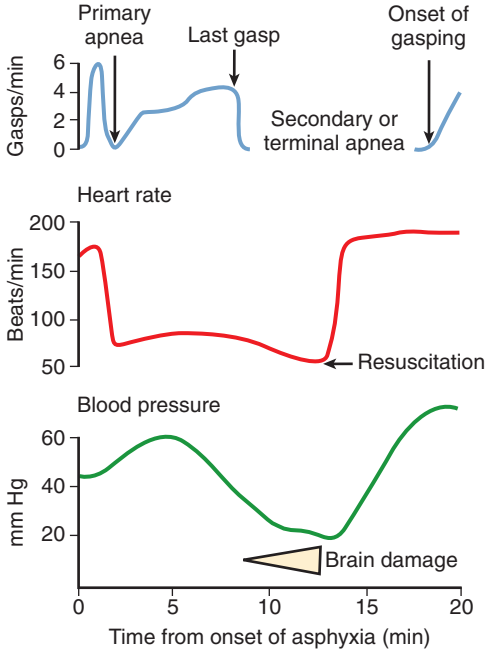

FIGURE 21-8. Schematic depiction of changes in rhesus monkeys during asphyxia and on resuscitation by positive-pressure ventilation. (Modified from Dawes GS: Foetal and Neonatal Physiology. Chicago, Year Book, 1968.)

The neonatal response to asphyxia follows a predictable pattern. Dawes investigated the responses of the newborn rhesus monkey (Figure 21-8).[21] After delivery, the umbilical cord was tied and the monkey's head was placed in a saline-filled plastic bag. Within about 30 seconds, a short series of respiratory efforts began. These were interrupted by a convulsion or a series of clonic movements accompanied by an abrupt fall in heart rate. The animal then lay inert with no muscle tone. Skin color became progressively cyanotic and then blotchy because of vasoconstriction in an effort to maintain systemic blood pressure. This initial period of apnea lasted about 30 to 60 seconds. The monkey then began to gasp at a rate of three to six per minute. The gasping lasted for about 8 minutes, becoming weaker terminally. The time from onset of asphyxia to last gasp could be related to postnatal age and maturity at birth; the more immature the animal, the longer the time. Secondary or terminal apnea followed and, if resuscitation was not quickly initiated, death ensued. As the animal progressed through the phase of gasping and then on to terminal apnea, heart rate and blood pressure continued to fall, indicating hypoxic depression of myocardial function. As the heart failed, blood flow to critical organs decreased, resulting in organ injury.

The response to resuscitation is qualitatively similar in many species, including humans. During the first period of apnea, almost any physical or chemical stimulus causes the animal to breathe. If gasping has already ceased, the first sign of recovery with initiation of positive-pressure ventilation is an increase in heart rate. The blood pressure then rises, rapidly if the last gasp has only just passed, but more slowly if the duration of asphyxia has been longer. The skin then becomes pink, and gasping ensues. Rhythmic spontaneous respiratory efforts become established after a further interval. For each 1 minute past the last gasp, 2 minutes of positive-pressure breathing is required before gasping begins and 4 minutes to reach rhythmic breathing. Later the spinal and corneal reflexes return. Muscle tone gradually improves over the course of several hours.

Delivery Room Management of the Newborn

A number of situations during pregnancy, labor, and delivery place the infant at increased risk for asphyxia: (1) maternal diseases, such as diabetes and hypertension, third-trimester bleeding, and prolonged rupture of membranes; (2) fetal conditions, such as prematurity, multiple births, growth restriction, fetal anomalies, and rhesus isoimmunization; and (3) conditions related to labor and delivery, including fetal distress, meconium staining, breech presentation, and administration of anesthetics and analgesics.

When an asphyxiated infant is expected, a resuscitation team should be in the delivery room. The team should have at least two persons, one to manage the airway and one to monitor heart rate and provide whatever assistance is needed. The necessary equipment for an adequate resuscitation is listed in Table 21-2. The equipment should be checked regularly and should be in a continuous state of readiness.

Steps in the resuscitation process[22] are as follows (Figure 21-9):

TABLE 21-2 EQUIPMENT FOR NEONATAL RESUSCITATION

CLINICAL NEEDS	EQUIPMENT
Thermoregulation	Radiant heat source with platform, mattress covered with warm sterile blankets, servo control heating, temperature probe
Airway management	Suction: bulb suction, meconium aspirator, wall vacuum suction with sterile catheters Ventilation: manual infant resuscitation bag connected to a pressure manometer capable of delivering 100% oxygen, appropriate masks for term and preterm infants, oral airways, stethoscope, gloves, compressed air source with oxygen blender and pulse oximeter and probe (optional) Intubation: neonatal laryngoscope with #0 and #1 blades; extra bulbs and batteries; endotracheal tubes 2.5, 3.0, 3.5, and 4.0 mm OD with stylet; scissors, tape, end tidal CO_2 detection device
Gastric decompression	Nasogastric tube, 8 Fr with 20-mL syringe
Administration of drugs/volume	Sterile gloves and sterile umbilical catheterization tray with scalpel or scissors, antiseptic prep solution, umbilical tape, three-way stopcock, umbilical catheters (3.5 and 5 Fr), volume expanders (normal saline), drug box with appropriate neonatal vials and dilutions (see Table 21-5), sterile syringes and needles
Transport	Warmed transport isolette with an oxygen source

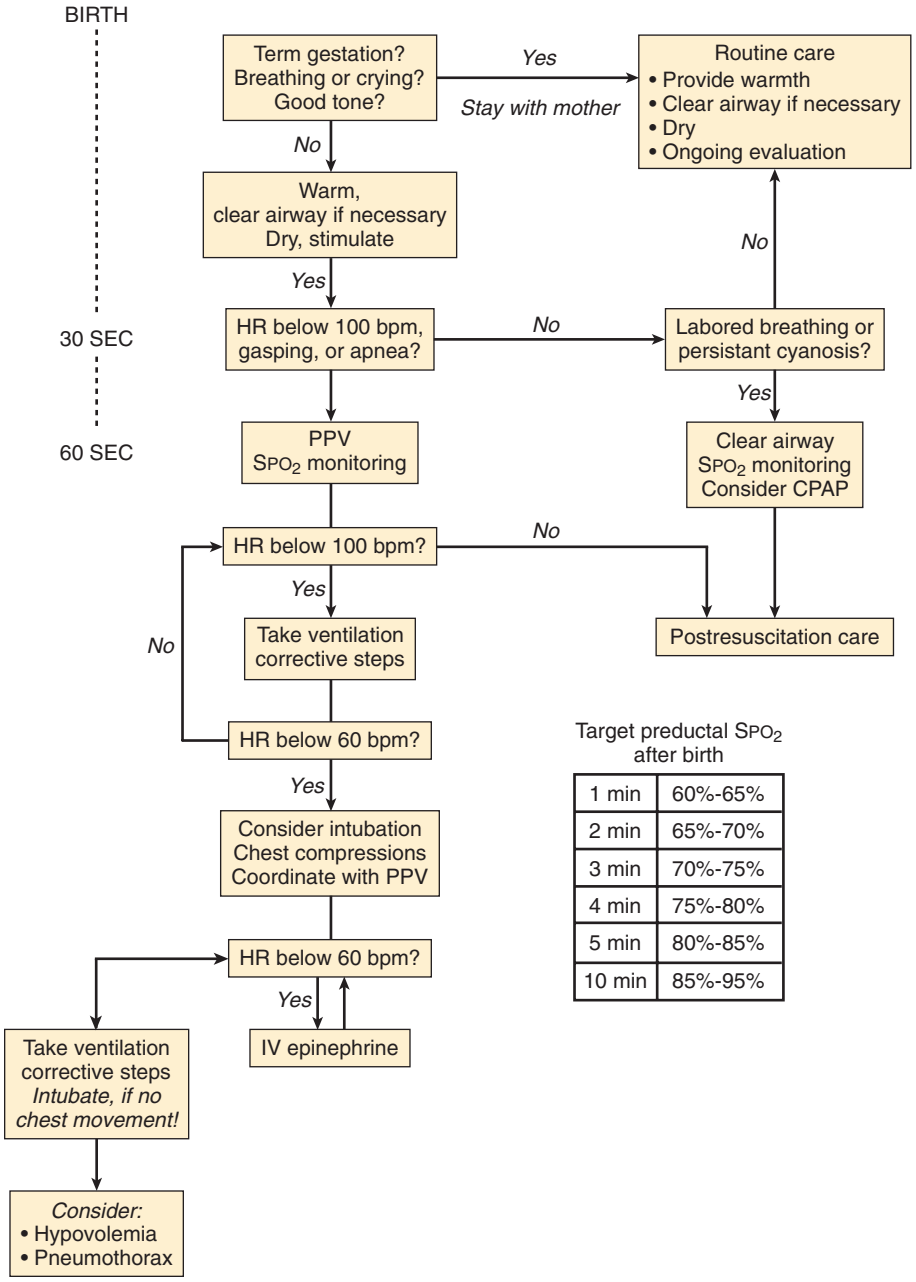

FIGURE 21-9. Delivery room management of the newborn. (From the American Heart Association and American Academy of Pediatrics: Neonatal Resuscitation Textbook, 2011.)

1. Dry the infant well and place under the radiant heat source on the back or side with the neck slightly extended. Do not allow the infant to become hyperthermic.
2. Gently suction the oropharynx and then the nose.
3. Assess the infant's condition (Table 21-3). The best criteria to assess are the infant's respiratory effort (apneic, gasping, regular) and heart rate (more or less than 100). A depressed heart rate indicative of hypoxic myocardial depression is the single most reliable indicator of the need for resuscitation.
4. Generally, infants who are breathing with heart rates over 100 bpm require no further intervention. If the infant is breathing with an adequate heart rate, but is cyanotic, provide supplemental oxygen. Infants with heart rates less than 100 bpm with apnea or irregular respiratory efforts should be gently stimulated by rubbing the baby's back with a towel.
5. If the baby fails to respond rapidly to tactile stimulation, proceed to bag and face mask ventilation using a soft mask that seals well around the mouth and nose. Choice of ventilation bags includes a flow-inflating bag (500 to 750 mL) with a pressure gauge and flow control valve or a self-inflating bag (240 to 750 mL) with an oxygen reservoir and pressure release valve (Figure 21-10). A T-piece resuscitation device may also be used. For the initial inflations, pressures of 30 to 40 cm H_2O may be necessary to overcome surface active forces in the lungs. Adequacy of ventilation is assessed by observing expansion of the infant's chest with bagging and a gradual improvement in color, perfusion, and heart rate. After the first few breaths, attempts should be made to lower the peak pressure to 15 to 20 cm H_2O. Rate of bagging should not exceed 40 to 60 bpm.
6. **Most neonates can be effectively resuscitated with a bag and face mask.** If the infant does not initially respond to bag and mask ventilation, try to reposition the head (slight extension), reapply the mask to achieve a good seal, consider suctioning the mouth and oropharynx, and try ventilating with the mouth open. It may be necessary to increase the pressure used. However, if there is no favorable response in 30 to 40 seconds, one can proceed to intubation:
   a. The head should be stable, with the nose in the sniffing position (pointing straight upward).
   b. Insert the laryngoscope blade, and sweep the tongue to the left.
   c. Advance the blade to the base of the tongue, and identify the epiglottis.
   d. Pick up the proper size endotracheal tube (2.5 mm outside diameter for infants <1000 g, 3.0 mm for infants 1000 to 2000 g, and 3.5 mm for larger infants) with the right hand.
   e. Slide the laryngoscope anterior to the epiglottis, and gently lift along the angle of the handle of the laryngoscope (Figure 21-11).
   f. Identify the vocal cords.
   g. Insert the tube in the right side of the mouth, and visualize the tube passing through the vocal cords. The tube should be located 7 cm at the lip for a 1000-g infant, 8 cm for a 2000-g infant, and 9 cm for a 3000-g infant.

TABLE 21-3 THE APGAR SCORING SYSTEM

SIGN	0	1	2
Heart rate	Absent	<100 bpm	>100 bpm
Respiratory effort	Apneic	Weak, irregular, gasping	Regular
Reflex irritability*	No response	Some response	Facial grimace, sneeze, cough
Muscle tone	Flaccid	Some flexion of arms and legs	Good flexion
Color	Blue, pale hands and feet blue	Body pink	Pink

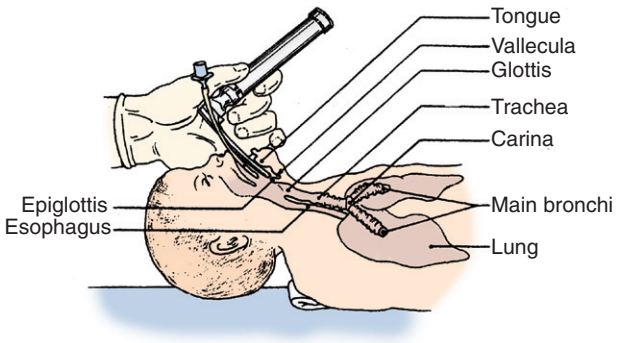

FIGURE 21-11. Anatomy of laryngoscopy for endotracheal intubation. (From the American Heart Association and American Academy of Pediatrics: Neonatal Resuscitation Textbook, 2000.)

TABLE 21-4 MECHANICAL CAUSES OF FAILED RESUSCITATION

CATEGORY	EXAMPLES
Equipment failure	Malfunctioning bag, oxygen not connected or running
Endotracheal tube malposition	Esophagus, right mainstem bronchus
Occluded endotracheal tube	
Insufficient inflation pressure to expand lungs	
Space-occupying lesions in the thorax	Pneumothorax, pleural effusions, diaphragmatic hernia
Pulmonary hypoplasia	Extreme prematurity, oligohydramnios

h. Ventilate as described earlier.
i. Failure to respond to intubation and ventilation can result from mechanical causes or severe asphyxia.
j. The mechanical causes listed in Table 21-4 should be quickly ruled out. Check to be sure the endotracheal tube passes through the vocal cords. A CO_2 detector placed between the endotracheal tube and the bag can be very helpful as a rapid confirmation of tube position in the airway. Occlusion of the tube should be suspected when there is resistance to bagging and no chest wall movement. If the endotracheal tube is in place and not occluded, and the equipment is functioning, a trial of bagging with higher pressures is indicated. The other causes listed in Table 21-4 are rare compared with equipment failure or tube problems. A pneumothorax is characterized by asymmetric breath sounds not corrected by repositioning the tube above the carina. Pleural effusions usually occur with fetal hydrops, whereas a diaphragmatic hernia should be ruled out in the setting of asymmetric breath sounds and a scaphoid abdomen. Pulmonary hypoplasia should be considered if the pregnancy has been complicated by oligohydramnios. **It is very unusual for a neonatal resuscitation to require either cardiac massage or drugs.** Almost all newborns respond to ventilation with supplemental oxygen.

TABLE 21-5 NEONATAL DRUG DOSES

DRUG	DOSE	ROUTE	HOW SUPPLIED
Epinephrine	0.1-0.3 mL/kg	IV or ET	1:10,000 dilution
Sodium bicarbonate*	1-2 mEq/kg	IV	0.5 mEq/mL (4.2% solution)
Volume†	10 mL/kg	IV	Normal saline, Ringer's lactate, whole blood
Naloxone‡	0.1 mg/kg	IV, ET	1 mg/mL IM, SC

Modified from American Heart Association and American Academy of Pediatrics: Neonatal Resuscitation Textbook. American Heart Association and American Academy of Pediatrics, 2006.
*For correction of metabolic acidosis only after adequate ventilation has been achieved; give slowly over several minutes.
†Infuse slowly over 5 to 10 minutes.
‡After proceeding with proper airway management and other resuscitative techniques
IV, Intravenous; *ET,* endotracheal; *IM,* intramuscular; *SC,* subcutaneous.

7. If mechanical causes are ruled out, external cardiac massage should be performed for persistent heart rate at less than 60 bpm after intubation and positive pressure ventilation for 30 seconds. Compression of one third of the anteroposterior diameter of the chest should be performed, interposed with ventilation at a 3:1 ratio (90 compressions, 30 breaths per minute).
8. If drugs are needed for a persistent heart rate less than 60 bpm after ventilation and chest compressions (Table 21-5), the drug of choice and preferred route of delivery is 0.1 to 0.3 mL/kg of 1:10,000 epinephrine through an umbilical venous line. If intravenous access is not established, epinephrine can be given via an endotracheal tube. Higher doses (0.5 to 1 mL/kg) of a 1:10,000 formulation may be required. If volume loss is suspected (e.g., documented blood loss with clinical evidence of hypovolemia), 10 mL/kg of a volume expander (normal saline or Ringer's lactate) should be administered through an umbilical venous line. The appropriateness of continued resuscitative efforts should always be reevaluated in an infant who fails to respond to all of the previously mentioned efforts. Today, resuscitative efforts are made even in "apparent stillbirths," that is, infants whose 1-minute Apgar scores are 0 to 1. However, efforts should not be sustained in the face of little or no improvement despite an appropriate resuscitation over a reasonable period of time (i.e., 10 to 15 minutes).[22]

Data now exist to support resuscitation with room air in lieu of 100% oxygen.[23,24] Concerns have been raised about the potential harmful effects of 100% oxygen, in particular the generation of oxygen free radicals. With that in mind, room air is a more appropriate gas than 100% oxygen. For term infants, all resuscitations should begin with room air targeting normal saturations for age in minutes (Figure 21-9).[22] If resuscitation is started with room air and there is no improvement, then supplemental oxygen can be given. **Normal healthy term infants require approximately 10 to 15 minutes to achieve oxygen saturations above 90%.**[25]

A few special circumstances merit discussion at this point. Infants in whom respiratory depression secondary to narcotic administration is suspected may be given naloxone (Narcan). However, this should not be done until the

airway has been managed and the infant resuscitated in the usual fashion. In addition, naloxone should not be given to the infant of an addicted mother, because it will precipitate withdrawal.

A second special group are preterm infants. Minimizing heat loss improves survival, so prewarmed towels should be available, and the environmental temperature of the delivery suite should be raised. The infant should be placed in a plastic covering after birth to minimize evaporative heat loss.[26] In the extremely-low-birthweight infant (<1000 g), proceed quickly to administration of continuous positive airway pressure (CPAP) and consider early intubation for surfactant administration. Volume expanders and sodium bicarbonate should be infused slowly to avoid rapid swings in blood pressure. Resuscitation in preterm infants also should begin with less than 100% (usually 30%-40%) oxygen.[24,27]

Finally, there is the issue of meconium-stained amniotic fluid. Meconium aspiration syndrome (MAS) is a form of aspiration pneumonia that occurs most often in term or postterm infants who have passed meconium in utero (7% to 20% of all deliveries).[28] Overall, 2% to 9% of children born through meconium-stained fluid are diagnosed with MAS.[28] Delivery room management of meconium in the amniotic fluid has been historically based on the notion that aspiration takes place with the initiation of extrauterine respiration and that the pathologic condition is related to the aspirated contents. This resulted in the practice of oropharyngeal suction on the perineum after delivery of the head, followed by airway visualization and suction by the resuscitator after delivery. Both of these assumptions are not entirely true. In utero aspiration has been induced in animal models and confirmed in autopsies of human stillbirths. In addition, the combined suction approach has not been uniformly successful in decreasing the incidence of MAS. These data have been confirmed by a large multicenter, prospective, randomized controlled trial assessing selective intubation of apparently vigorous meconium-stained infants.[29] Compared with expectant management, intubation and tracheal suction did not result in a decreased incidence of MAS or other respiratory disorders. Finally, oropharyngeal suction on the perineum before delivery of the shoulders does not prevent MAS.[30] The current recommended approach to meconium in the amniotic fluid is as follows:

1. The obstetrician carefully performs bulb suctioning of the oropharynx and nasopharynx after delivery of the baby.
2. If the baby is active and breathing and requires no resuscitation, the airway need not be inspected, thus avoiding the risk of inducing vagal bradycardia.
3. Any infant in need of resuscitation should have the airway inspected and suctioned before instituting positive-pressure ventilation.
4. Suction the stomach when airway management is complete and vital signs are stable.

Sequelae of Birth Asphyxia

The incidence of birth asphyxia is about 0.1% in term infants, with an increased incidence in infants of lower gestational age.[31] The acute sequelae that need to be managed in the neonatal period are listed in Table 21-6.

TABLE 21-6 THE ACUTE SEQUELAE OF ASPHYXIA

System	*Manifestations*
Central nervous system	Cerebral edema, seizures, hemorrhage and hypoxic-ischemic encephalopathy
Cardiac	Papillary muscle necrosis—transient tricuspid insufficiency, cardiogenic shock
Pulmonary	Aspiration syndromes (meconium, clear fluid), acquired surfactant deficiency, persistent pulmonary hypertension, pulmonary hemorrhage
Renal	Acute tubular necrosis with anuria or oliguria
Adrenal	Hemorrhage with adrenal insufficiency
Hepatic	Enzyme elevations, liver failure
Gastrointestinal	Necrotizing enterocolitis, feeding intolerance
Metabolic	Hypoglycemia, hypocalcemia
Hematologic	Coagulation disorders, thrombocytopenia

Widespread organ injury is evident. Management focuses on supportive care and treatment of specific abnormalities. This includes careful fluid management, blood pressure support, intravenous glucose, and treatment of seizures. Phenobarbital (40 mg/kg) 1 to 6 hours after the event given as neuroprotective therapy is associated with an improved neurologic outcome. **Hypothermia (selective head cooling or whole body hypothermia), especially if started within the first 6 hours of life, significantly improves outcomes at 18 to 22 months of age.**[32-34] The roles of oxygen free radical scavengers, excitatory amino acid antagonists, and calcium channel blockers in minimizing cerebral injury after asphyxia are still investigational.

If the infant survives, the major long-term concern is permanent CNS damage. The challenge is identifying criteria that can provide information about the risk of future problems for a given infant. A variety of markers have been examined to identify birth asphyxia and risk for adverse neurologic outcome. Marked fetal bradycardia is associated with increased risk, but use of electronic fetal monitoring and cesarean delivery have not altered the incidence of cerebral palsy over the last several decades. Low Apgar scores (≤3 beyond 5 minutes) at 1 and 5 minutes are not predictive, but infants with low scores that persist at 15 and 20 minutes after birth have a 50% chance of manifesting cerebral palsy if they survive. Cord pH is predictive of adverse outcome only if the pH is less than 7.00. The best predictor of outcome is the severity of the neonatal neurologic syndrome.[35] Infants with mild encephalopathy survive and are normal on follow-up examination. Moderate encephalopathy carries a 25% to 50% risk of severe handicap or death, whereas the severe syndrome carries a greater than 75% risk of death or disability. Diagnostic aids including electroencephalograms and magnetic resonance imaging (MRI) scans can also aid in predicting outcome. The circulatory response to hypoxia is to redistribute blood flow to provide adequate oxygen delivery to critical organs (e.g., brain, heart) at the expense of other organs. Thus, an insult severe enough to damage the brain should be accompanied by evidence of other organ dysfunction.

The long-term neurologic sequelae of intrapartum asphyxia are cerebral palsy with or without associated cognitive deficits and epilepsy. Although cerebral palsy can be related to intrapartum events, the large majority of cases are of unknown cause. Furthermore, cognitive deficits and epilepsy, unless associated with cerebral palsy, cannot be

related to asphyxia or to other intrapartum events. **To attribute cerebral palsy to peripartum asphyxia, there must be an absence of other demonstrable causes, substantial or prolonged intrapartum asphyxia (fetal heart rate abnormalities, fetal acidosis), and clinical evidence during the first days of life of neurologic dysfunction in the infant (see box, "Relationship of Intrapartum Events and Cerebral Palsy").**[36]

Relationship of Intrapartum Events and Cerebral Palsy

Essential Criteria

Evidence of a metabolic acidosis in fetal umbilical cord arterial blood obtained at delivery (pH < 7.00 and base deficit ≥12 mmol/L)

Early onset of severe or moderate neonatal encephalopathy in infants born at 34 or more weeks' gestation

Cerebral palsy of the spastic quadriplegic or dyskinetic type

Exclusion of other identifiable etiologies such as trauma, coagulation disorders, infectious conditions, or genetic disorders

Criteria That Suggest Intrapartum Timing but Are Not Specific to Asphyxial Insults

A sentinel hypoxic event occurring immediately before or during labor

A sudden sustained fetal bradycardia or the absence of fetal heart rate variability in the presence of persistent late or variable decelerations, usually after a hypoxic sentinel event when the pattern was previously normal

Apgar scores of 0-3 beyond 5 minutes

Onset of multisystem involvement within 72 hours of birth

Early imaging study showing evidence of acute nonfocal cerebral abnormality

Modified from American College of Obstetricians and Gynecologists, American Academy of Pediatrics: Neonatal Encephalopathy and Cerebral Palsy: Defining Pathogenesis and Pathophysiology. Washington DC, ACOG, 2003.

BIRTH INJURIES

Birth injuries are defined as those sustained during labor and delivery. **Factors predisposing to birth injury include macrosomia, cephalopelvic disproportion, shoulder dystocia, prolonged or difficult labor, precipitous delivery, abnormal presentations (including breech), and use of operative vaginal delivery.**[37] Injuries range from minor (requiring no therapy) to life threatening (Table 21-7).

Soft tissue injuries are most common. Most are related to dystocia and to the use of operative vaginal delivery. Accidental lacerations of the scalp, buttocks, and thighs may be inflicted with the scalpel during cesarean delivery. Cumulatively, these injuries are of a minor nature and respond well to therapy. Hyperbilirubinemia, particularly in the premature infant, is the major neonatal complication related to soft tissue bruising.

A cephalohematoma occurs in 0.2% to 2.5% of live births. Caused by rupture of blood vessels that traverse from the skull to the periosteum, the bleeding is subperiosteal and therefore limited by suture lines, with the most common site of bleeding being over the parietal bones.

TABLE 21-7 BIRTH INJURIES

CLASSIFICATION	EXAMPLE
Soft tissue injuries*	Lacerations, abrasions, fat necrosis
Extracranial bleeding	Cephalohematoma,* subgaleal bleed
Intracranial hemorrhage	Subarachnoid, subdural, epidural, cerebral, cerebellar
Nerve injuries	Facial nerve,* cervical nerve roots (brachial plexus palsies,* phrenic n., Horner's syndrome), recurrent laryngeal n. (vocal cord paralysis)
Fractures	Clavicle,* facial bones, humerus, femur, skull, nasal bones
Dislocations	Extremities, nasal septum
Eye injuries	Subconjunctiva* and retinal hemorrhages, orbital fracture, corneal laceration, breaks in Desçemet's membrane with corneal opacification
Torticollis†	
Spinal cord injuries	
Visceral rupture	Liver, spleen
Scalp laceration*	Fetal scalp electrode, scalpel
Scalp abscess	Fetal scalp electrode

*More common occurrences.
†Secondary to hemorrhage into the sternocleidomastoid muscle.

Associations include prolonged or difficult labor and mechanical trauma from operative vaginal delivery. Linear skull fractures beneath the hematoma have been reported in 5.4% of cases but are of no major consequence except in the unlikely event that a leptomeningeal cyst develops. Most cephalhematomas are reabsorbed in 2 weeks to 3 months. Subgaleal bleeds, which are not limited by suture lines, can occur in association with vacuum extraction alone (especially with multiple pop-offs and prolonged traction), in combination with the use of forceps, or with difficult forceps deliveries, and can result in life-threatening anemia, hypotension, or consumptive coagulopathy. Depressed skull fractures are also seen in neonates, but most do not require surgical elevations.

Intracranial hemorrhages related to trauma include epidural, subdural, subarachnoid, and intraparenchymal bleeds.[38] With improvements in obstetric care, subdural hemorrhages fortunately are now rare. Three major varieties of subdural bleeds have been described: (1) posterior fossa hematomas due to tentorial laceration with rupture of the straight sinus, vein of Galen, or transverse sinus or due to occipital osteodiastasis (a separation between the squamous and lateral portions of the occipital bone); (2) falx laceration, with rupture of the inferior sagittal sinus; and (3) rupture of the superficial cerebral veins. The clinical symptoms are related to the location of bleeding. With tentorial laceration, bleeding is infratentorial, causing brainstem signs and a rapid progression to death. Falx tears cause bilateral cerebral signs (e.g., seizures and focal weakness) until blood extends infratentorially to the brainstem. Subdural hemorrhage over the cerebral convexities can cause several clinical states, ranging from an asymptomatic newborn to one with seizures and focal neurologic findings. Infants with lacerations of the tentorium and falx have a poor outlook. In contrast, the prognosis for rupture of the superficial cerebral veins is much better, with the majority of survivors being normal. Primary subarachnoid hemorrhage is the most common variety of neonatal

intracranial hemorrhage.[38] Clinically, these infants are often asymptomatic, although they may present with a characteristic seizure pattern. The seizures begin on day 2 of life, and the infants are "well" between convulsions. In general, the prognosis for subarachnoid bleeds is good.

Trauma to peripheral nerves produces another major group of birth injuries. Brachial plexus injuries are caused by stretching of the cervical roots during delivery, usually when shoulder dystocia is present. Upper arm palsy (Erb-Duchenne), the most common brachial plexus injury, is caused by injury to the fifth and sixth cervical nerves; lower arm paralysis (Klumpke) results from damage to the eighth cervical and first thoracic nerves. Damage to all four nerve roots produces paralysis of the entire arm. Outcome for these injuries is variable, with some infants left with significant residual damage. Horner syndrome due to damage to sympathetic outflow through nerve root T1 may accompany Klumpke palsy, and approximately 5% of patients with Erb palsy have an associated phrenic nerve paresis. Facial palsy is another fairly common injury caused either by pressure from the sacral promontory or fetal shoulder as the infant passes through the birth canal or by operative vaginal delivery. Most of these palsies resolve, although in some infants, paralysis is persistent.

The majority of bone fractures resulting from birth trauma involve the clavicle and result from shoulder dystocia or breech extractions that require vigorous manipulations. Clinically, many of these fractures are asymptomatic, and when present, symptoms are mild. Prognosis for clavicular as well as limb fractures is uniformly good. The most commonly fractured long bone is the humerus.

Spinal cord injuries are a relatively infrequent but often severe form of birth injury. Accurate incidence is difficult to assess, because symptoms mimic other neonatal diseases and autopsies often do not include a careful examination of the spine. Depressed tone, hyporeflexia, and respiratory failure are clues to this diagnosis. Excessive longitudinal traction and head rotation during forceps delivery predispose to spinal injury, and hyperextension of the head in a footling breech is particularly dangerous. Outcomes include death or stillbirth caused by high cervical or brainstem lesions, long-term survival of infants with paralysis from birth, and minimal neurologic symptoms or spasticity.

NEONATAL THERMAL REGULATION

Physiology

The range of environmental temperatures over which the neonate can operate is narrower than that of an adult as a result of the infant's inability to dissipate heat effectively in warm environments and, more critically, to maintain temperature in response to cold. This range narrows with decreasing gestational age.

Although some increases in activity and shivering have been observed, nonshivering thermogenesis is the most important means of increased heat production in the cold-stressed newborn.[39] Nonshivering thermogenesis can be defined as an increase in total heat production without detectable (visible or electrical) muscle activity. The site of this increased heat production is brown fat located between the scapulae; around the muscles and blood vessels of the neck, axillae, and mediastinum; between the esophagus and trachea; and around the kidneys and adrenal glands. Brown fat cells contain more mitochondria and fat vacuoles, and have a richer blood and sympathetic nerve supply compared to white fat cells.

TABLE 21-8 NEONATAL RESPONSE TO THERMAL STRESS

STRESSOR	RESPONSE	TERM	PRETERM
Cold	Vasoconstriction	++	++
	↓ Exposed surface area (posture change)	±	±
	↑Oxygen consumption	++	+
	↑Motor activity; shivering	+	–
Heat	Vasodilation	++	++
	Sweating	+	–

++, Maximum response; +, intermediate; ±, may have a role; –, no response.

Heat loss to the environment is dependent on both an internal temperature gradient (from within the body to the surface) and an external gradient (from the surface to the environment). The infant can change the internal gradient by altering vasomotor tone and, to a lesser extent, by postural changes that decrease the amount of exposed surface area. The external gradient is dependent on purely physical variables. Heat transfer from the surface to the environment involves four routes: radiation, convection, conduction, and evaporation. Radiant heat loss, heat transfer from a warmer to a cooler object that is not in contact, depends on the temperature gradient between the objects. Heat loss by convection to the surrounding gaseous environment depends on air speed and temperature. Conduction or heat loss to a contacting cooler object is minimal in most circumstances. Heat loss by evaporation is cooling secondary to water loss at the rate of 0.6 cal/g water evaporated and is affected by relative humidity, air speed, exposed surface area, and skin permeability. In infants in excessively warm environments, under overhead radiant heat sources, or in very immature infants with thin, permeable skin, evaporative losses increase considerably. Table 21-8 summarizes the neonate's efforts to maintain a stable core temperature in the face of cold or heat stress. It is advantageous to maintain an infant in a neutral thermal environment (Figure 21-12). The neutral thermal environment for a given infant depends on size, gestational age, and postnatal age.[40] In general, maintaining the abdominal skin temperature at 36.5°C minimizes energy expenditure.

CLINICAL APPLICATIONS

Delivery Room

In utero, fetal thermoregulation is the responsibility of the placenta and is dependent on maternal core temperature, with fetal temperature 0.5° C higher than maternal temperature. At birth, the infant's core temperature drops rapidly from 37.8° C because of evaporation from its wet body and radiant and convective losses to the cold air and walls of the room. Even with an increase in oxygen consumption to the maximum capability of the newborn (15 mL/kg/min), the infant can produce only 0.075 cal/kg/min and will rapidly lose heat. Measures taken to reduce heat loss after birth depend on the clinical situation. For

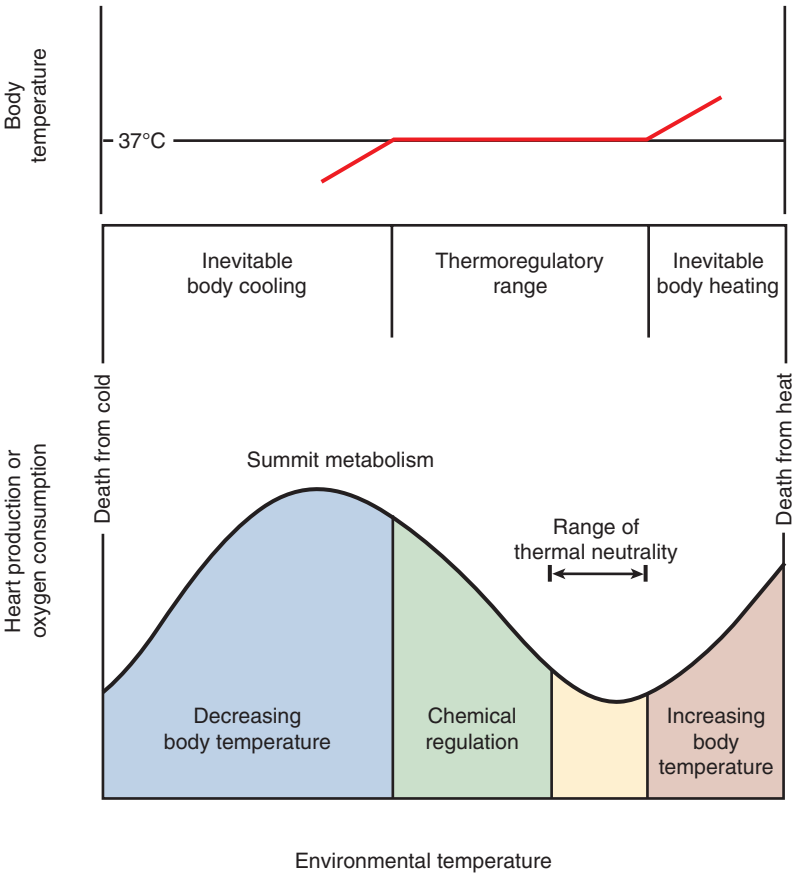

FIGURE 21-12. Effect of environmental temperature on oxygen consumption and body temperature. (Modified from Klaus MH, Fanaroff AA: The physical environment. *In* Klaus MH, Fanaroff AA [eds]: Care of the High-Risk Neonate, 5th ed. Philadelphia, WB Saunders Company, 2001, p 130.)

the well term infant, drying the skin and wrapping the baby with warm blankets is sufficient. When it is necessary to leave an infant exposed for close observation or resuscitation, the infant should be dried and placed under a radiant heat source. Room temperature can be elevated as an added precaution for the low-birthweight infant.

Nursery

Babies are cared for in the newborn nursery wrapped in blankets in bassinets (cot-nursed), in isolettes, or under a radiant heat source. Healthy full-term infants (weighing >2.5 kg) need only be clothed and placed in a bassinet under a blanket. Infants weighing 2 to 2.5 kg who are either slightly premature or growth restricted should be allowed 12 to 24 hours to stabilize in an isolette and then advanced to a bassinet. Lower birthweight babies (<2 kg) will require care in either isolettes or under radiant heat sources. **Adequate thermal protection of the low-birthweight infant is essential.** This is especially important for the very-low-birthweight infant (<1.5 kg), who often does not behave like a mature homeotherm. These neonates can react to a small change in environmental temperature with a change in body temperature rather than a change in oxygen consumption. In addition, warmer environments hasten growth of the premature infant.

The isolette, which heats by convection, is the most commonly used heating device for the low-birthweight nude infant. The major source of heat loss while in a neutral thermal environment is radiant to the walls of the isolette. The magnitude of this loss is predictable if room temperature is known. These losses can be minimized using double-walled isolettes in which the inner wall temperature is very close to the air temperature within the isolette. Once clinical status has been stabilized, the child can be dressed, which will afford increased thermal stability.

Radiant warmers can also be used to ensure thermal stability of both low-birthweight and full-sized infants. Radiant warmers are used most effectively for short-term warming during initial resuscitation and stabilization as well as for performing procedures. They provide easy access to the infant while ensuring thermal stability. The main heat losses are convection, which can be significant because of variable air speed in a room, and evaporation. Evaporative heat loss resulting in significant fluid losses is a major concern for the very-low-birthweight premature cared for under a radiant warmer. Placing a plastic shield over the infant or covering the skin with a semipermeable membrane can minimize these fluid losses.

The most economical means of thermal support for the low-birthweight infant is skin-to-skin contact with a parent. This "kangaroo" care has been shown to reduce serious illness and enhance lactation while providing adequate thermal support.

NEONATAL NUTRITION AND GASTROENTEROLOGY

At birth, the newborn infant must assume various functions performed during fetal life by the placenta.

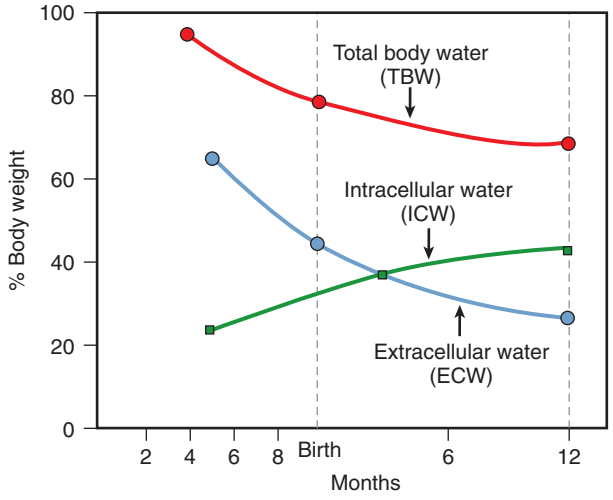

FIGURE 21-13. Changes in body water during gestation and infancy. (Modified from Friis-Hansen B: Water distribution in the foetus and newborn infant. Acta Paediatr Scand Suppl 305:7, 1983.)

Cardiopulmonary transition and thermoregulation have already been discussed. The final critical task for the newborn is the assimilation of calories, water, and electrolytes.

The required caloric, water, and electrolyte intake of the newborn depends on body stores and normal rate of energy expenditure. Body composition varies considerably with gestational age (Figure 21-13).[41] The average 1-kg preterm neonate consists of 85% water, 10% protein, and 3% fat as compared with 74% water, 12% protein, and 11% fat at term. Carbohydrate stores in the term infant are eight times higher. Rates of energy expenditure differ as well.

Water and Electrolytes

Maintenance water requirements are dependent on metabolic rate (evaporative losses to dissipate the heat of oxidation) and the necessary water to excrete the renal solute load. Other pertinent factors, especially for the premature infant, include environmental variation in insensible water losses and diminished ability to concentrate urine. It is normal during the first 3 to 4 postnatal days for an infant to experience a weight loss of up to 10% as the physiologic contraction of extracellular body fluid takes place. Maintenance electrolyte requirements are 2 to 3 mEq/kg/day for sodium, chloride, and bicarbonate and 1 to 2 mEq/kg/day for potassium. During periods of rapid growth, requirements will be higher.

Calories

Caloric needs are primarily dependent on oxygen consumption. The character of the feeding also affects caloric needs by altering specific dynamic action and fecal losses. The average caloric requirement for a normal full-term infant is estimated to be about 100 to 110 kcal/kg/day. The needs of the low-birthweight infant are more variable, but usually 105 to 130 kcal/kg/day is adequate.[42] Standard infant formulas and breast milk provide approximately 20 kcal/oz. Therefore, volumes of 150 to 180 mL/kg/day will provide the necessary caloric intake of 100 to 120 kcal/kg/day for the average term or preterm infant beyond 32 to 34 weeks' gestation. Infants weighing less than 1500 g should be fed with either formulas designed specifically for the premature or fortified breast milk. The goal for the growing premature is growth at a rate comparable to intrauterine growth during the third trimester.

Protein

Both the quantity and quality of protein intake are important for adequate growth, particularly for the premature infant.[42] Suggested intakes range from 2.25 to 4.0 g/kg/day (~3.5 g/kg/day for the premature infant).

Carbohydrate

Before birth, glucose is the major energy source for the human fetus. However, after birth carbohydrates are responsible for 40% to 50% of the total caloric needs. Intestinal disaccharidases develop early in fetal life, with lactase reaching mature levels at term. Both term and preterm infants can digest lactose, the major sugar in human milk and standard infant formulas. Although lactase levels are lower in preterm infants, which can lead to feeding intolerance, early initiation of enteral feeds rapidly increases lactase.

Fat

After birth, 40% to 50% of the calories oxidized are fat. Besides its role as an energy source, dietary fat is a carrier of fat-soluble vitamins and a source of essential fatty acids. Dietary fat is not completely absorbed; more so in the premature than in the term infant. For that reason, preterm formulas provide a portion of the fat energy as medium-chain triglycerides.

Infant Feeding

For the well term or slightly preterm infant, institution of oral feeds within the first 2 to 4 hours of life is reasonable practice. For infants who are SGA or large for gestational age (LGA), feeds within the first hour or two of life may be indicated to avoid hypoglycemia. Premature infants (<34 weeks' gestation) who are unable to nipple feed present a more complex set of circumstances. In addition to an inability to suck and swallow efficiently, such infants face a number of problems: (1) relatively high caloric demand; (2) small stomach capacity; (3) incompetent esophageal-cardiac sphincter, leading to gastroesophageal reflux; (4) poor gag reflex, creating a tendency for aspiration; (5) decreased digestive capability (especially for fat); and (6) slow gastric emptying and intestinal motility. These infants can initially be supported adequately with parenteral nutrition, followed by institution of nasogastric tube feedings when their cardiopulmonary status is stable.

Although a wide range of infant formulas satisfy the nutritional needs of most neonates, breast milk remains the standard on which formulas are based. The distribution of calories in human milk is 7% protein, 55% fat, and 38% carbohydrate. The whey/casein ratio is 70:30, enhancing ease of protein digestion and gastric emptying, while fat digestion is augmented by the presence of a breast milk lipase. Despite the low levels of several vitamins and minerals, bioavailability is high. In addition to the nutritional features, breast milk's immunochemical and cellular components provide protection against infection.[43]

The growth demands of the low-birthweight infant exceed what can be provided by human milk in terms of protein, calcium, phosphorus, sodium, zinc, copper, and possibly other nutrients. These shortcomings can be addressed through the addition of human milk fortifiers to mother's preterm breast milk.[44] Advantages of breast milk for the premature include its anti-infective properties, possible protection against NEC, and its role in enhancing neurodevelopmental outcome.[45]

Few contraindications to breastfeeding exist. Infants with galactosemia should not ingest lactose-containing milk. Infants with other inborn errors such as phenylketonuria may ingest some human milk, with close monitoring of the amount. The presence of environmental pollutants has been documented in breast milk, but to date no serious side effects have been reported. Most drugs do not contraindicate breastfeeding, but there are a few exceptions (see Chapter 8). Transmission of some viral infections via breast milk is a concern as well. Mothers who are human immunodeficiency virus (HIV) positive should not breastfeed if safe and effective alternatives to breast milk are available. The nursery staff must be aware of problems associated with breastfeeding and use lactation consultants to deal with poor infant latching, sore nipples, poor milk supply, and excessive hyperbilirubinemia. The obstetrician and pediatrician should serve as a source of knowledge and, most important, support. Table 21-9 illustrates what a mother can expect as she breastfeeds her infant.

Neonatal Hypoglycemia

Glucose is a major fetal fuel transported by facilitated diffusion across the placenta. After birth, before an appropriate supply of exogenous calories is provided, the newborn must maintain blood glucose through endogenous sources. Hepatic glycogen stores are almost entirely depleted within the first 12 hours after birth in the healthy term neonate and more rapidly in the preterm or stressed infant if there is no other glucose source. Fat and protein stores are then used for energy, while glucose levels are maintained by hepatic gluconeogenesis.

In the healthy unstressed neonate, glucose falls over the first 1 to 2 hours after birth, stabilizes at a minimum of about 40 mg/dL, and then rises to 50 to 80 mg/dL by 3 hours of life.[46] Low glucose concentrations can be defined as less than 45 mg/dL. **Infants at risk for low blood glucose concentrations and in whom glucose should be monitored include preterm infants, SGA infants, hyperinsulinemic (infant of a diabetic mother [IDM]), LGA infants, and infants with perinatal stress or asphyxia.** As in term babies, blood sugar drops after birth in preterm babies, but the latter are less able to mount a counterregulatory response. In addition, the presence of respiratory distress, hypothermia, and other factors can increase glucose demand, exacerbating hypoglycemia. SGA infants are at risk for hypoglycemia resulting from rapidly utilized glycogen stores as well as impaired gluconeogenesis and ketogenesis. Onset of hypoglycemia in SGA and preterm infants usually occurs at 2 to 6 hours of life. Hyperinsulinemia occurs in the infant of a diabetic mother as well as other rare conditions, including Beckwith-Weidemann syndrome and congenital hyperinsulinism. Onset of hypoglycemia in these infants can be in the first 30 to 60 minutes after birth. In the case of perinatal asphyxia, hypoglycemia is the result of excessive glucose demand and occasionally transient hyperinsulinism.[47,48] Infants with recurrent hypoglycemia over 3 to 4 days should be evaluated for endocrine (hyperinsulinism, decreased counterregulatory hormones—cortisol, growth hormone, and glucagon) and inborn errors of metabolism disorders (see box, Etiologies of Neonatal Hypoglycemia).

Etiologies of Neonatal Hypoglycemia

I. Transient neonatal hypoglycemia
   - A. Preterm and IUGR infants
   - B. Transient hyperinsulinism (IDM)
   - C. Perinatal stress (hypoxia, RDS)

II. Persistent neonatal hypoglycemia
   - A. Hyperinsulinism
     1. Potassium-ATP channel
     2. Glucokinase hyperinsulinism
     3. Glutamate dehydrogenase hyperinsulinism
     4. Beckwith-Wiedemann syndrome
   - B. Counterregulatory hormone deficiency (hypopituitarism)
   - C. Inborn errors of metabolism
     1. Glycogenolysis disorders
     2. Gluconeogenesis disorders
     3. Fatty acid oxidation disorders

ATP, Adenosine triphosphate; *IDM,* infant of a diabetic mother.

Symptoms of hypoglycemia include jitteriness, seizures, cyanosis, respiratory distress, apathy, hypotonia, and eye rolling.[46] However, many infants, particularly premature infants, are asymptomatic. Because of the risk of subsequent brain injury, hypoglycemia, when present, should be aggressively treated. However, the single best treatment is prevention by identifying infants at risk, including premature, SGA, IDM, LGA, and any stressed infant. These newborns should have blood glucose screened with a bedside glucose meter. All values less than or equal to 45 mg/dL should be confirmed with a laboratory measurement. Treatment is initiated by early institution of feeds or an intravenous glucose bolus (2 mL/kg of $D_{10}W$ solution) followed by a glucose infusion at a rate of 6 mg/kg/min.[49]

Congenital Gastrointestinal Surgical Conditions

Several congenital surgical conditions of the gastrointestinal tract interfere with a normal transition. Many of these conditions can be diagnosed with antenatal ultrasound, allowing transfer of the mother to a perinatal center for delivery.

Gastrointestinal Tract Obstruction

Tracheoesophageal fistula and esophageal atresia are characterized by a blind esophageal pouch and a fistulous connection between either the proximal or distal esophagus and the airway. Eighty-five percent of infants with these conditions have the fistula between the distal esophagus and the airway. Polyhydramnios is common because of the

TABLE 21-9 GUIDELINES FOR SUCCESSFUL BREAST FEEDING

	FIRST 8 HOURS	8-24 HOURS	DAY 2	DAY 3	DAY 4	DAY 5	DAY 6 ONWARD
Milk Supply	You may be able to express a few drops of milk.		Milk *should* come in between the 2nd and 4th day.			Milk should be in. Breasts may be firm and/or leak milk.	Breasts should feel softer after nursing.
Baby's activity	Baby is usually wide awake in the first hour of life. Put baby to breast within ½ hour of birth	Wake up your baby. Babies may not wake up on their own to feed.	Baby should be more cooperative and less sleepy.	Look for early feeding cues such as rooting, lip smacking, and hands to face.			Baby should appear satisfied after feedings.
Feeding routine	Baby may go into a deep sleep 2-4 hours after birth.	Use chart to write down time of each feeding. Feed your baby every 1-4 hr or as often as wanted—at least 8-12 times a day.				May go one longer interval (up to 5 hr between feeds) in a 24-hr period.	
Breastfeeding	Baby will wake up and be alert and responsive for several more hours after initial sleep.	As long as the mother is comfortable, nurse at both breasts as long as baby is actively sucking.	Try to nurse both sides each feeding, aiming at 10 min per side. Expect some nipple tenderness.	Consider hand expressing or pumping a few drops of milk to soften the nipple if the breast is too firm for the baby to latch on.	Nurse a minimum of 10-30 min per side every feeding for the first few weeks of life. Once milk supply is well established, allow baby to finish the first breast before offering the second.		Mother's nipple tenderness is improving or is gone.
Baby's urine output		Baby must have a minimum of one wet diaper in the first 24 hr.	Baby must have at least one wet diaper every 8-11 hr.	You should see an increase in wet diapers (up to four or six) in 24 hr.	Baby's urine should be light yellow.	Baby should have six to eight wet diapers per day of colorless or light yellow urine.	
Baby's stools		Baby may have a very dark (meconium) stool.	Baby may have a second very dark (meconium) stool.	Baby's stools should be in transition from black-green to yellow.		Baby should have three to four yellow, seedy stools a day.	The number of stools may decrease gradually after 4-6 wk.

Courtesy Beth Gabrielski, RN: The Children's Hospital, Denver, 1999, with permission.

high level of gastrointestinal obstruction. Infants present in the first hours of life with copious secretions, choking, cyanosis, and respiratory distress. Diagnosis can be confirmed with chest radiography after careful placement of a nasogastric tube to the point at which resistance is met. The tube will be seen in the blind esophageal pouch. If a tracheoesophageal fistula is present to the distal esophagus, gas will be present in the abdomen.[50]

Infants with high intestinal obstruction present early in life with either bilious or nonbilious vomiting. A history of polyhydramnios is common, and the amniotic fluid, if bile stained, can easily be confused with thin meconium staining. In duodenal atresia, vomitus may or may not contain bile, whereas malrotation with midgut volvulus and high jejunal atresia are characterized by bilious vomiting. Malrotation and midgut volvulus involve torsion of the intestine around the superior mesenteric artery, causing occlusion of the vascular supply to most of the small intestine. If not treated promptly, the infant can lose most of the small bowel due to ischemic injury. **Therefore, bilious vomiting in the neonate demands immediate attention and evaluation.** Diagnosis of high intestinal obstruction can be confirmed with radiographs. Duodenal atresia is characterized by a "double-bubble sign" (stomach and dilated duodenum). Diagnosis of midgut volvulus can be confirmed with an upper gastrointestinal tract series, looking for contrast not to pass the ligament of Treitz. Approximately 30% of cases of duodenal atresia are associated with Down syndrome.[51]

Low intestinal obstruction presents with increasing intolerance of feeds (spitting progressing to vomiting), abdominal distention, and decreased or absent stool.[51] Differential diagnosis of lower intestinal obstruction includes imperforate anus, Hirschsprung disease, meconium plug syndrome, small left colon, colonic and ileal atresia, and meconium ileus. Plain x-ray study of the abdomen shows gaseous distention, with air through a considerable portion of the bowel and air-fluid levels. Diagnosis of meconium ileus, meconium plug, and small left colon syndrome can be made by appearance on contrast enema. Rectal biopsy searching for absence of ganglion cells confirms the diagnosis of Hirschsprung disease. **Infants with meconium ileus and meconium plug should be screened for cystic fibrosis.**

Abdominal Wall Defects

Omphaloceles are formed by incomplete closure of the anterior abdominal wall after return of the midgut to the abdominal cavity. The size of the defect is variable, but usually the omphalocele sac contains some intestine, stomach, liver, and spleen. The abdominal cavity is small and underdeveloped. The umbilical cord can be seen to insert onto the center of the omphalocele sac. There is a high incidence of associated anomalies, including cardiac, other gastrointestinal anomalies, and chromosomal syndromes (trisomy 13). **Delivery room treatment involves covering the defect with sterile warm saline to prevent fluid loss and nasogastric tube decompression.**[52]

Gastroschisis is a defect in the anterior abdominal wall lateral to the umbilicus with no covering sac, with the herniated viscera usually limited to intestine. Furthermore, the intestine has been exposed to amniotic fluid and has a thickened, beefy red appearance. The herniation is thought to occur as a rupture through an ischemic portion of the abdominal wall. Other than intestinal atresia, associated anomalies are uncommon. Delivery room management is as described for omphalocele.[52]

Diaphragmatic Hernia

In diaphragmatic hernia, herniation of abdominal organs into the hemithorax (usually left) occurs because of a posterolateral defect in the diaphragm. Infants usually present in the delivery room with respiratory distress, cyanosis, decreased breath sounds on the side of the hernia, and shift of the mediastinum to the side opposite the hernia. The rapidity and severity of presentation with respiratory distress is dependent on the degree of associated pulmonary hypoplasia. The ipsilateral and to some extent contralateral lung are compressed in utero because of the hernia. Delivery room treatment is to intubate, ventilate, and decompress the gastrointestinal tract with a nasogastric tube. A chest radiograph confirms the diagnosis. The mortality due to diaphragmatic hernia is about 30%, with survival dependent upon the degree of lung hypoplasia and the presence of associated congenital heart disease.[53]

Necrotizing Enterocolitis

NEC is the most common acquired gastrointestinal emergency in the neonatal intensive care unit. This disorder predominantly affects premature infants, with higher incidences present with decreasing gestational age, although it is seen in term infants with polycythemia, congenital heart disease, and birth asyphyxia. The pathogenesis is multifactorial, with intestinal ischemia, infection, provision of enteral feedings, and gut maturity playing roles to varying degrees in individual patients.[54] Tocolysis with indomethacin presumably related to changes in intestinal circulation has been associated with an increased incidence of NEC and isolated intestinal perforation, whereas antenatal betamethasone may decrease the incidence.

Clinically, there is a varied spectrum of disease, from a mild gastrointestinal disturbance to a rapid fulminant course characterized by intestinal gangrene, perforation, sepsis, and shock. The hallmark symptoms are abdominal distention, ileus, delayed gastric emptying, and bloody stools. The radiographic findings are bowel wall edema, pneumatosis intestinalis, biliary free air, and free peritoneal air. Associated symptoms include apnea, bradycardia, hypotension, and temperature instability. Spontaneous intestinal perforation is a related, though likely distinct, disorder characterized by many of the same risk factors and clinical signs, but without extensive intestinal pathology.[55]

Neonatal Jaundice

The most common problem encountered in a term nursery population is jaundice. Neonatal hyperbilirubinemia occurs when the normal pathways of bilirubin metabolism and excretion are altered. Figure 21-14 demonstrates the metabolism of bilirubin. The normal destruction of circulating red cells accounts for about 75% of the newborn's

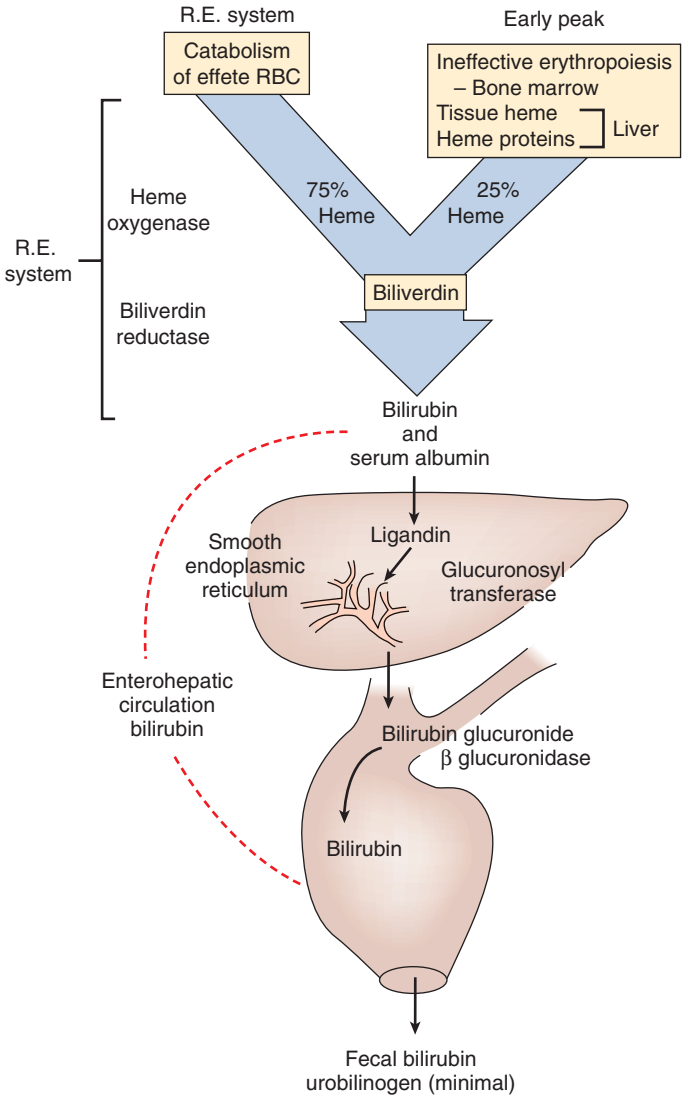

FIGURE 21-14. Neonatal bile pigment metabolism. (Modified from Maisels MJ: Jaundice. *In* Avery GB, Fletcher MA, MacDonald MG [eds]: Neonatology: Pathophysiology and Management of the Newborn, 5th ed. Philadelphia, Lippincott Williams & Wilkins, 1999, p 765.)

daily bilirubin production. The remaining sources include ineffective erythropoiesis and tissue heme proteins. Heme is converted to bilirubin in the reticuloendothelial system with carbon monoxide (CO) produced as a by-product. Unconjugated bilirubin is lipid soluble and transported in the plasma reversibly bound to albumin. Bilirubin enters the liver cells by dissociation from albumin in the hepatic sinusoids. Once in the hepatocyte, bilirubin is conjugated with glucuronic acid in a reaction catalyzed by uridine diphosphoglucuronosyl transferase (UDPGT). The water-soluble conjugated bilirubin is excreted rapidly into the bile canaliculi and into the small intestine. The enzyme β-glucuronidase is present in the small bowel and hydrolyzes some of the conjugated bilirubin. This unconjugated bilirubin can be reabsorbed into the circulation, adding to the total unconjugated bilirubin load (enterohepatic circulation). **Major predisposing factors of neonatal jaundice are (1) increased bilirubin load because of increased red cell volume with decreased cell survival, increased ineffective erythropoiesis, and the enterohepatic circulation; and (2) decreased hepatic uptake, conjugation, and excretion of bilirubin.** These factors result in the presence of clinically apparent jaundice in approximately two thirds of newborns during the first week of life and in most is considered physiologic.[56] Infants whose bilirubin levels are above the 95th percentile for age in hours and infants in high-risk groups to develop hyperbilirubinemia require close follow-up (see Figure 21-15 and the box, Risk Factors for Significant Hyperbilirubinemia).[57,58]

RISK FACTORS FOR SIGNIFICANT HYPERBILIRUBINEMIA

Jaundice observed at less than 24 hours
Blood group incompatibility with positive direct Coombs' test
Other hemolytic disease (G6PD deficiency)
Gestational age less than 35-36 weeks
Previous sibling needing phototherapy
Cephalohematoma, subgaleal blood collection, bruising
Exclusive breastfeeding, especially if nursing not going well
East Asian race

Modified from American Academy of Pediatrics Subcommittee on Hyperbilirubinemia: Management of hyperbilirubinemia in the newborn infant 35 or more weeks gestation. Pediatrics 114:297, 2004.

Pathologic jaundice during the early neonatal period is indirect hyperbilirubinemia, usually caused by overproduction of bilirubin. The leading cause in this group of patients is hemolytic disease, of which fetomaternal blood group incompatibilities (ABO, Rh, and other minor antibodies) are the most common (see Chapter 32). Other causes of hemolysis include genetic disorders such as hereditary spherocytosis and nonspherocytic hemolytic anemias, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency. Other etiologies of bilirubin overproduction include extravasated blood (bruising, hemorrhage), polycythemia, and exaggerated enterohepatic circulation of bilirubin because of mechanical gastrointestinal obstruction or reduced peristalsis from inadequate oral intake. Disease states involving decreased bilirubin clearance must be considered in the patients in whom no cause of overproduction can be identified. Causes of indirect hyperbilirubinemia in this category include familial deficiency of UDPGT (Crigler-Najjar syndrome), Gilbert syndrome, breast milk jaundice, and hypothyroidism. Mixed and direct hyperbilirubinemia are rare during the first week of life.

A strong association exists between breastfeeding and neonatal hyperbilirubinemia. The syndrome of breast milk jaundice is characterized by full-term infants who have jaundice that persists into the second and third weeks of life with maximal bilirubin levels of 10 to 30 mg/dL. If breastfeeding is continued, the levels persist for 4 to 10 days and then decline to normal by 3 to 12 weeks. Interruption of breastfeeding is associated with a prompt decline in 48 hours. In addition to this syndrome, breastfed infants as a whole have higher bilirubin levels over the first 3 to 5

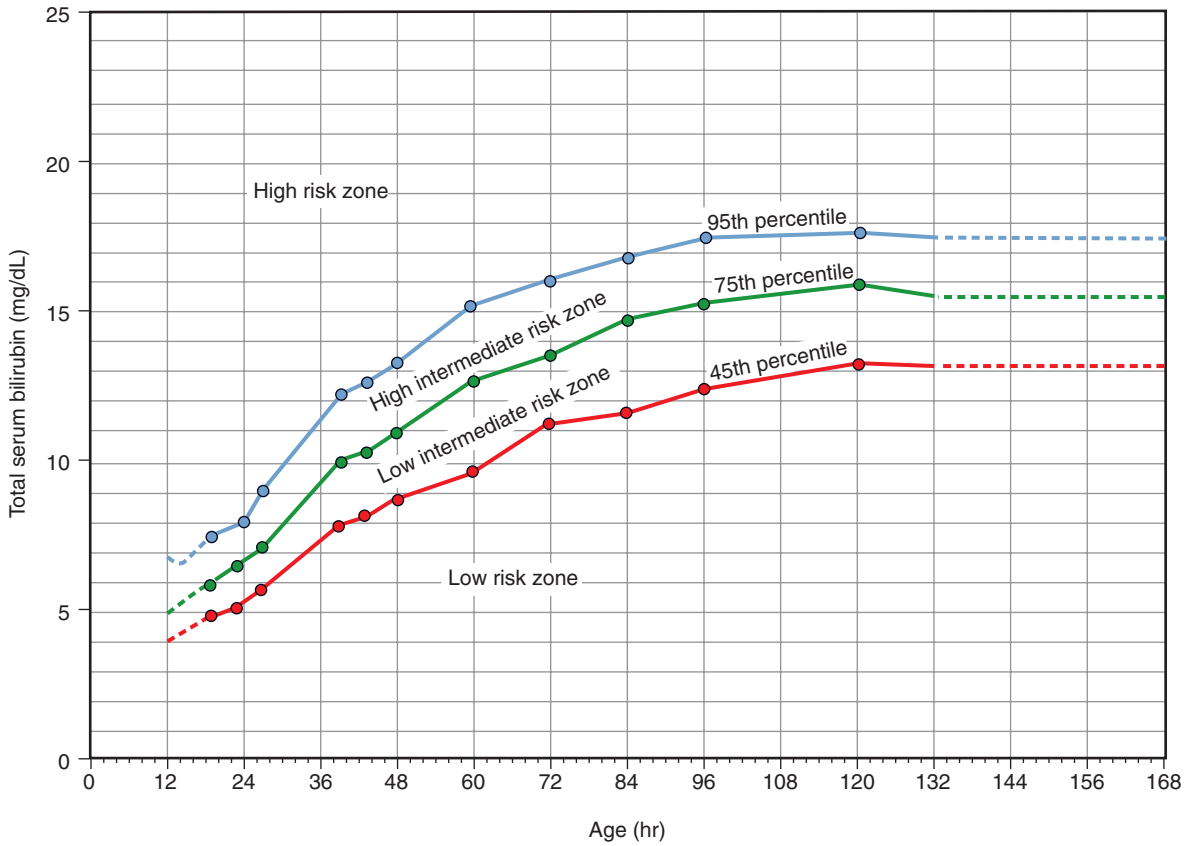

FIGURE 21-15. Risk of developing significant hyperbilirubinemia in term and near-term infants based on hour-specific bilirubin determinations. (From Bhutani VK, Johnson L, Sivieri EM: Predictive ability of a predischarge hour-specific serum bilirubin for subsequent significant hyperbilirubinemia in healthy term and near-term newborns. Pediatrics 103:6, 1999. Copyright 1999 American Academy of Pediatrics.)

days of life than their formula-fed counterparts (Figure 21-16). Rather than interrupting breastfeeding, this early jaundice is responsive to increased frequency of breastfeeding. Suggested mechanisms for breastfeeding-associated jaundice include decreased early caloric intake, inhibitors of bilirubin conjugation in breast milk, and increased intestinal reabsorption of bilirubin. In some patients, there is considerable overlap in these described syndromes.

The overriding concern with neonatal hyperbilirubinemia is the development of bilirubin toxicity causing the pathologic entity of kernicterus, the staining of certain areas of the brain (basal ganglia, hippocampus, geniculate bodies, various brainstem nuclei, and cerebellum) by bilirubin. Neuronal necrosis is the dominant histopathologic feature at 7 to 10 days of life. The early symptoms of bilirubin encephalopathy consist of lethargy, hypotonia, and poor feeding progressing to high-pitched cry, hypertonicity, and opisthotonos. Survivors usually suffer sequelae, including athetoid cerebral palsy, high-frequency hearing loss, paralysis of upward gaze, and dental dysplasia.[59] The risk of bilirubin encephalopathy is not well defined except in those infants with Rh isoimmunization in whom a level of 20 mg/dL has been associated with an increased risk of kernicterus. This observation has been extended to the management of other neonates with hemolytic disease, although no definitive data exist regarding these infants. The risk is probably small for term infants without hemolytic disease even at levels higher than 20 mg/dL. Recent descriptions of bilirubin encephalopathy in breastfed infants (in particular late preterm infants) with dehydration and hyperbilirubinemia in whom an adequate supply of breast milk has not been established mandates close follow-up of all breastfeeding mothers.[59] The true risk for nonhemolytic hyperbilirubinemia to produce brain damage in the preterm in the current era of liberal use of phototherapy that prevents marked elevation of severe bilirubin in these infants is unknown. However, most currently available data would suggest this risk is low.

NEONATAL HEMATOLOGY

Anemia

Early hematopoietic cells originate in the yolk sac. By 8 weeks' gestation, erythropoiesis is taking place in the liver, which remains the primary site of erythroid production through the early fetal period. By 6 months of gestation, the bone marrow becomes the principal site of red cell development. Normal hemoglobin levels at term range from 13.7 to 20.1 g/dL. In the very preterm infant, values as low as 12 g/dL are acceptable. Anemia at birth or appearing in the first few weeks of life is the result of blood loss, hemolysis, or underproduction of erythrocytes.[60] Blood loss resulting in anemia can occur prenatally, at the time of delivery, or postnatally. In utero blood loss can be the result of fetomaternal bleeding, twin-to-twin transfusion, or

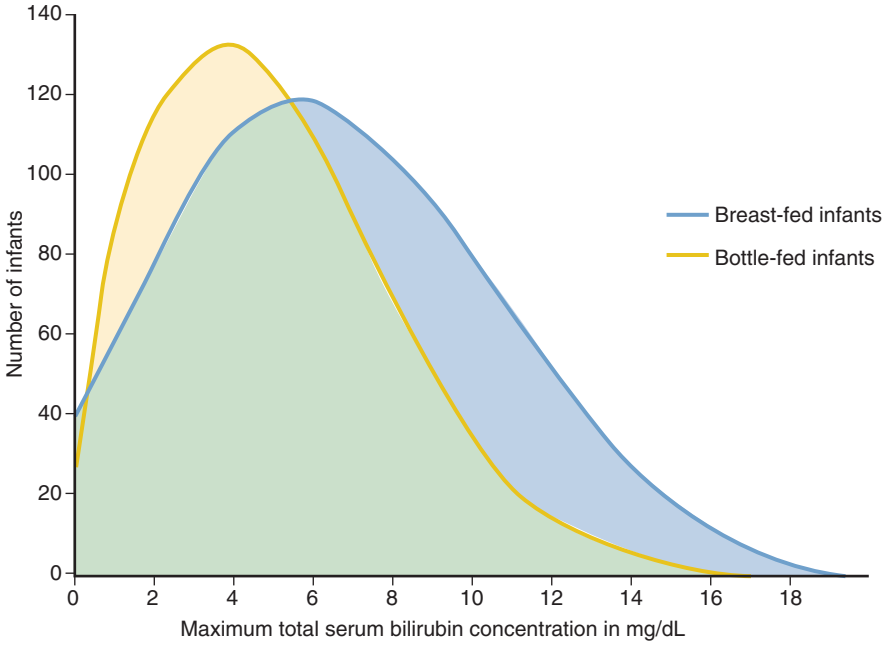

FIGURE 21-16. Distribution of maximum serum bilirubin concentrations in white infants who weigh more than 2500 g. (Modified from Maisels MJ, Gifford KL: Normal serum bilirubin levels in the newborn and the effect of breast-feeding. Pediatrics 78:837, 1986.)

blood loss resulting from trauma (maternal trauma, amniocentesis, external cephalic version). **The diagnosis of fetomaternal hemorrhage large enough to cause anemia can be made using flow cytometry or the Kleihauer-Betke technique of acid elution to identify fetal cells in the maternal circulation.** Blood loss at delivery can be caused by umbilical cord rupture, incision of the placenta during cesarean delivery, placenta previa, or abruptio placentae. Internal hemorrhage can occur in the newborn, often related to a difficult delivery. Sites include intracranial, cephalohematomas, subgaleal, retroperitoneal, liver capsule, and ruptured spleen. When blood loss has been chronic (e.g., fetomaternal), infants will be pale at birth, but well compensated and without signs of volume loss. The initial hematocrit will be low. Acute bleeding will present with signs of hypovolemia (tachycardia, poor perfusion, hypotension). The initial hematocrit can be normal or decreased, but after several hours of equilibration, it will be decreased. Anemia caused by hemolysis from blood group incompatibilities is common in the newborn period. Less common causes of hemolysis include erythrocyte membrane abnormalities, enzyme deficiencies, and disorders of hemoglobin synthesis. Impaired erythrocyte production is a rare cause of neonatal anemia.

Polycythemia

Elevated hematocrits occur in 1.5% to 4% of live births. Although 50% of polycythemic infants are appropriate for gestational age (AGA), the proportion of polycythemic infants is greater in the SGA and LGA populations. Causes of polycythemia include twin-to-twin transfusion, maternal-to-fetal transfusion, intrapartum transfusion from the placenta associated with fetal distress, chronic intrauterine hypoxia (SGA infants, LGA infants of diabetic mothers), delayed cord clamping, and chromosomal abnormalities. The consequence of polycythemia is hyperviscosity, resulting in impaired perfusion of capillary beds. Therefore, clinical symptoms can be related to any organ system (Table 21-10). Hyperviscosity is inferred from hematocrit because the major factor influencing viscosity in the newborn is red cell mass. Cord blood hematocrit greater than or equal to 57% and capillary hematocrit of at least 70% are indicative of polycythemia. Confirmation of the diagnosis is a peripheral venous hematocrit of at least 64%. Reduction of venous hematocrit to less than 60% may improve acute symptoms, but it has not been shown to improve long-term neurologic outcome.[61]

TABLE 21-10 ORGAN-RELATED SYMPTOMS OF HYPERVISCOSITY

Central nervous system	Irritability, jitteriness, seizures, lethargy
Cardiopulmonary	Respiratory distress caused by congestive heart failure or persistent pulmonary hypertension
Gastrointestinal	Vomiting, heme-positive stools, abdominal distention, necrotizing enterocolitis
Renal	Decreased urine output, renal vein thrombosis
Metabolic	Hypoglycemia
Hematologic	Hyperbilirubinemia, thrombocytopenia

Thrombocytopenia

Neonatal thrombocytopenia can be isolated or occur associated with deficiency of clotting factors. A differential diagnosis is presented in Table 21-11. The immune thrombocytopenias have implications for perinatal care. In idiopathic thrombocytopenic purpura (ITP), maternal antiplatelet antibodies that cross the placenta lead to destruction of fetal platelets. However, only 10% to 15% of infants born to mothers with ITP have platelet counts less than 100,000 and even in infants with severe thrombocytopenia, serious bleeding is rare. Alloimmune thrombocytopenia occurs when an antigen is present on fetal platelets but is not present on maternal platelets. On exposure to fetal platelets, the mother develops antiplatelet antibodies that cross the placenta causing destruction of fetal platelets. In the largest series of cases of suspected alloimmune thrombocytopenia, the majority were caused by HPA-1a alloantibodies. Because the maternal platelet

count is normal, the diagnosis is suspected on the basis of a history of a previously affected pregnancy. Intracranial hemorrhage is common with this condition (10% to 20%) and can occur in the antenatal or intrapartum periods.[62] Antenatal treatment is guided by the severity of thrombocytopenia and presence of intracranial hemorrhage in the previously affected fetus. Treatment options include intravenous immunoglobulin infusions and corticosteroids given to the mother.[62]

Vitamin K Deficiency Bleeding of the Newborn

Vitamin K_1 oxide (1 mg) should be given intramuscularly to all newborns to prevent hemorrhagic disease caused by a deficiency in vitamin K–dependent clotting factors (II, VII, IX, X).[63] Babies born to mothers who are on anticonvulsant medication are particularly at risk of having vitamin K deficiency. Bleeding occurs in 0.25% to 1.4% of newborns who do not receive vitamin K prophylaxis, generally in the first 5 days to 2 weeks but as late as 12 weeks. Oral vitamin K has been shown to be effective in raising vitamin K levels, but is not as effective in preventing late hemorrhagic disease of the newborn. Late hemorrhagic disease of the newborn most commonly occurs in breastfed infants whose courses have been complicated by diarrhea.

TABLE 21-11 DIFFERENTIAL DIAGNOSIS OF NEONATAL THROMBOCYTOPENIA

DIAGNOSIS	COMMENTS
Immune	Passively acquired antibody (e.g., idiopathic thrombocytopenic purpura, systemic lupus erythematosus, drug induced)
	Alloimmune sensitization to HPA-1a antigen
Infections	Bacterial; congenital viral infections (e.g., cytomegalovirus, rubella)
Syndromes	Absent radii; Fanconi's anemia
Giant hemangioma	
Thrombosis	
High-risk infant with respiratory distress syndrome, pulmonary hypertension, and so forth	Disseminated intravascular coagulation
	Isolated thrombocytopenia

HPA-1a, Human platelet antigen-1a.

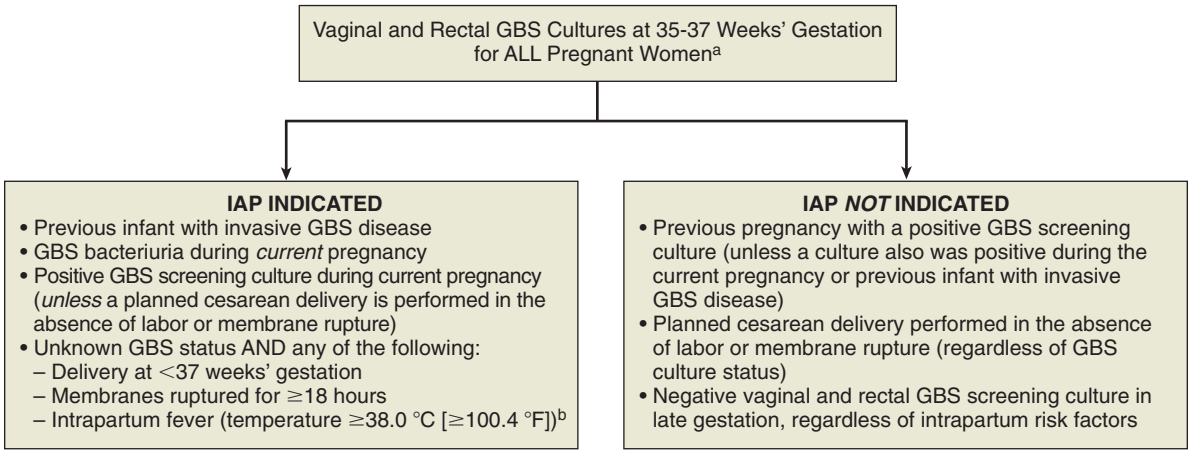
PERINATAL INFECTION

Early-Onset Bacterial Infection

The unique predisposition of the neonate to bacterial infection is related to defects in both innate and acquired immune responses.[64] The incidence of bacterial infection in infants younger than 5 days of age is 1 to 2 per 1000 live births. **Maternal colonization with group B streptococcus (GBS), rupture of membranes for more than 12 to 18 hours, and the presence of chorioamnionitis increase the risk of infection.**[65,66] Maternal fever from other etiologies (e.g., epidural anesthesia) does not increase the risk of neonatal infection and merits only close observation of the newborn. Irrespective of membrane rupture, infection rates are higher in preterm infants. The majority of early-onset bacterial infection presents on day 1 of life, with respiratory distress the most common presenting symptom. These infections are most often caused by GBS and gram-negative enteric pathogens. The algorithm for prevention of early-onset GBS infections is presented in Figure 21-17, with the approach to the newborn shown in Figure 21-18. Other etiologies of infection in the newborn are covered in Chapters 49-51.

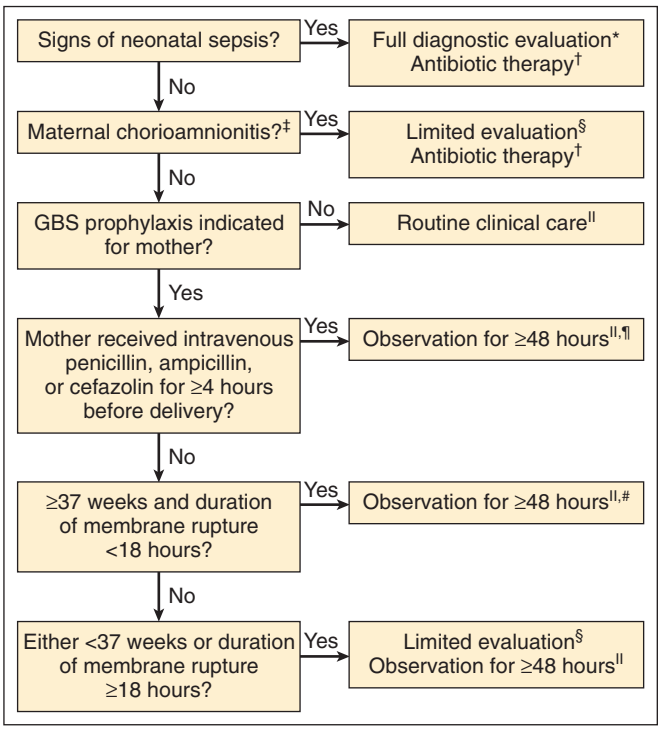
RESPIRATORY DISTRESS

The establishment of respiratory function at birth is dependent on expansion and maintenance of air sacs, clearance of lung fluid, and adequate pulmonary perfusion. In many



[a] Exceptions: women with GBS bacteriuria during the current pregnancy or women with a previous infant with invasive GBS disease.
[b] If chorioamnionitis is suspected, broad-spectrum antimicrobial therapy that includes an agent known to be active against GBS should replace GBS IAP.

FIGURE 21-17. Indications for intrapartum antimicrobial prophylaxis to prevent early onset GBS disease using a universal prenatal culture screening strategy at 35 to 37 weeks' gestation for all pregnant women. *GBS,* Group B streptococcus; *IAP,* intrapartum anitmicribial prophylaxis. (Reproduced from the American Academy of Pediatrics: RedBook 2003 Report of the Committee on Infectious Disease, 2009.)



* Full diagnostic evaluation includes a blood culture, a complete blood count (CBC) including white blood cell differential and platelet counts, chest radiograph (if respiratory abnormalities are present), and lumbar puncture (if patient is stable enough to tolerate procedure and sepsis is suspected).

† Antibiotic therapy should be directed toward the most common cause of neonatal sepsis, including intravenous ampicillin for GBS and coverage for other organisms (including *Escherichia coli* and other gram-negative pathogens) and should take into account local antibiotic resistance patterns.

‡ Consultation with obstetric providers is important to determine the level of clinical suspicionn for chorioamnionitis. Chorioamnionitis is diagnosed clinically and some of the signs are nonspecific.

§ Limited evaluation includes blood culture (at birth) and CBC with differential and platelets (at birth and/or at 6–12 hours of life).

‖ If signs of sepsis develop, a full diagnostic evaluation should be conducted and antibiotic therapy initiated.

¶ If ≥37 weeks'gestation, observation may occur at home after 24 hours if other discharge criteria have been met, access to medical care is readily available, and a person who is able to comply fully with instructions for home observation with be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48 hours and until discharge criteria are achieved.

Some experts recommend a CBC with differential and platelets at age 6–12 hours.

FIGURE 21-18. Algorithm for secondary prevention of early-onset GBS disease among newborns. (Reproduced from the Department of Health and Human Services Centers for Disease Control and Prevention. MMWR 59:RR-10, 2010.)

premature and other high-risk infants, developmental deficiencies or unfavorable perinatal events hamper a smooth respiratory transition. The presentation of respiratory distress is among the most common symptom complexes seen in the newborn and may be secondary to both noncardiopulmonary and cardiopulmonary etiologies (Table 21-12). The symptom complex includes an elevation of the respiratory rate to greater than 60 bpm with or without cyanosis, nasal flaring, intercostal and sternal retractions, and expiratory grunting. The retractions are the result of the neonate's efforts to expand a lung with poor compliance using a very compliant chest wall. The expiratory grunt is caused by closure of the glottis during expiration in an effort to increase expiratory pressure to help maintain functional residual capacity. The evaluation of such an infant requires use of history, physical examination, and laboratory data to arrive at a diagnosis. It is important to consider causes other than those related to the heart and lungs, because one's natural tendency is to focus immediately on the more common cardiopulmonary etiologies.

Cardiovascular Causes

Cardiovascular causes of respiratory distress in the neonatal period can be divided into two major groups—those with structural heart disease and those with persistent right-to-left shunting through fetal pathways and a structurally normal heart. **The two presentations of serious structural heart disease in the first week of life are cyanosis and congestive heart failure.**[67] Examples of cyanotic heart disease include transposition of the great vessels, tricuspid atresia, certain types of truncus arteriosus, total anomalous pulmonary venous return, and right-sided outflow obstruction including tetralogy of Fallot and pulmonary stenosis or atresia. Although cyanosis is the central feature in these disorders, tachypnea develops in many infants because of increased pulmonary blood flow or secondary to metabolic acidosis from hypoxia. Infants with congestive heart failure generally have some form of left-sided outflow obstruction (e.g., hypoplastic left heart syndrome, coarctation of the aorta). Left-to-right shunt lesions such as ventricular septal defect do not present with increased pulmonary blood flow and congestive heart failure until pulmonary vascular resistance is low enough to permit a significant shunt (usually 3 to 4 weeks of age at sea level). Infants with left-sided outflow obstruction generally do well the first day or so until the source of systemic flow, the ductus arteriosus, narrows. With ductal narrowing, dyspnea, tachypnea, and tachycardia develop, followed by rapid progression to congestive heart failure and metabolic acidosis. On examination, these infants have pulse abnormalities. With hypoplastic left heart syndrome and critical aortic stenosis, pulses are profoundly diminished in all extremities, whereas infants with coarctation of the aorta and interrupted aortic arch have differential pulses when the arms and legs are compared.

The syndrome of persistent pulmonary hypertension of the newborn (PPHN) occurs when the normal postnatal decrease in pulmonary vascular resistance does not occur, maintaining right-to-left shunting across the patent ductus arteriosus and foramen ovale.[19] Most infants with PPHN are full term or postmature and have experienced perinatal asphyxia. Other clinical associations include hypothermia, MAS, hyaline membrane disease (HMD), polycythemia, neonatal sepsis, chronic intrauterine hypoxia, pulmonary hypoplasia, and premature closure of the ductus arteriosus in utero.

On the basis of developmental considerations, these infants can be separated into three groups: (1) acute vasoconstriction caused by perinatal hypoxia, (2) prenatal increase in pulmonary vascular smooth muscle development, and (3) decreased cross-sectional area of the pulmonary vascular bed caused by inadequate vessel number. In

TABLE 21-12 RESPIRATORY DISTRESS IN THE NEWBORN

NONCARDIOPULMONARY	CARDIOVASCULAR	PULMONARY
Hypothermia or hyperthermia	Left-sided outflow obstruction	Upper airway obstruction
Hypoglycemia	Hypoplastic left heart	Choanal atresia
Metabolic acidosis	Aortic stenosis	Vocal cord paralysis
Drug intoxications; withdrawal	Coarctation of the aorta	Meconium aspiration
Polycythemia	Cyanotic lesions	Clear fluid aspiration
Central nervous system insult	Transposition of the great vessels	Transient tachypnea
Asphyxia	Total anomalous pulmonary venous return	Pneumonia
Hemorrhage	Tricuspid atresia	Pulmonary hypoplasia
Neuromuscular disease	Right-sided outflow obstruction	Primary
Werdnig-Hoffman disease		Secondary
Myopathies		Hyaline membrane disease
Phrenic nerve injury		Pneumothorax
Skeletal abnormalities		Pleural effusions
Asphyxiating thoracic dystrophy		Mass lesions
		Lobar emphysema
		Cystic adenomatoid malformation

the first group, an acute perinatal event leads to hypoxia and failure of pulmonary vascular resistance to drop. In the second, abnormal muscularization of the pulmonary resistance vessels results in PPHN after birth. The third circumstance includes infants with pulmonary hypoplasia (e.g., diaphragmatic hernia). Clinically, the syndrome is characterized by cyanosis, often unresponsive to increases in Fio_2, respiratory distress, an onset at less than 24 hours, evidence of right ventricular overload, systemic hypotension, acidosis, and no evidence of structural heart disease. There have been considerable advances in treatment for this condition using high-frequency ventilation, inhaled nitric oxide, and in refractory cases, extracorporeal membrane oxygenation.[19]

Pulmonary Causes

Of the causes of respiratory distress related to the airways and pulmonary parenchyma listed in Table 21-12, **the differential diagnosis in a term infant includes transient tachypnea, aspiration syndromes, congenital pneumonia, and spontaneous pneumothorax.** The syndrome of transient tachypnea presents as respiratory distress in nonasphyxiated term infants or slightly preterm infants. The clinical features include various combinations of cyanosis, grunting, nasal flaring, retracting, and tachypnea during the first hours after birth. The chest radiograph is the key to the diagnosis, with prominent perihilar streaking and fluid in the interlobar fissures. The symptoms generally subside in 12 to 24 hours, although they can persist longer. The preferred explanation for the clinical features is delayed reabsorption of fetal lung fluid. Transient tachypnea is seen more commonly in infants delivered by elective cesarean section or in the slightly preterm infant (see Mechanics of the First Breath, earlier).

At delivery, the neonate may aspirate clear amniotic fluid or fluid mixed with blood or meconium. Whether infants can aspirate a sufficient volume of clear fluid to cause symptoms is controversial. However, there are a group of infants whose clinical course is more prolonged (4 to 7 days) and severe than that of infants with transient tachypnea. These infants have a radiologic picture similar to transient tachypnea often associated with more marked hyperexpansion. Occasionally, the infiltrates are impressive, with evidence of far more fluid than is seen with transient tachypnea. MAS occurs in full-term or postmature infants. The perinatal course is often complicated by chronic intrauterine hypoxia, fetal distress, and low Apgar scores. These infants exhibit tachypnea, retractions, cyanosis, overdistended and barrel-shaped chest, and coarse breath sounds. Chest radiography reveals coarse, irregular pulmonary densities with areas of diminished aeration or consolidation. There is a high incidence of air leaks, and many of the infants exhibit persistent pulmonary hypertension.

The lungs represent the most common primary site of infection in the neonate. Both bacterial and viral infections can be acquired before, during, or after birth. The most common route of infection, particularly for bacteria, is ascending from the genital tract before or during labor. Infants with congenital pneumonia present with respiratory distress very early in life. The chest radiograph pattern is often indistinguishable from other causes of respiratory distress, particularly HMD.

Spontaneous pneumothorax occurs in 1% of all deliveries, but a much lower percentage results in symptoms. The risk is increased by manipulations such as positive-pressure ventilation. Respiratory distress is usually present from shortly after birth, and breath sounds may be diminished on the affected side. The majority of these air leaks resolve spontaneously without specific therapy.

HMD remains the most common etiology for respiratory distress in the neonatal period. It was the initial reports of Avery and Mead[68] demonstrating a high surface tension in extracts of lungs from infants dying of RDS that led to the present understanding of the role of surfactant in the pathogenesis of HMD. The deficiency of surfactant in the premature infant increases alveolar surface tension and, according to LaPlace's law (see Figure 21-2), increases the pressure necessary to maintain patent alveoli. The end result is poor lung compliance, progressive atelectasis, loss of FRC, alterations in ventilation-perfusion mismatch, and uneven distribution of ventilation. HMD is further complicated by the weak respiratory muscles and compliant chest wall of the premature infant. Hypoxemia and respiratory and metabolic acidemia contribute to increased pulmonary vascular resistance, right-to-left ductal shunting, and

TABLE 21-13 CUMULATIVE RESULTS OF PLACEBO-CONTROLLED SURFACTANT TRIALS*

	MODIFIED NATURAL† (%)		SYNTHETIC‡ (%)	
	Surfactant	Control	Surfactant	Control
Mortality	15	24	11	18
Patent ductus arteriosus	46	43	44	48
Severe ICH	19	19	7	8
Chronic lung disease	37	37	11	11

*Higher incidences of intracranial hemorrhage (ICH) and chronic lung disease in modified natural surfactant studies reflects the lower gestational age on average in both groups in these studies compared to the artificial surfactant studies.
†Studies with Survanta, Curosurf, and Infasurf; 2000 patients.
‡Studies with Exosurf; 4400 patients.

worsening ventilation-perfusion mismatch that exacerbate hypoxemia. Hypoxemia and hypoperfusion result in alveolar epithelial damage, with increased capillary permeability and leakage of plasma into alveolar spaces. Leakage of protein into airspaces serves to inhibit surfactant function, exacerbating the disease process. The materials in plasma and cellular debris combine to form the characteristic hyaline membrane seen pathologically. The recovery phase is characterized by regeneration of alveolar cells, including type II cells, with an increase in surfactant activity.

Clinically, neonates with HMD demonstrate tachypnea, nasal flaring, subcostal and intercostal retractions, cyanosis, and expiratory grunting. As the infant begins to tire with progressive disease, apneic episodes occur. If some intervention is not undertaken at this point, death ensues. The radiologic appearance of the lungs is consistent with an extensive atelectatic process. The infiltrate is diffuse, with a ground-glass appearance. Major airways are air filled and contrast with the atelectatic alveoli, creating the appearance of air bronchograms. The diaphragms are elevated because of profound hypoexpansion. Acute complications of HMD include infection, air leaks, and persistent patency of the ductus arteriosus.

Of more concern than acute complications are the long-term sequelae suffered by infants with HMD. The major long-term consequences are chronic lung disease (CLD) requiring prolonged ventilator and oxygen therapy, and significant neurologic impairment. In 1967, Northway et al.[69] first described the syndrome of bronchopulmonary dysplasia (BPD) in infants surviving severe HMD requiring mechanical ventilation. Today, many infants who develop CLD are extremely-low-birthweight infants who require prolonged ventilation for apnea and poor respiratory effort who initially did not have severe HMD. This is termed "new BPD" and the name differentiates this entity from that originally described by Northway, also called "old BPD." New BPD is characterized by a more uniform appearance with milder regions of injury compared to the old BPD. However, there are more prominent signs of impaired or arrested alveolarization and vascular growth, often described as alveolar simplification.[2,70] The incidence is especially high in infants born at less than 800 g. The severity is variable, ranging from very mild pulmonary insufficiency to severe disease with prolonged mechanical ventilation, frequent readmissions for respiratory exacerbations after nursery discharge, and a higher incidence of neurodevelopmental sequelae compared with very-low-birthweight controls. Although pulmonary function improves over time and most children do well, long-term pulmonary sequelae are evident. **Factors involved in the etiology of CLD are gestational age, elevated inspired oxygen concentration, ventilator volutrauma, severity of underlying disease, inflammation, and infection.**

Treatment for HMD involves supplemental oxygen, early use of nasal CPAP to maintain FRC, mechanical ventilation, and surfactant replacement therapy.[9] Modified natural surfactant, which is extracted by alveolar lavage or from lung tissue (usually bovine) and then modified by selective addition or removal of components, and true artificial surfactant, which is a mixture of synthetic compounds that may or may not be components of natural surfactant, have been used extensively. These agents (administered intratracheally) have shown efficacy in decreasing the severity of acute HMD and the frequency of air leak complications. Efficacy has been demonstrated when used in the delivery room to "prevent" or when used as a rescue treatment for established HMD. Although surfactant replacement therapy has decreased mortality and acute pulmonary morbidity, this therapy has not affected the frequency of other complications of prematurity (Table 21-13). Of note is that, despite resulting in lower ventilator settings and Fio_2 concentration over the first several days of life, the incidence of CLD has not been changed. However, the severity of long-term pulmonary complications is less. Long-term neurodevelopment follow-ups show rates of handicap similar to placebo-treated infants.

NEONATAL NEUROLOGY

Intraventricular Hemorrhage and Periventricular Leukomalacia

Periventricular/intraventricular hemorrhage (PVH/IVH) and periventricular leukomalacia (PVL) are the most common neurologic complications of prematurity. The overall incidence of PVH/IVH is 20% to 30% in infants weighing less than 1500 g or at less than 31 weeks' gestation with severe bleeds (grades 3 and 4) at 10%. The highest incidence is seen in babies of the lowest gestational age and birthweight; nearly 50% and 25%, respectively, for all IVH and severe bleeds for babies born at less than 700 g.[71] Bleeds are graded according to severity as indicated in Table 21-14. Diagnosis is confirmed with ultrasound. PVL is reported in about 2% to 4% of infants younger than 32 weeks' gestation,[71] but the cystic PVL reported likely underestimates the full spectrum of PVL (see later).

Bleeding originates in the subependymal germinal matrix located ventrolateral to the lateral ventricles in the

caudothalamic groove. The germinal matrix is made up of a meshwork of thin-walled vessels in the process of remodeling into a capillary network and a mass of undifferentiated cells that are destined to become cortical neurons, astrocytes, and oligodendroglia. Rupture of a germinal matrix hemorrhage into the ventricular system leads to intraventricular hemorrhage. A proposed pathogenesis derived from a review of available information is presented in Figure 21-19. The critical predisposing event is likely an ischemia-reperfusion injury to the vessels in the germinal matrix, which is a low blood flow region prone to ischemia. Furthermore, IVH is most reliably produced by a sequence of hemorrhagic hypotension followed by hypertension.[72] The amount of bleeding is then influenced by a variety of factors that affect the pressure gradient across the injured capillary wall. Likewise, for babies who manifest parenchymal bleeding (grade 4) and PVL, the inciting event is likely ischemia with reperfusion injury. The periventricular white matter is a border zone for cerebral blood flow in the preterm infant and is vulnerable to ischemic injury. Although cystic PVL (multifocal areas of necrosis with cyst formation in deep periventricular white matter) has been well characterized by ultrasound, the expanded use of MRI scans in preterm infants has identified infants (especially among those of lower gestational age) with diffuse white matter injury often accompanied by ventricular dilation at term.

TABLE 21-14 CLASSIFICATION OF INTRAVENTRICULAR HEMORRHAGE

GRADE	DEFINITION
I	Subependymal hemorrhage
II	Intraventricular hemorrhage without ventricular dilatation
III	Intraventricular hemorrhage with ventricular dilatation
IV	Intraventricular hemorrhage with associated parenchymal hemorrhage

Modified from Papile LA, Burstein J, Burstein R, Koffler H: Incidence and evolution of subependymal and intraventricular hemorrhage: a study of infants with birth weights less than 1500 g. J Pediatr 92:529, 1978.

These findings are far more common in the preterm population than cystic PVL and represent part of the spectrum of PVL. The other important clinical correlate of PVL is maternal chorioamnionitis and neonatal infection. Infection and ischemia are additive in the pathogenesis of PVL with the critical injury to preoligodendrocytes caused by reactive oxygen and nitrogen species.

There is also emerging evidence that secondary maturational and trophic disturbances also contribute to the evolution of this brain injury in the premature.[73]

The neurodevelopmental outcome of infants with IVH is related to the severity of the original bleed, development of posthemorrhagic hydrocephalus, and the degree of associated parenchymal injury. Although cranial ultrasound is the primary modality used to diagnose IVH and PVL, it is not a sensitive predictor of outcome. In extremely low-birthweight infants with no abnormalities on cranial ultrasound, nearly one third will have some degree of neurodevelopmental handicap (cerebral palsy or cognitive delays).[74] Infants with grade I or II IVH are at slightly greater risk for handicap.[75] School-aged children who had mild IVH display a variety of neurologic and cognitive abnormalities, including motor incoordination, hyperactivity, attention and learning deficits, and visual motor difficulties.[76] Infants with progressive ventricular dilatation (grade III) or periventricular hemorrhagic infarction (grade IV) are at higher risk for major neurodevelopmental handicap as well as less severe neurologic and cognitive disabilities.[77] The presence of severe cystic PVL carries a guarded prognosis with a high risk of cerebral palsy and associated cognitive deficit.

Although the incidence and severity of intracranial hemorrhage have progressively decreased as a result of advances in both obstetric and neonatal care, the therapeutic focus continues to be on strategies to prevent this complication of prematurity. Both antenatal and postnatal approaches have been developed. For the most part, postnatal pharmacologic strategies have not had a major effect in decreasing the incidence, severity, and neurodevelopmental

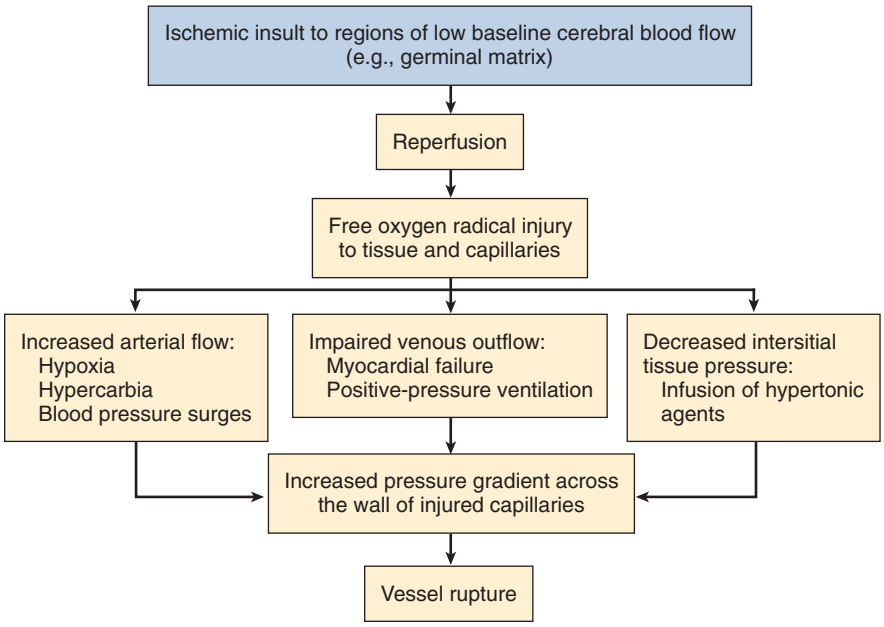


FIGURE 21-19. Pathogenesis of periventricular/intraventricular hemorrhage in the preterm infant.

outcomes of IVH. Because IVH and PVL are likely perinatal events, antenatal prevention holds the most promise. Both vitamin K and phenobarbital have been administered in this way. Antenatal phenobarbital resulted in a decrease in both frequency and severity of IVH. The proposed mechanism of action is thought to be scavenging of oxygen free radicals, although phenobarbital does decrease both brain blood flow and cerebral metabolic rate. However, two large randomized prospective studies failed to confirm the positive effects of phenobarbital shown in previous smaller studies.[78,79] One reason for the discrepancy is likely due to the widespread use of antenatal corticosteroids in the more recent studies. **Antenatal corticosteroids, although not used specifically to decrease the incidence of IVH and PVL, decrease the frequency of these complications and likely represent the most important antenatal strategy to prevent intracranial hemorrhage.**[5] Phenobarbital may still have a role in the mother who has not been "prepared" with betamethasone and is delivering at under 28 weeks' gestation.

Seizures

Newborns rarely have well-organized tonic-clonic seizures because of incomplete cortical organization and a preponderance of inhibitory synapses. Newborn seizures can be classified into four subtypes. The first is the subtle seizure characterized by ocular phenomena, oral-buccal-lingual movements, peculiar limb movements (e.g., bicycling movements), autonomic alterations, and apnea. Clonic seizures are characterized by rhythmic (one to three jerks per second) movements that can be focal or multifocal. The third seizure type is focal or generalized tonic seizures marked by extensor posturing. The fourth seizure type is myoclonic activity that is distinguished from clonic seizures by the more rapid speed of the myoclonic jerk and the predilection for flexor muscle groups. The differential diagnosis of neonatal seizures is presented in Table 21-15. The most frequent cause of neonatal seizures is hypoxic ischemic encephalopathy, with the second leading cause being intracranial hemorrhage. The prognosis for neonatal seizures depends on the cause. Difficult-to-control seizure activity, caused by hypoxic ischemic encephalopathy and hypoglycemic seizures in particular, have a high incidence of long-term sequelae.

TABLE 21-15 DIFFERENTIAL DIAGNOSIS OF NEONATAL SEIZURES

DIAGNOSIS	COMMENTS
Hypoxic-ischemic encephalopathy	Most common etiology (60%, onset first 24 hours)
Intracranial hemorrhage	≤15% of cases; PVH/IVH, subdural or subarachnoid bleeds, stroke
Infection	12% of cases
Hypoglycemia	SGA, IDM
Hypocalcemia, hypomagnesemia	Low-birthweight infant, IDM
Hyponatremia	Rare, seen with syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Disorders of amino and organic acid metabolism, hyperammonemia	Associated acidosis, altered level of consciousness
Pyridoxine deficiency	Seizures refractory to routine therapy; cessation of seizures after administration of pyridoxine
Developmental defects	Other anomalies, chromosomal syndromes
Drug withdrawal	
Benign familial neonatal seizures	
No cause found	10% of cases

IDM, Infant of diabetic mother.

CLASSIFICATION OF NEWBORNS BY GROWTH AND GESTATIONAL AGE

In assessing the risk for mortality or morbidity in a given neonate, evaluation of birthweight and gestational age together provide the clearest picture. When large populations are considered, maternal dates remain the single best determinant of gestational age. Early obstetric ultrasound is a very useful adjunct. However, in the individual neonate, especially when dates are uncertain, a reliable postnatal assessment of gestational age is necessary. A scoring system appraising gestational age on the basis of physical and neurologic criteria was developed by Dubowitz et al. and later simplified and updated by Ballard et al.[80] (Figure 21-20). The Ballard examination is less accurate before 28 weeks' gestation, but additional features can be examined to aid in the determination of an accurate gestational age. The anterior vascular capsule of the lens reveals complete coverage of the lens by vessels at 27 to 28 weeks. Foot length (from the heel to the tip of the largest toe) is 4.5 cm at 25 weeks and increases by 0.25 cm/wk. Infants can then be classified, using growth parameters and gestational age, by means of intrauterine growth curves such as those developed by Lubchenco et al.[81] (Figure 21-21). Infants born between 37 and 42 weeks are classified as term; less than 37 weeks, preterm; and greater than 42 weeks, postterm. In each grouping, infants are then identified according to growth as AGA if birthweight falls between the 10th and 90th percentiles, SGA if birthweight is below the 10th percentile, and LGA if birthweight is above the 90th percentile. Knowledge of a baby's birthweight in relation to gestational age is helpful in anticipating neonatal problems.

There are numerous causes of growth restriction (see Chapter 31). Those operative early in pregnancy such as chromosomal aberrations, congenital viral infections, and some drug exposures induce symmetric restriction of weight, length, and head circumference. In most cases, the phenomenon occurs later in gestation and leads to more selective restriction of birthweight alone. Such factors include hypertension or other maternal vascular disease and multiple gestation. Neonatal problems in addition to chromosomal abnormalities and congenital viral infections common in SGA infants include birth asphyxia, hypoglycemia, polycythemia, and hypothermia. In addition, congenital malformations are seen more frequently among undergrown infants.[82]

The most common identifiable conditions leading to excessive infant birthweight are maternal diabetes and maternal obesity. Other conditions associated with macrosomia are erythroblastosis fetalis, other causes of fetal

hydrops, and Beckwith-Wiedemann syndrome. LGA infants are at risk for hypoglycemia, polycythemia, congenital anomalies, cardiomyopathy, hyperbilirubinemia, and birth trauma.

NURSERY CARE

Nurseries are classified on the basis of level of care provided (see box, Levels of Nursery Care). Level I nurseries care for infants presumed healthy, with an emphasis on screening and surveillance. Level II nurseries can care for infants more than 32 weeks' gestation, who weigh at least 1500 g, and who require special attention, but will probably not need subspecialty services. Level III nurseries care for all newborn infants who are critically ill regardless of the level of support required.[83] A perinatal center encompasses both high-risk obstetric services and level III nursery services.

Care of the normal newborn involves observation of transition from intrauterine to extrauterine life, establishing breast- or bottle-feeds, noting normal patterns of stooling and urination, and surveillance for neonatal problems. Signs suggestive of illness include temperature instability, change in activity, refusal to feed, pallor, cyanosis, jaundice, tachypnea and respiratory distress, delayed (beyond 24 hours) passage of first stool or void, and bilious vomiting. In addition, the following laboratory screens should be performed: (1) blood type and direct and indirect Coombs' test on infants born to mothers with type O or Rh-negative blood; (2) glucose screen in infants at risk for hypoglycemia; (3) hematocrit in infants with signs and symptoms of anemia or polycythemia; and (4) mandated screening for inborn errors of metabolism, such as PKU and galactosemia, sickle cell disease, hypothyroidism, cystic fibrosis, and congenital adrenal hyperplasia. Many states now mandate or offer expanded newborn screening by tandem mass

Levels of Nursery Care

Level 1: A nursery with personnel and equipment to perform neonatal resuscitation, evaluate and provide newborn care for healthy infants, stabilize and provide care for infants born at 35-37 weeks' gestation who remain physiologically stable, and stabilize ill or less than 35 weeks' gestation infants before transport to a higher level facility.

Level 2: A facility able to provide care to infants born at more than 32 weeks' gestation weighing more than 1500 g who have physiologic immaturity; who are moderately ill with problems expected to resolve quickly; and who do not need urgent subspecialty care. Can provide convalescent care for infants after intensive care. A level 2A does not do mechanical ventilation or nasal continuous positive airway pressure, whereas a 2B can do short-term (less than 24 hours) ventilation.

Level 3: Provide care for the sickest and most complex infants.

3A: Care for infants beyond 28 weeks and 1000 g in need of conventional mechanical ventilation.

3B: Can provide care for infants less than 28 weeks and 1000 g, high-frequency ventilation, inhaled nitric oxide, on-site subspecialists, advanced imaging, on-site or nearby pediatric surgeons and anesthesiologists.

3C: Can provide ECMO and repair of complex congenital heart disease.

Modified from American Academy of Pediatrics Committee on Fetus and Newborn: Levels of neonatal care. Pediatrics 114:1341, 2004.
ECMO, Extracorporeal membrane oxygenation.

spectroscopy that looks for a variety of other inborn metabolic errors. All newborns should also have an initial hearing screen performed before discharge. Finally, babies routinely receive 1 mg intramuscular of vitamin K to prevent vitamin K–deficient hemorrhagic disease of the newborn and erythromycin ointment to prevent gonococcal ophthalmia neonatorum. Hepatitis B vaccine should be given to all newborns, and hepatitis B immunoglobulin is also administered to infants born to HB_sAg-positive mothers. Infants should be positioned supine for sleep to minimize the risk of sudden infant death syndrome.[84]

Discharge of the normal newborn is safe provided all criteria are met in the box entitled Infant Criteria for Early Discharge. The initial follow-up visit needs to occur 48 to 72 hours after discharge.[85]

Circumcision is an elective procedure to be performed only in healthy, stable infants. The procedure probably has medical benefits, including prevention of phimosis, paraphimosis, and balanoposthitis, as well as a decreased incidence of cancer of the penis, cervical cancer (in partners of circumcised men), sexually transmitted diseases (including HIV), and urinary tract infection in male infants. Most parents, however, make the decision regarding circumcision for nonmedical reasons. The risks of the procedure include local infection, bleeding, removal of too much skin, and urethral injury. The combined incidence of these complications is less than 1%. Local anesthesia (dorsal penile nerve block or circumferential ring block) with 1% lidocaine without epinephrine is safe and effective, and should always be used. Techniques that allow visualization of the glans throughout the procedure (Plastibell and Gomco clamp) are preferred to a "blind" technique (Mogen clamp) because of occasional amputation of the glans with the latter. Circumcision is contraindicated in infants with genital abnormalities. Appropriate laboratory evaluation should be performed before the procedure in infants with a family history of bleeding disorders.

Care of the Parents

Klaus and Kennell[86] outline these steps in maternal-infant attachment: (1) planning the pregnancy; (2) confirming the pregnancy; (3) accepting the pregnancy; (4) noting fetal movement; (5) accepting the fetus as an individual; (6) going through labor; (7) giving birth; (8) hearing and seeing the baby; (9) touching, smelling, and holding the baby; (10) caretaking; and (11) accepting the infant as a separate individual. Numerous influences can affect this process. A mother's and father's actions and responses are derived from their own genetic endowment, their own interfamily relationships, cultural practices, past experiences with this or previous pregnancies, and, most important, how they were raised by their parents. Also critical is the in-hospital experience surrounding the birth—how doctors and nurses act, separation from the baby, and hospital practices.

The 60- to 90-minute period after delivery is a very important time. The infant is alert, active, and able to follow with his or her eyes, allowing meaningful interaction to transpire between infant and parents. The infant's array of sensory and motor abilities evokes responses from the mother and initiates communication that may be helpful for attachment and induction of reciprocal actions. Whether a critical time period for these initial interactions exists is not clear, but improved mothering behavior does seem to occur with increased contact over the first 3 postpartum days. The practical implications of this information are that labor and delivery should pose as little anxiety as possible for the mother, and parents and baby should have time together immediately after delivery if the baby's medical condition permits.

Mothers with high-risk pregnancies are at increased risk for subsequent parenting problems. It is important for both obstetrician and pediatrician alike to be involved prenatally, allowing time to prepare the family for anticipated aspects of the baby's care as well as providing reassurance that the odds are heavily in favor of a live baby who will ultimately be healthy. If before birth one can anticipate a need for neonatal intensive care (known congenital anomaly, refractory premature labor), maternal transport to a center with a unit that can care for the baby should be planned. Before delivery, it is also very helpful to allow the parents to tour the unit their baby will occupy.

The basic principle in dealing with parents of a sick infant is to provide essential information clearly and accurately to both parents, preferably when they are together. With improved survival rates, especially in premature infants, most babies, despite early problems, will do well. Therefore, it is reasonable in most circumstances to be positive about the outcome. There is also no reason to emphasize problems that might occur in the future or to deal with individual worries of the

Infant Criteria for Early Discharge

1. Term newborn, defined as an infant born between 37 and 41 completed weeks of gestation.
2. No abnormalities that require continued hospitalization.
3. Vital signs are documented as being within normal ranges, with appropriate variations based on physiologic state, and stable for the 12 hours preceding discharge.
4. The infant has urinated regularly and passed stool spontaneously.
5. The infant has completed at least 2 successful consecutive feedings.
6. No significant bleeding at the circumcision site.
7. The clinical risk of development of subsequent hyperbilirubinemia has been assessed, and appropriate management and/or follow-up plans have been instituted.
8. The infant has been adequately evaluated and monitored for sepsis on the basis of maternal risk factors and in accordance with current guidelines for prevention of perinatal group B streptococcal disease.
9. Maternal blood test and screening results are available and have been reviewed, including maternal syphilis, hepatitis B surface antigen status; and a test for HIV in accordance with state regulations.
10. Infant blood tests are available and have been reviewed such as cord or infant blood type and direct Coombs' test results, as clinically indicated.
11. Newborn metabolic and hearing screenings have been completed per hospital protocol and state regulations.
12. The mother's knowledge, ability, and confidence to provide adequate care for her infant have been assessed for competency regarding:
    - breastfeeding or bottle feeding (the breastfeeding mother and infant should be assessed by trained staff regarding breastfeeding position, latch-on, and adequacy of swallowing).
    - the importance and benefits of breastfeeding for both mother and infant.
    - appropriate urination and defecation frequency for the infant.
    - cord, skin, and genital care, including circumcision care, for the infant.
    - the ability to recognize signs of illness and common infant problems, particularly jaundice.
    - infant safety (such as use of an appropriate car safety seat, supine positioning for sleeping, maintaining a smoke-free environment, and room sharing).
13. Family, environmental, and social risk factors have been assessed, and the mother and her other family members have been educated about safe home environment. These risk factors include but are not limited to:
    - untreated parental substance abuse or positive urine toxicology results in the mother or newborn.
    - history of child abuse or neglect.
    - mental illness in a parent who is in the home.
    - lack of social support, particularly for single, first-time mothers.
    - mothers who live in a shelter, a rehabilitation home, or on the street.
    - history of domestic violence, particularly during this pregnancy.
    - communicable illness in a parent or other members of the household.
    - adolescent mother, particularly if other above-listed conditions apply.
14. A medical home for continuing medical care for the infant has been identified and a plan for timely communication of pertinent clinical information to the medical home is in place. For newborns discharged less than 48 hours after delivery, an appointment should be made for the infant to be examined by a licensed health care professional, preferably within 48 hours of discharge based on risk factors but no later than 72 hours in most cases.
15. Barriers to adequate follow-up care for the newborn, such as lack of transportation to medical care services, lack of easy access to telephone communication, and non–English-speaking parents, have been assessed and, whenever possible, assistance has been given to the family to make suitable arrangements to address them.

physician. Questions, if asked, need to be answered honestly, but the list of parents' worries does not need to be voluntarily increased.

Before the parents' initial visit to the unit, a physician or nurse should describe what the baby and the equipment look like. When they arrive in the nursery, this can again be reviewed in detail. If a baby must be moved to another hospital, the mother should be given time to see and to touch her infant before the transfer. The father should be encouraged to meet the baby at the receiving hospital so he can become comfortable with the intensive care unit. He can serve as a link between baby and mother with information and photographs.

As a baby's course proceeds, the nursery staff can help the parents become comfortable with their infant. This can include participation in caretaking as well as skin-to-skin contact with the infant (kangaroo care). Individualized developmentally based care has also shown some benefit for high-risk infants.[87] It is also important for the staff to discuss among themselves any problems that parents may be having as well as to keep a record of visits and phone calls. This approach will allow early intervention to deal with potential problems.

The birth of an infant with a congenital malformation provides another situation in which staff support is essential. Parents' reactions to the birth of a malformed infant follow a predictable course. For most, there is initial shock and denial, a period of sadness and anger, gradual adaptation, and finally an increased satisfaction with and the ability to care for the baby. The parents must be allowed to pass through these stages and, in effect, to mourn the loss of the anticipated normal child.

The death of an infant or a stillborn is a highly stressful family event. This fact has been emphasized by Cullberg,[88] who found that psychiatric disorders developed in 19 of 56 mothers studied 1 to 2 years after the deaths of their neonates. One of the major predispositions was a breakdown of communication between parents. The

health care staff needs to encourage the parents to talk with each other, discuss their feelings, and display emotion. The staff should talk with the parents at the time of death and then several months later to review the findings of the autopsy, answer questions, and see how the family is doing.

OUTCOME OF NEONATAL INTENSIVE CARE AND THRESHOLD OF VIABILITY

More sophisticated neonatal care has resulted in improved survival of very-low-birthweight (<1500 g) infants, in particular those less than 1000 g (Figure 21-22). Current survival rates are 90% or greater for infants greater than 1000 g and 28 weeks' gestation, 85% at 800 to 1000 g and 26 to 27 weeks' gestation, and nearly 70% to 75% for infants 700 to 800 g and 25 weeks' gestation, with a considerable drop in survival below 700 g and 25 weeks.[89] **Predictions of survival can be significantly improved by consideration of clinical data in addition to birthweight and gestational age.** These data include an appropriate course of antenatal steroids, sex of the baby, and whether the pregnancy is singleton.[6] It is important to note that survival in terms of best obstetric estimate is greater at very low gestational ages than survival in terms of postnatal assessment of gestational age. The numbers in terms of best obstetric estimate based on data at the institution of birth should be referred to for antenatal counseling. This improved survival comes with a price, because a variety of morbidities are seen in these infants. The rate of severe neurologic disability is fairly constant at 10% of all very-low-birthweight survivors from 1000 to 1500 g. The number increases from 10% to 25% in infants of extremely low birthweight (<1000 g) and is particularly troubling for infants born at less than 25 weeks' gestation. In these infants, approximately half of the survivors have moderate or severe neurosensory disability (Figure 21-23).[89] In addition to the increase in severe disability, these infants have an increased rate of lesser disabilities including deficits in academic achievement, behavior and attention problems, and the need for special education in school.[90,91] Risk factors for neurologic morbidity include seizures, major intracranial hemorrhage or PVL, severe intrauterine growth restriction (IUGR), nec chorioamnionitis in the mother, neonatal infection, need for mechanical ventilation, CLD, poor early head growth, retinopathy of prematurity, and low socioeconomic class.

There are other morbidities that need to be considered as well. Because the number of survivors weighing less than 1000 g has increased, a reemergence of retinopathy of prematurity has been seen. This disorder, caused by retinal vascular proliferation leading to hemorrhage, scarring, retinal detachment, and blindness is triggered by low concentrations of insulin-like growth factor-1 (IGF-1) and relative hyperoxia in the early postnatal period leading to delayed retinal vessel growth. Later increases in IGF-1 allows a vascular endothelial growth factor (VEGF) induced angiogenesis resulting in an abnormal vascular

proliferation.[92] Incidence of acute proliferative retinopathy by birthweight is less than 10% in infants weighing more than 1250 g, 20% in those 1000 to 1250 g, 50% to 60% in those 750 to 1000 g, and 70% in those less than 750 g.[71] Severe retinopathy is evident in 5% of the infants 1000 to 1250 g, in 10% of infants 750 to 1000 g, and 25% to 40% of infants less than 750 g. Of the infants with severe retinopathy, 10% (4% of the total population) will go on to have severe visual problems. The other major neurosensory morbidity is hearing loss, which occurs in 2% of neonatal intensive care unit survivors. Other sequelae of neonatal intensive care include CLD, growth failure, short gut, and need for postdischarge rehospitalization.

The information presented earlier on outcome is relevant to discussions about obstetric and neonatal intervention at the threshold of viability. If one considers the end point of survival without major disability, this occurs in 0% at 22 weeks, less than 10% at 23 weeks, approximately 20% to 25% at 24 weeks, and approximately 45% to 50% at 25 weeks.[89] With this information in mind, most neonatologists believe that care is clearly beneficial beyond 25 completed weeks, whereas less than half believe that care is beneficial at 24 to 24 6/7 weeks, and virtually none believe that care is beneficial at less than 24 completed weeks. Having said that, more than half would intervene on behalf of an infant beyond 23 weeks' gestation. These discussions need to be modified depending on circumstances. For instance, morbidity and mortality would increase in the face of overt infection or severe IUGR. A reasonable approach would seem to be to encourage interventions on behalf of the fetus or newborn beyond 25 completed weeks' gestation and not intervene at less than 23 weeks gestation. The range between 23 and 25 weeks should be evaluated on a case-by-case basis.

THE LATE PRETERM INFANT

The rate of preterm births in the United States has been increasing, especially for births between 34 0/7 and 36 6/7 weeks, which now make up 70% of all preterm births. Of these births, as many as 23% had no recorded indication for early delivery noted on birth certificates.[93] **Compared with term infants, late preterm infants have a higher mortality and prevalence of acute neonatal problems including respiratory distress, temperature instability, hypoglycemia, apnea, jaundice, and feeding difficulties.**[94] The respiratory issues are caused by delayed clearance of fetal lung fluid, surfactant deficiency, or both, and can on occasion progress to respiratory failure. Feeding issues are caused by poor coordination of suck and swallow, which can interfere with bottle feeding and cause failure to establish successful breastfeeding. This can put the infant at risk for both dehydration and excessive jaundice. Late preterm infants have at least twice the risk of an infant born at term to have significantly elevated serum bilirubin concentrations. Rehospitalizations due to jaundice, proven or suspected infection, feeding difficulties, and failure to thrive are much more common than in term infants. Long-term neurodevelopmental outcome is also compromised with reports of cognitive and emotional regulation difficulties, school problems, and slightly lower IQs.[95] There is also an increase in deficits in lung function that may persist into adulthood due to immaturity of the respiratory system at birth.[96]

Late preterm infants, even if similar in size to their term counterparts, should be considered preterm rather than near term, and need close in-hospital monitoring for potential complications. Discharge of these babies should be delayed until they have demonstrated reliable oral intake and resolution of any acute neonatal problems. Initial outpatient follow-up visit should occur within 48 to 72 hours of discharge.

KEY POINTS

- Surfactant maintains lung expansion on expiration by lowering surface tension at the air-liquid interface in the alveolus.
- Respiratory distress syndrome in premature infants is in part caused by a deficiency of surfactant and can be treated with surfactant replacement therapy.
- Antenatal corticosteroids accelerate fetal lung maturation and decrease neonatal mortality and respiratory distress syndrome in preterm infants. In addition, corticosteroids are associated with a decrease in intracranial hemorrhage and NEC.
- Transition from intrauterine to extrauterine life requires removal of fluid from the lungs, switching from a fetal to neonatal circulation, and establishment of a normal neonatal lung volume.
- The most important step in neonatal resuscitation is to achieve adequate expansion of the lungs.
- MAS likely is the result of intrauterine asphyxia with mortality related to associated persistent pulmonary hypertension.
- The best predictor of neurologic sequelae of birth asphyxia is the presence of hypoxic ischemic encephalopathy in the neonatal period. The neurologic sequelae of birth asphyxia is cerebral palsy. However, the large majority of cerebral palsy is of unknown origin or etiologies other than perinatal asphyxia.
- The major neurologic complications seen in premature infants are PVH/IVH and PVL.
- Hypoglycemia is a predictable and preventable complication in the newborn.
- Survival, in particular for infants weighing less than 1000 g, has increased with improved methods of neonatal intensive care, but comes with the price of medical and neurodevelopmental sequelae.

Postpartum Thyroiditis	PPT

The postpartum time period, also called the *puerperium,* lasts from delivery of the placenta until 6 to 12 weeks after delivery. Most of the physiologic changes in pregnancy will have returned to their prepregnancy state by 6 weeks.[1] However, many of the cardiovascular changes and psychological changes may persist for many more months, and some such as changes in the pelvic musculature and cardiac remodeling will last for years. This chapter examines the physiologic adjustments of the postpartum period, the return of the female genital tract to its prepregnancy state (involution), the major puerperal disease states, and the natural course of lactation.

The postpartum period is associated with as much tradition and superstition as any other rite of passage in life because the health of a new infant is so important to the survival of any family or clan. In order to support the successful recovery of the mother and the healthy transition through the neonatal period, customs, taboos, and rituals have developed in most cultures. Indeed, many of the current medical recommendations about puerperium have developed from adaptations of socially acceptable traditions, rather than science. For example, the 6-week postpartum check approximates the end of the 40 days of rest and sexual separation required in traditional societies.

Cultures throughout the world have specific postpartum traditions that include both restrictions on activity and prescribed activities, different foods for the newly delivered mother, as well as particular and unique taboos regarding postpartum care (Table 22-1). For example, bathing after delivery is a taboo in some cultures. Because women often cherish these rituals, it is essential for physicians, midwives, and nurses to be sensitive to these customs even though a woman's place of delivery may be far from her native country.

This chapter examines the normal physiologic changes of the puerperium and the transitions to prepregnancy physiology. With respect to these changes, we evaluate the principles and practices of postpartum care, the role of the provider being to help the patient through the transition. As is true of most physiologic changes, disease may occur when the change is exaggerated or insufficient.

POSTPARTUM INVOLUTION

The Uterus

The crude weight of the pregnant uterus at term (excluding the fetus, placenta, membranes, and amniotic fluid) is about 1000 g, approximately 10- to 20-fold heavier than the nonpregnant uterus.[2] The specific time course of uterine involution has not been fully elucidated, but within 2 weeks after birth, the uterus has usually returned to the pelvis, and by 6 weeks, it is usually normal size, as estimated by palpation. The gross anatomic and histologic characteristics of the involutional process are based on the study of autopsy, hysterectomy, and endometrial biopsy specimens.[3] The decrease in the size of the uterus and cervix during the puerperium has been demonstrated with serial magnetic resonance imaging.[4] The findings are consistent with those of serial sonography and computed tomography.

Immediately after delivery, rapidly decreasing endometrial surface area facilitates placental shearing at the decidual layer. The average diameter of the placenta is 18 cm;

TABLE 22-1 EXAMPLES OF POSTPARTUM RITUALS

- In the rural Philippines, the mother, who works until she goes into labor, is prohibited from working after delivery, and she is given a new name. The maternal grandmother visits daily and does the housework and cooking for 8 weeks. The mother is bathed by the grandmother daily. When the umbilical cord falls off the infant, a feast is prepared. The cord is blessed at the feast. The new father is prohibited from building stone walls and from driving nails for 6 months. For 2 months, the relatives tend the fields.
- Postpartum taboos related to *hot and cold* are found worldwide.
  - In Asian, African, and Latin American cultures, heat and cold must be maintained in balance to promote health and prevent disease. Because blood, which is "hot," is lost during delivery, the parturient must replenish her "heat" by staying bundled and drinking warm liquids.
  - Several traditional Middle Eastern areas see the bones as open after delivery, and exposure to cold creates a vulnerability to disease. Bathing is often taboo for traditional women; sponge baths may be substituted.
  - In parts of rural India, the new mother returns to her mother's house for 16 weeks. She is given a hot bath every day. Cold baths are taboo because cold water is associated with disease.
  - Many cultures have rituals regarding treatment of the placenta. It may be dried and turned to powder for its "medical" powers. The umbilical cord was hung in a nearby tree by some eastern Native American tribes. In Eastern European tradition, it was buried under certain corners of the house, to ensure prosperity.

in the immediate postpartum uterus, the average diameter of the site of placental attachment measures 9 cm. In the first 3 days after delivery the placental site is infiltrated with granulocytes and mononuclear cells, a reaction that extends into the endometrium and superficial myometrium. By the 7th day, there is evidence of the regeneration of endometrial glands, often appearing atypical, with irregular chromatin patterns, misshapen and enlarged nuclei, pleomorphism, and increased cytoplasm. By the end of the first week, there is also evidence of the regeneration of endometrial stroma, with mitotic figures noted in gland epithelium; by postpartum day 16, the endometrium is fully restored.

Decidual necrosis begins on the first day, and by the seventh day, a well-demarcated zone can be seen between necrotic and viable tissue. An area of viable decidua remains between the necrotic slough and the deeper endomyometrium. Sharman[3] described how the non-necrotic decidual cells participate in the reconstruction of the endometrium, a likely role, given their original role as endometrial connective tissue cells. By the sixth week, decidual cells are rare. The immediate inflammatory cell infiltrate of polymorphonuclear leukocytes and lymphocytes persists for about 10 days, presumably serving as an antibacterial barrier. The leukocyte response diminishes rapidly after day 10, and plasma cells are seen for the first time. The plasma cell and lymphocyte response may last as long as several months. In fact, endometrial stromal infiltrates of plasma cells and lymphocytes are a sign (and may be the only sign) of a recent pregnancy.

Hemostasis immediately after birth is accomplished by arterial smooth muscle contraction and compression of vessels by the involuting uterine muscle. Vessels in the placental site are characterized during the first 8 days by thrombosis, hyalinization, and endophlebitis in the veins, and by hyalinization and obliterative fibrinoid endarteritis in the arteries. The mechanism for hyalinization of arterial walls, which is not completely understood, may be related to the previous trophoblastic infiltration of arterial walls that occurs early in pregnancy. Many of the thrombosed and hyalinized veins are extruded with the slough of the necrotic placental site, but hyalinized arteries remain for extended periods as stigmata of the placental site. Restoration of the endometrium in areas other than the placental site occurs rapidly, with the process being completed by day 16 after delivery. The gland epithelium does not undergo the reactivity or the pseudoneoplastic appearance noted in placental site glands.

The postpartum uterine discharge or lochia begins as a flow of blood lasting several hours, rapidly diminishing to a reddish brown discharge through the third or fourth day postpartum. This is followed by a transition to a mucopurulent, somewhat malodorous discharge, called *lochia serosa,* requiring the change of several perineal pads per day. The median duration of lochia serosa is 22 to 27 days.[5,6] However, 10% to 15% of women will have lochia serosa at the time of the 6-week postpartum examination. In most patients, the lochia serosa is followed by a yellow-white discharge, called *lochia alba*. Breastfeeding or the use of oral contraceptive agents does not affect the duration of lochia. Frequently, there is a sudden but transient increase in uterine bleeding between 7 and 14 days postpartum. This corresponds to the slough of the eschar over the site of placental attachment. Myometrial vessels of greater than 5 mm in diameter are present for up to 2 weeks postpartum, which accounts for the dramatic bleeding that can occur with this phenomenon.[6] Although it can be profuse, this bleeding episode is usually self-limited, requiring nothing more than reassurance of the patient. If it does not subside within 1 or 2 hours, the patient should be evaluated for possible retained placental tissue.

Ultrasound may be helpful in the management of abnormal postpartum bleeding. The empty uterus with a clear midline echo can often be distinguished from the uterine cavity expanded by clot (sonolucent) or retained tissue (echo dense)[7] (Figure 22-1). Serial ultrasound examinations of postpartum patients showed that in 20% to 30%, there was some retained blood or tissue within 24 hours after delivery. By the fourth postpartum day, only about 8% of patients showed endometrial cavity separation, a portion of which eventually had abnormal postpartum bleeding because of retained placental tissue.[8] In cases of abnormal postpartum bleeding, ultrasound examination may be a useful adjunct in detecting patients who have retained tissue or clot and, therefore, who will benefit from uterine evacuation and curettage. Those who have an empty uterine cavity will respond to therapy with oxytocin or methylergonovine.[9]

The Cervix

During pregnancy, the cervical epithelium increases in thickness, and the cervical glands show both hyperplasia and hypertrophy. Within the stroma, a distinct decidual reaction occurs. These changes are accompanied by a substantial increase in the vascularity of the cervix. Colposcopic examination performed after delivery has

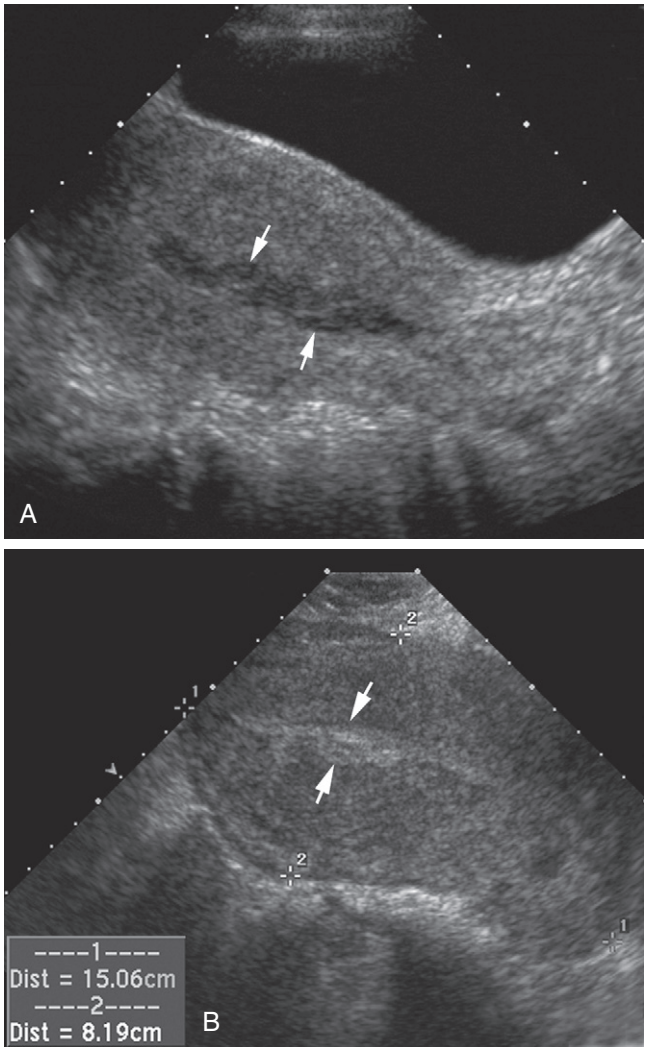

FIGURE 22-1. **A,** Sonogram of a normal postpartum uterus. **B,** Postpartum uterus with retained tissue. (From Poder L: Ultrasound evaluation of the Uterus. In Callen PW: Ultrasonography in Obstetrics and Gynecology, 5th ed. Philadelphia, Saunders, 2000, pp 939, 940.)

demonstrated ulceration, laceration, and ecchymosis of the cervix. Regression of the cervical epithelium begins within the first 4 days after delivery, and by the end of the first week, edema and hemorrhage within the cervix are minimal. Vascular hypertrophy and hyperplasia persist throughout the first week postpartum. By 6 weeks postpartum, most of the antepartum changes have resolved, although round cell infiltration and some edema may persist for several months.

The Fallopian Tube

The epithelium of the fallopian tube during pregnancy is characterized by a predominance of nonciliated cells, a phenomenon that is maintained by the balance between the high levels of progesterone and estrogen. After delivery, in the absence of progesterone and estrogen, there is further extrusion of nuclei from nonciliated cells and diminution in height of both ciliated and nonciliated cells. The number and height of ciliated cells can be increased in the puerperium by treatment with estrogen.

Fallopian tubes removed between postpartum days 5 and 15 demonstrate inflammatory changes of acute salpingitis in 38% of cases, but no bacteria are found. The specific cause of the inflammatory change is unknown. Furthermore, there is no correlation between the presence of histologic inflammation in the fallopian tubes and puerperal fever or other clinical signs of salpingitis.

Ovarian Function

Most women who breastfeed their infants are amenorrheic for extended periods of time, often until the infant is weaned. Several studies, using a variety of methods to indicate ovulation, have demonstrated that ovulation occurs as early as 27 days after delivery, with the mean time being about 70 to 75 days in nonlactating women.[10] Among women who are breastfeeding their infants, the mean time to ovulation is about 6 months.

Menstruation resumes by 12 weeks postpartum in 70% of women who are not lactating. The mean time to the first menstruation is 7 to 9 weeks. Depending on the population, as well as social and nutritional factors of the lactating women, regular menstruation may be delayed as long as 36 months. The duration of anovulation depends on the frequency of breastfeeding, the duration of each feed, and the proportion of supplementary feeds.[11] The likelihood of ovulation within the first 6 months postpartum, in a woman exclusively breastfeeding, is 1% to 5%.

The hormonal basis for puerperal ovulation suppression in lactating women appears to be the persistence of elevated serum prolactin levels. Prolactin levels fall to the normal range by the third week postpartum in nonlactating women but remain elevated into the sixth week postpartum in lactating patients. Estrogen levels fall immediately after delivery in both lactating and nonlactating women and remain depressed in lactating patients. In those who are not lactating, estrogen levels begin to rise 2 weeks after delivery and are significantly higher than in lactating women by postpartum day 17. Follicle-stimulating hormone (FSH) levels are identical in breastfeeding and nonbreastfeeding women, suggesting that the ovary does not respond to FSH stimulation in the presence of increased prolactin levels.

Weight Loss

One of the most welcome changes for most women who have recently given birth is the loss of the weight that was accumulated during pregnancy. The immediate loss of 10 to 13 lb is attributed to the delivery of the infant, placenta, and amniotic fluid and to blood loss. However, most women will not manifest that loss until 1 to 2 weeks after delivery because of fluid retention immediately after delivery. The physiologic stress of labor and delivery induces hormonal changes, including increased antidiuretic hormone, that lead to a short period of sodium and water retention. With operative birth, or epidural anesthesia with fluid boluses, the total body water increases dramatically. Women may be reassured that this temporary dependent edema is secondary to this fluid retention. For most women, weight loss postpartum does not tend to compensate for weight gain during gestation. By 6 weeks postpartum, only 28% of women will have returned to their

prepregnant weight. The remainder of any weight loss occurs from 6 weeks postpartum until 6 months after delivery, with most weight loss concentrated in the first 3 months. Women with excess weight gain in pregnancy (>35 lb) are likely to have a net gain of 11 lb. Breastfeeding has relatively little effect on postpartum weight loss. With a program of diet and exercise, weight loss of about 0.5 kg/week between 4 and 14 weeks postpartum in breastfeeding, overweight women did not affect the growth of their infants.[12] Similarly, aerobic exercise has no adverse effect on lactation.[13] In a longitudinal study of pregnancy weight gain, 540 women were followed for 5 to 10 years (mean, 8.5 years) after their index pregnancy. Women who returned to prepregnancy weight by 6 months after delivery were much more likely to have gained less weight at the 5- to 10-year follow-up compared with women who retained their pregnant weight gains. In this cohort, breastfeeding and aerobic exercise were associated with a significantly lower weight gain over time.[14] A study of 1656 deliveries in a retrospective cohort found that pregnant weight gain greater than the recommended amount was directly related to the increased weight of women 1 year later.[15] Phelan[16] has emphasized that pregnancy and postpartum are "teachable moments," ideal for counseling women about weight control.

Thyroid Function

Thyroid size and function throughout pregnancy and the puerperium have been quantitated with ultrasonography and thyroid hormone levels.[17] Thyroid volume increases about 30% during pregnancy and regresses to normal gradually over a 12-week period. Thyroxine and triiodothyronine, which are both elevated throughout pregnancy, return to normal within 4 weeks postpartum. For women taking thyroid medications, it is appropriate to check thyroid levels at 6 weeks postpartum to adjust dosing. It is now recognized that the postpartum period is associated with an increased risk for the development of a transient autoimmune thyroiditis that may in some cases evolve into permanent hypothyroidism. The relationship of subclinical thyroid dysfunction and postpartum depression is controversial.[18-20] Postpartum thyroiditis (PPT), an autoimmune disease that may present with hyperthyroid or hypothyroid symptoms, occurs in 2% to 17% of women, with a mean incidence about 10%. Women with type 1 diabetes have up to a 25% risk for PPT. Women with gestational diabetes and type 2 diabetes also have a slightly increased risk. Only that subset of women who develop symptoms should be treated. Puerperal hypothyroidism often presents with symptoms that include mild dysphoria; consequently, thyroid function studies are suggested in the evaluation of patients with suspected postpartum depression that occurs 2 to 3 months after delivery. Hyperthyroid symptoms are best treated with β-blockers, and hypothyroid symptoms with thyroid supplementation. Both are acceptable with breastfeeding. Methimazole and propylthiouracil are also safe with lactation. From 5% to 30% of women with PPT eventually develop hypothyroidism. If a woman becomes symptomatic and is treated, it is reasonable to stop medications after 1 year and reevaluate thyroid status before the patient considers becoming pregnant again.[18-20]

Cardiovascular System, Immunity, and Coagulation

Blood volume increases throughout pregnancy to levels in the third trimester about 35% above nonpregnant values. The greatest proportion of this increase consists of an expansion in plasma volume that begins in the first trimester and amounts to an additional 1200 mL of plasma, representing a 50% increase by the third trimester. Red blood cell volume increases by about 250 mL.

Immediately after delivery, plasma volume is diminished by about 1000 mL secondary to blood loss. By the third postpartum day, the plasma volume is replenished by a shift of extracellular fluid into the vascular space. In contrast, the total blood volume declines by 16% of the predelivery value, suggesting a relative and transient anemia. By 8 weeks postpartum, the red cell mass has rebounded and the hematocrit is normal in most women. As total blood volume normalizes, venous tone also returns to baseline. In a prospective evaluation of 42 women, at 4 and 42 days postpartum, significant reduction in deep vein vessel size and a concomitant increase in venous flow velocity in the lower extremities were observed.[21]

Pulse rate increases throughout pregnancy, as does stroke volume and cardiac output. Immediately after delivery, these remain elevated or rise even higher for 30 to 60 minutes. Following delivery, there is a transient rise of about 5% in both diastolic and systolic blood pressures throughout the first 4 days postpartum. Data are scant regarding the rate at which cardiac hemodynamics return to prepregnancy levels. Early studies suggested cardiac output had returned to normal when measurements were made 8 to 10 weeks postpartum. Clapp and Capeless[22] performed longitudinal evaluations of cardiac function at bimonthly intervals in 30 healthy women using M-mode ultrasound before pregnancy; during gestation; and at 12, 24, and 52 weeks postpartum. Cardiac output and left ventricular volume peaked at 24 weeks' gestation. There was a slow return to prepregnancy values over the year of study. However, even 1 year after delivery, there was a significantly higher cardiac output in both nulliparous and multiparous women than prepregnancy values. The authors suggested that this "cardiac remodeling" from pregnancy may last for an extended time in healthy women. Anecdotally, elite athletes have tried to take advantage of this physiologic boost to cardiac function by planning pregnancies a year before major sporting events.

Pregnancy is known to be a time of significantly increased coagulability that persists into the postpartum period.[23] The greatest level of coagulability is observed immediately postpartum through 48 hours. Fibrinogen concentrations gradually diminish over the first 2 weeks postpartum. Compared with antepartum values, there is a rapid decrease in platelets in some patients and no change or an increase in others. Within 2 weeks after delivery, the platelet count rises, possibly as a marker of increased bone marrow output as red cell mass is replaced. Fibrinolytic activity increases in the first 1 to 4 days after delivery and returns to normal in 1 week, as measured by levels of plasminogen activation inhibitor 1. D-dimer levels are increased over pregnancy levels and are a poor marker of thrombus formation. Protein-S levels and activated protein-C resistance are decreased for up to 6 weeks or longer. In general, tests for

thrombophilia and hemostasis should be delayed, if possible, for 10 to 12 weeks. The changes in the coagulation system, together with vessel trauma and immobility, account for the increased risk for thromboembolism noted in the puerperium, especially when an operative delivery has occurred.

The immune system, which is mildly suppressed during pregnancy, particularly cellular-mediated immunity, rebounds after delivery. This rebound may lead to "flare-ups" of autoimmune disease and latent infections with inflammatory reactions. The inflammatory reactions are what often produces the clinical symptoms. Autoimmune thyroiditis, multiple sclerosis, and lupus erythematosus are examples of some of the diseases that may show an increase in disease activity in the first few months postpartum.[24] Large cross-sectional studies of population databases have noted hospital admission rates after delivery to be higher than expected for age-matched controls. The readmissions are related to infections such as pneumonia, cholecystitis, and appendicitis. Postpartum admission rates vary from 0.8% to 1.5% for vaginal delivery and 1.8% to 2.7% for cesarean birth.[25-27]

The Urinary Tract and Renal Function

It is generally accepted that the urinary tract becomes dilated during pregnancy, especially the renal pelves and the ureters above the pelvic brim. These findings, demonstrated 70 years ago, affect the collecting system of the right kidney more than that of the left and are caused by compression of the ureters by the adjacent vasculature and enlarged uterus, combined with the effects of progesterone. Ultrasound studies of the urinary tract also document the enlargement of the collecting system throughout pregnancy. A study of serial ultrasound examinations of the urinary tract in 20 women throughout pregnancy included a single postpartum examination 6 weeks after delivery. The overall trend was that of dilation of the collecting system throughout pregnancy, estimated by measurements of the separation of the pelvicaliceal echo complex, from a mean of 5 mm (first trimester) to 10 mm (third trimester) in the right kidney and from 3 to 4 mm in the left collecting system. Measurements in all but two patients had returned to prepregnancy status at the time of the 6-week postpartum examination. With serial nephrosonography on 24 patients throughout pregnancy and the puerperium,[28] at 12 weeks postpartum, more than half of the patients demonstrated persistence of urinary stasis, described as a slight separation of the renal pelvis. This finding is evidence of hyperdistensibility and suggests that pregnancy has a permanent effect on the size of the upper renal tract. Intravenous urography studies also suggest that subtle anatomic changes take place in the ureters that persist long after the pregnancy has ended. Ureteral tone above the pelvic brim, which in pregnancy is higher than normal, returns to nonpregnant levels immediately after cesarean delivery.

Studies in which water cystometry and uroflowmetry were performed within 48 hours of delivery and again 4 weeks postpartum demonstrated a slight but significant decrease in bladder capacity (from 395.5 to 331 mL) and volume at first void (from 277 to 224 mL) in the study interval. Nevertheless, all the urodynamic values studied were within normal limits on both occasions. The results were not affected by the weight of the infant or by an episiotomy. However, prolonged labor and the use of epidural anesthesia appeared to diminish postpartum bladder function transiently.

The most detailed study of renal function in normal pregnancy is that of Sims and Krantz,[29] who studied 12 patients with serial renal function tests throughout pregnancy and for up to 1 year after delivery. Glomerular filtration, which increased by 50% early in pregnancy and remained elevated until delivery, returned to normal nonpregnant levels by postpartum week 8. Endogenous creatinine clearance, similarly elevated throughout pregnancy, also returned to normal by the eighth postpartum week. Renal plasma flow increased by 25% early in pregnancy, gradually diminished in the third trimester (even when measured in the lateral recumbent position), and continued to decrease to below-normal values in the postpartum period for up to 24 weeks. Normal values were finally established by 50 to 60 weeks after delivery. The reason for the prolonged postpartum depression of renal plasma flow is not clear. Because of the variable changes in renal clearance, mothers who are taking medications in which doses have been changed (because of the physiologic adaptations of pregnancy) will need to have medication levels rechecked. This should be done at 4 to 6 weeks postpartum.

Other Changes

Hair growth is altered in pregnancy and postpartum. After delivery, there is a more rapid hair turnover for up to 3 months. As a greater percentage of hair begins to undergo the growth phase, more hair falls out with combing and brushing. The loss is in a diffuse, not balding, pattern. This transient phenomenon is called *telogen effluvium,* and the patient may be reassured that her hair growth will return to normal within a few months and that the excess hair in the comb or brush will regrow.

Several investigators have reported on bone mineral changes with lactation and the associated amenorrhea. After delivery, there is a generalized decrease in bone mineralization that is temporary and resolves by 12 to 18 months postpartum in most women.[30] Bone loss appears to be greater in the femoral neck than in other areas of the skeleton.[31,32] Calcium supplementation does not seem to ameliorate the bone loss because it is not a problem of inadequate calcium stores, nor does exercise prevent it.[33] For almost all women, the bone loss is self-limited and reversible.

Management of the Puerperium

For most parturients, the immediate puerperium is spent in the hospital or birthing center. The ideal duration of hospitalization for patients with uncomplicated vaginal births has been controversial and culturally determined. During World War II, early discharge with nurse follow-up was initiated to support the "war bride" baby boom.[34] In the 1950s, the lying-in period after delivery was 8 to 14 days.[35] At present, most women stay in the hospital 24 to 48 hours after a vaginal birth. For patients with an uncomplicated postoperative course following cesarean delivery, the postpartum stay is 2 to 4 days. The optimal time is

dependent on a patient's needs and home support. About 3% of women who have vaginal deliveries and 9% of women who have cesarean deliveries have at least one childbirth-related complication requiring longer hospitalization after delivery or readmission to the hospital.[36] Studies that have evaluated the safety and outcomes of discharge before 48 hours have relied on nurse or midwife home visits. Unfortunately, most insurers do not cover this service.

In one study, 1249 randomly selected patients were questioned 8 weeks after delivery about health problems that occurred during the puerperium.[37] Eighty-five percent reported at least one problem during their hospitalization, and 76% noted at least one problem that persisted for 8 weeks. A wide range of problems were reported by the patients, including a painful perineum, difficulties with breastfeeding, urinary infections, urinary and fecal incontinence, and headache. Three percent of the patients had been rehospitalized, most commonly for abnormal bleeding or infection. This study draws attention to a substantial amount of symptomatic morbidity that occurs during the puerperium. Although longer hospitalization may not improve perineal pain or incontinence, open lines of communication with patients between discharge and the 6-week visit affect patient self-care and promote a more positive patient experience. In particular, lactation consultation may help to improve effective breastfeeding, and consideration should be given to postponing discharge in primiparas until this service can be performed.

If a patient has adequate support at home (i.e., help with housekeeping and meal preparation), there is little value in an extended hospital stay, provided the mother is adequately educated about infant care and feeding and in the identification of danger signs in either the infant or herself. Except for an increased incidence of rehospitalization of some neonates for hyperbilirubinemia, there are few disadvantages to postpartum hospitalization of less than 48 hours for many patients.[38-41] For mothers who do not have adequate support at home and who are insecure about infant care and feeding, extending the hospital stay will provide time for them to gain adequate education and some measure of self-confidence. Written and video presentations are also efficient means of patient education. To be most helpful, educational material should be presented both before delivery, sometime in the late third trimester, and at the postpartum discharge. Home nursing visits can be helpful in providing support, education, and advice to mothers in selected situations. Written materials or handouts are particularly necessary because memory is temporarily affected by the sleep deprivation that is the rule in the first few days after delivery.

Before discharge, women should be offered any vaccines that may be necessary to protect immunity. MMR (measles, mumps, and rubella) vaccine is given to rubella nonimmune mothers. Hepatitis B, Tdap (tetanus, diphtheria, and pertussis), MMR, and influenza are the four most common vaccines given. All are safe with breastfeeding.[42] Tdap should be given to all women regardless of the interval since the last Td,[43] and varicella vaccine initiated in those with a negative varicella titer.[42]

The time from delivery until complete physiologic involution and psychological adjustment has been called "the fourth trimester."[44] Patients should understand that lochia will persist for 3 to 8 weeks and that on days 7 to 14, there is often an episode of heavy vaginal bleeding, which occurs when the placental eschar sloughs. Tampons are permissible if they are comfortable upon insertion and are changed frequently and if there are no perineal, vaginal, or cervical lacerations, which preclude insertion of a tampon until healing has occurred. Physical activity, including walking up and down stairs, lifting moderately heavy objects, riding in or driving a car, and performing muscle-toning exercises can be resumed without delay if the delivery has been uncomplicated. Minig and associates reviewed the scientific evidence behind many postpartum recommendations.[45] They noted that very few, if any, of the traditional recommendations are evidence based. Lifting, sexual activity, driving, and exercise do not need to be overly restricted, even for women after cesarean births. Instructions regarding exercise are patient specific. Studies have found that exercise postpartum has no affect on lactation and may decrease anxiety levels as well as decrease symptoms of postpartum depression.[46-48] As such, exercise may have benefits beyond the mother's desire to "get back into shape." The most troublesome complaint is lethargy and fatigue. Consequently, every task or activity should be a brief one in the first few days of the puerperium. Mothers whose lethargy persists beyond several weeks must be evaluated, especially for thyroid dysfunction and postpartum depression.

Sexual activity may be resumed when the perineum is comfortable and when bleeding has diminished. The desire and willingness to resume sexual activity in the puerperium varies greatly among women, depending on the site and state of healing of perineal or vaginal incisions and lacerations, the amount of vaginal atrophy secondary to breastfeeding, and the return of libido,[49] which is greatly affected by sleep patterns among other new issues. Although the median time to resuming intercourse after delivery is 6 to 7 weeks, about half of women who do so have dyspareunia. In a substantial number, dyspareunia lasts for a year or more.[50,51] Signorello and coworkers[52] noted a 2.5-fold increased risk for dyspareunia 6 months after operative vaginal delivery compared with other subsets of postpartum women. For all women, breastfeeding at 6 months is associated with a more than fourfold increase in dyspareunia. Similarly, a large review of studies examining postpartum sexuality noted the greatest incidence of sexual dysfunction to be associated with operative vaginal delivery.[53] In contrast, 25% of all women reported a heightened sexual pleasure 6 months after delivery. Postpartum dyspareunia is not always related to vulvar trauma and occurs in some women who have a cesarean delivery. Dyspareunia has also been observed in women who use oral contraceptives and do not breastfeed, suggesting that lack of estrogen effect on the vagina is not the major cause of postpartum dyspareunia. In a study of 50 parturients, Ryding[54] found that 20% had little desire for sexual activity 3 months after delivery, and an additional 21% had complete loss of desire or aversion to sexual activity. This variation in attitude, desire, and willingness must be acknowledged when counseling women about the resumption of sexual activity. Women who breastfeed tend to begin intercourse later than average, and women who

deliver by cesarean section tend to begin sooner.[55] Clinicians commonly advise pregnant women on the use of vaginal lubricants for sexual activity in the first few months postpartum, because of the decreased natural lubrication with lower estrogen levels. This may be included in the written handouts given to patients when they go home. Astroglide gel and Comfort are more commonly recommended lubricants. KY Jelly is typically too dry. If patients are using barrier contraception, they should be advised against the use of petroleum-based lubricants such as Vaseline (Unilever, London, UK). If dyspareunia persists, a small amount of estrogen cream applied daily to the vagina may be helpful in breastfeeding women with atrophic changes. Clinicians may also counsel women about using different sexual positions with male partners, if deeper penetration is uncomfortable.[45]

Many patients return to work situations outside the home after their pregnancies. Frequently, the physician must complete insurance or employer forms to establish maternity leave for patients. As mentioned earlier, the 6-week return in the United States is derived from tradition, and 8 weeks are often allowed after a cesarean birth. Women will often experience discomfort, tiredness, and breast soreness well beyond 6 weeks. Similar to the return to exercise and sexual activity, the return to work should be individualized. Other nations and cultures have different standards for returning to prepregnancy routines. In China, 30 days is common, and in Western Europe and Canada, many months and even up to a year of maternity leave is offered.

HEALTH MAINTENANCE

The first follow-up visit is scheduled at the time of discharge. Many women without complications, who are multiparous, can be seen at 6 weeks. Other women, primiparous women, those with complicated labor and deliveries, those with increased pain, and those at risk for depression should be seen 2 weeks after discharge. At this visit, breastfeeding can be addressed as well as incisional checks and assessment of mood. Studies have shown that a routine postpartum visit to the physician at 1 or 2 weeks after delivery or a home visit by a nurse midwife does little to reduce maternal or infant morbidity.[56,57] However, for the patient with antepartum or intrapartum difficulties, this early postpartum visit or home visit by a nurse or nurse midwife is more productive in detecting problems and providing support for the mother. Thus, the need for this visit should be individualized.[58] Late puerperal infections, postpartum depression, and problems with infant care and feeding often occur before the 6-week postpartum visit. Open-ended questions should be asked to detect problems.

Women should also be seen about 6 weeks after delivery. At this visit, questions regarding depression, energy, sexuality, contraception, and future pregnancies should be addressed. Unfortunately, many women skip their 6-week postpartum check, deferring questions of contraception. A copy of the Edinburgh Postnatal Depression Scale (EPDS) is provided in Table 22-2. It may be used as a fast, reliable, and user-friendly tool to screen for depression. It is helpful to solicit questions about the delivery because women may be hesitant to ask them spontaneously, especially regarding sexuality and incontinence. If there are health issues that need addressing, such as glucose screens, thyroid levels, or other tests, they may be performed or scheduled at this visit.

Women with chronic medical diseases, such as collagen vascular disease, autoimmune disorders, and neurologic conditions, should be seen at close intervals because many patients with these disorders may experience flares of their symptoms after delivery. Ideally, these visits should be

TABLE 22-2 EDINBURGH POSTNATAL DEPRESSION SCALE

In the past 7 days:

1. I have been able to laugh and see the funny side of things:
   _ As much as I always could
   _ Not quite so much now
   _ Definitely not so much now
   _ Not at all
2. I have looked forward with enjoyment to things:
   _ As much as I ever did
   _ Rather less than I used to
   _ Definitely less than I used to
   _ Hardly at all
3. I have blamed myself unnecessarily when things went wrong:
   _ Yes, most of the time
   _ Yes, some of the time
   _ Not very often
   _ No, never
4. I have been anxious or worried for no good reason:
   _ No, not at all
   _ Hardly ever
   _ Yes, sometimes
   _ Yes, very often
5. I have felt scared or panicky for no very good reason:
   _ Yes, quite a lot
   _ Yes, sometimes
   _ No, not much
   _ No, not at all
6. Things have been getting on top of me:
   _ Yes, most of the time I haven't been able to cope at all
   _ Yes, sometimes I haven't been coping as well as usual
   _ No, most of the time I have coped quite well
   _ No, I have been coping as well as ever
7. I have been so unhappy that I have had difficulty sleeping:
   _ Yes, most of the time
   _ Yes, sometimes
   _ Not very often
   _ No, not at all
8. I have felt sad or miserable:
   _ Yes, most of the time
   _ Yes, quite often
   _ Not very often
   _ No, not at all
9. I have been so unhappy that I have been crying:
   _ Yes, most of the time
   _ Yes, quite often
   _ Only occasionally
   _ No, never
10. The thought of harming myself has occurred to me:
    _ Yes, quite often
    _ Sometimes
    _ Hardly ever
    _ Never

Response categories are scored 0, 1, 2, and 3 according to increased severity of the symptom. Items 3 and 5-10 are reverse scored (3, 2, 1, 0). The total score is calculated by adding together the scores for each of the 10 items.

From Cox JL, Holden JM, Sagovsky R: Detection of postnatal depression: development of the 10-item Edinburgh Postnatal Depression Scale. Br J Psychiatry 150:782, 1987.

scheduled in advance with the patient's primary care or subspecialty physician. Prophylactic therapy is not recommended for women with systemic lupus erythematosus or multiple sclerosis. However, warning patients to be attuned to signs and symptoms that reflect a flare of their illness allows for early and more effective interventions. For women with epilepsy, special attention to medication doses with the changing renal clearance is necessary. Additionally, increased postpartum sleep deprivation may induce a lower seizure threshold.

Perineal Care

Many women who give birth have lacerations of the perineum or vagina. In the United States, when an episiotomy is needed, it is more often performed as midline than as a mediolateral incision. Provided that the incision or the laceration does not extend beyond the transverse perineal muscle, that there is no hematoma or extensive ecchymosis, and a satisfactory repair has been accomplished, there is little need for perineal care beyond routine cleansing with a bath or shower. Analgesia can be accomplished in most patients with nonsteroidal anti-inflammatory drugs such as ibuprofen or naproxen sodium. These drugs are superior to acetaminophen or propoxyphene for episiotomy pain and uterine cramping. Furthermore, because of a low milk-to-maternal plasma drug concentration ratio, a short half-life, and transformation into glucuronide metabolites, ibuprofen is safe for nursing mothers.

A patient who has had a mediolateral episiotomy, third- or fourth-degree perineal laceration, periurethral lacerations, or extensive perineal bruising may experience considerable perineal pain.[59] Occasionally, the pain and periurethral swelling prevent the patient from voiding, making urethral catheterization necessary. When a patient complains of inordinate perineal pain, the first and most important step is to reexamine the perineum, vagina, and rectum to detect and drain a hematoma or to identify a perineal infection. Perineal pain may be the first symptom of the rare but potentially fatal complications of angioedema, necrotizing fasciitis, or perineal cellulitis.

In cases of moderate perineal pain, sitz baths will provide additional pain relief. Although hot sitz baths have long been customary therapy for perineal pain, there is rationale for using cold or "iced" sitz baths. This therapy is similar to that for the treatment of athletic injuries, for which considerable success has been achieved with cold therapy. Cold provides immediate pain relief as a result of decreased excitability of free nerve endings and decreased nerve conduction. Further pain relief comes from local vasoconstriction, which reduces edema, inhibits hematoma formation, and decreases muscle irritability and spasm. Patients who have alternated using hot and cold sitz baths usually prefer the cold. The technique for administering a cold sitz bath is first to have the patient sit in a tub of water at room temperature to which ice cubes are then added. This avoids the sensation of sudden immersion in ice water. The patient remains in the ice water for 20 to 30 minutes. Patients with perineal incisions or lacerations should be advised to postpone sexual intercourse until there is no perineal discomfort. Tampons may be inserted whenever the patient is comfortable doing so. However, to avoid any risk for toxic shock syndrome, the use of tampons should be confined to the daytime to prevent leaving a tampon in the vagina for prolonged periods.

Frequently, what appears to be severe perineal pain is, in fact, the pain of prolapsed hemorrhoids. Witch hazel compresses, suppositories containing corticosteroids, or local anesthetic sprays or emollients may be helpful. Occasionally, a thrombus occurs in a prolapsed hemorrhoid. It is a simple task to remove the thrombus through a small scalpel incision using local anesthesia by an obstetrician trained in this procedure or a general surgeon. Dramatic relief of pain usually follows this procedure. Stool softeners, laxatives, or both should be discussed for women with hemorrhoids.

Urinary and anal incontinence is a significant problem in women after delivery. Weidner and colleagues[60] studied 58 primiparous women after delivery. They found that 14 of 58 had levator ani neuropathy at 6 weeks. Seventeen of the 58 women had the neuropathy unresolved at 6 months postpartum. Elective cesarean delivery was protective for neuropathy in this series, yet labor with subsequent cesarean delivery was not protective. About one third of women at 8 weeks and 15% of women at 12 weeks have urinary incontinence. The incontinence, as would be expected, has a very detrimental effect on quality of life.[61] A strong predictor for incontinence after delivery is a history of prior urinary incontinence or new-onset incontinence during the index pregnancy. In addition to urinary incontinence, about 5% of women have anal incontinence 3 months after vaginal birth, with most experiencing flatal rather than fecal incontinence.[62,63] Forceps-assisted, but not vacuum-assisted, vaginal delivery is associated with an twofold increased risk for fecal incontinence in primparas.[64] Similarly, anal sphincter disruption in nulliparas is associated with a 2.3-fold increase in anal incontinence 5 years after delivery.[65] Nulliparous women with sphincter disruption or operative vaginal delivery should be screened specifically for symptoms at follow-up visits.

Perineal exercises were developed by Kegel in 1948 and involve voluntary contraction of the pelvic floor. A recent meta-analysis reviewed the effectiveness of perineal exercise in treating incontinence. Harvey's review[63] found that only when the exercises are performed with a vaginal biofeedback device was there improvement in the incidence of urinary incontinence. If symptoms of either urinary or flatal incontinence persist for more than 6 months, studies should be undertaken to define the specific neuromuscular or anatomic abnormality so that the appropriate pharmacologic, biophysical, or surgical treatment can begin. Women should be counseled regarding this plan at their postpartum visit so that they can return if symptoms persist.

Delayed Postpartum Hemorrhage and Postpartum Anemia

The causes and management of immediate postpartum hemorrhage are discussed in Chapter 19. Delayed postpartum uterine bleeding of sufficient quantity to require medical attention occurs in 1% to 2% of patients. One of the most common causes of postpartum hemorrhage that occurs 2 to 5 days after delivery is von Willebrand disease. Von Willebrand factor increases in pregnancy, and thus excessive bleeding usually does not occur in the first 48 hours after birth. Women presenting with bleeding more

than 48 hours after delivery should be screened for this condition.

Delayed bleeding occurs most frequently between days 8 and 14 of the puerperium.[66] Significant bleeding may require treatment with uterotonic agents or curettage. When suction evacuation and curettage are performed, retained gestational products, usually in small amounts, will be found in about 40% of cases.[67,68] Whether small placental remnants are the cause is not known. In the management of patients with heavy delayed bleeding, ultrasound examination usually determines whether there is a significant amount of retained material, although it is sometimes difficult to distinguish between blood clot and retained placental fragments (see Figure 22-1). Suction evacuation of the uterus is successful in arresting the bleeding in almost all cases whether or not there is histologic confirmation of retained gestational products. If curettage is required at this time, especially if a sharp curette is used, a course of broad-spectrum antibiotics with anaerobic coverage should be initiated before surgery, for their possible benefit in reducing the formation of uterine synechiae and the sequelae of Asherman syndrome. The curettage should be performed with care because the postpartum uterine wall is soft and easier to perforate. In those rare instances in which delayed postpartum hemorrhage does not respond to the use of oxytocic agents and curettage, selective arterial embolization may be effective in controlling the bleeding. Women with postpartum hemorrhage, and subsequent anemia, often have excessive fatigue in the postpartum period. Some investigators have advocated the use of recombinant erythropoietin as well as parenteral iron as alternatives to transfusion for symptomatic women with anemia.

Postpartum Infection

Although the standard definition of postpartum febrile morbidity is a temperature of 38° C (100.4° F) or higher on any two of the first 10 days after delivery, exclusive of the first 24 hours, most clinicians do not wait 2 full days to begin evaluation and treatment of patients who develop a fever in the puerperium. The most common cause of postpartum fever is endometritis, which occurs after vaginal delivery in about 2% of patients and after cesarean delivery in about 10% to 15%. The differential diagnosis includes urinary tract infection, lower genital tract infection, wound infections, pulmonary infections, thrombophlebitis, and mastitis. The diagnosis and management of postpartum infection are discussed in detail in Chapter 51. Almost all antibiotics are safe with lactation, and these are discussed in Chapter 8.

Maternal-Infant Attachment

Klaus and colleagues[69] were among the first investigators to study maternal-infant attachment and to bring attention to the importance of the first few hours of maternal-infant association. Their studies, as well as those of others, have contributed substantially to major changes in hospital policies dealing with patients in labor and delivery and postpartum. It is now recognized that there should be constant opportunities for parents to be with their newborns, particularly from the first few moments after birth and as frequently as possible during the first days thereafter. Immediate skin-to-skin contact is recommended. These associations are usually characterized by fondling, kissing, cuddling, and gazing at the infant, which are manifestations of maternal commitment and protectiveness toward her infant. Separation of mother and infant in the first hours after birth has been shown to diminish or delay the development of these characteristic mothering behaviors,[70] a problem that is intensified when medical, obstetrical, or newborn complications require intensive care for either the mother or her newborn infant.

Robson and Powell[71] summarized the literature on early maternal attachment and emphasized how difficult it is to perform valid research studies about this phenomenon, because of the multiple confounders. Although it is generally agreed that early association of the mother and infant is beneficial and should not be interfered with unnecessarily, there are still doubts about the long-term implications, if any, of a lack of early maternal-infant association. In their monograph summarizing their investigations about parent-infant attachment, Klaus and Kennel[72] warn against drawing far-reaching conclusions. Although favoring the theory of a "sensitive period" soon after birth, during which close parent-infant interaction facilitates subsequent attachment and beneficial parenting behavior, these investigators concur that humans are highly adaptable and state that "there are many fail-safe routes to attachment." Many hospitals and birth centers have recognized and placed emphasis on the mother-baby interactions in the first several hours after delivery. Delaying the first bath, eliminating well-baby nurseries, putting the baby onto the mother's chest in skin-to-skin contact (even during cesarean birth), and keeping the baby in the room with the mother during the first pediatric evaluation are all steps to support and promote that interaction.

The modern maternity unit should enhance and encourage parent-infant attachment by such policies as free visiting hours for the other parent and having the other parent rooming in with the mother and baby whenever possible, encouragement of the infant rooming with the mother, and strongly supportive attitudes about breastfeeding. These policies also allow the nursing staff to observe parenting behavior and to identify inept, inexperienced, or inappropriate behavior toward the infant. Some situations may call for more intensive follow-up by visiting nurses, home health visitors, or social workers to provide further support for the family during the posthospital convalescence. The role of postpartum home visits in enhancing parenting behavior is controversial. Gray and colleagues[73] found this approach beneficial. Siegel and coworkers[74] studied the effect of early and prolonged mother-infant contact in the hospital and a postpartum visitation program on attachment and parenting behavior. They found that early and prolonged maternal-infant contact in the hospital had a significant effect on enhancing subsequent parenting behavior, but the postpartum home visitations had no impact.

The development of the qualities associated with good parenting depends on many factors. Certainly, it does not depend solely on what transpires in the few hours surrounding the birth experience. There is evidence that specific identification of an infant with its mother's voice begins in utero during the third trimester. Furthermore,

the parents' own experiences as children, as well as their intellectual and emotional attitudes about children, must play a large role in their own parenting behavior. Areskog and associates[75] showed that women who expressed fear of childbirth during the antenatal period had more complications and more pain in labor and also had more difficulties in attachment to their infants. Consequently, the peripartum period provides opportunities to enhance parenting behavior and to identify families for which follow-up after birth may be necessary to ensure the most favorable child development. For example, adolescents, particularly primiparous adolescents, are a particularly high-risk group. Rates of domestic abuse are especially high in adolescent mothers.

In summary, the postpartum ward should be an environment that provides parents ample opportunity to interact with their newborn infant. Personnel, including nurses, nurses' aides, and physicians caring for mothers and infants should be alert to signs of abnormal parenting (e.g., refusal of the mother to care for the infant, the use of negative or abusive names in describing or referring to the infant, inordinate delay in naming the infant, or obsessive and unrealistic concerns about the infant's health). These or other signs that maternal-infant attachment is delayed or endangered are as deserving of frequent follow-up during the postpartum period as are any of the traditional medical or obstetric complications.

Lactation and breastfeeding are reviewed in detail in Chapter 23. All cultures have emphasized the importance of breastfeeding. There are multiple steps that should be taken during the postpartum period to promote and enhance breastfeeding. The use of audiovisual aids, telephone hotlines, and in-service training for personnel have been shown to increase the incidence of successful breastfeeding (see Chapter 23).

PREGNANCY PREVENTION AND BIRTH CONTROL

The immediate postpartum period is a convenient time for a discussion of family planning with patients; however, ideally these conversations should begin during prenatal care. The period of anovulation infertility lasts from 5 weeks in nonlactating women to 8 weeks or more in women who breastfeed their infants without supplementation. With exclusive breastfeeding, the pregnancy rate during lactational amenorrhea is 1% at 1 year postpartum.[76] Exclusive breastfeeding for this period of time is uncommon, and women are unlikely to know the actual duration they will breastfeed at hospital discharge. Even for women who leave the hospital breastfeeding exclusively, most will stop breastfeeding or begin supplementation by 6 weeks postpartum, especially if they return to work. Most women have resumed intercourse by 3 months, and for some, resumption of sexual activity begins much earlier.[77] Consequently, it is important that a decision be made about pregnancy prevention before the patient leaves the hospital, even though it is usually the last thing on a new mother's mind. Part of the discussion about contraception should include recommendations about pregnancy intervals. Short pregnancy intervals (time between births of less than 16 months) are associated with poorer sibling health, higher miscarriage rates, higher stillbirth rates, and many other adverse pregnancy outcomes.[78]

A patient should be made aware of the various options of pregnancy prevention and birth control in terms that she and her partner can understand. This may be done by individual instruction from nurses, physicians, or midwives or by a variety of films or videotapes. One study found that written material, plus a discussion, given at the time of hospitalization is most helpful to mothers. The decision about family planning methods depends on the patient's motivation, number of children, state of health, whether she is breastfeeding, and the religious background of the couple. It cannot be assumed that because a woman has used a method of contraception effectively before the current pregnancy she will need no counseling thereafter. More than half of patients change contraceptive techniques between pregnancies.

Natural Methods

The natural family planning methods, which depend on predicting the time of ovulation by use of basal body temperature or assessment of cervical mucus, cannot be used until regular menstrual cycles have resumed. In the first weeks or months following birth, provided there is little or no supplemental feeding for the infant, breastfeeding will provide 98% contraceptive protection for up to 6 months. At 6 months, or if menses return, or if breastfeeding ceases to be full or nearly full before the sixth month, the risk for pregnancy increases. Once regular menses have resumed, natural family planning methods, which depend on detection of the periovulation period using changes in cervical mucus or basal body temperature, or both, can be employed. However, it is important to note that a woman will have ovulated once before the resumption of normal menses as a warning flag. In women with regular cycles, for whom periods of abstinence are acceptable to her and to her partner, natural family planning techniques are associated with pregnancy rates very close to those for barrier methods of contraception (with spermicides).

Barrier Methods

Barrier methods of contraception and vaginal spermicides were long used in Europe and England before they were manufactured in this country beginning in the 1920s. The failure rate for the diaphragm varies from 2.4 to 19.6 per 100 woman-years. Because this method of contraception requires substantial motivation, instruction, and experience, it is more effective in older women who are familiar with the technique. The failure rate was 2.4 per 100 woman-years among diaphragm users who were older than 25 years of age and who had a minimum of 5 months' experience using it. The proper size of the diaphragm should be determined at the 6-week postpartum visit, even in patients who previously used this form of contraception. In women who are breastfeeding, anovulation leads to vaginal dryness and tightness, which may make the proper fitting of a diaphragm more difficult. The diaphragm should be used with one of the spermicidal lubricants, all of which contain nonoxynol-9.

The use of condoms alone or in combination with spermicides is often advised for women who wish to postpone a decision about sterilization or oral contraceptive therapy

until the postpartum visit. Pregnancy rates for the condom are reported to be from 1.6 to 21 per 100 woman-years, depending on the age and motivation of the population studied.

Hormonal Contraceptive Medications

The combined estrogen-progestin preparations have proved to be the most effective method of contraception, with pregnancy rates reported as less than 0.5 per 100 woman-years. Most compounds include 35 mcg or less of estrogen and varying amounts of progestins. Compounds containing the progestational components desogestrel, gestodene, or norgestimate appear to be less androgenic and have less impact on carbohydrate and lipid metabolism than compounds containing levonorgestrel or norethindrone. Cardiovascular complications, including hypertension, venous thrombosis, stroke, and myocardial infarction, have been substantially reduced with the reduction in estrogen content. The cardiovascular complications are found predominantly in women who smoke or have a family history of thromboembolic disease. However, all women have an increased risk for thrombosis in the early postpartum time period. In nonsmoking women, the risk-to-benefit ratio is clearly in favor of using oral contraceptive agents. This is particularly true when the additional benefits of these agents are considered, which include lowered risks for benign breast disease, ovarian and endometrial cancer, iron deficiency anemia, toxic shock syndrome, pelvic inflammatory disease, and ectopic pregnancy.

In patients who are not breastfeeding, combined hormonal contraceptive agents, oral, vaginal, or transdermal, can be taken as early as 2 to 3 weeks after delivery.[79] The effect of oral contraceptive agents on lactation is controversial. Controlled studies of the combined-type oral contraceptive agents with doses of ethinyl estradiol or mestranol of 50 mcg or more demonstrated a suppressive effect on lactation. The common contraceptives with 35 mcg or less of estrogen still have some suppressive effects. Progestin-only medications (e.g., norethindrone, 0.35 mg every day) do not diminish lactation performance and may, in fact, increase the quality and duration of lactation. There is no evidence that progestin-only contraceptive agents taken before the onset of lactation affect lactation success. A study by Halderman and Nelson[80] found that initiation of progestin-only contraception at the time of hospital discharge did not affect lactation patterns, incidence of supplementation, or discontinuation of breastfeeding. However, most clinicians begin low-dose progestin pills at 4 weeks postpartum. Depot medroxyprogesterone acetate (DMPA), 150 mg intramuscularly every 3 months, which has a contraceptive efficiency exceeding 99%, may be used with lactation as well.[81] The most troublesome side effect is unpredictable spotting and bleeding. The major advantages of this form of contraception are the ease of administration and patient convenience. Progestin-only oral contraceptives should be avoided in Hispanic women with gestational diabetes who are breastfeeding, because of an increased risk for the subsequent development of type 2 diabetes.[82]

Diaz and coworkers[83] studied the effect of a low-dose combination oral contraceptive containing 0.03 mg ethinyl estradiol and 0.15 mg levonorgestrel. The medication was begun after all women had been nursing for 1 month. Among those women taking the oral contraceptive medications, there was a small but significant decrease in lactation performance and in the weight gain of their infants compared with controls. In women whose motivation to breastfeed is marginal, the slight inhibition of lactation induced by oral contraceptive agents may be sufficient to discourage them from continuing to nurse their infants, so progestin-only preparations may be offered to these women. Combined hormonal vaginal rings begun less than 1 month after delivery may be problematic in some women, because of slower perineal and vaginal healing. However, in the nonlactating mother, use at 2 to 3 weeks is reasonable if there is no discomfort. Recent work by Espey and colleagues in a randomized controlled study showed similar effects on lactation between combined oral contraceptive and progestin only.[83a]

Levonorgestrel subdermal implants were approved by the U.S. Food and Drug Administration for contraceptive use in the United States in 1990.[84] Implants inserted 4 weeks after delivery have no effect on lactation or growth of an infant who is nursing, even though small amounts of levonorgestrel are excreted in the milk. Although the usual time of insertion is 4 to 6 weeks after delivery, the implants can be inserted in the immediate puerperium in women who are breastfeeding. Irregular uterine bleeding, expense, and the occasional difficulty in removing the implants are the major drawbacks to the use of this form of contraception. Despite the proven contraceptive effectiveness of levonorgestrel implants, there has been a decline in the perceived desirability of this method of birth control in recent years.[85] The contraceptive patch has not been well studied in the postpartum period for its effects on lactation. Many clinicians assume that it will have a lesser effect than oral contraceptives. Because it still may have some effects, it is reasonable to wait to initiate use after lactation has been established.

Intrauterine Devices

The copper-containing and progesterone-releasing intrauterine devices (IUDs) are highly effective in preventing pregnancy at rates that are comparable to tubal ligation (<1 pregnancy per 100 woman-years), yet with the added benefit of reversibility. The IUD is an ideal form of birth control in breastfeeding mothers, because of its lack of effect on milk production. Breastfeeding does not increase the risk for expulsion or other complications regardless of the time of insertion of the device. Significant complications of the IUD are infrequent and include uterine perforation (<0.7%), expulsion (5% to 10%), and discontinuation secondary to side effects (4% to 14%).[86] All women receiving an IUD should be counseled to present immediately to their physician if they suspect pregnancy so that the location of the pregnancy can be determined without delay.

Increased vaginal bleeding is noted in some women using copper-containing IUDs, but vaginal bleeding is decreased in women using progesterone-containing IUDs. Therefore, a woman's menstrual history is helpful in determining which type of IUD is ideal for her situation and decreasing copper IUD removal secondary to vaginal bleeding or dysmenorrhea.[87] Similarly, women who will be uncomfortable with amenorrhea should not be counseled

for a progesterone-containing IUD. Contraindications to IUD insertion include postpartum endometritis, uterine anomalies, incomplete uterine involution, and for IUDs containing copper, Wilson disease or a known allergy to copper. Syncope as a result of the vagal response at the time of IUD insertion is uncommon with IUD insertion at 6 weeks, given that the cervix remains slightly dilated.[88,89] Insertion of the IUD immediately after delivery is an alternative strategy.[90] Surprisingly, this practice is associated with fewer perforations than are insertions between 1 and 8 weeks. Not surprising, however, is the finding of a higher expulsion rate (10% to 21%).

The investigations of Alvarez and associates[91] convincingly support the concept that the principal mode of action of IUDs is by a method other than destruction of live embryos. Both the World Health Organization and the American College of Obstetricians and Gynecologists have reviewed the evidence and concluded that the IUD is not an abortifacient.[92]

Sterilization

Tubal sterilization is the most frequently used method of contraception in the United States. The puerperium is a convenient time for tubal ligation procedures to be performed in women who desire sterilization. The procedure can be performed at the time of a cesarean delivery or within the first 24 to 48 hours after delivery. In some hospitals, the operation is performed immediately after delivery in uncomplicated patients, especially when epidural anesthesia was given for labor analgesia. With the use of small paraumbilical incision, the procedure seldom prolongs the patient's hospitalization.

The 10-year failure rate of postpartum partial salpingectomy is 0.75%. There are several modifications of this procedure: the Pomeroy, Parkland, Uchida, and Irving (see Chapter 20). Because of the relaxed abdominal wall and the easy accessibility of the fallopian tubes, the minilaparotomy has the advantages of convenience and speed without the possible risks for visceral injury that might occur with the trocar of the laparoscope. More important than the type of procedure is the discussion with the mother about the timing of the procedure. Puerperal sterilization compared with interval sterilization is associated with an increased incidence of guilt and regret. Postponing tubal ligation procedures until 6 to 8 weeks after delivery is less convenient but does provide time to ensure that the infant is healthy and to review all the implications of the decision. Importantly, interval tubal ligation may not be covered by Medicaid in some states. Laparoscopic tubal ligation can be accomplished as an outpatient procedure, with a minimum of morbidity.

The risks of tubal ligation procedures, whether performed in the puerperium or as an interval procedure, include the short-term problems of anesthetic accidents, hemorrhage, injury of the viscera, and infection. These complications are infrequent, and deaths from the procedure occur in 2 to 12 per 100,000 procedures. Long-term complications are less well defined and more controversial. About 10% to 15% of patients have irregular menses and increased menstrual pain after tubal sterilization. This so-called posttubal syndrome is sufficiently severe in some cases to require hysterectomy. Well-controlled prospective studies, however, have failed to provide convincing evidence that these symptoms occur more commonly after tubal sterilization than in control patients of the same age and previous menstrual history.[93]

There has also been concern about poststerilization depression. Because depression is common in women of childbearing age and is even more common in the puerperium, it is unlikely that sterilization procedures are independent risk factors for depression. It is obvious, however, that the loss of fertility associated with a sterilization procedure will have important conscious and subconscious implications for many women. Therefore, it is not surprising that some patients manifest transient grief reactions in response to tubal ligation. The loss of libido that may occur in such situations may be frightening to some women and equally disturbing to their partners. Reassurance that such reactions are temporary and are not necessarily symptoms of a seriously disturbed psyche is an important means of support during this crisis. Both partners must be aware of the dynamics of this situation to avoid a sense of estrangement.

Obstetricians must remember that vasectomy is often a more advisable and desirable alternative for a couple considering sterilization.[94,95] It can be performed as an outpatient procedure under local anesthesia with insignificant loss of time from work or family. Furthermore, almost all the failures (about 3 to 4 per 1000 procedures) can be detected by a postoperative semen analysis. This is a decided advantage over the tubal ligation, in which failures are discovered only when a pregnancy occurs. Furthermore, vasectomy is less expensive and overall is associated with fewer complications. In addition, women whose husbands undergo vasectomy are less likely to have hysterectomies than are women who have had tubal sterilization.[96] Studies of long-term health effects of vasectomy found no evidence of an increased risk for atherosclerotic heart disease or other chronic illnesses.[94,97]

Tubal ligation can be reversed but is expensive and often not covered by insurance. A patient should not undergo sterilization if she is contemplating reversal. Success as measured by the occurrence of pregnancy following tubal reanastomosis varies from 40% to 85%, depending on the type of tubal ligation performed and on the length of functioning tube that remains. Success rates for vas reanastomosis vary from 37% to 90%, with higher success rates being associated with shorter intervals from the time of vas ligation.

Hysterectomy has been advocated as a means of sterilization that has the advantage of protecting the patient from future uterine or cervical cancer. However, the morbidity of cesarean or puerperal hysterectomy operations is sufficiently great to preclude their consideration for elective sterilization.[98]

POSTPARTUM PSYCHOLOGICAL REACTIONS

The psychological reactions experienced following childbirth include the common, relatively mild, physiologic, and transient "maternity blues" (50% to 70% of women), true depression occurring in 8% to 20% of women, and frank puerperal psychosis occurring in 0.14% to 0.26%. These problems are discussed in Chapter 52. In patients with underlying depression, in those with a previous history of postpartum depression, and in those who report

symptoms that develop during the immediate postpartum period, it is essential that a postpartum visit be scheduled sooner than the traditional 6 weeks. Other risk factors for postpartum depression include a family history of depression, a mother with postpartum depression, a poor social situation, and prolonged separation from her infant. The moderately depressed mother often experiences such guilt and embarrassment secondary to her sense of failure in her mothering role that she will be unable to call her physician or admit the symptoms of her depression. Consequently, ample time must be set aside to explore in depth even the slightest symptoms or sign of depression. Home visits in this situation may be appropriate to assess the patient. When a patient calls with a seemingly innocuous question, she should be asked two or three open-ended questions about her general status. These questions allow the patient to open up if there is an underlying depression that she is too guilty or afraid to express initially; for example:

1. How do you feel things are going?
2. How are things with the baby?
3. Are you feeling like you expected?

Because nursing staff often triage phone calls for physicians and midwives, it is important that such personnel be instructed to be alert to this protocol. Additionally, we recommend that both parents be warned before hospital discharge that if the maternity blues seem to be lasting longer than 2 weeks, or become "too tough" to handle, then either partner should call. An easy screening depression scale, the EPDS, is shown in Table 22-2. Puerperal thyroid disease will often present with symptoms that include mild dysphoria; consequently, thyroid function studies are suggested in the evaluation of patients with suspected postpartum depression that occurs 2 to 3 months after delivery.

MANAGING PERINATAL GRIEVING

For the most part, perinatal events are happy ones and are occasions for rejoicing. When a patient and her family experience a loss associated with a pregnancy, special attention must be given to the grieving patient and her family.

The most obvious cases of perinatal loss are those in which a fetal or neonatal death has occurred. Other, more subtle losses can be associated with a significant amount of grieving, such as the birth of a critically ill or malformed infant, an unexpected hysterectomy performed for intractable postpartum hemorrhage, or even a planned postpartum sterilization procedure. Grief occurs with any significant loss, whether it is the actual death of an infant or the loss of an idealized child in the case of the birth of a handicapped infant.

Mourning is as old as the human race, but the clinical signs and symptoms of grief and their psychological ramifications as they relate to loss suffered by women during their pregnancies have been given special consideration in recent years. In studying the relatives of servicemen who died in World War II, Lindemann recognized five manifestations of normal grieving. These include somatic symptoms of sleeplessness, fatigue, digestive symptoms, and sighing respirations; preoccupation with the image of the deceased; feelings of guilt; feelings of hostility and anger toward others; and disruption of the normal pattern of daily life. He also described the characteristics of what is now recognized as pathologic grief, which may occur if acute mourning is suppressed or interrupted. Some of the manifestations of this so-called morbid grief reaction are overactivity without a sense of loss; appearance or exacerbations of psychosomatic illness; alterations in relationships with friends and relatives; furious hostility toward specific persons; lasting loss of patterns of social interaction; activities detrimental to personal, social, and economic existence; and agitated depression.

Kennel and associates[99] studied the reaction of 20 mothers to the loss of their newborn infants. Characteristic signs and symptoms of mourning occurred in all the patients, even in situations in which the infant was nonviable. Similar grief reactions occurred in most of the parents of 101 critically ill infants who survived after referral to a regional neonatal intensive care unit, showing that separation from a seriously ill newborn is sufficient to provoke typical grief reaction. **Interestingly, studies over the last 15 years have found that women who do not see their stillborn infant actually have less depression; this suggests that best practice is to give mothers the choice of seeing their infant after delivery, and to hold their child, but not to necessarily encourage them to do it.**

It is important that the characteristics of the grieving patient be recognized and understood by health professionals caring for such patients; otherwise, substantial misunderstanding and mismanagement of the patient will occur. For example, if the patient's reaction of anger and hostility is not anticipated, a nurse or physician may take personally statements or actions by the patient or her family and avoid the patient at the very time she needs the most consolation and support. Because of their own discomfort with the implications of death, physicians, nurses, and others on the postpartum unit often find it uncomfortable to deal with patients whose fetus or infant has died. As a consequence, there is a reluctance to discuss the death with the patient and a tendency to rely on the use of sedatives or tranquilizers to deal with the patient's symptoms of grief. What is actually beneficial at such a time is a sympathetic listener and an opportunity to express and discuss feelings of guilt, anger, and hopelessness and the other symptoms of mourning.

It is not surprising that postpartum depression is more common and more severe in families that have suffered a perinatal loss. In one study, the prolonged grief response occurred more often in those women who became pregnant within 5 months of the death of the infant. This finding suggests that in counseling women after the loss of an infant, one should avoid the traditional advice of encouraging the family to embark soon on another pregnancy as a "replacement" for the infant who died. Just how long the normal grief reaction lasts is not known, and surely it varies with different families. Lockwood and Lewis[100] studied 26 patients who had suffered a stillbirth; they followed several patients for as long as 2 years. Their data suggest that grief in this situation is usually resolved within 18 months, invariably with a resurgence of symptoms at the first anniversary of the loss.

Somatic symptoms of grief, such as anorexia, weakness, and fatigue, are now well recognized; other psychological manifestations are also reported. Spontaneous abortion

TABLE 22-3 GUIDELINES FOR MANAGING PERINATAL LOSS

Keep parents informed; be honest and forthright.
Recognize and facilitate anticipatory grieving.
Inform parents about the grieving process.
Encourage support person to remain with the mother throughout labor.
Encourage the mother to make as many choices about her care as possible.
Support parents in seeing, touching, or holding the infant.
Describe the infant in detail, especially for couples who choose not to see the infant.
Allow photographs of the infant.
Prepare the couple for hospital paperwork, such as autopsy requests.
Discuss funeral or memorial services.
Assist the couple in how to inform siblings, relatives, and friends.
Discuss subsequent pregnancy.
Liberal use of follow-up home or office visits.

Modified from Kowalski K: Managing perinatal loss. Clin Obstet Gynecol 23:1113, 1980.

and infertility increase among couples who attempt to conceive after the loss of an infant. Physical changes that occur with grieving may account for this increase in poor reproductive success. Although the most intense suppression is noted within the first month after loss, a modified response may last for as long as 14 months.

The regionalization of perinatal health care has resulted in a large proportion of the perinatal deaths occurring in tertiary centers. In some of these centers, teams of physicians, nurses, social workers, and pastoral counselors have evolved to aid specifically in the management of families suffering a perinatal loss. Although this approach ensures an enlightened, understanding, and consistent approach to bereaved families, it suggests that the support of a grieving patient is a highly complex endeavor, to be accomplished only by a few specially trained individuals who care for postpartum patients. Enlightened and compassionate counseling of parents who have suffered a perinatal loss may be accomplished by any of the mother's health care professionals by using the guidelines listed in Table 22-3. Clearly, management of grief is not solely a postpartum responsibility. This is particularly true when a prenatal diagnosis is made of fetal death or fetal abnormality. A continuum of support is essential as the patient moves from the prenatal setting, to labor and delivery, to the postpartum ward, and finally to her home. Relaxation of many of the traditional hospital routines may be necessary to provide the type of support these families need. For example, allowing a loved one to remain past visiting hours, providing a couple a private setting to be with their deceased infant, or allowing unusually early discharge with provisions for frequent phone calls and follow-up visits often facilitates the resolution of grief.

It is also important to realize that the fathers of infants who die have somewhat different grief responses than do the mothers. In a study of 28 fathers who had lost infants, grief was primarily characterized by the necessity to keep busy with increased work, feelings of diminished self-worth, self-blame, and limited ability to ask for help. Stoic responses are typical of men and may obstruct the normal resolution of grief.

Postpartum Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) may occur after any physical or psychological trauma. The disorder commonly occurs after an unusual labor and delivery experience in which a woman is confronted with circumstances (pain, loss, trauma) that her defenses or sense of well-being cannot overcome. Thus, some women develop PTSD from an experience that other women will cope with easily, or that for the clinician may seem fairly unremarkable.

PTSD may lead to behavioral sequelae, including flashbacks, avoidance, and inability to function. Emergency operative deliveries, both vaginal and abdominal, and severe unexpected pain have been reported to have produced posttraumatic stress. The reaction may lead to fear of a subsequent delivery that may become incapacitating, as well as generalized symptoms of this disorder. Whenever an emergency procedure is indicated, debriefing afterward, both early and a few weeks later, may help to decrease the incidence of this problem. Women with adverse outcomes frequently experience transference of their previous experience as the next delivery approaches. One study of 1476 women who terminated pregnancies for fetal anomalies found that 46% of patients had PTSD at 4 months.[101] If anxiety is a predominant symptom at the postpartum visit, then discussions of a PTSD reaction may be indicated. The symptom complex of PTSD is less severe and sometimes eliminated with early intervention. Thus, if a woman seems to express psychological symptoms out of proportion to her labor and delivery experience, referral for further evaluation is appropriate.

KEY POINTS

- By 6 weeks postpartum, only 28% of women have returned to their prepregnant weight.
- About 50% of parturients experience diminished sexual desire during the 3 months following delivery.
- Postpartum uterine bleeding of sufficient quantity to require medical attention occurs in 1% to 2% of parturients. Of patients requiring curettage, 40% will be found to have retained placental tissue.
- Breastfeeding results in 98% contraceptive protection for up to 6 months after delivery, provided there is little or no supplemental feeding of the infant.
- Progestin-only contraceptive medication does not diminish lactation performance.
- Postpartum, major depression occurs in 8% to 20% of parturients; if possible, risk factors should be used to identify patients for increased screening and surveillance.
- Puerperal hypothyroidism often presents with symptoms that include mild dysphoria; consequently, thyroid function studies are suggested in the evaluation of patients with suspected postpartum depression that occurs 2 to 3 months after delivery.

Breastfeeding and breast milk are the global standard for infant feeding in undeveloped and developed countries. This statement is supported by the World Health Organization, the U.S. Surgeon General, the American Academy of Pediatrics,[1] the American College of Obstetricians and Gynecologists,[2] the American Academy of Family Practice, and the Academy of Breastfeeding Medicine. **The American Academy of Pediatrics has recently published an endorsement for breastfeeding at least through the first year of life and as an exclusive method for the first 6 months.**[1] The Healthy People 2020 (www.healthypeople.gov/2020) objectives (MICH 21.1-21.5, MICH 22.2) are as follows: any breastfeeding, 81.9%; any breastfeeding at 6 months, 60.6%; any breastfeeding at 12 months, 34.1%; exclusive breastfeeding at 3 months, 46.2%; exclusive breastfeeding at 6 months, 25.5%; and reduce the number of infants who receive supplemental formula in the first 48 hours by one half to 14.2%.

Unfortunately, we have challenges to meet these objectives; the majority of American infants are not breastfed exclusively nor for an appropriate duration. Figure 23-1 and Figure 23-2 describe the trends in breastfeeding behaviors in the United States. The latest estimates of breastfeeding performance (www.healthypeople.gov/2020) are that 74% of women initiate breastfeeding in the hospital and only 43.5% of those are still breastfeeding at 6 months. Approximately 23% of American infants meet the standard of breastfeeding 1 year or more. Only 33.6% and 14% of American infants are exclusively breastfeeding at 3 and 6 months, respectively; more than 24% received supplemental formula in the first 48 hours of life.

Specific populations are at greater risk for the failure to initiate and continue breastfeeding. **Women of lower socioeconomic status, those with less education, and teenagers initiate breastfeeding at about half to two thirds the rate of mature high-school graduates of middle and upper socioeconomic statuses (Table 23-1 and 23-2).**[3,4] **Fortunately, since 1989 more women at greatest risk for feeding their infants artificial breast milk are initiating breastfeeding in the hospital.**[4] Perceived breast milk insufficiency, sore nipples and breasts, the lack of family and professional support, and the decision to return to work are the most often cited reasons for early weaning. Cultural attitudes underlie many of these risk factors for failure to breastfeed successfully.

Although dysfunctional cultural and familial attitudes are outside the direct control of medicine, these attitudes may directly affect the care delivered by physicians. The normal function of the breasts, to produce breast milk, is muted by two cultural attitudes. One cultural attitude is the association of breasts with sexual attraction. The media is replete with examples that show beautiful, well-formed breasts as a sexual ideal. A corollary of this attitude is that breastfeeding will cause the breasts to sag and lose their sex appeal. The other opposing cultural attitude is that breastfeeding restricts self-fulfillment; mothers who stay

at home to breastfeed and care for their babies are considered poor examples of the modern, independent professional woman. These attitudes are exacerbated by a lack of knowledge about breastfeeding and lactation. The normal function of the breasts is excluded from the curriculum of primary and secondary schools on the basis of the connection between breasts and sex. After completion of their education, few women experience any examples of successful breastfeeding. Only 30% of grandmothers initiated breastfeeding (1970-1980), and few of these grandmothers have breastfed more than a few weeks. The lack of exposure to successful, experienced breastfeeding mothers seriously compromises the chances of success for today's women who attempt to breastfeed.

Physicians are products of the same culture as the women they help. Unfortunately, many have the same cultural biases as their patients and the same lack of primary and secondary education regarding the normal physiology of breastfeeding. The curricula of medical school and residency training programs contribute to the problem. Most physicians reflecting on their own education on breastfeeding will identify neither a structured curriculum nor practical experiences with successfully breastfeeding mother-infant dyads. At most, he or she has experienced only one or two lectures regarding breastfeeding, often focused on breast anatomy or the endocrinology of lactation. In fact, the most commonly cited resource for physicians is another nonmedical individual or a breastfeeding spouse. On obstetric rotations, medical students and obstetrics residents rarely see normal breastfeeding dyads longer than 1 to 3 days postpartum. On pediatric rotations, learners often see the baby only in the nursery and rarely see the normal mother breastfeed as an inpatient or at newborn visits. While pediatric residents observe and support the mother who pumps or nurses her growing preterm infant, the exposure is not normal, and often is negative. As a result, there are serious gaps in physician knowledge as they attempt to serve the over 3 million newborns and mothers per year who attempt to breastfeed. **A national survey of physician knowledge revealed that 20% to 40% of physicians (obstetricians, pediatricians, and family practitioners) did not know that breastfeeding is the "gold standard" for infant feeding, and similar percentages have serious and sometimes dangerous gaps in their knowledge in the management of breastfeeding problems. A survey of fellows of the American Academy of Pediatricians revealed that only 65% recommended exclusive breastfeeding during the first month of life, and more than half agreed with or had a neutral opinion about the statement that breastfeeding and formula-feeding are equally acceptable methods for feeding infants.**

The purpose of this chapter is to begin the educational process through which obstetricians will adopt the lactating mother as their patient. **In order to support the breastfeeding mother, the obstetrician must be convinced of the biologic superiority of breastfeeding and human breast milk over formula.** This chapter reviews breast anatomy and physiology of lactation in a framework pertinent to breastfeeding management. This chapter describes the vast differences between breast milk and formula, a difference directly related to unique needs and the short- and long-term health of the infant and mother. Specific issues related to the obstetrician (or other health care provider) will be addressed and include the role of the obstetrician in preconceptional counseling, prenatal care, delivery room management, and postpartum care for the breastfeeding mother.

BREAST ANATOMY AND DEVELOPMENT

The size and shape of the breast vary greatly by stage of development, physiologic state, and phenotype. The breast is located in the superficial fascia between the second rib and sixth intercostal cartilage in the midclavicular line. There is usually a projection of the central disk into each axilla, the *tail of Spence*. The mature breast weighs about 200 g in the nonpregnant state; during pregnancy, 500 g; and during lactation, 600 to 800 g. As long as glandular tissue and the nipple are present, the size or shape of the breast has little to do with the functional success of the breast. **The adequacy of glandular tissue for breastfeeding is ascertained by inquiring whether a woman's breasts have enlarged during pregnancy. If there is failure of the breast to enlarge as the result of pregnancy, especially if associated with minimal breast tissue on examination, the clinician should be wary of primary failure of lactation.**

The nipple, or *papilla mammae*, is a conical elevation in the middle of the areola, or *areola mammae*. The areola is a circular pigmented area, which darkens during pregnancy. The contrast with the fairer skin of the body provides a visual cue for the newborn who is attempting to latch-on. The areola contains multiple small elevations, *Montgomery's tubercles*, which enlarge during pregnancy and lactation. Montgomery's tubercles contain multiple ductular openings of sebaceous and sweat glands. These glands secrete lubricating and anti-infective substances (immunoglobulin A [IgA]) that protect the nipples and areola during nursing. These substances are washed away when the breasts and nipples are washed with soap or alcohol-containing compounds, leaving the nipple prone to cracking and infection.

Unlike the dermis of the body of the breast, which includes fat, the areola and nipple contain smooth muscle and collagenous and elastic tissue. With light touch or anticipation of nursing, these muscles contract and the nipple erects to form a teat. The contraction pulls the lactiferous sinuses into the nipple-areola complex, which allows the infant to milk the breast milk from these reservoirs.

The tip of the nipple contains the openings (0.4 to 0.7 mm in diameter) of 15 to 20 milk ducts (2 to 4 mm in diameter). Each of the milk ducts empties one tubuloalveolar gland, which is embedded in the fat of the body of the breast. A sphincter mechanism at the opening of the duct limits the ejection of milk from the breast. The competency of this mechanism is variable. About 20% of women do not demonstrate milk ejection from the contralateral breast when milk ejection is stimulated. If milk leakage is demonstrated from the contralateral breast during nursing, it is indicative of an intact let-down reflex and is highly suggestive of milk transfer to the infant.

Five to 10 mm from their exit, the milk ducts widen (5 to 8 mm) into the lactiferous sinuses (Figure 23-3). When these sinuses are pulled into the teat during nursing, the infant's tongue, facial muscles, and mouth squeeze the milk from the sinuses into the infant's oropharnyx.[5] The

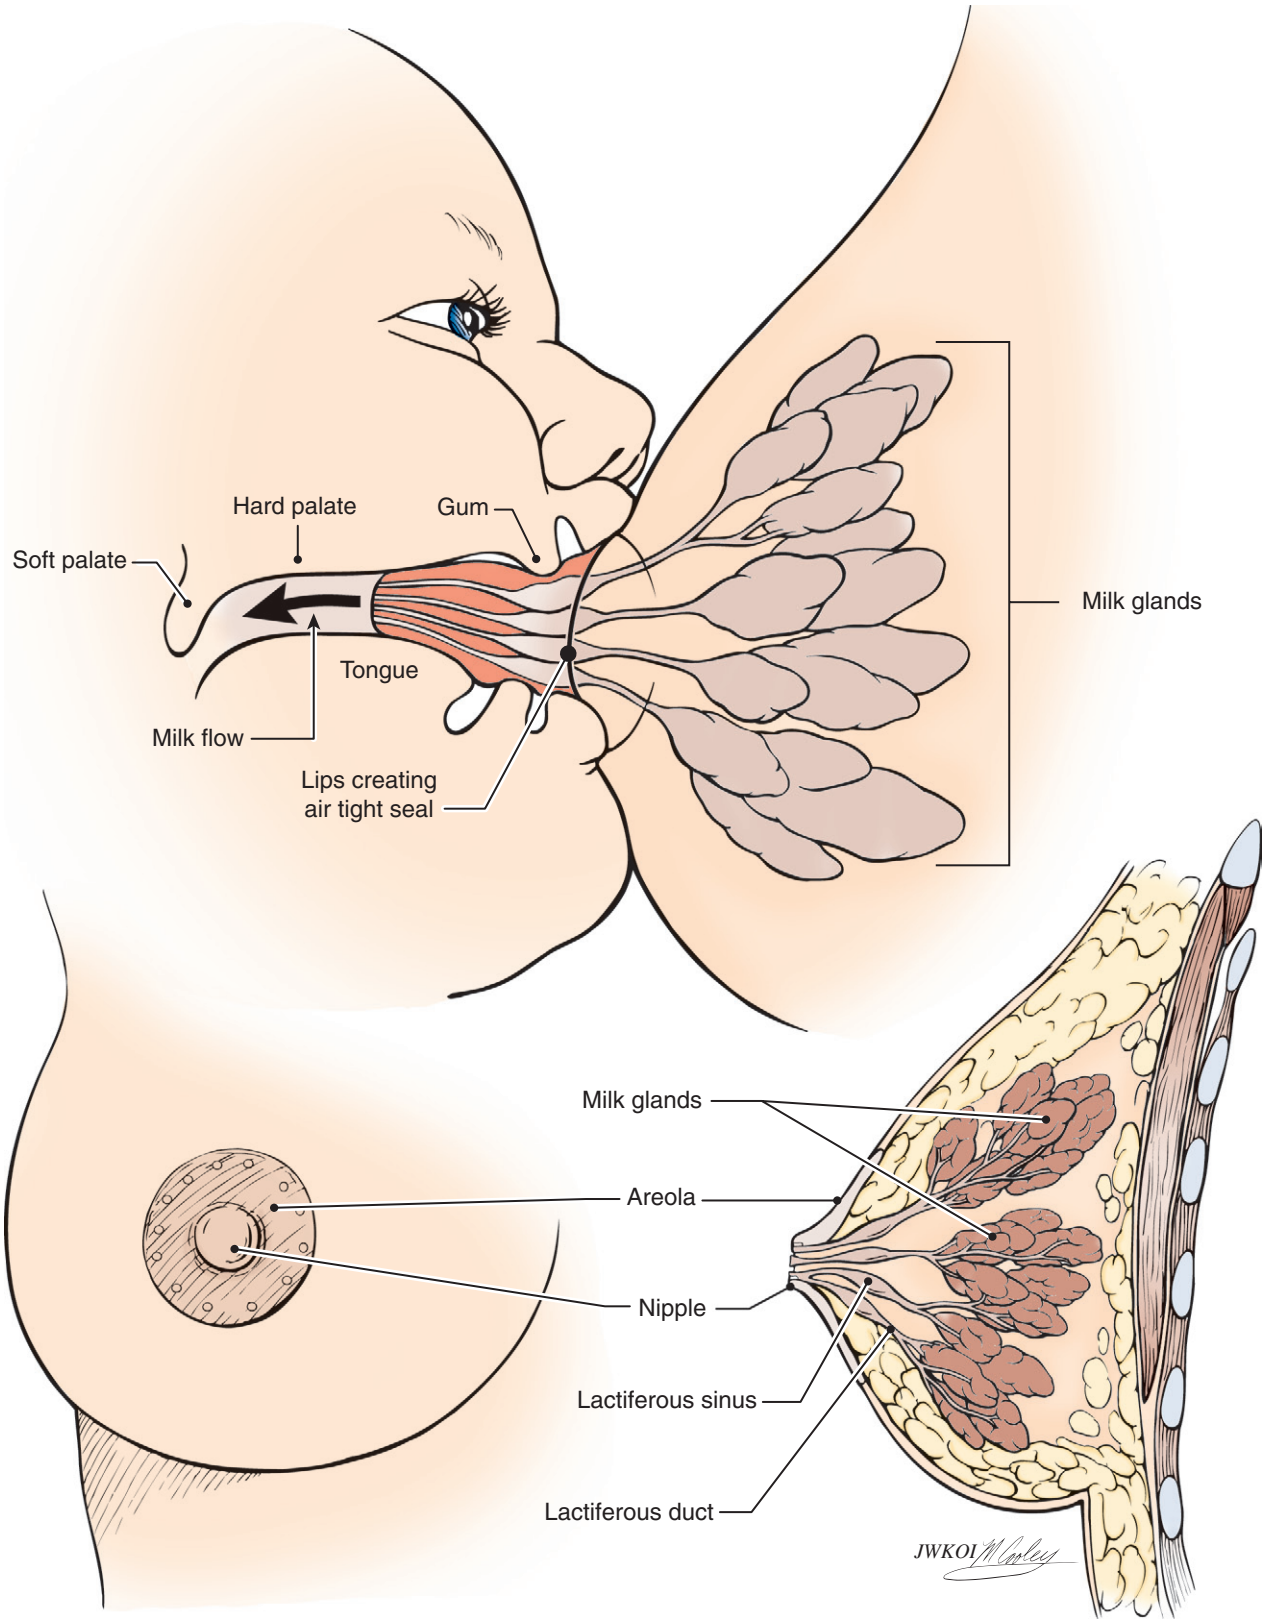

FIGURE 23-3. Anatomy of the breast.

tubuloalveolar glands (15 to 20) form lobi, which are arranged in a radial fashion from the central nipple-areola complex. The lobi and lactiferous ducts extend into the tail of Spence. Ten to 40 lactiferous ducts connect to each lactiferous sinus, each forming a lobulus. Each lobulus arborizes into 10 to 100 alveoli for tubulosaccular secretory units. The alveoli are the critical units of the production and ejection of milk. A sac of alveolar cells is surrounded by a basket of myoepithelial cells. The alveolar cells are stimulated by prolactin to produce milk. The myoepithelial cells are stimulated by oxytocin to contract and eject the recently produced milk into the lactiferous ducts, lactiferous sinuses, and beyond.

The radial projection of lactiferous ducts prompts important considerations relative to breast surgery on women who are breastfeeding or who will breastfeed. **Surgical skin incisions parallel to the circumareolar line, especially at the circumareolar line, have better cosmetic healing and are often chosen by surgeons. However, if the incision is taken deep into the parenchyma, the lactiferous ducts may be compromised; a superficial, parallel skin incision and a radial deep incision are preferred. In women who intend to breastfeed, a circumareolar incision is to be avoided. The incision compromises breastfeeding in three ways: occlusion of lactiferous ducts, restriction of the formation of a teat during nursing, and injury to the lateral cutaneous branch of the fourth intercostal nerve.**

Surgical disruption of the lateral cutaneous branch of the fourth intercostal nerve can have devastating effects on the success of breastfeeding.[6] This nerve is critical to the production and ejection of breast milk. Furthermore, the nerves provide organ-specific control of regional blood flow, and a tremendous increase in mammary blood flow occurs during a nursing episode. Disruption of this autonomic control may severely compromise lactation performance. The rate of breastfeeding failure is two to three times higher when a circumareolar incision has been performed. The obstetrician needs to be alert to old surgical incisions when a pregnant patient expresses a desire to breastfeed or when a breast biopsy is anticipated in a reproductive-aged woman.

As mammals, humans have the potential to develop mammary tissue (glandular or nipple tissue) anywhere along the milk line *(galactic band)*. The milk line extends from the axilla and inner upper arm to its current position, down the abdomen along the midclavicular line to the upper lateral mons and upper inner thigh. When accessory glands occur, this is termed hypermastia. This may involve accessory glandular tissue, supernumerary nipples, or both. Two to 6% of women have hypermastia, and the response to pregnancy and lactation is variable. **The most common site for accessory breast tissue is the axilla. These women may present at 2 to 5 days postpartum (galactogenesis) with painful enlargements in the axilla. Ice and symptomatic therapy for 24 to 48 hours is sufficient treatment. Supernumerary nipples *(polythelia)* are associated with renal abnormalities (11%).**

THE PHYSIOLOGY OF LACTATION

The best and most extensive research concerning the physiology of lactation focuses on the production of milk and has its roots in the research conducted by the multibillion-dollar dairy industry. Good milk-producing cattle, whose milk composition (i.e., milk fat percentage) can be controlled, create a competitive advantage in the marketplace. The translation of dairy research to human research plus the expected interest of pediatricians on infant nutrition has led to a preponderance of information on data on maternal milk production and delivery and its impact on neonatal and childhood outcomes. With the exception of the hypothalamic hypogonadism in the breastfeeding mother and its effect on menses and child spacing, very little is understood about the physiologic changes during the breastfeeding episode; these include vascular adaptation to the rapid production (10-30 minutes) of 100 to 200 mL of an extremely complex liquid. Most maternal benefits of breastfeeding are accrued in a dose-dependent fashion; the longer and the more intense (exclusive breastfeeding), the better the outcomes in terms of, for example, premenopausal breast cancer or cardiovascular disease. We are beginning to ask the question "why" and "how." Are the benefits of breastfeeding to the mother's health related to the duration of the hormonal changes? Is it the "antistress" effects of oxytocin? Is it the changes in gastrointestinal absorption of substrates? Is the intense pair-bonding between the mother and her breastfed children affecting allostatic load later in life? The answers to these questions will greatly improve our knowledge of the human experience.

The following sections summarize what is known about human lactation. The physiology of lactation has three major components: stages of lactogenesis, endocrinology of lactogenesis, and nursing behavior/milk transfer. Finally, the composition of mature human breast milk is summarized with a focus on the differences between breast milk and formula.

Stages of Lactogenesis

Full alveolar development and maturation of the breast must await the hormones of pregnancy (progesterone, prolactin, and human placental lactogen) for completion of the developmental process. By midpregnancy, the gland is competent to secrete milk (colostrum), although full function is not attained until the tissues are released from the inhibition of high levels of circulating progesterone. This is termed *lactogenesis stage 1*. Lactogenesis stage 2 occurs as the progesterone levels fall after delivery of the placenta, during the first 2 to 4 days after birth. Stage 2 includes dramatic increases in mammary blood flow and oxygen/glucose uptake by the breast. **At 2 to 5 days postpartum, the secretion of milk is copious and "the milk comes in." This is the most common time for engorgement if the breasts are not drained by efficient, frequent nursing.** Until lactogenesis stage 2 is developed, the breasts secrete colostrum. Colostrum is very different than mature milk in volume and constituents.[7] **Colostrum has more protein, especially secretory immunoglobulins, lactose, and lower fat content than mature milk.** Prolactin and glucocorticoids play important promoter roles in this stage of development.

After lactogenesis stage 2 (4 to 6 days postpartum) lactation enters an indefinite period of milk production formerly called galactopoiesis, now termed lactogenesis

stage 3. The duration of this stage is dependent on the continued production of breast milk and the efficient transfer of the breast milk to the infant. **Prolactin appears to be the single most important galactopoietic hormone, since selective inhibition of prolactin secretion by bromocriptine disrupts lactogenesis. Oxytocin appears to be the major galactokinetic hormone.** Stimulation of the nipple and areola or behavioral cues cause a reflex contraction of the myoepithelial cells that surround the alveoli and ejection of milk from the breast.

The final stage of development is involution and cessation of breastfeeding. As the frequency of breastfeeding is reduced to less than six episodes in 24 hours and milk volume is less than 400 mL/24 hr, prolactin levels fall and a cyclic pattern ends in the total cessation of milk production. After 24 to 48 hours of no transfer of breast milk to the infant, intraductal pressure[8] and lactation inhibitory factor[9] appear to initiate apoptosis of the secretory epithelial cells and proteolytic degradation of the basement membrane. Lactation inhibitory factor is a protein secreted in the milk, whose increasing concentration in the absence of drainage appears to decrease milk production by the alveolar cells.[10,11] It counterbalances pressures to increase milk supply (increased frequency of nursing) and allows for the day-to-day adjustment in infant demands.

The Endocrinology of Lactogenesis

Prolactin is the major hormone promoting milk production. Prolactin induces the synthesis of messenger RNAs (mRNAs) for the production of enzymes and milk proteins by binding to membrane receptors of the mammary epithelial cells. Thyroid hormones selectively enhance the secretion of lactalbumin. Cortisol, insulin, parathyroid hormone, and growth hormone are supportive metabolic hormones in the production of carbohydrates and lipids in the milk. Ovarian hormones are not required for the maintenance of established milk production and are suppressed by high levels of prolactin.

The alveolar cell is the principal site for the production of milk. Neville[12] describes five pathways for milk synthesis and secretion in the mammary alveolus, including four major transcellular and one paracellular pathway. They are (1) exocytosis (merocrine secretion) of milk protein and lactose in Golgi-derived secretory vesicles, (2) milk fat secretion via milk fat globules (apocrine secretion), (3) secretion of ions and water across the apical membrane, (4) pinocytosis-exocytosis of immunoglobulins, and (5) paracellular pathway for plasma components and leukocytes. During lactation as opposed to during pregnancy, very few of the constituents of breast milk are transferred directly from maternal blood. The junctions between cells, *tight junctions*, are closed. As weaning occurs, the tight junctions are released and sodium and other minerals easily cross to the milk, changing the taste of the milk.

The substrates for milk production are primarily absorbed from the maternal gut or produced in elemental form by the maternal liver. Glucose is the major substrate for milk production. Glucose serves as the main source of energy for other reactions and is a critical source of carbon. The synthesis of fat from carbohydrates plays a predominant role in fat production in human milk. Proteins are built from free amino acids derived from the plasma.

A sizable proportion of breast milk is produced during the nursing episode. In order to supply the substrates for milk production, there is increased blood flow to the mammary glands (20%-40%), gastrointestinal tract, and liver. Cardiac output is increased by 10% to 20% during a nursing episode. The vasodilation of the regional vascular beds is under the control of the autonomic nervous system. Oxytocin may play a critical role in directing the regional distribution of maternal cardiac output through an autonomic, parasympathetic action.

Given that milk is produced during the nursing episode, variation in content during a feed is expected. During a feeding episode the lipid content of milk rises by more than two- to threefold (1%-5%) with a corresponding 5% fall in lactose concentration.[12-15] The protein content remains relatively constant. At the extreme, there can be a 30% to 40% difference in the volume obtained from each breast.[15] Likewise, there are intraindividual variations in lipid and lactose concentrations.

The rising lipid content during a feed has practical implications in breastfeeding management. **If a woman limits her feeds to less than 4 minutes, but nurses more frequently, the calorie density of the milk is lower and the infant's hunger may not be satiated.** The infant wishes to feed sooner and the frequency of nursing accelerates. This stimulates more milk production and creates a scenario of a hungry infant despite apparent good volume and milk transfer. **Lengthening the nursing episode or using one breast for each nursing episode often solves the problem.**

The volume and concentration of constituents also vary during the day. Volume per feed increases by 10% to 15% in the late afternoon and evening. Nitrogen content peaks in the late afternoon and falls to a nadir at 5:00 A.M. Fat concentrations peak in the early morning and reach a nadir at 9:00 PM. Lactose levels stay relatively stable throughout the day. The variation in milk volume and content in working women who nurse only when at home has not been studied. Presumably, the variation in volume and content is preserved if the woman pumps during the day.

Does diet affect the volume and constitution of breast milk? For the average American woman with the range of diets from teenagers to mature, health-conscious adults, the answer is "no." There is no convincing evidence that the macronutrients in breast milk—protein, fats, and carbohydrates—vary across the usual range of American diets. Volume may vary in the extremes. In developing countries where there is widespread starvation and daily calorie intake is less than 1600 kcal during prepregnancy, and pregnancy in underweight breastfeeding mothers, milk volume and calorie density are minimally decreased (5%-10%), if at all.[16] In a controlled experiment,[17] well-nourished European women reduced their calorie intake by 33% for 1 week. Milk volume was not reduced when the diet was maintained at greater than 1500 kcal/day. If the daily energy intake was less than 1500 kcal/day, milk volume was reduced 15%. **Moderate dieting and weight loss postpartum (4.5 lb/mo) are not associated with changes in milk volume,**[18,19] **nor does aerobic exercise have any adverse effect.**[18,19]

In the first year of life, the infant undergoes tremendous growth; infants double their birth weight in 180 days. Infants fed artificial breast milk lose up to 5% of their birthweight during the first week of life, while breast-milk-fed infants lose about 7% of their birthweight. A maximum weight loss of 10% of birthweight is tolerated in the first week of life in breastfed infants. If this threshold is exceeded, the breastfeeding dyad needs immediate intervention by a trained health care provider. While supplementation with donor breast milk or artificial breast milk may be a necessary part of the intervention, the key focus of intervention is establishing good breast milk transfer by ensuring adequate production, correct nursing behavior, and adequate frequency. Once stage 3 of lactogenesis occurs, "the milk has come in"; the term breastfed infant will gain about 0.75 to 1 oz/day with adequate milk transfer. **By 14 days, the breastfed infant should have returned to birthweight.**

Food intake and energy needs are not constant. The infant's need for energy and/or fluids varies by day or week with growth spurts, greater activity, fighting illness, or greater fluid losses as in hot weather. Mammals have developed an extremely efficient mechanism to adjust milk supply within 24 to 48 hours depending on demand via oxytocin and the let-down reflex (Figure 23-4), and prolactin production. The prolactin and oxytocin travel to their target cells, prolactin to the alveolar epithelium in the breast, and oxytocin to the myoepithelial cells that shroud the alveolar epithelium. In lactating women, baseline prolactin levels are 200 ng/mL at delivery, 75 ng/mL between 10 and 90 days postpartum, 50 ng/ml between 90 and 180 days postpartum, and 35 ng/mL after 180 days postpartum. Maternal serum prolactin levels rise by 80% to 150% of baseline levels within seconds of nipple stimulation. As long as nursing frequency is maintained at more than eight episodes a day for 10 to 20 minutes with each episode in 24 hours, the serum prolactin levels will suppress the luteinizing hormone (LH) surges and ovarian function.[12,20]

Serum oxytocin levels also rise with nipple stimulation. However, the oxytocin response is much more affected by operant conditioning, and its response may precede the rise in prolactin levels. The maternal cerebrum is influenced by exposure to nursing cues as well as the influences of nipple stimulation. The cerebrum either stimulates or inhibits the hypothalamus to increase or decrease the production of prolactin inhibitory factor (dopamine) and, subsequently, the release of oxytocin from the posterior pituitary. Cerebral influences have a lesser effect on the release of prolactin. Positive sights, sounds, or smells related to nursing often stimulate the production of oxytocin, which, in turn, causes the myoepithelial cells to contact and milk to leak from the breasts. This observation is a good clinical clue indicating an uninhibited *let-down reflex*.

In a classic series of experiments, Newton and Egli[21] demonstrated the power of noxious influences to inhibit the release of oxytocin and to reduce milk transfer to the infant. The baseline milk production per feed was measured in controlled situations, about 160 g per feed. During a consecutive feed, a noxious event (i.e., saline injection) was administered during the feed. The amount of milk produced was cut in half, to 80 to 100 g per feed. Subsequently, the milk production was measured in a trial in which a noxious event was administered and intranasal oxytocin was given concomitantly. The milk production was restored to almost 90% of baseline production, 130 to 140 g. A wide variety of noxious events were able to elicit the same decrease in milk production. The noxious events included placing the mother's feet in ice water, applying electric shocks to her toes, having her trace shapes while

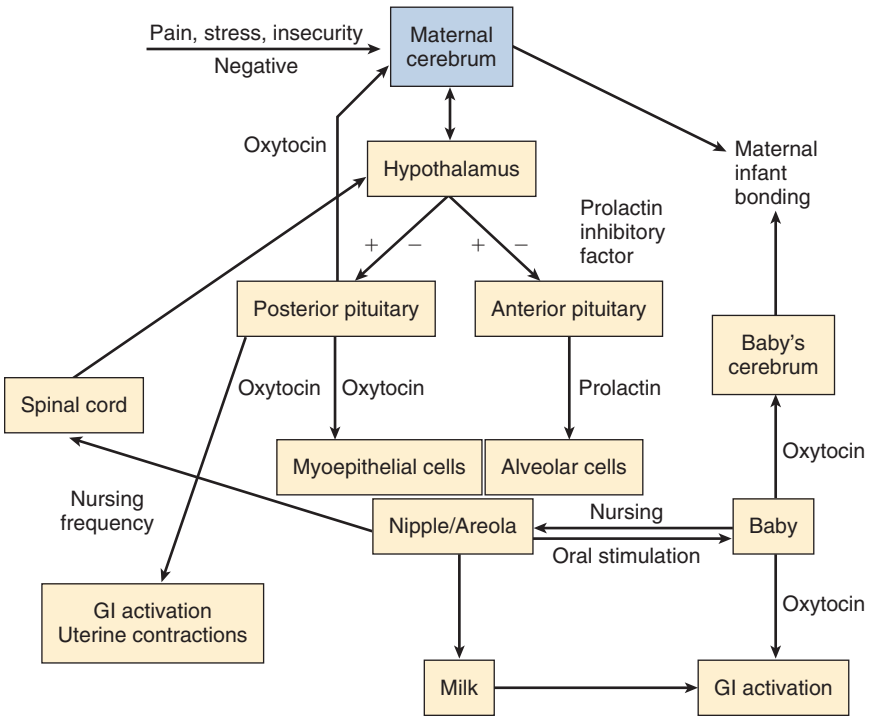

FIGURE 23-4. Oxytocin and the let-down reflex. The major reflex includes feedback stimulation from the nipple/areola to the hypothalamus to increase/decrease the release of oxytocin from the posterior pituitary and prolactin inhibitor factor (PIF-dopamine). The PIF affects the release of prolactin. Prolactin increases milk production. Oxytocin causes milk ejection. The release of both hormones is affected by positive or negative influences from the upper central nervous system. Oxytocin has three different target sites: the gastrointestinal tract (GI), uterus (contractions), and the upper CNS (mother-infant bonding). Oral stimulation in the infant initiates oxytocin release to improve GI activities and maternal-infant bonding. (From Rolland R, DeJong FJH. Schellekens LA et al: The role of prolactin in the restoration of ovarian function during the early postpartum period in the human: a study during inhibition of lactation by bromergocryptine. Clin Endocrinol 4:23, 1975.)

looking only through a mirror, or requiring her to proofread a document in a timed fashion. These observations have important implications concerning the management of breastfeeding. **Pain, anxiety, and insecurity may be hidden reasons for breastfeeding failure through the inhibitions of the let-down reflex. In contrast, the playing of a soothing motivational/educational audio tape to women who were pumping milk for their premature infants has improved milk yields.**[22] These observations have been confirmed by measuring the inhibition of oxytocin release by psychological stress.[23,24] The positive and negative influences of the cerebrum are further highlighted by the observation[25] that 75% of women who had a positive attitude during pregnancy were likely to be successful at breastfeeding. In contrast, 75% of women who had a negative attitude during pregnancy had an unsuccessful breastfeeding experience. This observation has been confirmed in more recent observations.[26] When the mother's attitude was very good or good and family was present, the exclusive breastfeeding rate was 20% at 6 months; if the mother's attitude was fair, the breastfeeding rate at 6 months was 5%.

Oxytocin has additional target cells in the mother. The effect of oxytocin on uterine activity is well known. Uterine involution is enhanced with breastfeeding. Animal and human research suggests that oxytocin is a neurohormone. Oxytocin is associated with an anti-fight/flight response in the autonomic nervous system, better toleration of stress by the mother, and improved maternal-infant bonding.[27]

In addition to the antistress effect, surges in oxytocin levels are associated with the release of gastrointestinal hormones and increased gastrointestinal motility. In the mother, these actions enhance the absorption of substrates necessary for lactogenesis. In infants, there is a growing body of knowledge that indicates similar associations with oxytocin surges. Skin-to-skin contact and the oral stimulation of nursing stimulate a parasympathetic, anti-fight/flight response in the infant. Kangaroo care of premature newborns (skin-to-skin contact) is associated with a physiologically stable state, improved stress responses, and improved weight gain.[28] Oxytocin appears to mediate this response. Breastfeeding is associated with far more skin-to-skin contact and maternal behaviors than bottle-feeding.

While the central nervous system locus for imprinting is unknown, imprinting immediately after birth is an important predictor of breastfeeding success. The survival of lambs depends on nursing within an hour after birth. If the lamb has not nursed during the critical period, maternal-infant bonding becomes dysfunctional and the lamb suffers failure to thrive. In humans, the consequences are not nearly as drastic. **Several trials with random assignment of subjects to early nursing (delivery room) or late nursing (2 hours after birth) demonstrated a 50% to 100% higher number of breastfeeding mothers at 2 to 4 months postpartum among those who had nursed in the delivery room.**[29] **One of the keys to obstetric management is have the mother nurse her newborn in the delivery room.**

Milk Transfer

Milk transfer to the infant is a key physiologic principle in lactation.[30] The initial step of this process is good latch-on. With light tactile stimulation of the cheek and lateral angle of the mouth, the infant reflexively turns its head and opens its mouth, as in a yawn (Figure 23-5). The nipple is tilted slightly downward using a "C-hold," or *palmar grasp*. In this hand position, the fingers support the breast from underneath and the thumb lightly grasps the upper surface 1 to 2 cm above the areola-breast line. The infant is brought firmly to the breast by the supporting arms while being careful to not push the back of the baby's head. The nipple and areola are drawn into the mouth as far as the areola-breast line (Figures 23-6 and 23-7). The posterior areola may be less visible than the anterior areola, and the lower lip of the infant is often curled out. The infant's lower gum lightly fixes the teat over the lactiferous sinuses. A slight negative pressure exerted by the oropharynx and mouth holds the length of the teat and breast in place and reduces the "work" to refill the lactiferous sinuses after they are drained. **The milk is extracted, not by negative pressure, but by a peristaltic wave from the tip of the tongue to the base.** There is no stroking, friction, or in-and-out motion of the teat; it is more of an undulating action. The buccal mucosa and tongue mold around the teat, leaving no space.

The peristaltic movement of the infant's tongue is most frequent in the first 3 minutes of a nursing episode; the mean latency from latch-on to milk ejection is 2.2 minutes. After milk flow is established, the frequency of sucking falls to a much slower rate. **The change in cadence is recognizable as "suck-suck-swallow-breath." Audible swallowing of milk is a good sign of milk transfer.** At the start of a feed the infant obtains 0.10 to 0.20 mL per suck. As the infant learns how to suck and as he matures he becomes more efficient at obtaining more milk in a shorter period of time. Eighty to 90% of the milk is obtained in the first 5 minutes the infant nurses on each breast, but the fat-rich and calorie-dense hind milk is obtained in the remainder

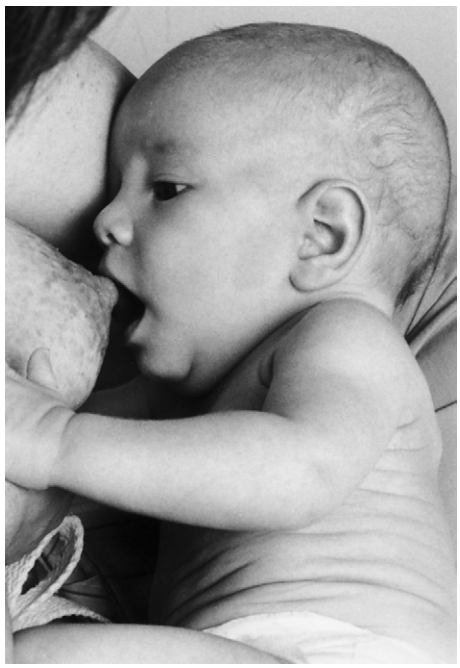

FIGURE 23-5. The latch-on reflex.

of the time sucking at each breast, usually less than 20 minutes total.[31] A bottle-feeding infant sucks steadily in a linear fashion, receiving about 80% of the artificial breast milk in the first 10 minutes.

Sucking on a bottle is mechanically very different from nursing on the human teat (Figure 23-8). The relatively inflexible artificial nipple resists the milking motion of the infant's tongue and mouth. The diameter of the artificial nipple expands during a suck, whereas the human teat collapses during the milk flow. The infant who is sucking on a bottle learns to generate strong negative pressures (>100 mm Hg) in order to suck the milk out of the bottle. Because rapid flow from the bottle can gag the infant, he or she quickly learns to use the tongue to regulate the flow. **When the infant who has learned to bottle-feed is put to the breast, the stopper function of the tongue may abrade the tip of the nipple and force the nipple out of the infant's mouth.** The efficiency of milk transfer falls drastically and the hungry infant becomes frustrated and angry. A similar rejection may occur at 4 to 8 weeks when the exclusively breastfeeding infant is given a bottle in preparation for the mother's return to work.

Milk transfer is made more efficient by proper positioning of the infant to the breast. Proper positioning places the infant and mother chest-to-chest. The infant's ear, shoulder, and hip are in line. The three most common

FIGURE 23-10. The football hold.

maternal positions are cross arm chest to-chest, side-lying, or the football hold (Figures 23-6, 23-9, and 23-10). Each has its advantages. Rotating positions of nursing allows improved drainage of different lobules, an observation important in the management of a "plugged" duct. **Maternal comfort and convenience are the major reasons for changing nursing positions; the football hold position and the side-lying position are more comfortable if there is an abdominal incision.**

Baseline prolactin levels appear to be the major determinant of the maternal hormonal state during lactation, a state of high-prolactin, low-estrogen, and low-progesterone levels. **As the frequency of nursing decreases below eight in 24 hours, the baseline prolactin levels drop to below a level where ovulation is suppressed (35 to 50 ng/mL), LH levels rise, and menstrual cycling is initiated.**[12] The intensity (adjusted odds ratio [OR]) of factors that initiate the onset of menses are the duration of sucking episodes less than 7 minutes (OR 2.4), night feeds less than four per 24 hours (OR 2.3), maternal age 15 to 24 years (OR 2.1), maternal age 25 to 34 years (OR 1.7), and day feeds less than seven per 24 hours (OR 1.6).[32] In women who feed their infants exclusively artificial breast milk, serum prolactin levels drop to prepregnant levels (8 to 14 ng/mL) within days. The total number of nursing episodes per day (more than eight per 24 hours) and night nursings are critical to the successful management of breastfeeding.

One of the major determinants of nursing frequency is the introduction of substitute nutriment sources for the infant, artificial breast milk or solids. **Breast milk has the nutritional content to satisfy the growth needs of the infant for at least 6 months postpartum.** In the first 6 months, feeding with artificial breast milk affects the physiology of successful lactation in three ways. Substitution with artificial breast milk reduces proportionally the nutriment requirements from breast milk, increases the gastric emptying time (slower digestion than breast milk) with a subsequent decrease in frequency of nursing episodes, and reduces the efficiency of nursing by the use of an opposing sucking technique on the artificial nipple.

Solid food (e.g., eggs, cereals, pureed food) have a similar effect on the hormonal milieu of the lactating woman. One of the errors in Western child care is the early, forced introduction of solids. In most cases, the infant's gut is filled with slowly digesting food with less nutritional quality than either artificial breast milk or breast milk. The long-term result may be childhood and adolescent obesity. The most logical time to start solid food substitution is when the infant has reached the neurologic maturity to grasp and bring food to its mouth from his or her mother's plate. The required neurologic maturity to perform this behavior usually occurs at about 6 months. As the infant matures, his or her ability to feed improves and the proportion of the diet supplied by solid food gradually increases.

The failure to develop good milk transfer is the major cause of lactational failure and breast pain, especially in the neonatal period. **Inhibition of the let-down reflex and failure to empty the breasts completely leads to ductal distention and parenchymal swelling (engorgement). Engorgement compromises the mechanics of nursing (Figure 23-11) and alveolar distention reduces secretion of milk by the alveolar cells.** Without adequate transfer of milk to the infant, lactation is doomed to fail. Distention of the alveoli by retained milk causes a rapid (6 to 12 hours) decrease in milk secretion and enzyme activity by the alveolar epithelium. The decreased production of milk is explained by pressure inhibition and by an inhibitor that is secreted in breast milk.[8,9] Distention of the alveoli inhibits secretion directly rather than indirectly by a decrease in nutriment or hormonal access.

BREAST MILK: THE GOLD STANDARD

One of the most common misconceptions by physicians and the lay public and heavily marketed by the formula industry is that modern "formulas" are equivalent to breast milk. Human breast milk is uniquely suited to our biologic needs

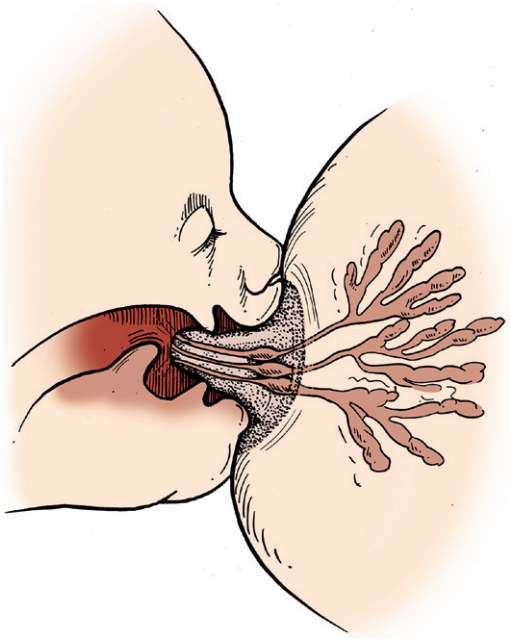

FIGURE 23-11. Breastfeeding and engorgement. The firm swollen breast parenchyma pushes the newborn's face away and she is unable to pull the teat into her mouth. Her tongue abrades the tip of the nipple.

and remains the best source of nutrition for the human infant. Human breast milk has a composition very different than that of bovine milk or soybean plants from which artificial breast milk is produced.[33] Nutritional, host-defense, hormonal, and psycho-physiological differences between human breast milk and breastfeeding versus formula and bottle feeding make the health benefits of breastfeeding understandable. This section will link the latter differences to a summary of a massive amount of basic and clinical research demonstrating the better health outcomes associated with breast milk and breastfeeding as compared to formula and bottle feeding.

The Agency for Healthcare Research and Quality (AHRQ) recently published (2007)[34] and updated (2009)[35] its analysis of the literature, "Breastfeeding and Maternal and Infant Health Outcomes in Developed Countries." The structure of the analysis is important for the reader to understand the effort and quality of the findings. Many different outcomes have been associated with a feeding method. The AHRQ used a panel of technical experts in the field of breastfeeding research to examine a specific outcome based on the following: the relevance and importance of an outcome in a developed country, date of the last systematic review on the outcome, availability or non-availability of data from a developed country, consistency or inconsistency of outcomes in previously reported studies, and consideration of the possibility that breastfeeding may have potential harms as well as benefits. All studies that were analyzed had to fulfill all the following four criteria: study designs included systematic reviews, randomized controlled trials, prospective cohort studies, and case-controlled studies; population included healthy term infants in developed countries; intervention included breastfeeding, breast milk feeding, exclusive or mixed feeding; and, the comparator was formula feeding (any type). Each primary study was graded as A (good—least bias and results are valid), B (fair—susceptible to some bias, but not sufficient to invalidate the results), or C (poor—significant biases which may invalidate the results). No conclusions were made from any Grade C studies. Prior meta-analyses were examined in a similar fashion and included sensitivity analysis in which the inclusion of poor quality studies might have affected the pooled estimates, and AHRQ tested its meta-analyses for heterogeneity.

Overview

The composition of mature human milk is very different from artificial breast milk or formula. Most artificial breast milk products use bovine milk or soybean constituents as a substrate. Minerals, vitamins, protein, carbohydrates, and fats are added to pasteurized bovine milk for perceived nutritional needs as well as marketing needs in order to make a product that will successfully compete with human breast milk. For example, human breast milk appears "thinner" than bovine milk. **Artificial breast milk manufacturers add constituents (e.g., palm- or coconut-based oils) to make artificial breast milk appear rich and creamy,** thereby creating a product that is more easily marketed to the American public.

Extensive research describes the unique composition of human milk. The infant formula industry has produced even greater volumes of data concerning their attempts to exactly reproduce human milk. In 1980, the U.S. Congress passed the Infant Formula Act (with revisions in 1985) as the result of severe health consequences when artificial breast milk failed to include key vitamins and minerals in new formula compositions. This law now requires that all formulas for artificial breast milk contain minimum amounts of essential nutrients, vitamins, and minerals. Although life-threatening omissions are unlikely, **current formulas have major differences in the total quantities and qualities of proteins, carbohydrates, minerals, vitamins, and fats when compared to human milk.** The reader is reminded that the recommended daily allowance (RDA) is the amount needed to prevent a deficiency disease, not the amount needed for the best health.

Breast milk promotes optimal somatic growth and metabolic competence. Human breast milk is designed for more efficient and better digestion by the human infant than the bovine or soybean derived formula.[33] Gastric emptying is faster in neonates fed breast milk versus formula, 1 to 2 hours versus 3 to 4 hours, respectively. The greater speed of digestion with breast milk relates to differences in casein: whey protein ratio, fatty acid content, fatty acid attachment to their glycerol backbone, and presence of gastrointestinal enzymes and gastrointestinal hormones to facilitate digestion, motility, and function. Formula contains limited and degraded hormones and enzymes appropriate for vegetarian ruminants, calves; or none in the formulas using a soybean base. In addition the bioavailability of naturally supplied vitamins and minerals in breast milk is 20% to 50% higher than the added vitamins and minerals in artificial breast milk.[33]

The nutritional differences between formula and human milk are reflected in differences in the growth patterns of infants who are exclusively breastfed for 4 to 6 months and

infants who are fed formula artificial breast milk.[36] **In general, breastfed infants have faster linear and head growth, whereas formula-fed infants tend to have greater weight gain and fat deposition.** The greater deposition in fat may relate in part to the earlier introduction of solid foods in the infants fed formula, a factor that has not been adequately controlled in current studies. **Regardless of the cause, formula has important adverse effects on the metabolic competence of the child, adolescent, and future adult (Table 23-3).**

Many clinicians feel that diet and exercise are the primary prevention intervention against obesity and cardiovascular disease. Their effect size is zero to 10%.[42] The primary prevention benefits of breastfeeding compares very well; its effect size is 15% to 560%. The alarming epidemic of obesity, especially in children and young adults, is a clarion call for breastfeeding for at least a year.

Breastfeeding enhances cognitive development. Human breast milk has superior capacity to enhance the development of the infant's brain and its integrative capacity through many defined and undefined differences between human breast milk and formula. The currently identified constituents of human breast milk that enhance integrative capacity include growth hormones, oligosaccharides, nucleotides, glycoproteins, and long-chain polyunsaturated fatty acids (LCPUFA). **In high-risk, premature neonates, human breast milk given by gavage in a dose-dependent fashion enhances the infant's later intelligence quotient (IQ) and performance on psychometric testing after controlling for maternal intelligence, family education, and socioeconomic status.**[43] While the effect is most dramatic among high-risk infants, smaller effects on IQ are seen in term infants: adjusted increment (95th CI)—3.16 points (2.35-3.98); versus low birthweight infants: 5.18 (3.59-6.77) points.[44] A recent large cohort study comparing very-low-birthweight infants[14] demonstrated that for every 10 mL/kg/day increment of breast milk fed to these high-risk neonates neurodevelopmental outcomes improved.[45] The information regarding breastfeeding, LCPUFA, and improved intelligence has been powerful enough for formula companies to change their concoctions to include more LCPUFA. However, just adding LCPUFA does not change the other deficiencies in formula. Another recent example of neurodevelopmental enhancement with breastfeeding is a strong association between breastfeeding and enhanced visual acuity: infants fed LCPUFA-enhanced formula had similar deficiencies in high-grade foveal stereoacuity—adjusted OR (95th CI) = 2.5(1.4-4.5), as infants fed standard formula.[46]

Breastfeeding enhances infant responses to infection and reduces allergic disease. At birth, the fetus enters an unsterile world with a naïve and immature immune system. Full development of the immune system may take up to 6 years. **Breast milk has a wide array of anti-infective properties that will support the developing immune system. The major mechanisms for the protective properties of breast milk include active leukocytes, antibodies, antibacterial products, competitive inhibition, enhancement of nonpathogenic commensal organisms, and suppression of proinflammatory immune responses.**[47] A critical event in host resistance is the recognition of pathogenic agents in the environment and the production of an antigen-specific adaptive immune response. Breastfeeding provides a unique system to help the infant fight infection with an adaptive antigen-specific response. Through breast milk, the neonate takes advantage of maternal recognition of these infectious agents (Figure 23-12). This important mechanism is described by Slade and Schwartz.[48] An antigen or infectious agent (virus, bacteria, fungus, and protozoa) stimulates the activity of leukocytes in the gastrointestinal or respiratory tract of

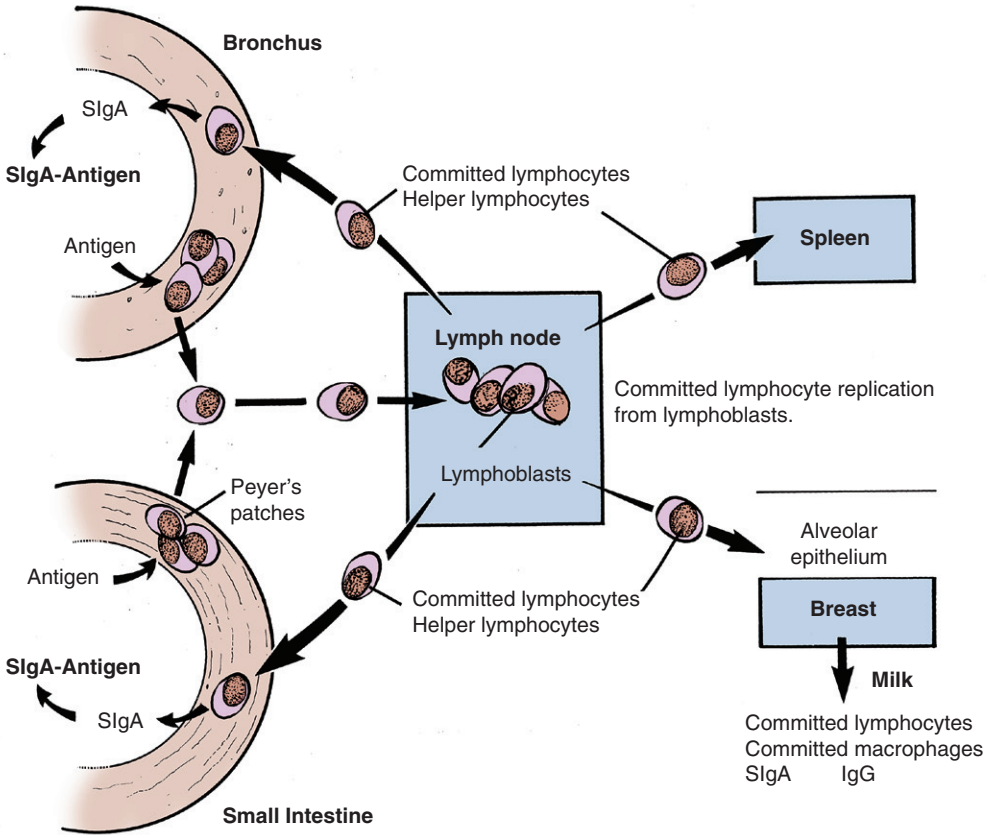

FIGURE 23-12. The immunology of the breast.

the mother. Lymphocytes, which are encoded with the antigen signature, travel to the nearest lymph node and stimulate lymphoblasts to develop cytotoxic T cells, helper T cells, and plasma cells programmed to destroy the initiating antigen through phagocytosis or complement/immunoglobulins produced by the B cells. The response is amplified by the migration of committed helper lymphocytes to other sites of white blood cell production, the spleen and bone marrow, where they stimulate the production of antigen-specific committed white blood cells. Some of the committed, antigen-specific helper lymphocytes travel to the mucosa of the breast in the lactating mother. Plasma cells, which produce secretory immunoglobulin A (sIgA), constitute 50% to 80% of the leukocytes in the breast submucosa. They may migrate into the breast milk (macrophages) or may produce immunoglobulins (sIgA, IgG—lymphocytes or plasma cells). Both are uniquely programmed to fight the specific infectious agent challenging the mother. **Active leukocytes are completely eliminated by pasteurization (formula) or freezing (stored, pumped breast milk).**

Immunoglobulins are a unique component to breast milk and absent in artificial breast milk. In contrast to monomeric serum IgA, the secretory immunoglobulin A (sIgA) in breast milk is dimeric or polymeric. Polymerization improves transport across the maternal alveolar cells into the breast milk. The sIgA is produced locally by plasma cells. The immunoglobulins in breast milk appear to be fully functional. Secretory immunoglobulin A does not activate, complement, or promote opsonic complement subfragments. As a consequence, sIgA is not bactericidal. It appears that sIgA blocks the mucosal receptors (adhesins) on the infectious agent. The virulence of pathogens is related to their ability to use adhesins capable of interacting with complementary gut epithelial cell-surface receptors. When the antigen-specific sIgA attaches, the pathogen is effectively neutralized.

In the last 5 to 10 years there has been an accelerating amount of focus and research on critically imprinting between neonatal gut flora and future immune responses. The neonate is an antigen-naïve organism and has an adaptive response that is delayed by the lack of exposure. In addition, the cytokine response to TOLL-like receptors stimulation appears to be exaggerated, especially in the preterm infant in whom damage is partly caused by cytokine-mediated injury (i.e., periventricular leukomalacia, necrotizing enterocolitis, and broncho-pulmonary dysplasia).[49] The adaptive immunologic response takes between 4 and 8 days to develop an effective defense; the neonate bombarded by new antigens/organisms during birth must rely on an innate host defense system to provide an immediate but controlled response during the first critical 0 to 7 days of breastfeeding.

Human breast milk actively limits the pathogenic microbes (e.g., *E. coli*) and promotes the growth of nonpathogenic, commensal microbes (e.g., *Bifidobacterium bifidum*).[50] The most important breast milk constituent is oligosaccharides, which are in very limited quantity in formula. Oligosaccharides are indigestible complex carbohydrate structures that have a microbe (genus)-specific

ability to bind to cell-surface receptors of the microbe. The unique oligosaccharide binding to the surface receptor blocks the binding of the microbe to the infant's mucosal receptors, thereby limiting microbe virulence. On the other hand, human milk contains an oligosaccharide homologous to the infant's mucosal receptors. The oligosaccharide-mucosal receptor complex allows specific attachment of *B. bifidum* to the intestinal mucosa, further competitively inhibiting the attachment of pathogenic organisms.

A similar attachment of *B. bifidum* to dendritic cells, which interdigitate through the intestinal epithelial cells, allows for a critical modulation of the developing neonatal immune system. The interaction upregulates the anti-inflammatory cytokine system, interleukin-10, soluble IL-1 receptor antagonist, etc., and orchestrates the conversion of naive T-helper cells into a mature balanced response. These early imprinting interactions have profound effects on the incidence of inflammatory diseases in the adult, intrinsic bowel disease, asthma, rheumatoid arthritis, and perhaps cardiovascular diseases.[51]

In addition to the crosstalk between commensal gut bacteria and the immune system of the neonate, human colostrum contains large quantities of a soluble form of the bacterial pattern recognition receptor CD14 (sCD14).[52] CD14 is a known modulator of host response to bacterial lipopolysaccharides (LPS). In particular, CD14 binds to TLR-4 receptors and limits the binding of LPS from gram-negative rods. The failure to activate the TLR-4 receptor reduces the exaggerated immature cytokine response possible in neonates. Recent therapeutic interventions have used the immunomodulating qualities of the commensal bacteria–host interactions to successfully treat several important human diseases: necrotizing enterocolitis, inflammatory bowel disease, *C. difficile*-associated colitis, acute gastroenteritis, and atopic dermatitis.[50,51]

Known and unknown constituents of human breast milk (not formula) inhibit the growth of and actively destroy pathogenic organisms. Certain vitamins and minerals are essential for the growth of pathogenic bacteria. A major mechanism by which breast milk protects the infant is the competition for "essential" nutriments for pathogenic bacteria. **Iron and vitamin B_{12} are two essential nutriments for pathogenic bacteria that have been studied relative to breast milk. Breast milk contains lactoferrin, an iron-binding glycoprotein, in large quantities (5.5 mg/mL in the colostrum to 1.5 mg/mL in mature milk) and is absent in artificial breast milk. The free iron form of lactoferrin competes with siderophilic bacteria for ferric iron, and thus disrupts the proliferation of these organisms. The binding of iron to lactoferrin also enhances iron absorption; less iron is required in breast milk in order to satisfy the iron needs of the infant.** The antibacterial role of lactoferrin is more complex than simple competition for ferric iron.[53] Lactoferrin causes a release of lipopolysaccharide molecules from the bacterial cell wall. This appears to sensitize the cell wall to attack by lysozyme. Lactoferrin and lysozyme work together to destroy the pathogenic organisms.

Table 23-4 describes the effects of breastfeeding on the adaptive and innate host defenses on health. The cause of sudden infant death syndrome is not clear, but a current theory includes an aberrant immune response.

The hormonal changes of lactation—low estrogen/progesterone, hyperprolactinemic amenorrhea—favor a reduction in maternal reproductive cancers, but the relationship is undefined and the relationship between the maternal immune system and her experience with breastfeeding has not been adequately explored. However, breastfeeding in a dose-dependent fashion reduces breast cancer per year of cumulative breastfeeding by 4.3% (95th CI, 2.9%-5.8%).[34,35] Likewise, breastfeeding for greater

than 12 months in her lifetime reduces ovarian cancer (adjusted OR [95th CI]—0.72 [0.54-0.97]); conversely, exclusive feeding with formula is associated with an enhanced risk of ovarian cancer (adjusted OR [95th CI]—1.39 [1.03-1.85]).

Breastfeeding enhances mother-infant bonding and reduces poor social adaptation. The human newborn infant is born entirely dependent on the mother for transportation, food, warmth, and social conditioning. Survival depends on a unique bond between mother and infant to enhance maternal protective behaviors. Like all other mammals, humans have a critical imprinting period (1-2 hours) for the establishment of mother-infant bonding. The most visible manifestation of the new bond is the duration of breastfeeding. Numerous studies with random assignment of breastfeeding dyads to early (<1 hr) or later initiation (>2 hrs) of breastfeeding demonstrate a significantly higher incidence of any breastfeeding or exclusive breastfeeding at 2 to 4 months after birth in those dyads who initiated breastfeeding early. A recent review by Moore et al. with Cochrane Database of Systematic Reviews (2009)[28] supports the benefits of early skin-to-skin contact. Their conclusions from the review of 30 studies involving 1925 mother-infant dyads were that early skin-to-skin contact was associated with babies who interacted more with their mothers, stayed warmer, and cried less. **Babies were more likely to be breastfed, and to breastfeed for longer, if they had early skin-to-skin contact.** More recently, a study with random assignment of subjects to immediate skin-to-skin contact or not, with timing of first feed being mother-directed and independently recorded, suggested that **early skin-to-skin contact was a better predictor of duration of exclusive breastfeeding than the timing of first sucking episode.**[55] This observation complements the success of "kangaroo mother care" in the performance of high-risk neonates in the neonatal intensive care unit.

Recent human studies based on robust animal data suggest that continued skin-to-skin contact and breastfeeding greatly affect the responsiveness to stress in the infant and mother. Experimental physiologic and psychological stressors have measured stress-induced changes in adrenocorticotropic hormone, cortisol, and autonomic responses in breastfeeding women versus women feeding their infant exclusively formula. In keeping with numerous animal studies, **the breastfeeding mothers had significantly blunted hypothalamic-pituitary-adrenal response (HPA axis), also known as "fight or flight response," to the experimental stressors.**[56] There appears to be a reciprocal relationship in the breastfeeding infant; the breastfed infant has greater parasympathetic tone and a blunted HPA-axis response than a similar infant fed formula. These observations may be partially explained by a decrease in skin-to-skin contact in infants fed formula. While "kangaroo mother care" has a salutary effect on breastfeeding incidence, the positive effects on weight gain and a blunted stress response are independently associated with the amount of skin-to-skin contact.[57,58]

The association between breastfeeding and better psychosocial outcomes has been the topic of much research over many decades. Critics have repeatedly pointed out the selection bias inherent with these studies. However, improved epidemiologic research design has confirmed the lifelong value for the breastfeeding dyad in subsequent stressful situations. Two powerful studies illustrate the risk of not breastfeeding. In the first study, **Strathearn et al. (2009)[59] explored whether breastfeeding was protective against maternal-perpetrated child maltreatment.** The study design monitored prospectively 7223 Australian mother-infant pairs (identified at first prenatal visit) and followed them over a 15-year period after birth. The outcome was substantiated maltreatment reports by a governmental child protection agency. Maternally-perpetrated substantiated abuse or neglect was identified in 313 (4.3% of cohort). The analyses adjusted for the 18 confounding variables including sociodemographic variables (5); prenatal behavior/attitudes (i.e., substance abuse, anxiety, attitude toward pregnancy) (4); infant factors, including neonatal intensive care admission (4); postnatal behaviors/attitudes (i.e., mother-infant separation, maternal stimulation/teaching of baby, maternal depression) (7). **The adjusted OR (95th CI) for maternal maltreatment cases among children fed exclusively formula was 2.2 (1.5-3.2) versus any breastfeeding, and 3.8 (2.1-7.0) versus exclusive breastfeeding for 4 months or longer.**

In the second study[1] the response of the child was measured. Montgomery et al. (2006)[60] used the data collected in the 1970 British Cohort Study. In this study the subjects were followed for 10 years; 8958 (71%) had complete data and were used in the analysis. The study analyzed childhood anxiety associated with parental divorce or separation as reported by their teachers on an analog scale of 0 to 50 related to the question, "Was (the subject) worried and anxious about many things?". Exclusive feeding with formula, after adjustment for many factors, was associated with a dramatic increase in perceived childhood anxiety, adjusted OR (95th CI) = 8.8 (5.3-12.2); whereas breastfeeding at entry had no significant effect on childhood anxiety associated with divorce, adjusted OR (95th CI) = 1.3 (–3.6-6.1).

Breastfeeding is cost-effective for the family and society. **The nonmedical costs of artificial breast milk (formula) feeding are considerably higher than for breastfeeding.**[61] The direct cost of artificial breast milk feeding includes the cost of the artificial formula (900 mL/day), bottles, and supplies. In eastern North Carolina (June 2011), the average retail cost of 900 mL of prepared formula was about $6.50 daily ($2373 yearly); of concentrate, about $4.50 daily ($1,642 yearly); and of powdered formula, about $3.65 daily ($1,332 yearly). A major indirect cost of artificial breast milk feeding is the environmental impact of large dairy herds to supply the bovine milk substrate.

Breastfeeding provides the right amount of a superior product at precisely the right time and at the right temperature. The nonmedical costs of breastfeeding include the cost of increased dietary calorie and protein needs ($1 to $2 daily), nursing bras and breast pads, and an increased number of diapers in the first 2 to 3 months. If an electric breast pump is used when the woman returns to work, the cost of breastfeeding will increase $3 to $5 per day.

Increase in acute medical diseases will manifest as increased costs of medical care for those families who choose to feed their infant artificial breast milk.[42-45] Among Medicaid populations in Colorado, California, and health

*2007 $US.

maintenance organizations in Arizona, the medical cost of artificial breast milk feeding amounts to $300 to $500 dollars per year per infant. Among patients who belonged to a large health maintenance organization in Tucson, Arizona, the excess yearly medical costs of 1000 never-breastfed infants versus 1000 infants who were exclusively breastfed for at least 3 months was $331,041[62] (Table 23-5).

The health care benefits are also reflected in the reduction of medical leave taken by the working mother to care for the sick child. **The recent data demonstrate fewer days for sick leave of women who work and continue to breastfeed than working women who bottle-feed.**[61,63]

A recent cost analysis by Bartick and Reinhold (2010)[64] calculated the excess pediatric costs with current U.S. breastfeeding initiation rates in 2005 (74%) and exclusive breastfeeding rates at 6 months (12.3%) as compared to 80% exclusive breastfeeding for 6 months using the published AHRQ analysis.[34,35] The total excess cost amounted to almost $10.5 billion and 714 deaths per year (Table 23-6). Their estimates do not account for the excess burden of chronic disease in the mother and child, obesity, Type II diabetes, and cardiovascular disease. The true burden is many folds greater than just the pediatric costs.

LIMITATIONS OF BREASTFEEDING RESEARCH

In the past there have been major flaws in the designs and conclusions of epidemiologic research regarding the benefits (or lack of benefits) of breastfeeding. In the last 10 years the quality has improved, but several cautions are warranted. **A major confounder is the difference in the demographic characteristics between women who breastfeed and women who use formula. Many breastfeeding outcomes, such as infections and chronic diseases, are also more prevalent in the lower socioeconomic groups.** When comparing outcomes between breastfeeding and artificial breast milk feeding, the effect of demographic differences should be analyzed and controlled in the analysis. In addition, cultural support and demographic differences of women who breastfeed their infants have changed. In the 1950s and 1960s cultural pressures pushed better educated, wealthier middle-class women away from breastfeeding; the incidence of initiation of breastfeeding reached its nadir in the early 1970s. This change is important when considering recall data used in studies evaluating differences in chronic diseases in the older adult, especially breast cancer.

Much of the older epidemiologic research has relied on self-report and recall data, usually long after the event has occurred. Memory is not perfect and biases are often introduced, such as combining events into convenient ages or socially acceptable times of weaning. One major area of recall bias is the definition of partial breastfeeding. An example of the confounding nature of this bias is a serial survey of nurses.[65] The study showed no significant benefit of breastfeeding in the reduction of premenopausal breast cancer, which was touted by the authors as evidence of no relationship between breastfeeding and breast cancer. As this was a population of nurses, in which a significant number were working at the time they were feeding their infant (this was not measured), the definition of breastfeeding may reflect intent more than actual intensity and duration of breastfeeding.

When analyzing any article involving breastfeeding, it is important to understand the author's definition of breastfeeding. **Exclusive breastfeeding is considered when the infant does not receive any additional food or nutriment other than breast milk. Partial breastfeeding needs to be defined by the proportion of feeds that are breast milk or artificial breast milk. If an infant consumes 700 mL of formula per day, then the proportion of breast milk consumed is small regardless of the frequency of breastfeeding episodes.** Control for the "dose" effect is important in physiologic as well as epidemiologic studies. The content and character of breast milk are affected by the frequency of feeds, the duration of the feed, when in the feed the breast milk is collected, the method of breast milk collection, and the time of day of the collection.

After statistical control for demographic variables, an unavoidable bias remains self-selection. Intrinsic personality characteristics may be determinants of feeding choice; a random allocation of feeding method is not possible. The random assignment of "at risk" preterm neonates to receiving breast milk or formula designed for preterm neonates, in the evaluation of cognitive development[66] or infections[67] avoids some of the maternal self-selection. However, a well-designed prospective cohort study with a sufficient sample size remains the standard method for the design of good breastfeeding research.

Recently, newer population research designs reduce the self-selection bias. Cluster-randomized trials of breastfeeding promotion intervention modeled on the WHO/UNICEF Baby-Friendly Hospital initiative (see box, 10 Steps to Successful Breastfeeding)[68] **have been used in two separate populations.**[69,70] In these studies, maternity clinics and hospitals are assigned randomly to receive intensive educational programs to increase breastfeeding rates. The outcomes of interest are breastfeeding rates and short-term neonatal morbidities (infections, atopic dermatitis, etc.) **In both studies, breastfeeding rates were improved significantly (P <0.001) with exclusive breastfeeding at 3 months, 43.4% versus 6.4% in Belarus**[69] **and 79% versus 48% in India.**[70] **The interventions were associated with 30% to 50% lower prevalence of gastrointestinal infections and atopic dermatitis and better infant growth.**

10 Steps to Successful Breastfeeding

1. Have a written policy to support breastfeeding.
2. Train all health care providers.
3. Inform all pregnant women about the benefits of management of breastfeeding.
4. Initiate breastfeeding within 1 hour after birth.
5. Show mothers how to breastfeed and maintain lactation even if they are separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Allow mothers and infants to remain together 24 hours a day (i.e., rooming in).
8. Encourage breastfeeding on demand.
9. Give no artificial teats or pacifiers.
10. Foster the establishment of breastfeeding support groups and refer mothers to them on discharge from the hospital or clinic.

Modified from WHO/UNICEF: Protesting, promoting, and supporting breastfeeding: the special role of maternity services, a joint WHO/UNICEF statement. Geneva, World Health Organization, 1989.[68]

A potential new variable is the prevalence and intensity of breast pumping, a variable incompletely measured in breastfeeding research. **The breast pump is a critically important adaptation where breastfeeding is difficult and sometimes impossible. The availability of breast pumps have allowed women and their children to get through the difficult times and successfully feed their infant breast milk for a prolonged period.** These women will accrue much of the benefit of breastfeeding; a choice much better than formula feeding. However, the differences between exclusively breastfeeding and exclusively breast milk feeding have the potential to negatively affect some of the benefits of breastfeeding.

As many as 80% of professional women rely heavily on the breast pump. In observational surveys, many of these women will report themselves as exclusively breastfeeding when they are actually partially breastfeeding and partially feeding breast milk obtained through a breast pump, often frozen, and bottle-fed at a later time. **Pumping and bottle-feeding the breast milk later upsets the delicate supply-and-demand relationship between the dyad and reduces skin-to-skin contact, and freezing may affect the nutritional, anti-infective qualities of the stored breast milk.** The use of bottles may increase acute otitis media and negate the positive benefits seen in breastfeeding dyads, as bottle feeding is a strong predictor of acute otitis media. There is paucity of information regarding this bias and behavior; it presents a great opportunity for research.

THE ROLE OF THE OBSTETRICIAN AND GYNECOLOGIST

The gynecologist plays a primary role in the initiation of breastfeeding.[71] Between 50% and 70% of women make a decision regarding how they will feed their infants before their pregnancies. The gynecologist needs to start promotion before the first pregnancy. When the reproductive-aged woman seeks initial family planning advice and contraception, there is high likelihood she will become pregnant in the next 2 to 5 years. **The breast examination is a regular part of the family planning visit;** it is used extensively to screen for breast cancer despite its rare occurrence at the ages of usual pregnancies (less than 35 years old). **This visit is a good opportunity to reassure the woman of her normal breast anatomy and build her self-efficacy for lactation success through vocal and visible support of breastfeeding.**

The obstetrician/gynecologist amplifies support for breastfeeding by community advocacy, office environment, and personal choices. The office environment needs to be "breastfeeding friendly." **Visible, active support of breastfeeding includes the presence of breastfeeding mothers, patient educational programs on breastfeeding, a quiet area for nursing mothers, the absence of material supplied by formula companies, and visible support for office personnel who choose to breastfeed.** The physician, especially a female obstetrician/gynecologist, can be a positive role model for patients. Women will ask the female gynecologist whether and how long she breastfed her children. Her answers will have a powerful influence.

An important role of the obstetrician is to identify (early in pregnancy) those women who cannot breastfeed or who may have challenges (Table 23-7).[72] The liberal use of lactation consultants as case managers, the use of galactagogues, and tube feeding devices can mediate challenges related to breast milk production or breast milk transfer. The WHO has good guidelines regarding the use of formula in cases in which breastfeeding is contraindicated.

The obstetrician plays a major role in directing and supporting prenatal patient education about breastfeeding in the last trimester. Patient education has been shown to

TABLE 23-7 IDENTIFICATION OF WOMEN AT HIGH RISK FOR UNSUCCESSFUL BREASTFEEDING OUTCOMES

CONDITION	RISK ASSESSMENT	MANAGEMENT
HIV in United states	Contraindicated	Formula feeding
Untreated active tuberculosis	Contraindicated	Neonatal antibiotic treatment, resume breastfeeding after 2 weeks of maternal therapy if mother asymptomatic
Herpes of nipple	Contraindicated on infected side	Isolate lesions, treat mother and infant systemically
Maternal antineoplastic medications	Contraindicated	Formula feeding
Neonatal galactosemia	Breast milk and "formula" contraindicated	Lactose-free supplement
Breast reduction surgery	High risk	Prenatal consultation with lactation consultant and pediatrician
Breast augmentation	Moderate risk	Prenatal consultation with lactation consultant and pediatrician
Failure of breasts to enlarge during pregnancy, small tubular breasts	Moderate to high risk	Prenatal consultation with lactation consultant and pediatrician
Unsuccessful breastfeeding with prior child	Moderate risk	Identify issues, prenatal education, prenatal consultation with lactation consultant

increase the initiation and maintenance of breastfeeding. A recent review[73] by the U.S. Preventive Service Task Force of 38 well-conducted trials with **random assignment of subjects to primary care interventions to promote breastfeeding versus "usual care" demonstrated significantly increased rates of short-term (1 to 3 months) and long-term (6 to 8 months) exclusive breastfeeding.** In subgroup analysis a combined prenatal and postnatal intervention had a larger effect on increasing breastfeeding duration than a prenatal or postnatal intervention alone. Interventions that included individual-level professional support and lay counselors had the most impact. A similar review[74] demonstrated that a combined educational and support intervention improved breastfeeding rates (95th CI): initiation—21% (7%-35%), short-term—36% (22%-49%), and long-term—13% (1%-25%).

At the 36-week visit, the obstetrician readdresses the mother's choice and knowledge regarding breastfeeding. Simple concepts of breastfeeding physiology are reinforced: early feeds, frequent feeds (>10 per day), reinforcing environment, and no supplementation unless directed by a pediatrician. The obstetrician reinforces the appropriate way to latch the baby to the breast and ensures that the increase in her breast size reflects the hormonal readiness for breastfeeding. The patient is warned of hospital policies and attitudes that interfere with breastfeeding success. The 36-week visit is a good time to address the appropriateness of medications and breastfeeding.

In the 1980s, international professional organizations recognized that several behaviors enhance the initiation and maintenance of breastfeeding. **In 1989, the essential 10 steps (see box, 10 Steps to Successful Breast-Feeding)[68] in protecting, promoting, and supporting breastfeeding were published in a joint statement by the World Health Organization (WHO)/United Nations Children's Fund (UNICEF).**[68] These have become institutionalized in the Baby-Friendly Hospital Initiative (BFHI) and accreditation process. **These steps are well founded on evidence-based medicine that demonstrates improvement in breastfeeding success.**[75-77] Unfortunately, the United States is far behind the rest of the world in designating their maternity facilities as Baby Friendly; in 2008 only 1.93% of live births occurred in a facility designated as Baby Friendly (BFHI). In 2009, the Center for Disease Control started reporting the breastfeeding-related maternity practices and outcomes[78] (www.cdc.gov/breastfeeding/data). These data will be used to measure the quality of care given by hospitals and their providers. The obstetrician will be a key player in quality improvement related to breastfeeding and the application of the essential 10 steps, also known as the Baby-Friendly Hospital Initiative.

After postpartum discharge, the obstetrician is primarily focused on maternal concerns about breastfeeding: maternal diet, breast symptoms and signs, hormonal function postpartum, contraception, maternal medications, and as a breastfeeding advocate when the mother is referred to other specialists. A secondary but equally important focus is the growth and development of the infant. Traditionally, the obstetrician sees the mother at 4 to 6 weeks postpartum, but often the obstetrician and the mother communicate before that visit. By inquiring about the growth and feeding of her infant, the obstetrician provides an important reinforcement of the mother's decision to breastfeed and an important screen for the pediatrician regarding the growth and feeding of the infant. The obstetrician can identify critical or developing problems regarding infant growth and feeding for the pediatrician. The obstetrician must know the indicators of adequate infant growth and clinical indicators that milk is being produced and transferred. When the obstetrician remains a verbal participant in the mother's breastfeeding experience at the 4- to 6-week postpartum visit, the likelihood that the mother will continue to breastfeed at 16 weeks is almost doubled.[79] During the interpregnancy interval, the obstetrician/gynecologist identifies the challenges, myths, and obstacles in the last pregnancy and helps correct them for the subsequent lactational period.

SUCCESSFUL MANAGEMENT OF BREASTFEEDING

The successful management of breastfeeding requires the active cooperation of the mother, her support group, the obstetric care provider, and the infant care provider. In our current culture, a lactation consultant often becomes an active participant in the care of the breastfeeding dyad. There are numerous reliable resources for additional information (Table 23-8).

ANATOMIC ABNORMALITIES OF THE BREAST

The relationship between breast anatomy and lactation should be addressed during the well-woman or family planning visits in women who anticipate future pregnancy. During pregnancy, infant feeding becomes a major focus, and the woman needs this issue addressed, as often there are hidden questions and concerns regarding her adequacy to breastfeed. The breast examination at the first prenatal visit is an excellent opportunity to address infant feeding concerns and myths relative to her breast anatomy. Self-doubt concerning the size or shape of the breasts should be addressed, and the patient should be reassured that less than 5% of lactational failures are caused by faulty anatomy.

Congenital abnormalities of the breasts (excluding inverted nipples) are rare, less than 1 in 1000 women. The most significant defect is glandular hypoplasia. These women have no development or abnormal development of one or both breasts during sexual maturation. Women with no development of the breasts often have normally shaped and sized nipples and areolas, and they may have sought consultation from a plastic surgeon. One manifestation of abnormal development is referred to as the *tubular breast*. The nipple and areola, which are often normal in size, shape, and appearance, are attached to a tube of fibrous cords. Whatever the shape or size of the breasts in a nonpregnant woman, the final evaluation of adequate glandular tissue must await the expected growth during pregnancy. The size of the average breast will grow from 200 g to 600 g during pregnancy; most women will easily recognize this growth. **A routine screening question at the 36-week prenatal visit should be, "Have your breasts grown during pregnancy?" If the response is negative in a woman with unusually small or abnormally shaped breasts, lactational failure is a possibility and prenatal consultation with a lactation expert is recommended.** Unilateral abnormalities are usually not a problem except for increased asymmetry, as the normal breast can usually produce more than enough milk for the infant. The texture of the breast and tethering of the nipple are also assessed. An inelastic breast gives the impression that the skin is fixed to dense underlying tissue, whereas the elastic breast allows elevation of the skin and subcutaneous tissue from the parenchyma. Lack of elasticity may complicate nursing because of increased rigidity with engorgement. Massage of the periareolar tissue four times a day for 10 minutes is recommended. Engorgement should be assiduously avoided in the postpartum period by early, frequent nursing.

Congenital tethering of the nipple to underlying fascia is diagnosed by squeezing the outer edge of the areola (Figure 23-13); normally, the nipple will protrude. **Severe tethering is manifested by an inverted nipple.** The most severe forms of tethering occur in less than 1% of women.

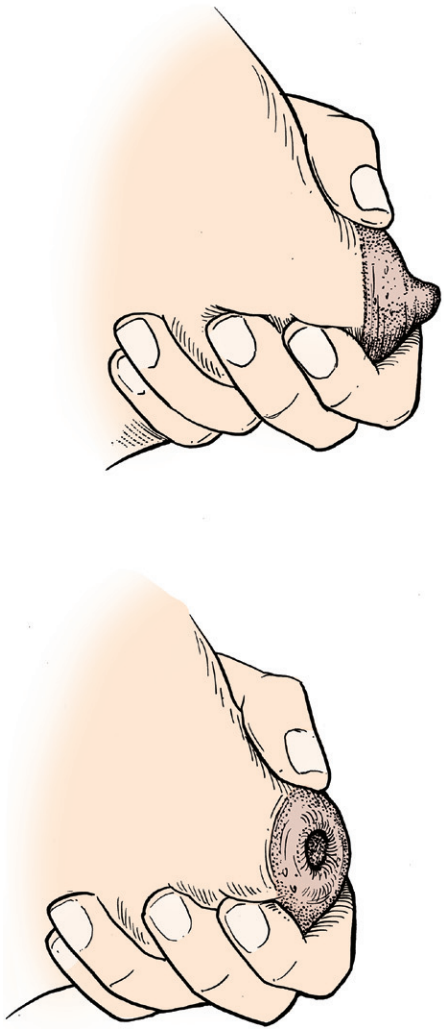

FIGURE 23-13. Assessment of nipple tethering.

While successful breastfeeding is possible in these severe cases, prenatal consultation and close follow-up are very important to identify and treat poor milk transfers. Flat or inverted nipples are much less likely to preclude successful breastfeeding. Three prenatal methods of treating tethered nipples have been described: nipple pulling, Hoffman's exercises, and nipple cups (shells). **A controlled trial failed to demonstrate efficacy[80] of either shells or Hoffman's exercises and recommended that these should be abandoned.**

In the early neonatal period, a breast pump may be of help in women with flat or inverted nipples. The breast is gently pumped at low settings until the teat is drawn out. The infant is immediately offered that breast. The same procedure is performed on the other side. Usually this is only required for a few days. If it is required for more than a few days, a relatively cheap alternative can be created from a 10- or 20-mL plastic syringe, the sizes depending on the size of the nipple. The end of the syringe where the needle attaches is removed and the plunger is reversed. The nipple is placed in the smooth, plunger end of the syringe and gentle traction is applied until the nipple everts. While pumping and syringe suction are practical solutions, no controlled trials have supported their efficacy.

Modern clothing (especially protective brassieres) prevents friction that toughens the skin and helps protect the nipple from cracking during early lactation. In the second half of pregnancy, nipple skin may be toughened by wearing a nursing brassiere with the flaps open. **However, washing with harsh soaps; buffing the nipple with a towel; and using alcohol, benzoin, or other drying agents are not helpful and may increase the incidence of cracking. Normally, the breast is washed with clean water and should be left to air-dry.** A cautiously used sunlamp or hair dryer may facilitate drying. Trials involving application of breast cream or expression of colostrum have not shown a reduction in nipple trauma or sensitivity when compared to those with untreated nipples.

Previous breast surgery may have significant adverse effects on breastfeeding success. The major issues are loss of sensation in the nipple or areola by nerve injury or compromise of the lactiferous ducts. Women who have had breast surgery, breast biopsy, chest surgery, or augmentation have a threefold higher incidence of unsuccessful breastfeeding.[81] Circumareolar skin incisions, which are used for cosmetic considerations in breast biopsies or breast augmentation, may compromise both the nerve and ducts.

Breast augmentation has significant potential to disrupt breastfeeding.[82] In a carefully studied, prospective series, 27 of 42 **(64%) of women who exclusively breastfed after preconceptional breast augmentation had insufficient lactation,** and the infant growth rate was less than 20 g/day. **Circumareolar incision was the dominant predictor. One half of women with a submammary or axillary incision had insufficient lactation, whereas all 11 women after a circumareolar incision for breast augmentation had lactation failure.** Compromise of the lactiferous ducts and loss of nipple sensation contribute to lactational insufficiency. Loss of nipple sensation occurs in one third to half of patients after circumareolar incision. If the woman has had a silicone implant, she can be reassured that there is no evidence that breastfeeding places her infant at risk. The concentration of silicone in artificial formula or cow's milk is 5 to 10 times higher than in breast milk from women who have silicone implants.[83] **Large epidemiologic studies of infants who have nursed from breasts with silicone implants have not shown excess adverse events.**[82]

Reduction mammoplasty is always associated with lactation insufficiency if exclusive breastfeeding is relied upon for infant nutrition. If the reduction involves the removal of greater than 500 g per breast or the procedure uses the free nipple graph technique, the production of a nominal amount of breast milk is rare. If the nipple and areola are relocated on a pedicle of vascular tissue and ducts, partial breastfeeding is a small possibility. **In any case of reconstructive surgery on the breast (i.e., reduction mammoplasty), the breastfeeding dyad is considered at high risk for lactation failure.** This observation was recently confirmed by a controlled study.[84] The control and mammoplasty reported any breastfeeding at 1 month of 94% and 58%, respectively. Similarly, the rate of exclusive breastfeeding at 1 month was 70% and 21% in the respective groups. Prenatal referral to an expert on lactation is appropriate.

LABOR AND DELIVERY MANAGEMENT

Approximately 15% of women who state they wish to breastfeed at the onset of term labor are discharged either completely feeding their infant artificial breast milk or giving the majority of the infant's feeds as artificial breast milk. A combination of obstetric management, hospital policies, and pediatric management contribute to this attrition. Obstetric interventions are often critical for the health of the mother or infant, and they may affect the success of lactation.[85] Few if any interventions directly inhibit the physiology of lactation. Most obstetric interventions reduce the success of lactation by indirect interference with physiology. Induction of labor is not associated with lactation failure, but a long, tiring induction and labor will reduce the likelihood that the mother will get appropriate amounts of infant contact in the delivery room and in the first 24 hours after birth. Cesarean delivery reduces the incidence of breastfeeding by 10% to 20% in the first week after birth. **After most cesarean sections and difficult vaginal deliveries, the infant is not put to the breast immediately after birth nor will the mother breastfeed her infant more than eight times in the first 24 hours.**[86] Well-meaning nurses become concerned for the baby's nutrition and artificial breast milk is given to the infant until the mother "recovers."

Labor analgesia (i.e., meperidine and promethazine) has long been associated with poor breastfeeding success. Intrapartum narcotics appear to adversely affect the infant's ability to nurse effectively. **Epidural anesthesia with local anesthetic agents seems to be better for breastfeeding than parenteral narcotics.** Epidural anesthesia with local anesthetics does not appear to have a major effect. The effect of epidural or intrathecal narcotics on sucking behavior and/or lactation success has been shown to be a decrease in breastfeeding success in a double-blind study with random assignment of subjects.[87] The presence of a doula, or a labor companion other than family, appears to be an effective method to reduce the need for epidural anesthesia and operative deliveries. An added benefit is earlier initiation and longer duration of breastfeeding.

Postsurgical pain control is best achieved with morphine rather than meperidine, which adversely affects neonatal behavior. Obstetric and pediatric protocols can be very effective in separating mother and baby. Several prominent examples include magnesium sulfate therapy for preeclampsia, a positive maternal group B streptococcus culture, maternal fever workup, and diabetes mellitus/hypoglycemia protocols. All of these medical interventions produce major barriers to delivery room nursing and an adequate frequency of nursing in the first 24 to 48 hours.

The peripartum period is critical for achieving successful lactation. The obstetrician must apply the five basic principles of lactation physiology: early imprinting, frequent nursing, good latch-on, a confident and comfortable mother, and no supplementation unless medically indicated. Nursing should be initiated within 30 minutes after birth, preferably in the delivery room. Contraindications include (1) a heavily medicated mother, (2) an infant with a 5-minute Apgar test result less than 7, or (3) a premature infant at less than 34 to 36 weeks' gestation.

The instructor should pay special attention to the mother's position during the first feeding; she should be in a relaxed, comfortable position. With skin-to-skin contact, the infant is presented to the breast with his ventral surface to the mother's ventral surface. A dry neonate, skin-to-skin contact, and supplemental radiant heating will prevent neonatal cold stress. Routine eye treatment should be delayed, as it may disrupt the important family bonding process.

In the recovery room and on the ward, the best place for the neonate is with the mother. This maximizes mother-infant bonding and allows "on-demand" feeding every 1 to 2 hours. Rooming-in allows the mother to participate in the care of her baby and gives her an opportunity to ask questions. **The mother should be encouraged to sleep when the neonate sleeps.** Since the hospital runs on an adult diurnal pattern, the patient should be discharged early in order to get her rest.

The frequency of early feeding is proportional to milk production and weight gain in neonates.[88] Therefore, supplementation with glucose or formula should be discouraged. Supplementation decreases milk production through a reduction in nursing frequency by satiation of the neonate and slower digestion of formula. Supplementation also undermines the mother's confidence about her lactational adequacy.[89,90] When obstetricians give information at the first prenatal visit about breastfeeding that was developed by makers of artificial breast milk, the duration of breastfeeding is significantly reduced when compared to packet information on breastfeeding developed by "breastfeeding-friendly" obstetricians and pediatricians. **A randomized trial of giving or withholding free formula samples at the time of discharge demonstrated a significantly reduced incidence of breastfeeding at 1 month and an increased likelihood of solid food introduction by the mothers given the formula samples.** This was most significant in high-risk groups: those less educated, primiparas, and those reporting illness since leaving the hospital.

Other factors influencing the success of lactation are improper positioning and nursing technique, which can lead to increased nipple trauma and incomplete emptying. In the early postpartum period, nursing technique should be evaluated in three areas: presentation and latching-on, maternal-infant positioning, and breaking of the suction. The infant should not have to turn its head to nurse. A ventral surface-to-ventral surface presentation is necessary. When latching on to the nipple, the neonate should take as much of the areola as possible into its mouth. This is facilitated by gently stimulating the baby's cheek to elicit a yawn-like opening of its mouth and rapid placement of the breast into it. A supporting hand on the breast helps; the C-hold involves four fingers cupping and supporting the weight of the breast, which is especially important in the weak or premature neonate whose lower jaw may be depressed by the weight of the breast. The thumb rests above and 1 to 2 cm away from the areolar edge and points the nipple downward. Retraction by the thumb will pull the areola away from the mouth and cause an incorrect placement. Any position that is comfortable and convenient, while allowing the appropriate mouth-areola attachment, should be encouraged; the sitting position is the most common. In cesarean section patients in whom pressure on the abdomen is uncomfortable, a side-lying or football hold may be better. **A rotation of positions is recommended to reduce focal pressure on the nipple and to**

ensure complete emptying. Removal of the nursing infant can be a problem; suction by the neonate can injure the nipple if it is not broken prior to disengagement. **A finger inserted between the baby's lips and the breast will break the suction.**

The single most difficult management issue is the control of routines and hospital attitudes detrimental to lactation. Policies that work against the physiology of lactation include formula distribution and supplementation without a medical indication, constant questioning of the mother about breastfeeding, preprinted orders for lactation suppression medication, pediatric clearance prior to the first feeding, limited maternal access to the infant, and little educational material for new mothers or staff.

When providers are not well informed or are apathetic about lactation, success of lactation is unlikely. This theme underscores the role of the obstetrician, as an opinion leader, in the education of patients, nursing staff, and support personnel about the physiology and benefits of lactation.

Breast Milk Expression

The flow of milk can be improved by placing the mother in a quiet, relaxed environment. The breast is massaged in a spiral fashion, starting at the top and moving toward the areola; the fingers are moved in a circular fashion from one spot to another, much like a breast examination. After the massage, the breast is stroked from the top of the breast to the nipple with a light stroke and shaken, while the woman leans forward. Once milk starts to flow, manual expression is begun.

Manual expression is performed by holding the thumb and first two fingers on either side of the areola, in a half circle, but the breast should not be cupped. The hand pushes the breast straight into the chest wall, as the thumb and fingers are rolled forward. Large, pendulous breasts may need lifting prior to this. The maneuver is repeated in all four quadrants of the areola to drain as many reservoirs as possible. The procedure is repeated rhythmically and gently, since squeezing, sliding, or pulling may injure the breast. The sequence of massage, stroke, shake, and express is useful in providing milk immediately for the vigorous infant, in allowing an improved latch-on by reducing periareolar engorgement, and in reducing high suction pressures on a traumatized nipple.

MATERNAL NUTRITION AND EXERCISE DURING LACTATION

The efficiency of conversion of maternal foodstuff to milk is about 80% to 90%. **If the average milk volume per day is 900 mL, and milk has an average energy content of 75 kcal/dL, the mother must consume an extra 794 kcal/day, unless stored energy is used. During pregnancy, most women store an extra 2 to 5 kg (19,000 to 48,000 kcal) in tissue, mainly as fat, in physiologic preparation for lactation.** These calories and nutrients supplement the maternal diet during lactation. As a result, the required dietary increases are easily attainable in healthy mothers and infants.

In lactation, most vitamins and minerals should be increased 20% to 30% over nonpregnant requirements. Folic acid should be doubled. Calcium, phosphorus, and magnesium should be increased by 40% to 50%, especially in the teenager who is lactating. In practical terms, these needs can be supplied by the following additions to the diet: 2 cups of milk, 2 oz of meat or peanut butter, a slice of enriched or whole wheat bread, a citrus fruit, a salad, and an extra helping (½ to ¾ cup) of a dark green or yellow vegetable. **The appropriate intake of vitamins can be ensured by continuing prenatal vitamins with 1 mg of folic acid throughout lactation.** The mother should drink at least 1 extra liter of fluid per day to make up for the fluid loss through milk.

Vegetarianism has become increasingly more common, and if the nursing mother is a vegetarian, dietary deficiencies may include B vitamins (especially B_{12}), total protein, and the full complement of essential amino acids. The recommendation should be to take a good dietary history with the focus on protein, iron, calcium, and vitamins D and B; supplement with soy flour, molasses, or nuts; use complementary vegetable protein combinations; and avoid excess phytate and bran.

Many women are concerned about losing weight postpartum.[17-19] Dewey and colleagues examined the effects of diet and exercise on maternal weight, breast milk volume, breast milk composition, and infant growth through random assignment of affluent, highly motivated, and exclusively breastfeeding women to intervention and control groups. The exercise group had training to reach a level of 45 minutes at 60% to 70% of heart rate reserve four to six times a week for 12 weeks. The target diet was individually adjusted to reduce calories and maintain protein intake. In these controlled populations, **the women lost 1.0-1.5 kg/week. There were no significant changes in the volume or composition of breast milk.** The infant grew approximately 2000 g in both the intervention and control groups. On a practical level, if 700 to 1200 kcal are used daily to nourish an infant, a mother could lose weight by not increasing her caloric intake, but a thoughtful selection of food groups and the elimination of "empty calories" are necessary. A reduction of total calories (<25 kcal/kg) and total protein (<0.6 g/kg) may reduce the daily milk volume by 20% to 30%, but not the milk quality, unless the mother is more than 10% below her ideal body weight. Because dieting mobilizes fat stores that may contain environmental toxins, women with high exposure to such toxins should not lose weight during lactation.

BREAST AND NIPPLE PAIN

Breast or nipple pain is one of the most frequent complaints of lactating mothers.[91-94] The frequency of pain is related to failure in the initial management of lactation: late first feed, decreased frequency of feedings, poor nipple grasp, and/or poor positioning. The differential diagnosis of breast pain includes problems with latching-on, engorgement, nipple trauma, mastitis and, occasionally, the let-down reflex.

Symptoms and the infant's personality help make the differential diagnosis. In some cases, the nipple and breast pain starts with latching-on and diminishes with let-down. Women describe the let-down reflex as painful; this occurs after the first minute of sucking and usually lasts only a minute or two as the ductal swelling is relieved by nursing.

Classically, the anxious, vigorous infant, who sucks strongly against empty ducts until the let-down occurs, is associated with this pain pattern. Contact pain suggests nipple trauma and may persist as long as the nipple is manipulated. The nipple-confused infant who chews on the nipple and abrades the tip with his tongue is associated with this pattern.

Engorgement causes a dull, generalized discomfort in the whole breast, worse just before a feed and relieved by it. Localized, unilateral, and continuous pain in the breast may be caused by mastitis. A physical examination and observation of nursing technique can confirm the impression left by a good history. Through observation of a nursing episode, an infant's personality and nursing technique can be assessed. The whole of the nipple and much of the areola should be included in the infant's mouth. An examination of the nipple may reveal a fissure or blood blister. Bilateral breast firmness and tenderness may indicate engorgement. Engorgement may be peripheral, periareolar, or both. Mastitis is characterized by fever, malaise, localized erythema, heat, tenderness, and induration (see below).

Infection may be a cofactor associated with the pain of nipple injury. When the microbiology of the nipple/milk of 61 lactating women with nipple pain was compared to 64 lactating women without nipple pain and 31 nonlactating women, *Candida albicans* (19%) and *Staphylococcus aureus* (30%) were more common in women with pain and nipple fissures than in controls (3%-5%).[93] The use of antibiotics is effective in treatment of nipple pain and trauma.[93]

The management of breast pain consists of general as well as specific steps. Prevention is a key component. Appropriate nursing technique and positioning will prevent, or significantly decrease, the incidence of nipple trauma, engorgement, and mastitis. Rotation of nursing position will reduce the suction pressure on the same part of the nipple, as well as ensuring complete emptying of all lobes of the breast. Frequent nursing will reduce engorgement and milk stasis. The use of soaps, alcohol, and other drying agents on the nipples tends to increase nipple trauma and pain. The nipples should be air-dried for a few minutes after each feed, and clean water is sufficient to cleanse the breast, if necessary. Some experts recommend that fresh breast milk be applied to the nipples and allowed to dry after each feed.

Stimulating a let-down and manual expression of milk is useful in the management of many breast problems. The let-down produced by manual expression is never as complete as a normally elicited one. An effective let-down can be elicited by initiating nursing on the side without nipple trauma or mastitis. This will effectively reduce breast pain.

In the first 5 days after birth, about 35% of the nipples of breastfeeding mothers show damage, and 69% of mothers have nipple pain.[92-94] The management of painful, tender, or injured nipples includes prefeeding manual expression, correction of latching-on, rotation of positions, and initiation of nursing on the less painful side first, with the affected side exposed to air. Drying is facilitated by the cautious application of dry heat (e.g., with hair dryer on low setting) for 20 minutes four times per day. Aspirin or codeine (15 to 30 mg) given half an hour before nursing, may be helpful in severe cases. Engorgement can be avoided, but if it occurs, feeding frequency should be maintained or increased by pumping. **A wide variety of preparations have been applied to traumatized nipples, including lanolin, A & D ointment, white petrolatum, antibiotics, vitamin E oil, and used tea bags, but few of these have been evaluated scientifically. Soap and alcohol have been shown to injure nipples.** Nipple shields should be used only as a last resort because of a 20% to 60% reduction in milk consumption. Thin latex shields may be better than the traditional red rubber ones, although milk flow is still reduced by 22%.

Engorgement of the breast occurs when there is inadequate drainage of milk.[92] Swollen, firm, and tender breasts are caused by distention of the ducts and increased extravascular fluid. Aside from the discomfort, engorgement leads to dysfunctional nursing behavior and nipple trauma. The firm breast tissue pushes the infant's face away from the nipple. The widened base of the nipple disrupts the attachment, and the infant's thrusting tongue abrades the tip. This leads to further engorgement, decreased milk production and, in some cases, early termination of breastfeeding.

The best treatment is prevention, but when this has not occurred, management is centered on symptomatic support and relief of distention. Proper elevation of the breasts is important. The mother should wear a firm-fitting nursing brassiere, with neither thin straps nor plastic lining. A warm shower or bath, with prefeed manual expression, is effective. Frequent suckling (every 1 to 2 hours) is the most effective mechanism to relieve engorgement; postfeed electric pumping from each breast may be helpful. In selected cases, intranasal oxytocin may be given just prior to each feed if let-down seems to be inhibited.

MASTITIS AND BREAST ABSCESS

Mastitis is an infectious process of the breast characterized by high fever (39° to 40° C), localized erythema, tenderness, induration, and palpable heat over the area.[95] Often these signs are associated with nausea, vomiting, malaise, and other flulike symptoms. Mastitis occurs most frequently in the first 2 to 4 weeks postpartum and at times of marked reduction in nursing frequency. Risk factors include maternal fatigue, poor nursing technique, nipple trauma, and epidemic *Staphylococcus aureus.* **The most common organisms associated with mastitis are *S. aureus, S. epidermidis,* streptococci and, occasionally, gram-negative rods.** The incidence of sporadic mastitis is 2% to 10% in lactating mothers and less than 1% in nonlactating mothers.

Until recently, the management of mastitis has been directed by retrospective clinical reviews of experience. In most cases, this consisted of bed rest, continued lactation, and antibiotics, with an 80% to 90% cure rate, a 10% abscess rate, a 10% recurrence rate, and a 50% cessation of breastfeeding. Starting in the 1980s, several important articles were published concerning pathophysiology, diagnosis, and treatment of mastitis. The diagnosis and prognosis of inflammatory symptoms of the breast could be established by counts of leukocytes and bacteria in breast milk. This is obtained after careful washing of the mother's hands and breasts with a mild soap. The milk is manually expressed, and the first 3 mL discarded. A microscopic analysis is performed on an unspun specimen. When the

leukocyte count was greater than 10^6 leukocytes/mL, and the bacterial count less than 10^3 bacteria/mL, the diagnosis was noninfectious inflammation of the breast. With no treatment, the inflammatory symptoms lasted 7 days; 50% developed mastitis, and only 21% returned to normal lactation. When the breast was emptied frequently by continued lactation, the symptoms lasted 3 days, and 96% returned to normal lactation.

If the breast milk showed greater than 10^6 leukocytes/mL and greater than 10^3 bacteria/mL, the diagnosis was mastitis. Delay in therapy resulted in abscess formation in 11%, and only 15% returned to normal lactation. Frequent emptying of the infected breast by continued nursing eliminated abscess formation, but only 51% returned to normal lactation. Additional antibiotic therapy increased the return to normal lactation in 97% with resolution of symptoms in 2.1 days.

In summary, the management of mastitis includes the following: (1) breast support; (2) fluids; (3) assessment of nursing technique; (4) nursing initiated on the uninfected side first to establish let-down; (5) the infected side emptied by nursing with each feed (occasionally, a breast pump helps to ensure complete drainage); and (6) dicloxacillin, 250 mg every 6 hours for 7 days. Erythromycin may be used in patients allergic to penicillin. It is important to continue antibiotics for a full 7 days, since abscess formation is more likely with shorter courses. Maternal handwashing before each feed reduces nosocomial infection rates. Hand washing and the use of antiseptic gels by health care workers reduces nosocomial infection rates; and, more important, MRSA-associated mastitis. In the era before universal handwashing by hospital personnel, rooming-in did not reduce the acquisition of hospital strains of *S. aureus* or infection rates. In the more infection conscious environment of today, isolation (rooming-in) and early discharge may add to the benefits of handwashing by reducing the rates of MRSA-associated mastitis and abcess.[96]

Breast abscess will occur in about 10% of women who are treated for bacterial mastitis. The signs include a high fever (39° to 40° C) and a localized area of erythema, tenderness, and induration. In the center a fluctuant area may be difficult to palpate. The patient feels sick, like having the "flu." Abscesses usually occur in the upper outer quadrants and *S. aureus* is usually cultured from the abscess cavity.

The management of breast abscess is similar to that for mastitis, except that (1) drainage of the abscess is indicated and (2) breastfeeding should be limited to the uninvolved side during the initial therapy.[97] The infected breast should be mechanically pumped every 2 hours and with every let-down. Serial percutaneous needle aspiration under ultrasound guidance is the best and standard method to drain the abscess. Occasionally, surgical drainage is required. The skin incision should be made over the fluctuant area in a manner parallel to and as far as possible from the areolar edge. While the skin incision follows skin lines, the deeper extension should be made bluntly in a radial direction. Sharp dissection perpendicular to the lactational ducts increases blood loss, the risk of a fistula, and the risk of ductal occlusion. Once the abscess cavity is entered, all loculations are bluntly reduced and the cavity irrigated with saline. American surgeons pack the wound open for drainage and secondary closure. British surgeons advocate removal of the abscess wall and primary closure. In either case, wide closure sutures should be avoided, as they may compromise the ducts. Patients have a protracted recovery of 18 to 32 days and recurrent abscess formation in 9% to 15% of cases. Breastfeeding from the involved side may be resumed, if skin erythema and underlying cellulitis have resolved, which may occur in 4 to 7 days.

Candida albicans infection is considered a common cause of breast pain. **Candida infection of the breast is a commonly diagnosed by clinical presentation. Women describe severe pain when the infant nurses. She will describe the pain as "like a red hot poker being driven through my chest."** Often she has received antibiotics recently, she is a diabetic, or the infant has evidence of oral thrush or diaper rash (*C. albicans*). The areola and nipple are erythematous with a scaly sheen to the nipple. Unfortunately, the clinical presentation of candida infection of the breast is not as specific nor as accurate as a prudent clinician needs. The differential diagnosis includes let-down pain, poor latch-on, nipple trauma, allergic reaction, Raynaud's of the nipple, and early bacterial mastitis.

Often the mother is given strong antifungal agents for causes of the symptoms that are not amenable to antifungal agents. In a classic study by Hale and Berens[98] only one of 21 patients with a "classic" presentation of candida mastitis had a breast milk specimen positive for yeast. Given the nonspecificity of the clinical diagnosis, a focused physical examination and biologic confirmation of candida is prudent. Biologic confirmation is obtained through a microscopic examination and culture of a midstream sample of breast milk. The nipples and areola are gently cleaned with warm water. A letdown of breast milk is induced and a sample of breast milk is obtained after the first 5 mL have been discarded. A potassium hydroxide (KOH) smear can confirm the diagnosis. A drop of the midstream milk is combined with a drop of 10% KOH and examined under high-power light microscopy. A typical pattern of hyphae and spores will be visualized. The remainder of the sample is sent for culture and isolation of bacteria and fungus. In cases in which there have been multiple antibiotics and antifungal agents used, a sensitivity panel on the fungal isolates may be helpful. A fungal culture may take 7 to 10 days for isolation and identification, longer than for antibiotic sensitivities. Given the intensity of maternal symptoms and the risk of discontinuing breastfeeding, empiric therapy is warranted prior to the availability of culture results.

The initial treatment is to massage nystatin cream or miconazole oral gel into both nipples after each feed and in the infant's mouth three times a day for 2 weeks. Recurrent or persistent candida mastitis can be treated by swabbing the infant's mouth with gentian violet liquid (0.5%) and immediately latching the baby to the breast, twice a day for 3 days. The major disadvantage of this therapy is the permanent staining associated with gentian violet. An alternative therapy in severe cases is oral fluconazole, 200-mg loading dose followed by 100 mg/day for 14 days.

MILK TRANSFER AND INFANT GROWTH

When is an exclusive diet of breast milk insufficient to supply the nutritional needs of the growing infant? Women

who wean in the first 8 weeks most often say that insufficient milk is the reason for quitting, and well-meaning family members often ask, "When are you going to start feeding your child real food?"

Correct answers are not readily available. Many nondietary factors affect the growth of infants, including high birth order, lower maternal age, low maternal weight, poor maternal nutrition during pregnancy, birth interval, birth weight less than 2.4 kg, multiple gestation, infection, death of either parent, and divorce or separation.

In addition, there are inconsistencies in the standard reference charts for growth or nutritional needs. Most growth charts are based on formula-fed infants, who often receive solid food supplementation earlier and in greater proportion than comparable breastfed infants. Reference charts with sufficiently large numbers of exclusively breastfed infants from developed countries are lacking. As milk volume is a quantitative measure of nutrition, variations in volume and concentrations of constituents caused by individual variation and different methods of collection compound the interpretation.

Despite the latter concerns, it is apparent that **a healthy and successfully breastfeeding mother can supply enough nutrition through breast milk alone for 6 months.** The clinical markers for adequate breast milk transfer include an alert, healthy appearance, good muscle tone, good skin turgor, six wet diapers per day, eight or more nursing episodes per day, three or four loose stools per day, consistent evidence of a let-down with operant conditioning, and consistent weight gain (0.75-1.0 oz/day after galatogenesis III has started, engorgement or "the milk has come in").

The term "failure to thrive" has been used loosely to include all infants who show any degree of growth failure. For the breastfeeding mother, it may just be a matter of comparing the growth of her infant to growth charts compiled from formula-fed infants. The loosely applied term can seriously undermine the mother's confidence, and ill-advised supplementation further compromises milk volume and may mask other important underlying causes. The infant should be evaluated for failure to thrive or slowed growth if (1) it continues to lose weight after 7 days of life, (2) it does not regain birthweight by 2 weeks, or (3) it gains weight at a rate below the 10th percentile beyond the first months of age. If the mother or the maternal care provider recognize jaundice after the first 7 to 10 days of life, the neonate needs to have a serum bilirubin and be seen by his care provider in an emergent fashion. If the infant is premature, ill, or small for gestational age, other growth measurements (ponderal index, height, skinfold thickness, etc.) can be used to define adequate growth. The cause of failure to thrive is often complex and is beyond the scope of this chapter.

JAUNDICE IN THE NEWBORN

Ten to 15% of breastfed neonates will have jaundice, defined by a peak serum bilirubin greater than 12 mg/dL in term infants.[99] Pediatric concerns include hemolysis, liver disease, or infection as underlying causes, and kernicterus as a consequence. **Unconjugated serum bilirubin greater than 20 mg/dL is considered the critical level for the development of kernicterus in term infants.** When the serum bilirubin is greater than 5 mg/dL in the first 24 hours, a serious disease process (hemolysis) may be present, and intervention is appropriate.

The focus on breastfeeding as related to neonatal jaundice results from the characterization of two syndromes, breastfeeding jaundice syndrome and breast milk jaundice syndrome. In the early 1960s, 5% to 10% of lactating women were found to have a steroid metabolite of progesterone, 5β-pregnane-3(α), 20(β)-diol, in their icterogenic milk, but the compound was not found in the milk of women whose infants were normal (breast milk jaundice syndrome). This metabolite is associated with an inhibition of glucosyl transferase in the liver, differences in the metabolism of long-chain unsaturated fatty acids, and/or increased resorption of bile acids in jaundiced infants.

In breast milk jaundice syndrome, the neonates are healthy and active. The hyperbilirubinemia develops after the fourth day of life and may last several months, with a gradual fall in level. When breastfeeding is stopped for 24 to 48 hours, there is a 30% to 50% decline in bilirubin levels. With resumption of nursing, serum levels will rise slightly (1 to 2 mg/dL), plateau, and then start to fall slowly, regardless of feeding method. **After excluding other causes of jaundice, and with careful monitoring of serum bilirubin, breastfeeding can continue.**

Unfortunately, the focus on rare breast milk jaundice cases, the concern about kernicterus, and the increased bilirubin in many breastfed neonates between 2 and 7 days old led to routine supplementation of infants with water, glucose, and formula, even when bilirubin concentrations were in the moderate range of 8 to 12 mg/dL. The cause of the elevated bilirubin-reduced feeding frequency or low milk transfer is often unrecognized. **It has been clearly demonstrated that feeding frequency greater than eight feedings per 24 hours is associated with lower bilirubin levels. Likewise, water supplementation studied in a controlled fashion does not decrease the peak serum bilirubin.** Management consists of prevention by improvement in the quality and frequency of nursing. Rooming-in and night feedings should be encouraged. If the mother, family, or obstetrician recognizes jaundice in an infant greater than 7 days old, an immediate referral to the child's caregiver and a serum bilirubin should be obtained; this is a pediatric emergency. The management of jaundice in the breastfeeding newborn is effectively outlined in a specific protocol produced by the Academy of Breastfeeding Medicine (www.ABM.org).

GALACTOGOGUES: DRUGS TO IMPROVE MILK PRODUCTION

Obstetricians may interface with the breastfeeding dyad when there is a question of adequate milk production and transfer by the mother. The mother and/or the pediatrician will ask for a galactogogue to be prescribed by the obstetrician.

Numerous agents have been shown to increase prolactin production; and galactorrhea is a clinical issue for women on phenothiazines or metoclopramide. It is reasonable that these drugs might be used where milk supply seems insufficient. The most understandable clinical scenarios include premature delivery requiring mechanical

pumping, glandular hypoplasia, reduction mammoplasty, and relactation (nursing an adoptive child). The most common clinical presentation is perceived poor milk supply or inhibited milk let-down (oxytocin inhibition). Clinical trials with random assignment of subjects have demonstrated the effectiveness of metoclopramide, sulpiride, and nasal oxytocin for increasing milk production.

Metoclopramide (Reglan) is used to promote gastrointestinal tone; however, a secondary effect is to increase prolactin levels. Most studies demonstrate a multiple fold increase in basal prolactin levels and a 60% to 100% increase in milk volume. The effects of metoclopramide are very dose dependent; the usual dose is 10 to 15 mg three times a day. The side effects—gastric cramping, diarrhea, and depression—may limit its use. The incidence of depression increases with long-term use; treatment should be tapered over time and limited to less than 4 weeks. There appears to be little effect on the infant. The dose that the infants receive is much less than the amount used therapeutically to treat esophageal reflux, regardless of the time postpartum.

Domperidone is an agent similar to metoclopromide that blocks the dopamine receptors in the gut and brainstem but with fewer of the psycho-neurologic side-effects of metoclopromide. Domperidone is used in Canada as an antiemetic, but it is not FDA-approved in the United States. **In placebo controlled trials in mothers with decreased milk supply, domperidone increases prolactin levels and milk supply twofold- to threefold.**[100] The usual dose to improve milk supply is 10 to 20 mg, 3 to 4 times a day. Slow tapering (reduce 10 mg/week) is suggested as acute withdrawal rapidly diminishes milk supply. The relatively high protein binding in maternal serum limits transfer to the neonate, relative infant dose of 0.04%. Recently, the FDA issued a warning against its use because of a risk of cardiac arrhythmias. These potentially life-threatening reactions occurred in older patients with hypokalemia and who were receiving chemotherapy for cancer. Intravenous domperidone was used in high doses as an antiemetic in these patients.

Sulpiride is a selective dopamine antagonist used in Europe as an antidepressant and antipsychotic. Smaller doses (50 mg twice daily) do not produce neuroleptic effects in the mother, **but prolactin and milk production are increased significantly. Clinical studies suggest an increase in milk production (20%-50%) less than that seen with metoclopramide.** In a placebo-controlled study with random assignment of 130 subjects, sulpiride 50 mg twice daily for the first 7 days postpartum increased the total milk yield from 916±66 mL in the control group to 1211±65 mL in the sulpiride-treated group. The transfer of sulpiride to the breast milk was minimal and no adverse effects were seen in the infants. Sulpiride is not available in the United States.

Intranasal oxytocin substitutes for endogenous oxytocin to contract the myoepithelial cells and cause milk let-down. In theory, its use is to overcome an inhibited let-down reflex. Oxytocin is destroyed by gastrointestinal enzymes and is not given orally. Until recently, oxytocin intranasal spray was available commercially, but it has been taken off the market. A pharmacist can prepare an intranasal spray with a concentration of 2 IU per drop. The let-down dose is a spray (3 drops) to each nostril; the total let-down dose is approximately 12 IU. This is taken within 2 or 3 minutes of each nursing episode. The suggested duration of therapy is unclear. Underlying causes for an inhibited let-down reflex need to be identified and controlled.

There have been few clinical trials using oxytocin alone to improve milk production. **In a double-blind group sequential trial, intranasal oxytocin alone was used to enhance milk production in women during the first 5 days after delivery of a premature infant. The cumulative volume of breast milk obtained between the second and fifth days was 3.5 times greater in primiparas given intranasal oxytocin than in primiparas given placebo.** Because of oxytocin's complementary mechanism to prolactin-stimulating medications, they are often used in combination.

While metoclopramide, domperidone, sulpiride, and oxytocin appear to be effective and relatively safe for the mother and infant, they are only secondary support interventions. The primary focus should be to enhance prolactin and oxytocin through the natural mechanisms, appropriate and frequent stimulation of the nipple and areola. Galactagogues should only be used for a short duration (2 to 4 weeks) and in conjunction with hands-on counseling by an individual with the time, energy, and knowledge to enhance the "natural" production of breast milk.

MATERNAL DISEASE

In the vast majority of cases of lactating mothers with intercurrent disease, there is no medical reason to stop breastfeeding. However, appropriate management requires individualizing the care of the nursing dyad in order to preserve the supply-and-demand relationship of lactation. For example, a hospitalized nursing mother should have her nursing baby with her in the hospital for on-demand feedings. This situation stretches the flexibility of hospital administrators and nursing services, but the problem can be overcome by education.

The first principle is to maintain lactation. An acute hospitalization for a surgical procedure is a common complication. **If breast milk was the neonate's only source of nutrition, an acute reduction in nursing may lead to breast engorgement, confusing postoperative fever, and mastitis. The infant should be put to the breast just before premedication, and the breasts should be emptied in the recovery room. The most effective way is to have the mother nurse. Although some anesthetic may be present in the milk, most are compatible with lactation.** If there is legitimate concern or if the mother cannot communicate (on a ventilator), the breasts should be pumped mechanically and subsequently emptied every 2 to 3 hours by nursing or pumping.

The second principle is to adjust for the special nutritional requirements of nursing mothers. This principle is especially pertinent when intake is restricted postoperatively and when maternal diet must be manipulated. In the postoperative period, the surgeon must account for the calories and fluid required for lactation. **Until oral intake is established, a lactating mother needs an additional 500 to 1000 mL of fluid per day. Early return to a balanced diet is essential to offset the additional energy and protein requirements of lactation and wound healing.**

The third principle is to ensure that the maternal disease will not harm the infant. This is most pertinent with infectious disease, but it is equally important in cases in which a mother's judgment is in question, such as severe mental disease, substance abuse, or a history of physical abuse. The benefits of breastfeeding in the latter situations must be carefully evaluated, using the resources of the patient, her family, and social services.

Infection is the most common area where breastfeeding is questioned. In general, the necessary exposure of the infant to the mother in day-to-day care is such that breastfeeding does not add to the risk. This recommendation assumes that appropriate therapy is being given to both mother and infant. Isolation of infected areas should still be practiced, such as a mask in the case of respiratory infection and lesion isolation in herpes. **The three acute infections in which breastfeeding are contraindicated are herpes simplex lesions of the breast, untreated active (not just purified protein derivative [PPD]-positive) tuberculosis, and human immunodeficiency viral (HIV) disease.**

The fourth principle is to evaluate adequately the need and type of medication used for therapy (see Chapter 8). The drug management of chronic hypertension illustrates this principle. First, the need for medication must be scrutinized. There is considerable controversy in the literature as to whether or not to treat patients with mild chronic hypertension (diastolic blood pressure 90 to 100 mm Hg). The desire of a mother with mild hypertension to breastfeed may change the risk/benefit ratio so that antihypertensive drug therapy should be delayed until after lactation. Second, the medication should be evaluated for its effect on milk production. **In the first 3 to 4 months of therapy, diuretics reduce intravascular volume and, subsequently, milk volume.** On the other hand, if a patient has been on low doses of thiazide diuretics for more than 6 months, the effect on milk volume is minimal as long as adequate oral intake is maintained. Third, the medication should be evaluated for its secretion in breast milk and its possible effects on the infant. Thiazide diuretics, ethacrynic acid, and furosemide also cross into breast milk in small amounts. These agents have the potential to displace bilirubin, and their use during lactation is of concern when the infant is less than 1 month old or is jaundiced. In general, most other antihypertensive drugs are compatible with breastfeeding. Although new drugs come onto the market often, it is wise to use drugs that have had a long history of clinical use.

A fifth principle and a constant challenge is the blanket proscription by radiologists (and x-ray technicians) to "pump and dump" breast milk for 24 to 48 hours when radiocontrast agents are used. Most agents have very poor oral bioavailability and the effective infant dose is <0.1%. The guidelines of the American College of Radiology (2004) review the use of contrast media in breastfeeding mothers. On a practical level, the mother should feed her infant just before the injection of the contrast media. The delay of 2 to 3 hours until the next feed allows the mother to clear the agent before potential infant exposure; the half-life of many of these agents is less than 2 to 3 hours. If the mother is comfortable with expression or pumping, stored breast milk is an alternative for interim feeds for 2 to 3 half-lives.

DRUGS IN BREAST MILK

Most medications taken by the mother appear in the milk (see Chapter 8), but the calculated doses consumed by the nursing infant range from 0.001% to 5% of the standard therapeutic doses and are tolerated by infants without toxicity (see Table 23-8, Medications and Mother's Milk).

The following guidelines are helpful:

1. Evaluate the therapeutic benefit of medication. Diuretics given for ankle swelling provide very different benefits from those for congestive heart failure. Are drugs really necessary, and are there safer alternatives?
2. Choose drugs most widely tested and with the lowest milk/plasma ratio.
3. Choose drugs with the lowest oral bioavailability.
4. Select the least toxic drug with the shortest half-life.
5. Avoid long-acting forms. Usually, these drugs are detoxified by the liver or bound to protein.
6. Schedule doses so that the least amount gets into the milk. The rate of maternal absorption and the peak maternal serum concentration are helpful in scheduling dosage. Usually, it is best for the mother to take the medication immediately after a feeding.
7. Monitor the infant during the course of therapy. Many pharmacologic agents for maternal use are also used for infants. This implies the availability of knowledge about therapeutic doses and the signs and symptoms of toxicity.

BREAST MASSES DURING LACTATION

Breast cancer is the most common cancer of the reproductive organs of the female. While the risk of breast cancer increases tremendously after the age of 40, 1% to 3% of all breast cancers occur during pregnancy and lactation. Breast cancer diagnosed during lactation may have its origin before or during pregnancy. As a result of this assumption and small numbers of pregnant or lactating women, most studies have lumped the populations together. Recently, researchers in Japan have analyzed breast cancer in age-matched control women (n = 192), women who were pregnant at diagnosis (n = 72), and women who were lactating at diagnosis (n = 120). **The prognosis for breast cancer that is diagnosed during pregnancy or lactation is poorer than for breast cancer diagnosed at other times.** The 10-year survival for age-matched controls without lymph node metastasis was 93%; for women who were diagnosed during pregnancy or lactation the survival was 85%. When the lymph nodes were involved, the 10-year survival was 62% in controls and 37% in women who were diagnosed during pregnancy or lactation. The difference in survival is partially explained by a longer duration of symptoms prior to diagnosis (6.3 vs. 5.4 months), tumor size on palpation (4.6 vs. 3.0 cm), and tumor size on cut surface (4.3 vs. 2.6 cm), in lactating women versus control women, respectively. **The delay in diagnosis and the greater size at diagnosis in lactating women is a failure of the obstetric care provider and/or the lactating woman to aggressively sample a breast mass.**

The lactating woman is most likely to recognize a breast mass through her daily manipulations of her breasts. In her framework of reference, she usually considers this mass a "plugged duct." She should be encouraged to report a plugged duct that persists more than 2 weeks despite efforts to initiate drainage of that lobule. Her provider faces an expanded differential diagnosis. Fibromas and fibroadenomas are more common in young women. These solid tumors are rubbery, nodular, and mobile, and they may grow rapidly with the hormonal stimulation of pregnancy. The most common diagnosis is a dilated milk duct, a completely benign diagnosis.

A needle aspiration of the mass is the mainstay of diagnosis. **Percutaneous fine-needle aspiration is performed in the same manner as in nonpregnant women.** The use of local anesthetic is optional; infiltration of the area around a small lesion may increase the likelihood of a nondiagnostic aspiration. The area over the mass is swabbed with iodine or alcohol and, using sterile techniques, the lesion is fixed between the thumb and fingers of the nondominant hand. Using a 22-gauge needle attached to a 20-mL syringe, the center of the lesion is probed. Initial aspiration usually reveals the nature of the lesion. If milk or greenish fluid (fibrocystic disease) is found and the lesion disappears, no further diagnostic procedures need to be performed. If the tumor is solid or fails to disappear completely after aspiration, the needle is passed several times through the lesion under strong negative pressure. The aspirated tissue fluid is air-dried on a slide and sent for cytologic evaluation. The pathology requisition should note the age and lactating status. **Fine-needle aspiration biopsy appears to have the same accuracy in pregnancy and lactation as in the nonpregnant, nonlactating woman.** In a study of 214 fine-needle aspirations during pregnancy and lactation, eight (13.7%) were cancer, and the sensitivity, specificity, and positive predictive values were 100%, 81%, and 61%, respectively.

Ultrasound is an accurate method of determining the cystic nature of a breast mass in lactating women. Mammography is more difficult to interpret during lactation. Young breasts are generally more dense, and the massive increase in functioning glands may obscure small cancers. However, the accuracy is still good if the films are interpreted by experienced radiologists. In general, mammography is a secondary diagnostic modality.

A core biopsy using ultrasound or radiographic guidance is a reasonable option to avoid a surgical procedure. If a surgical biopsy is required, the surgeon will usually need guidance regarding the management of lactation. Most breast biopsies can be performed under local anesthesia. **If the mother nurses just before the procedure, she will empty the breast, which makes the surgery easier, and will allow 3 to 4 hours until the next feed.** Local anesthetics are not absorbed orally and pose no risk to the infant. The mother should be allowed to nurse on demand. Most anesthetics used for general anesthesia enter the breast milk in small amounts (1% to 3%) of the maternal dose, and minimal behavioral effects in infants have been observed. In most cases the mother can nurse within 4 hours of the anesthetic. The mother's breasts should be pumped 3 to 4 hours after the last feed regardless of the anesthetic status. She will begin to feel the discomfort of engorgement, and the fever of engorgement may confuse the postoperative picture as early as 8 or 10 hours. The failure to empty the breasts within 12 hours will begin to adversely affect milk supply.

Surgical biopsy usually has little effect on breastfeeding performance unless the procedure is done in the periareolar area or the nerves supplying the nipple are compromised. Circumareolar incisions are to be avoided if possible. Milk fistulas are an uncommon risk (5%) of central biopsy. The fistulas are usually self-limited and will spontaneously heal over several weeks. Prohibiting breastfeeding does not change the likelihood of ultimate healing.

BACK-TO-WORK ISSUES

In 2009, according to the Centers for Disease Control (CDC), about 50% of women in the workplace have a child at home less than 12 months old. One third returned to work within 3 months of birth and two thirds returned within 6 months. More than half are supplementing the feedings with formula and the duration of exclusive breastfeeding is well below the recommended duration. As a consequence, the CDC, other national organizations, and state legislatures have enhanced or initiated a major campaign to counter this challenge. The CDC has guidelines for workplace safety for working mothers who wish to express breast milk (www.cdc.gov/breastfeeding/promotion/employment.htm). **In March 2011, federal law amended Section 7 of the Fair Labor Standards Act to require employers to provide "reasonable break time for an employee to express breast milk for her nursing child for 1 year after the child's birth each time such employee has need to express the milk."**

The separation between mother and infant adversely affects the psychology and physiology of lactation through a decrease in the frequency of nursing, breast engorgement, and unsatisfied needs of the baby. The anxiety and fatigue associated with the combination of employment and lactation inhibits the let-down reflex, weakens maternal host defenses, and disrupts family dynamics. The infant must adapt to another caregiver, a new sucking technique, and unfamiliar infectious agents found in day-care settings. Therefore, it is not surprising that formula feeding is viewed as an improvement in mothers' lives, but it does create feelings of inadequacy and guilt in some women.

Breastfeeding during employment is both possible and fulfilling. Preparation, milk storage, and choice of childcare are the cornerstones to easy adaptation to employment. Preparation involves preemployment change in lifestyle to accommodate the increased stresses. **Lactation should be well established with frequent nursing (10 to 14 times per day) and no supplementation prior to return to work.** Return to full-time work prior to 4 months has a greater negative impact than return to work after 4 months. Part-time work lessens the impact. About 2 weeks prior to work, the mother should change her nursing schedule at home. During the workday, she should express or pump her breasts two or three times a day, while increasing her nursing with short, frequent feeds before and after work times. The infant is fed bottles of stored breast milk by a different person in a different place to allow it to adapt more easily.

During the 2 weeks prior to employment, the day-care arrangements should be carefully selected and observed. In addition to references, several questions are pertinent to the selection of the day-care setting. Is the sitter a mother herself, and does the sitter have experience with nursing babies? Is the mother welcome to use the child-care site for a midday nursing? Does the day-care center provide in-arm feeding, or does it use high chairs and propped bottle-feedings? Is the time and activity of the center highly structured and rigid, or is it flexible to mother or infant needs and requests? Does the staff treat the parents and children with respect? Many of these questions can be answered by an extended (1 to 2 hours) observation of the center and its children.

Fatigue is the number one enemy of the working mother. Emotional and physical support of the mother is critical. Some helpful suggestions include (1) bringing the infant's bed into the parent's room, or the construction of a temporary extension to the parents' bed; (2) use of labor-saving devices, division of domestic chores, and the elimination of less important household chores to reduce the workload; and (3) taking naps and frequent rest periods to conserve energy.

Continued stimulation of the breast during working hours is important. Pumping not only improves milk supply but it also supplies human milk for the infant. Manual expression and/or mechanical pumping should be performed more frequently (two to three times) in the first 6 months postpartum. After 6 months, the frequency can be reduced and eliminated as the infant is supplemented by fluids or solids during the day.

The collection of breast milk has become simple with the wide variety of mechanical pumps available in the market. Mechanical pumps that employ a bulb syringe produce the least amount of milk and have the highest rate of bacterial contamination. **Cyclic electric pumps produce the most milk with the least amount of nipple trauma.** Water-driven pumps are both cheap and relatively effective. The most efficient pumps are not as effective as the efficiently nursing infant in increasing milk volume and raising prolactin levels. Milk collection can be enhanced by pumping in a quiet place with soothing music in the background. Observing her infant making vocalizations can be instrumental in allowing let-down to occur.

The concern about bacterial growth in expressed and stored milk has been alleviated by recent studies showing that bacterial contamination does not increase significantly for up to 6 hours after expression, when the milk is stored at room temperature, nor were there differences in bacterial counts between specimens stored at room temperature and those stored under refrigeration for 10 hours. **Freshly refrigerated milk should be used within 2 days.** Four to 6 oz of human milk can be frozen in partially filled resealable plastic bags. When human milk is frozen, it should be cooled briefly prior to transfer to the freezer. **The milk will keep for 2 to 4 weeks in the refrigerator freezer and up to 6 months in a freezer set at 0° F.** The milk should be stored in layers and thawed quickly in warm tap water. **Frozen milk should not be thawed in the microwave, as the heating is uneven and severe oral burns have been reported. After it is thawed it should be used within 6 to 8 hours.**

WEANING

The American Academy of Pediatrics recommends exclusive breastfeeding for the first 6 months of life and continuation beyond the first 12 months of life. This recommendation in 1997 initiated a firestorm of controversy regarding "the excessive duration of breastfeeding." Breastfeeding is both a biologic process and a culturized activity. In the United States, breastfeeding has been culturized to breastfeeding for less than 6 months. From a broader biologic and historical perspective, the United States experience reflects cultural bias, not biologic reality. In a remarkable review, **Dettwyler[71] makes a very cogent argument for the "natural" age of weaning in the human to be 3 to 4 years.** She has several arguments. Traditional and prehistoric societies wean between the third and fourth year. Based on weaning when the infant weight is four times its birthweight, similar to other primates, weaning should occur between 2 and 3 years. If weaning corresponds to attainment of one third the adult weight, then weaning would occur between 3 and 4 years. If humans behaved like chimpanzees or gorillas and weaned at six times the gestational period, humans would wean at 4.5 years. The dental, neurologic, and immunologic systems are still developing until 6 years of age; breastfeeding and breast milk provide unique support for these systems up to 4 to 6 years. Developmentally, the infant is able to place solid food in its mouth at 6 months, but this intake, if left to the infant's own skills, would not reach a significant proportion of the nutritional requirements until 18 to 24 months. The ability to drink from a cup occurs close to the second year. As the infant supplements an increasing proportion of its nutritional needs with solid or liquid food, the mother will begin to ovulate. Subsequent pregnancy is increasingly more likely. **Breastfeeding, through its suppression of gonadal function, maintains a birth interval of 3 to 4 years. Clearly, breastfeeding into the third or fourth year is a cultural exception in the United States, but prolonged breastfeeding does not constitute abnormal or deviant behavior as expressed by many "modern" Americans.** As we learn more about the benefits of long-term lactation, our culture may return to more reasonable expectations for duration of breastfeeding.

KEY POINTS

- The World Health Organization, the U.S. Surgeon General, the American Academy of Pediatrics, the American Academy of Family Practice, the American College of Obstetricians and Gynecologists, and the Academy of Breastfeeding Medicine endorse breastfeeding as the gold standard for infant feeding.
- Breastfeeding accrues many health benefits for the infant, including protection against infection, less allergy, better growth, better neurodevelopment, and lower rates of chronic disease such as insulin-dependent diabetes and childhood cancer.
- Breastfeeding accrues more health benefits for the mother, including faster postpartum involution,

improved postpartum weight loss, less premenopausal breast cancer, lower rates of cardiovascular disease, and less insulin-resistant diabetes mellitus, better mother-infant bonding, and less economic burden.

- Formula lacks key components including defenses against infection, hormones and enzymes to aid digestion, polyunsaturated fatty acids, which are necessary for optimal brain growth, and adequate composition for efficient digestion.
- Prolactin is the major promoter of milk synthesis. Oxytocin is the major initiator of milk ejection. The release of prolactin and oxytocin results from the stimulation of the sensory nerves supplying the areola and nipple.
- Oxytocin released from the posterior pituitary can be operantly conditioned and is influenced negatively by pain, stress, or loss of self-esteem.
- Contact with the breast within one half hour after birth increases the duration of breast feeding. Correct positioning of the nursing infant and correct latch-on promote efficient milk transfer and reduce the incidence of breast pain and nipple injury. A frequency of nursing greater than eight per 24 hours, night nursing, and a duration of nursing longer than 15 minutes are needed to maintain adequate prolactin levels and milk supply.
- The nursing actions on a human teat versus on an artificial teat are very different. Poor lactation is the major cause of nipple injury and poor milk transfer. Perceived or real lack of milk transfer is the major reason for discontinuation of nursing.
- Milk production is reduced by an autocrine pathway through a protein that inhibits milk production by the alveolar cells, and by distention and pressure against the alveolar cells.

About 1 in 500 women will require nonobstetrical surgery during pregnancy.[1] The care of the pregnant surgical patient requires a multidisciplinary approach involving the obstetrician, surgeon, anesthesiologist, and pediatrician. There are numerous unique challenges that arise when caring for a pregnant woman presenting with symptoms that may require surgery. Evaluation of these patients is often confounded by the various changes in maternal physiology, concern for fetal well-being, and the potential risk to the continuing pregnancy. The introduction of new imaging diagnostic modalities has increased our diagnostic capabilities; however, their safety in pregnancy continues to be evaluated. In this chapter, we focus on (1) specific adaptations to pregnancy, both physiologic and anatomic, that the clinician needs to be aware of when evaluating a gravid patient; (2) the diagnostic challenges of evaluating a pregnant woman, with specific attention to radiologic studies, (3) the unique issues that arise when providing surgical anesthesia to the gravid patient; and (4) the potential risks to the pregnancy that are assumed when nonobstetrical surgery becomes necessary. Finally, although some of the more common indications for surgery in pregnancy, such as appendicitis, cholecystitis, and trauma, are addressed in more detail elsewhere, we address clinical circumstances that are being seen with increasing frequency during pregnancy, including the use of laparoscopy, the evaluation and treatment of adnexal masses, and issues related to obesity and bariatric surgery.

MATERNAL PHYSIOLOGY

Pregnancy-induced changes in maternal physiology and anatomy can confuse the clinical picture when evaluating the gravid patient presenting with abdominal complaints. Abdominal discomfort, nausea, vomiting, diarrhea, and constipation are often encountered in pregnancy in the absence of intra-abdominal pathology. Furthermore, laboratory changes that are commonly seen as abnormal in the nonpregnant surgical patient may be normal in the gravid state. Therefore, familiarity with these changes is essential when evaluating pregnant women with abdominal symptoms (Table 24-1; see Chapter 3).

Pregnancy causes profound changes in cardiovascular, hematologic, and respiratory physiology. Cardiovascular adaptations to pregnancy include a significant increase in cardiac output, heart rate, and intravascular volume.[2,3] Because the heart rate increases by up to 15 to 20 beats/minute compared with the nongravid state, it may be difficult to determine whether a mild tachycardia is physiologic or related to an underlying pathologic condition. These physiologic changes must be accounted for when evaluating a pregnant woman with a potential surgical diagnosis.

Respiratory physiology is also altered in pregnancy. The gravid uterus leads to a decrease in functional residual capacity and total lung capacity. In addition, the stimulatory effect of progesterone on respiratory drive leads to an increase in tidal volume and minute ventilation. Of note, the respiratory rate remains unchanged. As a result, pregnancy is associated with a state of relative hyperventilation and mild respiratory alkalosis.

TABLE 24-1 RELEVANT MATERNAL PHYSIOLOGIC CHANGES

I. **Cardiovascular changes**
- Increased cardiac output
- Increased blood volume
- Increased heart rate
- Decreased blood pressure
- Decreased systemic vascular resistance
- Decreased venous return from the lower extremities

II. **Respiratory changes**
- Increased minute ventilation
- Decreased functional residual capacity

III. **Gastrointestinal changes**
- Decreased gastric motility
- Delayed gastric emptying

IV. **Coagulation changes**
- Increased clotting factors, I, VII, VIII, IX, X
- Increased fibrinogen
- Increased risk for thromboembolic disease

V. **Renal changes**
- Increased renal plasma flow and glomerular filtration rate
- Increased ureteral dilatation

VI. **Laboratory values**
- Decreased serum creatinine
- Decreased blood urea nitrogen (BUN)
- Decreased hemoglobin and hematocrit
- Increased white blood cell count
- Increased alkaline phosphatase level
- Increased fibrinogen levels
- Increased D-dimer levels
- Increased erythrocyte sedimentation rate

The physical examination of the pregnant abdomen may present a unique challenge. The enlarging gravid uterus becomes an abdominal organ after 12 weeks' gestation and may displace or compress intra-abdominal organs, making localization of pain difficult. For example, there is progressive upward displacement of the appendix, which does not return to its original position until 1 to 2 weeks postpartum.[4] However, despite the altered location, the most consistent and reliable symptom in pregnant women with appendicitis remains right lower quadrant pain.[5,6] Many other classic signs and symptoms of appendicitis, such as nausea, vomiting, and leukocytosis, may be normal findings in pregnancy. Similarly, physical examination findings of rebound and guarding may not be reliable indicators of intraperitoneal inflammation in pregnancy.[7,8] In addition, abdominal tenderness may be a sign of a pregnancy-specific complication, such as chorioamnionitis or placental abruption. Thus, the evaluation of abdominal pain in pregnancy often presents a challenging diagnostic dilemma.

The gravid uterus may also limit the ability of diagnostic imaging of abdominal organs. After the first trimester, the maternal adnexa are displaced cephalad and may be difficult to image with ultrasound. Some anatomic changes related to the growing uterus may confound the interpretation of diagnostic imaging. For example, mild to moderate hydroureter is commonly encountered in pregnancy secondary to compression of the distal ureters by the uterus, as well as progesterone-induced smooth muscle relaxation. This finding is more common on the right side and may even be associated with mild hydronephrosis. Because the incidence of both pyelonephritis and nephrolithiasis in increased in pregnancy, it is important to recognize that a degree of dilation of the upper urinary tract is often a normal finding in a pregnant patient.

Laboratory evaluation of the pregnant woman is also altered in pregnancy. Maternal blood volume is increased out of proportion to the increase in red blood cell mass. This leads to a dilutional anemia of pregnancy, especially in the later stages of pregnancy. This physiologic anemia may be mistaken for occult blood loss in the patient who is being evaluated for a surgical abdomen. Pregnancy is also associated with a progressive rise in peripheral white blood cell count, with a mean value of 14,000 cells/mm^3 during the second trimester. This physiologic leukocytosis, in conjunction with tachycardia and anemia, may confound the clinical picture and lead to an incorrect diagnosis. Other laboratory values, such as D-dimer, serum creatinine, and alkaline phosphatase, are significantly altered in pregnancy, limiting or altering their role in the diagnostic evaluation of the pregnant patient (see Table 24-1).

These significant changes in normal maternal physiology and diagnostic evaluation can complicate the diagnostic workup of the pregnant patient presenting with concerning symptoms. The utmost vigilance is necessary to rule out true pathology and arrive at the correct diagnosis in a timely fashion so that the appropriate management can be implemented and the risks to mother and fetus minimized. Familiarity with the normal pregnancy-related changes is critical to achieving optimal care.

DIAGNOSTIC IMAGING

A common concern that arises when evaluating a pregnant patient is the safety of diagnostic radiologic tests in pregnancy. When considering the potential risks related to imaging, it is important balance any small potential for harm against the significant risks associated with an erroneous or delayed diagnosis. Failure to accurately diagnose a serious condition in a timely manner can cause significant harm to the woman and her fetus.

Ionizing Radiation

The biggest concern related to diagnostic imaging is regarding the exposure of the developing fetus to ionizing radiation. The critical factors that determine the risk to the fetus are the dose of radiation to which the fetus is exposed and the gestational age of the exposure (Table 24-2). Very early in gestation, within the first 2 weeks of conception, any significant cell damage caused by radiation is believed to result in a miscarriage. This is believed to be an "all or none" phenomenon so that if the fetus remains viable after this early exposure, no adverse effects are expected. Radiation doses of greater than 50 to 100 mGy (5-10 rad; 1 mGy = 0.1 rad) are likely necessary to cause embryonic death. Postconception weeks 2 through 8 are particularly sensitive to teratogenicity because this is the period of organogenesis. At this stage, the embryo is more resistant to radiation-induced death, with doses of more than 250 to 500 mGy (25-50 rad) being necessary to cause fetal demise.[9,10]

The fetal central nervous system is the most sensitive to radiation damage during weeks 8 to 15 because this is a period of rapid neuronal development. Significant radiation exposure of 60 to 310 mGy during this period may lead to severe mental retardation and microcephaly. These risks to the fetal central nervous system persist up until about 25 weeks, although increasingly high doses of radiation are necessary to cause significant damage with

TABLE 24-2 Fetal Effects of Radiation Exposure by Gestational Age

GESTATIONAL AGE (FROM LMP)	ADVERSE EFFECT	ESTIMATED MINIMUM RADIATION DOSE
Weeks 3-4 (first 2 weeks postconception)	Embryonal demise ("all or none")	5-20 cGy
Weeks 4-8	Death, congenital anomalies, IUGR	20-50 cGy
Weeks 8-15*	IUGR, microcephaly, severe mental retardation†	6-50 cGy
Weeks 16-25	Mental retardation	25-150 cGy

Data from Brent RL: Saving lives and changing family histories: appropriate counseling of pregnant women and men and women of reproductive age, concerning the risk of diagnostic radiation exposures during and before pregnancy. Am J Obstet Gynecol 200:4-24, 2009; and Patel SJ, Reede DL, Katz DS, et al: Imaging the pregnant patient for nonobstetric conditions: algorithms and radiation dose considerations. Radiographics 27:1705-1722, 2007.)

*Period of neuronal development that is most sensitive to radiation damage.

†Exposure to 1 Gy of radiation during this period has been associated with a loss of 30 IQ points.

IUGR, Intrauterine growth restriction; *LMP*, last menstrual period.

TABLE 24-3 Estimated Fetal Exposure to Radiation from Common Diagnostic Radiologic Studies

RADIOLOGIC STUDY	ESTIMATED FETAL DOSE* (cGy)
Chest radiograph (posteroanterior, lateral)	0.0002
Abdominal radiograph	0.1-0.3
Head computed tomography (CT)	0.0005
Chest CT	0.002-0.02
Abdominal CT	0.4-0.8
Abdominopelvic CT	2.5-3.5
Abdominopelvic CT (stone protocol)	1
Ventilation scan	0.007-0.05
Perfusion scan	0.04
Intravenous pyelography	0.6-1
Bone scan	0.3-0.5
Positron emission scan	1-1.5
Thyroid scan	0.01-0.02
Mammography	0.007-0.02
Small bowel series	0.7
Barium enema	0.7

*Fetal dose can vary significantly based on a variety of patient and imaging parameters. If necessary, more precise estimates can be obtained through consultation with a radiation safety officer or radiation physicist.

increasing gestational age. After 25 weeks, the fetus is fairly resistant to radiation-induced abnormalities.[9,10]

In addition to teratogenic risk, there may be a concern for potential carcinogenic effects of ionizing radiation to the developing fetus. Some authors have estimated that the incidence of childhood leukemia and other cancers may increase by about 0.06% from baseline with each centigray of exposure.[11] Given the low background risk, diagnostic doses of radiation do not appear to significantly increase the absolute risk to the fetus.[9,12] However, the causative link between fetal exposure to diagnostic radiation and childhood leukemia has been called into question.[9]

Table 24-3 shows the estimated doses of fetal radiation exposure from various commonly used diagnostic imaging examinations that involve ionizing radiation.[12-14] It is important to note that the amount of radiation exposure from any of these diagnostic studies is well below the dose threshold for teratogenic risk. **Therefore, when evaluating a pregnant patient presenting with significant symptoms, the patient should be reassured that the radiation exposure to the fetus from a diagnostic radiologic test does not confer a significant risk for fetal harm.**[15,16] It is important for the clinician to be familiar with the relative radiation doses delivered by commonly ordered tests because this information may aid in the decision to choose one modality over another. In addition, when performing a radiologic study on a pregnant patient, the use of low-exposure techniques and abdominal lead shielding for nonpelvic studies can also help reduce the degree of fetal exposure. When clinically appropriate, consideration should be given to other diagnostic modalities, such as ultrasound or magnetic resonance imaging (MRI), that do not involve radiation.

Ultrasound

Ultrasound remains the initial imaging study of choice in the evaluation of the pregnant woman presenting with acute abdominal pain. Ultrasound involves the use of sound waves and is not a form of ionizing radiation. However, ultrasound does have the potential to transfer energy to the tissues being imaged.[17] There have been no confirmed adverse effects of diagnostic ultrasound procedures. Thus, the safety and versatility of ultrasonography has made it the first-line diagnostic tool during pregnancy whenever appropriate to address the clinical question at hand.

Magnetic Resonance Imaging

There are numerous advantages to MRI use during pregnancy. Like ultrasound, MRI does not use ionizing radiation, and there have been no reported harmful effects to the mother or fetus. In recent years, the use of MRI has expanded greatly as the image quality and availability have increased. For example, MRI has proved useful for evaluation of pathologies such as adrenal tumors, uterine and ovarian masses, gastrointestinal lesions, and retroperitoneal space evaluation, while avoiding the radiation exposure associated with computed tomography (CT) scanning.[18]

The use of diagnostic imaging in pregnant women requires adequate patient counseling to allay concerns of fetal harm and to balance any small potential risk against the need to arrive at an accurate and timely diagnosis. Although every effort should be made to minimize radiation exposure, it is widely accepted that exposure of less than 50 mGy does not confer a significant risk for fetal harm.[19,20] In fact, according to the American College of Obstetricians and Gynecologists (ACOG), "women should be counseled that x-ray exposure from a single diagnostic procedure does not result in harmful fetal effects. **Specifically, exposure to less than 50 mGy (5 rads) has not been associated with an increase in fetal anomalies or pregnancy loss."**[12]

ANESTHESIA DURING NONOBSTETRICAL SURGERY

When anesthesia is required during pregnancy for a surgical procedure, several potential issues arise that must be addressed. From the perspective of the patient, the concern

for possible adverse effects on the pregnancy is of primary importance. From the clinician's perspective, it is important to consider the physiologic changes of pregnancy that affect the delivery of safe and effective anesthesia.

Anesthesia and Teratogenicity

As is the case when examining the potential teratogenicity of any prenatal exposure, the data are limited to retrospective information emanating from case series and registries. These methods are significantly limited by a variety of potential biases that can lead to incorrect conclusions being drawn. However, because prospective research focusing on the teratogenicity of a medication is not ethically or logistically feasible, patients must be counseled based on the existing data, with acknowledgment of the inherent limitations.

Several early studies have raised the possibility that exposure to anesthesia in the first trimester may be associated with an increased risk for central nervous system malformations.[21,22] However, the methodologies used to arrive at these conclusions were particularly limited and not supported by subsequent data.[21] This example underscores the significant limitations to the data supporting a possible teratogenic risk of surgical and anesthetic exposure in the first trimester.

Most of the data have been reassuring that a significant risk for congenital malformations is unlikely when surgery occurs in the first trimester.[23,24] For example, Mazze and Kallen[24] reported on 5405 women from the Swedish Birth Registry who underwent nonobstetrical surgery during pregnancy, which included more than 720,000 deliveries between 1973 and 1981. More than 40% of these surgeries took place in the first trimester, yet there was no significant difference in the rate of congenital malformation compared with women without exposure to surgery in pregnancy. Furthermore, a recent systematic review of the literature identified more than 12,000 pregnancies exposed to nonobstetrical surgery and reported an overall 2% incidence of congenital malformation (3.9% when surgery occurred in the first trimester). Although there was no control group available in this review, the observed rate of malformation falls well within the range of expected rates of congenital malformation. Thus, the best available data appear to support the lack of a significant increased risk for malformations among pregnancies exposed to nonobstetrical surgery and anesthesia. However, unless clinically necessary, it may be preferable to defer surgical intervention until the second trimester, when the theoretical risk for teratogenicity, as well as spontaneous miscarriage, is further decreased.

Anesthesia and Pregnancy Physiology

As discussed earlier, there are many significant physiologic changes that occur in pregnancy that can have a profound impact on the delivery of safe and effective anesthesia in pregnancy (see Table 24-1). For example, several physiologic changes contribute to the increased risk for aspiration in pregnant women undergoing general anesthesia. Gastric emptying time is prolonged in pregnancy, especially in the third trimester and in obese women.[25] There is also a progesterone-mediated decreased tone at the gastroesophageal junction. Therefore, strategies to decrease the risk for aspiration, such as preoperative fasting, antacid prophylaxis (e.g., 30 mL of sodium citrate), and airway protection, are essential. In some situations, administration of histamine-2 blocker or a gastric motility agent (e.g., metoclopramide), or both, should be considered as well.

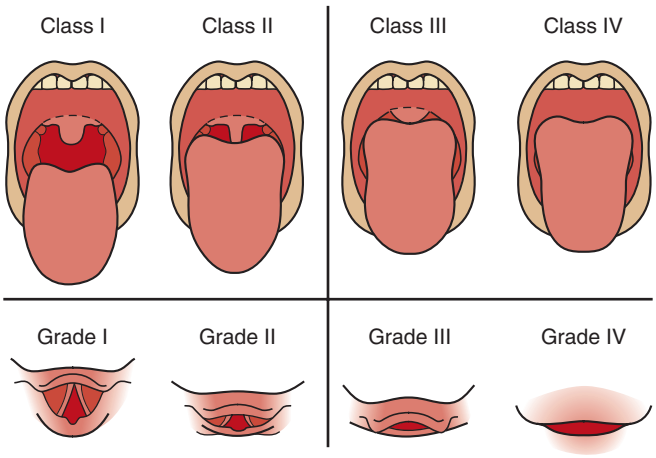

FIGURE 24-1. Mallampati airway examination with corresponding laryngoscopic view of the vocal cords. (Modified from Hughes SC, Levinson, G, Rosen MA [eds]: Shnider & Levinson's Anesthesia for Obstetrics, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2002.)

Oropharyngeal edema and narrowing of the glottis opening are common in pregnancy and can affect the safe access to the airway in a pregnant patient, especially in an emergency situation. **The Mallampati airway examination is often used to assess the airway and predict the degree of difficulty of intubation, with progression from low-risk airways (class I) to high-risk airways (class IV)** (Figure 24-1).[26] **In fact, there is a 34% increase in class IV Mallampati airways at term compared with the first trimester.**[27] **These changes are more pronounced in the third trimester, in obese women, and in patients with preeclampsia. Thus, preoperative airway examination is critical.**

One of the most significant physiologic phenomena in pregnancy is related to aortocaval compression by the gravid uterus, especially in the supine position and in the latter half of pregnancy. Compression of the inferior vena cava by the gravid uterus results in decreased preload and cardiac output with a resultant decrease in uterine and placental perfusion. In addition, venous stasis in the lower extremities increases the risk for venous thromboembolism. Thus, it is essential for the pregnant patient undergoing a surgical procedure to be positioned with a lateral tilt to relieve some of this compression by displacing the gravid uterus to the side. This can often be accomplished by placing a wedge under the right hip. Proper patient positioning, especially in the later stages of pregnancy, can help optimize cardiovascular physiology during surgery.

NONOBSTETRICAL SURGERY AND PREGNANCY OUTCOME

The largest study to explore pregnancy outcomes in women undergoing nonobstetrical surgery is based on the Swedish Birth Registry. Mazze and Kallen[24] identified 5405 nonobstetrical surgeries from more than 720,000 births between 1973 and 1981, for a prevalence of 0.75%.

The nonobstetrical surgeries included 1331 abdominal surgeries, 1008 genitourinary or gynecologic procedures, and 868 laparoscopies. Type of anesthesia was documented for only 68% of cases, but 2929 procedures (54% of all cases) were documented as being performed under general anesthesia. The authors found no difference in rate of congenital malformation or stillbirth. However, the rates of low birthweight (<2500 g) and very low birthweight (<1500 g) were significantly higher in the surgical group compared with the controls, with risk ratios of 2.0 and 2.2, respectively. The authors reported that observed reduced birthweight was due to both fetal growth restriction and prematurity. In fact, the incidence of preterm birth was increased in the surgery group (7.5% vs. 5.1%; P <.001). Another significant finding was an increased rate of neonatal death within 7 days of life (incidence, 1%; risk ratio, 2.1; 95% confidence interval [CI], 1.6 to 2.7). However, it is difficult to separate the multiple confounding factors that could potentially play a causative role in the development of adverse pregnancy outcomes, such as type of surgery, type of anesthesia, and underlying indication for surgery. In fact, the authors did not identify a specific type of surgical procedure or mode of anesthesia that had a significantly increased rate of adverse outcome. They conclude that the underlying illness that led to the surgery likely plays a significant role in determining the outcome.

More recently, Cohen-Kerem and coworkers[28] reviewed the literature from 1966 to 2002 and identified 12,452 pregnancies that underwent nonobstetrical surgery. The incidence of major birth defect was 2%, and the rate of prematurity was 8.2%. In addition, they found that surgical intervention led to delivery of the fetus in 3.5% of cases, although they could not differentiate whether this was caused by the procedure itself or the underlying condition that necessitated the surgical intervention. Although the lack of matched controls limits the interpretation of their data, it does support the notion that most pregnancies that undergo nonobstetrical surgery will have favorable outcomes.

Taken together, it would seem reasonable to reassure pregnant patients faced with the need for surgery in pregnancy that the rate of adverse perinatal outcome is low. In addition, although there may be an increased risk for low birthweight, preterm birth, and neonatal demise, these risks must be weighed against the potential for complications related to the underlying indication for surgery. In cases of semielective surgery, such as for an enlarged adnexal mass or refractory and severe biliary colic, it is still prudent to defer surgery until after the first trimester when the risk for spontaneous miscarriage is decreased and the theoretical concerns of teratogenicity are avoided. Similarly, surgery in the late-second and third trimesters may affect intraoperative visibility and lead to an increased risk for preterm birth. Therefore, the early second trimester is considered the optimal time for elective surgery that cannot be safely deferred until after the pregnancy.

FETAL MONITORING

The question of whether continuous intraoperative fetal monitoring should be employed when a pregnant woman requires nonobstetrical surgical intervention is a matter of debate.[29,30] Factors in favor of monitoring include the potential for changes in fetal heart rate and uterine activity during the surgery, the potential for fetal well-being to serve as an indicator of maternal status, and the potential to intervene in a case of persistently nonreassuring fetal status. On the other hand, interpretation of the fetal tracing may be unreliable in very preterm fetuses. In addition, the changes in fetal heart tracing occasionally seen, such as a decreased variability and lower baseline heart rate, are often transient and not necessarily an indication of fetal distress. Thus, continuous intraoperative fetal monitoring may lead to an unnecessary emergent cesarean delivery with significant risk for both maternal and neonatal morbidity. A recent survey of the Association of Professors of Gynecology and Obstetrics found that most respondents do not routinely perform intraoperative fetal monitoring, but simply monitor the fetus before and after the procedure.[31] **Because of the lack of data to guide management, the ACOG recommends consultation with an obstetrician who can properly counsel the pregnant women facing surgery and individualize the decision based on factors such as gestational age, type of surgery, and facilities available.**[32,33] In most cases, determining the presence of fetal heart activity before and after surgical intervention seems appropriate.

LAPAROSCOPY IN PREGNANCY

Although the safety of laparoscopy in pregnancy is widely accepted, there are several important physiologic considerations specific to pregnancy that must be considered. Pneumoperitoneum further decreases functional residual capacity and can cause ventilation-perfusion mismatch and hypercapnia. These effects can be further exacerbated by Trendelenburg positioning. Bhavani-Shanker and colleagues[34] prospectively demonstrated that end-tidal carbon dioxide pressures correlate well with arterial P_{CO_2} and that maintaining an end-tidal CO_2 of about 32 mm Hg and a systolic blood pressure within 20% of baseline was effective in preventing respiratory acidosis during laparoscopy. Once again, left lateral maternal position is essential to displace the gravid uterus, helping relieve aortocaval compression and optimize cardiac output.

The intra-abdominal pressure required to obtain adequate laparoscopic visualization during surgery can have significant physiologic effects for both the pregnant women and the fetus. Early animal studies showed that cardiac output decreases with increasing intraperitoneal pressure. Reedy and colleagues[35] performed laparoscopic baboon studies and compared intra-abdominal pressures of 10 and 20 mm Hg. At the higher pressure, there was a significant increase in pulmonary capillary wedge pressure, central venous pressure, pulmonary artery pressure, and peak airway pressure. In addition, a significant increase in ventilator rate was required to maintain oxygenation and end-tidal CO_2. A pressure of 20 mm Hg was also associated with an increased risk for respiratory acidosis. **Similar studies have shown significant changes in both maternal and fetal physiology at pressures greater than 15 mm Hg.**[36] **Therefore, although lower insufflation pressures may lead to limited surgical visualization, it is important to try and keep insufflation pressures below 15mm Hg.** If higher

pressures are required to safely complete the procedure, it would be advisable to periodically release the pneumoperitoneum to allow for physiologic recovery. This is particularly important in obese patients, who often require higher pressures to counteract the weight of the anterior abdominal wall. Although various techniques, such as gasless laparoscopy[37,38] and mechanical lift retractors,[39] have been proposed to avoid high intra-abdominal pressures during laparoscopy, they are not widely performed.

Laparoscopic Entry Techniques in Pregnancy

Although the conventional entry approach has been using a Veress needle, a variety of other closed and open techniques have been proposed in an effort to decrease the incidence of entry complications in nonobstetrical laparoscopic procedures. However, review of the literature fails to support a significant difference in complications between the various approaches.[40,41] Nonetheless, accidental placement of a Veress needle into a 21-week uterus with subsequent pneumoamnion and pregnancy loss has been reported.[42] Thus, it may be reasonable to use an open approach in the latter half of pregnancy. Nonetheless, the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) guidelines support laparoscopic entry with any technique provided that the location of the entry is adjusted to account for the gravid uterus (Table 24-4).[43] Thus, procedures performed in the later stages of pregnancy may require a left upper quadrant insertion of the initial trocar. **The upper limit of gestational age up to which a laparoscopic approach can be performed safely in pregnancy has not be determined. Concerns related to the gravid uterus have led some to recommend that laparoscopy be avoided in the third trimester.**[44] However, current practice guidelines do not impose such a limitation.[43] Because the available evidence is insufficient to impose a definitive recommendation, the decision regarding the optimal surgical approach should be individualized.

Laparoscopy and Pregnancy Outcome

Laparoscopy has become increasingly prevalent in both pregnant and nonpregnant populations. The minimally invasive nature of laparoscopy allows for an easier recovery, with less pain, earlier return of bowel function, and shorter hospital stay. Furthermore, the quicker postoperative ambulation helps reduce the potential for venous stasis and deep venous thrombosis, which is especially important in a pregnant population that is already at increased risk for such complications.

The safety of laparoscopy in pregnancy is supported by the analysis of the Swedish Birth Registry. Reedy and coworkers[45] compared fetal outcomes of 2181 pregnancies that underwent laparoscopy between 4 and 20 weeks' gestation to 1522 pregnancies that underwent laparotomies. No differences were noted in any of the fetal outcome parameters examined. Several other series have further supported the safety of laparoscopy in pregnancy.[46-51] Nevertheless, several reports and case series have been published raising the possible increased risk for adverse outcomes. Amos and associates[52] reported a series of seven laparoscopies performed in pregnancy and found that four of the seven resulted in a fetal demise. Although this report raised a significant concern regarding the safety of laparoscopy in pregnancy, it is important to note that the four pregnancies that suffered a fetal demise were undergoing the surgery for a serious medical conditions known to be associated with intra-abdominal inflammation (three with gallstone pancreatitis and one with a perforated appendix). Therefore, it is difficult to separate the underlying indication for surgery from the surgical approach in trying to establish am etiology for these adverse outcomes.

Walsh and coworkers[53] performed a systematic review of the literature and concluded that an open appendectomy may be safer than a laparoscopic approach when managing appendicitis. This conclusion was based on the 5.8% incidence of fetal loss following a laparoscopic appendectomy

Table 24-4 Relevant Guidelines for Laparoscopy in Pregnancy from the Society of American Gastrointestinal and Endoscopic Surgeons

- Diagnostic laparoscopy is safe and effective when used selectively in the workup and treatment of acute abdominal processes in pregnancy.
- Laparoscopic treatment of acute abdominal processes has the same indications in pregnant and nonpregnant patients.
- Laparoscopy can be safely performed during any trimester of pregnancy.
- Gravid patients should be placed in the left lateral recumbent position to minimize compression of the vena cava and the aorta.
- Initial access can be safely accomplished with open (Hassan), Veress needle, or optical trocar technique if the location is adjusted according to fundal height, previous incisions, and experience of the surgeon.
- CO_2 insufflation of 10 to 15 mm Hg can be safely used for laparoscopy in the pregnant patient. Intra-abdominal pressure should be sufficient to allow for adequate visualization.
- Intraoperative CO_2 monitoring by capnography should be used during laparoscopy in the pregnant patient.
- Intraoperative and postoperative pneumatic compression devices and early postoperative ambulation are recommended prophylaxis for deep venous thrombosis in the gravid patient.
- Laparoscopic cholecystectomy is the treatment of choice in the pregnant patient with gallbladder disease regardless of trimester.
- Laparoscopic appendectomy may be performed safely in pregnant patients with suspicion of appendicitis.
- Laparoscopic adrenalectomy, nephrectomy, and splenectomy are safe procedures in pregnant patients when indicated, and standard precautions are taken.
- Laparoscopy is safe and effective treatment in gravid patients with symptomatic adnexal cystic masses. Observation is acceptable for all other adnexal cystic lesions provided ultrasound is not worrisome for malignancy and tumor markers are normal. Initial observation is warranted for most adnexal cystic lesions smaller than 6 cm.
- Laparoscopy is recommended for both diagnosis and treatment of adnexal torsion unless clinical severity warrants laparotomy.
- Fetal heart monitoring should occur before and after operation in the setting of urgent abdominal surgery during pregnancy.
- Obstetrical consultation can be obtained before and after operation based on the acuteness of the patient's disease, gestational age, and availability of the consultant.
- Tocolytics should not be used prophylactically but should be considered perioperatively when signs of preterm labor are present in coordination with obstetrical consultation.

From Yumi H: Guidelines for diagnosis, treatment, and use of laparoscopy for surgical problems during pregnancy: this statement was reviewed and approved by the Board of Governors of the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES), September 2007. It was prepared by the SAGES Guidelines Committee. Surg Endosc 22:849-861, 2008.

compared with a 3.1% incidence reported after open appendectomy (P = .001). However, multiple potential confounders, such as severity of the appendicitis, gestational age at the time of surgery, background rate of miscarriage, and reporting bias, may have significantly affected their analysis. Furthermore, they showed a significant increase in preterm delivery in open appendectomy cases (8.1% vs. 2.1%; $P < .0001$). Thus, no definitive data support a significantly increased risk for adverse pregnancy outcome using the laparoscopic approach.

Similarly, McGory and colleagues[54] identified more than 3000 cases of appendectomy in pregnancy using the California Inpatient File and found that, after controlling for several potential confounders, laparoscopic appendectomy was associated with an increased risk for fetal loss compared with open appendectomy (odds ratio, 2.31; 95% CI, 1.51 to 3.55). However, the gestational age at the time of surgery was not available. Furthermore, they defined fetal loss as the presence of a diagnosis code for spontaneous abortion or intrauterine death or of a procedure code for a dilation and curettage associated with the same hospital admission as the appendectomy. The limitations and potential inaccuracies of this method of data collection are obvious. Therefore, it remains unclear whether the laparoscopic procedure itself contributed to the observed rate of fetal loss.

Overall, laparoscopy should be considered a safe option when considering surgery in a pregnant patient. In fact, the SAGES practice guidelines support laparoscopy and a safe and effective surgical approach in any trimester of pregnancy with the same indications as in nonpregnant women (see Table 24-4).[43]

ADNEXAL MASSES IN PREGNANCY

The increased use of prenatal ultrasound, the high prevalence of physiologic cysts related to ovulation, and the use of ovulation induction in the treatment of infertility make the evaluation of an adnexal mass in pregnancy a common clinic scenario. The reported prevalence of adnexal masses in pregnancy ranges from less than 1% to 25% and is dependent on a variety of factors, such as gestational age and the criteria used to characterize an adnexal finding as a mass rather than a simple follicle.[55]

Fortunately, most adnexal masses encountered in pregnancy are benign and spontaneously resolve during the course of pregnancy. In fact, rates of spontaneous resolution have been reported to be as high as 72% to 96%.[55] Most of these cysts are simple follicular cysts, which are thin-walled, unilocular cysts and contain anechoic fluid. Alternatively, a corpus luteum cyst may develop and contain varying amounts of hemorrhage within the thick-walled and unilocular cyst (Figure 24-2). These are also benign and transient findings, which generally resolve by the second trimester and rarely require further surveillance. In patients who have undergone ovulation induction for the treatment of infertility, one may encounter thin-walled, multicystic ovaries containing anechoic fluid and lacking internal septations or papillae. These usually resolve during the course of the pregnancy, although they can cause patient discomfort if they are particularly enlarged (see Figure 24-2). Theca-lutein cysts are an uncommon type of multicystic ovarian mass in pregnancy and are related to hyperelevations of β-human chorionic gonadotropin, such as in gestational trophoblastic disease and multiple gestations. They appear as thick-walled, multicystic masses with no papillae. Although they generally contain anechoic fluid, internal hemorrhage can occur, especially in large masses (see Figure 24-2).

Although most benign masses encountered in pregnancy are physiologically related to the gestation, it is not uncommon to incidentally detect other benign ovarian masses, such as mature cystic teratomas (i.e., dermoid cysts), cystadenomas, or endometriomas. *Dermoids* can contain a variety of tissue types, leading to a variable appearance on ultrasound. Often, a hyperechoic area, known as Rokitansky tubercle, can help confirm the nature of these masses. These masses are benign and persist throughout the pregnancy. Fortunately, malignant degeneration is exceedingly rare, especially in women of childbearing age. Therefore, increased surveillance and surgical intervention are rarely necessary in an asymptomatic woman. As with all sizable masses, the patient should be counseled about the risk for ovarian torsion and be educated about the typical presenting symptoms (Figure 24-3). *Cystadenomas* often contain thin internal septations and may exhibit a small mural nodule. These masses are generally hypovascular and may contain anechoic fluid (serous cystadenomas) or fluid with low-level echoes (mucinous cystadenomas) (see Figure 24-3). *Endometriomas,* benign ovarian masses containing ectopic endometrial tissue, most often display a characteristic appearance with diffuse, low-level echoes (see Figure 24-3). Affected patients often have a history of endometriosis or dysmenorrhea. These masses generally persist throughout pregnancy without significant change in size. However, occasionally, an endometrioma can undergo decidualization during pregnancy as the endometrial tissue responds to the hormonal changes. In these cases, the mass may appear heterogeneous with increased vascularization and papillary projections, sharing many of the sonographic features of an ovarian malignancy (Figure 24-4). A known history of an endometrioma before pregnancy may be helpful in differentiating this mass from a malignancy, but close surveillance and thorough patient counseling are indicated.

Although most adnexal masses encountered in pregnancy are benign, one should not discount the rare possibility of malignancy. In fact, between 1% and 3% of masses removed in pregnancy are found to be malignant.[56,57] However, these data are confounded by the indication for surgery and likely represent a high-risk group of patients. In the largest series of adnexal masses in pregnancy, Leiserowitz and coworkers[56] identified 9375 adnexal masses associated with pregnancy, 87 (0.93%) of which were found to be malignant. In their population, this translated into 1 ovarian cancer per 56,000 deliveries. An additional 115 (1.25%) cases were found to be borderline tumors. Taken together, the prevalence of clinically significant ovarian tumors was 1 in 23,800 deliveries. In addition to being extremely rare, ovarian cancer in pregnancy is associated with more favorable characteristics, such as lower stage and a higher proportion of germ cell tumors.[56,57] This is likely because of the younger patient population and the incidental

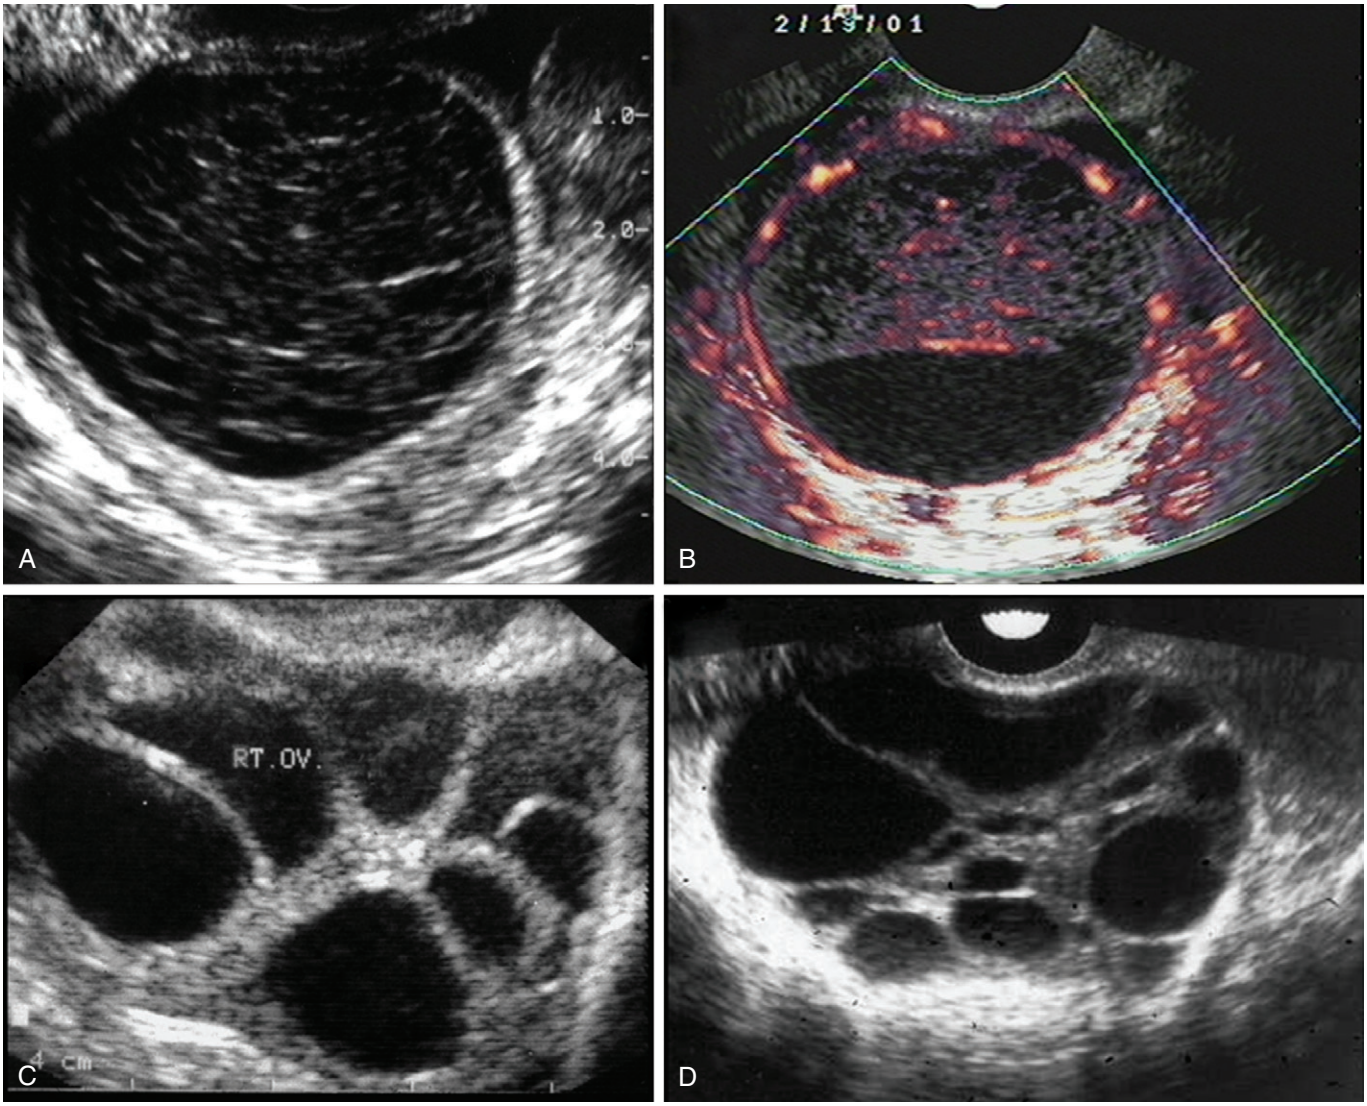

FIGURE 24-2. **A** and **B,** Variable appearance of a corpus luteum. The layered echogenicity represents hemorrhage within the cyst. Circumferential vascularity on power Doppler imaging is a typical finding. **C,** A thecal lutein cyst is seen as a thick-walled and multiloculated cyst with anechoic fluid. **D,** A typical appearance of a stimulated ovary with multiple follicular cysts after infertility treatment. (From Schwartz N, Timor-Tritsch IE, Wang E: Adnexal masses in pregnancy. Clin Obstet Gynecol 52:570-585, 2009.)

detection of these masses in asymptomatic women. Nevertheless, when a suspicious adnexal mass is encountered in pregnancy, the possibility of malignancy must be considered.

Although other imaging modalities such as MRI may be helpful in some cases in which a thorough evaluation of the mass is difficult because of the gravid uterus, ultrasound examination remains the diagnostic tool of choice when evaluating the adnexa. Several sonographic features have been associated with an increased risk for malignancy, such as size greater than 7 cm, heterogeneity with solid and cystic components, papillary excrescences or mural nodules, thick internal septations, irregular borders, increased vascularity, and low-resistance blood flow. However, the specificity of any of these findings remains limited, and no single high-risk feature is pathognomonic for malignancy. Rather, overall pattern recognition by experienced sonologists is likely the most accurate approach.[58-60] Surgical resection may become necessary when the degree of suspicion is high.

Another potential complication of an adnexal mass is ovarian torsion, which is estimated to occur in up to 7% of adnexal masses in pregnancy. Sixty percent of torsions occur in the first trimester.[61,62] Concern for this complication often leads to the recommendation to electively resect masses in pregnancy in an effort to prevent torsion. However, Lee and colleagues[61] compared 36 cases of emergency surgery for torsion in pregnancy with 53 cases of electively removed adnexal masses and found no difference in pregnancy outcomes, indicating that reserving intervention for acute torsion likely does not put the patient at increased risk for a complication. Thus, because nonobstetrical surgery in pregnancy is not without risk, preventive surgical intervention may not be appropriate. **Rather, patients with persistent adnexal masses in pregnancy should be counseled about the signs and symptoms**

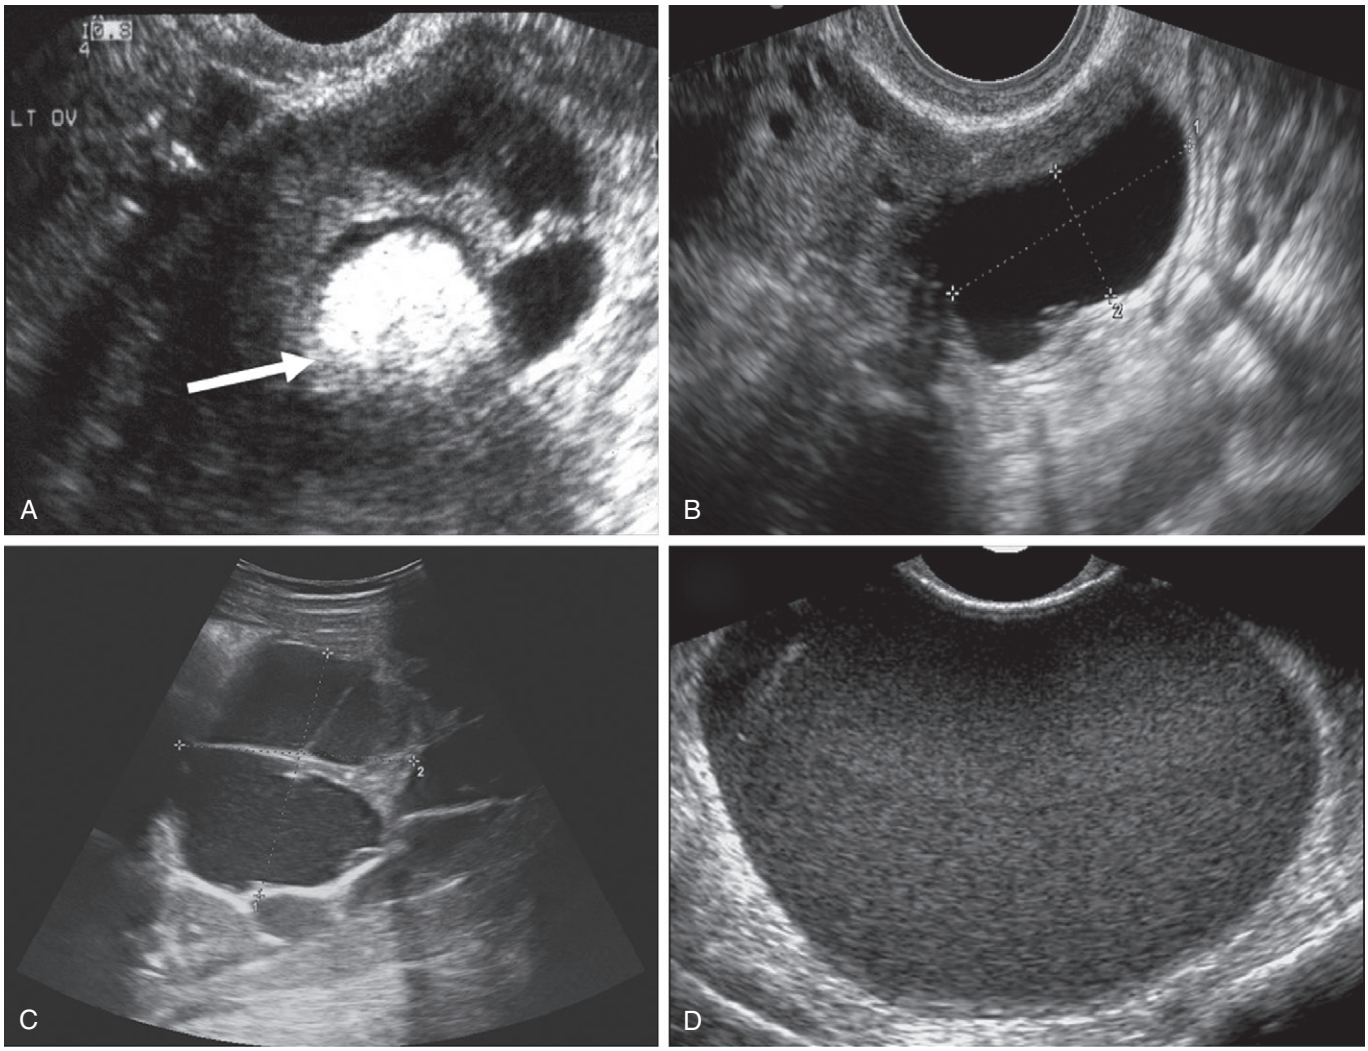

FIGURE 24-3. **A,** A dermoid cyst with heterogeneous contents and a typical Rokitansky nodule *(arrow)*. **B,** A benign, serous cystadenoma presenting as an anechoic cyst with a small mural nodule. **C,** This cystic mass with thin internal septations was shown to be a mucinous cystadenoma. **D,** Endometriomas often present as cystic masses containing homogeneous low-level echoes. (From Schwartz N, Timor-Tritsch IE, Wang E: Adnexal masses in pregnancy. Clin Obstet Gynecol 52:570-585, 2009.)

of ovarian torsion, with surgical resection reserved for symptomatic patients and for those in whom there is a suspicion of malignancy.

When ovarian torsion is confirmed during surgery, there is a question of whether there is a role for detorsion with ovarian conservation in cases in which there does not appear to be extensive necrosis (Figure 24-5). There is evidence that lends support to this approach in nonpregnant women.[63-65] **Although pregnancy data are more limited, there are several reports of successful management of ovarian torsion in pregnancy with preservation of the ovary**.[66-68] There are reports of ovarian necrosis requiring a repeat operation 2 days after a detorsion in pregnancy.[69] Therefore, the potential for recurrence must be taken into account when deciding to preserve the twisted ovary. Some authors recommend performing an oophoropexy to stabilize the ovary in the hope of minimizing recurrence, although this cannot be recommended as a routine approach. If a discrete ovarian cyst or mass is noted, excision of the mass should reduce the chance of recurrence, especially if there is any concern for potential malignancy. **Ultimately, the decision to untwist and preserve the torsed ovary should be individualized based on intraoperative findings and risk factors for recurrence.**

Overall, when presented with an adnexal mass that requires surgical resection, the decision to proceed with laparoscopy or laparotomy is based on the same approach taken outside of pregnancy. Laparoscopy has been shown to be a safe and effective method to remove adnexal masses in pregnancy,[37,51,70-72] although laparotomy may be preferred in certain scenarios, such as in patients with prior abdominal surgeries or large masses and in those who present late in pregnancy when visualization may be compromised. In general, although some have reported the safe aspiration of large simple cysts in pregnancy, this method runs the risk for leakage of cyst contents into the abdomen, which would be especially harmful if an unsuspected malignancy were present. In addition, cytologic analysis of the cyst contents may not be an accurate method to determine the pathology of the mass.[73] Therefore, cyst

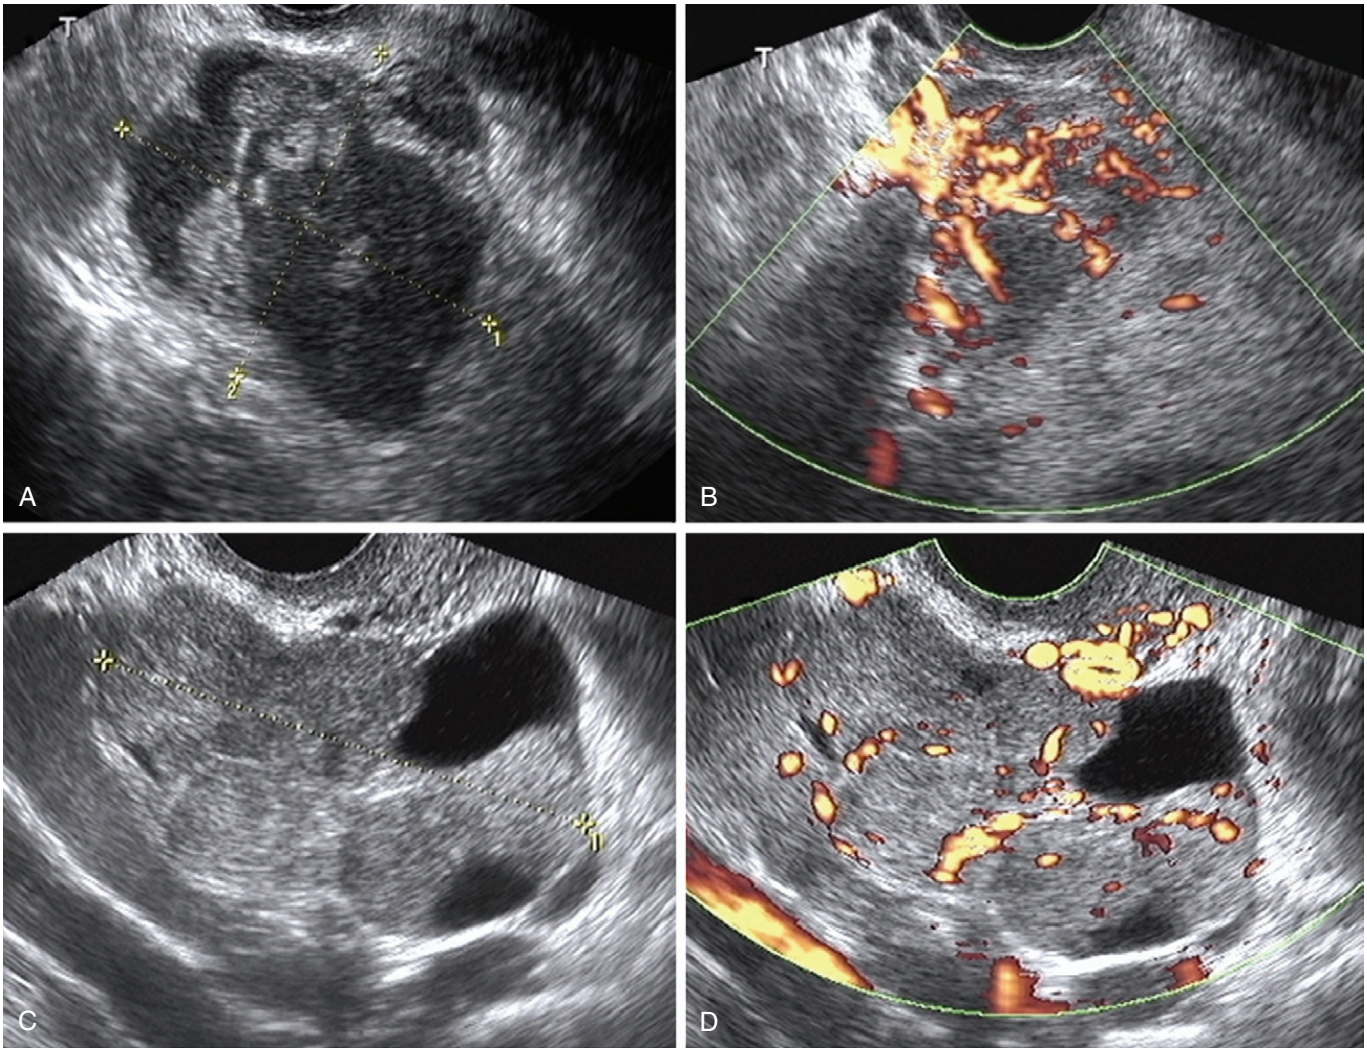

FIGURE 24-4. **A** and **B,** A complex and heterogeneous mass with thickened septations and increased vascularity in a patient with a known endometrioma. The sonographic features were suspicious for malignancy, leading to surgical excision in the middle trimester. Pathology showed it to be a decidualized endometrioma. **C** and **D,** A similar-appearing heterogeneous mass with increased vascularity. This was also excised and shown to be a stage I cystadenocarcinoma. (From Schwartz N, Timor-Tritsch IE, Wang E: Adnexal masses in pregnancy. Clin Obstet Gynecol 52:570-585, 2009.)

aspiration cannot be considered a standard approach for managing adnexal masses in pregnancy. Regardless of the surgical approach, it is important to remember that before 8 weeks' gestation, the corpus luteum is the primary source of progesterone for the pregnancy. Therefore, progesterone supplementation should be administered to patients who undergo adnexal surgery before 8 to 10 weeks' gestation.

OBESITY, BARIATRIC SURGERY, AND PREGNANCY

Maternal obesity is an increasingly common condition in pregnancy. In 2008, up to 36% of adult women in the United States were obese.[74] Obesity is associated with an increased risk for numerous significant medical comorbidities, including diabetes, hypertension, cardiac disease, and respiratory conditions. Furthermore, maternal obesity is an independent risk factor for several pregnancy-related complications, including gestational diabetes, preeclampsia, cesarean delivery, infectious morbidity, and thromboembolism. There is also an increase in fetal complications, such as congenital malformations, macrosomia, and stillbirth.[75-77] Bariatric surgery is an increasingly common and effective treatment for obesity and has been associated with a significant improvement in overall health, as well as a reduction in adverse pregnancy outcomes.[78,79] For the purposes of this chapter, it is important to review the special considerations related to surgery in the obese pregnant patient, as well as the implications of prior bariatric surgery in pregnancy.

Obesity presents unique management challenges in the perioperative period and is a risk factor for a multitude of adverse outcomes related to both general anesthesia and surgery.[80-82] Intubation is often more difficult in obese patients, and preoperative assessment of the airway using the Mallampati classification is essential.[83-85] Furthermore, gestational changes in respiratory physiology, such as a

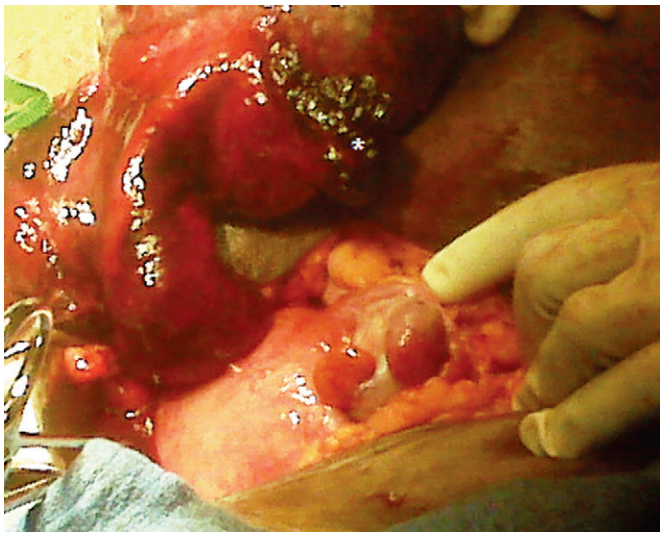

FIGURE 24-5. Intraoperative photograph of an ovarian torsion at 11 weeks' gestation. A 9-cm adnexal mass *(upper left of photograph)* was torsed around an edematous vascular pedicle. The mass was removed by laparotomy, because of concern for necrosis of the fimbria (*). The normal-appearing left ovary and tube are seen on the right, with the gravid uterus in the center. Pathology confirmed a dermoid cyst with areas of necrosis. (Courtesy Stephanie Jean, MD.)

decreased functional residual capacity and increased work of breathing, can lead to impaired ventilation and an increase in adverse respiratory events in obese pregnant patients undergoing anesthesia. In addition, the aortocaval compression seen in pregnancy may be exacerbated by maternal body habitus. For these reasons, many authors recommend various maneuvers such as adjusting patient positioning and preoperative hyperoxygenation when caring for the obese patient.

Another consideration unique to obese patients undergoing anesthesia is related to the altered pharmacokinetics of anesthetic drugs and to the volume of distribution and concentration of lipophilic drugs in the adipose tissues. Therefore, care must be taken when dosing anesthetic agents for obese patient, as well as when monitoring the recovery from anesthesia after surgery.[86,87] **Regional anesthesia should be considered if possible to avoid some of these risks, although the type of surgery and difficulty accomplishing regional anesthesia may not allow for this approach in some cases.**

Obesity is also an independent risk factor for venous thromboembolism in the postoperative period. Therefore, early ambulation should be encouraged. Prophylaxis with compression devices or with subcutaneous heparin should be considered. In addition, given the increased risk for wound infection and dehiscence in obese patients, adequate antibiotic prophylaxis is recommended.[82]

Significant weight loss before pregnancy is the most effective means of reducing the medical risks related to obesity, including pregnancy-related risks.[78,79] One of the most successful treatments for obesity is bariatric surgery, which is becoming an increasingly common procedure in the United States. Thus, it is imperative for obstetrical providers to be familiar with some of the unique concerns that arise in pregnant patients who have previously undergone bariatric surgery.

In general, bariatric surgery can be divided into restrictive procedures, such as gastric banding, and malabsorptive procedure, such as gastric bypass. Restrictive procedures are less invasive and can often be accomplished laparoscopically. These procedures do not result in the dramatic weight reduction seen with malabsorptive procedures, but they are associated with a lower risk for nutrient deficiencies and other complications related to malabsorption. The gastric band can be adjusted to lessen the degree of gastric restriction, allowing for adequate food intake in pregnancy.

The most commonly performed malabsorptive procedure is the Roux-en-Y gastric bypass, in which a proximal stomach pouch is created and the most of the stomach and proximal small bowel is bypassed. This often leads to rapid and significant weight loss, especially in the first 1 to 2 years. In fact, some recommend that pregnancy be delayed until 1 to 2 years after the procedure to avoid having rapid weight loss during pregnancy, and thorough contraception counseling is imperative.[88,89] Conception rates shortly after bariatric surgery appear to be increased,[89,90] which may be related to poor absorption of oral contraception, resumption of regular menstrual cycles, and inadequate contraceptive counseling. **The reduced absorptive capacity of the stomach and proximal small bowel often leads to deficiency in several essential nutrients, including iron, vitamin B_{12}, vitamin D, folate, and calcium. Unfortunately, long-term compliance with vitamin supplementation is poor among bariatric surgery patients.**[91,92] **Obtaining a baseline evaluation of these nutrients preconceptionally or early in pregnancy is recommended. In addition, consultation with a nutritionist should be considered.**[93]

Finally, although there is no evidence to suggest that pregnancy increases the risk for postoperative complications related to prior bariatric surgery, such complication may occur during pregnancy.[94,95] It is therefore important for obstetrical providers to be familiar with the possible complications so that the bariatric surgeon can be notified. Some known complications include anastomotic leaks, bowel obstruction, internal hernias, and erosion or migration of gastric bands. Many of these complications first manifest with symptoms commonly experienced during normal pregnancy, such as nausea, vomiting, and abdominal discomfort, so there is the potential that the accurate diagnosis of these complications can be delayed in a pregnant patient. In fact, maternal deaths have been reported.[96,97] Therefore, clinicians should have a high degree of suspicion when such patients present with significant abdominal complaints.[93]

One final complication that can be encountered in pregnant patients with a history of malabsorptive bariatric surgery is *dumping syndrome*. The consumption of simple sugars can lead to significant fluid shifts into the small intestine, causing cramping, nausea, vomiting, and diarrhea. In severe cases, the patient can become tachycardic and diaphoretic and complain of palpitations. Consideration should be given to monitoring blood glucose levels because hypoglycemia can result from hyperinsulinemia. Patients sensitive to sugar intake may not tolerate the glucose tolerance test for gestational diabetes. Having the

patient monitor fasting and postprandial fingersticks for 1 to 2 weeks may be a reasonable screening approach in sensitive patients.[98]

Overall, bariatric surgery and successful weight loss can significantly improve pregnancy outcomes. With the increasing prevalence of surgical treatment of obesity among young women, clinicians should familiarize themselves with some of the unique concerns that arise when managing these patients during pregnancy.

KEY POINTS

- Care of the pregnant surgical patient requires a multidisciplinary approach with an understanding of the physiologic alterations in gestation.
- Expansion of maternal blood volume during pregnancy may mask signs of maternal hemorrhage, and clinically significant blood loss can occur before hemodynamic changes are evident.
- Delay in surgical intervention results in increased maternal and fetal morbidity and mortality, significantly increasing the risk for preterm labor and fetal loss.
- Diagnostic doses of radiation (<5 cGy) from radiographs and CT scans are unlikely to pose any significant harm to the developing fetus. MRI and ultrasound can be safely used when appropriate to further minimize radiation exposure.
- There does not appear to be a significant difference in the rate of congenital malformations in women who require nonobstetrical surgery in pregnancy. Although there may be an increased risk for preterm birth, low birthweight, and neonatal death, this may be due to the underlying illness more than the surgical procedure itself.
- Laparoscopy is a safe surgical modality in pregnancy. The use of a laparoscopic approach in the latter stages of pregnancy should be individualized based on indication and experience of the surgeon. Abdominal insufflation pressures should be kept below 15 mm Hg whenever possible.
- Adnexal masses are commonly encountered in pregnancy, although most are benign. Pregnant women diagnosed with an adnexal mass should be counseled about the signs and symptoms of ovarian torsion. Surgical resection can be reserved for symptomatic women or for masses that are suspicious for malignancy.
- There is a lack of data to guide management regarding fetal heart rate monitoring intraoperatively. In most cases, preoperative and postoperative FHR monitoring is appropriate.
- Preoperative corticosteroid administration for fetal well-being needs to be based on gestational age and nature of the planned surgery.
- Thromboembolic prophylaxis with compression devises should be considered for all gravid surgical patients.
- Obesity presents unique management challenges in the perioperative period, most notably with anesthesia-related risk, intraoperative risk, antibiotic prophylaxis, and thromboembolic prophylaxis. If early ambulation is not possible, subcutaneous heparin should be considered.
- Bariatric surgery with subsequent weight loss may reduce the risk for an adverse pregnancy outcome. The gravid patient with a history of bariatric surgery presenting with vague abdominal complaints should be critically evaluated as delay in diagnosis from internal hernias, bowel obstruction, or anastomosis leaks can often lead to catastrophic events. Such women should also be evaluated for nutritional deficiencies.

INCIDENCE OF TRAUMA IN PREGNANCY

Traumatic injuries complicate 6% to 8% of all pregnancies and are the leading cause of nonobstetrical maternal death.[1-3] Approximately 30,000 pregnant women sustain treatable injuries in the United States each year as a result of trauma. Worldwide, trauma is responsible for at least 1 million deaths annually and is the leading cause of death in individuals under 40 years of age in the United States.[4] The risk of maternal death resulting from trauma is related to injury severity. In a large California database study of women hospitalized for trauma between 1991 and 1997, El Kady and colleagues found that internal injuries are the most common type of injury leading to maternal death.[5] Intracranial injury resulting from trauma was the second most common cause of maternal death.[5]

In addition to risk for maternal morbidity and mortality, traumatic injuries increase the risk for fetal death and other adverse outcomes of pregnancy.[4] Based on a review of fetal death certificates in Pennsylvania, it is estimated that motor vehicle crashes (MVCs) result in between 90 and 367 fetal deaths in the United States each year.[6] However, because of nonstandardized reporting of fetal death or injury resulting from maternal trauma, the exact magnitude of disease burden to the fetus resulting from maternal trauma is unknown, but is almost certainly underreported.[4] Risk factors for traumatic injury during pregnancy include young maternal age, African-American or Hispanic ethnicity, domestic violence, non-seatbelt use, and drug or alcohol use.[1,7] Alcohol may be involved in as many as 45% of MVCs including pregnant women, and the use of illicit substances has been implicated frequently in maternal trauma during pregnancy as well.[7]

Traumatic injuries may be categorized according to type, including blunt trauma, penetrating trauma, fractures, and thermal injuries. The most frequent causes of maternal trauma in the United States are MVCs (51%), falls (22%), and assaults (22%).[2,8] Gunshot wounds account for 4% of maternal trauma and burns account for 1%.[9] **The most common obstetrical complications following maternal trauma are abruptio placentae, preterm labor, and fetal loss.**[10]

ANATOMIC AND PHYSIOLOGIC CHANGES OF PREGNANCY

The importance of maternal physiologic changes during pregnancy and an understanding of fetal physiology are crucial to effective resuscitation of the injured pregnant woman. This is especially important relative to the maternal response to stress and hypovolemia resulting from trauma. Fundamental differences exist in the physiologic response to trauma as a result of pregnancy, and a working

knowledge of the basics of these differences is important to trauma resuscitation.

Fetal Physiology

Several factors are important in determining the impact of a traumatic event on pregnancy outcome. These include gestational age, type and severity of trauma, and the extent of disruption of normal maternal and fetal physiology.[11,12] In the first week following conception, the nonimplanted embryo is relatively resistant to noxious stimuli. Even during the first trimester, the uterus resides relatively safely within the confines of the bony pelvis and is protected to a large degree from direct uterine trauma. At any gestational age after implantation, however, maternal hypovolemic shock may have a significant impact on the developing embryo/fetus. Uterine blood flow is not autoregulated and is maximally dilated in the normal physiologic state. Maternal hypovolemia may result in vasoconstriction in many vascular beds, including those of the uterus. In experimental hypovolemic shock, pregnant sheep will decrease uterine blood flow at rates greater than would be expected based on the decrease in maternal blood pressure alone. Even in the absence of uterine artery vasoconstriction, decreases in maternal blood pressure due to hypovolemia will result in decreased uterine blood flow. These facts underlie the importance of maintaining adequate maternal blood volume as an initial step in fetal resuscitation. The third-trimester fetus can adapt to decreased uterine blood flow and oxygen delivery by redistributing blood flow to the heart, brain, and adrenal glands. Furthermore, because fetal hemoglobin has a greater affinity for oxygen than adult hemoglobin, fetal oxygen consumption does not decrease until oxygen delivery is reduced by 50%.[13]

Blunt or penetrating trauma may result in rupture of the amniotic membranes. In the second trimester, rupture with oligohydramnios may result in pulmonary hypoplasia or orthopedic deformity. Injury to the placenta may precipitate placental abruption leading to fetal anemia, hypoxemia, or hypovolemia.

Maternal Anatomic and Physiologic Changes

Nearly every maternal organ system undergoes anatomic or physiologic changes during pregnancy. The description that follows emphasizes consideration of these changes that affect the usual practice of trauma management.

A major concern in the management of trauma victims is internal hemorrhage and hypovolemia. The sentinel findings on examination are vital sign abnormalities—typically, hypotension and tachycardia. Consideration should be given to the normal decrease in systemic vascular resistance resulting in a decrease in mean blood pressure of 10 to 15 mm Hg and in increased pulse of 5-15 beats per minute, particularly in the second trimester. These changes can be accentuated if the trauma victim is laid supine (e.g., strapped to a long board in order to secure the cervical spine). The resultant potential decrease in venous return from the lower extremities can reduce central venous volume and result in a diminished cardiac output by as much as 30%. Simple manual displacement of the uterus to the left, or placement of a rolled towel under the backboard while ensuring that the spine remains secure alleviates most of this effect.

Blood volume increases by a mean of 50% in the singleton gestation. This is usually maximal by 28 to 30 weeks' gestation. Red blood cell mass increases to a lesser degree than does plasma volume, resulting in a slight decrease in hemoglobin concentration and decrease in hematocrit. Iron-deficiency anemia is also common during pregnancy, and together with the normal dilution, hemoglobin concentrations may be as low as 9 to 11 g/dL. These hematologic changes have two potential implications: (1) anemia may be confused with active bleeding and hypovolemia, and (2) blood volume estimates should be adjusted upward during fluid resuscitation.

Several major pregnancy-induced changes in the gastrointestinal tract are also important for trauma management. Compartmentalization of the bowel upward serves to protect it during lower abdominal trauma, but increases the risk of injury when there is penetrating trauma to the upper abdomen in later pregnancy. Complex injuries to the small bowel can be encountered with multiple entry and exit wounds as a result of its being crowded and compacted into the upper abdomen. Decreased gastric motility results in a prolonged gastric emptying time, thereby increasing the risk of aspiration. Rebound tenderness and guarding may be less apparent in later gestation due to stretching and attenuation of the abdominal musculature and peritoneum.

The dramatic increase in uterine blood flow, up to 600 mL/minute, may result in rapid exsanguination if there is avulsion or injury to the uterine vasculature or rupture of the uterus. Retroperitoneal hemorrhage from remarkably hypertrophied pelvic vasculature is a common complication of pelvic fracture. Enlargement of the uterus makes it susceptible to direct abdominal trauma. Injury to the uterus itself (uterine laceration or rupture), or its contents (abruptio placentae or direct fetal injury), or adjacent organs (bladder rupture) are more likely during pregnancy, especially in later pregnancy. While some of these complications are associated with more direct and violent trauma, for example, direct fetal injury or uterine rupture, some injuries (e.g., abruptio placentae) can occur after relatively minor trauma.

BLUNT TRAUMA

Blunt trauma to the maternal abdomen is an important cause of abruptio placentae. This is because blunt trauma exposes the gravid uterus to acceleration-deceleration forces that have a differential effect on the uterus and the attached placenta. By changing its shape, the myometrial tissue can stretch, adapting to these forces, while the placenta is relatively inelastic. This mismatch between myometrial and placental ability to stretch creates a shearing force at the utero-placental interface that, if sufficient, can result in separation of the placenta from its myometrial attachments (i.e., placental abruption).[4,10,14] Maternal trauma may also result in intramyometrial bleeding that leads to increased uterine contractile activity through activation of thrombin, lysosomal enzymes, cytokines, and prostaglandins.[10] Severe blunt trauma may also lead to maternal splenic, hepatic, and retroperitoneal injuries that

result in maternal hemorrhage and hemodynamic instability.[10] Severe injuries resulting in hypovolemia place both maternal and fetal well-being at risk.

Motor Vehicle Crashes

MVCs are the most common cause of trauma-associated fetal loss in the United States.[4,8] The likelihood that a MVC will result in fetal loss is directly related to crash severity as well as to maternal injury severity.[4,12] **For example, estimates based on case series would suggest that only about 1% of minor MVC will result in abruptio placentae, whereas as many as 40% to 50% of severe maternal trauma may result in abruptio placentae.**[10] In addition, lack of seatbelt use has been found to be associated with fetal loss, particularly if the mother has experienced ejection from the vehicle and head trauma.[12,15] However, even nonsevere MVC without substantial maternal injury may result in placental abruption and fetal loss because of exposure to the shearing acceleration-deceleration forces described earlier.[2,4,12] The forces leading to placental abruption after motor vehicle trauma are depicted in Figure 25-1.

Falls

Because pregnancy changes the center of gravity and postural stability, loss of balance is not uncommon and the likelihood of a significant fall is increased.[16-18] In fact, one retrospective study found that as many as a quarter of pregnant women experience a fall at some time during pregnancy.[16] Like MVCs falls expose the placenta to the shearing forces associated with blunt trauma. However, compared with MVCs, the likelihood that a fall may result in placental abruption and fetal death is low, accounting for only 3% of trauma-associated fetal deaths in one series.[6] In a more recent prospective cohort study involving 153 women experiencing falls during pregnancy, there were no instances of placental abruption.[19] Nonetheless, compared with pregnant women who did not experience fall-related hospitalization during their pregnancy, women hospitalized for falls remain at increased risk for adverse outcomes of pregnancy. One retrospective cohort study of 693 women hospitalized for falls during pregnancy (most of whom were in the third trimester) found that these women were at increased risk for preterm labor, placental abruption, cesarean delivery, "fetal distress," and fetal hypoxia.[18]

Domestic Violence

Pregnant women are at increased risk to suffer violent assault at home compared with nonpregnant women.[20] **The period prevalence of intimate partner violence during pregnancy has been reported to range from 6% to 22%, and up to 45% of pregnant women report a history of domestic abuse at some time during their lifetime.**[20] In one study, murder was the most frequent cause of maternal death during pregnancy and during the year subsequent to pregnancy.[21] In this study, a majority of the perpetrators of maternal homicides were found to be current or former intimate partners.[21] The analysis of pregnancy-associated homicides found that intimate partner homicides were

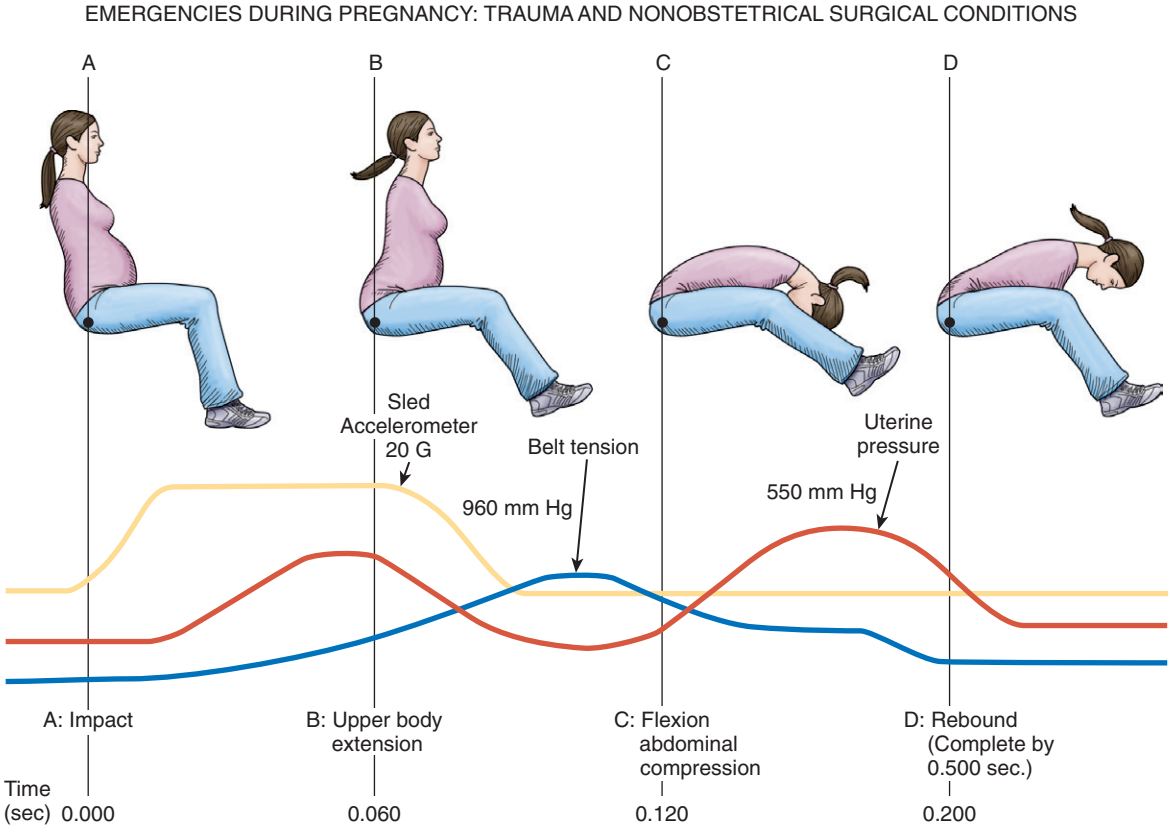

FIGURE 25-1. Impact sequence. Relationship between body motion, uterine pressure, and belt tension. (Modified from Hankins CVD: Operative Obstetrics. Stamford, CT: Appleton & Lange, 1995, Figure 35-3, p 655.)

most likely to occur during the first 3 months of pregnancy.[21] Although domestic violence occurs in all ethnic and socioeconomic groups, African-American and Native-American women and women from households with lower incomes are at increased risk for victimization by domestic violence compared with other women.[20] According to a California database study of maternal discharge records between 1991 and 1999, assaults were significantly associated with uterine rupture, and conferred significant long-term risk for placental abruption and low birthweight, even if the victim was not delivered during the initial hospitalization.[22]

SPECIFIC INJURIES

Fractures

Fractures are the most common type of maternal injury requiring hospitalization during pregnancy.[3] **The lower extremities are the most common site of fractures complicating pregnancy.[3] While pelvic fractures are less frequent than fractures of the extremities, pelvic fractures are most likely to result in adverse outcomes of pregnancy, including placental abruption, fetal death, neonatal death, and infant death.**[3] As such, pelvic fractures are thought to be an independent risk factor for adverse fetal outcome.[8] Pelvic fractures may also be associated with significant maternal hemorrhage and shock due to significant hypertrophy of the pelvic retroperitoneal vasculature, and subsequent laceration of these vessels due to sharp bone fragments, with resultant retroperitoneal bleeding.[23] Pelvic fractures may also be associated with bladder and urethral trauma.[1] Pelvic fractures are not a contraindication to vaginal delivery unless the fracture results in obstruction of the birth canal, or if the pelvic fracture is unstable; greater than 80% of women who have sustained pelvic fractures can deliver vaginally.[23]

Penetrating Trauma

Gunshot and stab wounds are the most frequent types of penetrating trauma during pregnancy.[4,15] Penetrating trauma during pregnancy is less likely to result in death than in nonpregnant individuals, owing to the protective effect of the gravid uterus in relation to the abdominal viscera.[14,15] However, when penetrating wounds occur during pregnancy and involve the upper abdomen, they pose major risk for complex maternal bowel injury due to the compartmentalization of the bowel in the upper abdomen by the enlarged uterus.[15] By contrast, penetrating trauma to the uterus is strongly associated with poor fetal outcome.[4,10] **The risk of fetal death has been reported to be as high as 71% after gunshot wounds and as high as 42% following stabbings.**[15]

Thermal Injuries (Burns)

Maternal and fetal prognosis after thermal injury are a reflection of the percentage of body surface involved.[23] Minor burns involving 10% or less body surface area are unlikely to result in maternal or fetal compromise and do not always require hospitalization.[10] Significant burns of 50% body surface or more have been associated with high maternal and fetal mortality. In the past, delivery of the fetus was recommended in an attempt to improve maternal prognosis.[23] More recent studies have suggested that maternal prognosis after severe thermal injury is not different between pregnant and nonpregnant individuals.[23] However, because of maternal physiologic changes associated with pregnancy, a pregnant woman with a severe burn will require more aggressive fluid resuscitation than a nonpregnant individual.

Major burns may result in maternal hypovolemia and cardiovascular instability, as well as sepsis, respiratory distress, renal failure, and liver failure.[10] Because of the decreased colloid osmotic pressure and increased body surface area associated with pregnancy, pregnant individuals who sustain burns are at risk for increased fluid loss compared with nonpregnant individuals.[24] Preterm labor may result from maternal hypovolemia, which can also result in decreased uteroplacental perfusion. Aggressive fluid resuscitation is critical to forestall this complication.[10,24]

Individuals suffering from major burns often also sustain inhalation injuries, which carry a higher maternal mortality risk and may also lead to fetal jeopardy.[10,25] In particular, carbon dioxide freely crosses the placenta and is highly bound by fetal hemoglobin, causing risk for fetal cardiac failure.[10] Administration of oxygen to the mother is recommended to reduce the half-life of carboxy-hemoglobin.[10]

Direct Fetal Injuries

Direct fetal injuries are uncommon, but are most likely to occur with both direct and severe abdominal or pelvic impact, and also in later pregnancy when the fetal head is engaged in the maternal pelvis.[4,10] Direct injury has been reported to result in rupture of the fetal spleen, fracture of the fetal skull, fetal intracranial hemorrhage, and cerebral edema.[4] These injuries have been reported to result in long-term developmental disabilities resulting from vascular infarctions, global cerebral damage, and periventricular leukomalacia.[4]

PATHOPHYSIOLOGY OF FETAL LOSS RESULTING FROM MATERNAL TRAUMA

The most frequent cause of fetal loss resulting from trauma is placental abruption.[9] Maternal hypotension and hypovolemia are also important predictors of poor fetal outcome.[6,12,15] Fetal loss may result from placental hypoperfusion due to maternal hemorrhagic shock.[9] In the instance of severe blood loss resulting from maternal trauma, maternal blood is redistributed away from the uterus via uterine artery vasoconstriction, to continue to perfuse the heart and brain. Fetal mortality in the setting of maternal hemorrhagic shock has been estimated at 80%.[26] Maternal trauma may also result in preterm labor and preterm premature rupture of membranes, resulting in morbidity or mortality related to preterm delivery.

PREDICTORS OF FETAL MORTALITY

Abruptio placentae is by far the leading cause of fetal death in published series, accounting for between 50% and 70% of all fetal losses due to trauma.[23] **Placental abruption will complicate about 1% to 2% of cases of maternal trauma with**

low injury severity scores, and up to 40% of severe maternal abdominal trauma.[15] If a placental abruption occurs, the risk of fetal mortality has been reported to be as high as 50% to 80%.[4] Maternal death has been reported as the next most frequent cause of fetal death after placental abruption, accounting for about 10% of losses.[10] In a large California database study, gestational age at delivery was the strongest predictor of fetal, neonatal, or infant death.[5] MVCs (82%) are the most frequent mechanism of injury leading to fetal death, followed by gunshot wounds (6%) and falls (3%).[4] In particular, lack of seatbelt use is a substantial risk factor for poor fetal outcome, morbidity, or mortality.[15,27,28]

Schiff and colleagues used the injury severity score to categorize the severity of maternal injuries.[29,30] The risk for adverse maternal, fetal, and neonatal outcomes was greatest among the women with severe injuries, but was also increased for women with mild injuries compared with uninjured controls. They found that injury severity scoring had limited predictive accuracy for placental abruption and fetal death and that even relatively minor injuries may result in these adverse fetal outcomes.[29,30] **Because minor injuries are much more common than severe injuries, they are responsible for 60% to 70% of fetal losses attributable to trauma, even though a severe injury is much more likely to result in loss than a nonsevere injury.**[4]

MANAGEMENT CONSIDERATIONS

Initial Approaches

Emergency personnel are often the first to evaluate and treat pregnant women experiencing trauma. The Centers for Disease Control and Prevention (CDC) has provided published guidelines for first responders and emergency medical personnel providing care in the field to injured pregnant women.[31] Guidelines for emergency medical personnel include displacing the uterus from the inferior vena cava, by positioning the mother in the lateral decubitus position.[26] During the initial evaluation, the spine immobilization board may be tilted leftward by placing a 6-inch rolled towel under the long board to achieve the same result.[26] The CDC panel recommended that, if possible, women with a pregnancy at least 20 weeks be transported to a trauma center with access to obstetrical care.

Improved outcomes can be expected by following a coordinated approach among emergency medicine physicians, trauma surgeons, and obstetricians in the evaluation of the maternal patient who has sustained traumatic injuries. All pregnant women (regardless of gestational age) who sustain or who are suspected to have sustained serious injuries should be evaluated in the emergency department first, and maternal well-being is prioritized over fetal assessment. Stabilization of the mother with identification of maternal injury is the initial priority. Fetal evaluation and interventions can be conducted in the emergency department as needed. A suggested algorithm for care of the pregnant trauma patient is presented in Figure 25-2.

Evaluation on Labor and Delivery

After clearance for severe maternal injury has been completed in the Emergency Department, we suggest that women experiencing trauma who are at or beyond 23 weeks' gestation (the threshold of fetal viability) be admitted to Labor and Delivery for observation and monitoring for signs and symptoms of placental abruption and preterm labor. Women below this threshold should have evaluation for fetal life in the Emergency Department, but do not necessarily require admission to Labor and Delivery. Based on the patient's clinical presentation and uterine contraction frequency, the patient is observed either for 4 or 24 hours prior to hospital discharge.

Fetal Monitoring

Fetal and uterine contraction monitoring is the most sensitive method for detecting abruptio placentae following trauma. Following trauma, in pregnant women who are beyond 23 to 24 weeks' gestation, frequent uterine contractions are nearly always present in women who have abruptio placentae.[32,33] **Moreover, a non-reassuring fetal heart rate pattern may reflect maternal hemorrhagic shock or hypotension.**[14] **Uterine contraction monitoring is unquestionably more sensitive than ultrasound in detecting placental abruption, with ultrasound detecting only about 40% of abruptio placentae in the setting of trauma.**[14,15,34] While several authors have recommended incorporating assessment of fetal status into the standard Focused Abdominal Sonography for Trauma (FAST) exam, it should not replace fetal monitoring.[8,10] The standard FAST exam is performed to evaluate for intraperitoneal hemorrhage and has replaced diagnostic peritoneal lavage in many centers because of its excellent sensitivity (80%-83%) for detection of intraperitoneal fluid.[8] A fetal biophysical profile test and middle cerebral artery Doppler studies may be performed at the time of the FAST exam for further information regarding fetal well-being, though its ability to predict fetal outcome in the setting of trauma has not been thoroughly assessed.[8,10] The fetal heart rate tracing has been called "the fifth vital sign," because it may provide the earliest evidence of maternal hypovolemia or hypotension.[10] Likewise, frequent uterine contractions provide the most reliable warning sign of placental abruption or preterm labor.[11,34,35] **If uterine contractions occur less frequently than every 15 minutes over 4 hours of observation, placental abruption is unlikely to occur.**[11,34,35] **Therefore, if the fetus is at or beyond 24 weeks' gestation, we recommend 4 hours of fetal monitoring. If frequent contractions are noted (every 15 minutes or more frequent), then 24 hours of monitoring is recommended because clinical identification of abruptio placentae has been reported up to 48 hours after maternal trauma.**[10,14,34]

Laboratory Testing

Laboratory tests that may be helpful in the evaluation of trauma include a complete blood count with platelets, type and Rh testing, evaluation of coagulation function if abruptio placentae is of concern, as well as a Kleihauer Betke (KB) test in the Rh-negative woman.[10] The KB test is an acid elution test designed to quantify the amount of fetal blood in the maternal circulation.[36] Published studies have demonstrated an approximate fourfold increase in the incidence of fetomaternal hemorrhage compared to uninjured controls. This increase in fetomaternal hemorrhage appears to be most important in assuring that RH-negative women are adequately protected against isoimmunization. The

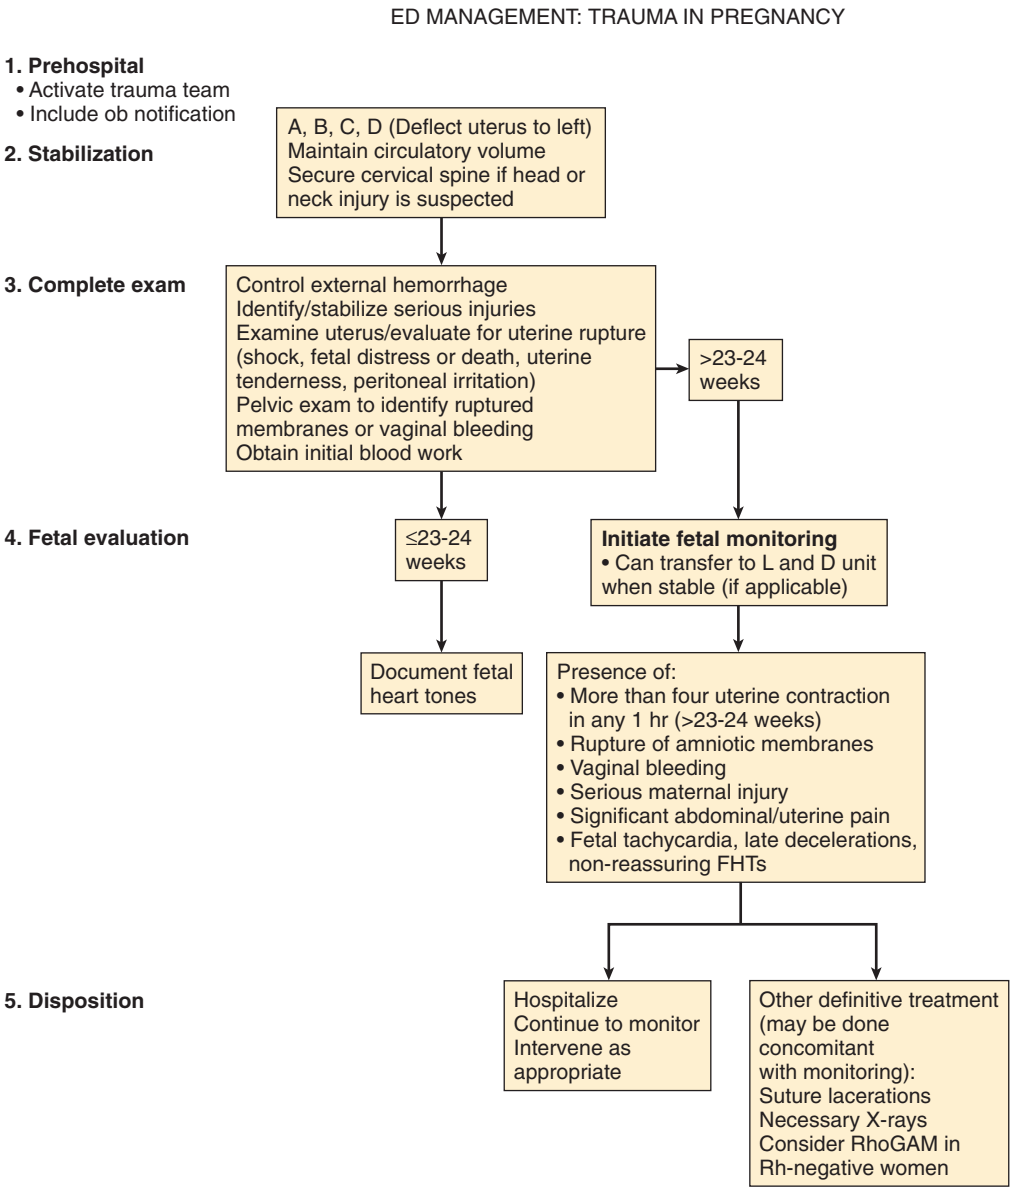

FIGURE 25-2. Algorithm with suggested plan of care for pregnant women experiencing trauma.

KB test may be used to determine whether additional vials of Rh immune globulin are needed for Rh-negative women experiencing trauma.[9,34] For about 90% of pregnant women experiencing trauma, the fetal-maternal hemorrhage will be less than 30 mL and 1 vial of Rh immune globulin will be sufficient to prevent sensitization.[14] There is some controversy regarding the utility of this test among Rh-positive women. Based on a series of 71 women, Muench has recommended its use as a predictor of risk for preterm labor after trauma.[37] In that study, the authors found that the KB test had a 100% sensitivity for prediction of preterm labor.[37] Other studies have not supported the use of this test as a predictor of adverse fetal outcome.[35,38] **Our experience has been that KB testing has utility for determining those *few Rh-negative women who require additional Rh immune globulin* to protect against isoimmunization, but has little predictive value of other adverse pregnancy outcomes such as abruptio placentae, preterm birth, or fetal hypoxemia. Moreover, the use of fetal monitoring is much more likely to provide a timely diagnosis of these complications of pregnancy than KB testing.**

Coagulation studies, including PT, PTT, platelets, and fibrinogen, may be useful if there is evidence or suspicion of abruptio placentae or if the patient is experiencing massive hemorrhage that may result in dilutional coagulopathy. A urinalysis may be obtained as well. Hematuria on urinalysis may be associated with pelvic fractures or renal tract injury.[15] Given the strong association of drug and alcohol use with traumatic injuries, a urine toxicology screen is preferred if clinically indicated.[15]

DIAGNOSTIC IMAGING DURING PREGNANCY

Ultrasound

Ultrasound may be used to assess fetal well-being without exposing the fetus to ionizing radiation. Additionally, abdominal ultrasound may be a useful tool in the

TABLE 25-1 BIOLOGIC EFFECTS OF IN-UTERO EXPOSURE TO IONIZING RADIATION

MENSTRUAL OR GESTATIONAL AGE	CONCEPTION AGE	<50 mGy (<5 rad)	50-100 mGy (5-10 rad)	>100 mGy (>10 rad)
0-2 weeks (0-14) days	Prior to conception	None	None	None
3rd and 4th weeks (15-28) days	1st and 2nd weeks (1-14) days	None	Probably none	Possible spontaneous abortion.
5th and 10th weeks (29-70) days	3rd and 8th weeks (15-56) days	None	Potential effects are scientifically uncertain and probably too subtle to be clinically detectable.	Possible malformations increasing in likelihood as dose increases.
11th and 17th weeks (71-119) days	9th and 15th weeks (57-105) days	None	Potential effects are scientifically uncertain and probably too subtle to be clinically detectable.	Increased risk of deficits in IQ or mental retardation that increase in frequency and severity with increasing dose.
18th and 27th weeks (120-189) days	16th and 25th weeks (106-175) days	None	None	IQ deficits not detectable at diagnostic doses.
>27 weeks (>189 days)	>25 weeks (>175 days)	None	None	None applicable to diagnostic medicine.

Modified from ACR Practice Guidelines for Imaging Pregnant or Potentially Pregnant Adolescents and Women with Ionizing Radiation. American College of Radiology, 2008, p 3.

evaluation of the pregnant trauma victim for free intraperitoneal fluid, with reported sensitivity between 61% and 83%, but specificity between 94% and 100%.[39] Ultrasound is not particularly sensitive for detecting abruptio placentae, with reported identification of only approximately 40%. There are no clear established guidelines whether further imaging is necessary in the event of a negative ultrasound study in a hemodynamically stable patient. The Food and Drug Administration (FDA) has arbitrarily established a safe upper limit for energy exposure during ultrasonography at 94 mW/cm^2.[40]

Ionizing Radiation

Because of concerns about fetal exposure to ionizing radiation, clinicians may be hesitant to order indicated diagnostic tests in the setting of maternal trauma. Concerns regarding exposure to ionizing radiation involve both risk for teratogenesis and risk for development of cancer in later life.[41] The most significant risk for fetal malformation involves microcephaly and mental retardation, which has been observed after human exposure to doses of 100 to 200 cGy. Exposure to ionizing radiation in utero may elevate the risk of childhood leukemia from a background of 1 in 3000 to a risk after exposure to 1 in 2000.[40,42] Similarly, exposure to 50 mGy (5 rads) ionizing during pregnancy may be associated with a 2% lifetime attributable risk for development of malignancy.[43] The risk of teratogenesis or carcinogenesis with exposure to ionizing radiation is dose-dependent.[43] Both the American College of Radiology and the American College of Obstetricians and Gynecologists have published imaging guidelines for the use of diagnostic radiologic techniques during pregnancy.[40,43] **However, in the setting of maternal trauma, the risk to the fetus for morbidity or mortality from untreated maternal injury far outweighs theoretical concerns for risks of development of malignancy in later life. Indicated diagnostic procedures should not be delayed due to concerns about fetal radiation.**[39]

Table 25-1 summarizes effects of in-uterus exposure to ionizing radiation during different stages of pregnancy. The American College or Radiology posits that "Nearly all abdominal radiographic procedures can be modified to reduce radiation exposure to a pregnant patient and her fetus."[43] For example, dose from single-phase CT study of the abdomen and pelvis would be 20 to 35 mGy. Radiation doses associated with common diagnostic tests are listed in Table 25-2.

MRI

MRI may be an attractive option because this modality does not involve the use of ionizing radiation, though there is less evidence of efficacy and safety of its use during pregnancy than other more established methods. Currently, the Food and Drug Administration states that the safety of MRI for the fetus "has not been established."[42] However, there is currently no evidence from studies of children exposed to MRI in utero of any teratogenic effects or of any long-term adverse developmental consequences.[39,42] The American College of Radiology described guidelines for the safe use of MRI, and provided support for the use of MRI during all trimesters of pregnancy if necessary for accurate diagnosis.[39,44] The precise role for the use of MRI in the management of trauma in pregnancy has not yet been clearly established.

Contrast Agents

Iodinated contrast agents cross the placenta via simple diffusion.[45] Because they are taken up by the fetal thyroid and may pose a theoretical risk for fetal hypothyroidism, iodinated contrast images are generally avoided during pregnancy, unless clearly necessary for diagnosis.[40,45] However, no cases of fetal goiter or abnormal neonatal thyroid function have been reported after clinical use of iodinated contrast agents.[45] Neonates whose mothers have received iodinated contrast media during pregnancy should be screened for hypothyroidism, an already standard practice.[42] **A recent guideline for use of CT and MRI during pregnancy has posited that the use of iodinated contrast agents during pregnancy is preferable to the patient receiving repetitive CT studies due to the suboptimal nature of studies performed without contrast agents.**[42]

The use of gadolinium for MRI in pregnancy is controversial. Gadolinium crosses the placenta and accumulates in amniotic fluid.[45] Gadolinium has not been found to be teratogenic or carcinogenic in doses that are used clinically.[15,45] However, administration of gadolinium to children and adults with underlying renal insufficiency has resulted in a syndrome known as nephrogenic systemic fibrosis in rare cases, raising theoretical concerns of toxicity after fetal exposure.[42,46] Thus, the use of gadolinium should be avoided in patients with acute or chronic renal insufficiency.

Suggested Guidelines for Radiologic Evaluation of Trauma

A recent evidence-based guideline for use of diagnostic imaging after maternal trauma has recommended the use of ultrasound as the initial modality, but recommend the use of CT as the preferred method of evaluation when visceral injuries, or injuries of the chest, aorta, mediastinum, spine, bones, bowel, or bladder are suspected.[42] Similarly, Patel has suggested an algorithm-based approach to radiologic evaluation after maternal trauma.[39] See Figure 25-3.

TABLE 25-2 RADIATION DOSES ASSOCIATED WITH COMMON DIAGNOSTIC PROCEDURES

PROCEDURE	FETAL DOSE
Single-phase CT of abdomen and pelvis, and lumbar spine	3.5 rad
Hip film (single view)	200 mrad
Chest x-ray	0.02-0.07 mrad
CT of head or chest	<1 rad
Diagnostic fluoroscopy of abdomen and pelvis	<10 rad

Modified from ACOG Committee on Obstetric Practice: ACOG Committee Opinion #299: Guidelines for Diagnostic Imaging During Pregnancy and ACR Practice Guidelines for Imaging Pregnant or Potentially Pregnant Adolescents and Women with Ionizing Radiation.

SURGERY FOR TRAUMATIC INJURIES DURING PREGNANCY

Penetrating trauma is the most common indication for nonobstetrical surgery for traumatic injuries during pregnancy.[10] Historically, surgical exploration was recommended for evaluation and repair of abdominal injuries resulting from penetrating trauma; however, given the differing pattern of abdominal injuries resulting from penetrating trauma during pregnancy, the decision for expectant management or surgery may be individualized.[10] Muench and Canterino recommend an individualized approach to penetrating trauma depending on whether the wound is in the upper or lower abdomen.[10] **Because of the significantly increased risk for bowel injury after penetrating trauma to the upper abdomen, women with penetrating wounds to the upper abdomen should undergo surgical exploration. Because the gravid uterus provides some protection from visceral injury, women sustaining penetrating wounds to the lower abdomen may be managed conservatively if they are hemodynamically stable.** Penetrating wounds to the gravid uterus increase risk for direct fetal injury, but may be managed conservatively if they do not extend past the myometrium.[10] Conservative management may include diagnostic peritoneal lavage, which may be undertaken during pregnancy through a supraumbilical incision that

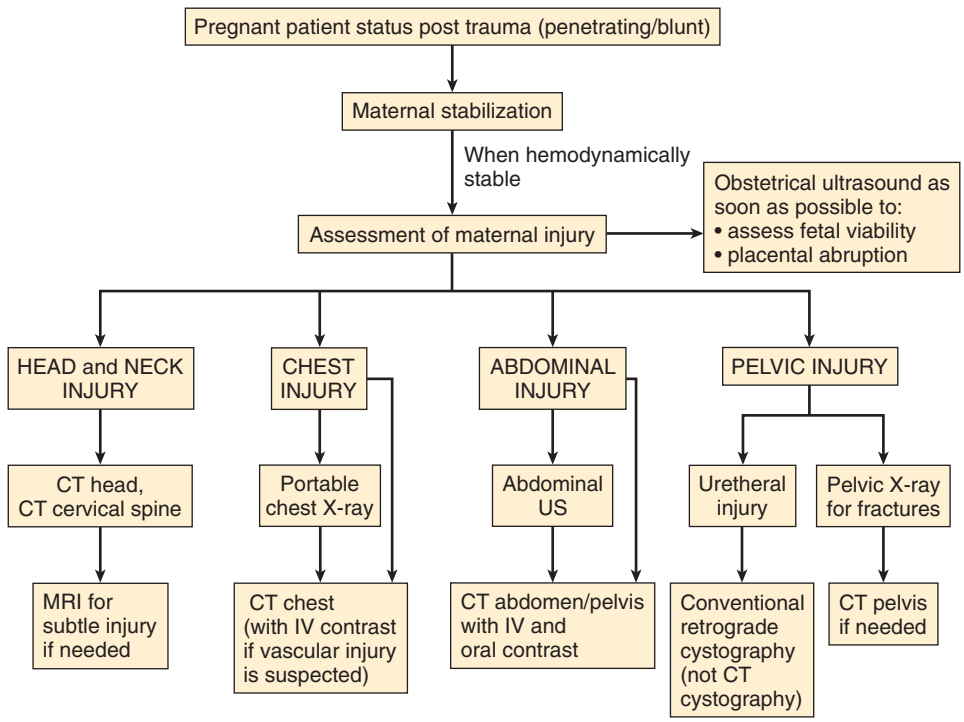

FIGURE 25-3. Algorithm with suggested plan for diagnostic imaging studies for pregnant women experiencing trauma. (Modified from: Patel SJ, Reede DL, Katz DS, et al: Imaging the pregnant patient for nonobstetric conditions: algorithms and radiation dose considerations. Radiographics 27:1719, 2007.)

may be facilitated under ultrasound guidance.[10,15] Indications for surgical exploration include penetrating trauma to the upper abdomen, gunshot wounds to the abdomen, clinical evidence of active intra-abdominal hemorrhage, or suspicion for bowel injury.

If exploratory laparatomy is undertaken, care should be taken to minimize traction on the gravid uterus and the nature and extent of any injuries should be evaluated.[10] Exploratory laparotomy does not always necessitate delivery of the fetus.[15] In the event that fetal death has occurred prior to surgical exploration, vaginal delivery after induction of labor may be a preferable approach, although Brown recommends surgical uterine evacuation if there is abruption and potential for coagulopathy.[15] In some circumstances, delivery of the fetus may be necessary to adequately explore the abdomen or to facilitate surgical repair of injured viscera.

If the pregnancy is at or beyond 24 weeks, fetal monitoring should be carried out intermittently during the surgical procedure. If non-reassuring fetal status is detected during the procedure, in most instances it can be corrected by attention to and correction of maternal hypovolemia or hypoxemia. If these supportive measures are not effective, cesarean delivery may be necessary.[15]

Uterine Rupture

Both blunt and penetrating injuries may result in uterine rupture, which occurs in approximately 0.6% to 1% of instances of maternal trauma.[15,34] **Uterine rupture most often results from direct abdominal impact, and may occur at any gestational age, although the risk for uterine rupture increases in late pregnancy.**[1,47] **The risk for uterine rupture is particularly increased for women who have experienced assaults.**[22] Most instances of uterine rupture resulting from maternal trauma are fundal in location.[34] Uterine rupture may also result in complete avulsion of the uterine arteries and massive hemorrhage.[1] Signs of uterine rupture may range from fetal heart rate abnormalities in a hemodynamically stable patient, to maternal cardiovascular instability and hypovolemic shock.[34] Uterine rupture carries a poor prognosis for the fetus and requires immediate laparotomy. Whether a hysterectomy is required depends on the extent of the myometrial and vascular injury. Uterine rupture may be associated with massive maternal hemorrhage due to the increased uterine vascularity associated with pregnancy; aggressive replacement of red cells and clotting factors is recommended.[15] Maternal mortality may be as high as 10% following traumatic uterine rupture.[4]

Perimortem Cesarean Section

In instances of severe maternal injury and maternal cardiac arrest, cardiopulmonary resuscitation may be less successful due to maternal physiologic alterations associated with pregnancy. The gravid uterus may interfere with systemic perfusion by compression of the inferior vena cava and interference with venous return. Emptying the uterus may facilitate more effective maternal resuscitation. **Long-term outcomes for children born after maternal cardiac arrest are most likely to be favorable if the child is delivered within 5 minutes of cessation of maternal circulation.**[26] Therefore we recommend that if the pregnancy is at or beyond fetal viability (23-24 weeks' gestation), perimortem cesarean delivery commence 4 minutes after maternal cardiac arrest if resuscitation has not restored maternal circulation.[10] If the maternal resuscitation is successful, we recommend that that patient be transferred to the operating theater for closure of the uterus and abdominal wound and to ensure adequate hemostasis.

OTHER CONSIDERATIONS

Long-Term Effects of Trauma

In some reports, up to 38% of women experiencing trauma during pregnancy will require delivery in the same hospitalization,[15] though in most published experiences, the great majority of pregnant women experiencing trauma will be discharged home undelivered.[4,32] Although most placental abruptions resulting from maternal trauma will occur within the first 24 hours after the event, some reports suggest that women who have experienced trauma may remain at risk for other complications including intrauterine growth restriction, intrauterine fetal demise, "fetal distress," placental abruption, and a higher risk of cesarean delivery.[3,4,48] By contrast, a prospective controlled study demonstrated that pregnancy outcomes beyond 48 hours in injured women are similar to those in the uninjured controls.[32] Suggested discharge instructions are shown in the box, Suggested Discharge Instructions for Pregnant Women Hospitalized for Observation After Trauma.

Suggested Discharge Instructions for Pregnant Women Hospitalized for Observation After Trauma

- Discharge after 24 hours of observation. Discharge may be indicated in the absence of signs or symptoms of the following: labor, abruption, rupture of membranes, fetal compromise, maternal compromise.
- Health education
  - A. After discharge, woman should be instructed to call Labor and Delivery with decreased fetal movement, vaginal bleeding, rupture of membranes, abdominal pain, or uterine contractions >3 per hour.
  - B. Advise fetal movement count twice daily.
  - C. Advise follow-up with provider within the week.
  - D. Advocate correct seatbelt use: shoulder belt between breasts and uterine fundus, lap belt under uterus and across spines of pelvis.
  - E. If domestic violence is suspected, order social work consult.

Prevention of Trauma

Education and reinforcement of seatbelt use during pregnancy should be undertaken as a routine part of prenatal education and care. In a primate model of motor vehicle impact trauma and its fetal effects, three-point restraints significantly reduced fetal mortality compared with two-point restraints.[2] In a recent study of MVCs involving 43 pregnant women between 1996 and 1999, Klinich and colleagues from the University of Michigan demonstrated that proper use of seatbelts was significantly associated with good fetal outcome. The authors speculated that proper seatbelt use could prevent as many as 84% of adverse fetal outcomes.[12] **Proper counseling by the obstetrical care provider for seatbelt usage has also been shown to**

significantly improve compliance with seatbelt use during pregnancy.[49] Proper placement of seatbelts includes placing the lap belt below the lower bump of the uterus overlying the anterior superior iliac spines. The shoulder belt should be positioned off to the side of the uterus, between the breasts, and over the midportion of the clavicle.[1] Although some have expressed concern about possible harmful effects of air bag deployment in the event of a motor vehicle accident during pregnancy, the National Highway Traffic Safety Administration (NHTSA) and the American College of Obstetricians and Gynecologists do not recommend disabling air bags during pregnancy.[34,50] Indeed, a retrospective cohort study of pregnant women involved in MVCs in the state of Washington between 2002 and 2005 concluded that air bags do not increase risk for adverse outcomes of pregnancy.[51]

Screening and Identification of Women at Risk for Domestic Violence

Traumatic injuries may also be prevented by early screening and detection of intimate partner violence during pregnancy. The American College of Obstetricians and Gynecologists recommends screening all pregnant women for intimate partner violence at the first prenatal visit and at least once per trimester of pregnancy. They recommend use of a brief three-question screening tool to identify women who are at risk to experience domestic violence during pregnancy (see box, Suggested Domestic Violence Screening Questions).[52]

Suggested Domestic Violence Screening Questions

"Because violence is so common in many women's lives and because there is help available for women being abused, I now ask every patient about domestic violence:

1. Within the past year—or since you have been pregnant—have you been hit, slapped, kicked or otherwise physically hurt by someone?
2. Are you in a relationship with a person who threatens or physically hurts you?
3. Has anyone forced you to have sexual activities that made you feel uncomfortable?"

KEY POINTS

- Maternal trauma is the most frequent cause of nonobstetrical maternal death.
- Abruptio placentae complicates 1% to 2% of cases of minor blunt abdominal trauma and up to 40% of cases of severe abdominal trauma.
- Abruptio placentae is the most frequent cause of fetal death after trauma.
- Concerns about fetal effects of ionizing radiation should not delay imaging necessary to care for pregnant trauma victims.
- Seatbelt use may reduce adverse fetal outcome resulting from trauma by as much as 84%.

Not all conceptions result in a live-born infant, and human reproduction is extremely inefficient compared with that of other mammal species.[1] About 50% to 70% of spontaneous conceptions are lost before completion of the first trimester, most before implantation or during the first month after the last menstrual period. These losses are often not recognized as conceptions. Of clinically recognized pregnancies, 10% to 15% are lost. Although epidemiologic data on animals living in the wild, such as monkeys, are limited, laboratory rodents are known to have postimplantation pregnancy loss rates of less than 10%.[1] Among married women in the United States, 4% have experienced two fetal losses, and 3% three or more.[2] A subset of women manifest repetitive spontaneous miscarriages, as opposed to randomly having repeated untoward events. This chapter considers the frequency and timing of pregnancy losses, the causes of fetal wastage, and the management of couples experiencing repetitive losses.

FREQUENCY AND TIMING OF PREGNANCY LOSS

Embryos implant 6 days after conception. Physical signs are not generally appreciated until 5 to 6 weeks after the last menstrual period. Fewer than half of preimplantation embryos persist, as witnessed by assisted reproductive technology (ART) success rates rarely exceeding 30% to 40% of cycles initiated. Even after implantation, judged preclinically by the presence of β-human chorionic gonadotropin (β-hCG), about 30% of pregnancies are lost.[1] After clinical recognition, 10% to 12% are lost. Most clinical

pregnancy losses occur before 8 weeks. Before widespread availability of ultrasound, embryonic demise was often not appreciated until 9 to 12 weeks' gestation, at which time there was bleeding and passage of tissue (products of conception). With widespread availability of ultrasound, it has been shown that fetal demise actually occurs weeks before overt clinical signs are manifested. This conclusion was reached on the basis of cohort studies showing that only 3% of viable pregnancies are lost after 8 weeks' gestation[3]; studies involving obstetrical registrants reached similar conclusions. Fetal viability thus ceases weeks before maternal symptoms of pregnancy loss. That almost all losses are retained in utero for an interval before clinical recognition means that virtually all losses could be considered "missed abortions"; thus, this once widely used term is actually archaic.

After the first trimester, pregnancy losses occur at a slower rate. Loss rates are only 1% in women confirmed by ultrasound to have viable pregnancies at 16 weeks. Two confounding factors influencing clinical pregnancy loss rates are clinically relevant. Maternal age is positively correlated with pregnancy loss rates, a 40-year-old woman having twice the risk of a 20-year-old woman. This occurs in euploid as well as aneuploid pregnancies, as discussed later. Prior pregnancy loss also increases loss rates, but far less than once believed. Among nulliparous women who have never experienced a loss, the likelihood of pregnancy loss is low: 5% in primiparas and 4% in multiparas (Table 26-1). After one loss, the risk of another is increased but does not exceed 30% to 40% even for women with three or more losses.[4] These risks apply not only to those women whose losses were recognized at 9 to 12 weeks' gestation but also to those whose pregnancies were ascertained in the fifth week of gestation.[5] Of clinical relevance, there is no scientific evidence that women with three losses are etiologically distinct from those with two losses or even one loss. The situation may be different if, rarely, four or more losses have occurred; different etiologic factors may exist in this uncommon subgroup.

The clinical consequence of the above information is that in order to be judged efficacious in preventing recurrent first-trimester spontaneous abortions, therapeutic regimens must show success rates substantially greater than 70%. Essentially no therapeutic regimen can make this claim.

TABLE 26-1 Approximate Recurrence Risk Figures Useful for Counseling Women with Repeated Spontaneous Abortions*

	PRIOR ABORTIONS	RISK (%)
Women with live-born infant	0	5-10
	1	20-25
	2	25
	3	30
	4	30
Women without live-born infant	3	30-40

*Recurrence risks are slightly higher for older women.

PLACENTAL ANATOMIC CHARACTERITICS OF SUCCESSFUL AND UNSUCCESSFUL PREGNANCIES

As judged by adult tissue criteria, the human fetus develops in a low oxygen (O_2) environment. Development of the human placenta is modulated heavily by the intrauterine environment.[6-9] During the first trimester, development takes place in a low oxygen environment supported by histotrophic nutrition from the endometrial glands. Consequently, the rate of growth of the chorionic sac is almost invariable across this period and is remarkably uniform between individuals. Toward the end of the first trimester, the intrauterine environment undergoes radical transformation in association with onset of the maternal arterial circulation and the switch to hemotrophic nutrition. The accompanying rise in intraplacental oxygen concentration poses a major challenge to placental tissues, and extensive villous remodeling takes place at this time.

The human gestational sac is designed to minimize the flux of O_2 from maternal blood to the fetal circulation.[6] In particular, the extravillous trophoblast that migrates inside the uterine tissue to anchor the pregnancy creates a cellular shell with plugs inside the tip of the uteroplacental arteries.[2,9] This additional barrier keeps most of the maternal circulation outside the placenta and thus reduces the chemical activity of free oxygen radicals inside the placenta during most of the first trimester of the human pregnancy.[6,7] In normal pregnancies, the onset of the maternal circulation is a progressive phenomenon, starting at about 9 weeks at the periphery and gradually extending toward the center of the placenta.[2,7,9] This process correlates closely with the pattern of trophoblast invasion across the placental bed (Figure 26-1).

In about two thirds of early pregnancy failures, there is anatomic evidence of defective placentation, which is mainly characterized by a thinner and fragmented trophoblast shell and reduced cytotrophoblast invasion of the lumen at the tips of the spiral arteries.[2,10-12] This is associated with premature onset of the maternal circulation throughout the placenta in most cases of miscarriages.[2,9,10-12] These defects are similar in euploid and most aneuploid miscarriages but are more pronounced in hydatidiform moles (Figure 26-2). In vivo ultrasound data and histopathologic data indicate that in most early pregnancy losses, the onset of the intervillous circulation is premature and widespread owing to incomplete transformation and plugging of the uteroplacental arteries.[7,10,11] In about 80% of missed miscarriages, the onset of the maternal placental circulation is both precocious and generalized throughout the placenta. This occurs independent of the karyotype of the conceptus,[11] leading to higher O_2 concentrations during early pregnancy, widespread trophoblastic oxidative damage, and placental degeneration. Although in vitro studies have demonstrated the ability of damaged syncytium to regenerate from the underlying cytotrophoblast, it is likely that in the face of extensive damage, this ability

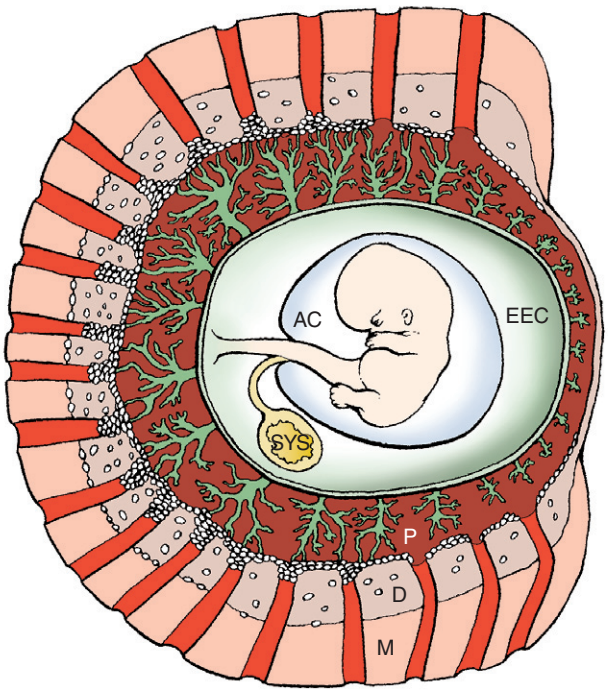

FIGURE 26-1. A gestational sac at the end of the second month (8 to 9 weeks) showing the myometrium *(M)*, the decidua *(D)*, the placenta *(P)*, the exocoelomic cavity *(ECC)*, the amniotic cavity *(AC)*, and the secondary yolk sac *(SYS)*. J Clin Endocrinol Metab 89:1452, 2004.)

will be overwhelmed, leading to complete pregnancy failure.[2,12]

NUMERICAL CHROMOSOMAL ABNORMALITIES: THE MOST FREQUENT CAUSES OF EARLY PREGNANCY LOSS

Chromosomal abnormalities are the major cause of both preimplantation and clinically recognized pregnancy loss. The frequency of losses in human preimplantation embryos is very high. Of morphologically normal embryos, 25% to 50% show chromosomal abnormalities (aneuploidy or polyploidy),[13] depending on maternal age. The frequency of chromosomal abnormalities in morphologically abnormal embryos is even higher. Moreover, these data are based on studies using fluorescence in situ hybridization (FISH) with chromosome-specific probes for only seven to nine chromosomes; rates would be higher using technologies that can assess all chromosomes, for example, 24-chromosome FISH, single nucleotide polymorphism (SNP), or array comparative genome hybridization (CGH) analysis. The high aneuploidy rate in morphologically normal embryos is consistent with 5% to 10% aneuploidy in sperm of ostensibly normal men and 20% aneuploidy in oocytes (deduced from polar bodies) of women undergoing ART. Aneuploidy rates in oocytes and embryos predictably increase as maternal age increases.

At least 50% of *clinically recognized pregnancy* losses result from a chromosomal abnormality.[14] The frequency is probably higher because if one analyzes chorionic villi recovered by chorionic villus sampling (CVS) immediately after ultrasound diagnosis of fetal demise (rather than culturing spontaneously expelled products), the chromosomal abnormalities are detected in 75% to 90%.[15] In addition, CGH (microarray analysis) can detect abnormalities not evident by karyotype.

Among second-trimester losses, one observes chromosomal abnormalities more similar in type to those observed in live-born infants: trisomies 13, 18, and 21; monosomy X; and sex chromosomal polysomies. This also holds among losses after 20 gestational weeks (stillborn infants), in which the frequency of chromosomal abnormalities is about 8% to 13%, exceeding 20% of anatomic abnormalities.[16] This frequency is less than that observed in earlier abortuses but much higher than that found among live-born infants (0.6%).

Types of Numerical Chromosomal Abnormalities

Autosomal Trisomy

Autosomal trisomies represent the largest (about 50%) single class of chromosomal complements in cytogenetically abnormal spontaneous abortions. That is, 25% of all abortuses are aneuploid, given half of all abortuses have a chromosomal abnormality. Frequencies of various trisomies are listed in Table 26-2. Trisomy for every chromosome has been observed. The most common trisomy is trisomy 16. Most trisomies show a maternal age effect, but the effect varies markedly among chromosomes. The increased maternal age effect is especially impressive for double trisomies. Attempts have been made to correlate placental morphologic abnormalities with specific trisomies, but these relationships are imprecise. Comparison of ultrasound findings and placental histology indicates that villous changes following in utero fetal demise could explain the low predictive value of placental histology in identifying an aneuploidy or another nonchromosomal etiology. (By contrast, the histologic features of complete and partial hydatidiform molar gestations are so distinctive that most molar miscarriages can be correctly diagnosed by histologic examination alone.)

Trisomies incompatible with life predictably show slower growth than trisomies compatible with life (e.g., trisomies 13, 18, 21), but otherwise there are usually no features distinguishing the two groups. Abortuses from the former group may show anomalies consistent with those found in full-term live-born trisomic infants. Malformations present have been said to be more severe than those observed in induced abortuses following prenatal diagnosis.

Aneuploidy usually results from errors at meiosis I, specifically maternal meiosis I. Errors of maternal meiosis I are associated with advanced maternal age.[17-19] Once thought to involve mostly missegregation of whole chromosomes, it is now clear that chromatid errors are an equally prevalent cause of maternal meiotic errors.[20] Irrespective, the cytologic mechanism involves decreased or absent meiotic recombination.[21] In trisomy 13 and trisomy 21, 90% of these maternal cases arise at meiosis I; almost all trisomy 16 cases arise in maternal meiosis I.[18] An exception is trisomy 18, in which two thirds of the 90% of maternal meiotic cases arise at meiosis II.[18]

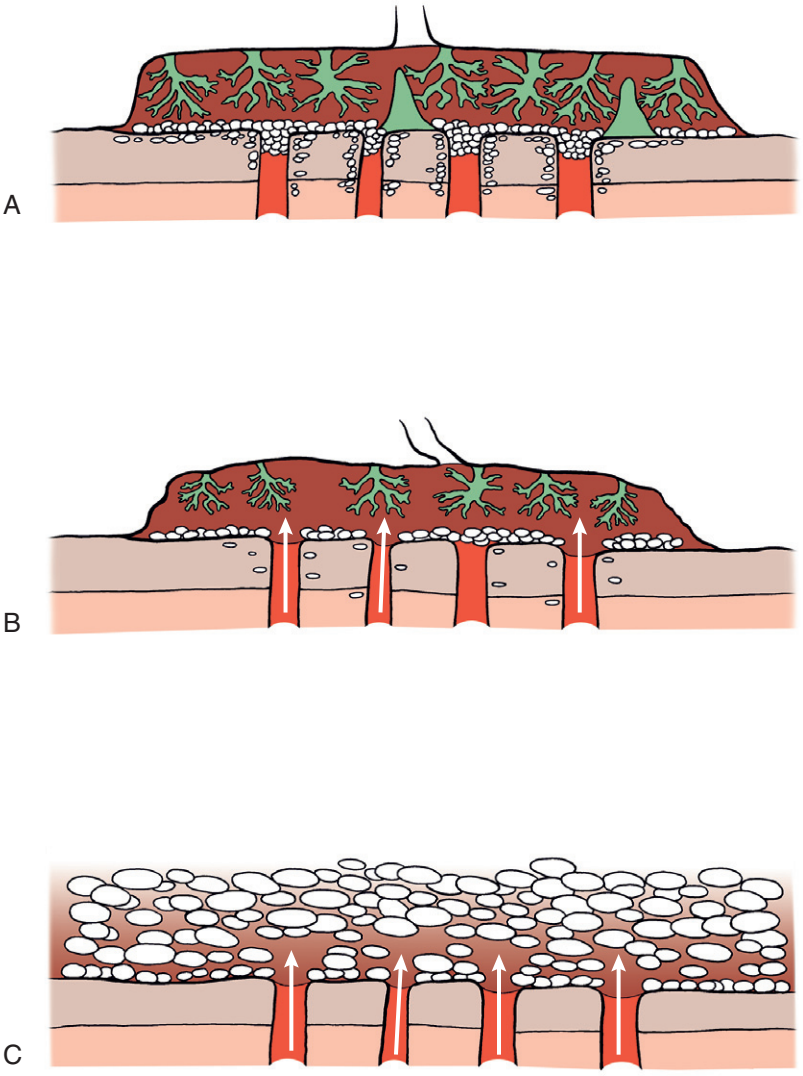

FIGURE 26-2. Placentation in a normal ongoing pregnancy **(A)**, in an early pregnancy failure **(B)**, and in a complete hydatidiform mole **(C)**. **A,** Note the continuous trophoblastic shell, the plugs in the lumens of the spiral arteries, and the interstitial migration of the extravillous trophoblast through the decidua down to the superficial layer of the myometrium. **B,** Note the discontinuous trophoblastic shell, the absence of plugs, and the reduced migration of extravillous trophoblastic cells. **C,** Note the absence of trophoblastic plugs and interstitial migration. (From Jauniaux E, Burton GJ: Pathophysiology of histological changes in early pregnancy loss. Placenta 26:114, 2005.)

A practical consequence of these data is that deducing chromosomal status of oocytes by analysis of polar bodies can detect 95% of more of chromosomally abnormal embryos. This is relevant because polar body analysis is a more robust predictions of embryo status than analysis of blastomere from a 3-day-old embryo. In the latter, mitotic nondisjunction can lead to spurious and unrepresentative results. Errors in *paternal* meiosis account for 10% of acrocentric (13, 14, 15, 21, and 22) trisomies.[18] In trisomy 21, paternal meiotic errors are equally likely to arise in meiosis I or II,[21] a circumstance that contrasts with the situation in maternal meiotic errors. Among nonacrocentric chromosomes, paternal contribution is uncommon. A surprising exception involves trisomy 2.

Polyploidy

In polyploidy, more than two haploid chromosomal complements are present. Nonmosaic triploidy (3n = 69) and tetraploidy (4n = 92) are common in abortuses. This phenomenon is presumably distinct from the diploid or triploid mosaicism that is found in about 30% of blastocysts.[22] Triploid abortuses are usually 69,XXY or 69,XXX, resulting from dispermy. An association exists between diandric (paternally inherited) triploidy and hydatidiform mole, a "partial" mole said to exist if molar tissue and fetal parts coexist. The more common "complete" (classic) hydatidiform mole is 46,XX, androgenetic in origin, and composed exclusively of villous tissue. Pathologic findings in diandric triploid and tetraploid placentas include a disproportionately large gestational sac, focal (partial) hydropic degeneration of placental villi, and trophoblast hyperplasia. Placental hydropic changes are progressive and may be difficult to identify in early pregnancy. By contrast, placental villi often undergo hydropic degeneration after fetal demise. This can occur in all types of miscarriage; thus, histologic and cytogenetic investigations are essential to differentiate between true mole and pseudomole because only a true mole can be associated with persistent trophoblastic disease. Fetal malformations associated with triploid miscarriage include neural tube defects and omphaloceles, anomalies reminiscent of those observed in triploid conceptuses surviving to term. Facial dysmorphia

and limb abnormalities have also been reported. Tetraploidy is uncommon, rarely progressing beyond 2 to 3 weeks of embryonic life. This chromosomal abnormality can also be associated with persistent trophoblastic disease and thus needs to be identified in order to offer hCG follow-up.

Sex Chromosomal Polysomy (X or Y)

The complements 47,XXY and 47,XYY each occur in about 1 per 800 live-born male births; 47,XXX occurs in 1 per 800 female births. X or Y polysomies are only slightly more common in abortuses than in live-born infants. In pregnancies conceived by intracytoplasmic sperm injection (ICSI), the frequency of 47,XXX and 47,XXY embryos and fetuses appears to be increased.[23]

Monosomy X

Monosomy X is the single most common chromosomal abnormality among spontaneous abortions, accounting for 15% to 20% of abnormal specimens. Monosomy X embryos usually consist of only an umbilical cord stump. Later in gestation, anomalies characteristic of Turner syndrome may be seen, such as cystic hygromas and generalized edema (Figure 26-3). Unlike live-born 45,X individuals, 45,X abortuses show germ cells; however, germ cells rarely develop beyond the primordial germ cell stage. The pathogenesis of 45,X germ cell failure thus involves not so much failure of germ cell development as more rapid attrition in 45,X compared with 46,XX embryos.[24,25] Monosomy X usually (80%) occurs as result of paternal sex chromosome loss. This observation is consistent with the lack of a maternal age effect in 45,X or possibly even an inverse age effect.

Relationship Between Recurrent Losses and Numerical Chromosomal Abnormalities

In both preimplantation and first-trimester abortions, recurrent aneuploidy occurs more often than expected by chance. Recurrent aneuploidy is a frequent explanation, at least until the number of losses reaches or exceeds four. In a given family, successive abortuses are likely to be either recurrently normal or recurrently abnormal. Table 26-3 shows that if the complement of the first abortus is abnormal,[26,27] recurrence usually involves aneuploidy, although not necessarily of the same chromosome.

Further supporting recurrent aneuploidy as a genuine phenomenon is the occurrence of trisomic preimplantation embryos in successive ART cycles. Rubio and collegues[28] showed increased aneuploid embryos in couples with repeated abortions compared with couples undergoing preimplantation genetic diagnosis (PGD) for mendelian indications. Frequencies of chromosomal abnormalities were 71% versus 45%, respectively. In a similar study, Munné and associates[29] found rates to be 37% versus 21% in women younger than 35 years, and 34% versus 31.5% in women older than 35 years.

Expectation of Abortus Karyotype in Recurrent Abortion

The concept of recurrent aneuploidy implies certain corollaries, one of which has often been the subject of controversy. Recurrent aneuploidy stratifies into recurrent losses in which couples have either experienced chromosomally abnormal abortuses repeatedly and recurrent losses that repeatedly show chromosomally normal abortuses. Given that 50% of all abortuses are abnormal cytogenetically, aneuploidy should be as likely to be detected in a randomly karyotyped abortus as in a sporadic abortus. This has proved to be true. Stern and coworkers[30] found a 57% prevalence of chromosomal abnormalities among abortuses of repetitively aborting women, a frequency coincidentally identical among abortuses of sporadically aborting women. Among 420 abortuses obtained from women with repeated losses, Stephenson and colleagues[31] found 46% chromosomal abnormalities; 31% of the original sample was trisomic. Their comparison was unselected pooled data, which showed 48% of abortuses to be abnormal; 27% of the original sample was trisomic.

From Warburton D, Kline J, Stein Z, et al: Does the karyotype of a spontaneous abortion predict the karyotype of a subsequent abortion? Evidence from 273 women with two karyotyped spontaneous abortions. Am J Hum Genet 41:465, 1987.

In contrast to these data, fetal loss—recurrent or not—are much more likely to be cytogenetically normal (85%) when occurring after the first trimester.[16] Carp and coworkers[32] found that among women having three or more abortuses, the likelihood that the abortus would have an abnormal karyotype was only 29%. In that series, inclusion criteria extended to 20 weeks' gestation, a time at which there is less reason to expect recurrent aneuploidy than recurrence of other etiologies.

Genetic Counseling for Recurrent Aneuploidy

Couples predisposed to recurrent aneuploidy are at increased risk not only for aneuploid abortuses but also for aneuploid live-born neonates. The autosome trisomic in a subsequent pregnancy might be compatible with life (e.g., trisomy 21). Indeed, the risk for live-born trisomy 21 following an aneuploid abortus has been stated to be about 1% (see Chapter 10). A meta-analysis[33] has confirmed this long-standing recurrence risk. The risk is considered similar following other aneuploides. Bianco and associates[34] provided a counseling algorithm applicable following a prior abortion of unknown karyotype. If abortions are recurrent but no information is available on the chromosomal status, the odds ratio can be used to derive a patient-specific risk. For example, if the a prior Down syndrome risk is 1 in 300 and the odds ratio is 1.5, a woman's calculated risk after three abortions would be 1/300 × 1.5, or 1/200.

Clinical Management of Recurrent Aneuploidy

If no information is available concerning the chromosomal status of prior abortuses, paraffin blocks of products of conception can be used to detect aneuploidy using FISH or array CGH. If results show a trisomy, likelihood of a

live-born trisomy is increased in subsequent pregnancies. If no information can be obtained, it is unclear whether prenatal genetic diagnosis is appropriate. However, the risk for an aneuploid offspring is increased and can be calculated according to Bianco and associates.[34] The small but finite risk for amniocentesis or CVS is troublesome to couples who have had difficulty maintaining a pregnancy. Thus, noninvasive approaches (see Chapter 10) are typically the chosen option. However, the sensitivity for detecting aneuploidy by noninvasive methods is not the nearly 100% possible with CVS or amniocentesis. PGD (see Chapter 11) is another option, especially if the couple eschews clinical pregnancy termination. Selective transfer of euploid embryos clearly decreases the rate of clinical abortions in couples with repeated losses,[35,36] and live-born trisomies should be decreased.

CHROMOSOMAL REARRANGEMENTS

Translocations

Structural chromosomal abnormalities are an unequivocal explanation for repetitive abortions. The most common structural rearrangement encountered is a translocation, **found in about 5% of couples experiencing repeated losses.** Individuals with balanced translocations are phenotypically normal, but their offspring (abortuses or abnormal live-born infants) may show chromosomal duplications or deficiencies as result of normal meiotic segregation. Among couples with repetitive abortions, about 60% of translocations are reciprocal and 40% robertsonian. Women are about twice as likely as men to show a balanced translocation.[37]

The clinical consequences of a balanced translocation are illustrated in Figure 26-3. If a child has Down syndrome as result of a centric fusion (robertsonian) translocation, the rearrangement will have originated de novo in 50% to 75% of cases. That is, a balanced translocation will not exist in either parent. The likelihood of Down syndrome recurring in subsequent offspring is minimal. On the other hand, the risk is significant in the 25% to 50% of families in which individuals have Down syndrome as result of a balanced parental translocation [e.g., parental complement 45,XX,-14,-21,+t(14q;21q)]. The theoretical risk for having a child with Down syndrome is 33%, but empirical risks are considerably less. The risk is only 2% if the father carries the translocation; the risk is 10% if the mother carries the translocation.[38,39] If robertsonian (centric fusion) translocations involve other chromosomes, empirical risks are lower. In t(13q;14q), the risk for live-born trisomy 13 is 1% or less.

Reciprocal translocations do not involve centromeric fusion, but rather interchanges between two or more chromosomes. Empirical data for specific translocations are usually not available, but generalizations can be made on the basis of pooled data derived from many different translocations.[40] Again, theoretical risks for abnormal offspring (unbalanced reciprocal translocations) are far greater than empirical risks. Overall, the risk is 12% for offspring of either female heterozygotes or male heterozygotes.[38,39] Detecting a chromosomal rearrangement thus profoundly affects subsequent pregnancy management. Antenatal cytogenetic studies should be offered. The frequency of unbalanced fetuses is lower if parental balanced translocations are ascertained through repetitive abortions (3%) than through anomalous live-born infants (nearly 20%).[38] Presumably more unbalanced products are lethal.

Analysis of preimplantation embryos using PGD reveals that most embryos are unbalanced: 58% in robertsonian translocations and 76% in reciprocal translocations.[41] This means that most conceptuses would be lost, usually preclinically. When a balanced translocation is detected in a couple experiencing recurrent abortions, *cumulative* prognosis for a live-born infant is little different than if a translocation had not been detected[42]; however, the length of time to achieve pregnancy is greatly increased (mean, 4 to 6 years). Thus, a more realistic strategy is to use PGD to identify and transfer only the few balanced embryos, increasing the statistical likelihood of conception.[43] This strategy is most attractive when the prospective is relatively older and nearly imperative in the fifth decade. Using standard techniques (FISH), one can readily exclude an unbalanced embryo; however, FISH does not distinguish a balanced (translocation heterozygote) from a normal embryo lacking any translocation. Novel techniques now allow a more precise diagnosis in experienced hands.[41] This involves treating a day 3 blastomere with caffeine and colchicine, and one day later generating a metaphase that can be analyzed by fluorescent techniques (FISH) using whole chromosome painting; the "conversion" rate is about 70%.

Rarely, a translocation precludes normal live-born infants. This occurs when a translocation involves homologous, acrocentric chromosomes (e.g., t[13q13q] or t[21q21q]). If the father carries such a structural rearrangement, artificial insemination may be appropriate. If the mother carries the rearrangement, donor oocytes or donor embryos and ART should be considered.

Inversions

Inversions are uncommon parental chromosomal rearrangements but are responsible for repetitive pregnancy losses analogous to translocations. In inversions, the order of genes is reversed. Individuals heterozygous for an inversion should be normal if their genes are merely rearranged. However, individuals with inversions suffer untoward reproductive consequences as a result of normal meiotic phenomena. Crossing-over that involves the inverted segment yields unbalanced gametes (see Simpson and Elias for more details).[44] Pericentric inversions are present in perhaps 0.1% of women and 0.1% of men experiencing repeated spontaneous abortions. Paracentric inversions are even rarer.

Women with a *pericentric* inversion have a 7% risk for abnormal live-born infants; men carry a 5% risk. Pericentric inversions ascertained through phenotypically normal probands are less likely to result in abnormal live-born infants.

Inversions involving only a small portion of the total chromosomal length paradoxically are less significant clinically because large duplications or deficiencies arise following crossing-over, usually conferring lethality. By contrast, inversions involving only 30% to 60% of the total chromosomal length are relatively more likely to be characterized by duplications or deficiencies compatible with survival. Prenatal cytogenetic studies should be offered.

Paracentric inversions should carry less risk for unbalanced products than pericentric inversions because nearly all paracentric recombinants should in theory be lethal. However, abortions and abnormal live-born infants have been observed within the same kindred, and the risk for unbalanced viable offspring has been tabulated at 4%.[45] Prenatal cytogenetic studies should thus still be offered.

MENDELIAN AND POLYGENIC/ MULTIFACTORIAL ETIOLOGY

That 30% to 50% of first-trimester abortuses show no chromosomal abnormalities does not mean genetic causation is excluded. Fetal demise may have occurred as a result of other genetic etiologies. Specifically, neither mendelian nor polygenic/multifactorial disorders show chromosomal abnormalities, and yet these etiologies explain far more congenital anomalies than do chromosomal abnormalities. It would thus be naïve to assume that mendelian and polygenic/multifactorial factors do not play pivotal roles in embryonic mortality. Indeed, there are innumerable candidate genes. Especially likely to be mendelian or polygenic in etiology are abortuses that demonstrate isolated structural anomalies. Cytogenetic data are often lacking on dissected specimens, making it nearly impossible to determine the relative role of cytogenetic versus mendelian or polygenic mechanisms in early embryonic maldevelopment. Philipp and Kalousek[46] correlated cytogenetic status of missed abortuses with morphologic abnormalities at embryoscopy. Embryos with chromosomal abnormalities usually showed one or more external anomalies, but some euploid embryos also showed anatomic anomalies.

In addition to traditional single-gene perturbations (mendelian etiology), novel nonmendelian forms of inheritance probably play a greater role in embryonic loss than in live-born abnormalities. Mosaicism may be restricted to the placenta, the embryo per se being normal. This phenomenon is termed *confined placental mosaicism*. Losses caused by this mechanism may already be subsumed in extant data because most studies involved analysis only of villous material. A corollary of confined placental mosaicism is uniparental disomy, in which both homologues for a given chromosome are derived from a single parent. This presumably occurs as result of expulsion of a chromosome from a trisomic zygote ("trisomic rescue"). Although the karyotype would appear normal (46,XX or 46,XY), the product would lack a contribution from one parent.

LUTEAL PHASE DEFECTS

Implantation in an inhospitable endometrium is a plausible explanation for pregnancy loss. Progesterone deficiency in particular could result in the estrogen-primed endometrium being unable to sustain implantation. Luteal phase deficiency (LPD) has long been hypothesized, specifically caused by inadequate progesterone secreted by the corpus luteum.

Once almost universally accepted as a common cause of fetal wastage, LPD is now generally considered an uncommon explanation. One pitfall is that endometrial histology identical to that observed with luteal phase "defects" is observed in fertile women. Efficacy of treatment has also never been proved—no randomized studies exist. Indeed, meta-analysis has shown[47] no beneficial effect of progesterone treatment. The current consensus is that LPD is either an arguable entity or not proved to be treated successfully with progesterone or progestational therapy.

Luteal phase abnormalities arising during ovulation stimulation and necessitated during ART could be a different phenomenon. It is considered standard to administer progesterone until about 9 weeks' gestation. In this circumstance, the cells surrounding the oocyte, which would ordinarily contribute to the corpus luteum, may have been removed when the oocyte was aspirated.

THYROID ABNORMALITIES

Decreased conception rates and increased fetal losses are logically associated with overt hypothyroidism or hyperthyroidism. The role of subclinical thyroid dysfunction is less clear and not generally considered an explanation for repeated losses. However, Negro and colleagues[48] reported that pregnancy loss was higher in thyroid peroxidase–negative women whose thyroid-stimulating hormone (TSH) level was 2.5 to 4 mIU/L compared with those whose TSH level was less than 2.5 mIU/L (6.1% vs. 3.6%). Increased frequency of thyroid antibodies has in addition been observed in several series, and some consider autoimmune thyroid disease a significant cause.[49] However, the value of treatment in such circumstances is unproved.

Elevations of maternal thyroid hormone per se are clearly deleterious. This effect was shown by a family from the Azores in which a gene conferring resistance to thyroid hormone was segregating.[50] Family members with an autosomal dominant mutation in the thyroid receptor-β (TRβ) gene *(Arg243Gln)* secreted large amounts of TSH to compensate for end-organ resistance. During pregnancy, the fetus of such a mother becomes unavoidably exposed to high levels of maternal TSH because TSH and thyroxine readily cross the placenta. Loss rates were 22.8% in pregnancies of mothers who had the *Arg243Gln* mutation, 2% in those of normal mothers whose male partner had the mutation, and 4.4% in couples in which neither partner had the mutation.

DIABETES MELLITUS

Women whose diabetes mellitus is poorly controlled are at increased risk for fetal loss. Mills and colleagues[51] showed in a National Institute of Child Health and Human Development (NICHD) collaborative study that women whose glycosylated hemoglobin level was greater than 4 standard deviations (SD) above the mean had higher pregnancy loss rates than women with lower glycosylated hemoglobin levels. This finding is consistent with that of many retrospective studies.[52] Poorly controlled diabetes mellitus should be considered one cause for early pregnancy loss. On the other hand, well-controlled or subclinical diabetes should not be considered a cause of early miscarriage. Neither the Royal College of Obstetricians and Gynaecologists (RCOG) nor American College of Obstetricians and Gynecologists (ACOG) recommend testing for occult diabetes mellitus.

INTRAUTERINE ADHESIONS (SYNECHIAE)

Intrauterine adhesions could interfere with implantation or early embryonic development. Adhesions may follow overzealous uterine curettage during the postpartum period, intrauterine surgery (e.g., myomectomy), or endometritis. Curettage is the usual explanation, with adhesions most likely to develop when the procedure is performed 3 or 4 weeks after delivery. Individuals with uterine synechiae usually manifest hypomenorrhea or amenorrhea, but perhaps 15% to 30% have repeated abortions. If adhesions are detected in a woman experiencing repetitive losses, lysis under direct hyperoscopic visualization should be performed. Postoperatively, an intrauterine device or inflated Foley catheter temporarily placed postoperatively in the uterus discourages reapposition of healing uterine surfaces. Estrogen administration should also be initiated. About 50% of patients conceive after surgery, but the frequency of pregnancy losses remains high.

MÜLLERIAN FUSION DEFECTS

Müllerian fusion defects are an accepted cause of *second-trimester* losses and pregnancy complications. Low birthweight, breech presentation, and uterine bleeding are the most common abnormalities associated with müllerian fusion defects compared with women having hysterosalpingogram-proven normal uteri.[53] However, reports typically lack controls.

Losses are more likely to be associated with a uterine septum than a bicornuate uterus.[54] In 509 women with recurrent losses studied by three-dimensional (3D) ultrasound, Salim and associates[55] found greater uterine distortion in women recounting a history of losses. However, the major problem in attributing cause and effect for second-trimester complications and uterine anomalies is that uterine anomalies are frequent in the general population; thus, adverse outcomes could merely be coincidental. For example, in the Salim study, 23.8% of women with recurrent miscarriage had some uterine anomalies on 3D ultrasound.[55] In another study, unsuspected bicornuate uteri were found in 1.2% of 167 women undergoing laparoscopic sterilization; 3.6% had a severely septate uterus, whereas 15.3% had fundal anomalies.[56] In another series, müllerian defects were found in 3.2% (22 of 679) of fertile women; 20 of the 22 defects were septate.[57]

Treatment has traditionally involved surgical correction, namely metroplasty. Ludmir and colleagues[58] wondered whether aggressive nonsurgical treatment could be just as efficacious. A total of 101 women with an uncorrected malformation were tracked longitudinally. After first being followed without surgery and without a defined nonsurgical regimen, the same women underwent a surgically conservative but medically aggressive protocol consisting of decreased physical and tocolysis. Fetal survival rates in both bicornuate and septate groups were, however, not significantly different before (52% and 53%, respectively) or after (58% and 65%, respectively) the change in management.

In conclusion, early first-trimester abortions may be caused by müllerian fusion defects, but other explanations are more likely even when such a defect is found. Septate uteri are most plausibly causative, implantation occurring on a poorly vascularized and inhospitable surface. Abortions occurring after ultrasonographic confirmation of a viable pregnancy at, say, 8 or 9 weeks, may more properly be attributed to uterine fusion defects. Women experiencing second-trimester abortions could benefit from uterine reconstruction, but reconstructive surgery is not necessarily advisable if losses are restricted to the first trimester.

LEIOMYOMAS

Although leiomyomas are frequent, relatively few women develop symptoms requiring medical or surgical therapy. That leiomyomas cause first- or second-trimester pregnancy wastage per se, rather than obstetrical complications like prematurity, is plausible but probably uncommon. Analogous to uterine anomalies, the coexistence of two common phenomena, uterine leiomyomas and reproductive losses, need not necessarily imply a causal relationship. Hartmann and Herring[59] correlated ultrasonographically detected leiomyomas with pregnancy outcome in a cohort of North Carolina women. Of 1313 women studied early in pregnancy, the 131 with leiomyomas as ascertained by ultrasound had an increased prior spontaneous abortion rate (odds ratio [OR], 2.17). One pitfall is that uterine contractions can mimic fibroids on ultrasound.

Location of leiomyomas is probably more important than size. Submucous leiomyomas are more likely to cause abortion than subserous leiomyomas. Postulated mechanisms leading to pregnancy loss include (1) thinning of the endometrium over the surface of a submucous leiomyoma, predisposing to implantation in a poorly decidualized site; (2) rapid growth caused by the hormonal milieu of pregnancy, compromising the blood supply of the leiomyoma and resulting in necrosis ("red degeneration") that, in turn, leads to uterine contractions and eventually fetal expulsion; and (3) encroachment of leiomyomas on the space required for the developing fetus, leading to premature delivery through mechanisms presumably analogous to those operative in incomplete müllerian fusion. In pregnancies that are not lost, the relative lack of space can also lead to fetal deformations (i.e., positional abnormalities arising in a genetically normal fetus).

Surgical procedures to reduce leiomyomas may occasionally be warranted in women experiencing repetitive second-trimester abortions. More often, however, leiomyomas have no etiologic relationship to pregnancy loss. Surgery should be reserved for women whose abortuses were both phenotypically and karyotypically normal and in which viability until at least 9 to 10 weeks was documented.

CERVICAL INSUFFICIENCY

A functionally intact cervix and lower uterine cavity are obvious prerequisites for a successful pregnancy. Characterized by painless dilation and effacement, cervical incompetence (now, preferably insufficiency) usually occurs during the middle second or early third trimester. Cervical insufficiency usually followed traumatic events such as cervical amputation, cervical lacerations, forceful

cervical dilation, or cervical conization. However, etiology may be genetic, for example, perturbation of a connective tissue gene (e.g., collagen, fibrillin). Indications for surgery and techniques to correct cervical incompetence are discussed in Chapter 27.

INFECTIONS

Infections are known causes of late fetal losses and logical causes of early fetal losses. Microorganisms associated with spontaneous abortion include variola, vaccinia, *Salmonella typhi*, *Vibrio fetus*, malaria, cytomegalovirus, *Brucella*, toxoplasmosis, *Mycoplasma hominis*, *Chlamydia trachomatis*, and *Ureaplasma urealyticum*. Transplacental infection occurs with each of these microorganisms, following which sporadic losses could logically result. However, infections as a cause of *repetitive* losses are much less likely.

Of the many organisms implicated in repetitive abortion, *U. urealyticum* and *M. hominis* seem most plausibly related to repetitive spontaneous abortions because they fulfill two important prerequisites: (1) the putative organism can persist in an asymptomatic state, and (2) virulence is not always so severe as to cause infertility due to fallopian tube occlusion and, hence, preclude the opportunity for pregnancy. Studies have also suggested a relationship between bacterial vaginosis, presumed to be *Gardnerella vaginalis*, and abortion. However, the latter is more typically, if not exclusively, associated with complications (premature delivery) in the second and third trimesters.

Given lack of evidence for causality for recurrent losses, one might wonder whether the infectious agents discussed previously actually cause fetal losses or merely arise after fetal demise from other causes. Cohort surveillance for infections can best shed light on the true role of infections in early pregnancy loss. The frequency of clinical infections was assessed prospectively in 386 diabetic subjects and 432 control subjects seen weekly or every other week beginning early in the first trimester.[60] Infection occurred no more often in 112 subjects experiencing pregnancy loss than in 706 experiencing successful pregnancies. This held true both for the 2-week interval in which a given loss was recognized clinically and the prior 2-week interval. Similar findings were observed in both control and diabetic subjects and were substantiated when data were stratified into ascending genital infections only versus systemic infection only.

In conclusion, infections doubtless explain some early pregnancy losses and certainly many later losses. However, in the first trimester, attributable risk is low even in sporadic cases, and in recurrent losses, infections are much less likely.

ACQUIRED THROMBOPHILIAS

An association between *second-trimester* pregnancy loss and certain autoimmune diseases is well accepted[16] (see Chapter 44). **For first-trimester losses, consensus holds that a less significant relationship exists.** The spectrum of antibodies found in women with pregnancy loss encompasses nonspecific antinuclear antibodies as well as antibodies against individual cellular components like phospholipids, histones, and double- or single-stranded DNA. The primary antigenic determinant is β_2-glycoprotein, which has an affinity for negatively charged phospholipids.[61] The antiphospholipid syndrome encompasses (1) lupus anticoagulant (LAC) antibodies, (2) anticardiolipin antibody (aCL), *or* (3) anti-β_2–glycoprotein. Values for the latter two should be greater than the 99th percentile, of moderate or higher titers, and 12 weeks apart. Descriptive studies in the 1980s initially seemed to show increased aCLs in women with first-trimester pregnancy losses. A pitfall proved to be selection bias, studying couples only following spontaneous abortions. That antibodies did not arise until *after* the pregnancy loss was also not excluded. To address this, Simpson and associates[62] analyzed sera obtained prospectively from women within 21 days of conception. A total of 93 women who later experienced pregnancy loss were matched 2 to 1 with 190 controls who subsequently had a normal live-born offspring. No association was observed between pregnancy loss and presence of either aPL or aCL. In the most recent ACOG bulletin on the topic,[61] three or more losses before the 10th week of pregnancy is considered to fulfill diagnostic criteria for antiphospholipid syndrome in the sense of justifying prophylactic heparin therapy. It was stated that this assumes "no maternal anatomic or hormonal abnormalities, and no paternal or maternal chromosomal abnormalities [are] excluded." However, ACOG provided the caveat that such an increase neither explains many losses nor confers a greatly increased risk for another loss. Given this, treatment regimens should be judicious, perhaps aspirin and heparin, if embarked on at all. Control groups of fertile women showed not dissimilar frequencies.

INHERITED THROMBOPHILIAS

Inherited maternal hypercoagulable states are unequivocally associated with increased fetal losses in the second trimester, but less convincingly in the first trimester. Postulated associations include factor V Leiden (Q1691G→A), prothrombin 2021G→A, and homozygosity for 677C→T in the methylene tetrahydrofolate reductase gene *(MTHFR)*. Meta-analysis of 31 studies published as of 2003 revealed associations between recurrent (two or more) fetal losses earlier than 13 weeks for these thrombophilias: factor V Leiden (G1691A), activated protein C resistance, prothrombin (*20210A0* gene), and protein S deficiency.[63] There were no associations between *MTHFR*, protein C, and antithrombin deficiencies and recurrent pregnancy loss. A second meta-analysis of 16 studies published by Kovalesky and coworkers[64] reported an association between recurrent pregnancy loss, defined as two or more losses in the first two trimesters, and maternal heterozygosity for either factor V Leiden or prothrombin 20210G7→A.

Evidence is less strong for an association between inherited thrombophilias and recurrent early (<10 weeks' gestation) pregnancy loss. Most authors recommend testing for factor V Leiden, activated protein C resistance, fasting homocysteine, antiphospholipid antibodies, and the prothrombin gene. Pending salutary results in randomized clinical trials, treatment for recurrent first-trimester losses with heparin or other antithrombotic or anticoagulant therapies should be initiated with caution.

EXOGENOUS AGENTS

Various exogenous agents have been implicated in fetal losses, although studies fail to stratify by sporadic and recurrent losses. Of course, every pregnant women is exposed to low doses of ubiquitous agents. Rarely are data adequate to determine with confidence the role these exogenous factors play in early pregnancy losses.

Outcomes following exposures to exogenous agents can usually be derived only on the basis of case-control studies. In such studies, women who experienced an adverse event (e.g., abortion) recalled exposure to the agent in question more often than controls. However, case-control studies have inherent biases. The primary bias is accuracy of recall, control women having less incentive to recall antecedent events than subjects experiencing an abnormal outcome. Employers also naturally attempt to limit exposure to women of reproductive age; thus, exposures to potentially dangerous chemicals are usually unwitting and, hence, poorly documented. Pregnant women are also exposed to many agents concurrently, making it nearly impossible to attribute adverse effects to a single agent. Given these caveats, **physicians should be cautious about attributing pregnancy loss to exogenous agents.** On the other hand, common sense dictates that exposure to potentially noxious agents be minimized.

X-Irradiation and Chemotherapeutic Agents

Irradiation and antineoplastic agents in high doses are acknowledged abortifacients. Of course, therapeutic radiographs or chemotherapeutic drugs are administered during pregnancy only to seriously ill women whose pregnancies often must be terminated for maternal indications. More frequently encountered, pelvic x-ray exposure of up to perhaps 10 cGy places a woman at little to no increased risk. The exposure is usually to doses that are far less (1 to 2 cGy). It is also prudent for pregnant hospital workers to avoid handling chemotherapeutic agents and to minimize exposures during diagnostic imaging.

Alcohol

Alcohol consumption should be avoided during pregnancy for reasons independent of pregnancy loss (see Chapters 6 and 8). However, alcohol probably increases pregnancy loss only slightly. Some authors found a slightly increased risk for abortion in women who drank in the first trimester, whereas others[65] found alcohol consumption to be nearly identical in women who did and did not experience an abortion: 13% of women who aborted and 11% of control women drank on average three to four drinks per week; other investigations have reached a similar conclusion. Armstrong and colleagues[66] found the odds ratio to be 1.82 with 20 drinks or more per week.

Abstinence should not be expected to prevent pregnancy loss, and evaluation for other causes is still in order. Thus, women should not attribute a loss to social alcohol exposure during early gestation.

Caffeine

In data gathered in cohort fashion, Mills and colleagues[67] showed that the odds ratio for association between pregnancy loss and caffeine (coffee and other dietary forms) was only 1.15 (95% confidence interval [CI], 0.89 to 1.49).[67] Women exposed to much higher levels may, however, be at greater risk; Klebanoff and coworkers[68] reported an association between pregnancy losses and caffeine ingestion greater than 300 mg daily (1.9-fold increase). A confounding problem with investigating caffeine is difficulty in taking into account the effects of nausea, which is believed to be more common in successful pregnancies. In general, reassurance can be given concerning moderate caffeine exposure and pregnancy loss.

Contraceptive Agents

Conception with an intrauterine device in place increases the risk for fetal loss and can rarely result in second-trimester sepsis characterized by a flulike syndrome. If the device is removed before pregnancy, there is no increased risk for spontaneous miscarriage. Oral contraceptives use before or during pregnancy is not associated with fetal loss. The same applies for injectable or implantable contraceptives. There is no evidence for increased pregnancy loss after spermicide exposure before or after conception.

Chemicals

Limiting exposure to potential toxins in the workplace is prudent for pregnant women. The difficulty lies in first defining the precise effect of lower exposures and then attributing a specific risk. False alarms concerning potential toxins are frequent. **Various chemical agents have been claimed to be associated with fetal losses, but only a few are accepted as potentially causative.**[69] These include anesthetic gases, arsenic, aniline dyes, benzene, solvents, ethylene oxide, formaldehyde, pesticides, and certain divalent cations (lead, mercury, cadmium). Workers in rubber industries, battery factories, and chemical production plants are among those at potential risk.

Cigarette Smoking

Active and passive maternal smoking has a damaging effect in every trimester of human pregnancy. Cigarette smoke contains scores of toxins that exert a direct effect on the placental and fetal cell proliferation and differentiation and can explain the increased risk for miscarriage, fetal growth restriction (FGR), stillbirth, preterm birth, and placental abruption reported by epidemiologic studies.[70] Smoking during pregnancy is often claimed to cause miscarriage, but in available studies, confounding variables are rarely excluded. Increased miscarriage rates reported in smokers do, however, appear to be independent of maternal age and alcohol consumption[71]; based on urinary cotinine levels, 400 women with spontaneous abortions were compared with 570 who experienced ongoing pregnancies. Women with urinary cotinine had increased risk for miscarriage, but the odds ratio was only 1.8 (95% CI, 1.3 to 2.6).

Smoking is associated, from early in pregnancy, with a thickening in the placenta of the trophoblastic basement membrane, an increase in collagen content of the villous mesenchyme, and a decrease in vascularization. These anatomic changes are associated with changes in placental enzymatic and synthetic functions. In particular, nicotine depresses active amino acid uptake by human placental

villi and trophoblast invasion, and cadmium decreases the expression and activity of 11β-hydroxysteroid dehydrogenase type 2, which is causally linked to FGR.[70] Within this context, direct damage to placental tissue could explain the higher rate of miscarriage in heavy smokers.

TRAUMA

Women commonly attribute pregnancy losses to trauma, such as a fall or blow to the abdomen. Actually, fetuses are well protected from external trauma by intervening maternal structures and amniotic fluid. The temptation to attribute a loss to minor traumatic events should be avoided. A nested case-control study of 392 cases and 807 controls showed no relationship between physical violence and miscarriage.[72]

PSYCHOLOGICAL FACTORS

That impaired psychological well-being predisposes to early fetal losses has been claimed but never proved. Certainly, neurotic or mentally ill women experience losses, but so, too, do normal women. Whether the frequency of losses is higher in the former is less certain because potential confounding variables have not been taken into account, nor have confounding genetic factors been considered.

Investigations most frequently cited as showing a benefit of psychological well-being are those of Stray-Pedersen and Stray-Pedersen.[73] Pregnant women who previously experienced repetitive abortions received increased attention but no specific medical therapy ("tender loving care"). These women ($n = 16$) were more likely (85%) to complete their pregnancy than women ($n = 42$) not offered such close attention (36%). One pitfall was that only women living "close" to the university were eligible to be placed in the increased-attention group. Women living farther away served as "controls"; however, these women may have differed from the experimental group in other ways as well.

Other studies have also reported a beneficial effect of psychological well-being.[74,75] Again, however, pitfalls exist in study design, and the biologic explanation for this salutary effect remains obscure.

MANAGEMENT OF RECURRENT EARLY PREGNANCY LOSS

Faced with a couple having experienced a spontaneous abortion, the obstetrician has several immediate obligations: (1) provide the couple information on the overall frequency of fetal wastage (10% to 12% of clinically recognized pregnancies, and many more unrecognized) and likely etiology (genetic and especially cytogenetic); (2) provide applicable recurrence risks (see Table 26-2); and (3) determine the necessity for a formal clinical evaluation. Fulfilling responsibility to inform patients can be facilitated by summarizing the salient facts cited in this chapter, emphasizing common etiologies responsible for fetal losses covered. Explicitly worth citing is the positive correlation between loss rates and both maternal age and prior losses. The maternal age effect is not solely the result of increased trisomic abortions but is also reflective of endometrial factors.

When Is Formal Evaluation Necessary?

A couple experiencing even one loss should be counseled and provided recurrence risk rates. However, not every couple needs formal assessment and a battery of tests. Infertile couples in their fourth decade may choose to be evaluated formally after only two losses. After three losses, couples have traditionally been directed to formal evaluation. Although lacking firm scientific basis for waiting until three losses, this is the benchmark for the RCOG and the European Society of Human Reproduction and Embryology (ESHRE).[76] The ACOG defines recurrent loss as either two or three consecutive losses. This 2001 ACOG guideline[77] is perhaps more defensible scientifically, but "consecutive" is arguable.

A couple being evaluated should undergo all tests employed by a given practitioner. There is little rationale for pursuing certain studies after two losses yet deferring others until three or more losses.

Any couple having a stillborn or anomalous live-born infant should undergo cytogenetic studies unless the stillborn was known to have a normal chromosomal complement. Parental chromosomal (conventional metaphase) rearrangements (i.e., translocations or inversions) should be excluded. If chromosomal studies on the stillborn were unsuccessful, common trisomies can still be ruled out by performing FISH on stored deparaffined tissue.

Recommended Evaluation

1. Couples experiencing only one first-trimester abortion should receive relevant information, but not necessarily be evaluated formally. Provide the relatively high (10% to 15%) pregnancy loss rate in the general population and the beneficial effects of miscarriage in eliminating abnormal conceptuses. Provide relevant recurrence risks, usually 20% to 25% subsequent losses in the presence of a prior live-born infant and only slightly higher in the absence of a prior live-born infant (see Table 26-1). Risks are, however, higher for older women than younger women. If a specific medical illness exists, treatment is obviously necessary. If present, intrauterine adhesions should be performed. Otherwise, no further evaluation need be undertaken, even if uterine anomalies or leiomyomas are present.
2. Investigation may or may not be necessary after two spontaneous abortions, depending on the patient's age and personal desires. After three spontaneous abortions, evaluation is usually indicated. If not done previously, one should (a) obtain a detailed family history, (b) perform a complete physical examination, (c) discuss recurrence risks, and (d) order selected tests enumerated in this chapter. Occurrence of a stillborn or live-born infant with anomalies warrants genetic evaluation irrespective of the number of pregnancy losses.
3. Parental chromosomal studies should be undertaken on all couples having repetitive losses. Antenatal chromosomal studies should be offered if a balanced chromosomal rearrangement is detected in either

parent or if autosomal trisomy occurred in any previous abortus.

4. Although perhaps impractical to karyotype all abortuses, cytogenetic information on abortuses is valuable. Detection of a trisomic abortus suggests recurrent aneuploidy, justifying prenatal cytogenetic studies in future pregnancies. Performing invasive prenatal cytogenetic studies solely on the basis of repeated losses is more arguable, but not unreasonable among women aged 30 years and older.
5. Endocrine causes for repeated fetal losses include poorly controlled diabetes mellitus, overt thyroid dysfunction, and elevated maternal TSH levels. Subclinical diabetes or subclinical thyroid disease should not be considered firm explanations. Luteal phase defects are no longer considered a likely explanation, although luteal support is still prescribed in pregnancies achieved with in vitro fertilization.
6. Of infections agents, only *C. trachomatis* seems of equal plausibility. These two agents are more likely to cause sporadic than repetitive losses. The endometrium could be cultured for *U. urealyticum*. Alternatively, a couple could be treated empirically with doxycycline (Vibramycin).
7. If an abortion occurs after 8 to 10 weeks' gestation, a uterine anomaly or submucous leiomyoma should be considered a potential cause. The uterine cavity should be explored by hysteroscopy or hysterosalpingography. Intrauterine adhesions should be lysed. If a müllerian fusion defect (septate or bicornuate uterus) is detected in a woman experiencing one or more second-trimester spontaneous abortions, surgical correction may be warranted. A large submucous leiomyoma may also justify myomectomy. However, the same strategies do not necessarily apply following first-trimester losses. Cervical incompetence should be managed by cervical cerclage during the next pregnancy.
8. Women with either acquired or inherited thrombophilias appear to have a slightly increased risk for first-trimester pregnancy loss. Thrombophilias explain at best only a small portion of first-trimester losses. There is a much greater likelihood that thrombophilias are the cause of a second-trimester loss.
9. One should discourage exposure to cigarettes and alcohol, yet not necessarily ascribe cause and effect in an individual case. Similar counsel should apply for exposures to other potential toxins.

LATE PREGNANCY LOSS (STILLBIRTH)

***Stillbirth* is the term used to describe pregnancy loss at 20 weeks' gestation or greater**. By weight, the definition is 350 g, the 50th percentile at that week of gestation. The frequency of stillbirths in the United States is 1 in 160 deliveries, or 25,000 annually. Stillbirths are increased in a large number of conditions, whose management is discussed elsewhere in this text. These conditions include obesity, multiple gestations with or without prematurity, infections (e.g., parvovirus-B19), and a host of systemic maternal diseases that include but are not limited to diabetes mellitus, chronic and gestational hypertension, autoimmune diseases, and renal and thyroid diseases. Table 26-4 shows prevalence and estimated rates compiled by Fretts in 2005[78] and reproduced by the ACOG in 2009.[16]

TABLE 26-4 ESTIMATES OF MATERNAL RISK FACTORS AND RISK FOR STILLBIRTH

CONDITION	PREVALENCE AMONG STILLBORNS	ODDS RATIO
General population	—	1.0
Previous growth-restricted infant (<10%)	7%	2-4.6
Previous stillbirth	1%	1.4-3.2
Multiple gestation		
Twins	3%	1.0-2.8
Triplets	0.1%	2.8-3.7
Low-risk pregnancies	80%	0.86
Hypertensive disorders		
Chronic hypertension	6%-10%	1.5-2.7
Pregnancy-induced hypertension		
Mild	6%-8%	1.2-4.0
Severe	1%-3%	1.8-4.4
Diabetes		
Treated with diet	3%-5%	1.2-2.2
Treated with insulin	2.4%	1.7-7.0
Systemic lupus erythematosus	<1%	6-20
Renal disease	<1%	2.2-30
Thyroid disorders	0.2%-2%	2.2-3.0
Thrombophilia	1%-5%	2.8-5.0
Cholestasis of pregnancy	<0.1%	1.8-4.4
Smoking >10 cigarettes	10%-20%	1.7-3.0
Obesity (prepregnancy)		
BMI 25-29.9 kg/m^2	21%	1.9-2.7
BMI >30	20%	2.1-2.8
Advanced maternal age (reference <35 yr)		
35-39 yr	15%-18%	1.8-2.2
≥40 yr	2%	1.8-3.3
Black women compared with white women	15%	2.0-2.2
Low educational attainment (<12 yr vs. ≥12 yr)	30%	1.6-2.0

Modified from ACOG Practice Bulletin: Management of Stillbirth. No. 102:1, 2009.

Pregnancy loss after 20 weeks is overall higher in African Americans (11 per 1000) than in other ethnic groups (6 per 1000), which include Hispanics and Native Americans.[16]

Recurrence

Recurrence reflects disease severity and ability to treat. Thus, blended figures are not necessarily appropriate. However, a few risk factors are broadly applicable. Maternal age is positively correlated with stillborn risk. This reflects not only the predictable known fetal etiologies (e.g., chromosomal abnormalities) but also maternal complications that are simply age related.

Stillbirth occurs more often in primiparous women of a given age than in multiparous women of comparable age. This may correlate to difficulty in achieving pregnancy, which is of greatest relevance to women requiring ART. Women who are subfertile (increased time to pregnancy) but never require ART have an increased risk for birth defects compared with women who achieve pregnancy in less than 1 year.[78] **Offspring of both ART couples[79] and subfertile couples not requiring ART[80] have**

20% to 30% more birth defects (OR, 1.2 to 1.3) than those of women becoming pregnant within 12 months of attempting.

Risks for stillbirth are highest (twofold) in women delivered of a growth-restricted infant earlier than 32 weeks' gestation.[81,82] This risk is, incidentally, independent of mode of delivery (cesarean or vaginal delivery). Using Scottish Morbidity Records (1981 to 2000),[83] the odds ratio for stillbirth recurring in the *second* pregnancy was 1.94.[83]

Genetic Factors

Genetic factors for stillbirths are receiving increased recognition with ACOG, which has provided specific management recommendations. **Chromosomal abnormalities are detected in 5% to 13% of stillbirths.**[84,85] Thus, special effort should be made to determine chromosomal status of a stillborn. It is now recognized that the traditional approach of obtaining fetal tissue after a stillborn infant has been delivered is suboptimal. Cell culture often fails, leading to no results in perhaps 50% to 75% of cases. **Successful culture for chromosomal analysis occurs in 80% when amniocentesis is used to obtain cells.**[16] It is tempting to eschew an invasive procedure in an already stressed patient, but this would not be in her long-term best interest.

Detecting even trisomies clinically by examination of a stillbirth is unexpectedly difficult because maceration occurs within days of fetal demise. Thus, medical records stating lack of dysmorphia should be suspect, save for obvious structural defects (e.g. cleft lip, myelomeningocele). Ultrasound results obtained when the pregnancy was still viable are probably more reliable. If amniocentesis cannot be performed or if cultures fail, one should attempt to obtain FISH results to exclude common trisomies. This can be done on placental tissues, umbilical cord segments, or internal (noncontaminated) tissues such as connective tissue.

The major yield of autopsy for a stillborn fetus is detection of an unrecognized mendelian explanation. This obviously alters management in subsequent pregnancies, for which reason a major effort should be exerted. Whole body photographs and whole body radiographs are appropriate, as is placental examination by a physician with requisite expertise. Considerable success has been made in particular in diagnosing skeletal dysplasia, often an autosomal recessive disorder that can recur in subsequent pregnancies. Other disorders may be autosomal dominant disorders arising as a result of de novo mutations. Distinguishing between these two possibilities is important because the recurrence risk should be almost nil if the etiology is de novo autosomal dominant. If parents refuse autopsy, the provider should attempt to obtain as much information as possible: photographs, radiographs or magnetic resonance images, examination by a geneticist, ultrasound. A head-sparing autopsy is preferable to no autopsy and may be acceptable to the parents.

Polygenic/Multifactorial

The frequency of virtually any isolated birth defects is higher among stillborn fetuses than neonates. This reflects adverse selection in utero, a phenomenon recognized for years in ultrasound surveillance.

TABLE 26-5 Maternal Laboratory Tests Recommended by the ACOG Following Stillbirth

All Mothers Having Stillbirths
- Complete blood count
- Kleihauer-Betke or other test for fetal cells in maternal circulation
- Human parvovirus-B19 immunoglobulin G; immunoglobulin M antibody
- Syphilis
- Lupus anticoagulant
- Anticardiolipin antibody
- Thyroid-stimulating hormone

Selected Mothers Having Stillbirths
- Thrombophilia
  - Factor V Leiden
  - Prothrombin gene mutation
  - Antithrombin III
  - Homocysteine (fasting)
- Protein S and protein C activity
- Parental karyotypes
- Indirect Coombs test
- Glucose screening (oral glucose tolerance test, hemoglobin A1c)
- Toxicology screen

Data from ACOG Practice Bulletin: Management of Stillbirth. No. 102:1, 2009.

If an isolated, organ-specific defect occurs (e.g., cardiac), polygenic/multifactorial etiology and recurrence risks (2% to 5%) usually apply. On the other hand, such a defect may be merely the only one evident but actually a component of a multiple malformation complex. Ability to distinguish between these possibilities is a major reason for autopsy. The multiple malformation syndrome could indicate mendelian etiology.

Maternal Evaluation

Certain maternal laboratory tests are recommended by ACOG (Table 26-5). Of course, a mother whose pregnancies has medical complications has already undergone many tests, and the cause of the stillbirth may seem obvious (e.g., diabetes mellitus). It is prudent, however, to order all these laboratory tests because the ostensible diagnosis may prove erroneous. Of note, ACOG does not recommend testing for antinuclear antibodies, for certain serologies (toxoplasmosis, rubella, cytomegalovirus, herpes simplex virus), nor at this time for genetic tests other than a karyotype. It is likely in the foreseeable future that array CGH (see Chapter 10), a panel of organ-specific mutations (e.g., skeletal dysplasias), or other genetic tests will prove practical. Caution is necessary before concluding that a stillbirth was caused by a condition signified by a positive laboratory test (e.g., thrombophilia). Such a finding does not obviate the need for fetal autopsy and fetal genetic tests.

Management in Subsequent Pregnancies

High-quality ultrasound and vigilant fetal surveillance are universally recommended. Induction is recommended at 39 weeks, but before that time, only with demonstrated fetal lung maturity.[86] Management otherwise will focus on any specific maternal factors identified (e.g., diabetes mellitus). In some pregnancies, management will differ little from that of the general obstetrical patient. In others, prenatal genetic diagnosis will be necessary.

OBSTETRICAL OUTCOME AFTER EARLY PREGNANCY COMPLICATIONS

Most early pregnancy complications occur before 12 weeks of gestation and involve placentation and early placental development. There is increasing evidence showing that many failures of placentation are associated with an imbalance of free radicals, which will further affect placental development and function and may subsequently have an influence on both the fetus and its mother[2] but are often ignored by clinicians.

Complications, including miscarriage, threatened miscarriage with or without an intrauterine hematoma, and vanishing twin, are extremely common in early pregnancy throughout the world. Very little is known about the short- and long-term consequences of these complications on ongoing and, in particular, subsequent pregnancies. Most data available are derived from small retrospective series of many different complications and pathologies or large series describing specific pathology but with wide variations in the definitions of the pathophysiology.

Recent meta-analysis and reviews have indicated an increased risk for adverse outcome in ongoing pregnancies after an early pregnancy event. Clinically relevant associations of adverse outcome in the subsequent pregnancy with an odds ratio higher than 2 after complications in a previous pregnancy are the risk for perinatal death after a single previous miscarriage, the risk for very preterm delivery (VPTD) after two or more miscarriages, and the risk for placenta previa, premature preterm rupture of membranes, VPTD, and low birthweight (LBW) after recurrent miscarriage.[87] Clinically relevant associations of adverse obstetrical outcome in the ongoing pregnancy with an odds ratio higher than 2 after complications in the index pregnancy are the risks for preterm delivery (PTD), VPTD, placental abruption, small for gestational age (SGA), LBW, and very low birthweight (VLBW) after a threatened miscarriage episode; pregnancy-induced hypertension, preeclampsia, placental abruption, PTD, SGA, and low 5-minute Apgar score following the detection of an intrauterine hematoma; and VPTD, VLBW, and perinatal death after a vanishing twin phenomenon.[88] These data indicate a link between early pregnancy complications involving the placenta and subsequent adverse obstetrical and perinatal outcomes.

There is observed heterogeneity among most studies, and many of the older controlled studies did not make adjustments for relevant confounders for adverse obstetrical outcome, such as age, ART, economic status, education level, ethnicity, height, marital status, parity, previous obstetrical outcome, prolonged infertility, smoking, and maternal weight or did not stratify for other first-trimester complications.[87,88] However, overall more recent large meta-analyses and controlled population-based prospective studies have confirmed previous data indicating a strong association between specific early pregnancy events and subsequent late obstetrical complications in the subsequent or ongoing pregnancy.[88] In particular, the risk for PTD and VPTD is increased after most first-trimester complications. This suggests that the early detection of these risk factors could improve the screening of women at high risk for specific obstetrical complications in ongoing and subsequent pregnancies. Furthermore, the antenatal identification of these parameters during the first half of pregnancy should enable better management protocols and new therapeutic guidelines aimed at improving the perinatal outcome in these groups of women at higher risk for abnormal pregnancy outcome.

KEY POINTS

- About 50% to 70% of conceptions are lost, most in the first trimester. Losses in preimplantation embryos are especially high: 25% to 50% of morphologically normal and 50% to 75% of morphologically abnormal embryos.
- Pregnancy loss is age dependent, a 40-year-old women having twice the loss rate of a 20-year-old women. Most of these pregnancies are lost before 8 weeks' gestation.
- At least 50% of clinically recognized pregnancy losses show a chromosomal abnormality. Chromosomal abnormalities in abortuses differ from those found in live-born infants, but autosomal trisomy still accounts for 50% of abnormalities. A balanced translocation is present in 5% of couples having repeated spontaneous abortions.
- Many nongenetic causes of repetitive abortions have been proposed, but few are proved. Efficacy of treatment often remains uncertain.
- Uterine anomalies are accepted causes of *second-trimester* losses, but their role in first-trimester losses is less clear. Couples experiencing a second-trimester loss may benefit from metroplasty or hysteroscopic resection of a uterine septum.
- Drugs, toxins, and physical agents are uncommon causes of spontaneous abortion, especially repetitive. One should not assume that exposures to toxicants explain repetitive losses.
- Antiphospholipid syndrome (antibodies to LAC, aPL, and anti-B1-glycoprotein) is an accepted cause of second-trimester losses; its role in first-trimester losses is arguable. Strict ACOG criteria exist for applying the diagnosis of antiphospholipid syndrome to a woman having repeated first-trimester spontaneous abortions.
- In recurrent abortions, prognosis is good even without therapy. The live-birth rate is 60% to 70% even with up to four losses and no prior live-born infants. An efficacious therapeutic regimen should show success rates greater than these expected background rates, or should be assessed in a randomized control trial. Women having greater than four losses are less likely to have a cytogenetic explanation and may have a different prognosis.
- The frequency of chromosomal abnormalities in stillbirths (losses after 20 weeks' gestation or weighing at least 350 g) is underappreciated, as are nonchromosomal genetic factors (e.g., syndromes). Tissue for cytogenetic studies should be obtained by amniocentesis or chorionic villus sampling; cultures initiated from postdelivery products often lead to unsuccessful culture.

- A major effort should be exerted to obtain full autopsy and imaging on all stillbirths because findings can alter management in future pregnancies. If a couple declines autopsy, whole body radiographs, magnetic resonance imaging, and other noninvasive imaging should be pursued.
- Adverse first-trimester events or complications in a current or in a previous pregnancy may interfere with normal placentation and increase the risks for specific later obstetrical complications.

Since the initial description in 1658 of the cervix being "so slack that it cannot keep in the seed" by Cole and Culpepper,[1] few subjects in obstetrics have generated as much controversy as the term "cervical incompetence," now more correctly termed "**cervical insufficiency**." The competent or "sufficient" human uterine cervix is a complex organ that undergoes extensive changes throughout gestation and parturition. It is a key structure responsible for keeping the fetus and membranes inside the uterus until the end of gestation, and for undergoing significant changes that allow the delivery of the baby during spontaneous or induced labor.

The cervix is primarily fibrous connective tissue composed of an extracellular matrix consisting of collagen types I and II, elastin and proteoglycans, and a cellular portion consisting of smooth muscle and blood vessels. A complex remodeling process of the cervix occurs during gestation involving timed biochemical cascades, interactions between the extracellular and cellular compartments, and cervical stromal infiltration by inflammatory cells.[2] Any disarray in this timed interactions could result in early cervical ripening, cervical insufficiency, and preterm birth or miscarriage.

The incidence of cervical insufficiency in the general obstetrical population is reported to vary between approximately 1 in 100 and 1 in 2000.[3-5] Wide variation in incidence estimates is likely due to real biologic differences among study populations, the criteria used to establish the diagnosis, and reporting bias between general practitioners and referral centers.

THE SPONTANEOUS PRETERM BIRTH SYNDROME

Because spontaneous preterm birth is not a discrete, well-characterized disease process, it is best characterized as a *syndrome* comprising several anatomic and related functional components.[6] These include the uterus and its myometrial contractile function (i.e., preterm labor), decidual activation and loss of chorioamnionic integrity (i.e., preterm rupture of membranes), and finally, diminished cervical competence, either from a primary anatomic defect or from early pathologic cervical ripening (i.e., cervical insufficiency). In a particular pregnancy, a single anatomic feature may appear to predominate, even though it is more likely that most cases of spontaneous preterm birth result from the interaction of multiple stimuli and pathways that culminate in the overt clinical syndrome. Nevertheless, the relative importance of these components varies not only among different women but also in successive pregnancies for a particular patient.

Because the underlying processes (e.g., infection, inflammation) and their interactions with the anatomic components of the syndrome remain poorly characterized, the specific series of events leading to spontaneous preterm birth cannot be accurately determined, either during pregnancy, when the syndrome is recognized and managed, or by a careful retrospective analysis of the past obstetrical events. Thus, finding effective preventive management strategies has been generally unsuccessful and only empirically based.

THE DIAGNOSIS OF CERVICAL INSUFFICIENCY

Cervical insufficiency is primarily a clinical diagnosis, characterized by recurrent painless dilation and spontaneous midtrimester birth, usually of a living fetus. Because cervical insufficiency is likely part of a broader preterm birth syndrome, the diagnosis is usually retrospective and made only after poor obstetrical outcomes have occurred (or rarely, are in evolution). Because there are few proven objective criteria, and lack of a specific histologic diagnosis other than a rare, gross cervical malformation, a careful history and review of the past obstetric records are crucial to making an accurate diagnosis. Unfortunately, in many instances, the records are incomplete or unavailable, and many women cannot provide a reliable history. Even with excellent records and a complete history, clinicians might disagree on the diagnosis in all but the most classic cases. Confounding factors in the history, medical records, or current physical assessment might be used to either support or refute the diagnosis, based on their perceived importance. The physician managing a patient who experiences a spontaneous midtrimester birth is in the optimal position to assess whether the typical clinical criteria for cervical insufficiency were present. Possibly a more specific diagnosis of cervical insufficiency can be made by witnessing acute cervical insufficiency, a possible indication for *physical examination–indicated* (a.k.a. emergent) cerclage that will be covered later in the chapter. Because cervical insufficiency is generally a retrospective diagnosis and depends on a history of poor outcomes, clinicians have sought criteria that might lead to a prospective and more objective diagnosis. In women considered to be at risk for cervical insufficiency, based on an atypical history or because of other identified risk factors, serial examinations may be performed to detect progressive shortening and dilation, leading to a presumptive diagnosis of insufficiency, which may be amenable to therapeutic intervention (see box, Diagnostic Criteria for Cervical Insufficiency). Vaginal sonography as a screening and diagnostic aid will be discussed later in separate sections.

Diagnostic Criteria for Cervical Insufficiency

Historical Factors:
- History of painless cervical dilatation with preterm (midtrimester) delivery

Index Gestation:
- Painless cervical shortening and dilatation detected by serial digital evaluations
- Short cervix detected by midtrimester sonography in women with a history of spontaneous preterm birth

CERVICAL COMPETENCE AS A BIOLOGIC CONTINUUM

In 1962, Danforth and Buckingham[7] suggested that cervical incompetence was not an all or none phenomenon. Rather, it comprised degrees of insufficiency, and combinations of factors could cause "cervical failure." This concept never gained wide acceptance in spite of the obvious heterogeneity observed in clinical practice. Cervical insufficiency was generally viewed as dichotomous, possibly because available treatment strategies were similarly devised. These classic investigations demonstrated that the normal cervix is comprised predominantly of connective tissue, unlike the uterine corpus. This fibrous band is the chief mechanical barrier against the loss of the enlarging products of conception. The cervix and mucous glands also play an important immunologic role in preventing organisms from ascending into the normally sterile intrauterine environment.

In a subsequent report, these investigators analyzed cervical biopsies taken from postpartum women and compared them with hysterectomy specimens from nonpregnant patients.[8] Pregnancy was associated with increased water content, a marked decline in collagen and glycoprotein, and increased glycosaminoglycans. The cellular and biochemical changes suggested that cervical dilation in pregnancy is a dynamic process, and this might explain why a woman could have a pregnancy outcome consistent with cervical insufficiency in one pregnancy but, then without treatment, have a subsequent term birth. Presumably, the factors inciting the pathologic cervical changes might vary among pregnancies. Women with a more muscular cervix might have an unusual susceptibility or lower threshold for the effects of the factors that precipitated the clinical syndrome of preterm birth.

These earlier observations were enlarged by Leppert and colleagues,[9] who reported an absence of elastic fibers in the cervix of women with clinically well-characterized cervical insufficiency on the basis of their reproductive history. Conversely, cervical biopsy specimens from women with normal pregnancies showed normal amounts and orientation of these elastic fibers. Rechberger and colleagues[10] also compared cervical biopsy specimens among nonpregnant controls, women in the midtrimester with clinically defined cervical insufficiency, and women with normal postpartum gravidas. Compared with normal postpartum patients, they found increased collagen extractability and collagenolytic activity in women with cervical insufficiency, suggesting a high collagen turnover characterized by higher proportions of newly synthesized collagen with lower mechanical strength. It is unknown whether these microstructural and biochemical phenomena were congenital, acquired from previous trauma, or the result of other pregnancy-associated pathology. Collectively, these biochemical and ultrastructural findings support the variable, and often unpredictable, clinical course of women with a history of cervical insufficiency.[11]

Although the traditional paradigm has depicted the cervix as either competent or incompetent, both clinical data[12-15] and interpretative reviews[16-18] suggest that, as with most other biologic processes, cervical competence is rarely an all or none phenomenon and more likely functions along a continuum of reproductive performance. Although some women have tangible anatomic evidence of poor cervical integrity, most women with a clinical diagnosis of cervical insufficiency have ostensibly normal cervical anatomy. In a proposed model of cervical competence as a continuum, a poor obstetrical history results from a process of premature cervical ripening, induced by a myriad of underlying factors, including infection, inflammation, local or systemic hormonal effects, or even genetic

predisposition. If and when cervical integrity is compromised, other processes may be stimulated, appearing clinically as other components of the spontaneous preterm birth syndrome (e.g., premature membrane rupture, or preterm labor). Knowing whether diminished cervical competence was due to a primary mechanical deficiency or other exogenous factors would define the optimal therapy.

TESTS FOR CERVICAL INSUFFICIENCY

Because the diagnosis of cervical insufficiency has been determined primarily from past reproductive performance and physical examination findings, the obvious limitations associated with the clinical diagnosis have prompted the search for sensitive and specific tests that could be applied in a prospective manner to women deemed at risk for cervical insufficiency, thus obviating the need for recurrent pregnancy loss. Such a test might provide a timely diagnosis and the potential for optimal therapeutic intervention.

Most of the earlier reported tests for cervical insufficiency were based on the functional anatomy of the interval os in the nonpregnant state and are of historical interest. Attempts at objective assessments include passage of a #8 Hegar dilator into the nonpregnant cervical canal without resistance[19] and traction forces required to dislodge a Foley catheter whose balloon was placed above the internal os and filled with 1 mL of saline solution.[20] Subjectively effortless passage of the dilator or removal of the Foley balloon with less than 600 g of traction force would make an objective diagnosis.

In 1988, Kiwi and colleagues[21] estimated the elastic properties of the nonpregnant cervix in two cohorts of women: 247 women with a poor obstetrical history and 42 controls. Although women in the poor obstetrical history group had significantly lower elastance values than the controls, there was significant overlap between the two groups. They reported no subsequent pregnancy outcomes, proposed no clinically useful cut-off for their evaluation, and could only suggest that such objective evaluation might ultimately prove to be clinically useful to accurately select patients for cerclage.

In 1993, Zlatnick and Burmeister[22] reported their experience with a cervical compliance score derived from the results of three other tests: hysterosalpingography, passage of a #8 Hegar dilator, and intrauterine balloon traction performed in 138 nonpregnant women. Their histories included prior delivery less than 34 weeks following clinically diagnosed preterm labor or preterm membrane rupture, with or without antecedent bleeding. A small portion of their cohort had a questionable history of cervical insufficiency. Scores could range from 0 to 5, and women with low scores of 2 or less were more likely to have been delivered at 27 to 34 weeks as compared with women with higher scores, who were more likely to have been delivered in the midtrimester at 14 to 26 weeks ($P = .01$). In subsequent pregnancies, cerclage was recommended in all women with a high score of greater than 2, and most underwent surgery. Surprisingly, in spite of surgical intervention, more women with high scores delivered at 14 to 29 weeks' gestation ($P = .07$), casting doubt on the clinical utility of this scoring system.

All such attempts at providing an objective diagnosis of cervical insufficiency failed because the tests were not evaluated with regard to standard characteristics (e.g., sensitivity, specificity) against some reference standard for the diagnosis. Moreover, none of these tests could reasonably predict pregnancy-associated conditions that would lead to premature ripening and cervical dilation (i.e., functional insufficiency). Finally, because there is no universally applicable standard for the diagnosis of insufficiency, and because the results of such tests were never evaluated and linked to a proved effective treatment, their clinical utility was, at best, theoretical. Because no test for cervical insufficiency in the nonpregnant patient has been validated, none of these tests are in common use today. **Clinical assessment of the cervix is performed in the index pregnancy when the diagnosis of cervical insufficiency is suspected.**

RISK FACTORS FOR CERVICAL INSUFFICIENCY

Based largely on the epidemiologic associations between the clinical diagnosis of cervical insufficiency and antecedent historic factors, numerous risk factors for cervical insufficiency have been recognized. These include prior cervical surgery (e.g., trachelectomy, cone biopsy), in utero diethylstilbestrol (DES) exposure, prior induced or spontaneous first- and second-trimester abortions, uterine anomalies, multiple gestations, or prior spontaneous preterm births that did not meet typical criteria for cervical insufficiency. Because DES usage was effectively curtailed in the early 1970s, this congenital risk factor should soon be of only historic interest.

Cervical damage from surgery is diminishing as indications for cone biopsy and more radical surgical procedures are diminishing. More common is the patient who has undergone a loop electrosurgical excision procedure (LEEP), usually for cervical dysplasia. These procedures are plausibly a risk factor for cervical insufficiency. Regrettably, it has not been feasible to simultaneously control for the epidemiologic risk factors that are associated with both preterm birth and dysplasia. In 1995, Ferenczy and colleagues[23] reported 574 women who had undergone LEEP and examined the reproductive performance of 55 women who conceived after the surgery. Their goal had been to obtain a nominal 7-mm thick specimen, and they cited a maximum excisional depth of 1.5 cm. In this series, there were no spontaneous preterm births before 37 weeks observed. Data from a similar series of 52 women revealed an incidence of spontaneous preterm birth of less than 10% and no midtrimester losses that might suggest a clinical diagnosis of cervical insufficiency.[24] A more recent and much larger retrospective cohort study by Sadler et al.[25] examined 652 women treated with laser conization, laser ablation, or LEEP, and compared these with a cohort of 426 untreated patients. The overall adjusted rates of preterm birth before 37 weeks' gestation were similar; however, the group with the highest tertile of cone height (≥1.7 cm) did have more than a threefold increased risk of preterm chorioamnion rupture compared with untreated women. Even considering the effect on preterm membrane rupture, the overall effect on preterm birth was not

statistically significant, as the 95% confidence interval (CI) included 1.0.

Published data on cone biopsy is similarly reassuring. Weber[26] reported an incidence of preterm birth of only 7% in 577 pregnancies of women with a prior cone biopsy. Leiman[27] concluded that the risk of preterm birth was greater only when the maximum cone height was greater than 2 cm or the volume removed was greater than 4 mL. Raio and colleagues[28] performed a matched cohort study of 64 women who had undergone prior laser conization and observed no difference in the incidence of preterm birth compared with their controls (9.4% vs. 4.7%), and statistically similar gestational ages at delivery and birthweights. However, in a secondary analysis, a laser cone height greater than 10 mm was a significant independent risk factor for preterm birth. Other earlier reports have also suggested that larger cone biopsies increased the risk of preterm birth. Nevertheless, the distribution of preterm births in these populations did not confirm a disproportionate incidence of midtrimester loss consistent with a clinical diagnosis of cervical insufficiency.

Kuoppala and Saarikoski[29] retrospectively reviewed 62 women who had undergone cone biopsy and an equal number of matched control patients. The pregnancy outcomes of 22 who underwent elective cerclage were similar to those managed without cerclage, with fetal salvage rates of 97% and 100%, respectively. On the basis of their findings and review of seven other published reports, they concluded that prophylactic cerclage was not routinely indicated. Of note, in the largest published randomized trial of cerclage (summarized later), women with one or more cone biopsies *or* cervical amputations had an overall preterm birth rate of 35%. However, in this population, there was no benefit from prophylactic cerclage placement.

In summary, most women with prior LEEP or cone biopsy do not appear to have a clinically significant rate of second-trimester loss or preterm birth. However, women in whom a large cone specimen was removed or destroyed (including cervical amputations), or who have undergone multiple prior procedures, probably have an increased risk of spontaneous preterm birth. Whether prophylactic cerclage would be an effective preventive strategy in these at-risk women remains speculative. The available clinical trial data does not suggest a benefit from prophylactic cerclage, and so these women may be followed clinically for evidence of premature cervical changes. **Women with a history of prior cervical surgery and spontaneous midtrimester loss, suggesting a clinical diagnosis of insufficiency, should be considered for history-indicated (a.k.a. prophylactic) cerclage in future pregnancies.**

USE OF CERCLAGE FOR RISK FACTORS

Because of epidemiologic associations, clinicians have tried to expand the role of cerclage to include women with risk factors. To date there have been four randomized trials that included women with various risk factors for spontaneous preterm birth (and *possible* cervical insufficiency) whose managing physicians did not believe they required a prophylactic cerclage for a typical history of cervical insufficiency. Three of the trials[30-32] were relatively small and included women based on a scoring system[30]: twin gestation[31] and recurrent spontaneous preterm birth.[32] None of these trials showed a benefit to cerclage but generally confirmed a higher rate of hospitalizations and medical interventions in the cerclage groups.

The largest randomized trial of cerclage was conducted by the Royal College of Obstetricians and Gynecologists between 1981 and 1988.[33] A total of 1292 women were enrolled in 12 countries because of uncertainty on the part of their managing physicians as to whether a history-indicated cerclage was indicated. As anticipated, these patients comprised a heterogeneous group with at least six distinct risk-factor subgroups identified on the basis of their dominant history or physical examination findings. Although women assigned to cerclage had a significantly lower rate of preterm birth earlier than 33 weeks (13% vs. 17%; $P = .03$), the investigators estimated that approximately 25 cerclage procedures would be required to prevent one such birth. Moreover, women assigned to cerclage received more tocolytic medications and spent more time in the hospital. Puerperal fever was significantly more common in the cerclage group. Of interest is the finding in a secondary analysis that only the subgroup of women with multiple pregnancies affected, defined as at least three prior spontaneous preterm births including midtrimester losses, appeared to benefit from cerclage with lower rates of preterm birth (15% vs. 32%; $P = .02$). This secondary analysis confirmed the importance of assessing clinical history in considering the diagnosis and treatment of cervical insufficiency.

CAN SONOGRAPHIC EVALUATION OF THE CERVIX DIAGNOSE INSUFFICIENCY?

Over the past two decades numerous investigators have suggested that cervical insufficiency can be diagnosed by midtrimester sonographic evaluation of the cervix. Various sonographic findings, including cervical length, funneling at the internal os, and dynamic response to provocative maneuvers (e.g., fundal pressure), have been used to select women for treatment, generally cerclage (Figure 27-1). In these earlier reports, the sonographic evaluations were not blinded, leading to uncontrolled interventions and difficulty determining their value. Diagnostic criteria were disparate and, in some cases, not described in a quantitative or reproducible manner.

Later, large, blinded observational studies using reproducible methods were published.[13,34-37] These investigators reported the relationship between midtrimester cervical sonographic findings and preterm birth. The Eunice Kennedy Shriver National Institutes of Child Health and Human Development (NICHD) Maternal-Fetal Medicine (MFM) Units Network[13] completed a study of 2915 unselected women with a singleton pregnancy that underwent a blinded cervical sonographic evaluation at 24 weeks' gestation. The relative risk of spontaneous preterm birth increased inversely proportionally to cervical length. In spite of this highly significant relationship, as a test for predicting spontaneous preterm birth at less than 35 weeks, a cervical length cut-off of less than 26 mm (the

FIGURE 27-1. Short cervix *(calipers)* by transvaginal sonogram at 20⅘ weeks' gestation. Note the presence of a biofilm (sludge) that has been associated as a potential marker for subclinical infection.[73]

population 10th percentile) had low sensitivity (37%), and poor positive predictive value (18%).

In a subsequent study, the NICHD MFM Units Network[37] examined the utility of cervical ultrasound as a predictor of spontaneous preterm birth at less than 35 weeks in high-risk women, defined as at least one prior spontaneous preterm birth at less than 32 weeks. Women believed to have cervical insufficiency (based on a clinical history) were not eligible. Beginning at 16 to 18 weeks of gestation, 183 gravidas underwent serial, biweekly sonographic evaluations until the 23rd week of gestation. The study design permitted analysis of the shortest observed cervical length over time, which also included any fundal pressure-induced (or spontaneously occurring) cervical length shortening. As in the previous study,[13] there was a highly significant inverse relationship between cervical length and spontaneous preterm birth. However, in this high-risk population, at a cervical length cut-off of less than 25 mm, the sensitivity increased to 69% and the positive predictive value to 55%. A secondary analysis of the data suggested that these high-risk women with shortened cervical length may have a clinically significant *component* of diminished cervical competence, because there was a preponderance of midtrimester births at less than 27 weeks in this group.[38]

These reports[13,37] support the concept that cervical length, as a surrogate measure of cervical competence, operates along a continuum of reproductive performance and provides prospective confirmation of an earlier published retrospective analysis.[12] Nevertheless, in spite of the consistent relationship between shortened cervical length and spontaneous preterm birth, the actual identification of an appropriate cervical length action cut-off and confirmation of the potential contribution of related cervical sonographic findings (e.g., funneling at the internal os) remains problematic. Clearly, cervical sonography performs poorly as a screening test in low-risk women,[12,13] but it appears to have significant clinical utility in high-risk women, defined as a prior early spontaneous preterm birth.[35-37] Whether cervical ultrasound has similar predictive values in other populations of at-risk women (e.g., DES, prior cervical surgery, multiple induced abortions, and so on) remains speculative, because it has not been well studied. Although some investigators have included women with these risk factors in their study populations composed primarily of women with previous spontaneous preterm birth, the results could not be subcategorized because of small sample sizes.[39] However, in a recent series of 64 women with various uterine anomalies, the authors observed an overall preterm delivery rate at less than 35 weeks of 11% and a significant relationship between cervical length of less than 25 mm and preterm birth,[40] with summary predictive values similar to other high-risk populations.[37]

Use of cervical ultrasound in twin gestations has also been reported.[41-42] However, the test characteristics, especially sensitivity and positive predictive value (<40%), appear to be generally lower than for women with a prior early spontaneous preterm birth. A systematic review[43] summarized the predictive value of vaginal sonography for preterm birth in 46 published series of both asymptomatic and symptomatic gravidas carrying singleton or twin gestations.

CERCLAGE FOR CERVICAL SONOGRAPHIC INDICATIONS

Under the presumption that shortened cervical length (with or without funneling at the internal os) is diagnostic of cervical insufficiency, several investigators have studied the effect of sonographically indicated cerclage on reproductive performance. Several investigators published retrospective analyses of uncontrolled use of cerclage in various at-risk populations with conflicting results, suggesting that cerclage was either effective[44,45] or ineffective.[46-49] In addition to the inherent biases present in these study designs and differences among study populations, small sample size, variable sonographic criteria, type of cerclage, inclusion of ancillary clinical findings, and definition of pregnancy outcome led to an inconclusive analysis.

Currently, four randomized trials of cerclage for sonographic indications have been published (Table 27-1). Althuisius and her colleagues in the Netherlands,[50,51] performed a two-tiered randomized clinical trial of high-risk patients, the majority of whom were believed to have cervical insufficiency based on their obstetrical history. In the first tier, eligible patients were randomly assigned to receive either prophylactic cerclage or to begin sonographic surveillance. Thirty-five of the patients assigned to the cervical ultrasound group were found to have a shortened cervical length less than 25 mm and underwent a second randomization to either cerclage or no cerclage. Both cerclage and no cerclage groups were instructed to use modified home rest. Of the 19 assigned to cerclage, there were no preterm births before 34 weeks versus a 44% preterm birth rate in the no cerclage–home rest group ($P = .002$). None of the women who maintained a cervical length of at least 25 mm experienced a preterm birth. Interestingly, the women who received cerclage for shortened cervical length had outcomes almost identical to women who received the earlier prophylactic cerclage. Rust and colleagues[52] enrolled 138 women who had various risk factors

for preterm birth (including 12% with multiple gestations) and randomly assigned them to receive a McDonald cerclage or no cerclage after their cervical length shortened to less than 25 mm or they developed funneling less than 25%. Preterm birth before 34 weeks was observed in 35% of the cerclage group versus 36% of the control group.

In a multinational trial comprising 12 hospitals in six countries, To and colleagues[53] screened 47,123 unselected women at 22 to 24 weeks' gestation with vaginal ultrasound to identify 470 with a shortened cervical length of 15 mm or less. Of these 470, 253 participated in a randomized trial whose primary outcome was the intergroup rates of delivery before 33 weeks' gestation. Women assigned to the cerclage group ($N = 127$) underwent a Shirodkar procedure. They had a similar rate of preterm birth as the control population ($N = 126$), 22% versus 26%; $P = .44$. The authors did not specifically comment on the proportion of women in the control group who were delivered in the midtrimester after a presentation consistent with clinically defined cervical insufficiency; however, they observed four stillbirths attributed to birth at 23 to 24 weeks and five neonatal deaths in deliveries at 23 to 26 weeks. In the cerclage group, the respective counts were three and four.

Berghella and colleagues[54] screened women with various risk factors for spontaneous preterm birth (prior preterm birth, curettages, cone biopsy, DES exposure) with vaginal scans every 2 weeks from 14 to 23 weeks' gestation and randomly assigned 61 with a cervical length less than 25 mm or funneling less than 25% to a McDonald cerclage or to a no-cerclage control group. Preterm birth before 35 weeks was observed in 45% of the cerclage group and 47% of the control group.

The trial by Althuisius and colleagues[50,51] focused on women whom they believed had a clinical diagnosis of cervical insufficiency and who would have likely been candidates for history-indicated cerclage in the United States. Nevertheless, their study does suggest a potential role for cervical ultrasound in women with a clinical diagnosis of cervical insufficiency, if the intent is to *avoid* cerclage when the cervical length is maintained at 25 mm or greater.

A meta-analysis[55] of the four randomized trials[51-54] described earlier, analyzed patient-level data to estimate whether certain subgroups of women with midtrimester cervical shortening might benefit from cerclage, where benefit was defined as a reduction in the relative risk of preterm birth before 35 weeks. They observed a marginal benefit from cerclage in women with singleton gestations and especially in those who had experienced a prior spontaneous preterm birth (relative risk 0.6, 95% CI 0.4-0.9). Paradoxically, they demonstrated a significant *detriment* in women with multiple gestations (relative risk 2.15, 95% CI 1.15-4.01). Although this harmful effect has never been confirmed in a randomized trial, authors of cohort studies have not observed this relationship.[48,49]

Based on an earlier review of the utility of vaginal ultrasound for the diagnosis of cervical insufficiency,[56] the fifth randomized trial was performed by a consortium of 15 U.S. centers[57] and included only women who had had at least one prior spontaneous preterm birth at 17 to 34 weeks' gestation. They were followed with serial vaginal scans beginning at 16 weeks' gestation. As long as the cervical length was at least 30 mm, scans were scheduled every 2 weeks, but the frequency was increased to weekly if the cervical length was 25 to 29 mm. Women who developed a short cervix <25 mm between 16 and 22⅐ weeks were assigned to McDonald cerclage or no cerclage. These investigators observed a statistically significant decrease in previable births <24 weeks (6% vs. 14%), perinatal mortality (9% vs. 16%), and birth <37 weeks (45% vs. 60%), but a nonsignificant decrease in the comparative rates of preterm birth <35 weeks (32% vs. 42%). The number of patients with short cervix needed to be treated with cerclage to prevent one previable birth was 13. Of note was the observation that cerclage benefit was closely linked to cervical status and women with cervical length <15 mm at randomization accrued a much greater benefit than those who were randomized with a cervical length of 15-24 mm. This suggested that shorter lengths are more likely to be associated with a primary cervical etiology and thus more amenable to mechanical support, although the "optimal" cervical length (e.g., <25 mm, <15 mm, etc.) for recommending cerclage could not be established. Similarly the finding of a U-shaped funnel (but not a V-shaped funnel) was also a significant additional risk factor for earlier birth, even considering cervical length; in these women the beneficial effect of cerclage for prolonging gestation was also pronounced. **The results of this trial confirmed the findings of the meta-analysis**[55]

described above and established the utility of screening and ultrasound-indicated cerclage in selected women based on their *obstetrical history*.

PATIENT SELECTION FOR CERCLAGE

Most of what is known about the management of the cervical insufficiency is based on case series that reported surgical correction of the presumed underlying mechanical defect in the cervical stroma. The contemporary mainstay of treatment has been a surgical approach using one of the classic cerclage procedures, although both medical treatments and other mechanical supportive therapies have been used. Like many aspects of clinical medicine, current therapeutic standards are often based more on expert opinion and results of studies using uncontrolled interventions than the findings of randomized clinical trials.[58] This is particularly true for cervical insufficiency in which, to date, there have been no published placebo-controlled randomized trials of cerclage in women with a typical clinical history.

Branch in 1986[61] and Cousins in 1980[62] collectively tabulated over 25 case series of cerclage efficacy published between 1959 and 1981. Branch[59] estimated a precerclage survival range of 10% to 32% versus a perinatal survival range of 75% to 83% in the same cohorts of women managed with Shirodkar cerclage. Similarly, case series that used McDonald cerclage reported a cohort perinatal survival range of 7% to 50% before and 63% to 89% after cerclage. Cousins[60] estimated a "mean" survival before Shirodkar of 22% versus 82% post-therapy and 27% and 74%, respectively, for investigators who used the McDonald technique. In total, more than 2000 patients have been reported in these historic cohort comparisons. Interpretation of these series, as noted by Cousins,[60] is limited by the facts that (1) diagnostic criteria were not consistent or always reported; (2) definitions of treatment success were inconsistent (but generally recorded as perinatal survival, as opposed to a gestational age-based end point); (3) treatment approaches were not always detailed and might involve multiple combinations of surgery, medication, bed rest, and other uncontrolled therapies; and (4) cases were not subcategorized according to etiology (e.g., anatomic defects vs. a presumed functional cause). Nevertheless, based on compelling but potentially biased efficacy data, the surgical management of women with clinically defined cervical insufficiency has become standard practice, and it is unlikely that a well-designed intervention trial for classic cervical insufficiency will ever be performed if it includes a placebo or no-treatment group. Although interpretation of efficacy based on historic control groups is always problematic, collectively these reports demonstrate that even women with typical histories may have successful pregnancies without cerclage and that cerclage as a treatment is not universally effective. Both of these observations support the multiple etiologies and interactive pathways characteristic of the spontaneous preterm birth syndrome.

Because of its unproven efficacy in randomized clinical trials, and the attendant surgical risks, the recommendation for prophylactic cerclage should be limited to women with recurrent spontaneous preterm birth syndrome, when a careful history and physical examination suggest a dominant cervical component. Unless the physical examination confirms a significant cervical anatomic defect, consistent with disruption of its circumferential integrity, the clinician should assess the history for other components of the preterm birth syndrome: cervical insufficiency remains a diagnosis of exclusion.

Women with cervical insufficiency often have some premonitory symptoms such as increased pelvic pressure, vaginal discharge, and urinary frequency. These symptoms, although neither specific for cervical insufficiency nor uncommon in a normal pregnancy, should not be immediately dismissed, particularly in women with risk factors for spontaneous preterm birth. Thus, the history of rapid, relatively painless labor should perhaps better characterize the diagnosis of cervical insufficiency.

Although a history of preterm labor is generally considered to exclude the diagnosis of insufficiency, patients may develop some clinically evident uterine activity once their cervix has spontaneously dilated (Ferguson's reflex) but generally have a rapid progress in labor.

Similarly, a history of midtrimester spontaneous membrane rupture alone can neither confirm nor refute the diagnosis of cervical insufficiency, because spontaneous membrane rupture may occur after some pathologic cervical ripening and dilation has exposed the membranes to the genital tract flora. After spontaneous membrane rupture occurs, chorioamnionitis, vaginal bleeding (placental abruption), or labor may ensue, and these events may obscure the underlying etiology. However, if midtrimester membrane rupture occurs in the setting of a closed cervix on physical examination, or if it is followed by a typical course of either spontaneous or induced labor, causes other than cervical insufficiency should be emphasized. Conversely, if physical examination after membrane rupture shows marked cervical softening, effacement, and dilation with no antecedent history of painful contractions, the diagnosis of cervical insufficiency is supported, particularly if followed by a rapid and relatively painless labor.

A legitimate clinical question arises over the optimal management of a patient who has experienced one spontaneous midtrimester birth, especially when causes other than cervical insufficiency have been excluded by history and physical examination. The observation of a second similar midtrimester birth increases the specificity of the diagnosis and also the likelihood that history-indicated cerclage would be an effective treatment in the next pregnancy. Clearly, if the index midtrimester birth was associated with an identifiable anatomic defect, interval repair or prophylactic cerclage should be encouraged in the next pregnancy. However, in contemporary obstetrical practice, such anatomic defects are increasingly uncommon.

A systematic review by Blickman and colleagues addressed this issue of whether ultrasound-indicated or history-indicated cerclage was associated with better pregnancy outcomes in women at risk for cervical insufficiency.[61] They performed a thorough literature search and identified six relevant studies with varying methodologies, including cohort, case-control, and randomized trial designs. In none of these six reports was either strategy favored for preventing preterm birth. In the ultrasound-indicated groups, cerclage was avoided in 40% to 68% of

women who underwent ultrasound surveillance. A more recent multicenter randomized trial of women with at least one prior spontaneous birth <34 weeks, demonstrated similar rates of preterm birth <34 weeks in the history (15%) and ultrasound (15%) groups[62]; however, in this trial fewer cerclage procedures were performed (19% vs. 32%) in the history-indicated group. Women were randomly assigned to the history or ultrasound arm prior to clinician's assessment of the history and the (clinical) diagnosis of insufficiency. While this trial confirmed the systematic review in that neither history nor ultrasound cerclage indication yields superior outcomes, the indications for cerclage in the history group were not thoroughly described (and reproducible), but rather left solely to clinician judgment. **Thus, although controlled clinical data are lacking, it seems reasonable to follow a patient with a history of suspected cervical insufficiency, using serial cervical ultrasound evaluations in the second trimester instead of empirically recommending cerclage (see box, Patient at Risk for Cervical Insufficiency: History-Indicated vs. Ultrasound-Indicated Cerclage).**

Patient at Risk for Cervical Insufficiency: History-Indicated vs. Ultrasound-Indicated Cerclage

- Preterm births will occur regardless of strategy chosen.
- Both strategies have similar rates of preterm birth.
- Fewer cerclages are performed with ultrasound-indicated cerclage strategy.
- It seems reasonable to follow patients at risk with sonography and perform cerclage based on sonographic findings.

ACUTE CERVICAL INSUFFICIENCY

Although the efficacy of cerclage for the treatment of a clinically defined history of cervical insufficiency remains unproven in controlled studies, women who present with acute cervical insufficiency, generally defined as a midtrimester cervical dilation of at least 2 cm, visible membranes, and no other predisposing cause (labor, infection, bleeding, ruptured membranes), are often considered for physical examination–indicated cerclage. Similar to case series proposing the presumed benefit of history-indicated cerclage, reports describing the outcome of women who present with acute cervical insufficiency generally have not always included a contemporary control group managed with bed rest or other intervention.

Aarts and colleagues[63] reviewed eight series published between 1980 and 1992 comprising 249 patients who received an emergent midtrimester cerclage and estimated a mean neonatal survival rate of 64% (reported range 22%-100%). Novy and colleagues[45] published 35 cases of insufficiency in evolution (cervical dilation 2-5 cm); the two cohorts included 19 women who received physical examination–indicated cerclage and 16 who were managed with bed rest. Neonatal survival was 80% in the cerclage cohort versus 75% in the bed rest group.

In a prospective, although uncontrolled, evaluation of cerclage versus bed rest (cerclage was utilized at the discretion of the attending physician), Olatunbosun and colleagues[64] studied women presenting with more advanced cervical dilation greater than 4 cm. The cerclage group comprised 22 women versus 15 in the bed-rest group. Although neonatal survival was not significantly different (17/22 with cerclage vs. 9/15 with bed rest, $P = .3$), gestational age at birth was a mean 4 weeks older in the cerclage group (33 vs. 29 weeks, $P = .001$). Rates of chorioamnionitis were similar between the two groups.

Although these reports are not of sufficient scientific quality on which to base firm management recommendations, collectively they demonstrate several important concepts. The earlier the gestational age at presentation and the more advanced the cervical dilation, the greater the risk of poor neonatal outcome. The finding of membrane prolapse into the vagina is also a significant risk factor for poor outcome.[65]

In a historical cohort study conducted by the Global Health Network for Perinatal and Reproductive Health, (women between 14 and 25⁄7 weeks gestation with cervical dilatation were identified.[66] Of 225 women, 152 received a physical examination–indicated cerclage, and 73 were managed expectantly. Patients with cervical dilatation of 4 cm or more were more likely to be managed expectantly. In this study patients managed with cerclage demonstrated longer interval from presentation to delivery, improved neonatal outcome, and fewer deliveries before 28 weeks compared to expectant management.

Althuisius and colleagues[67] published a randomized clinical trial of physical exam–indicated cerclage plus bed rest versus bed rest alone in 23 women who presented with cervical dilation and membranes prolapsing to or beyond the external os before 27 weeks' gestation. Both singleton and twin gestations were eligible; however, no information on the amount of cervical dilation was reported, and so it is not known whether the groups were comparable in this important aspect. They observed a longer mean interval from presentation to delivery (54 days vs. 20 days; $P = .046$) in the cerclage group. Neonatal survival was 9/16 with cerclage and 4/14 in the bed-rest group. Although the survival differences were not statistically significant, there was significantly lower neonatal composite morbidity (which included death) in the cerclage and bed-rest group (10/16 vs. 14/14 in the bed-rest alone group; $P = .02$).

Other reports show that women who present with acute cervical insufficiency have an appreciable (nominal 50%) incidence of bacterial colonization of their amniotic fluid or other markers of subclinical chorioamnionitis[68,69] or proteomic markers of inflammation or bleeding.[70] Women with abnormal amniotic fluid markers have a much shorter presentation-to-delivery interval, regardless of whether they receive a cerclage or are managed expectantly with bed rest.

Mays and colleagues[69] performed amniocentesis in 18 women who presented with this syndrome and analyzed the amniotic fluid for glucose, lactate dehydrogenase, Gram stain, and culture; abnormal results suggested subclinical infection. Of 11 women who underwent cerclage with no evidence of subclinical infection, the neonatal survival was 100% and the mean latent phase duration from presentation to delivery was 93 days. Of the 7 women with abnormal biochemistries in whom cerclage was withheld, no neonatal survivors were observed, and the mean latent phase was 4 days. Recognizing that at least a portion

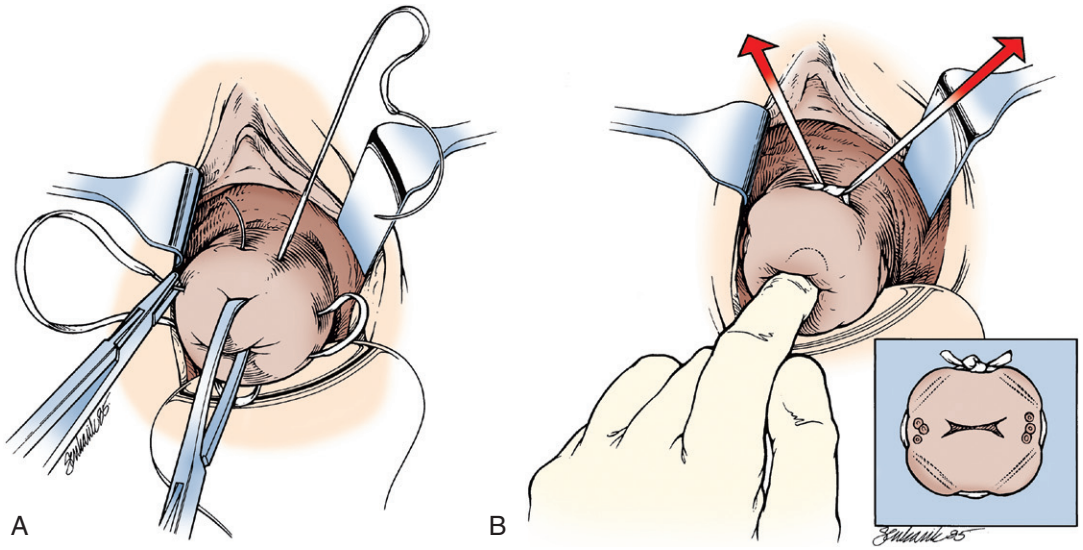

FIGURE 27-2. Placement of sutures for McDonald cerclage. *A,* We use a double-headed Mersilene band with four bites in the cervix, avoiding the vessels. *B,* The suture is placed high up in the cervix, close to the cervicovaginal junction, approximately at the level of the internal os.

of the 7 women who declined amniocentesis, but who received emergent cerclage, also had subclinical infection, it was predictable that the mean latent phase in this cohort was intermediate (17 days) as compared with the groups with amniotic fluid analyses. These investigators suggested that amniocentesis could aid in selecting candidates for emergent therapeutic cerclage. Interestingly, a sonographic marker of intrauterine subclinical infection has been reported (see Figure 27-1).[71]

In summary, the optimal management of women who present with cervical insufficiency in evolution remains indefinite. Although emergent cerclage may benefit some, patient selection remains largely empiric. Although not standard care, the evaluation of amniotic fluid makers of infection and inflammation appears to have important prognostic value, but it is still unclear whether and to what extent the results should direct patient management.

CERCLAGE TECHNIQUE

History-Indicated (a.k.a. Prophylactic) and Ultrasound-Indicated Cerclage

In 1950, Lash and Lash described repair of the cervix in the nonpregnant state involving partial excision of the cervix to remove the area of presumed weakness.[72] Unfortunately, this technique was associated with a high incidence of subsequent infertility. In 1955, Shirodkar reported successful management of cervical insufficiency with the use of a submucosal band.[73] Initially, he used cat gut as suture material, and later he used Mersilene placed at the level of the internal cervical os. The procedure required anterior displacement of the bladder in an attempt to place the suture as high as possible at the level of cervical internal os. This type of procedure resulted in a greater number of patients being delivered by cesarean delivery because of the difficulty in removing the suture buried under the cervical surface and may require leaving the suture in place postpartum. Several years later, McDonald described a suture technique in the form of a purse string, not requiring cervical dissection, which was easily placed during pregnancy.[74] This technique involves taking four or five bites as high as possible in the cervix, trying to avoid injury to the bladder or the rectum, with placement of a knot anteriorly to facilitate removal (Figure 27-2). Several types of suture material have been used.[75] We have been successful in using a Mersilene tape. However, the use of thinner suture material, such as Prolene or other synthetic nonabsorbable sutures like Ethibond, is advocated by others, with the argument that the width of the Mersilene tape places the patient at greater risk for infection.[75,76] Currently, there is no evidence that placing two sutures results in better outcomes than placing one.[77-79] Preoperative patient preparations, including the use of prophylactic antibiotics or tocolytics, have not been proven to be of benefit. We perform a culture for group B streptococcus and give preoperative penicillin to the patient with a positive culture, although the use of perioperative cultures prior to cerclage placement has not been evaluated in a proper way. History-indicated cerclage placement is performed after the first trimester, to avoid the risk of spontaneous loss most likely attributable to chromosomal abnormalities.[77,78] The choice of anesthesia for cerclage varies.[80] Chen et al.[81] did not show a difference in outcome between general versus regional anesthesia. In our experience, a short-acting regional anesthetic is sufficient. We advise patients to remain on bed rest for the first 48 hours after cerclage and to avoid intercourse until their follow-up postoperative visit. Decisions regarding physical activity and intercourse are individualized, and based on the status of the cervix as determined by outpatient digital evaluation or sonographic findings (Figure 27-3).[82] The suture is usually removed electively at 37 weeks. However, recent data suggest that removing the cerclage at the time of labor does not result in greater morbidity for the mother.[83] The mean interval between cerclage removal and spontaneous delivery is 14 days.[84]

In patients with a hypoplastic cervix, such as those exposed to DES in utero, history of a large cervical

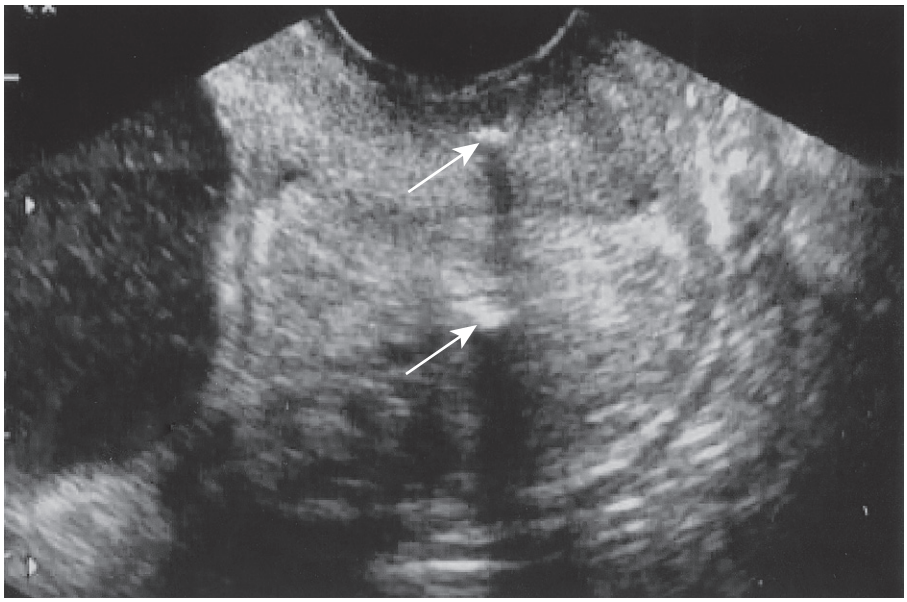

FIGURE 27-3. Transvaginal sonogram of the cervix after cerclage placement. The internal os is closed, and there is no funneling. Echogenic spots in the cervix correspond to cerclage *(arrows)*.

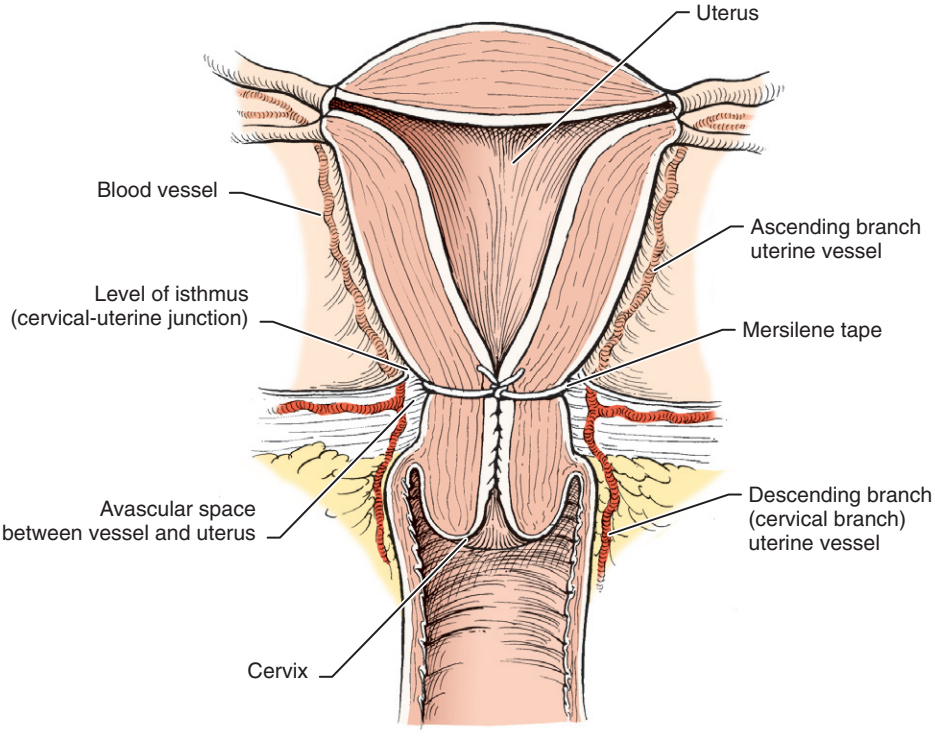

FIGURE 27-4. Abdominal cerclage. Surgical placement of circumferential Mersilene tape around uterine isthmus and median to uterine vessels. Knot is tied anteriorly.

conization, or a prior history of failed vaginal cerclage, an abdominal cerclage has been recommended.[85] This procedure is usually done between 11 and 13 weeks, and requires a laparotomy. A bladder flap is created, and a Mersilene tape is placed at the level of the junction between the lower uterine segment and the cervix, lateral to the uterus and medial to the uterine vessels (Figure 27-4). Greater morbidity, including injury to the uterine vessels, requires expertise with this procedure. In our experience with more than 60 cases, we have found it helpful to have an assistant provide fundal traction while the surgeon grasps the uterine vessels and retracts them laterally, exposing an avascular space between the artery and the cervix. A right angle clamp is passed anteriorly to posterior through this avascular space, tenting and incising the posterior leaf of the broad ligament and grasping a Mersilene tape that is brought back through the space. The same procedure is repeated on the opposite side, and the tape is tied anteriorly (Figures 27-5 to 27-8). Novy and colleagues[86] reported extensive experience with this procedure, with

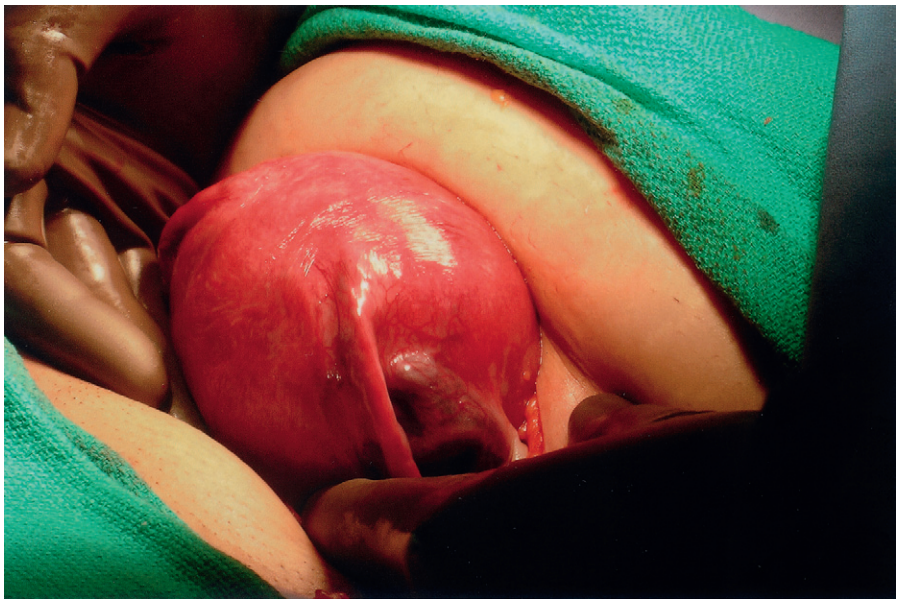

FIGURE 27-5. Abdominal cerclage at 12 weeks' gestation. Uterus is exteriorized.

FIGURE 27-6. Abdominal cerclage. Bladder flap has been created and surgeon identifies and palpates uterine vessel.

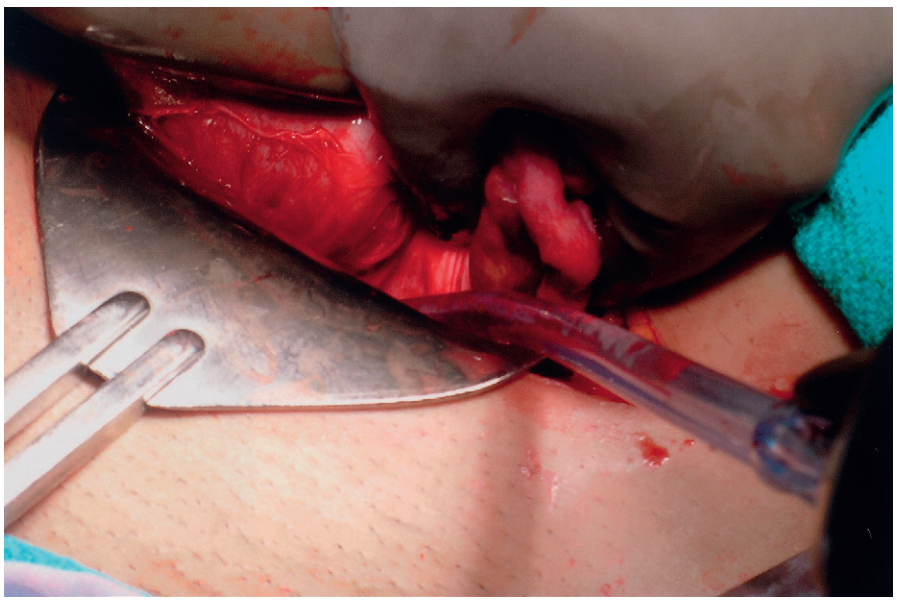

FIGURE 27-7. Abdominal cerclage. Surgeon retracts uterine vessel laterally to create an avascular space between uterus and vessel, before passing right angle clamp with Mersilene tape through this space.

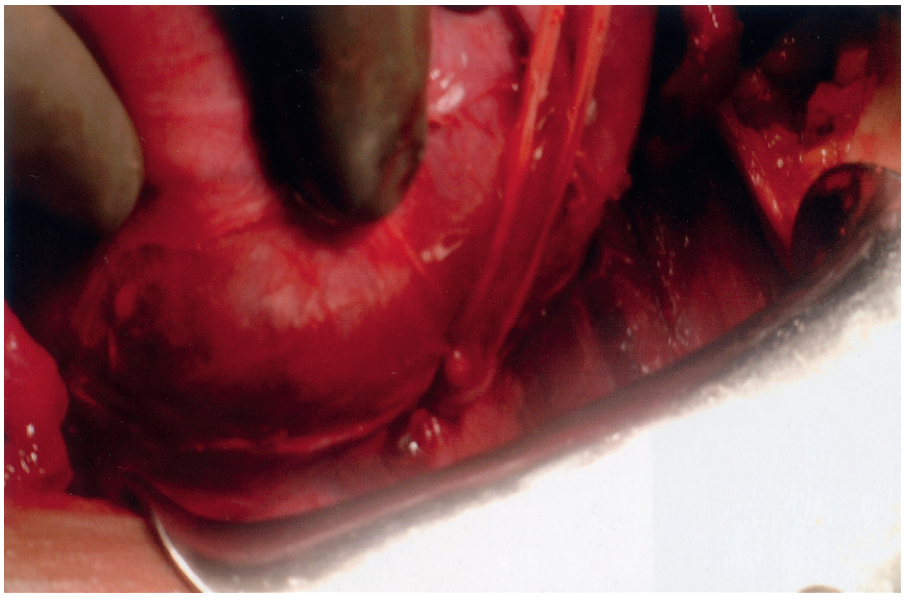

FIGURE 27-8. Abdominal cerclage. Mersilene tape has been placed circumferencially around uterine isthmus and tied anteriorly. Notice ballooning of the lower uterine segment above suture.

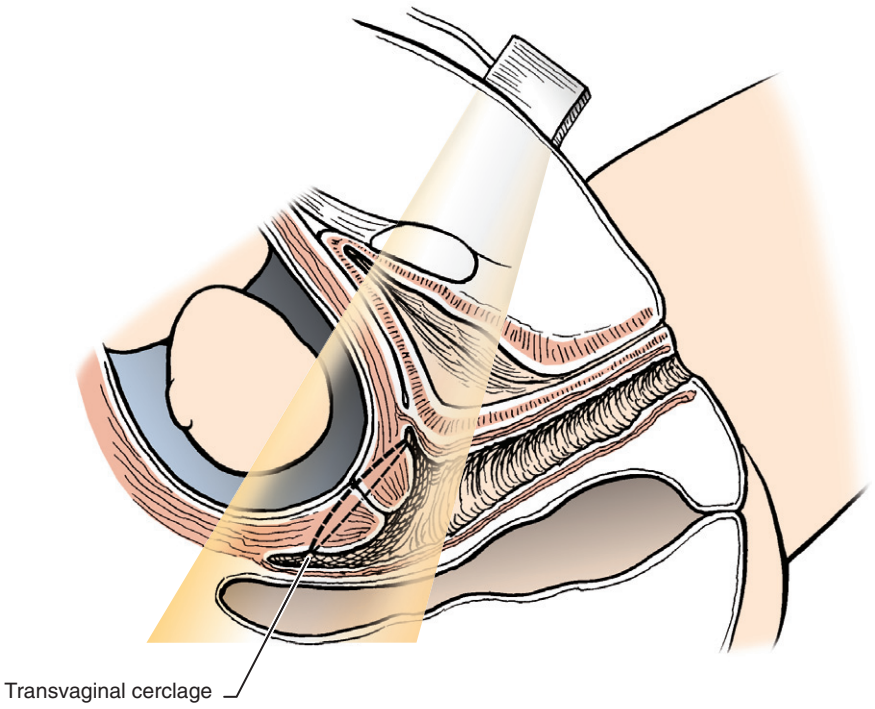

FIGURE 27-9. Transvaginal cerclage under ultrasound guidance. (Modified from Ludmir J, Jackson GM, Samuels P: Transvaginal cerclage under ultrasound guidance in cases of severe cervical hypoplasia. Obstet Gynecol 75:1067, 1991.)

low morbidity and favorable outcome. Cesarean delivery is necessary, and the suture is left in place if future fertility is desired. In cases of pregnancy complications requiring midtrimester delivery, we have either performed a posterior colpotomy, cutting the tape and allowing for vaginal delivery, or performed laparotomy and hysterotomy, leaving the suture intact. In most of the reported series of abdominal cerclage, including ours, this surgical procedure was performed during gestation.[86] However, recently Groom and colleagues[87] described this procedure as an interval cerclage in the nonpregnant state with subsequent good pregnancy outcome. Advantages of an interval procedure include avoidance of laparotomy in pregnancy and less bleeding morbidity. Disadvantages include inability to become pregnant and the difficulties of pregnancy management if the gestation results in a first-trimester miscarriage. Currently, there are no studies comparing interval versus abdominal cerclage during gestation that enable us to make specific recommendations about timing of the procedure.

To avoid an abdominal procedure in selected patients, we have described the placement of a transvaginal cerclage in cases of a hypoplastic cervix, or when the cervix is flush against the vaginal wall.[88] Under ultrasound guidance, the supravaginal portion of the cervix is dissected away from the bladder and a suture is placed either in a purse-string fashion, or in cross fashion from 12 to 6 o'clock and 3 to 9 o'clock (Figure 27-9). We have performed this procedure

in 22 patients, avoiding an abdominal procedure, with successful pregnancy outcome. Fifty percent of patients had a cesarean delivery, and the rest delivered vaginally after the suture was cut through a small posterior colpotomy incision. In the last few years, a laparoscopic abdominal approach to the cervix has been described using the same principles as an abdominal cerclage.[89,90] The procedure has been described primarily in nonpregnant women with subsequent good pregnancy outcome. Cho and colleagues[91] performed laparoscopic abdominal cerclage during pregnancy in 20 patients with minimal morbidity, and reported successful outcome in 19 of them. Recently, robotic-assisted laparoscopic placement of transabdominal cerclage during pregnancy has been described by Wolfe et al.[92] and we have started to use this technique in selected cases. Because of the lack of proper evaluation of these newer modalities of cerclage placement, recommendations based on evidence cannot be made. **There is a need for randomized trials evaluating these newer techniques in the nonpregnant and pregnant state, compared with a vaginal approach to determine the best approach to patients with a history of failed cerclage or extremely short cervix that prevents a vaginal approach.**

Physical Examination–Indicated (a.k.a. Emergent) Cerclage

Patients demonstrating cervical change either by digital evaluation or transvaginal sonography may benefit from a cerclage.[93-96] However, the gestational age limit for cerclage placement is ill defined. Although some clinicians offer this therapeutic modality up to 28 weeks,[97] we do not advocate the use of cerclage beyond 24 weeks' gestation, because of fetal viability concerns and the potential to cause a preterm delivery while placing the cerclage. Some of these patients have been managed successfully with strict bed rest.[98] If the decision is made to place a cerclage, we treat preoperatively with antibiotics and nonsteroidal anti-inflammatory agents, such as indomethacin, although the perioperative management of these patients has not been subject to rigorous study. The patient is placed on strict bed rest for the first 72 hours and is advised to refrain from intercourse and strenuous physical activity for the remainder of the pregnancy. We follow these patients with frequent sonographic assessment of the cervix and recommend strict bed rest if the membranes are prolapsing to the level of the suture.[99] Prophylactic tocolytics are not used after the procedure.

In situations in which the cervix has dilated enough to allow visualization of the membranes or the membranes have prolapsed into the vagina, placing a cerclage may be difficult, but should be considered.[97,99-103] These patients are at high risk of having a subclinical infection and subsequent poor outcome, as described previously.[100,104] To rule out infection, some clinicians advocate amniocentesis before cerclage placement.[69] Several techniques have been described to reduce the prolapsing membranes, including the following: placing the patient in Trendelenburg position; the use of a pediatric Foley catheter to tease the membranes into the endocervical canal; and instilling 1 L of saline into the bladder with upper displacement of the lower uterine segment (Figure 27-10).[102-105] The efficacy of antibiotics or tocolytics has not been properly studied, but most series advocate their use. Although clinicians have been reluctant to offer cerclage in patients with protruding membranes, some reports have suggested salvage rate in excess of 70% despite advanced cervical dilatation.[106-108]

Risks of Cerclage

Cervical lacerations at the time of delivery are one of the most common complications from a cerclage, occurring in 1% to 13% of patients.[77] Three percent of patients require cesarean delivery because of the inability of the cervix to dilate secondary to cervical scarring and dystocia.[77] Although the risk of infection is minimal with a prophylactic cerclage, the risk increases significantly in cases of advanced dilatation with exposure of membranes to the birth canal.[104] However, this infectious morbidity may be the result of subclinical chorioamnionitis. Cervical cerclage displacement occurs in a small number of patients. We have not performed revision of the cerclage during the index pregnancy, although small series have reported successful surgical treatment of a failed cerclage.[79] When the clinician is faced with premature rupture of membranes distant from term in a patient with cerclage, the decision to remove or leave the suture is controversial. Our own data suggest that with suture retention, there is an increased period of latency, at the expense of an increased risk for neonatal sepsis and mortality.[109] These data have been challenged by reports from Jenkins and colleages[110] suggesting an increased latency period (244 vs. 119 hours) without an increase in neonatal morbidity, in cases of retained cerclage, and by McElrath and colleagues,[111] who did not find differences in latency or neonatal outcome in patients when the suture was left in situ after rupture of the membranes. Decisions to remove the suture at the time of ruptured membranes should be individualized until more information becomes available. Finally, even though cerclage placement is considered a benign procedure, a maternal death secondary to sepsis in a patient with retained cerclage has been reported.[112] Because of associated risks, and questionable effectiveness, the liberal use of this surgical procedure is discouraged and the decision should be carefully balanced against potential harm, in particular for patients in whom the indications for cerclage are not clear.

Alternative Treatments to Cervical Cerclage

Nonsurgical interventions have been advocated for patients with presumed cervical insufficiency. The rationale for the recommendation for bed rest alone, or in conjunction with cerclage, relies in the theoretical concept of putting less pressure on the cervix while in the recumbent position. The validity of this concept has not been scientifically proven and to date there are no proper studies evaluating this intervention alone versus cerclage, in a randomized prospective fashion. The efficacy of pharmacologic agents such as indomethacin, progesterone, antibiotics, and others remains to be elucidated. The NICHD MFM Units Network reported their results, comparing weekly injections of 17-alpha hydroxyprogesterone caproate for the prevention of preterm birth in women with a history of prior spontaneous preterm delivery. Patients receiving the progestational agent had a 33% reduction in preterm birth

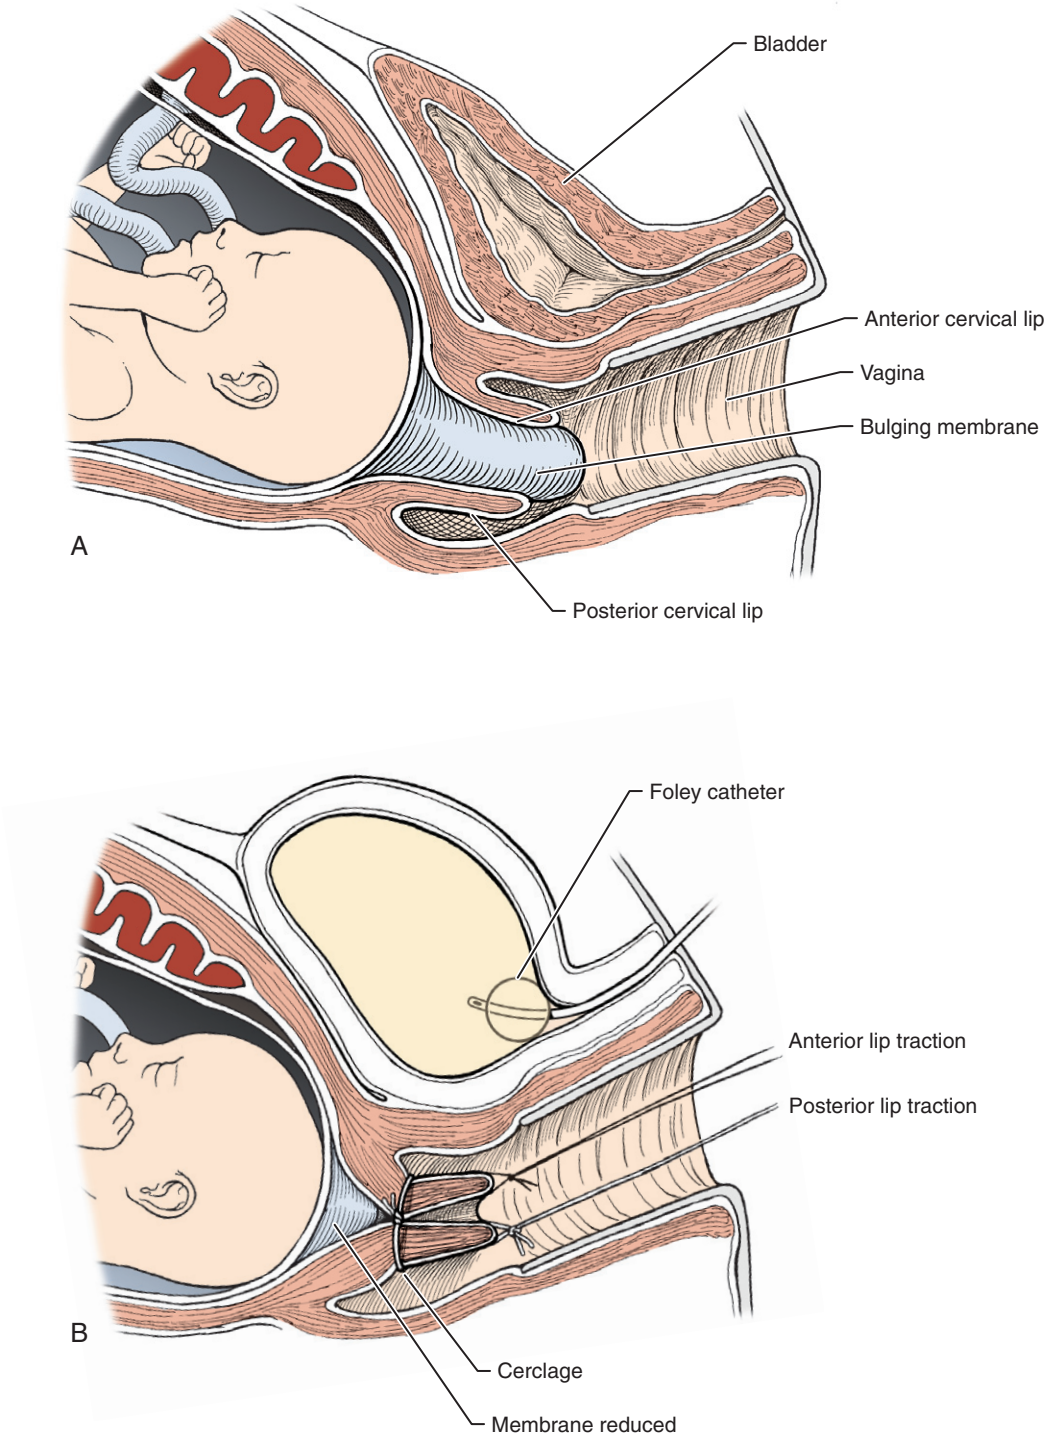

FIGURE 27-10. Emergent cerclage for bulging membranes at 23 weeks. **A,** Cervix dilated 3 cm with membranes protruding through the external cervical os into the vagina. **B,** Patient placed in Trendelenburg position, and bladder filled with saline. Stay silk sutures placed on anterior and posterior lip for traction while reducing membranes. McDonald cerclage placed distal to reduced membranes.

compared with those receiving placebo.[113] Vaginal progesterone has been associated with a reduction of preterm birth in women with a very short cervical length.[114] At this time, it is unclear how this information may be applied to patients with a clinical history of cervical insufficiency, with or without the concurrent use of cerclage, and further investigation is necessary. The authors of a recent investigation concluded that 17-alpha-hydroxyprogesterone may not confer additional benefit to ultrasound-indicated cerclage in women with prior spontaneous preterm birth.[115]

Since the description by Vitsky in 1961 of the use of a vaginal pessary instead of cerclage for patients with cervical insufficiency,[116] several studies, mainly in Europe, suggest the same outcome for patients managed with this noninvasive modality compared with a surgical intervention.[117] Recently Arabin et al.[118] studied the use of a vaginal

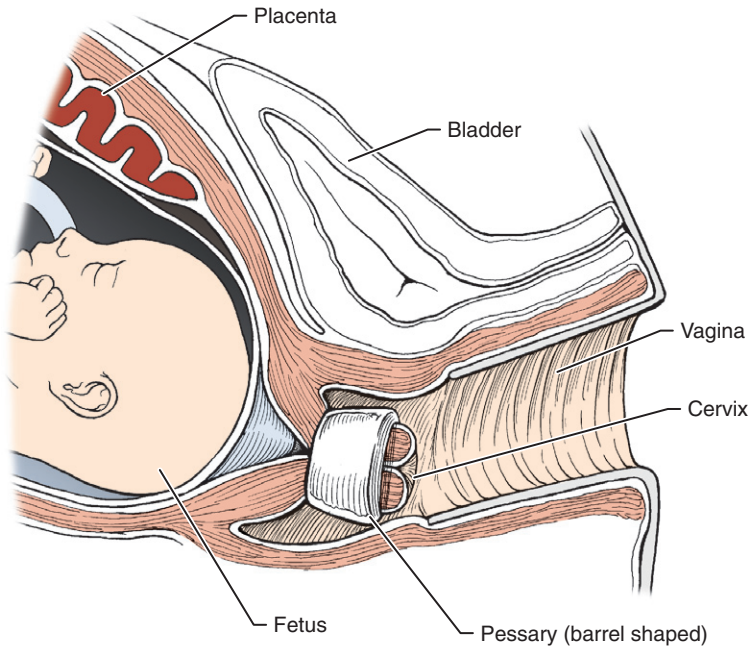

FIGURE 27-11. Vaginal pessary (Arabin type) placed at 22 weeks in patient with cervical length of 2.2 cm, funneling, and prior history of preterm delivery at 26 weeks.

pessary in patients with a sonographically detected short cervix (Figure 27-11). Patients managed with a pessary gained 99 days compared to 67 days for patients managed with bed rest alone ($P = .02$). We have reported our initial experience[119] using the same type of vaginal pessary studied by Arabin in patients with sonographic cervical shortening and a prior history of preterm delivery. When compared with bed rest alone, patients with pessaries gained significantly greater gestational age (10.0 ± 41 weeks vs. 5.1 ± 3.6 weeks; $P = .03$). Currently there are four ongoing randomized studies of pessaries in singleton and multiple gestations with short cervical length being conducted in Europe (www.clinicaltrials.gov). We are waiting for the results of these trials, and further prospective, randomized trials comparing pessary, cerclage, and bed rest are needed before conclusions regarding the efficacy of any of these interventions can be established.

SUMMARY

Cervical insufficiency is rarely a distinct and well-defined clinical entity but only one part of a larger and more complex spontaneous preterm birth syndrome. The original paradigm of obstetrical and gynecologic trauma as a common antecedent of cervical insufficiency has been replaced by the recognition of functional, as opposed to anatomic, deficits as the more prevalent origin. Cervical competence functions along a continuum, influenced by both endogenous and exogenous factors that interact through various pathways with other recognized components of the preterm birth syndrome: uterine contractions and decidual/membrane activation. Thus, the clinically convenient term, *cervical insufficiency*, may actually represent an oversimplified, incomplete version of the broader, though poorly understood, pathophysiologic process. Consequently, the continued use of traditional therapies, unsubstantiated by results of clinical trials, must be questioned. Effective, evidence-based management guidelines will stem from a more complete understanding of the preterm birth syndrome. This will improve patient selection and permit specifically tailored treatment regimens, confirmed by the results of well-designed intervention trials.

***Cervical insufficiency* remains primarily a clinical diagnosis, although cervical ultrasound has emerged as a proven, clinically useful screening and diagnostic tool in selected populations of high-risk women based on an obstetrical history of a prior (early) spontaneous preterm birth. Women with this history who then develop shortened midtrimester cervical length appear to have a treatable *component* of cervical insufficiency.** Surgical intervention in the form of prophylactic cerclage, sonographically indicated cerclage, emergent cerclage, and abdominal/laparoscopic cerclage may be reasonable in carefully selected patients. Alternative or adjunctive interventions such as bed rest and a vaginal pessary require further investigation.

KEY POINTS

- Cervical insufficiency is primarily a clinical diagnosis characterized by recurrent painless dilatation and spontaneous midtrimester loss.
- Cervical insufficiency is rarely a distinct and well-defined clinical entity, but only one component of the larger and more complex spontaneous preterm birth syndrome.
- Current evidence suggests that cervical competence functions along a continuum, influenced by both endogenous and exogenous factors, such as uterine contractions and decidual/membrane actuation.
- The traditional nomenclature of cerclage type as prophylactic, therapeutic, and emergent should

be replaced by history-indicated, ultrasound-indicated, and physical examination–indicated cerclage.

- There is no objective preconception diagnostic test for cervical insufficiency.
- History-indicated cerclage for patients with clinical history of cervical insufficiency remains a reasonable approach.
- Cervical ultrasound performs poorly as a screening test in low-risk women, but it has been proven to be a clinically useful screening and diagnostic tool in selected high-risk populations who may have a treatable *component* of cervical insufficiency.
- In women with nonclassic clinical histories of cervical insufficiency, serial sonographic evaluations of the cervix may be an acceptable alternative approach to prophylactic cerclage.
- Physical examination–indicated cerclage may be beneficial in reducing preterm birth in a subgroup of patients without markers of infection.
- Abdominal cerclage may be considered for those patients with history of failed vaginal cerclage, or for those patients with an extremely short cervix in whom a vaginal approach is not feasible.
- There is a need for randomized studies to evaluate alternative treatments for cervical insufficiency such as bed rest, pharmacologic therapy, and vaginal pessary.

The average duration of normal human pregnancy is 267 days after conception, or 280 days (40 weeks) from the first day of the last normal menstrual period. Infants born at 39 and 40 weeks of gestation have the lowest rates of adverse outcomes. **Complications related to preterm birth account for more newborn and infant deaths than any other cause.**[1] **Although advances in neonatal care have led to increased**

survival and reduced short- and long-term morbidity for infants born preterm, surviving infants have increased risk of visual and hearing impairment, chronic lung disease, cerebral palsy, and delayed development in childhood. The causes of preterm birth are diverse, but can be usefully considered according to whether or not the parturitional process (cervical preparation, decidual-membrane activation, and/or myometrial contractions) had begun before birth occurred. Preterm births that do not follow spontaneous initiation of parturition most often are iatrogenic, when the health of the mother and/or fetus is at risk (e.g., due to major hemorrhage, hypertension, or poor fetal growth).

DEFINITIONS

A *preterm birth* is commonly defined as one that occurs after 20 weeks' gestation and before the completion of 37 menstrual weeks of gestation, regardless of birth weight. Low birth weight is defined by the size of the infant at birth, regardless of gestational age. Gestational age and birth weight are related by the terms *small for gestational age* (birth weight less than the 10th percentile for gestational age), *appropriate for gestational age* (birth weight between the 10th and 90th percentiles), *and large for gestational age* (birth weight above the 90th percentile). A **preterm** or **premature** infant is one born before 37 weeks of gestation (259 days from the first day of the mother's last normal menstrual period, or 245 days after conception). **Low birth weight** (LBW) is defined as birth weight below 2500 g, **very low birth weight** (VLBW) as birth weight below 1500 g, and **extremely low birth weight** (ELBW) as birth weight below 1000 g. The gestational boundaries of 20 and 37 weeks are historical, not scientific.[2] Infants born at 36, 37, and even 38 weeks of gestation may experience neonatal and even lifetime morbidity related to immaturity of one or more organs. The risk factors, etiologies, and recurrence risk for spontaneous births at 16 to 19 weeks do not differ from those of births at 20 to 25 weeks.[3,4] **Recognition that some infants born after 37 weeks are not fully mature, and that many births before 20 weeks arise from the same causes that lead to preterm births, has led to reevaluation of these definitions and boundaries.**[5]

FREQUENCY OF PRETERM AND LOW BIRTH WEIGHT DELIVERY

The World Health Organization has estimated **that 9.6% of all births in 2005 were preterm—almost 13 million worldwide.** Africa and Asia accounted for almost 11 million.[6] Rates are lowest in Europe (6.2%), compared to the highest rates seen in Africa (11.9%) and North America (10.6%). In the United States, the preterm birth rate rose from 10.6% in 1990 to 12.8% of all births in 2006. The rise resulted from improved pregnancy dating by ultrasound that shifted the gestational age distribution to the left, increased use of assisted reproduction techniques, and, most important, from increased willingness to choose delivery when medical or obstetrical complications occur after 34 weeks' gestation. The rate of preterm birth fell to 12.7% in 2007, 12.3% in 2008, and 12.1% in 2009 (Figure 28-1).[7] The decline has been attributed to improved fertility practices that reduce the risk of higher-order multiple gestation, to quality improvement programs that limited scheduled late preterm and near-term births to only those with valid indications, and to increased use of strategies to prevent recurrent preterm birth.

National vital statistics reports web release, vol 59, no 3, Hyattsville, MD, National Center for Health Statistics, 2010.)

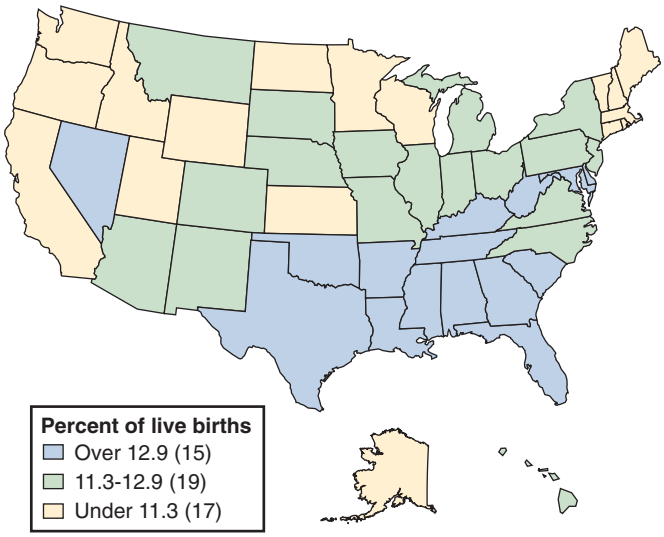

FIGURE 28-2. Percentage of live preterm births in the United States by state. (© 2011 March of Dimes Foundation. All rights reserved.)

The rates of preterm birth vary substantially across the United States (Figure 28-2). Reasons for the geographic variation are complex but are heavily influenced by the percentage of the population that is African American. **African Americans have rates of preterm birth that are almost twofold higher than other racial/ethnic groups.** The disparity is particularly striking for births less than 32 weeks' gestation (Figure 28-3).

Outcomes for Infants Born Preterm

Gestational age at birth is strongly correlated with adverse pregnancy outcomes, including stillbirth (fetal death after 20 weeks' gestation), neonatal (less than 28 days after birth) and infant (less than 12 months after birth) death, and long-term physical and intellectual morbidities.

PERINATAL MORTALITY

Perinatal mortality is defined as the sum of stillbirths after 20 weeks' gestation + neonatal deaths through 28 days of

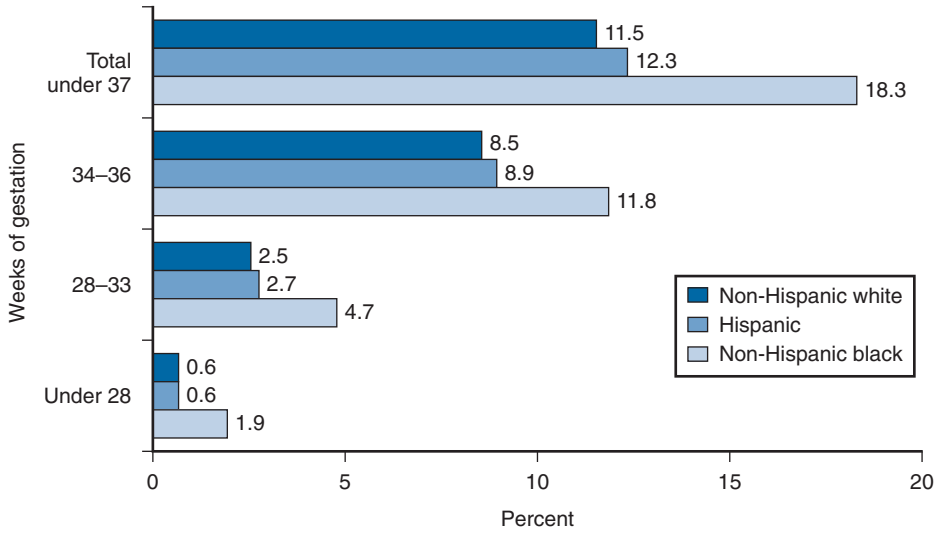

FIGURE 28-3. Percentage of live preterm births by racial group. (Data from Martin JA, Hamilton BE, et al: Births: final data for 2007. Natl Vital Stat Rep 58:1, 2010.)

life per 1000 total births (live-born + stillborn). Perinatal mortality increases markedly as gestational age and birth weight decline. Because this measure encompasses prenatal, intrapartum, and neonatal events, it reflects obstetrical and neonatal care. Stillbirth and preterm birth have a similar epidemiological profile, especially before 32 weeks. Rates of perinatal mortality declined between 1990 and 2003, mainly due to a decrease in fetal deaths after 27 weeks' gestation.[8]

Infant Mortality

The infant mortality rate is the number of deaths among live-born infants before 1 year of age per 1000 *live* births. Although congenital malformations are often listed as the leading cause of infant mortality, this ranking is achieved by separating conditions related to preterm birth into several categories. The proportion of all infant deaths in the United States in 2005 by gestational age at birth is shown in Figure 28-4.

Infant and childhood mortality and morbidity in surviving preterm infants rise as gestational age at birth declines, and vary with the level of neonatal care received. Of the estimated 8.8 million deaths in children younger than 5 years worldwide in 2008, 41% (3.6 million) occurred in neonates, and more than 1 million (12%) were attributed to preterm birth complications.

Regionalized care for high-risk mothers and preterm LBW infants, antenatal administration of corticosteroids, neonatal administration of exogenous pulmonary surfactant, and improved ventilator technology have improved outcomes for very preterm infants. Survival rates rise with gestational age at birth, from 6% for infants born at 22 weeks' gestation to more than 90% at 28 weeks' gestation for infants cared for in tertiary intensive care units.[9] Outcomes can be more accurately predicted by considering fetal number (singleton or multiple), gender, exposure or nonexposure to antenatal corticosteroids, and birth weight, in addition to gestational age.[9] Long-term survival rates by gestational age at birth in 903,402 infants born in Norway[10] are shown in Figure 28-5.

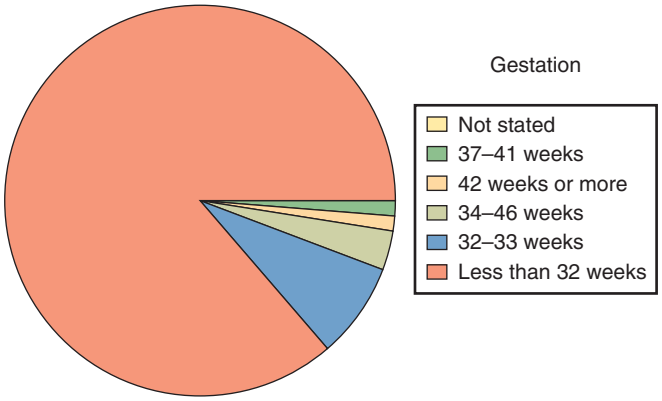

FIGURE 28-4. Proportion of all infant deaths in the United States in 2005 by gestational age at birth. (Modified from Centers for Disease Control and Prevention. National Center for Health Statistics. VitalStats. Available at www.cdc.gov/nchs/vitalstats.htm.)

Perinatal Morbidity

Preterm infants are at risk for specific diseases related to immaturity of various organ systems as well as to the cause and circumstances of preterm birth. **Common complications in premature infants include respiratory distress syndrome (RDS), intraventricular hemorrhage (IVH), bronchopulmonary dysplasia (BPD), patent ductus arteriosus (PDA), necrotizing enterocolitis (NEC), sepsis, apnea, and retinopathy of prematurity (ROP). Rates of morbidity also vary primarily by gestational age, but are also affected by birth weight, fetal number (singleton vs. multifetal), geographic location, proximity to neonatal intensive care, and the maternal and/or fetal condition(s) that led to preterm birth.** The frequency of major morbidity rises as gestational age decreases, especially below 30 weeks' gestation. There is wide geographic variation in the frequency of neonatal morbidities especially for VLBW infants. Reports of survival and morbidity also vary according to the denominator employed. Obstetrical datasets include all living fetuses at entry to the obstetrical suite, whereas neonatal datasets exclude intrapartum and delivery room deaths and thus report rates based on newborns admitted to the nursery. Rates of survival and morbidity at the same gestational age and/or birth weight are thus somewhat higher in neonatal datasets.

Long-term Outcomes

Major neonatal morbidities related to preterm birth that carry lifetime consequences include chronic lung disease, grades III and IV IVH (associated with cerebral palsy), NEC, and vision and hearing impairment. Follow-up studies of infants born preterm and LBW infants reveal increased rates of cerebral palsy, neurosensory impairment, reduced cognition and motor performance, academic difficulties, and attention-deficit disorders.

The incidence of long-term morbidity in survivors is especially increased for those born before 26 weeks. In a study from the United Kingdom, 78% of 308 survivors born before 25 weeks were followed and compared to classmates of normal birth weight. Almost all had some disability at age 6: 22% had severe neurocognitive disabilities (cerebral palsy, IQ greater than 3 SD below mean, blind, or deaf), 24% had moderate disability, 34% had mild disability, and 20% had no neurocognitive disability.

EPIDEMIOLOGY OF PRETERM BIRTH

The numerous maternal and fetal diagnoses that precede preterm birth may be considered according to whether parturition began spontaneously or not. **Spontaneous preterm parturition may first manifest as cervical softening and ripening, decidual activation, and/or uterine contractions. Cervical softening is the most common initial evidence that parturition has begun.** In women who later delivered spontaneously between 28 and 36 weeks' gestation, cervical length measurements at 22 to 24 weeks' gestation were significantly shorter than in women who delivered at term, indicating that cervical softening had begun before 24 weeks.[11] This same study found that more than half of women with evidence of very preterm cervical effacement delivered after 35 weeks, indicating that spontaneous preterm parturition does not always progress to preterm birth. Women with signs and symptoms of spontaneous preterm parturition often have one or more of the demographic characteristics shown in the accompanying box, Demographic Profile of Women with Spontaneous Preterm Birth, but it is important to note that approximately half of women who deliver preterm have no obvious risk factors. Among 2521 women who received prenatal care at 10 collaborating university clinics, 323 (12.8%) delivered before 37 weeks. Of these, 234 (9.3% of the total and 72% of those preterm) were born after spontaneous initiation of parturition and 89 (3.5% of the total and 27% of those preterm) were born preterm as the result of medical/obstetrical indication.[11]

Demographic Profile of Women with Spontaneous Preterm Birth

- History of genital tract colonization, infection, or instrumentation
  - Urinary tract infection and bacteriuria
  - Sexually transmitted infections such as *Chlamydia,* gonorrhea, human papillomavirus, or *Trichomonas*
  - Bacterial vaginosis
  - Cervical dysplasia and treatment for same
  - Spontaneous or induced abortion
- African American
- Bleeding of uncertain origin in pregnancy
- History of a previous spontaneous preterm birth
- Uterine anomaly
- Assisted fertility care
- Multifetal gestation
- Cigarette smoking, substance abuse
- Poor nutrition and low prepregnancy weight (body mass index <19.6)
- Periodontal disease
- Limited education, low income, and low social status
- Late registration for prenatal care
- High levels of personal stress in one or more domains of life

Women whose preterm birth is not preceded by spontaneous parturition have medical and/or obstetrical conditions that lead to the onset of parturition or to iatrogenic intervention to benefit the mother or fetus. Their demography reflects this (see box, Demographic and Medical Profile of Women with Indicated Preterm Birth) and efforts to prolong pregnancy are primarily aimed at optimal management of their medical condition. This strategy is more successful in some, for example, in diabetes, in which maintenance of euglycemia often leads to birth at term, than in others, for example, chronic hypertension, where good blood pressure control does not prevent preeclampsia.

CLINICAL RISK FACTORS FOR SPONTANEOUS PRETERM BIRTH

Risk factors for spontaneous preterm birth arise from host factors, prior pregnancy history, and current pregnancy risks.

Demographic and Medical Profile of Women with Indicated Preterm Birth

- Diabetes, diagnosed before or during pregnancy
- Chronic or acute (preeclampsia) hypertension
- Obstetrical disorders or risk conditions in the current or previous pregnancy
  - Preeclampsia
  - Previous uterine surgery (e.g., prior cesarean birth via a vertical or T-shaped uterine incision)
  - Cholestasis
  - Placental disorders
    - Placenta previa
    - Premature separation (abruption) of the placenta
- Medical disorders
  - Seizures
  - Thromboembolism
  - Connective tissue disorders
  - Asthma and chronic bronchitis
  - Maternal HIV or HSV
  - Obesity
  - Smoking
- Advanced maternal age
- Fetal disorders
  - Fetal compromise
    - Chronic—poor fetal growth
    - Acute—fetal distress, for example, abnormal fetal testing (NST or BPP)
  - Excessive (polyhydramnios) or inadequate (oligohydramnios) amniotic fluid
  - Fetal hydrops, ascites, blood group alloimmunization
  - Birth defects
  - Fetal complications of multifetal gestation (e.g., growth deficiency, twin-to-twin transfusion syndrome)

Host Factors

Medical

Infections

Systemic and genital tract infections are associated with preterm birth. In women in spontaneous preterm labor and intact membranes, lower genital tract flora are commonly found in the amniotic fluid, placenta, and membranes. The flora include *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Fusobacterium species*, *Gardnerella vaginalis*, peptostreptococci, and bacteroides species. Clinical evidence and histologic evidence of infection are more common as the gestational age at delivery decreases, especially before 30 to 32 weeks. Positive cultures of fetal membranes have been reported in 20% to 60% of women with preterm labor before 34 weeks' gestation. The frequency of positive cultures increases as gestational age decreases, from 20% to 30% after 30 weeks to 60% at 23 to 24 weeks' gestation. Evidence of infection is less common after 34 weeks.

BV is a condition in which the ecosystem of the vagina is altered so that gram-negative anaerobic bacteria (e.g., *Gardnerella vaginalis*, *Bacteroides*, *Prevotella*, *Mobiluncus*, and *Mycoplasma species*) largely replace the normally predominant lactobacilli. BV is associated with a twofold increased risk of spontaneous preterm birth. The association between BV and preterm birth is stronger when BV is detected early in pregnancy. Despite the association, antibiotic eradication of BV does not consistently reduce the risk of preterm birth. Infections outside the genital tract have also been related to preterm birth, most commonly to urinary tract and intra-abdominal infections, for example, pyelonephritis and appendicitis. The presumed mechanism of disease is inflammation of the nearby reproductive organs, but infections at remote sites, especially if they are chronic, have also been associated with increased risk of spontaneous preterm birth.

Periodontal Disease

Women with periodontal disease have an increased risk of preterm birth that is not reduced by periodontal care, suggesting shared susceptibility rather than a cause-effect relation. The genitourinary and alimentary tracts are both major sites of microbial colonization where host immune factors defend the interior of the body, so shared risk factors are not surprising.

Genitourinary Tract Factors

Cervical Length

Cervical length as measured by transvaginal ultrasound is inversely related to the risk of preterm birth in both singletons and twins. Women whose cervical length at 22 to 24 weeks' gestation was at or below the 10th percentile (25 mm by endovaginal ultrasound) had a 6.5-fold increased risk (95% CI, 4.5 to 9.3) of preterm birth before 35 weeks' gestation and a 7.7-fold increased risk (95% CI, 4.5 to 13.4) of preterm birth before 32 weeks' gestation when compared with women whose cervical length measurement was greater than the 75th percentile.[12] The explanation for the linkage between cervical length and preterm birth risk was once thought to reflect a "continuum of cervical competence" in which variable cervical resistance to uterine contractions explained the relationship. However, there is now substantial evidence that contractions do not herald the onset of preterm birth,[13] and that progesterone supplementation slows the progression of cervical shortening and reduces the risk of preterm birth when initiated before 24 weeks in women with and without a prior preterm birth.[14-18] These studies support the conclusion that preterm cervical shortening (softening and ripening) is not the passive result of tissue weakness, but instead is an active process indicating that pathologic preterm parturition has begun, regardless of its underlying cause.[11]

Cervical Procedures

A history of cervical surgery including conization and Loop electrosurgical excision procedure (LEEP) is a risk factor for preterm birth, whether by uterine colonization or cervical injury.

Congenital Abnormalities of the Uterus

Congenital structural abnormalities of the uterus, known as müllerian fusion defects, may affect the cervix, the uterine corpus, or both. The risk of preterm births in women with uterine malformations is 25% to 50% depending on the specific malformation and obstetrical history. Implantation of the placenta on a uterine septum may lead to preterm birth by means of placental separation and hemorrhage. A T-shaped uterus in women exposed in utero to diethylstilbestrol has also been associated with an increased risk of preterm labor and birth.

Behavioral

In general, studies of behavioral influences on preterm birth have, with the exception of tobacco smoking, not found a consistent relationship between maternal activities and preterm birth.

Smoking and Substance Abuse

Smoking is associated with an increased risk of preterm birth, and unlike most other risks is amenable to intervention during pregnancy.

Physical Activity

Controversy exists as to whether excessive physical activity is associated with early delivery.

Nutritional Factors

Low maternal prepregnancy weight (BMI <19.8 kg/m^2) has been regularly found to be associated with an increased risk of preterm birth.[19,20] Women who consume one or more servings of fish per month have lower rates of preterm birth than women who rarely or never eat fish.[21] Numerous studies of various nutritional deficiencies have been reported to be related to risk of preterm birth, but there are few if any for which supplementation has been found to reduce the incidence of prematurity.

Demography, Stress, and Social Determinants of Health

Social disadvantage is persistently associated with increased risk of preterm birth: poverty; educational attainment; geographic residence in disadvantaged neighborhoods, states, and regions; and lack of access to prenatal care are all linked to significantly higher rates of preterm birth.[22] These associations were once deemed to be social, not medical, and thus beyond the reach of medical care. The effect of the social environment on reproduction has since been examined in greater detail, revealing evidence of a causative relationship. The magnitude of the increased risk of preterm birth according to educational level is shown in Table 28-1. There is a nearly twofold difference in the rate of preterm birth for women of all racial and ethnic groups between those with the highest and lowest levels of education (Table 28-2).

Equally striking is the persistence of the disparity in rates of preterm birth in African American women regardless of their educational level, and in Table 28-2, their access to early prenatal care.

African Americans

African American women have a uniquely increased risk for preterm birth when compared to women from any other racial or ethnic background.[23] The rate of preterm birth averaged 18.4% among African American women, compared to 10.8% in Asian Americans, 11.6% in white, 12.6% in Hispanic, and 14.2% in Native American women in 2005-2007. The disparity in preterm birth rate persists after social and medical risk factors are accounted for[22,24,25] and is evident in African American but not African women. The origins of the disparity are not well understood. Regardless of the etiology, all African American women may be considered to have increased risk of preterm birth even in the absence of other risk factors.

Stress[26] and depression[27] are consistently reported to have moderate association with preterm birth, though the mechanisms again remain uncertain.

Genetic Contributors to Preterm Birth

The notion that there may be some genetic contribution to preterm birth is based on several observations. First, a woman's family history of preterm birth influences her own risk. Porter and colleagues found that a mother who was herself born preterm had an inceased risk for delivering a child preterm; the magnitude of that increased risk was inversely related to the gestational age of her own

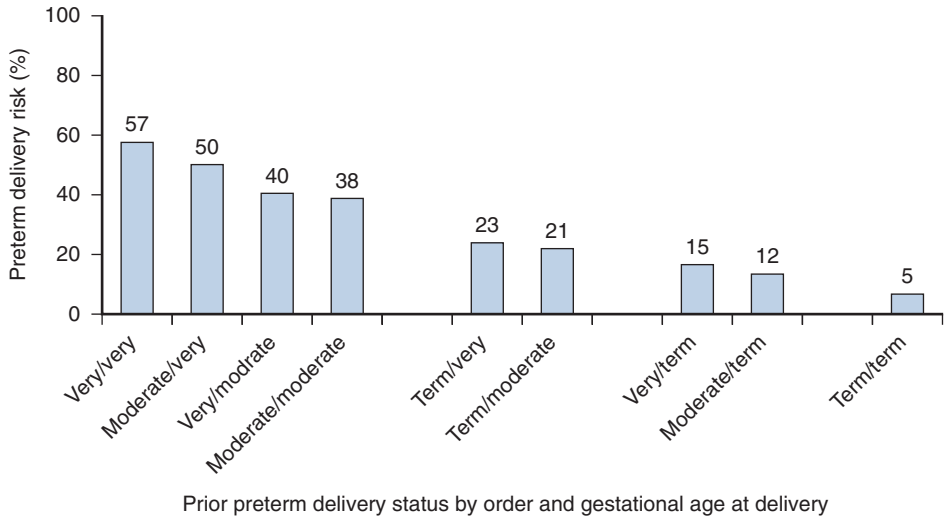

FIGURE 28-6. Risk of recurrent preterm birth in 19,025 women with two prior births according to the order and gestational age of the previous birth. (Modified from McManemy J, Cooke E, et al: Recurrence risk for preterm delivery. Am J Obstet Gynecol 196:576e1, discussion 576e6, 2007.)

birth. The odds ratio for preterm birth was 1.18 (95% CI, 1.02 to 1.37) for women who were born at 36 weeks of gestation to 2.38 (95% CI, 1.37 to 4.16) for women who were born at 30 weeks of gestation. A second set of observations supporting a genetic contribution to preterm birth are from twin studies. Treloar and colleagues[28] studied 905 female Australian twin pairs to determine whether delivery had occurred more than 2 weeks preterm. In this study, "all-cause" preterm birth was the outcome.[28,29] Twin pair correlations were higher from monozygotic twin pairs than dizygotic twin pairs ($r = 0.3 \pm 0.08$ vs. 0.03 ± 0.11 SE, respectively). Heritability was calculated at 17% for preterm delivery in the first pregnancy and 27% for preterm delivery in any pregnancy. A Scandinavian population-based twin study observed 868 monozygotic and 1141 dizygotic female twin pairs that delivered single births between 1973 and 1993.[28,29] Correlation for gestational length was higher for monozygotic compared with dizygotic twins, and heritability estimates from model fitting were approximately 30% for gestational age and 36% for preterm birth. The pattern of preterm births that occur in family pedigrees suggests the dominant form of inheritance is non-Mendelian; rather, the observed pedigrees are more consistent with the influence of many genes. There are numerous studies aimed at discovering variation in genes that contribute to preterm birth, with many associations failing to replicate across populations. **Insights into the complex genetics of preterm birth holds promise for giving insight into pathophysiology and, potentially, to risk-identification; at present, neither of these potential benefits influences clinical care.**

Past Pregnancy History

The strongest historical risk factor is a previous birth between 16 and 36 weeks' gestation. This history is often reported to confer a 1.5-fold to twofold increased risk, but varies widely according to the number, sequence, and gestational age of prior preterm births (Figure 28-6).

When the prior preterm birth occurred in a twin pregnancy, the risk of preterm birth in a subsequent singleton gestation rises as the gestational age at delivery of the twins falls below 34 weeks' gestation. There is minimal if any increased risk for women whose prior twin birth occurred after 34 weeks' gestation, but the risk of singleton preterm birth may be as much as 40% when the prior twin birth occurred before 30 weeks.

Prior stillbirth[30] and pregnancies ending between 16 and 20 weeks' gestation[3] are also associated with increased risk of preterm birth in subsequent pregnancy.

Pregnancy termination in the first and second trimesters is also associated with an increased risk of subsequent preterm birth, especially when performed with mechanical dilation or curettage, or when performed repeatedly.[31] Increased risk of preterm birth has also been found after spontaneous as well as induced abortion.[32]

Current Pregnancy Risks

Mode of conception also affects the risk of preterm birth. The increased rate of preterm birth after assisted reproduction is due not only to the increased occurrence of multiple gestations but to an increased rate of preterm births in singleton pregnancies as well. A nearly twofold increased risk of preterm birth is observed in singleton pregnancies conceived with all methods of fertility care, including ovulation promotion.[33] A meta-analysis of 15 studies that compared 12,283 IVF pregnancies with 1.9 million spontaneously conceived singleton births found approximately twofold increased rates of perinatal mortality, preterm birth, LBW and VLBW, and small for gestational age for infants born after IVF. Rates of preterm birth among multiple gestations do not appear to be increased after assisted conception relative to spontaneously conceived twins and triplets, so the explanation for the increased rates in singletons is not clear. Microbial colonization of the upper genital tract, increased stress among infertile couples, side effects of super-ovulation, and increased rates of birth defects have been proposed.

Bleeding and Vanishing Twins

Women who experience unexplained vaginal bleeding after the first trimester have an increased risk of subsequent preterm birth that increases with the number of episodes. Perhaps reflecting similar cause(s), the risk of preterm birth is also increased in women whose pregnancies are complicated by vanishing twin or by an unexplained elevation in maternal serum alpha-fetoprotein.

Multifetal Gestation and Uterine Distention

Multifetal gestation is one of the strongest risk factors for preterm birth. Rates of preterm, very preterm, LBW, and VLBW births according to fetal number are shown in Chapter 30. Slightly more than 50% of women with twins deliver before 37 weeks. The risk of early birth rises with the number of fetuses, suggesting uterine overdistention and fetal signaling as potential pathways to early initiation of labor. In addition to spontaneous preterm labor, multiple gestations are more commonly complicated by medical and obstetrical disorders that lead to indicated preterm delivery. Poor fetal growth, fetal anomalies, hypertension, abruptio placentae, and fetal compromise are more common in multiple gestation, and increase with the number of fetuses. The chorionicity of twin gestation is also an important factor in the risk of adverse pregnancy outcomes. Monochorionic twin pregnancies are more likely than dichorionic twin gestations to be complicated by stillbirth and fetal growth restriction. Newborn monochorionic twins are more likely than dichorionic twins to experience necrotizing enterocolitis and neuromorbidity. It is unclear how much of the excess rate of preterm birth among monochorionic twins is due to indicated versus spontaneous preterm birth.

Scoring Systems

Attempts to develop scoring systems based on historical and epidemiologic data plus current pregnancy risk factors have had low sensitivity to identify women who will give birth preterm, but did not include some of the historical risks listed here.

PATHOPHYSIOLOGY OF SPONTANEOUS PRETERM BIRTH

Term and preterm parturition share anatomic, physiologic, and biochemical features that are considered part of the common pathway of parturition. This pathway includes (1) increased uterine contractility, (2) cervical ripening, and (3) membrane/decidual activation. However, although spontaneous labor at term results from physiologic activation of the common pathway of parturition, preterm labor is the result of a pathologic activation of this pathway. The insult responsible for activation may lead to asynchronous recruitment of each pathway. Asynchrony is recognized clinically as (1) cervical insufficiency when the process affects predominantly the cervix; (2) preterm uterine contractions when the process affects the myometrium; or (3) preterm premature rupture of membranes if the insult targets the chorioamniotic membranes. Synchronous activation in the preterm gestation would be labeled as preterm labor with intact membranes. Whether at or before term, parturition culminates in a common pathway composed of cervical changes, persistent uterine contractions, and activation of the decidua and membranes. The fundamental difference is that labor at term is a normal physiologic activation of the common pathway, whereas preterm parturition is the result, entirely or in part, of pathologic processes that activate one or more of the components of the common pathway.

Although labor is of short duration (hours or days at the most), parturition is a longer process that includes a preparatory phase of the key organs involved in the common pathway. Thus, cervical changes occur over weeks, there is increased myometrial contractility before the onset of labor, and the appearance of fetal fibronectin in the cervicovaginal mucous can be considered to reflect extracellular matrix degradation, indicating activation of the decidua and membranes.

Normal parturition at term is currently understood as beginning several weeks before actual labor during which cervical ripening occurs as evidenced by changes in cervical consistency and effacement. A fetal maturity-based signal for labor originates in the fetal hypothalamus and leads to increased secretion of corticotropin-releasing hormone, which, in turn, stimulates adrenocorticotrophic hormone and cortisol production by the fetal adrenals, which ultimately leads to activation of the common pathway of parturition. The fetus may contribute to the onset of preterm labor in the context of the fetal inflammatory response syndrome (see later).

Spontaneous preterm birth may best be understood as a syndrome in which the clinical presentations of preterm labor, preterm ruptured membranes, and preterm cervical effacement and dilation without labor occur as the result of multiple etiologies that can occur alone or in combination. Some act to initiate preterm parturition acutely, for example, an acute posttraumatic placental abruption, but most follow a more subacute or indolent path over several weeks. It is helpful to remember that the normal process of parturition proceeds for several weeks before clinically evident labor begins. Thus, pathologic stimuli of parturition may act in concert with the normal physiologic preparation for labor, especially after 32 weeks of pregnancy. Before 30 to 32 weeks, a greater proportion of preterm labor has a pathologic stimulus.

Cervical Changes (Ripening)

The cervix is a critical structure in pregnancy and parturition; the cervix must maintain structural integrity and act as a physical barrier during pregnancy and subsequently transitions to allow passage of the fetus during delivery. This change is not acute; physiologic parturition occurs over the course of gestation, and requires evolving biochemical and biomechanical changes in the cervix that manifest as cervical ripening.[34,35] Molecular processes underlying cervical ripening are different between physiologic and pathologic parturition and may differ among etiologies of pathologic parturition. Although collagen is the main contributor to the tensile strength of the cervix, glycosaminoglycans (GAGs) are critical to determining the viscoelastic properties of the tissue. GAGs are long unbranched polysaccharides that are vital components of the extracellular matrix and serve many roles: they help to determine tissue hydration, which contributes to viscous

tissue properties, and stabilize the overall architecture of the extracellular matrix. In addition, small leucine-rich proteoglycans (GAGs linked to core proteins) such as decorin have been shown to interact with soluble growth factors and mediators of inflammation. Tight junctions in the cervical epithelial cells provide structural support and regulate fluid fluxes. Cervical epithelia have numerous functions that include proliferation, differentiation, maintenance of fluid balance, protection from environmental hazards, and paracellular transport of solutes via tight junctions. Epithelial functions must be tightly regulated during pregnancy and parturition, and molecules important in epithelial integrity and function are key components of cervical changes in animal models and in women at term. Extracellular matrix turnover in the cervix is high, and thus, the mechanical properties of the cervix can change rapidly. Changes in extracellular matrix during cervical ripening include an influx of inflammatory cells (macrophages, neutrophils, mast cells, eosinophils, and so on) into the cervical stroma in a process similar to an inflammatory response. These cells produce cytokines and prostaglandins that affect extracellular matrix metabolism. Prostaglandins effect cervical ripening physiologically and have been widely used as pharmacologic agents to ripen the cervix for induction of labor. Cervical ripening is influenced by estrogen, which induces ripening by stimulating collagen degradation, and by progesterone, which blocks these estrogenic effects. Furthermore, administration of progesterone receptor antagonist can induce cervical ripening, and administration of progesterone has been reported to delay or even reverse ripening. Another mediator implicated in the mechanisms of cervical ripening is nitric oxide (NO), which can act as an inflammatory mediator.

Cervical changes normally precede the onset of labor, are gradual, and develop over several weeks. Preterm birth is often preceded by cervical ripening over a period of weeks in the second and third trimesters, evidenced in clinical examination by softening and thinning of the cervix and in ultrasound examination of the cervix by cervical "funneling" and shortening of the length of the endocervical canal.

Increased Uterine Contractility

Labor is characterized by a change in uterine contractility from episodic uncoordinated myometrial contractures that last several minutes and produce little increase in intrauterine pressure to more coordinated contractions of short duration that produce marked increases in intrauterine pressure that ultimately effect delivery. The change from the contracture to the contraction pattern typically begins at night, suggesting neural control. The transition from contractures to contractions may progress to normal labor or may occur dyssynchronously as the result of inflammation, for example, with maternal infection or abdominal surgery. Fasting may also induce the switch in humans. Oxytocin is produced by the decidua and the paraventricular nuclei of the hypothalamus, indicating both an endocrine and a paracrine role. Plasma concentrations of oxytocin mirror uterine contractility, suggesting that oxytocin may mediate the circadian rhythm in uterine contractility.

Cellular communication is another feature of labor, promulgated by formation of gap junctions that develop in the myometrium before labor and disappear after delivery. Gap junction formation and the expression of the gap junction protein connexin 43 in human myometrium is similar in term and preterm labor. These findings suggest that the appearance of gap junctions and increased expression of connexin 43 may be part of the underlying molecular and cellular events responsible for the switch from contractures to contractions before the onset of parturition. Estrogen, progesterone, and prostaglandins have been implicated in the regulation of gap junction formation, as well as in influencing the expression of connexin 43. Lye and colleagues have proposed that changes in a set of distinct proteins called "contraction-associated proteins" are characteristic of this stage of parturition.

Decidual Membrane Activation

The maternal decidua and adjacent fetal membranes undergo anatomic and biochemical changes over the final weeks of gestation that ultimately result in spontaneous rupture of membranes. Premature activation of this mechanism leads to preterm prelabor rupture of membranes (PROM), the clinical antecedent for up to 40% of all preterm deliveries. Although rupture of membranes normally occurs during the first stage of labor, histologic studies of prematurely ruptured membranes show decreased amounts of collagen types I, III, and V and an increased expression of tenascin (expressed during tissue remodeling and wound healing) and disruption of the normal wavy collagen pattern, suggesting that preterm rupture is a process that precedes the onset of labor.

Structural extracellular matrix proteins such as collagens have been implicated in the tensile strength of the membranes, whereas the viscoelastic properties were attributed to elastin. Dissolution of extracellular cements (i.e., fibronectins) is thought to be responsible for the process that allows the membranes to separate from the decidua after the birth of the infant. Degradation of the extracellular matrix, assessed by the detection of fetal fibronectin, is part of the common pathway of parturition. The presence of fetal fibronectin in cervicovaginal secretions between 22 and 37 weeks is evidence of disruption of the decidual-chorionic interface and is associated with an increased risk of preterm birth.

The precise mechanism of membrane-decidual activation is uncertain, but matrix-degrading enzymes and apoptosis (programmed cell death) have been proposed. Increased levels of matrix metalloproteinases (MMPs) and their regulators (TIMPs) have been documented in the amniotic fluid of women with preterm PROM.

Apoptosis may also play a role in the mechanism of membrane rupture, through increased expression of pro-apoptotic genes and decreased expression of antiapoptotic genes. MMP-9 may induce apoptosis in amnion.

Fetal Participation in the Onset of Labor

A fetal signal contributes to the onset of labor in animals and humans. Destruction of the paraventricular nucleus of the fetal hypothalamus results in prolongation of pregnancy in sheep. The human counterpart to this animal experiment is anencephaly, which is also characterized by

prolonged pregnancy when women with polyhydramnios are excluded. The current paradigm is that once maturity has been reached, the fetal brain, specifically the hypothalamus, increases corticotrophin-releasing hormone (CRH) secretion, which, in turn, stimulates adrenocorticotrophic hormone (ACTH) and cortisol production by the fetal adrenals. This increase in cortisol in sheep and dehydroepiandrosterone sulfate in primates eventually leads to activation of the common pathway of parturition. A role for the human fetus in the onset of preterm labor has been proposed in the context of the fetal inflammatory response syndrome.

The Preterm Parturition Syndrome

Obstetrical taxonomy is largely based on clinical presentation, not the mechanism of disease. Preterm labor may occur as the common clinical presentation of infection, vascular insult, uterine overdistention, abnormal allogeneic recognition, stress, or other pathologic processes. Often more than one of these factors is operative in the same patient. Thus, preterm labor is a syndrome for which there is no single diagnostic test or treatment. Obstetrical syndromes share the following features:

- Multiple etiologies
- Chronicity
- Fetal involvement
- Clinical manifestations that are adaptive
- Variable susceptibility due to gene-environment interactions

Each of these features is true of preterm birth. There are clearly *multiple etiologies* for preterm labor, as listed earlier. Pathways to preterm labor are demonstrated to be *chronic*, as seen in the time interval between observation of a short cervix or increased concentrations of fetal fibronectin in vaginal fluid in the midtrimester of pregnancy and subsequent preterm labor or delivery. *Fetal involvement* has been demonstrated in women with microbial invasion of the amniotic cavity, in which fetal bacteremia and cytokine production have been detected in 30% of women with preterm PROM and a positive amniotic fluid culture for microorganisms. Similarly, neonates born after spontaneous preterm labor or preterm PROM are more likely to be small for gestational age, suggesting chronically compromised fetal supply. Preterm labor may be seen as an *adaptive* mechanism of host defense against infection that allows the mother to eliminate an infected tissue and the fetus to exit from a hostile environment. If the clinical manifestations are adaptive, it is not surprising that treatments aimed at the common terminal pathway of parturition, such as tocolysis or cerclage, and not at the fundamental mechanism of disease-inducing activation of the pathway (myometrial contractility, cervical dilation, and effacement), would not be effective. There is increasing evidence of gene-environment interaction in the steps leading to preterm labor, complicated by the presence, and even perhaps the conflicting interests, of two genomes (maternal and fetal). This is most evident in studies of the relationship between maternal genital tract colonization and preterm birth. Finally, there may be additional mechanisms not yet identified.

Pathologic processes implicated in the preterm parturition syndrome include intrauterine infection, uterine ischemia, uterine overdistention, abnormal allograft reaction, allergy-induced causes, cervical insufficiency, and endocrine disorders.

Intrauterine Infection

Systemic maternal infections such as pyelonephritis and pneumonia are frequently associated with the onset of premature labor in humans. Intrauterine infection is a frequent and important mechanism of disease leading to preterm delivery. Intrauterine infection or systemic administration of microbial products to pregnant animals can result in preterm labor and delivery, and there is substantial evidence that subclinical intrauterine infections are associated with preterm labor and delivery. Moreover, fetal infection and inflammation have been implicated in the genesis of fetal or neonatal injury leading to cerebral palsy and chronic lung disease. Microbiologic and histopathologic studies suggest that infection-related inflammation may account for 25% to 40% of cases of preterm delivery.

Frequency of Intrauterine Infection in Spontaneous Preterm Birth

The prevalence of positive amniotic fluid cultures for microorganisms in women with preterm labor and intact membranes is approximately 13%, with additional instances of infection that are identifiable using PCR techniques rather than culture. The earlier the gestational age at preterm birth, the more likely that microbial invasion of the amniotic cavity is present. In preterm PROM, the prevalence of positive amniotic fluid cultures for microorganisms is approximately 32%. Among women with a dilated cervix in the midtrimester, the prevalence of positive amniotic fluid cultures is 51%. Microbial invasion of the amniotic cavity occurs in 12% of twin gestations with preterm labor and delivering a preterm neonate. The most common microorganisms found in the amniotic cavity are genital *Mycoplasmas* and *U. urealyticum*.

Intrauterine Infection as a Chronic Process

Evidence in support of chronicity of intrauterine inflammation/infection is derived from studies of the microbiologic state of the amniotic fluid, as well as the concentration of inflammatory mediators at the time of genetic amniocentesis. Genital mycoplasmas including *M. hominis* and *U. urealyticum* have been recovered from amniotic fluid samples obtained at second-trimester genetic amniocentesis, with subsequent preterm delivery and histologic chorioamnionitis, especially in those with *U. urealyticum*. Increased levels of many inflammatory markers have been found in second-trimester amniotic fluid samples obtained from women who subsequently delivered preterm. These observations suggest that infection and inflammation in the amniotic cavity in the midtrimester of pregnancy can lead to preterm delivery weeks later. The most advanced stage of intrauterine infection is fetal infection. Fetal bacteremia has been detected in blood obtained by cordocentesis in 33% of fetuses with positive amniotic fluid culture and 4% of those with negative amniotic fluid culture.

Molecular mediators that trigger parturition (cytokines and other inflammatory mediators) are similar to those that

protect the host against infection. The onset of preterm labor in response to intrauterine infection is thus very likely a host defense mechanism with survival value for mother and, after viability, for the fetus as well.

Infection, Preterm Labor, and Neonatal Outcomes

The scenario postulated from the preceding evidence is that microorganisms that reside in or ascend to reach the decidua may, depending on host defense and environmental influences, stimulate a local inflammatory reaction, as well as the production of proinflammatory cytokines, chemokines, and inflammatory mediators. This inflammatory process, which is initially extra-amniotic, may produce cervical effacement, further inflammation of the choriodecidual interface, and uterine contractions, and may progress to the amniotic fluid and, ultimately, the fetus as well. Microorganisms are known to cross intact membranes into the amniotic cavity, where inflammatory mediators are produced by resident macrophages and other host cells within the amniotic cavity. Finally, microorganisms that gain access to the fetus may elicit a systemic inflammatory response, the fetal inflammatory response syndrome (FIRS), characterized by increased concentrations of IL-6 and other cytokines, as well as cellular evidence of neutrophil and monocyte activation. FIRS is a subclinical condition originally described in fetuses of mothers with preterm labor and intact membranes and preterm PROM. Fetuses with FIRS have a higher rate of neonatal complications and are frequently born to mothers with subclinical microbial invasion of the amniotic cavity. Evidence of multisystemic involvement in cases of FIRS includes increased concentrations of fetal plasma MMP-9, neutrophilia, a higher number of circulating nucleated red blood cells, and higher plasma concentrations of G-CSF. The histologic hallmark of FIRS is inflammation in the umbilical cord (funisitis) or chorionic vasculitis. The systemic fetal inflammatory response may result in multiple organ dysfunction, septic shock, and death in the absence of timely delivery. Newborns with funisitis are at increased risk for neonatal sepsis as well as long-term handicaps, including BPD and cerebral palsy.

When the inflammatory process does not involve the chorioamniotic membranes and decidua, systemic fetal inflammation and injury may occur in the absence of labor with eventual delivery at term. An example of this is fetal alloimmunization in which there is an elevation of fetal plasma concentrations of interleukin 6, but not preterm labor.

Gene-Environment Interactions

Gene-environment interactions underlie many complex disorders such as atherosclerosis and cancer. A gene-environment interaction is said to be present when the risk of a disease (occurrence or severity) among individuals exposed (to both genotype and an environmental factor) is greater or lower than that which is predicted from the presence of either the genotype or the environmental exposure alone. The inflammatory response to the presence of microorganisms is modulated by interactions between the host genotype and environment that determine the likelihood and course of some infectious diseases. An example of such an interaction has been reported for BV, an allele for TNF-a and preterm delivery. Maternal BV is a consistently reported risk factor for spontaneous preterm delivery, yet treatment of BV does not reliably prevent preterm birth in women with BV. One potential explanation has come from a study of preterm birth rates in women according to their carriage of BV and whether or not they had allele 2 of TNF-a known to be associated with spontaneous preterm birth. Both BV (OR 3.3; 95% CI 1.8 to 5.9) and TNF-a allele 2 (OR 2.7; 95% CI 1.7 to 4.5) were associated with increased risk for preterm delivery, but the risk of spontaneous preterm birth was substantially increased (OR 6; 95% CI 1.9 to 21.0) in women with both BV and the TNF-a allele 2. It is reasonable to assume that other gene-environment interactions may contribute to preterm birth.

Uteroplacental Ischemia/Decidual Hemorrhage

After inflammation, the most common abnormalities seen in placental pathology specimens from spontaneous preterm births are vascular lesions of the maternal and fetal circulations. Maternal lesions include failure of physiologic transformation of the spiral arteries, atherosis, and thrombosis. Fetal abnormalities include decreased number of villous arterioles and fetal arterial thrombosis.

One proposed mechanism linking vascular lesions and preterm labor/delivery is uteroplacental ischemia, evidenced in primate models and in studies that found failure of physiologic transformation in the myometrial segment of the spiral arteries, a phenomenon typical of preeclampsia and intrauterine growth restriction, in women with preterm labor and intact membranes and preterm PROM as well. Abnormal uterine artery Doppler velocimetry indicating increased impedance to flow in the uterine circulation has been reported in women with apparently idiopathic preterm labor.

The mechanisms responsible for preterm parturition in cases of ischemia have not been determined, but uterine ischemia has been postulated to lead to increased production of uterine renin from the fetal membranes. Angiotensin II can induce myometrial contractility directly or through the release of prostaglandins.

Decidual necrosis and hemorrhage can activate parturition through production of thrombin, which stimulates myometrial contractility in a dose-dependent manner. Thrombin also stimulates production of MMP-1, urokinase-type plasminogen activator (uPA), and tissue-type plasminogen activator (tPA) by endometrial stromal cells in culture. These factors can, directly or indirectly, digest important components of the extracellular matrix in the chorioamniotic membranes. Thrombin/antithrombin complexes, a marker of in vivo generation of thrombin, are increased in plasma and amniotic fluid of women with preterm labor and preterm PROM. Decidua is a rich source of tissue factor, the primary initiator of coagulation and of thrombin activation. These observations are consistent with clinical associations among vaginal bleeding, retroplacental hematomas, and preterm delivery.

Uterine ischemia should not be equated with fetal hypoxemia. Studies of fetal cord blood do not support fetal hypoxemia as a cause (or consequence) of preterm parturition.

Uterine Overdistention

The mechanisms responsible for the increased frequency of preterm birth in multiple gestations and other disorders associated with uterine overdistention are unknown. Central questions are how the uterus senses stretch, and how these mechanical forces induce biochemical changes that lead to parturition. Increased expression of oxytocin receptor, connexin 43, and the *c-fos* mRNA have been consistently demonstrated in the rat myometrium near term. Progesterone blocks stretch-induced gene expression in the myometrium. Mitogen-activated protein kinases have been proposed to mediate stretch-induced *c-fos* mRNA expression in myometrial cells. Stretch can have effects on the membranes. For example, in vitro studies have demonstrated an increase in the production of collagenase, IL-8, and prostaglandin E_2 (PGE_2), as well as the cytokine pre–B-cell colony-enhancing factor. These observations provide a possible link between the mechanical forces operating in an overdistended uterus and rupture of membranes.

Abnormal Allograft Reaction

The fetoplacental unit has been considered nature's most successful semiallograft. Abnormal recognition and adaptation to fetal antigens has been proposed as a mechanism of recurrent pregnancy loss, intrauterine growth restriction, and preeclampsia. Chronic villitis, a lesion indicative of placental rejection, has been found in the placentas of some women who deliver after spontaneous preterm labor.

Allergy-Induced Preterm Labor

Case reports indicate that preterm labor has occurred after exposure to an allergen that generates an allergic-like mechanism (type I hypersensitivity reaction) and that some women with preterm labor have eosinophils as the predominant cells in amniotic fluid, suggesting a form of uterine allergy. Mast cells in the uterus produce histamine and prostaglandins, both of which can induce myometrial contractility. Premature birth can be induced by exposure to an allergen in sensitized animals, and can be prevented by treatment with a histamine H_1 receptor antagonist.

Cervical Insufficiency

In response to cervical ultrasound measurements showing an increased risk of preterm birth in women with short cervix, the understanding of cervical function evolved from a categorical concept of cervical "incompetence" versus "competence" to one of "competence as a continuum."[12] However, subsequent analyses of this same data[11] were conducted in response to clinical trials demonstrating that preterm cervical shortening (softening and ripening) is not the passive result of tissue weakness but instead is an active process that can be slowed or prevented by progesterone supplementation in some women.[14-18] These studies have led to the conclusion that short cervix in the second trimester of pregnancy is evidence that parturition has begun, presumably in response to decidual membrane activation in response to microbial colonization and/or decidual hemorrhage, perhaps aided by cervical factors and/or subclinical myometrial activity. Figure 28-7 shows the length of the cervix at 22 to 24 weeks' gestation and the subsequent rate of cervical shortening in women who later presented after 28 weeks' gestation with preterm labor or preterm PPROM, compared to women who delivered at term or preterm due to medical indication. Significant differences in cervical length were already evident at 22 to 24 weeks, more than a month before clinical presentation, and accelerated for several weeks before clinical presentation.

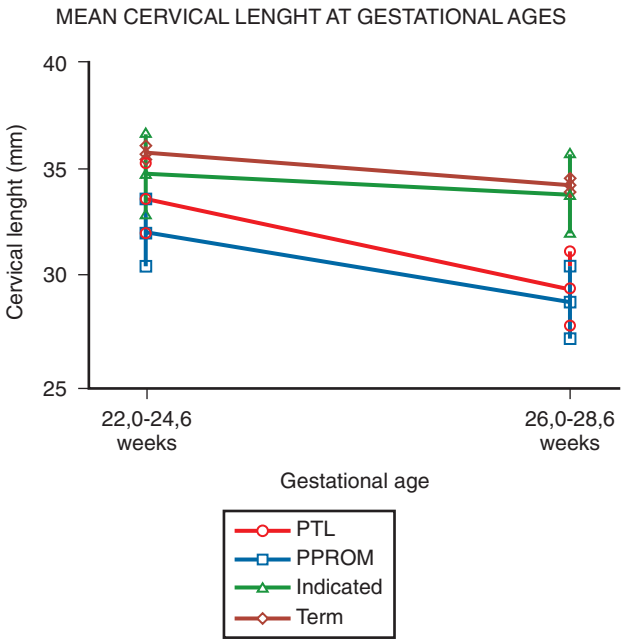

FIGURE 28-7. Length of the cervix at 22 to 24 weeks' gestation and the subsequent rate of cervical shortening in women presenting after 28 weeks with preterm labor or preterm PPROM, compared to women who delivered at term or preterm due to medical indication.

Endocrine Disorders

Estrogen and progesterone play a central role in the endocrinology of pregnancy. Progesterone is thought to maintain myometrial quiescence and inhibit cervical ripening. Estrogens have been implicated in increasing myometrial contractility and excitability, as well as in the induction of cervical ripening before the onset of labor. In many species, a fall in maternal serum progesterone concentration occurs before spontaneous parturition, but the mechanism for this progesterone withdrawal depends primarily on whether the placenta or the corpus luteum is the major source of progesterone.

A fall in serum progesterone levels has not been demonstrated before parturition in humans. Nevertheless, inhibition of progesterone action could result in parturition. Alternative mechanisms posited to explain a suspension of progesterone action without a serum progesterone withdrawal include binding of progesterone to a high-affinity protein and, thus, reduced functional active form; increased cortisol concentration that competes with progesterone for binding to the glucocorticoid receptors, resulting in functional progesterone withdrawal; and conversion of progesterone to an inactive form within the target cell before interacting with its receptor. None of

these hypotheses are proven. Recent research has focused on alterations in the number and function of estrogen-progesterone receptors and progesterone binding.

The human progesterone receptor (PR) exists as two major subtypes, PR-A and PR-B. Another isoform, PR-C, has recently been described, but its function is not well understood. The human estrogen receptor (ER) also exists as two major subtypes, ERa and ERb. A functional progesterone withdrawal has been proposed in which expression of PR-A in myometrium suppresses progesterone responsiveness and that functional progesterone withdrawal occurs by increased expression of the PR-A relative to PR-B. An alternative mechanism of functional progesterone withdrawal has been proposed wherein activation of nuclear factor k B in amnion represses progesterone function. Regardless of the mechanism, there is a building consensus that a localized functional progesterone withdrawal occurs in myometrium during human parturition.

Summary of the Preterm Parturition Syndrome

Preterm parturition is a syndrome caused by multiple etiologies with several clinical presentations including uterine contractility (preterm labor), preterm cervical ripening without significant clinical contractility (cervical insufficiency or advanced cervical dilation and effacement), or rupture of the amniotic sac (preterm PROM). The clinical presentation varies with the type and timing of the insult or stimulus to the components of the common pathway of parturition, the presence or absence of environmental cofactors, and individual variations in host response by both mother and fetus. This conceptual framework has implications for the understanding of the mechanisms responsible for the initiation of preterm parturition, as well as the diagnosis, treatment, and prevention of preterm birth.

CLINICAL CARE FOR WOMEN IN PRETERM LABOR

Clinical evaluation of preterm parturition begins with assessment of potential causes of labor, looking first for conditions that threaten the health of mother and fetus. Acute maternal conditions, for example, pyelonephritis, pneumonia, asthma, peritonitis, trauma, and hypertension, or obstetrical conditions including preeclampsia, placental abruption, placenta previa, and chorioamnionitis may mandate delivery. Fetal compromise may be acute, manifested by an abnormal fetal heart rate tracing, or chronic, indicated by fetal growth restriction or oligohydramnios, and may require delivery depending on the severity and potential for in utero versus ex utero treatment. Fetal growth restriction is more common in infants delivered after preterm labor or preterm PROM, even in apparently otherwise uncomplicated pregnancies. **Conditions that suggest specific therapy such as preterm ruptured membranes or cervical insufficiency should then be sought and treated accordingly.**

The next concerns are the accuracy of preterm labor diagnosis and the balance of risks and benefits that accompany active attempts to inhibit labor versus allowing delivery. Several issues arise:

- What is the gestational age, and what is the level of confidence about the accuracy of the gestational age?
- What, in the absence of advanced labor (cervical effacement >80% with dilation >2 cm) and a clear cause of preterm labor, is the accuracy of the diagnosis of preterm labor?
- Are confirmatory diagnostic tests such as cervical sonography, fetal fibronectin, or amniocentesis for infection necessary?
- What is the anticipated neonatal morbidity and mortality at this gestational age in this clinical setting?
- Should labor be stopped?
- Is transfer to a more appropriate hospital required?
- Should fetal lung maturity be tested?
- What interventions can be applied that will reduce the risks of perinatal morbidity and mortality?
- Should drugs to arrest labor (tocolytics), glucocorticoids, and/or antibiotics be given?

DIAGNOSIS OF PRETERM LABOR

Given the pathways for preterm parturition described earlier, clinical recognition of preterm labor requires attention to the biochemical as well as the biophysical features of the onset of labor. Pathologic uterine contractility rarely occurs in isolation; cervical ripening and decidual membrane activation are almost always in progress as well, most often before uterine contractions are clinically evident. Therefore, preterm labor must be considered whenever a pregnant woman reports recurrent abdominal or pelvic symptoms that persist for more than an hour in the second half or pregnancy. Symptoms of preterm labor such as pelvic pressure, increased vaginal discharge, backache, and menstrual-like cramps occur frequently in normal pregnancy, and suggest preterm labor more by persistence than severity. **Contractions may be painful or painless, depending on the resistance offered by the cervix.** Contractions against a closed, uneffaced cervix are likely to be painful, but persistence of recurrent pressure or tightening may be the only symptoms when cervical effacement precedes the onset of contractions.

For decades, the clinical diagnosis of preterm labor has been based on the presence of regular, painful uterine contractions accompanied by cervical dilation and/or effacement. These criteria assume a crisp demarcation between "preterm parturition" and "preterm labor" that is increasingly understood as being more gradual than previously thought. If thought of as screening criteria for the outcome "preterm birth," clinical signs and symptoms demonstrate poor sensitivity and specificity. Identifying women with preterm contractions who will actually deliver preterm is an inexact process. In like fashion, identifying those women who are at increased risk of not just preterm birth, but imminent preterm birth, remains elusive. A systematic review noted that approximately 30% of preterm labor cases resolved spontaneously. In subsequent studies, 50% of patients hospitalized for preterm labor actually delivered at term. **The inability to distinguish women in "true preterm labor" from women in "false labor" accurately has greatly hampered the assessment of therapeutic interventions, since as many as 50% of untreated (or placebo treated) subjects do not actually deliver preterm. Optimal criteria**

for initiation of treatment are not clear. Contraction frequency of six or more per hour, cervical dilation of 3 cm, effacement of 80%, ruptured membranes, and bleeding are symptoms of preterm labor most often associated with preterm delivery. When lower thresholds for contraction frequency and cervical change are used, "false-positive" diagnosis (defined in randomized controlled trials as delivery at term after treatment with placebo only) occurs in nearly 40% of women, but sensitivity does not rise. Difficulty in accurate diagnosis is the product of the high prevalence of the symptoms and signs of early preterm labor in normal pregnancy, the gradual onset of preterm labor discussed earlier, and the imprecision of digital examination of the cervix below 3 cm dilation and 80% effacement. The practice of initiating tocolytic drugs for contraction frequency without additional diagnostic criteria results in unnecessary treatment of women who are not at increased risk of imminent spontaneous preterm birth.[36]

Diagnostic Tests for Preterm Labor

Women with symptoms whose cervical dilation is less than 2 cm and whose effacement is less than 80% present a diagnostic challenge. Diagnostic accuracy may be improved in these patients by testing other features of parturition, such as cervical ripening, assessed by transvaginal sonographic measurement of cervical length; and decidual activation, tested by an assay for fetal fibronectin in cervicovaginal fluid.[37,38] Both tests aid diagnosis primarily by reducing false-positive diagnosis. Transabdominal sonography has poor reproducibility for cervical measurement and should not be used clinically without confirmation by a transvaginal ultrasound. A cervical length of 30 mm or more by endovaginal sonography indicates that preterm labor is unlikely in symptomatic women if the examination is properly performed.

Similarly, a negative fibronectin test in women with symptoms before 34 weeks' gestation with cervical dilation less than 3 cm can also reduce the rate of false-positive diagnosis if the result is returned promptly and the clinician is willing to act on a negative test result by not initiating treatment. When both tests were performed in a study of 206 women with possible preterm labor, the fetal fibronectin test improved the performance of sonographic cervical length only when the sonographic cervical length was less than 30 mm (see the accompanying box, Clinical Evaluation of Patients with Possible Preterm Labor).

Clinical Evaluation of Patients with Possible Preterm Labor

1. **Patient presents with signs/symptoms of preterm labor:**
   Persistent contractions (painful or painless)
   Intermittent abdominal cramping, pelvic pressure, or backache
   Increase or change in vaginal discharge
   Vaginal spotting or bleeding
2. **General physical examination:**
   Sitting pulse and blood pressure
   Temperature
   External fetal heart rate and contraction monitor
3. **Sterile speculum examination**
   pH
   Fern
   Pooled fluid
   Fibronectin swab (posterior fornix or external cervical os, avoiding areas with bleeding)
   Cultures for chlamydia (cervix), and *Neisseria gonorrhoeae* (cervix), and group B streptococcus (outer third of vagina and perineum)
4. **Transabdominal ultrasound examination**
   Placental location
   Amniotic fluid volume
   Estimated fetal weight and presentation
   Fetal well-being
5. **Cervical examination** (after ruptured membranes excluded)
   a. **Cervix >3 cm dilation/≥80% effaced**
      Preterm labor diagnosis confirmed. Evaluate for tocolysis.
   b. **Cervix 2 to 3 cm dilation/<80% effaced**
      Preterm labor likely but not established. Monitor contraction frequency and repeat digital examination in 30-60 minutes. Diagnose preterm labor if cervical change. If not, send fibronectin or obtain transvaginal cervical ultrasound. Evaluate for tocolysis if any cervical change, cervical length <20 mm, or positive fibronectin.
   c. **Cervix <2 cm dilation and <80% effaced**
      Preterm labor diagnosis uncertain. Monitor contraction frequency, send fibronectin and/or obtain cervical sonography, and repeat digital examination in 1 to 2 hours. Evaluate for tocolysis if there is a 1 cm change in cervical dilation, effacement >80%, cervical length <20 mm, or positive fibronectin.
6. **Use of Cervical Ultrasound**
   Cervical length <20 mm *and* contraction criteria met = preterm labor
   Cervical length 20-30 mm *and* contraction criteria met = probable preterm labor
   Cervical length >30 mm = preterm labor *very unlikely* regardless of contraction frequency

Amniocentesis for Women with Preterm Labor

The goal of care for women with preterm labor is to reduce perinatal morbidity and mortality, most of which is caused by immaturity of the respiratory, gastrointestinal, coagulation, and central nervous systems of the preterm infant. Fetal pulmonary immaturity is the most frequent cause of serious newborn illness, and the fetal pulmonary system is the only organ system whose function is directly testable before delivery. If the quality of obstetrical dating is good and intrauterine fetal well-being is not compromised, the likelihood of neonatal RDS may be estimated from the gestational age.

Amniotic fluid studies may be useful in women with possible preterm labor in the following circumstances:

1. *Fetal pulmonary maturity testing.* Generally speaking, gestational age at birth is the best predictor of the frequency and severity of the consequences of prematurity to the newborn. As noted earlier, generally speaking, labor inhibition and antenatal glucocorticoid therapy are used when birth is anticipated to occur between 24 and 34 weeks' gestation. When dates are uncertain (e.g., late prenatal

care, fetal size larger than expected for dates, suggesting a more advanced gestation), it may be reasonable in some circumstances to use amniotic fluid lung maturity studies to help guide management decisions.

2. *Testing for infection*. Among women with preterm labor and intact membranes, early gestational age, short cervix, and progressive labor despite a tocolytic are all risk factor particularly increasing the probability of occult amniotic fluid infection. In this setting, amniotic fluid studies for infection may guide counseling of women and influence management decisions regarding antibiotics, labor inhibition, and delivery. In this setting, amniotic fluid glucose (amniotic fluid glucose levels less than 20 mg/dL suggest intra-amniotic infection), Gram stain for bacteria, cell count, and culture may be used.
3. *Determining fetal karyotype*. The presence of polyhydramnios or a fetal anomaly suggests that preterm labor may have occurred due to uterine distention or placental insufficiency associated with fetal aneuploidy. Fluorescence in situ hybridization studies for the most common aneuploid conditions can be available within 48 hours. In the absence of other fetal features suggestive of aneuploidy, the presence of preterm labor alone is insufficient indication for determination of fetal karyotype.

GOALS OF TREATMENT FOR WOMEN IN PRETERM LABOR

Treatment with drugs to inhibit labor after contractions and cervical change are well established or membranes have ruptured does not prolong pregnancy sufficiently to allow further intrauterine growth and maturation, but their use can often delay preterm birth long enough to permit four interventions that have been shown to reduce neonatal morbidity and mortality:

1. Antenatal transfer of the mother and fetus to the most appropriate hospital.
2. Antibiotics in labor to prevent neonatal infection with the group B streptococcus (GBS).
3. Antenatal administration of glucocorticoids to the mother to reduce neonatal morbidity and mortality due to respiratory distress, intraventricular hemorrhage, and other causes.
4. Administration of maternal magnesium sulfate at the time of preterm birth before 32 weeks to reduce the incidence of cerebral palsy.

Maternal Transfer

Many states have adopted systems of regionalized perinatal care in recognition of the advantages of concentrating care for preterm infants, especially those born before 32 weeks. Hospitals and birth centers caring for normal mothers and infants are designated as Level I. Larger hospitals that care for the majority of maternal and infant complications are designated as Level II centers; these hospitals have neonatal intensive care units staffed and equipped to care for most infants with birth weights greater than 1500 g. Level III centers typically provide care for the sickest and smallest infants, and for maternal complications requiring intensive care. This approach has been associated with improved outcomes for preterm infants.

Antibiotics

Women with preterm labor should be treated with antibiotics to prevent neonatal GBS infection (see Chapter 51). Because preterm infants have a greater risk of neonatal GBS infection than infants born at term, intrapartum prophylaxis with penicillin is recommended.[39] This policy has successfully reduced the incidence of neonatal GBS infection to such a degree that most GBS infections now occur in full-term infants. There is also evidence that infants born to women with preterm PROM have reduced perinatal morbidity when antepartum antibiotic prophylaxis has been administered for 3 to 7 days.

Antibiotic therapy in women with preterm labor and intact membranes is not effective to prolong pregnancy. The failure of antibiotics to prolong pregnancy may be attributed to treatment of women whose preterm labor did not result from infection, and to the timing of treatment relative to the infectious process. Rather than an acute infection due to the recent ascent of vaginal organisms into the uterus, the pathologic sequence in which infection-driven preterm labor occurs is often much more indolent. **Antimicrobial therapy of women in preterm labor should be limited to GBS prophylaxis, women with preterm PROM, or treatment of a specific pathogen (e.g., urinary tract infection).**

Antenatal Corticosteroids

Glucocorticoids act generally in the developing fetus to promote maturation over growth. In the lung, corticosteroids promote surfactant synthesis, increase lung compliance, reduce vascular permeability, and generate an enhanced response to postnatal surfactant treatment. Glucocorticoids have similar maturational effects on other organs including the brain, kidneys, and gut.

Studies by Liggins of mechanisms of parturition in sheep led to the discovery of the beneficial effect of antenatal glucocorticoids on the maturation and performance of the lung in prematurely born infants. Subsequent studies have shown conclusively that antepartum administration of the glucocorticoids betamethasone or dexamethasone to the mother reduces the risk of death, RDS, intraventricular hemorrhage, NEC, and PDA in the preterm neonate. Guidelines for appropriate clinical use of antenatal glucocorticoids have evolved from initial skepticism and selective use, through a period of broad and repeated treatment following the first NICHD panel report in 1994, to the practice of a single course of treatment recommended by the NICHD Consensus Panel in 2000. More recently, clinical trials support the notion that administration of a single rescue course of ACS before 33 weeks improves neonatal outcome (e.g., decreased respiratory distress syndrome, ventilator support, and surfactant use) without apparent increased short-term risk.[40] A single rescue course of antenatal corticosteroids may be considered if the antecedent treatment was given more than 2 weeks prior, the gestational age is less than $32^{6/7}$ weeks, and the women are judged by the clinician to be likely to give birth within the next week. However, regularly scheduled repeat courses or multiple courses (more

than two) are not recommended.[41] Betamethasone and dexamethasone, the only drugs found beneficial for this purpose, are potent glucocorticoids with limited if any mineralocorticoid effect. A course of treatment consists of two doses of 12 mg of betamethasone (the combination of 6 mg each of betamethasone acetate and betamethasone phosphate) administered intramuscularly twice, 24 hours apart, or four doses of 6 mg of dexamethasone given intramuscularly every 12 hours. Other corticosteroids (prednisolone, prednisone) and routes of administration (oral) are not suitable alternatives because of reduced placental transfer, lack of demonstrated benefit, and, in the case of oral dexamethasone, increased risk of adverse effects when compared with the intramuscular route.

Fetal Effects

Randomized placebo-controlled trials and meta-analyses confirm the beneficial effects of antenatal corticosteroids. Infants born to treated women were significantly less likely to experience RDS (OR 0.53), IVH (OR 0.38), and neonatal death (OR 0.60). The beneficial effects on IVH are independent of the effects on respiratory function. Other morbidities of preterm birth are also reduced by antenatal glucocorticoids, including NEC, PDA, and BPD. Although both are considered effective, betamethasone may be superior to dexamethasone with respect to reduction in morbidity and mortality to the preterm newborn.

Other Fetal Effects of Glucocorticoids

Transient reduction in fetal breathing and body movements sufficient to affect the interpretation of the biophysical profile have been described with both drugs but are more common after betamethasone, typically lasting 48 to 72 hours after the second dose. Transient suppression of neonatal cortisol levels has been reported, but neonatal response to ACTH stimulation was unimpaired.

Maternal Effects

Antenatal glucocorticoids produce a transient rise in maternal platelet and WBC count lasting 72 hours; WBC counts in excess of 20,000 are rarely due to steroids. Maternal glucose tolerance is challenged as well and often requires insulin therapy to maintain euglycemia in women with previously well-controlled gestational or pregestational diabetes. Maternal blood pressure is unaffected by antenatal steroid treatment; neither betamethasone nor dexamethasone has significant mineralocorticoid effect. Women treated with multiple courses of steroids during pregnancy had a blunted response to ACTH stimulation later in pregnancy or the puerperium.

Duration of Benefit

The duration of the beneficial fetal effects after a single course of glucocorticoids is not clear. The issue is difficult to study because the interval between treatment and delivery in clinical trials is variable, and because some effects may be transient whereas others are permanent. Neonatal benefit has been most easily observed when the interval between the first dose and delivery exceeds 48 hours, but some benefit is evident after an incomplete course. One large multicenter trial found evidence of benefit for as long as 18 days after the initial course of treatment.

Risks of Antenatal Corticosteroid Treatment

The recommendation of the 1994 NICHD Consensus Conference to increase the use of antenatal steroids, coupled with uncertainty about the duration of neonatal protection from a single course of treatment and difficulty in predicting imminent preterm delivery, resulted in increased treatment of mothers at risk. Although more women received treatment, many did not deliver within 7 days but remained at risk and were treated weekly until delivery or 34 weeks' gestation. The safety and benefit of one course of steroids has never been questioned. Long-term follow-up studies of infants in the original cohorts of infants treated with a single course of antenatal steroids have displayed no differences in physical characteristics or mental function when compared with gestational age–matched controls. The increasing use of repeated courses prompted animal and human studies that have raised concerns about the effects of prolonged exposure to steroids on fetal growth and neurologic function. The animal studies may be summarized as showing reduced fetal growth and adverse brain and neurologic development in several species.

Human studies also found reduced growth in fetuses exposed to multiple courses of antenatal steroids. An Australian study found a twofold increase in birth weights below the 10th percentile and significantly reduced head circumference in infants exposed to more than three antenatal courses of steroids. Others have also found reduced head circumference.

Other Antenatal Treatments to Reduce Fetal/Neonatal Morbidity

Respiratory Distress

The occurrence of RDS among infants born to women treated with steroid therapy has led to investigation of alternative treatment approaches to further enhance pulmonary maturation. Neonatal treatment with surfactant is an effective adjunctive therapy that adds independently and synergistically to the benefit of corticosteroids in reducing RDS-related morbidity. More than 4600 women have been enrolled into 13 trials of maternal treatment with antenatal thyrotropin-releasing hormone (TRH) to reduce neonatal lung disease. There were no benefits compared with corticosteroids alone for any neonatal outcome. Prenatal treatment with TRH actually increased risk of adverse outcomes for infants in some trials.

Neurologic Morbidity

Antenatal maternal treatment with phenobarbital, vitamin K, and magnesium sulfate has been studied to reduce or prevent neonatal neurologic morbidity. Phenobarbital was not effective in reducing intraventricular hemorrhage when given alone or in combination with vitamin K.

Antenatal maternal treatment with magnesium has been inconsistently associated with reduced rates of IVH, cerebral palsy, and perinatal mortality in premature infants. A randomized placebo-controlled trial of antenatal magnesium conducted in 1062 women delivered before 30 weeks' gestation found significantly lower rates of gross motor dysfunction and nonsignificant trends of reduced mortality and cerebral palsy in surviving infants in the treated group at 2 years of age. There were no significant adverse effects

noted in infants exposed to antenatal magnesium sulfate. In the 1990s, observational studies suggested an association between prenatal exposure to magnesium sulfate and less frequent subsequent neurologic morbidities. Subsequently, several large clinical studies have evaluated the evidence regarding magnesium sulfate, neuroprotection, and preterm births.[42-45] If tocolysis is indicated, the most effective agent with the most favorable side effect profile should be given. None of the trials demonstrated significant pregnancy prolongation when magnesium sulfate was given for neuroprotection. **However, the available evidence suggests that magnesium sulfate given before anticipated early preterm birth reduces the risk of cerebral palsy in surviving infants.**[46]

We suggest limiting magnesium sulfate for neuroprotection to women who are at least 24, but less than 32, weeks of gestation, given that the two largest trials of neuroprotective effects did not enroll women beyond this gestational age range.[45,47]

The impact of gestational age on the neuroprotective effect of antenatally administered magnesium was assessed in one meta-analysis, which included the five trials in the Cochrane review.[48] These trials were stratified by the gestational age at randomization: less than 32 to 34 weeks (5235 fetuses) or less than 30 weeks (3107 fetuses).

Major findings were similar for both gestational age ranges[48]:

- There was no significant difference in the primary outcome of "death or cerebral palsy" at 18 to 24 months of corrected age or for the outcome of perinatal/infant "death."
- The largest reduction in risk was for "moderate to severe cerebral palsy."
- Less than 32 to 34 weeks: RR 0.60 (95% CI 0.43 to 0.84).
- Less than 30 weeks: RR 0.54 (95% CI 0.36 to 0.80).
- There were statistically significant reductions in the risk of "cerebral palsy" (RR 0.7 and 0.69 at less than 32 to 34 weeks and less than 30 weeks, respectively) and for "death or moderate to severe cerebral palsy" (RR 0.85 and 0.84 at less than 32 to 34 weeks and less than 30 weeks, respectively).
- The numbers needed to treat to prevent one case of cerebral palsy in the less than 32 to 34 weeks group and the less than 30 weeks group were 56 and 46 women, respectively.

Until further data are available, a 4-g bolus of magnesium sulfate with a 1 g/hr maintenance dose is a regimen that is anticipated to have a more favorable side effect and safety profile than a higher dose regimen. Neither the neuroprotective mechanism nor the dose response to magnesium sulfate is well understood. While it seems likely that the neuroprotective effects of magnesium sulfate are secondary to residual concentrations of the drug in the neonate's circulation, there are insufficient data regarding the maternal dose that confers neonatal benefit.

Administration of magnesium sulfate is appropriate for women with preterm premature rupture of membranes or preterm labor who have a high likelihood of imminent delivery (e.g., within 24 hours), or before an indicated preterm delivery. If emergency delivery is necessary given maternal or fetal status, it should not be delayed to administer magnesium sulfate. Therapy should be reserved for women who are at high risk of imminent delivery rather than women who simply are diagnosed with preterm labor or preterm premature rupture of membranes. We do not recommend continuing the magnesium infusion for longer than 24 hours if delivery has not occurred.

Treatment Protocol

Magnesium sulfate must be given parenterally to achieve serum levels greater than the normal range. Therapeutic dosage regimens are similar to those used for intravenous seizure prophylaxis of preeclampsia. A loading dose of 4 g is given over 30 minutes, followed by an infusion of 1 g/hr.

If renal function is normal, magnesium is excreted rapidly in the urine. In patients with evidence of renal impairment, for example, oliguria or serum creatinine levels greater than 0.9 mg/dL, magnesium should be administered cautiously, followed with frequent vital signs, deep tendon reflexes and serum levels, and doses adjusted accordingly. Magnesium sulfate should not be used in patients with myasthenia gravis because the magnesium ion competes with calcium.

A clinical protocol for magnesium sulfate for fetal neuroprotection is shown here:

1. Administer loading dose of 4 g magnesium sulfate in 10% to 20% solution over 30 minutes (60 mL of 10% magnesium sulfate in 1 L D_5 0.9 normal saline).
2. Maintenance dose of 1 g/hr (40 g of magnesium sulfate added to 1 L D_5 0.9 normal saline or Ringer's lactate at 50 mL/hr).
3. Limit intravenous (IV) fluid to 125 mL/hr. Follow fluid status closely; an indwelling urinary catheter is recommended.
4. Patients treated with magnesium sulfate should be assessed with the following examinations:
   a. Deep tendon reflexes and vital signs including respiratory rate should be recorded hourly.
   b. Intake and output every 2 to 4 hours.
   c. Magnesium levels if any clinical concern about side effects.
5. Calcium gluconate should be readily available to reverse the respiratory effects of magnesium.

Tocolysis

Because the contracting uterus is the most often recognized antecedent of preterm birth, stopping contractions has been the focus of therapeutic approaches. This strategy is based on the naïve assumption that clinically apparent contractions are commensurate with the initiation of the process of parturition; by logical extension, successfully inhibiting contractions should prevent delivery. The inhibition of myometrial contractions is called tocolysis, and an agent administered to that end is referred to as a tocolytic. Although there are no medications available for use that are approved for the indication of tocolysis by the U.S. Food and Drug Administration (FDA), there are a number of classes of drugs that are used for this purpose.

Efficacy

The efficacy of tocolytic drugs has been addressed through studies that compare one tocolytic drug with another, or,

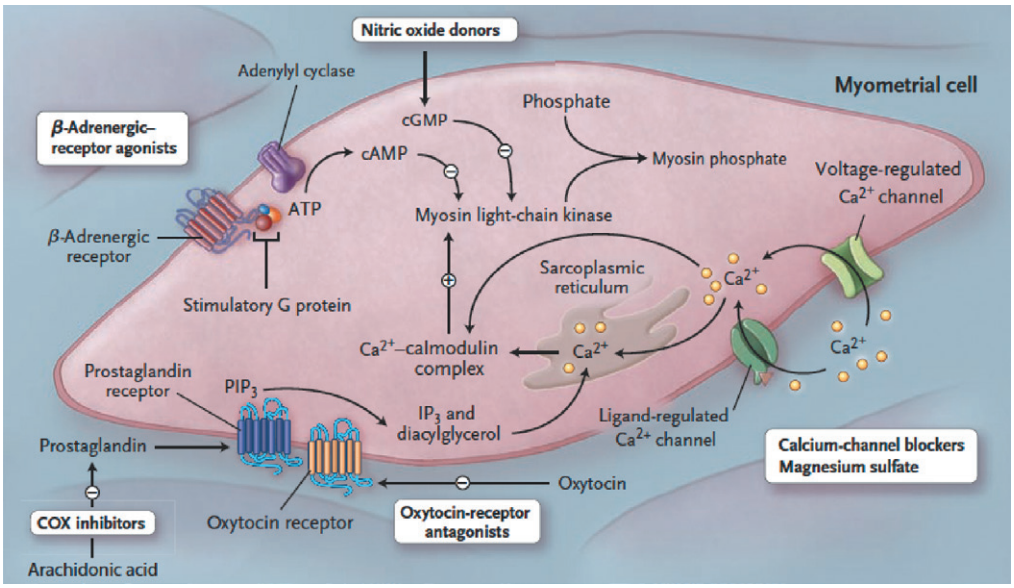

FIGURE 28-8. Site of action of commonly used tocolytics.

less commonly, to a placebo in their ability to prolong pregnancy for 48 hours (the time sufficient to attain the benefit of antenatal corticosteroids), or 1 week (the time considered sufficient to gain significant additional in utero fetal maturation). No studies have shown that any tocolytic can reduce the rate of preterm birth. Most are too small to allow firm conclusions so that reviews or meta-analyses, wherein several studies of similar design are combined, are the best available means to judge efficacy. The Cochrane Collaboration (www.cochrane.org/index0.htm) regularly produces meta-analyses of obstetrical interventions including tocolytic drugs. Recent Cochrane meta-analyses of tocolytic agents indicate that calcium channel blockers and oxytocin antagonists can delay delivery by 2 to 7 days with the most favorable ratio of benefit to risk, that β-mimetic drugs delay delivery by 48 hours but carry greater side effects, that there is insufficient evidence regarding cyclooxygenase (COX) inhibitors, and that magnesium sulfate is ineffective.

Meta-analyses of studies of individual tocolytic drugs typically report limited prolongation of pregnancy but no decrease in preterm birth and rarely offer information about whether prolongation of pregnancy was accompanied by improved infant outcomes. Delayed delivery for 48 hours to allow antenatal transport and corticosteroids to reduce neonatal morbidity and mortality are thus the main rationale for use of these drugs.

Choosing a Tocolytic Agent

PHARMACOLOGY

Figure 28-8 depicts a myometrial cell and the site(s) of action of commonly used tocolytic agents. The key process in actin-myosin interaction, and thus contraction, is myosin light-chain phosphorylation. This reaction is controlled by myosin light-chain kinase (MLCK). The activity of tocolytic agents can be explained by their effect on the factors regulating the activity of this enzyme, notably calcium and cyclic adenosine monophosphate (cAMP). For the myometrium to contract in a coordinated and effective manner (i.e., labor, whether term or preterm), individual smooth muscle cells must be functionally interconnected and able to communicate with adjacent cells. There are no agents used for tocolysis that influence the function or expression of gap junctions.

CONTRAINDICATIONS TO TOCOLYSIS

Common maternal contraindications to tocolysis include severe preeclampsia or severe gestational hypertension, hemorrhage, and significant maternal cardiac disease. Preterm labor accompanied by maternal hypertension places both mother and fetus at risk of acute hypertensive crises, and may occur in response to fetal stress or distress, uterine ischemia, or occult placental abruption. Although vaginal spotting may occur in women with preterm labor because of cervical effacement or dilation, any bleeding beyond light spotting is rarely due to labor alone. Placenta previa and placental abruption must be considered, because both may be accompanied by uterine contractions. In general, both diagnoses place a woman at greater risk of hemodynamic compromise in the setting of tocolytic treatment. However, in rare instances, use of tocolysis in women with these dangerous diagnoses may be considered to achieve time for corticosteroids in the setting of extreme prematurity when the bleeding is believed to occur in response to contractions. Such treatment is fraught with difficulty, because even low doses of some tocolytic agents can be hazardous in a patient with bleeding. β-Mimetic agents and calcium channel blockers may hamper maternal cardiovascular response to hypotension, and prostaglandin inhibitors may impair platelet function. Cardiac disease is a contraindication because of the risks of tocolytic drug treatment in these patients. Fetal contraindications to tocolysis include gestational age of greater than 37 weeks, fetal demise or lethal anomaly, chorioamnionitis, and evidence of acute or chronic fetal compromise.

TABLE 28-3 SIDE EFFECT PROFILES OF TOCOLYTIC AGENTS

	SIDE EFFECTS		
AGENT OR CLASS	**MATERNAL**	**FETAL OR NEONATAL**	**CONTRAINDICATIONS**
β-Adrenergic-receptor agonists	Tachycardia and hypotension, tremor (39% vs. 4% with placebo), shortness of breath (15% vs. 1% with placebo), chest discomfort (10% vs. 1% with placebo), pulmonary edema (0.3%), hypokalemia (39% vs. 6% with placebo), hyperglycemia (30% vs. 10% with placebo)	Tachycardia	Tachycardia-sensitive maternal cardiac disease, poorly controlled diabetes mellitus
Magnesium sulfate	Flushing, diaphoresis, nausea, loss of deep-tendon reflexes (at doses of 9.6 to 12 mg/dL), respiratory paralysis (at doses of 12 to 18 mg/dL), cardiac arrest (at doses of 24 to 30 mg/dL); when used with calcium channel blockers, suppression of heart rate, contractility and left ventricular systolic pressure, and neuromuscular blockade.	Conflicting data with regard to effect on perinatal mortality	Myasthenia gravis
Calcium channel blockers	Dizziness, flushing, hypotension when used with magnesium sulfate, suppression of heart rate, contractility, and left ventricular systolic pressure and neuromuscular blockade; elevation of hepatic aminotransferase levels		Hypotension, preload-dependent cardiac lesions (e.g., aortic insufficiency)
Cyclo-oxygenase inhibitors	Nausea, esophageal reflux, gastritis, and emesis; platelet dysfunction (rarely of clinical significance in patients without underlying bleeding disorder)	In utero closure of ductus arteriosus (risk associated with use for >48 hr), patent ductus arteriosus in neonate (conflicting data)	Platelet dysfunction or bleeding disorder, hepatic or renal dysfunction, gastrointestinal or ulcerative disease, asthma (in women with hypersensitivity to aspirin)
Oxytocin-receptor antagonists	Hypersensitivity injection-site reactions	For atosiban, an increased rate of fetal or infant death (may be attributable to the lower gestational age of infants in the atosiban group)	None
Nitric oxide donors	Dizziness, flushing, hypotension		Hypotension, preload-dependent cardiac lesions (e.g., aortic insufficiency)

Tocolytic drugs may be safely used when standard protocols are followed. The choice of tocolytic requires consideration of the efficacy, risks, and side effects for each patient. Table 28-3 describes the side effect profiles of commonly used tocolytic agents.

CALCIUM CHANNEL BLOCKERS

Calcium channel blockers are used commonly for treatment of hypertension, angina, and arrhythmias and are increasingly being used as tocolytic drugs. Nifedipine is the calcium channel blocker most studied as a tocolytic agent; it more selectively inhibits uterine contractions compared with other calcium blockers such as verapamil. Calcium channel blockers directly block the influx of calcium ions through the cell membrane and also inhibit release of intracellular calcium from the sarcoplasmic reticulum, thus increasing calcium efflux from the cell. The ensuing decrease in intracellular free calcium leads to inhibition of calcium-dependent myosin light-chain kinase–mediated phosphorylation and results in myometrial relaxation. Calcium channel blockers are rapidly absorbed after oral administration. There are no placebo-controlled trials of calcium channel blockers as tocolytics. The Cochrane Collaboration meta-analyses support calcium channel blockers as short-term tocolytics compared with other available agents because of relatively greater contraction suppression and fewer side effects than other agents in 12 reported trials. Rates of birth within 7 days of treatment (RR 0.76, 95% CI 0.60 to 0.97) and before 34 weeks' gestation (RR 0.83, 95% CI 0.69 to 0.99) were significantly reduced with calcium channel blockers, as were the rates of neonatal morbidities including RDS (RR 0.63, 95% CI 0.46 to 0.88), NEC (RR 0.21, 95% CI 0.05 to 0.96), IVH (RR 0.59, 95% CI 0.36 to 0.98), and jaundice (RR 0.73, 95% CI 0.57 to 0.93) when compared with treatment with other tocolytics. Fewer women treated with calcium channel blockers ceased treatment owing to adverse drug reactions (RR 0.14, 95% CI 0.05 to 0.36).

Maternal Effects

Nifedipine has fewer side effects when compared with β-mimetics and magnesium sulfate. Hypotension occurs frequently with nifedipine, but other side effects are more frequent with magnesium and β-mimetics. Nicardipine displayed similar advantages when compared in a randomized trial with magnesium. Pretreatment with IV fluids may reduce the frequency of maternal side effects related to hypotension such as headache (20%), flushing (8%), dizziness, and nausea (6%). Most effects are mild, but

serious complications have been reported, including a documented myocardial infarction 45 minutes after the second dose of nifedipine given to a young healthy woman. Concomitant or sequential use of calcium channel blockers with β-mimetics is not recommended, nor is concurrent administration of magnesium, owing to reports of skeletal muscle blockade when nifedipine was given with magnesium sulfate.

Fetal Effects

Initial animal studies raised questions of fetal hypotension, but a study of women treated for preterm labor revealed no changes in fetal middle cerebral artery, renal artery, ductus arteriosus, umbilical artery, or maternal vessels.

Treatment Protocol

An optimal nifedipine dosing regimen has not been defined. A common approach is to administer an initial loading dose of 20 mg orally, followed by an additional 20 mg orally in 90 minutes. An alternative regimen is to administer 10 mg orally every 20 minutes for up to four doses. If contractions persist, 20 mg can be given orally every 3 to 8 hours for up to 72 hours, with a maximum dose of 180 mg/day.The half-life of nifedipine is approximately 2 to 3 hours and the duration of action of a single orally administered dose is up to 6 hours. Plasma concentrations peak in 30 to 60 minutes. Nifedipine is almost completely metabolized in the liver and excreted by the kidney.

Summary of Treatment with Calcium Channel Blockers

Nifedipine has been used increasingly as a tocolytic because of its low incidence of significant maternal and fetal side effects and ease of administration. Nifedipine should not be combined with magnesium or β-mimetics, and should be avoided in the presence of intrauterine infection, maternal hypertension, and cardiac disease. Use should follow published dosage schedules, and the cautions noted should be kept in mind.

Magnesium Sulfate

The basis for the clinical use of magnesium sulfate as a labor-inhibiting agent is the observation from the 1960s of a reduction of human uterine contractility in vivo and in vitro. At a pharmacologic concentration (5 mmol/L), magnesium sulfate inhibits contractile response and decreases intracellular calcium concentration in pregnant human myometrial strips. Despite in vitro observations, the largest placebo-controlled randomized trial of magnesium as a tocolytic failed to demonstrate any benefit over placebo in prolongation of pregnancy. A meta-analysis that compared magnesium to controls observed no difference in the risk of birth within 48 hours of treatment for women given magnesium (RR 0.85, 95% CI 0.58 to 1.25, 11 trials, 881 women). Magnesium appeared to confer no benefit on the risk of preterm birth (less than 37 weeks) or very preterm birth (less than 34 weeks). The risk of death (fetal and pediatric) was higher for infants exposed to magnesium (RR 2.82, 95% CI 1.20 to 6.62, 7 trials, 727 infants) The body of available literature fails to support efficacy of magnesium sulfate as a tocolytic agent. Thus, in women 24 to 32 weeks of gestation who are candidates for tocolysis, we recommend that another therapy be used for labor inhibition in women also receiving magnesium sulfate for fetal neuroprotection. Because of the increased risk of maternal complications with the concomitant use of nifedipine and magnesium sulfate, an agent such as indomethacin may be a reasonable choice for tocolysis in the woman receiving magnesium sulfate for neuroprotection of the fetus.

Maternal Effects

Magnesium has a low rate of serious maternal side effects, but flushing, nausea, vomiting, headache, generalized muscle weakness, diplopia, and shortness of breath occur frequently. Chest pain and pulmonary edema have been reported with a frequency similar to that of β-mimetics.

Neonatal Effects

Magnesium crosses the placenta and achieves serum levels comparable to maternal levels, but serious short-term neonatal complications are uncommon. Lethargy, hypotonia, and respiratory depression may occur. Prolonged treatment for more than 7 days has been associated with neonatal bone abnormalities. One small trial suggested that magnesium sulfate may have adverse effects on neonatal and infant morbidity and mortality, but these observations were not confirmed by larger studies that enrolled more than 10 times as many subjects.

Summary of Treatment with Magnesium Sulfate

Magnesium sulfate has historical familiarity, but tocolytic efficacy is not supported by data. Magnesium may have a beneficial effect on the preterm newborn with respect to reducing the risk of cerebral palsy.

Cyclo-oxygenase Inhibitors

Prostaglandins are mediators of the final pathways of uterine muscle contraction. Prostaglandins cause an increase in free intracellular calcium levels in myometrial cells and increased activation of MLCK, resulting in uterine contractions. Myometrial gap junction formation, an important step in synchronized uterine activity, is enhanced by prostaglandins. Prostaglandins given to pregnant women can ripen the cervix or induce labor, depending on the dosage and route of administration. Prostaglandin synthase, also known as cyclo-oxygenase (COX), converts arachidonic acid to prostaglandin G_2. Prostaglandin synthesis is increased when the COX-2 form of this enzyme is induced by cytokines, bacterial products such as phospholipases and endotoxins, and corticosteroids, and reduced by inhibition of COX by nonsteroidal anti-inflammatory drugs (NSAIDs). The NSAID agents vary in their activity, potency, and side effect profile. Indomethacin is the NSAID most often used as a tocolytic. Indomethacin crosses the placenta. Unlike aspirin, indomethacin binds reversibly to COX, so that inhibition lasts only until the drug is cleared metabolically. Umbilical artery serum concentrations equal maternal levels within 6 hours of oral administration. The half-life in the mother is 4 to 5 hours, and in a full-term infant is 15 hours, but is significantly longer in preterm infants. The Cochrane Review concluded that indomethacin administration was associated with a significant reduction in births before the 37th week,

increased gestational age at birth, and increased birth weight.

Maternal Effects

Prostaglandin inhibition has multiple side effects because of the abundance of prostaglandin-mediated physiologic functions. Nevertheless, serious maternal side effects are uncommon when the agent is used in a brief course of tocolysis. As with any NSAID, gastrointestinal side effects such as nausea, heartburn, and vomiting are common but usually mild. Less common but more serious complications include gastrointestinal bleeding, prolonged bleeding time, thrombocytopenia, and asthma in aspirin-sensitive patients. Prolonged treatment with NSAIDs can lead to renal injury, especially when other nephrotoxic drugs are used. Hypertensive women may rarely experience acute increased blood pressure after indomethacin treatment. The antipyretic effect of an NSAID may obscure a clinically significant fever. Maternal contraindications to indomethacin tocolysis include renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, and platelet disorders.

Fetal and Neonatal Effects

In actual practice, serious complications to the fetus/newborn with maternal administration of indomethacin have been rare, but there is risk of injury to the fetus if treatment protocols are not followed carefully. Three principal side effects raise concern: (1) in utero constriction of the ductus arteriosus, (2) oligohydramnios, and (3) neonatal pulmonary hypertension. The ductal constriction occurs because formation of prostacyclin and PGE_2, which maintain ductal vasodilation, is inhibited by indomethacin. Doppler evidence of ductal constriction was found in 7 of 14 fetuses of women treated with indomethacin between 27 and 31 weeks of pregnancy, but resolved within 24 hours after the medication was discontinued. The likelihood of ductal constriction increased from 5% to 10% before 32 weeks to 50% after 48 hours of treatment at 32 to 35 weeks. Ductal constriction is usually transient and responds to discontinuation of the drug, but persistent ductal constriction and irreversible right-sided heart failure have been reported. A review of fetal echocardiographs obtained from 61 women treated with indomethacin for preterm labor found evidence of ductal constriction in 50% of fetuses. A larger study of 124 women given indomethacin for labor inhibition for more than 48 hours revealed a 6.5% frequency of in utero ductal narrowing. In both of these studies, the ductal narrowing reversed in all fetuses after cessation of medication.

Oligohydramnios associated with indomethacin tocolysis is due to reduced fetal urine production, which is caused by indomethacin-induced reduction of normal prostaglandin inhibition of antidiuretic hormone and by direct effects on fetal renal blood flow. Prolonged treatment with indomethacin incurs a 7% frequency of oligohydramnios. These effects are reversible, but neonatal renal insufficiency and death after several weeks of unmonitored antenatal maternal treatment has been reported.

Primary pulmonary hypertension in the neonate is a potentially fatal illness that has also been associated with prolonged (greater than 48 hours) indomethacin therapy. Primary neonatal pulmonary hypertension has not been reported with 24 to 48 hours of therapy, but the incidence may be as high as 5% to 10% with long-term therapy, although more modern series of longer-term use failed to identify an increased frequency of newborn pulmonary hypertension compared with untreated gestational age–matched controls.

Other complications, including NEC, small bowel perforation, PDA, jaundice, and IVH, have been observed when indomethacin administration was outside of standardized protocols that did not limit the duration of treatment or employed the drug after 32 weeks. No association with IVH was noted in studies in which standard protocols were used. A review of outcomes of 1621 fetuses treated in utero with indomethacin found no significant differences compared with 4387 infants not exposed.

Sulindac is an NSAID that has less placental transfer than indomethacin, but tocolytic efficacy has not been studied in large numbers. Because of the effect on fetal urine production and amniotic fluid volume, indomethacin may be an appropriate tocolytic when preterm labor is associated with polyhydramnios. Indomethacin has been used to treat preterm labor in women with polyhydramnios, and for polyhydramnios without labor. Uterine activity and pain associated with degenerating uterine fibroids in pregnancy also respond well to indomethacin.

Treatment Protocol

Indomethacin is well absorbed orally. The usual regimen is a 50-mg oral loading dose followed by 25 to 50 mg by mouth every 6 hours. Therapy is limited to 2 to 3 days because of concern about side effects described earlier.

Protocol for Indomethacin Tocolysis

1. Limit use to preterm labor before 32 weeks' gestation in women with normal amniotic fluid volume and normal renal function.
2. Loading dose is 50 mg by mouth.
3. Give 25 mg orally every 6 hours for 48 hours.
4. If the drug is used beyond 48 to 72 hours, amniotic fluid volume should be monitored serially with ultrasound and ductus arteriosus flow should be evaluated with Doppler echocardiography. If amniotic fluid is significantly reduced or the ductus is narrowed, the drug should be discontinued.
5. Discontinue therapy promptly if delivery seems imminent.
6. Fetal contraindications to use of indomethacin include renal anomalies, chorioamnionitis, oligohydramnios, ductal-dependent cardiac defects, and twin-twin transfusion syndrome.

Summary of Treatment with Indomethacin

Indomethacin is an effective tocolytic agent that is generally well tolerated by the mother. Concern about fetal side effects has appropriately limited use of indomethacin to brief courses of therapy in patients with preterm labor before 32 weeks.

β-Mimetic Tocolytics

β-Sympathomimetic drugs including terbutaline, ritodrine, and others have been widely used as tocolytics for many

years. Structurally related to epinephrine and norepinephrine, these agents act to relax smooth muscle, for example, in the bronchial tree, blood vessels, and myometrium, through stimulation of the β-receptors. β-Receptors are divided into β1- and β2-subtypes. The β1-receptors are largely responsible for the cardiac effects, whereas β2-receptors mediate smooth muscle relaxation, hepatic glycogen production, and islet cell release of insulin. Stimulation of β-receptors in the heart, vascular system, and liver accounts for the side effects of these drugs. The most commonly used β-mimetic in the United States is terbutaline (marketed as a drug for asthma), but others including albuterol, fenoterol, hexoprenaline, metaproterenol, nylidrin, orciprenaline, and salbutamol are used in other countries. Ritodrine was approved by the FDA as a parenteral tocolytic in 1980, but it did not achieve wide use because of frequent maternal side effects. Ritodrine is no longer marketed in the United States. Terbutaline has a rapid effect when given subcutaneously (3 to 5 minutes). Published protocols often employ subcutaneous administration, with a usual dose of 0.25 mg (250 mg) every 4 hours. A single subcutaneous dose of terbutaline to arrest contractions during the initial evaluation of preterm contractions may aid in the diagnosis of preterm labor. In one study, women whose contractions persisted or recurred after a single dose were more likely to have true preterm labor than those whose contractions ceased. The Cochrane Database reported an analysis of 1332 women enrolled into 11 randomized placebo-controlled trials of β-mimetic drugs found that treated subjects were less likely to deliver within 48 hours (RR 0.63, 95% CI 0.53 to 0.75), but not within 7 days. Although a 48-hour delay in delivery allows sufficient time for in utero transfer and treatment with steroids, perinatal and neonatal death, and perinatal morbidity were not reduced in this analysis. Side effects requiring change or cessation of treatment were frequent.

Side Effects and Complications of β-Mimetic Tocolysis

Maternal side effects of the β-mimetic drugs are common and diverse owing to the abundance of β-receptors in the body. Maternal tachycardia, chest discomfort, palpitation, tremor, headache, nasal congestion, nausea and vomiting, hyperkalemia and hyperglycemia are significantly more common in women treated with β-mimetics. Most are mild and of limited duration, but serious maternal cardiopulmonary and metabolic complications have been reported.

Cardiopulmonary Complications of β-Mimetics. The β-mimetic agents produce a 5 to 10 mm Hg fall in diastolic blood pressure, and the extensive peripheral vasodilatation makes it difficult to mount a normal response to hypovolemia. Signs of excessive blood loss (e.g., maternal and fetal tachycardia) are masked by β-mimetics, so their use may be dangerous in women with antepartum hemorrhage. The most important steps to prevent cardiac complications are (1) excluding patients with prior cardiac disease and (2) limiting infusion rates so that maternal pulse does not exceed 130 beats/minute. Symptomatic cardiac arrhythmias and myocardial ischemia have occurred during β-agonist tocolytic therapy. Tocolysis should be discontinued and oxygen administered whenever a patient develops chest pain during β-mimetic therapy. Arrhythmias noted in association with β-mimetic therapy usually respond to discontinuation of the drug and oxygen administration. Baseline or routine electrocardiograms before or during treatment are not helpful. An electrocardiogram is indicated if there is no response to oxygen and cessation of β-mimetic therapy. Pulmonary edema has been reported with β-mimetic therapy. Restricting the duration of treatment to less than 24 hours, careful attention to fluid status, and detection of complicating conditions such as intrauterine infection may reduce this risk.

Metabolic Complications. β-Mimetic agents induce transient hyperglycemia and hypokalemia during treatment. Measurement of glucose and potassium before initiating therapy, and on occasion during the first 24 hours of treatment, is appropriate to identify significant hyperglycemia (greater than 180 mg/dL) or hypokalemia (less than 2.5 mEq/L). These metabolic changes are mild and transient, but prolonged treatment beyond 24 hours may induce significant alterations in maternal blood sugar, insulin levels, and energy expenditure. The risk of abnormal glucose metabolism is further increased by simultaneous treatment with corticosteroids, a common combination for threatened preterm labor. Other agents should be chosen for women with pregestational diabetes, and usually for those with gestational diabetes as well. β-Mimetic treatment in these women requires frequent monitoring and insulin infusion to maintain euglycemia.

Neonatal Effects. Neonatal hypoglycemia, hypocalcemia, and ileus may follow treatment with β-mimetics, and can be clinically significant if the maternal infusion is not discontinued 2 hours or more before delivery. Long-term data on neurodevelopmental outcomes in humans are lacking.

Protocols for continuous subcutaneous infusion of terbutaline have been reported to have fewer side effects than oral administration, but have had no improvement on rates of preterm birth or perinatal morbidity in randomized placebo-controlled trials. Terbutaline has been the subject of an FDA warning: "terbutaline administered by injection or through an infusion pump should not be used in pregnant women for prevention or prolonged (beyond 48-72 hours) treatment of preterm labor due to the potential for serious maternal heart problems and death. In addition, oral terbutaline tablets should not be used for prevention or treatment of preterm labor."[49] No placebo-controlled trials demonstrating effectiveness have been reported since the FDA advisory was issued.

Given their potential for clinically significant side effects and the availability of alternative choices, the β-sympathomimetic agents should not be used in women with known or suspected heart disease, severe preeclampsia or eclampsia, pregestational gestational diabetes requiring insulin, or hyperthyroidism. These drugs are contraindicated when suspected preterm labor is complicated by maternal fever, fetal tachycardia, leukocytosis, or other signs of possible chorioamnionitis.

Summary of Treatment with β-Mimetic Tocolysis

β-Mimetic drugs were once among the most commonly used tocolytics but have been replaced by agents with

better safety and side effect profiles. Terbutaline has relatively few serious side effects when used as a single subcutaneous injection of 0.25 mg to facilitate maternal transfer or to initiate tocolysis, while another agent with a slower onset of action is being given. Long-term oral or subcutaneous treatment has not been shown in controlled trials to reduce prematurity or neonatal morbidity.

Other Tocolytic Agents

Atosiban is a selective oxytocin-vasopressin receptor antagonist. Although commonly used in Europe, it is not available in the United States. In normal parturition, oxytocin stimulates contractions by inducing conversion of phosphatidylinositol to inositol triphosphate, which binds to a protein in the sarcoplasmic reticulum causing release of calcium into the cytoplasm. A Cochrane review analyzed six randomized trials (n = 1695 women) comparing the oxytocin receptor antagonist atosiban to placebo. Use of atosiban increased the risk of birth within 48 hours of initiation of treatment (RR 2.50, 95% CI 0.51 to 12.35), increased the risk of PTB at less than 28 weeks of gestation (RR 2.25, 95% CI 0.80 to 6.35), and increased the risk of PTB at less than 37 weeks (RR 1.17, 95% CI 0.99 to 1.37); however, none of these increases reached statistical significance. All neonatal morbidity and mortality outcomes evaluated were similar in both groups. There was, however, an imbalance in allocation of women with threatened PTL under 26 weeks such that significantly more women in this subgroup were allocated to the atosiban group. In addition, more women in the placebo group than the atosiban group received rescue treatment, which may have confounded the estimate of the true effects of atosiban when compared to placebo. The use of rescue tocolytics complicated analysis of these trials, since the criteria for switching therapies was not strictly defined. Last, the trial protocol did not define how glucocorticoids should be used, which resulted in a great deal of variation in use among study sites. The FDA declined to approve the use of atosiban for tocolysis because of concerns about the drug's safety when used in fetuses of less than 28 weeks' gestation.[50]

Nitric oxide donors also promote myometrial relaxation. Meta-analysis of trials comparing NO donors to other agents support the notion that NO donors do not delay delivery or improve neonatal outcome when compared with placebo, no treatment, or alternative tocolytics such as ritodrine, albuterol, and magnesium sulfate. There was, however, a reduction in number of deliveries less than 37 weeks when compared with alternative tocolytics, but the numbers of deliveries before 32 and 34 weeks were not influenced. Side effects (other than headache) were reduced in women who received nitric oxide donors rather than other tocolytics. However, women were significantly more likely to experience headache when NO donors had been used.

Clinical Use of Tocolytic Drugs

Tocolytic therapy is employed in several clinical circumstances. In a patient who is in active labor with advanced cervical effacement, the diagnosis is not in question and the goal is prompt treatment to allow maternal transfer and time for steroids and GBS prophylaxis. In this setting, initial treatment with oral indomethacin or oral nifedipine may be the best choice to stop contractions promptly. Treatment for preterm labor may be continued until contractions have stopped or occur less frequently than four times per hour without additional cervical change, or until a full course of steroid therapy is completed (48 hours).

Persistent Contractions

If contractions persist despite therapy, the wisdom of tocolytic treatment should be reevaluated. The cervix should be reexamined; if cervical dilation has progressed beyond 4 cm, and imminent delivery is thought to be inevitable, tocolytic therapy in most cases should be discontinued. In the setting of progressive preterm labor despite labor inhibition, it is critical to acknowledge the higher probability of placental abruption and/or subclinical chorioamnionitis. Clinical evaluation with focused history, physical examination, and laboratory assessment should be used to address the probability of these conditions.

Some women will have persistent uterine contractions and may exhibit a "nonthreatening" cervical examination that does not change over serial examinations. If a fibronectin swab was collected before therapy was begun, it should be sent for analysis. A positive result is not confirmatory, but a negative fibronectin, if collected before performance of a digital examination, suggests that the risk of imminent delivery is low. Alternatively, a transvaginal cervical ultrasound examination may be performed. A length of 30 mm or more substantially reduces the likelihood of imminent delivery.

Serum levels are not clinically helpful to adjust the dose of tocolytics. A change to a second agent, or combination therapy with multiple agents, may slow contractions but may result in increased risks. Combined use of β-mimetics or magnesium sulfate with calcium channel blockers should also be avoided (see the accompanying box, Management of Persistent Contractions Despite 12 to 24 Hours of Tocolysis).

Management of Persistent Contractions Despite 12 to 24 Hours of Tocolysis

1. Is subclinical amniotic fluid infection present? Repeat clinical examination, white blood cell counts, and fetal assessment. Consider amniocentesis for glucose, Gram stain, leukocyte esterase, and culture.
2. Is the fetus compromised? Review the fetal heart tracings and, if needed, do a biophysical assessment.
3. Is there evidence of abruption? Is there a suspicion of uterine anomaly with implantation of the placenta on the septum? Evaluate vitals signs for evidence of hemodynamic response to blood loss and repeat hemoglobin, hematocrit, and fibrinogen, and abdominal sonography for placental implantation site.
4. Is the diagnosis of preterm labor correct? Is the cervix changing? Do a transvaginal cervical ultrasound to measure cervical length. Send a fibronectin swab.
5. If infection, fetal compromise, and abruption can be excluded, stop parenteral tocolysis for 24 hours and observe. Most patients will stop contractions spontaneously.

Care After Acute Treatment for Preterm Labor

Maintenance Tocolytic Treatment

Continued suppression of contractions after acute tocolysis does not reduce the rate of preterm birth. Meta-analyses of these data also find no evidence of prolongation of pregnancy or decline in the frequency of preterm birth.

Posthospitalization surveillance with outpatient monitoring of uterine contractions did not improve the rate of delivery before 37 weeks, birth weight, or gestational age at delivery in any of three randomized trials or in a meta-analysis of these. A multicenter randomized trial in which uterine activity was monitored, but in which the data were masked from care providers in one group, also found no improvement in preterm birth rate when contraction data were used.

The duration of hospitalization for an episode of preterm labor varies according to several factors, including the examination of the cervix, ease of tocolysis, gestational age, obstetrical history, distance from hospital, and the availability of home and family support. Associated risk factors that may complicate or increase the risk of recurrent preterm labor, such as a positive genital culture for chlamydia or gonorrhea, urinary tract infection, and anemia, should be addressed before discharge from hospital care. Social issues such as homelessness, availability of child care, or protection from an abusive partner are important determinants of a patient's ability to adhere to recommendations for medical care, and these issues must be considered before the patient is discharged from the hospital.

CONDUCT OF LABOR AND DELIVERY FOR THE PRETERM INFANT

Intrapartum care for women in labor before term is often complicated by conditions such as malpresentation, hypertension, amnionitis, abruption, oligohydramnios, or fetal growth restriction that increase the chance of intrapartum fetal compromise. When labor is induced preterm for maternal or fetal indications, the lower uterine segment and cervix may not be well prepared for labor, leading to a prolonged latent phase.

Intrapartum Assessment of the Preterm Fetus

Intrapatrum fetal surveillance has been associated with significantly lower frequency of intrapartum death and neonatal seizures for preterm infants. Ominous heart rate tracings in preterm fetuses have the same associations with fetal acidosis as they do later in gestation. Mean fetal heart rate falls continuously, from 160 beats/minute at 22 weeks' gestation, to 140 beats/minute at term due to a gradual increase in parasympathetic tone. Fetal heart rate patterns should be considered as representative of well-being in the preterm fetus as they are at term.

Labor and Delivery

The duration of labor in preterm gestation may be shorter than that of term pregnancy. The active phase of the first stage and the second stage may be particularly brief. Care should be taken to ensure that the fetus does not have a precipitous delivery without control of the fetal head. There is no benefit for prophylactic forceps to "protect" the fetal head. The neonatal care team should be alerted to the circumstances of a preterm birth well in advance of the delivery so that appropriate personnel and equipment are available.

Cesarean Delivery

Routine cesarean delivery of all preterm or VLBW infants is not justified. Trends favoring cesarean section disappear after adjustment for confounding factors. A review of studies of neonatal and maternal morbidities after vaginal versus cesarean delivery for infants born between 24 and 36 weeks found increased maternal morbidity without clear benefit for the infant. Neonatal intracranial hemorrhage occurs as often before and after labor as it does during labor and delivery.

For infants in breech presentation, there are intuitive reasons for cesarean birth, particularly to avoid entrapment of the after-coming head and other manipulations that could lead to trauma or hypoxia. Older retrospective studies that suggested a benefit for cesarean delivery led to the current custom of cesarean delivery for preterm breech fetuses, but data in support for this practice are weak. It is illogical to perform a cesarean to avoid a traumatic vaginal delivery only to encounter a difficult cesarean birth because of an inadequate abdominal or uterine incision. The operation should be conducted to minimize the trauma of delivery through as roomy an incision as necessary. In a study of delivery mode for "high-risk" VLBW infants (e.g., preeclampsia, vaginal bleeding, abnormal heart rate tracing) versus "low-risk" VLBW infants (e.g., preterm labor, incompetent cervix), cesarean section was of no value in the low-risk group, but was associated with significantly improved survival rates in the high-risk group. Considering these factors, optimal delivery of the VLBW fetus may at times appropriately lead to a decision to perform a cesarean without labor. Generally speaking, the appropriate mode of delivery for the preterm fetus ought to be based on similar standards of obstetrical indications as at term.

PREVENTION OF PRETERM BIRTH

Care of preterm birth may be described according to the public health model as *tertiary* (treatment initiated after the parturitional process has begun to limit perinatal morbidity and mortality), *secondary* (identification and treatment for individuals with increased risk), or *primary* (prevention and reduction of risk in the population). Tertiary care described in the preceding section of this chapter has improved perinatal outcomes, but has no effect on the incidence of preterm birth. Efforts to identify women likely to deliver preterm to reduce or eliminate their risk have not achieved high sensitivity, and until recently, there were no effective interventions to reduce risk.

Prevention efforts aimed at risk factors have been undertaken with the expectation that preterm birth would decline in proportion to the contribution of that risk factor as a cause of preterm birth. The failure of this approach underlies the current understanding of preterm birth as a syndrome in which multiple factors, known and unknown, contribute to the initiation and progression of preterm parturition. Rather than a distinct entity for which there are

specific tests, preterm birth is more appropriately considered as the result of various pathologic events that affect the timing and progress of parturition. Understanding maternal risk factors, symptoms, and tests as clues to steps in a parturitional sequence that may or may not progress to early delivery, rather than "tests for preterm labor," brings some clarity to the sometimes confusing literature on this subject.

Secondary Prevention of Preterm Birth

Identification and elimination or reduction of risk may be applied before and/or after conception.

Before Pregnancy

Prepregnancy medical risk factors occur in as many as 40% of preterm births, but preconceptional medical interventions to reduce preterm birth in these women have been disappointing. A history of second trimester loss or preterm birth is most easily identified,[3,51] recalling that the risk increases as the gestational age of the previous preterm birth declines and as the number of preterm births increases. Preconceptional interventions include surgical correction of müllerian anomalies and preconceptional abdominal cerclage. A randomized trial in 1579 women of interconceptional home visits and counseling to reduce low birth weight and preterm birth reported no evidence of benefit. Another randomized placebo-controlled trial tested interconceptional antimicrobial treatment in women with a prior early preterm birth. Subjects were randomly assigned to receive metronidazole and azithromycin or placebo at 3-month intervals between pregnancies, but the recurrence risk of preterm birth was not improved.

During Pregnancy

Postconceptional prevention strategies have most often been studied in women with a prior preterm birth, with a major risk factor such as multifetal gestation or bleeding, and/or in women with a sign, symptom, or positive screening test indicating increased risk. Previous editions of this text have decried the absence of any effective interventions, but recent studies have demonstrated reduced risk in selected populations, for example, women with a prior preterm birth and with short cervix.

Modification of Maternal Activity

Despite a lack of supporting evidence, bed rest, limited work, and reduced sexual activity are often recommended to reduce the risk of preterm birth in pregnancies at risk for indicated and spontaneous births. Yost and colleagues found no relationship between coitus and risk of recurrent preterm birth.

Nutritional Supplements

Supplemental use of omega-3 polyunsaturated fatty acids (PUFA) has been recommended because populations with a high dietary intake have low rates of preterm birth, perhaps because omega-3 PUFAs reduce levels of pro-inflammatory cytokines. European trials of omega-3 supplements and supplemental fish oil found significant reductions preterm birth, but a placebo-controlled U.S. trial of supplemental omega-3 polyunsaturated fatty acids in women with a prior preterm birth found no benefit in women who were treated with 17 hydroxy-progesterone caproate.[52] Interestingly, women in both arms of this study who consumed more than one fish meal per month had a significantly lower rate of preterm birth than those who consumed fish once per month or less. Trials of supplemental vitamins C and E and calcium also did not reduce preterm birth risk.[53]

Enhanced Prenatal Care

Although perhaps helpful in adolescents, programs of enhanced prenatal care providing social support, home visits, and education have not reduced preterm birth. Frequent provider-initiated contact for women with a prior preterm birth also did not decrease recurrent preterm birth in randomized trials.

However, reduced rates of preterm birth have been reported for women receiving prenatal care in novel settings: Group prenatal care in Connecticut, a regional program to standardize care for an indigent population in Texas,[54] and a specialized prematurity clinic in Utah for women with a prior preterm birth have all reported lower rates of premature birth, but all are retrospective and merit confirmation.

Periodontal Care

The association of periodontal disease with increased risk of prematurity prompted intensive study of the effects of periodontal care on the rate of preterm birth. Results have been negative, suggesting shared susceptibility rather than a causal linkage.

Antibiotic Treatment

Screening and antibiotic treatment of women with abnormal genital flora has been largely ineffective to prevent preterm birth. Antibiotic treatment for women with a prior preterm birth who have bacterial vaginosis was associated with reduced risk of recurrent preterm birth in secondary analyses. Reviews and meta-analyses have also been negative, and a U.S. Preventive Services Task Force review[55] cautioned that there may be "unintended potential for harm" from screening and treatment for bacterial vaginosis in pregnancy. Antibiotic prophylaxis has also been studied in women with positive fetal fibronectin test results. Rates of preterm birth were actually increased in fibronectin-positive women who received antibiotic treatment. Similar results were reported from a trial of antibiotics in women with *Trichomonas*.

Progesterone

Progesterone supplementation for women at risk for preterm birth has been investigated based on several plausible mechanisms of action, including reduced gap junction formation and oxytocin antagonism leading to relaxation of smooth muscle, maintenance of cervical integrity, and anti-inflammatory effects. Studies performed before 1990 in women with recurrent miscarriage and preterm birth were reviewed by Keirse, who found "no support for the view that 17 alpha-hydroxy-progesterone caproate protects against miscarriage, but suggests that it does reduce the occurrence of preterm birth."[56] **Subsequent randomized trials have demonstrated an approximately 40% decrease in the rate of preterm birth in women**

TABLE 28-4 STUDIES OF PROGESTERONE TO REDUCE PRETERM BIRTH

AUTHOR	YEAR	POPULATION	EFFECT ON PTB RATE

with a prior preterm birth and/or short cervix (below 15 to 20 mm before 24 weeks' gestation) who were treated with either intramuscular 17 alpha-hydroxy-progesterone caproate 250 mg weekly, or with vaginal progesterone suppositories or cream daily between 16 and 36 weeks' gestation (Table 28-4).[14-16,18,57,58]

Several randomized placebo-controlled trials have found that progesterone supplementation does not affect the rate of preterm birth in women with multifetal gestations, indicating that the mechanism of progesterone's action to reduce risk of preterm birth in singletons is not related to uterine stretch.[59-62]

Importantly, the effect of supplemental progesterone compounds is not universally observed in women with a prior preterm birth, indicating first that some pathways to recurrent preterm birth are not influenced by this therapy, and also that many women with a preterm birth will deliver at term without treatment. The recurrence risk of spontaneous preterm birth without treatment is related to cervical length at 22 to 24 weeks, ranging from more than 35% in women whose cervical length is below 25 mm, to 15% in women with cervical lengths 25 to 35 mm, and to less than 10% in those with a cervical length above 35 mm. In the only study of women with a previous preterm birth in which supplemental progesterone did not reduce the risk of recurrent preterm birth,[16] the mean cervical length at 18 to 22 weeks' gestation was 37 mm, suggesting that women with a prior preterm birth who do not also have a short cervix will not benefit from progesterone supplementation. Indeed, a secondary analysis of this study found a reduced risk of preterm birth in women who later had short cervix.[14] Taken together, these studies indicate that *short cervix* rather than *prior preterm birth* is the most appropriate criterion for institution of progesterone therapy. However, a history of preterm birth will continue to be an indication for progesterone treatment until additional studies demonstrate that such treatment is unnecessary in women with a prior preterm birth who maintain a normal cervical length beyond 24 weeks' gestation.

Trials of progesterone in women with other risk factors, for example, a positive fetal fibronectin or bleeding, have not been reported. The mechanism of action is uncertain, but the absence of effect in multifetal gestation coupled with reductions in preterm birth in women with short cervix suggest that the pathway may be related primarily to modulation of cervical softening, a conclusion also suggested by basic studies.

The optimal strategy to identify candidates for progesterone therapy has not been determined. Universal cervical length screening of all pregnant women at 18 to 24 weeks has been proposed based on two favorable cost-effectiveness studies[63,64] and expert opinion,[65] but universal application of any screening test in obstetrical care is always accompanied by unanticipated costs and consequences, in this case likely related to reproducibility of cervical sonography and uncertain adherence to recommended treatment protocols.

An alternative list of indications for selective screening for short cervix with transvaginal ultrasound is shown in the accompanying box, Indications for Cervical Ultrasound Screening in the Second Trimester. These women are candidates for screening with the expectation that progesterone supplementation will be considered if the cervical length measurement at 16 to 24 weeks is 20 mm or less. The value and timing of repeat cervical ultrasound in women with marginal cervical length measurements is uncertain. The schema suggested is likely to be modified by broader experience with cervical sonographic screening.

INDICATIONS FOR CERVICAL ULTRASOUND SCREENING IN THE SECOND TRIMESTER

- Any previous pregnancy delivered between 16 and 36 weeks' gestation
- All pregnancies conceived after fertility care
- All women with a history of cervical instrumentation
  - Cervical cone biopsy or LEEP
  - Dilation and curettage for diagnosis or therapeutic indications, including first- and second-trimester pregnancy terminations
- All women with prior genital tract infections or persistently abnormal Pap smear
- All African Americans
- All women with depression, low body mass index (<19.6), or who smoke
- All women whose cervical length is <30 mm on a midtrimester transabdominal ultrasound examination
  - Women with signs or symptoms of preterm parturition in the current pregnancy
    - Vaginal bleeding or spotting without obvious cause
    - Persistent symptoms of pelvic pressure, cramps, change in vaginal discharge after 16 weeks' gestation

CERVICAL CERCLAGE

The link between short cervix and risk of preterm birth was initially interpreted as evidence of diminished cervical strength or competence, but subsequent clinical experience and interventional studies do not support that conclusion. Cerclage is not a uniformly effective treatment for short cervix. Although beneficial for women with a prior preterm birth whose cervical length is very short (less than 15 to 25 mm),[66,67] cerclage treatment does not reduce preterm birth risk in women with short cervix (less than 15 mm) without a history of preterm birth,[68] and actually appears to increase the risk of preterm birth in women with twins

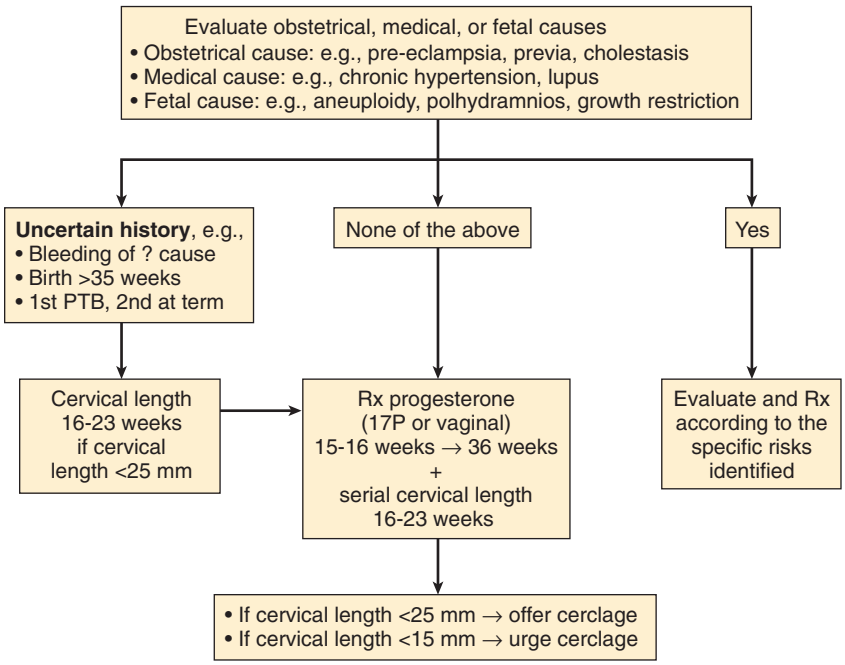

FIGURE 28-9. Care algorithm for women with a prior preterm birth at 16 to 36 weeks' gestation.

and short cervix.[68,69] In women with a prior preterm birth, cerclage is paradoxically most beneficial in women with the shortest cervical length (less than 15 mm),[66,67] suggesting that the benefit of cerclage may relate more to protection of exposed membranes than to bolstering cervical strength.

Clinical Use of Progesterone and Cerclage to Prevent Preterm Birth

The increasing evidence that progesterone is effective in reducing the risk of preterm birth in women with short cervix with or without a history of preterm birth has influenced the clinical care of women who would previously have been considered to be candidates for prophylactic cervical cerclage. Similarly, results from the NICHD Vaginal Ultrasound Cerclage Trial[66] indicate that only 30% of the more than 1000 women with a history of a preterm birth between 17 and 34 weeks displayed a cervical length of 25 mm or less before 24 weeks when followed with cervical sonography. These observations led to development of the protocol displayed in Figure 28-9 used in our clinic.[70] Cerclage is reserved for women with a history of cervical injury, uterine anomaly, and/or progressive cervical shortening to a length below 25 mm despite progesterone therapy. In these patients, cerclage is offered at 25 mm, and strongly urged if the cervical length is 15 mm or below, or membranes are visible.

Late Preterm Birth

In 2008, 12.3% of births in the United States were preterm, and 71% of these (8.8%) were *late preterm*, occurring between $34^{0/7}$ and $36^{6/7}$ weeks' gestation. Though these infants fare better than those born before 34 weeks' gestation, they experience substantially increased morbidity and mortality compared to infants born after 37 weeks' gestation and account for the overwhelming majority of admissions to neonatal intensive care. Approximately 70% of preterm births are spontaneous, but the relative percentage has declined in recent years as indicated preterm births have increased. **The rise in preterm births between 1990 and 2006 in singletons was almost entirely explained by an increased rate of indicated preterm births between 34 and 36 weeks' gestation. The principal driver of this increase was an increased willingness to consider scheduled birth as a safer option than continuing the pregnancy in women with various pregnancy complications. The rise in late preterm indicated preterm births was accompanied by a corresponding decrease in the rate of fetal deaths after 28 weeks, and a decline in overall perinatal mortality.** Figure 28-10 displays these trends, but does not show the effects of the increase in indicated preterm births on the number and rate of late preterm infants admitted to neonatal intensive care.

The decision to choose indicated preterm birth over continuation of the pregnancy at any gestational age carries great potential to create as well as to prevent or reduce perinatal morbidity and mortality. Unfortunately, the relative risks and benefits of delivery versus expectant management are difficult to weigh accurately, especially in the late preterm period. Before 34 weeks' gestation, there is clear benefit to be gained by daily increases in fetal maturity. At 34 weeks, the risks of immaturity have been considered to be acceptable in complicated pregnancies, but the

morbidity and mortality rates for infants born between 34 and 37 weeks are higher than previously realized. Reddy and colleagues[71] examined the records of 292,627 late preterm singleton births and found that 49% were associated with spontaneous labor. Remarkably, no reason was recorded in 23% of late preterm births. In another study, 7.8% of all births and 65.7% of preterm births were late preterm. Of these, 29.8% followed spontaneous labor; 32.3% followed preterm PROM; 31.8% had an obstetrical, maternal, or fetal condition leading to late preterm birth following induction of labor or cesarean section in the absence of labor; and 6.1% were unknown.[72] Specific guidelines for choosing late preterm birth in complicated pregnancies are lacking, but recent efforts to document the reasons and track the risks and benefits of these births are expected to help in the future (Table 28-5).[73]

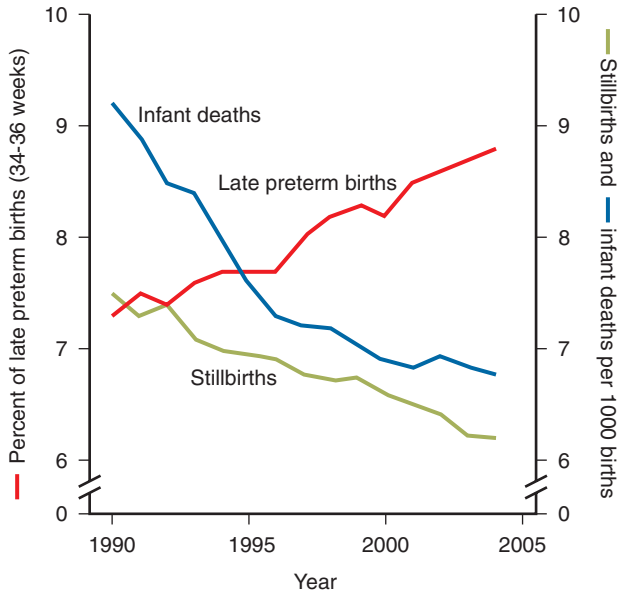

FIGURE 28-10. Trends in late preterm birth, stillbirth, and infant mortality, United States, 1990-2004. (From Ananth CV, Gyamfi C, Jain L: Characterizing risk profiles of infants who are delivered at late preterm gestations: does it matter? Am J Obstet Gynecol 199:329, 2008.)

Primary Prevention of Preterm Birth

Primary prevention strategies for preterm birth will require consistent efforts through education and public policy because the public and government currently underestimate the magnitude of the societal burden. Preconceptional interventions are needed because as many as 50% of preterm births occur in women without known risk factors.

Public Educational Interventions

Greater awareness of the increased risk of preterm birth in singleton gestations associated with assisted reproductive technology could affect attitudes and choices made in fertility care. Similar strategies to reduce the prevalence of smoking, use condoms to prevent sexually transmitted infections, and promote recognition and early treatment of depression might all have an eventual effect on preterm birth rates. Promotion of long-acting reversible contraceptives for women at risk, especially after a preterm delivery, offers a chance to reduce the risk of recurrent preterm birth.

TABLE 28-5 GUIDANCE REGARDING TIMING OF DELIVERY WHEN CONDITIONS COMPLICATE PREGNANCY AT 34 WEEKS OF GESTATION OR LATER

CONDITION	GESTATIONAL AGE* AT DELIVERY	GRADE OF RECOMMENDATION†
Placental and Uterine Issues		
Placenta previa‡	**36-37 wk**	B
Suspected placenta accrete, increta, or percreta with placenta previa‡	**34-35 wk**	B
Prior classical cesarean (upper segment uterine incision)‡	**36-37 wk**	B
Prior myomectomy necessitating cesarean delivery‡	**37-38 wk** (may require earlier delivery, similar to prior classical cesarean, in situations with more extensive or complicated myomectomy)	B
Fetal Issues		
Fetal growth restriction—singleton	**38-39 wk:**	
	Otherwise uncomplicated, no concurrent findings	B
	34-37 wk:	
	Concurrent conditions (oligohydramnios, abnormal Doppler studies, maternal risk factors, comorbidity)	B
	Expeditious delivery regardless of gestational age:	
	Persistent abnormal fetal surveillance suggesting imminent fetal jeopardy	
Fetal growth restriction—twin gestation	**36-37 wk:**	
	Dichorionic-diamniotic twins with isolated fetal growth restriction	B
	32-34 wk:	
	Monochorionic-diamniotic twins with isolated fetal growth restriction	B
	Concurrent conditions (oligohydramnios, abnormal Doppler studies, maternal risk factors, comorbidity)	B
	Expeditious delivery regardless of gestational age:	
	Persistent abnormal fetal surveillance suggesting imminent fetal jeopardy	

Public and Professional Policies

Policies promulgated by fertility specialists intended to reduce the risk of higher-order multiple gestation have been successful in Europe, Australia, and the United States. Rates of triplet and higher-order multiple pregnancies had been rising rapidly in the United States until 1998, when the increase was arrested by voluntary adoption of limitations on the number of ova transferred. The rate of higher-order multiples fell by 50% between 1996 and 2003. A societal approach to improve pregnancy

TABLE 28-5 GUIDANCE REGARDING TIMING OF DELIVERY WHEN CONDITIONS COMPLICATE PREGNANCY AT 34 WEEKS OF GESTATION OR LATER—cont'd

CONDITION	GESTATIONAL AGE* AT DELIVERY	GRADE OF RECOMMENDATION†
Fetal congenital malformations‡	**34-39 wk:** Suspected worsening of fetal organ damage Potential for fetal intracranial hemorrhage (e.g., vein of Galen aneurysm, neonatal alloimmune thrombocytopenia) When delivery prior to labor is preferred (e.g., EXIT procedure) Previous fetal intervention Concurrent maternal disease (e.g., preeclampsia, chronic hypertension) Potential for adverse maternal effect from fetal condition	B
	Expeditious delivery regardless of gestational age: When intervention is expected to be beneficial Fetal complications develop (abnormal fetal surveillance, new-onset hydrops fetalis, progressive or new-onset organ injury) Maternal complications develop (mirror syndrome)	B
Multiple gestations: dichorionic-diamniotic‡	**38 wk**	B
Multiple gestations: monochorionic-diamniotic‡	**34-37 wk**	B
Multiple gestations: dichorionic-diamniotic or monochorionic-diamniotic with single fetal death‡	If occurs at or after 34 wk, consider delivery (recommendation limited to pregnancies at or after 34 wk; if occurs before 34 wk, individualize based on concurrent maternal or fetal conditions)	B
Multiple gestations: monochorionic-monoamniotic‡	**32-34 wk**	B
Multiple gestations: monochorionic-monoamniotic with single fetal death‡	Consider delivery; individualized according to gestational age and concurrent complications	B
Oligohydramnios—isolated and presistent‡	**36-37 wk**	B
Maternal Issues		
Chronic hypertension—no medications‡	**38-39 wk**	B
Chronic hypertension—controlled on medication‡	**37-39 wk**	B
Chronic hypertension—difficult to control (requiring frequent medication adjustments)‡	**36-37 wk**	B
Gestational hypertension§	**37-38 wk**	B
Preeclampsia—severe‡	At diagnosis (recommendation limited to pregnancies at or after 34 wk)	C
Preeclampsia—mild‡	**37 wk**	B
Diabetes—pregestational, well controlled‡	LPTB or ETB not recommended	B
Diabetes—pregestational, with vascular disease‡	**37-39 wk**	B
Diabetes—pregestational, poorly controlled‡	**34-39 wk** (individualized to situation)	B
Diabetes—gestational, well controlled on diet‡	LPTB or ETB not recommended	B
Diabetes—gestational, well controlled on medication‡	LPTB or ETB not recommended	B
Diabetes—gestational, poorly controlled on medication‡	**34-39 wk** (individualized to situation)	B
Obstetrical Issues		
Prior stillbirth—unexplained‡	LPTB or ETB not recommended	B
	Consider amniocentesis for fetal pulmonary maturity if delivery planned at less than 39 wk	C
Spontaneous preterm birth: preterm premature rupture of membranes‡	**34 wk** (recommendation limited to pregnancies at or after 34 wk)	B
Spontaneous preterm birth: active preterm labor‡	Delivery if progressive labor or additional maternal or fetal indication	B

From Spong CY, Mercer BM, D'Alton M, et al: Timing of indicated late-preterm and early-term birth. Obstet Gynecol 118(2 Pt 1):323, 2011.

*Gestational age is in completed weeks; thus, 34 weeks includes $34^{0/7}$ weeks through $34^{6/7}$ weeks.

†Grade of recommendation is based on the following: recommendations or conclusions or both are based on good and consistent scientific evidence (A); limited or inconsistent scientific evidence (B); primarily consensus and expert opinion (C). The recommendations regarding expeditious delivery for imminent fetal jeopardy were not given a grade. The recommendation regarding severe preeclampsia is based largely on expert opinion; however, higher-level evidence is not likely to be forthcoming because this condition is believed to carry significant maternal risk with limited potential fetal benefit from expectant management after 34 weeks.

‡Uncomplicated, thus no fetal growth restriction, superimposed preeclampsia, etc. If these are present, the complicating conditions take precedence and earlier delivery may be indicated

§Maintenance antihypertensive therapy should not be used to treat gestational hypertension.

ETB, Early-term birth at $37^{0/7}$ weeks through $38^{6/7}$ weeks; *LPTB*, late-preterm birth at $34^{0/7}$ weeks through $36^{6/7}$ weeks.

outcomes has been adopted in most European countries, where policies to protect pregnant women include minimum paid pregnancy leave, time off for prenatal visits, exemption from night shifts, and protection from workplace hazards. The Europop Study (European Programme of Occupational Risks and Pregnancy Outcome) of such policies found that risk of preterm birth was increased among women who worked more than 42 hours per week (OR 1.33, CI 1.1 to 1.6) and who were required to stand for more than 6 hours per day (OR 1.26, CI 1.1 to 1.5).

Social Determinants of Health

Racial disparities in health are not confined to perinatal medicine but rather are reflected throughout the life span. The increased rates of many illnesses in African Americans and other disadvantaged groups are being addressed by the public health community through the social determinants of health: promotion of school attendance and completion, food security, neighborhood nutritional programs, job fairs, and an increasing role for hospital and health providers as local leaders.[74]

SUMMARY

Preterm birth is a syndrome, the final result of several pathways that often overlap to initiate parturition. Obstetrical interventions to reduce infant morbidity such as antenatal glucocorticoids and antibiotics for group B streptococcal prophylaxis are effective tertiary therapies but have no opportunity to reduce the incidence of preterm birth. Detection of pregnancies at risk through careful review of prior pregnancies and selective or universal use of cervical ultrasound screening to identify candidates for progesterone therapy and selective use of cerclage are welcome advances. Adherence to protocols for timing of scheduled births and documentation of indications for iatrogenic preterm birth are needed to further reduce the rate of stillbirth while limiting the associated morbidity of late preterm birth.

KEY POINTS

- More than 70% of fetal, neonatal, and infant morbidity and mortality occurs in infants born preterm.
- The rate of preterm birth peaked in 2006 as the result of the increased use of assisted reproductive technology, ultrasound dating, and indicated preterm births. It has since declined largely because of the adoption of fertility practices to reduce multifetal gestations associated with infertility treatment.
- Major risk factors for preterm birth are a history of previous preterm delivery, multifetal gestation, and bleeding after the first trimester of pregnancy, but most women who deliver preterm have no apparent risk factors. Every pregnancy is potentially at risk.
- Spontaneous preterm birth is a syndrome in which the parturitional process may be initiated by one or more pathways culminating in cervical ripening, decidual activation, uterine contractions, and ruptured membranes.
- Four interventions have been shown to reduce perinatal morbidity and mortality:
  - Transfer of the mother and fetus to an appropriate hospital before preterm birth.
  - Administration of maternal antibiotics to prevent neonatal GBS infection.
  - Administration of maternal corticosteroids to reduce neonatal RDS and intraventricular hemorrhage, and neonatal mortality.
  - Administration of maternal magnesium sulfate at the time of preterm birth <32 weeks to reduce the incidence of cerebral palsy
- The risk of recurrent preterm birth may be reduced in women with a prior preterm birth and/or a short cervix <20 mm by administration of prophylactic supplemental progesterone, and by selective use of cervical cerclage.

Membrane rupture that occurs spontaneously before the onset of labor is described as premature rupture of the membranes (PROM) regardless of the gestational age at which it occurs. PROM complicates about 8% to 10% of pregnancies. Birth certificate data suggest that preterm PROM, occurring before 37 weeks' gestation, complicates about 1% of deliveries overall and is twofold more common in African Americans.[1] Like preterm labor and cervical insufficiency, PROM is considered a cause of "spontaneous preterm birth." The relative contribution of PROM to prematurity appears to vary greatly among patient populations, affecting about 10% of preterm births in national databases but 28% in certain high-risk populations, and its frequency appears to have declined during the past decade.[1,2]

PROM at any gestational age is associated with brief latency from membrane rupture to delivery and also increased risks for perinatal infection and umbilical cord compression due to oligohydramnios. Because of this, term and preterm PROM are significant causes of perinatal morbidity and mortality. When PROM occurs at term, there is a low risk for severe neonatal complications with delivery of a noninfected and nonasphyxiated infant. Clinical management should be directed toward delivery. Although complications can occur, delivery at 32 to 36 weeks' gestation is generally associated with good infant outcomes, particularly if the fetus has documented pulmonary maturity. Given the risks of continued pregnancy and anticipated brief latency, delivery of the mature fetus is generally warranted, particularly at 34 weeks' gestation or later. At 32 to 33 weeks' gestation, the immature fetus may benefit from measures to continue the pregnancy and to accelerate fetal maturation. With immediate delivery after preterm PROM at 23 to 31 weeks' gestation, there is a significant risk for newborn complications that can be reduced through delay of delivery. In the absence of contraindications, management is directed toward continuing the pregnancy, with attention to potential risks for umbilical cord compression, intrauterine infection, and abruptio placentae. When PROM occurs before the limit of viability, newborn death is inevitable with immediate delivery. Although conservative management can still lead to previable delivery, some women will benefit from extended latency with delivery

of a potentially viable infant. Regardless of the gestational age, the patient should be well informed regarding the potential maternal, fetal, and neonatal complications of PROM and preterm birth. These issues are discussed in detail in this chapter.

FETAL MEMBRANE ANATOMY AND PHYSIOLOGY

The fetus develops within the amniotic sac, which is surrounded like a balloon by the fetal membranes. These membranes consist of a thin amnion layer lining the amniotic cavity and a thicker outer chorion that is directly apposed to maternal decidua. The amnion fuses to the chorion near the end of the first trimester of pregnancy, and these layers are subsequently attached by a collagen-rich connective tissue zone. For the remainder of the pregnancy, the fetal membranes include a single cuboidal amnion epithelium with subjacent compact and spongy connective tissue layers, and a thicker chorion consisting of reticular and trophoblastic layers. Together, the amnion and chorion are stronger than either layer independently; individually, the amnion has greater tensile strength than the chorion.

As the pregnancy progresses, changes in collagen content and type, intercellular matrix, and cellular apoptosis result in structural weakening of the fetal membranes. Membrane remodeling is more evident near the internal cervical os and can be stimulated by matrix metalloproteinases (e.g., MMP-1, MMP-2, MMP-9), decreased levels of tissue inhibitors of matrix metalloproteinases (e.g., TIMP-1, TIMP-3) within the membranes, and increased poly[ADP-ribose] polymerase (PARP) cleavage.[3,4] Contractions subject the amniochorionic membranes to additional physical strain that can lead to membrane rupture. Should the fetal membranes not rupture before labor, advancing cervical dilation decreases the work needed to cause membrane rupture over the internal cervical os. **Preterm PROM likely results from a variety of factors ultimately leading to accelerated membrane weakening through an increase in local cytokines and an imbalance in the interaction between MMPs and TIMPs, increased collagenase and protease activity, or other factors that cause increased intrauterine pressure (e.g., polyhydramnios).**[3-5]

ETIOLOGY OF PREMATURE RUPTURE OF THE MEMBRANES

A number of risk factors have been associated with the occurrence of preterm PROM. Among these are low socioeconomic status, uterine overdistention, second- and third-trimester bleeding, low body mass index, nutritional deficiencies of copper and ascorbic acid, maternal cigarette smoking, cervical conization or cerclage, pulmonary disease in pregnancy, connective tissue disorders (e.g., Ehlers-Danlos syndrome), and preterm labor or symptomatic contractions in the current gestation. Each risk factor, individually or in concert, could lead to PROM through the mechanisms outlined previously. However, the ultimate clinical cause of membrane rupture is often not apparent, and many at-risk patients will deliver at term without PROM.

Preterm PROM has also been linked to infections involving the urogenital tract. *Neisseria gonorrhoeae, Chlamydia trachomatis,* and *Trichomonas vaginalis* have each been associated with preterm PROM.[6] Although vaginal group B β-hemolytic streptococcus (GBS) colonization does not appear to be associated with preterm PROM, cervical colonization may be associated, and GBS bacteruria is associated with preterm PROM and low-birthweight infants.[7,8] Although bacterial vaginosis has been associated with spontaneous preterm births, including preterm PROM, it is unclear whether bacterial vaginosis is the inciting condition, facilitates ascent of other bacteria to the upper genital tract, or is simply a marker of maternal predisposition to abnormal genital tract colonization.[9,10] Bacterial invasion can facilitate membrane rupture through direct release of proteases and also through stimulation of a host inflammatory response resulting in the elaboration of local cytokines, metalloproteases, and prostaglandins. Histologic studies of the membranes after preterm PROM often demonstrate significant bacterial contamination along the choriodecidual interface with minimal involvement of the amnion.[11] Further evidence linking preterm PROM and genital tract infection is that these women have a high incidence of positive amniotic fluid cultures (25% to 35%) even in the absence of clinically suspected intrauterine infection.[12,13] Although some of these findings may reflect ascending infection subsequent to membrane rupture, it is probable that ascending colonization and infection are integral to the pathogenesis of preterm PROM in many cases.

Although the onset of vaginal fluid leakage is an acute event, there is evidence that the factors and events leading to membrane rupture are sometimes subacute or even chronic. Women with a prior preterm birth, especially because of PROM, are at increased risk for preterm birth due to PROM in future pregnancies. Studies have also suggested associations between maternal inflammatory proteins genotype and spontaneous preterm birth due to preterm labor or PROM.[14,15] Further, asymptomatic women with a short cervical length in the second trimester are at increased risk for preterm PROM occurring weeks later.[16]

PREDICTION AND PREVENTION OF PRETERM PREMATURE RUPTURE OF THE MEMBRANES

Once preterm PROM occurs, delivery is often required or inevitable. Optimally, prevention of PROM itself would offer the best opportunity to avoid its complications. **Prior preterm birth and especially prior preterm PROM have been associated with preterm PROM in a subsequent pregnancy.**[17] **The risk increases with decreasing gestational age of the index preterm birth.** Those with a prior delivery near the limit of viability (23 to 27 weeks) have a 27.1% risk of subsequent preterm birth. Those with a prior history of preterm birth due to PROM have a 3.3-fold higher risk for preterm birth due to PROM (13.5% versus 4.1%) and a 13.5-fold higher risk for preterm PROM before 28 weeks (1.8 versus 0.13%) in a subsequent gestation ($P < .01$ for each). In an analysis from a prospective evaluation of preterm birth prediction, nulliparas and women with prior deliveries were evaluated separately because those without

a prior birth lacked important historical information available to those with a prior term or preterm birth.[16] In that study, multivariable analysis revealed medical complications (including pulmonary disease in pregnancy), work during pregnancy, recent symptomatic uterine contractions, and bacterial vaginosis to be significant markers for subsequent preterm birth in nulliparas, when assessed at 22 to 24 weeks' gestation (Table 29-1). Among women with prior deliveries, prior preterm birth due to preterm labor or PROM and a positive cervicovaginal fetal fibronectin screen were statistically significant clinical markers for subsequent preterm PROM after controlling for other factors. Short cervical length (<25 mm) identified by transvaginal ultrasound and low maternal body mass index (<19.8 kg/m^2) were associated with an increased risk for subsequent PROM in both nulliparas and multiparas. Nulliparas with a positive cervicovaginal fetal fibronectin and a short cervix had a 16.7% risk for preterm birth due to preterm PROM. Among multiparas, women with a prior preterm birth due to PROM, a short cervix on ultrasound, and positive cervicovaginal fetal fibronectin screen had a 10.9-fold higher risk for PROM with delivery before 35 weeks' gestation (25% versus 2.3%) than those without risk factors (Table 29-2).

Unfortunately, such risk assessment systems identify only a small fraction of women who will ultimately deliver preterm. Further, although clinical and ancillary testing has increased our ability to identify women at increased risk because of potentially modifiable factors (e.g., cigarette smoking, poor nutrition, urinary tract and sexually transmitted infections, pulmonary disease, severe polyhydramnios), it is unknown whether modification of these in a given patient will reduce the risk for PROM. Regardless, women at risk for preterm birth due to PROM based on clinical findings can be counseled regarding the symptoms of membrane rupture and contractions and encouraged to seek medical care should symptoms occur.

There is current evidence to support progesterone treatment for women with a prior preterm birth due to PROM or preterm labor.[18,19] Data regarding the value of vitamin C supplementation in preventing PROM are conflicting but are not generally supportive. In one study, such treatment was associated with a lower risk (7.7% versus 24.5%; $P = .02$).[20] However, other studies have not shown a significant benefit from treatment, and review of studies in which vitamin C was given alone or in combination with other supplements suggested a negative impact on membrane strength and an increased risk for preterm birth.[21,22] Because of this, **vitamin C supplementation to prevent preterm PROM is not currently recommended.**

PROM, Premature rupture of the membranes; not significant in final model.

CLINICAL COURSE AFTER PREMATURE RUPTURE OF THE MEMBRANES

A hallmark of PROM is brief latency from membrane rupture to delivery. On average, latency increases with decreasing gestational age at membrane rupture. At term, half of expectantly managed gravidas deliver within 5 hours and 95% deliver within 28 hours of membrane rupture.[23] Of all women with PROM before 34 weeks, 93% deliver in less than 1 week. After excluding those requiring delivery soon after admission, 50% to 60% of those conservatively managed and treated with antibiotics for pregnancy prolongation will deliver within 1 week of membrane rupture.[24] A small proportion of women with membrane rupture can anticipate cessation of fluid leakage (2.6% to

13%). About 86% of those with leakage after amniocentesis will reseal.[25,26]

RISKS OF PREMATURE RUPTURE OF THE MEMBRANES

Maternal Risks

Chorioamnionitis is the most common maternal complication after preterm PROM. This risk increases as the duration of membrane rupture becomes more prolonged and decreases with advancing gestational age at PROM.[27] With PROM remote from term, chorioamnionitis occurs in 13% to 60% of pregnancies and endometritis complicates 2% to 13% of cases.[28,29] **Abruptio placentae can cause PROM or occur subsequent to membrane rupture and affects 4% to 12% of these pregnancies.[30] Uncommon but serious complications of PROM managed conservatively near the limit of viability include retained placenta and hemorrhage requiring dilation and curettage (12%), maternal sepsis (0.8%), and maternal death (0.14%).[31]**

Fetal and Neonatal Risks

Fetal complications after membrane rupture include infection and fetal distress due to umbilical cord compression or placental abruption. Umbilical cord compression due to oligohydramnios is common after PROM.[32] Frank or occult umbilical cord prolapse can also occur, particularly with fetal malpresentation. Because of these factors, women with PROM have a higher risk for cesarean delivery for non-reassuring fetal heart rate patterns than those with isolated preterm labor (7.9% versus 1.5%). Fetal death complicates 1% to 2% of cases of conservatively managed PROM.[24]

The frequency and severity of neonatal complications after PROM vary inversely with gestational age at membrane rupture and at delivery. Respiratory distress syndrome (RDS) is the most common serious acute morbidity after preterm PROM at any gestational age. Necrotizing enterocolitis, intraventricular hemorrhage (IVH), and sepsis are common with early preterm birth but relatively uncommon near term. Serious perinatal morbidities with delivery remote from term can lead to long-term sequelae such as chronic lung disease, visual or hearing difficulties, mental retardation, developmental and motor delay, cerebral palsy, and death. Although specific data are not available for those delivering after preterm PROM, general community-based survival and morbidity data suggest that long-term morbidities and death are uncommon with delivery after about 32 weeks' gestation.[33] It is controversial whether gestational age–specific mortality is increased for preterm infants delivering after preterm PROM.[34,35]

Preterm PROM increases the risk of neonatal sepsis twofold over that seen after preterm birth due to preterm labor with intact membranes.[36] Neonatal infection can result from the same organisms present in the amniotic fluid or from others and can present as acute congenital pneumonia, sepsis, or meningitis. Late-onset bacterial or fungal infections can also occur. There is accumulating evidence that suggests fetal-neonatal infection and inflammation are associated with an increased risk for long-term neurologic complications. Cerebral palsy and cystic periventricular leukomalacia (PVL) have been linked to chorioamnionitis, which is more commonly seen after preterm PROM and is more likely with conservative management after membrane rupture.[37] Elevated amniotic fluid cytokines and fetal systemic inflammation have also been associated with preterm PROM, PVL, and cerebral palsy.[38] Although there are no data to suggest that immediate delivery on admission with PROM will avert these sequelae, these findings highlight the importance of restricting conservative management after PROM to circumstances in which there is the potential to reduce neonatal morbidity through either antenatal corticosteroid administration or extended pregnancy prolongation for fetal maturation.

Pulmonary hypoplasia is a severe complication of oligohydramnios in the second trimester that results from a lack of terminal bronchiole and alveolar development during the canalicular phase of pulmonary development.[39] It is most accurately diagnosed pathologically using radial alveolar counts and lung weights.[40] Clinical findings such as a small chest circumference with severe respiratory distress and persistent pulmonary hypertension in the newborn and radiographic findings such as small well-aerated lungs with a bell-shaped chest and elevation of the diaphragm are also supportive of the diagnosis. Whether because of fluid efflux and tracheobronchial collapse after membrane rupture or through loss of intrinsic factors within the tracheobronchial fluid, pulmonary hypoplasia develops over weeks after membrane rupture. Pulmonary hypoplasia complicates an average of about 6% of cases in series of midtrimester PROM and carries a 70% mortality rate.[41] Its incidence is inversely correlated with gestational age at membrane rupture, complicating nearly 50% of cases with membrane rupture before 19 weeks and prolonged latency.[39,42] The frequency of pulmonary hypoplasia can be as high as 74% to 82% with PROM at 15 to 16 weeks, persistent oligohydramnios, and a latency 28 days.[43] Lethal pulmonary hypoplasia rarely occurs with PROM after 26 weeks of gestation (0% to 1.4%).[44] However, other pulmonary complications such as pneumothorax and pneumomediastinum related to poor pulmonary compliance and high ventilatory pressures can occur with lesser degrees of this condition. Restriction deformities occur in about 1.5% of infants delivered after conservative management after midtrimester PROM but complicate up to 27% of fetuses with prolonged oligohydramnios.[31,45]

DIAGNOSIS OF PREMATURE RUPTURE OF THE MEMBRANES

The diagnosis of PROM involves clinical history and physical examination, as well as laboratory evaluation in some cases.

The diagnosis of membrane rupture is confirmed by the presence of the following findings:

- Visualization of evident amniotic fluid passing from the cervical canal, or
- Vaginal sidewall or posterior fornix pH of more than 6.0 to 6.5, and
- Microscopic arborized crystals ("ferning"), owing to the interaction of amniotic fluid proteins and salts, form dried vaginal secretions obtained by swabbing the posterior fornix with a sterile swab.

False-positive pH results may occur with blood or semen contamination, alkaline antiseptics, or bacterial vaginosis. Cervical mucus can yield a false-positive ferning pattern; however, the crystals appear as a more floral pattern. The fern pattern in samples heavily contaminated with blood is atypical and appears more "skeletonized." Prolonged leakage with minimal residual fluid can result in a false-negative result on visual inspection, pH, or ferning testing. If the diagnosis is equivocal after initial testing, the patient can be placed in a Trendelenburg position and reexamined after a few hours. The diagnosis of membrane rupture can be made unequivocally by ultrasound-guided dye amnioinfusion (1 mL indigo carmine plus 9 mL sterile saline), followed by observation for passage of dye onto a perineal pad. Although oligohydramnios without evident fetal urinary tract malformations or fetal growth restriction may be suggestive of membrane rupture, ultrasound alone is not definitive.

Noninvasive cervicovaginal markers such as fetal fibronectin, α-fetoprotein, prolactin, human chorionic gonadotropin, placental α-microglobulin-1 (PAMG-1), and insulin-like growth factor-binding protein-1 (IGFBP-1) have been studied for their ability to confirm or exclude membrane rupture. These have not generally been evaluated in women with an unclear diagnosis of membrane rupture after clinical examination, so their predictive value in this relevant population is uncertain. Although membrane rupture can be confirmed by the presence of PAMG-1 in cervicovaginal secretions, it has also been found to be present in nearly one third of laboring women and in 1 of 20 nonlaboring women without suspected membrane rupture.[46]

MANAGEMENT OF PREMATURE RUPTURE OF THE MEMBRANES

General Considerations

Management of PROM is based primarily on an individual assessment of the estimated risk for fetal and neonatal complications should conservative management or delivery be pursued. The risks for maternal morbidity should also be considered, particularly when PROM occurs before the limit of potential viability (currently 23 weeks' gestational age).

The diagnosis of membrane rupture is confirmed and the duration of membrane rupture determined to assist the pediatric caregivers with subsequent management decisions. The patient is assessed for fetal presentation, contractions, findings suggestive of intrauterine infection, and evidence of fetal well-being. GBS carriage is ascertained, if available, from a recent anovaginal culture performed within 5 weeks.

In general, digital cervical examinations should be avoided until it is determined that delivery is inevitable. Digital examination has been associated with a shortening of latency from membrane rupture to delivery.[47] Visualization of the cervix during a sterile speculum examination offers helpful information regarding cervical dilation and effacement. Brown and colleagues found visual estimation to be within 1 cm of digitally determined cervical dilation in 64% and within 2 cm in 84% of examinations, whereas visually estimated cervical effacement was within 1 cm in 83% of cases.[48] In addition to providing confirmatory evidence of membrane rupture, sterile speculum examination can provide the opportunity to inspect for cervicitis and to obtain appropriate cervical and vaginal cultures.

The benefit of narrow-spectrum intrapartum prophylaxis with intravenous penicillin G (5 million units intravenous [IV], then 2.5 to 3 million units IV every 4 hours) or ampicillin (2 g IV, then 1 g IV every 4 hours), to prevent vertical transmission and early-onset neonatal GBS sepsis from maternal GBS carriers has been well established, and the Centers for Disease Control and Prevention published a revised guideline for the prevention of perinatal group B streptococcal disease in November 2010.[49,50] Current indications for intrapartum GBS prophylaxis and alternative antibiotic regimens for those with a penicillin allergy are discussed in Chapter 51. Known GBS carriers with PROM at any gestation and those with preterm PROM and unknown GBS status should receive intrapartum prophylaxis regardless of prior antibiotic treatment. GBS carriers with PROM and chorioamnionitis should receive broad-spectrum intrapartum antibiotic therapy, including agents effective against GBS. Intrapartum antibiotics are not recommended if chorioamnionitis is not suspected clinically and there is a recent negative anovaginal culture for GBS because of the potential for selection of resistant organisms should neonatal sepsis occur.[51]

Although practice varies regarding the management of preterm PROM, there is general consensus regarding some issues. Gestational age should be established based on clinical history and prior ultrasound assessment, where available (Figure 29-1). Ultrasound should be performed to assess fetal growth, position, residual amniotic fluid volume, and gross fetal abnormalities that might cause polyhydramnios and PROM. Those with advanced labor, intrauterine infection, significant vaginal bleeding, or nonreassuring fetal testing are best delivered. **If conservative management of preterm PROM is to be pursued, the patient should be admitted to a facility capable of providing emergent delivery for placental abruption, fetal malpresentation in labor, and fetal distress due to umbilical cord compression or in utero infection. The facility should also be capable of providing 24-hour neonatal resuscitation and intensive care because conservative management should generally be performed only in pregnancies in which there is a significant risk for neonatal morbidity and mortality.** If the need for transfer to a tertiary care facility is anticipated, this should occur early in the course of management to avoid emergent transfer once delivery is imminent or complications arise.

Management of Premature Rupture of the Membranes at Term

Studies published in the 1970s and 1980s suggested that immediate induction after PROM at term would increase the risks for perinatal infection and cesarean delivery.[52] However, currently available data do not support these concerns. In four large studies, induction with oxytocin after PROM at term did not increase either of these complications.[23,53-55] In fact, the largest prospective study to date has found oxytocin induction in this setting to reduce the median duration of membrane rupture after PROM (17.2 versus 33.3 hours) and the frequency of

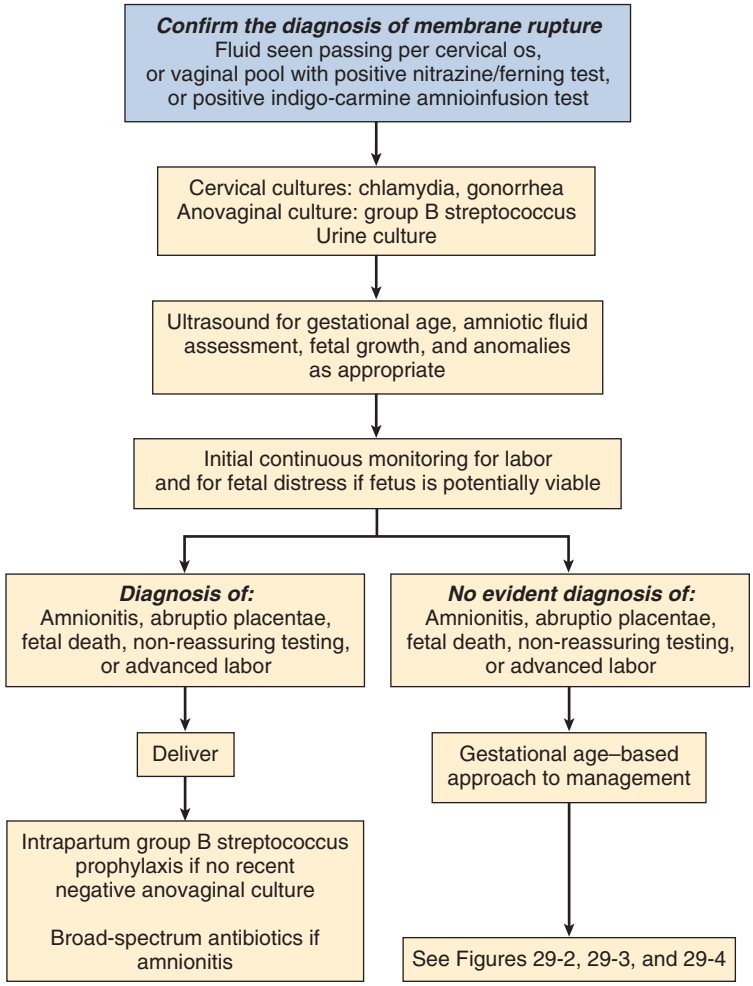

FIGURE 29-1. Initial assessment and management of women with preterm premature rupture of the membranes. (From Mercer BM: Preterm premature rupture of the membranes: diagnosis and management. Clin Perinatol 31:765, 2004.)

chorioamnionitis (4% versus 8.6%) and postpartum fevers (1.9% versus 3.6%; $P \leq .008$ for each), without increasing cesarean deliveries (13.7% versus 14.1%) or neonatal infections (2% versus 2.8%).[23] An additional benefit of early oxytocin induction in this trial was a reduction in neonatal antibiotic therapy (7.5% versus 13.7%; $P < .001$). Meta-analysis of 12 studies including a total of 6814 women regarding early delivery versus expectant management for PROM at term confirmed less frequent chorioamnionitis and endometritis with planned delivery, with no increases in caesarean delivery or neonatal infection.[56] Fewer infants in the early delivery group required neonatal intensive care unit (NICU) or special care admission. Analysis of studies of prostaglandin versus oxytocin induction after PROM at or near term found increased chorioamnionitis (odds ratio [OR], 1.51; 95% confidence interval [CI], 1.07 to 2.12), neonatal infection (OR, 1.63; 95% CI, 1 to 2.66), and prolonged NICU stay (OR, 1.43; 95% CI, 1.07 to 1.91) without improvement in cesarean delivery rates (OR, 0.92; 95% CI, 0.73 to 1.16) with prostaglandin treatment.[57] This meta-analysis was dominated by the TermPROM trial, which found shorter latency from membrane rupture to delivery with oxytocin than with prostaglandin therapy (median, 17.2 versus 23 hours; $P < .001$).[23] Taken together, these data suggest that **women with PROM at term should be offered early delivery, generally with a continuous oxytocin infusion, to reduce the risk for maternal and neonatal complications.** Adequate time for latent phase of labor should be allowed. During labor, transcervical amnioinfusion of warm normal saline solution may prove useful if significant umbilical cord compression is suspected and immediate delivery is not required.[58,59]

Management of Preterm Premature Rupture of the Membranes Near Term (32 to 36 Weeks)

Severe acute newborn complications are uncommon when preterm birth occurs between 34 and 36 weeks' gestation, and antenatal corticosteroids for fetal maturation are not usually administered to accelerate fetal pulmonary maturity in this gestational age range.[33] Alternatively, **conservative management after PROM at 34 to 36 weeks' gestation only briefly prolongs pregnancy while increasing the risk for chorioamnionitis** (16% versus 2%; $P = .001$) and reducing newborn umbilical cord pH (7.35 versus 7.25; $P = .009$) without preventing neonatal complications.[60,61]

Management of the woman with PROM at 32 to 33 weeks' gestation is more controversial because pulmonary and other gestational age–dependent complications can occur, but the likelihood of survival at this gestation is

high and long-term complications are uncommon. Neerhoff and colleagues found modest benefits in the duration of newborn hospital stay and the frequency of hyperbilirubinemia with conservative management at 32 to 33 weeks' gestation.[61] Alternatively, two prospective trials comparing early delivery and conservative management of PROM near term have provided useful insights. Cox and coworkers found conservative management of PROM at 30 to 33[6] weeks' gestation to increase latency only briefly (59% versus 100% delivered within 48 hours; P <.001).[62] Mercer and colleagues, in a study of PROM at 32 to 36[6] weeks' gestation, found a similar brief lengthening of latency with conservative management (36 hours versus 14 hours; P <.001).[63] However, both studies found conservative management to increase the risk for chorioamnionitis (15% versus 2%, P = .009, and 27.7% versus 10.9%, P = .06, respectively) without evident reduction in newborn complications. Secondary analysis of those with PROM at 32 to 33[6] weeks' gestation in the latter trial revealed similar trends regarding latency, infection, and infant morbidities in this subgroup.[64] The potential for umbilical cord compression during conservative management of PROM was highlighted by one stillbirth and the high incidence of non-reassuring fetal heart rate patterns found on intermittent monitoring in these studies.[62,63]

At 32 to 33 weeks' gestation, it can be helpful to assess fetal pulmonary maturity and to treat with antenatal corticosteroids those pregnancies without documented fetal maturity. Either vaginal pool or amniocentesis specimens can be used for testing. Because there is increased potential for inadvertent fetal or umbilical cord puncture during amniocentesis when the amniotic fluid volume is decreased, vaginal pool specimen collection is preferable if an adequate specimen can be obtained. If amniocentesis is required, color Doppler imaging can be helpful in differentiating umbilical cord loops from a small residual fluid pocket. Pulmonary phospholipids are not present in lavage fluid from the vagina when the membranes are intact.[65] Studies of women with ruptured membranes have found a high concordance rate (89% to 100%) between specimens collected vaginally and by amniocentesis for pulmonary phospholipids such as lecithin, phosphatidylglycerol (PG), phosphatidylinositol, phosphatidylethanolamine, and phosphatidylserine.[66] Lewis and associates found no cases of RDS among infants delivered after a mature PG result from vaginal pool fluid.[67] Similarly, in a study of vaginally collected samples, Russell and associates found no cases of RDS after a mature lecithin-to-sphingomyelin (L/S) ratio or PG result.[68] Although mature TDx-FLM and TDx-FLM II assay results are highly predictive of fetal pulmonary maturity, this platform is no longer available in the United States.[69] The presence of PG on perineal pad–collected fluid is also predictive of fetal pulmonary maturity (97.8%), and its absence is predictive of pulmonary immaturity (33.7%).[70] The lamellar body count (LBC) may also be performed from vaginally collected amniotic fluid specimens and has been shown by some to have a high predictive value for fetal pulmonary maturity.[71] Amniotic fluid pulmonary maturity testing can be confounded by the presence of contaminants such as blood and meconium (see Chapter 12). Realistically, expeditious delivery should be considered if significant blood or meconium is present in a vaginal pool or amniocentesis specimen after PROM.

Based on the available data, early delivery should be pursued when PROM occurs at 34 to 36 weeks' gestation (Figure 29-2). The infant delivered after PROM at 30 to 33 weeks' gestation is at risk for infectious and other gestational age–dependent morbidities, but the presence of fetal pulmonary maturity at 32 to 33[6] weeks' gestation suggests that there is a low risk for complications with immediate delivery. Because of the increased risk for infectious morbidity and potential for occult umbilical cord compression with conservative management, **delivery should be initiated before complications ensue if there is documented fetal pulmonary maturity after PROM at 32 to 33 weeks.** If fetal pulmonary maturity is not evident on testing, or if amniotic fluid cannot be obtained for testing, conservative management with antenatal corticosteroid administration for fetal maturation and antibiotic therapy to reduce the risk for infection (see later) is appropriate. The issue of continued conservative management versus delivery after steroid treatment is a matter of opinion. Pragmatically, if elective delivery is planned within 1 week, it is unlikely that prolonging the pregnancy further will offer significant opportunity for significant additional fetal maturation and delivery should be considered after steroids have been administered. Alternatively, if several weeks of conservative management are to be attempted, there may be benefit to continuing the pregnancy.

Management of Premature Rupture of the Membranes Remote from Term (23 to 31 weeks)

Infants born at 23 to 31 weeks' gestation are at increased risk for perinatal death, and survivors commonly suffer acute and long-term complications. Pregnancy prolongation can reduce these risks, and because of this, inpatient conservative management is generally attempted unless intrauterine infection, significant vaginal bleeding, placental abruption, and advanced labor are evident or fetal testing becomes non-reassuring. Fetal malpresentation, funic presentation, human immunodeficiency virus (HIV), primary herpes simplex virus (HSV) are examples of exceptions that might warrant expeditious delivery because of the increased potential for fetal death or infection with prolonged membrane rupture.

During conservative management, initial care generally consists of prolonged continuous fetal heart rate and maternal contraction monitoring for evidence of umbilical cord compression and occult contractions and to establish fetal well-being. If initial testing is reassuring, the patient can be transferred to an inpatient ward for modified bedrest (Figure 29-3). Because the fetus with preterm PROM remote from term is at risk for heart rate abnormalities resulting from umbilical cord compression (32% to 76%),[31] fetal assessment should be performed at least daily. More frequent or continuous monitoring may be appropriate if there are intermittent fetal heart rate decelerations but otherwise reassuring findings. Although both nonstress and biophysical profile testing have the ability to confirm fetal well-being in the setting of preterm PROM, fetal heart rate monitoring offers the opportunity to identify periodic heart rate changes and allows concurrent

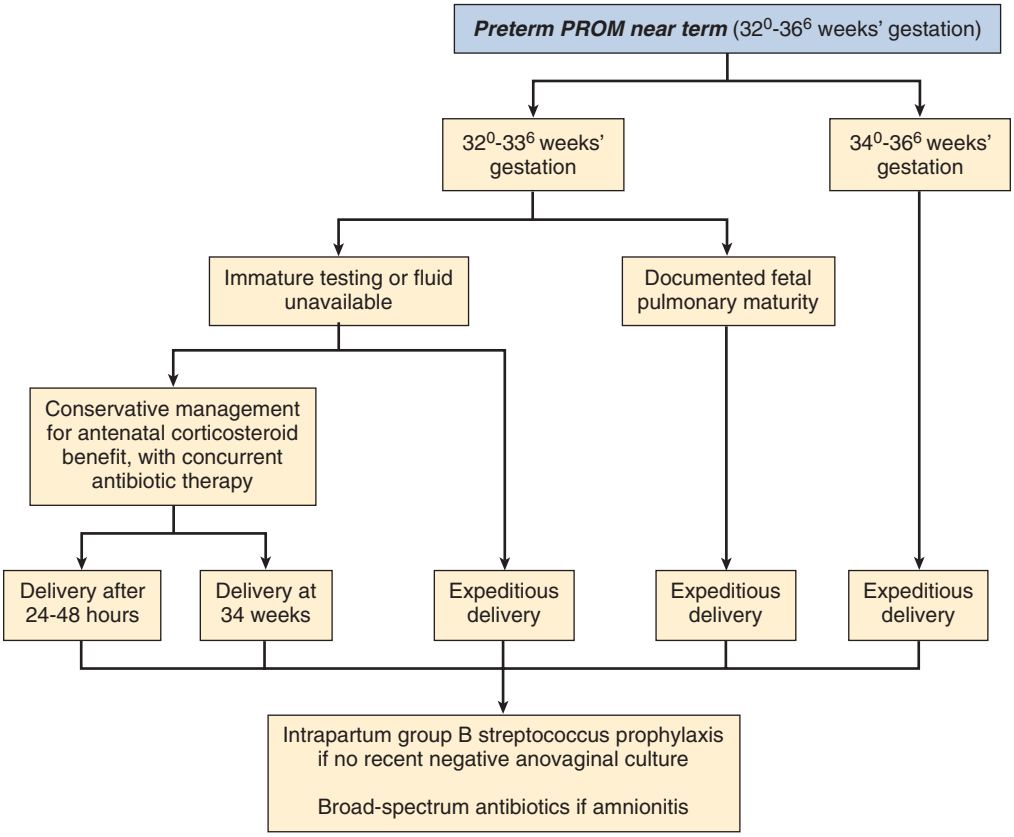

FIGURE 29-2. Management algorithm for preterm premature rupture of the membranes (PROM) near term (32 to 36 weeks' gestation). (From Mercer BM: Preterm premature rupture of the membranes: diagnosis and management. Clin Perinatol 31:765, 2004.)

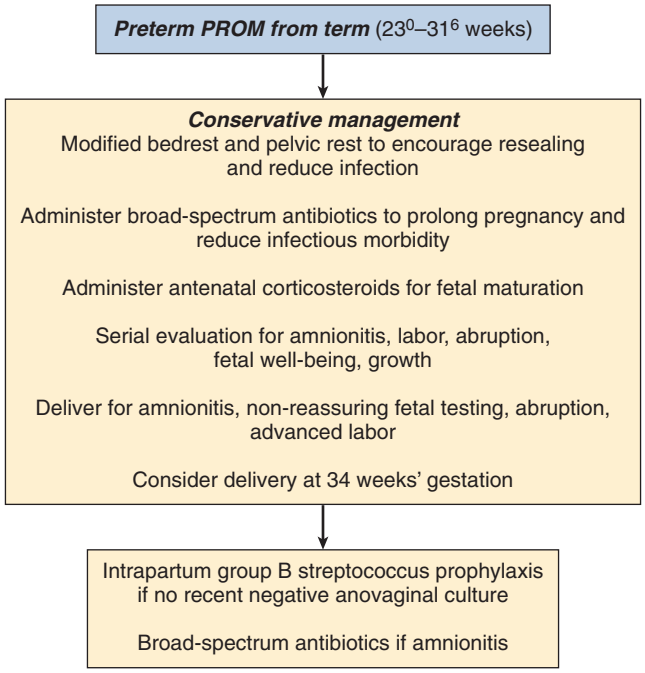

FIGURE 29-3. Management algorithm for preterm premature rupture of the membranes (PROM) remote from term (23 to 31 weeks' gestation). (From Mercer BM: Preterm premature rupture of the membranes: diagnosis and management. Clin Perinatol 31:765, 2004.)

evaluation of uterine activity. Biophysical profile testing may be confounded by the presence of oligohydramnios but can be helpful should the nonstress test result be equivocal (see Chapter 12). **Although a low initial amniotic fluid index is associated with shorter latency and an increased risk for chorioamnionitis, it does not accurately predict who will ultimately develop these complications and should not be used in isolation to make management decisions.** Prolonged bedrest in pregnancy may increase the risk for deep venous thrombosis.[72] Preventive measures such as leg exercises, antiembolic stockings, and/or prophylactic doses of subcutaneous heparin may be of value during conservative management of PROM.

Twofold to fourfold increases in perinatal mortality, IVH, and neonatal sepsis have been reported in infants born after chorioamnionitis compared with gestational age–matched controls born to noninfected mothers.[28] The clinical diagnosis is made when maternal fever (temperature ≥38° C [100.4° F]) with uterine tenderness and maternal or fetal tachycardia are identified in the absence of another evident source of infection. The maternal white blood cell count can be helpful if clinical findings are equivocal. An increase in the white blood cell count from a baseline level obtained on admission is suggestive of infection but may be artificially elevated if antenatal corticosteroids have been administered within 5 to 7 days. If

additional confirmation of intrauterine infection is required, amniocentesis may be helpful.[12,73] A positive amniotic fluid culture is also supportive of a clinical suspicion of clinical chorioamnionitis (sensitivity, 65% to 85%; specificity, 85%), but the clinical diagnosis will likely become clear during the 48 hours needed to achieve a culture result. An amniotic glucose concentration below 16 to 20 mg/dL (sensitivity and specificity, 80% to 90% for positive culture) or a Gram stain positive for bacteria (sensitivity, 36% to 80%; specificity, 80% to 97% for positive culture) are supportive of a clinically suspicious diagnosis of chorioamnionitis and can be rapidly obtained. However, the presence of white blood cells only in amniotic fluid is not diagnostic of intrauterine infection after PROM. Elevated amniotic fluid interleukin levels have also been associated with an increased risk for early delivery and perinatal infectious morbidity, but cytokine analyses are not readily available in most clinical laboratories,[73] limiting their utility in clinical practice. Once chorioamnionitis is diagnosed, broad-spectrum antibiotics should be initiated, and delivery should be pursued.

Corticosteroid Administration

A single course of antenatal corticosteroids, either betamethasone (12 mg intramuscularly [IM] every 24 hours for two doses) or dexamethasone (6 mg IM every 12 hours for four doses) before anticipated preterm birth has been shown to reduce the risks for RDS, IVH, necrotizing enterocolitis, perinatal death, and long-term neurologic morbidities. **Meta-analysis regarding antenatal corticosteroid administration after preterm PROM has confirmed steroid therapy to significantly reduce the risks for RDS (20% versus 35.4%), IVH (7.5% versus 15.9%), and necrotizing enterocolitis (0.8% versus 4.6%), without increasing the risks for maternal (9.2% versus 5.1%) or neonatal (7.0% versus 6.6%) infection.**[74]

Repeated courses of antenatal corticosteroids after preterm PROM have been associated with increased newborn infection in some studies and have not been consistently associated with improvements in newborn outcomes.[75] Ghidini and colleagues found less IVH and chorioamnionitis, but no reduction in the risk for RDS with repeated antenatal corticosteroid doses.[76] Alternatively, Abbassi and associates observed a lower risk for RDS with more than one course of antenatal corticosteroids after PROM (34.9% versus 45.2%).[75] Given the potential risks and the lack of clear data supporting the benefit of repeated weekly antenatal corticosteroid administration, such treatment does not appear warranted. It remains to be determined whether a single repeat "rescue" course could benefit the woman who receives an initial course of antenatal corticosteroids after PROM near the limit of viability but then remains pregnant through 30 to 33 weeks' gestation.

Antibiotic Administration

The goal of antibiotic therapy during conservative management of preterm PROM remote from term is to treat or prevent ascending infection in order to prolong pregnancy and reduce perinatal infectious and gestational age–dependent morbidity. Meta-analyses have summarized a large number of randomized controlled clinical trials in this regard.[77,78] These evaluations suggest that **antibiotic treatment significantly prolongs latency after membrane rupture, reduces chorioamnionitis and postpartum endometritis, and also prevents newborn complications including neonatal sepsis, pneumonia, and IVH.** Several published trials offer valuable insights regarding the potential role of adjunctive antibiotics in this setting. The National Institutes of Child Health and Human Development Maternal Fetal Medicine Units (NICHD-MFMU) Research Network studied women with preterm PROM remote from term (24 to 32 weeks, 0 days' gestation).[79,80] Participants received 48 hours of broad-spectrum intravenous therapy (ampicillin [2 g every 6 hours] and erythromycin [250 mg every 6 hours]), followed by 5 days of oral (PO) therapy (amoxicillin [250 mg every 8 hours] and enteric-coated erythromycin-base [333 mg every 8 hours]) or a matching placebo. GBS carriers in both study arms received ampicillin for one week and then again in labor. Antibiotic treatment doubled the likelihood of undelivered after 7 days, and this benefit persisted up to 3 weeks after randomization, suggesting that antibiotics successfully treated rather than just suppressing subclinical infection. Antibiotics improved neonatal health by reducing the number of babies with one or more major infant complication from 53% to 44% (composite morbidity: death, RDS, early sepsis, severe IVH, severe necrotizing enterocolitis; $P < .05$), and also reduced individual newborn complications including RDS (40.5% versus 48.7%), stage 3 or 4 necrotizing enterocolitis (2.3% versus 5.8%), patent ductus arteriosus (11.7% versus 20.2%), and chronic lung disease (bronchopulmonary dysplasia: 20.5% versus 13.0%) ($P < .05$ for each). Regarding individual infectious morbidities, antibiotics reduced the frequencies of chorioamnionitis overall (32.5% versus 23%), and also neonatal sepsis (8.4% versus 15.6%) and pneumonia (2.9% versus 7%), among those who were not GBS carriers ($P \leq .04$ for each). In a second multicenter placebo controlled trial, Kenyon and colleagues studied oral therapy with erythromycin, amoxicillin–clavulanic acid, or both for up to 10 days after preterm PROM before 37 weeks.[81] In summary, erythromycin prolonged latency only briefly (not significant at 7 days) but did reduce the need for supplemental oxygen (31.1% versus 35.6%) and the frequency of positive blood cultures (5.7% versus 8.2%) ($P = .02$ for both). Amoxicillin–clavulanic acid prolonged pregnancy (43.3% versus 36.7% undelivered at 7 days) and reduced the need for supplemental oxygen (30.1% versus 35.6%) but increased the risk for necrotizing enterocolitis (1.9% vs. 0.5%) ($P \leq .05$ for each). Long-term follow-up of infants delivered within this trial revealed no evident differences between antibiotic and control groups.[82] Subsequent studies have attempted to determine whether the duration of antibiotic therapy could be shortened but are of inadequate size and power to evaluate infant outcomes adequately.[83]

In summary, there appears to be a role for a 7-day course of parenteral and oral antibiotic therapy with erythromycin and amoxicillin-ampicillin during conservative management of preterm PROM remote from term, to prolong latency and to reduce infectious and gestational age–dependent neonatal complications. Extended-spectrum ampicillin–clavulanic acid treatment is not recommended because it may be harmful.

Tocolysis

There is limited evidence that prophylactic tocolysis, administered after preterm PROM and before the onset of contractions, can prolong pregnancy briefly.[84] However, therapeutic tocolysis initiated only after the onset of contractions has not been shown to prolong latency after preterm PROM. A report from the National Institutes of Health collaborative study on antenatal steroids suggested an association between tocolytic treatment after preterm PROM and subsequent neonatal RDS, but subsequent small prospective studies have found neither an increase nor decrease in neonatal complications with such tocolytic treatment.[85] Although it is plausible that tocolysis could facilitate initial uterine quiescence to allow additional time for antibiotic and corticosteroid benefits, there have been no studies of tocolytic therapy after preterm PROM in which concurrent antenatal corticosteroid and antibiotic treatments were given. In a recent small randomized controlled trial, weekly progesterone treatment did not prolong latency after PROM.[86] Pending further study, **tocolysis and progesterone therapy should not be considered expected practices after preterm PROM.**

Cervical Cerclage

After cervical cerclage, preterm PROM is a common complication, affecting about one in four elective cerclages and half of emergent procedures.[87] There are no prospective studies regarding the management of preterm PROM and a cervical cerclage in situ. Retrospective studies reveal that perinatal complications are similar to PROM without a cerclage if the stitch is removed on admission.[88] Studies comparing pregnancies in which the stitch was retained or removed after preterm PROM have been small but have yielded consistent patterns.[89,90] Each has found insignificant trends toward increased maternal infections and only brief pregnancy prolongation; one study found increased infant mortality and death due to sepsis when the cerclage was not removed.[89] **No well-controlled study has found cerclage retention to reduce the frequency or severity of newborn complications after PROM. Based on these data, early cerclage removal is recommended when PROM occurs.** The risks and benefits of short-term cerclage retention during antenatal corticosteroid treatment have not been determined.

Herpes Simplex Virus

Neonatal HSV infection most commonly results from direct maternal-fetal transmission during the delivery process, with newborn infection rates of 34% to 80% after primary and 1% to 5% after secondary maternal infection.[91] When neonatal HSV infection occurs, the mortality rate is 50% to 60%, and up to 50% of survivors will suffer serious sequelae.[92] Based on small case series of women with an active maternal genital HSV infection by Amstey ($N = 9$) and Nahmias and colleagues ($N = 26$), both in 1971, the accepted belief has been that extended latency after membrane rupture (>4 to 6 hours) is associated with an increased risk for newborn infection.[93] Major and coworkers have reported on a case series of 29 gravidas managed expectantly with PROM before 32 weeks' gestation with active *recurrent* HSV lesions.[94] Latency after membrane rupture ranged from 1 to 35 days, and cesarean delivery was performed if active lesions were present at the time of delivery. None of the infants delivered under this regimen developed neonatal herpes infection. These data are supportive of conservative management of PROM complicated by recurrent maternal HSV infection; however, such treatment should be considered only at an early gestational age when the likelihood of infant mortality and long-term complications with early delivery is high. Prophylactic treatment with antiviral agents (e.g., acyclovir) to reduce viral shedding and the frequency of recurrences is prudent under this circumstance.

Management of Previable Premature Rupture of the Membranes

The cause of PROM before the limit of viability has implications for the anticipated pregnancy outcome and can be helpful in guiding counseling and management. Previable PROM subsequent to second-trimester amniocentesis is likely related to continued leakage of fluid through a small membrane defect without concurrent infection. Under this circumstance it is likely that the membranes will reseal, and extended pregnancy can be anticipated. Alternatively, previable PROM subsequent to second-trimester bleeding, oligohydramnios, or an elevated maternal serum α-fetoprotein more likely reflects an abnormality of placentation and has a poorer prognosis. The patient with previable PROM and no indication for immediate delivery should be counseled regarding the potential risks and benefits of conservative management. Counseling should include a realistic appraisal of fetal and neonatal outcomes and the risks for maternal complications.

Most available data regarding women with preterm PROM near the limit of viability are derived from retrospective studies. **In a recent review of preterm PROM occurring at or before 24 weeks' gestation, Waters and Mercer found that median latency ranged from 6 to 13 days.**[31] Another recent evaluation found that 38% delivered within 1 week and 69% delivered within 5 weeks after periviable PROM.[95] **Other maternal risks during conservative management of PROM at 24 weeks or less include chorioamnionitis (35%), abruptio placentae (19%), retained placenta (11%), and endometritis (14%).**[31] **Maternal sepsis (0.8%) and death (1 in 619 pregnancies overall) are rare but serious complications.** Conservative management can also lead to muscle wasting, bone demineralization, and deep venous thrombosis due to prolonged bedrest. Overall infant survival after conservatively managed periviable PROM occurs in 44% of cases, but this varies with gestational age at membrane rupture (14.4% before 22 weeks versus 57.7% at 22 to 24 weeks). Stillbirth is common, complicating up to 23% to 53% of cases. Neonatal complications include pulmonary hypoplasia (19%), RDS (66%), grade III or IV IVH (5%), sepsis (19%), and necrotizing enterocolitis (4%), as well as long-term complications such as bronchopulmonary dysplasia (29%), stage III retinopathy of prematurity (5%), and contractures (3%). Prediction of individual outcomes is difficult because of the inability to predict the ultimate gestational age at delivery in any given case.

A potential management scheme for PROM before the limit of viability is presented in Figure 29-4. There is no consensus regarding the advantages of inpatient versus

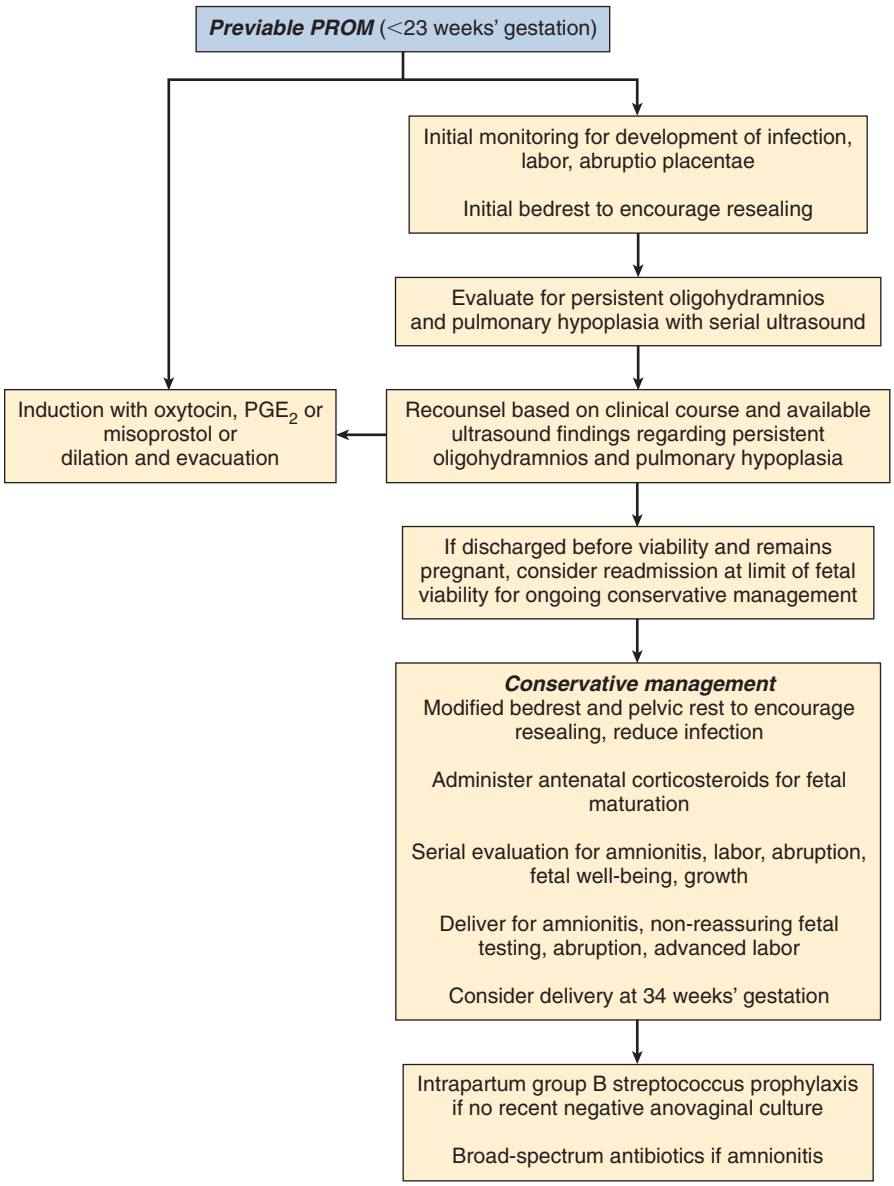

FIGURE 29-4. Management algorithm for preterm PROM before the limit of potential viability (currently 23 weeks' gestation). *PGE_2,* prostaglandin E_2. (From Mercer BM: Preterm premature rupture of the membranes: diagnosis and management. Clin Perinatol 31:765, 2004.)

outpatient management for the patient electing conservative management after previable PROM. The benefits of an initial period of inpatient observation may include bedrest and pelvic rest to increase the opportunity for membrane resealing, as well as early identification of infection, fetal demise, and abruption. A number of novel treatments, including amnioinfusion and fibrin-platelet-cryoprecipitate or Gelfoam sealing of the membranes, have been preliminarily investigated.[96-98] The risks and benefits of these aggressive interventions have not been adequately studied to suggest that such therapy be incorporated into routine clinical practice. Typically, women with previable PROM who have been managed as outpatients are readmitted to hospital once the pregnancy reaches the limit of viability. Administration of antenatal corticosteroids for fetal maturation is appropriate at this time.

During conservative management, serial ultrasound performed every 1 to 2 weeks can evaluate for reaccumulation of amniotic fluid and interval pulmonary growth. Although persistent severe oligohydramnios is a strong marker for subsequent development of lethal pulmonary hypoplasia, serial fetal biometric evaluation (e.g., lung length, chest circumference), and ratios that adjust for overall fetal size (thoracic-abdominal circumference, thoracic circumference–femur length) can demonstrate a lack of fetal pulmonary growth over time and have a high predictive value for lethal pulmonary hypoplasia.[39,42,99,100] Studies of pulmonary artery and ductus arteriosus waveform modulation with fetal breathing movements have shown some promise but can be technically difficult to perform.

Some women will not choose to undertake the potential risks for maternal complications after previable PROM either after initial counseling or with evidence of developing pulmonary hypoplasia. Delivery can be accomplished by labor induction with vaginal prostaglandin E_2, prostaglandin E_1 (misoprostol), high-dose intravenous oxytocin, or dilation and evacuation. The optimal approach depends on patient characteristics (e.g., gestational age, evident

chorioamnionitis, prior cesarean delivery), available facilities, and physician experience.

SUMMARY

The potential for significant perinatal complications exists when PROM occurs at term or preterm. Early delivery of the patient with PROM at or near term can reduce the risk for perinatal infections without increasing the likelihood of operative delivery. Careful conservative management of PROM remote from term offers the potential to reduce infectious and gestational age–dependent morbidities. Early transfer to a facility capable of providing urgent obstetrical and neonatal intensive care is important should adequate facilities not be available locally. Regardless of the management approach, infants delivering after preterm PROM and after PROM before the limit of potential viability are at high risk for perinatal complications, many of which cannot be avoided with current technology and management algorithms.

KEY POINTS

- PROM complicates about 8% to 10% of pregnancies and is a significant cause of gestational age–dependent and infectious perinatal morbidity and mortality.
- Latency from membrane rupture to delivery is typically brief and decreases with increasing gestational age at membrane rupture.
- Chorioamnionitis is common after preterm PROM and increases in frequency with decreasing gestational age at membrane rupture.
- Women with a prior preterm birth due to PROM have a 3.3-fold higher risk for subsequent preterm birth due to PROM and a 13.5-fold higher risk for preterm PROM before 28 weeks' gestation.
- Some potentially preventable causes of preterm PROM include urogenital tract infections, poor maternal nutrition with a low body mass index (<19.8 kg/m^2), and cigarette smoking.
- Vaginally collected amniotic fluid can reliably predict the presence of fetal pulmonary maturity after preterm PROM.
- Conservative management after preterm PROM with documented fetal pulmonary maturity near term (32 to 36 weeks) prolongs latency only briefly but increases the risk for perinatal infection and does not improve neonatal outcomes.
- Antenatal corticosteroid administration and limited duration broad-spectrum antibiotic administration have been shown to reduce newborn complications when given in the setting of PROM remote from term.
- Cervical cerclage retention after preterm PROM has not been shown to improve neonatal outcomes.
- Lethal pulmonary hypoplasia is common after PROM occurring before 20 weeks and can be predicted with serial ultrasound assessment of lung and chest growth.

Very Low Birthweight	VLBW

The increase in multiple births during the past 30 years has been well documented, making multiple gestations one of the most common high-risk conditions encountered by obstetricians. The increase in multiples is due primarily to assisted reproduction technology but also in part to older maternal age at childbirth, which is a known risk factor for spontaneous dizygotic twinning. After years of rapidly increasing twin birth rates, the rates now seem to show signs of stabilizing. The twin birth rate rose 70% from 1980 to 2004. According to the most recent National Vital Statistics data, however, the twin rate remained stable between 2004 and 2006 at 32.1 per 1000. Likewise, rates of triplets and higher-order multiples increased by more than 400% during the 1980s and 1990s, reaching an all-time high in 1998 at a rate of 193.5 per 100,000. Since that peak, triplets and higher-order multiples have decreased by 20% to 30%, with the most recent available triplet rate at 143.4 per 100,000 and the quadruplet and higher-order birth rate at 9.89 per 100,000.[1] The apparent plateau of the twin birth rate and the decline of triplet and higher-order multiple births are likely due to refinements in assisted reproduction techniques and recommendations from the American Society for Reproductive Medicine to limit the number of embryos transferred during in vitro fertilization (IVF) procedures. Issues remain with the current use of ovulation-induction drugs.

ZYGOSITY AND CHORIONICITY

Twins can be either monozygotic (MZ) or dizygotic (DZ). Zygosity refers to the genetic makeup of the twin pregnancy, and chorionicity indicates the pregnancy's placental composition (Figure 30-1). **Chorionicity is determined by the mechanism of twinning and, in MZ twins, by the timing of embryo division. Early determination of chorionicity is vital because it is a major factor in determining obstetrical**

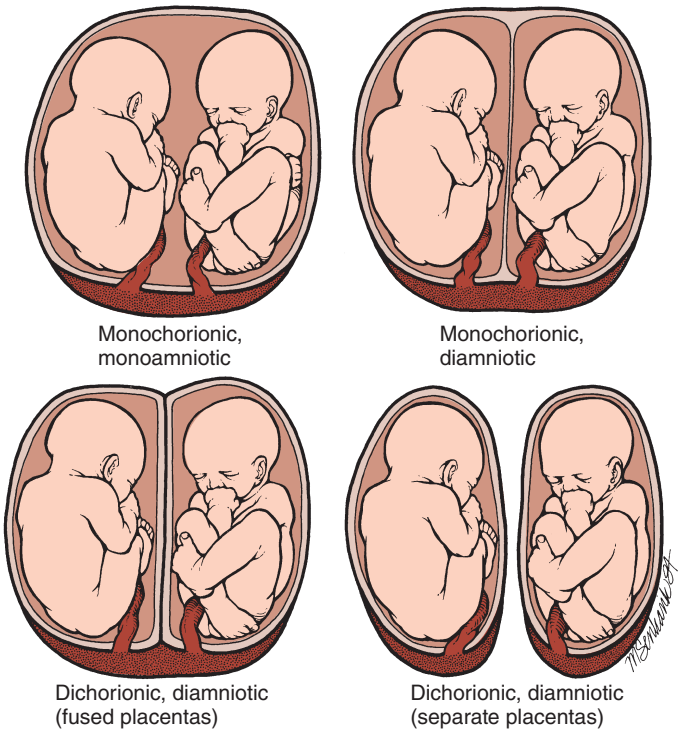

FIGURE 30-1. Placentation in twin pregnancies.

risks, management and outcomes. DZ twins, because they result from the fertilization of two different ova by two separate sperm, always develop a dichorionic, diamniotic placentation because each blastocyst generates its own placenta. An MZ twin pregnancy is created by the fertilization of one egg by one sperm and then subsequent spontaneous cleavage of the fertilized ovum. Thus, the type of placentation that develops is determined by the timing of this cleavage (Table 30-1).

MZ twins are at higher risk for adverse outcomes than are DZ twins. Not only do MZ twins have higher rates of anomalies than DZ twins, but they also deliver earlier, have a lower birthweight, and have higher rates of intrauterine and neonatal death. **However, several studies, including one by Carroll and colleagues using DNA analysis to confirm zygosity, have shown that monochorionicity, rather than monozygosity per se, is the determining factor.**[2] Since MZ dichorionic twins result from an earlier embryonic split, it is logical that they would have more complete separation, and thus fewer fetal anomalies and placental abnormalities, than twins in whom the embryonic split occurs later.

DISTRIBUTION AND CAUSES OF DIZYGOTIC VERSUS MONOZYGOTIC TWINNING

Among natural conceptions, DZ twins arise in about 1% to 1.5% of pregnancies and MZ twins occur in 1 in 250 pregnancies. Rates of spontaneous DZ twinning are greatly affected by maternal age, family history, and race. The risk for DZ twinning increases with maternal age, peaking at 37 years of age.[3] Maternal family history, particularly in first-degree relatives, also increases the chance of spontaneous DZ twinning; paternal family history contributes little or nothing to this risk. Finally, women of African descent have higher rates of DZ twinning than white women, who in turn have higher rates than women of Asian descent. For instance, in Japan, 1 in 250 newborns is a twin, whereas in Nigeria, 1 in 11 babies is a product of a twin gestation.[3]

TABLE 30-1 Determination of Monozygotic Twin Placentation

TIMING OF CLEAVAGE OF FERTILIZED OVUM	RESULTING PLACENTATION	PERCENTAGE OF MONOZYGOTIC TWINS
<72 hr	Diamniotic, dichorionic	25%-30%
Days 4-7	Diamniotic, monochorionic	70%-75%
Days 8-12	Monoamniotic, monochorionic	1%-2%
≥Day 13	Conjoined	Very rare

The causes of DZ twinning are much better understood than the causes of MZ twinning. DZ twins result from multiple ovulation, which is associated with higher maternal follicle-stimulating hormone (FSH) levels. FSH levels, and thus rates of DZ twinning, vary with season, geography, maternal age, and body habitus. Increases in DZ twins have been reported in summer months, locations with more daylight hours, and taller, heavier, and older mothers.[3]

The causes of MZ twinning are less clear. There are no naturally occurring animal models for MZ twinning, with the exception of armadillos, which produce MZ quadruplets or octuplets. However, MZ twinning has been induced by delayed fertilization in rabbits and by iatrogenic hypoxia in mice.[3] It has been proposed that MZ twinning in humans is a teratogenic event. Theories for MZ twinning in humans include fertilization of an "old" ovum with a more fragile zona pellucida or inadequate cytoplasm and with damage to the inner cell mass leading to two separate points of regrowth and splitting of the fertilized ovum.[3] **MZ twinning rates are constant across all variables, with the exception of assisted reproduction.** IVF and ovulation induction have been shown to produce higher rates of MZ twins. Against a spontaneous rate of 0.4% in the general population, studies have reported that the rate of MZ twinning may be more than 10-fold higher in pregnancies conceived by assisted fertility. One theory to explain these increased rates of MZ twinning is that injury to the zona pellucida may be responsible for the increased tendency toward iatrogenic zygote splitting.

DIAGNOSIS OF MULTIPLE GESTATIONS

Prenatal ultrasound is invaluable in the early diagnosis of a multiple gestation. Before the advent of routine prenatal ultrasound, many twins were not diagnosed until late in gestation or at delivery. **Using transvaginal ultrasound, separate gestational sacs with individual yolk sacs can be identified as early as 5 weeks from the first day of the last menstrual period and embryos with cardiac activity can**

TABLE 30-2 DETERMINATION OF CHORIONICITY AND AMNIONICITY IN FIRST-TRIMESTER PREGNANCIES

PLACENTATION	NO. OF GESTATIONAL SACS	NO. OF YOLK SACS	NO. OF AMNIOTIC CAVITIES
Dichorionic, diamniotic	2	2	2 (thick dividing membrane)
Monochorionic, diamniotic	1	2	2 (thin dividing membrane)
Monochorionic, monoamniotic	1	1*	1

*Although this is nearly always true, there have been case reports of two yolk sacs in early pregnancy in twins later confirmed to be monoamniotic.

usually be seen by 6 weeks. Retromembranous collections of blood or fluid or a prominent fetal yolk sac should not be confused with a twin gestation. Another entity that could be confused with a multiple gestation would be a singleton pregnancy with a separate pseudosac in a bicornuate uterus (or other anomaly with a second uterine horn, such as a unicornuate uterus with a rudimentary horn or a uterine didelphys). The sonographer must be compulsive in examining the entire uterine cavity in order to avoid underdiagnosing or overdiagnosing a multiple gestation.

Determination of Chorionicity

Accurate determination of chorionicity and amnionicity early in pregnancy is vital to optimal obstetrical care. A recent editorial argued that "there is no diagnosis of twins" but rather any twin gestation must be further described as either monochorionic or dichorionic.[4] **Knowledge of chorionicity is essential in counseling patients on obstetrical and neonatal risks because chorionicity is a major determinant of pregnancy outcome.** Furthermore, in some cases, precise knowledge of chorionicity is paramount. For instance, when contemplating selective reduction of a multiple gestation, incorrectly assuming dichorionicity when the pregnancy is in fact monochorionic could have tragic consequences.

Determination of chorionicity is easiest and most reliable when assessed in the first trimester. Between 6 and 10 weeks, counting the number of gestational sacs and evaluating the thickness of the dividing membrane is the most reliable method of determining chorionicity (Table 30-2). Two separate gestational sacs, each containing a fetus, and a thick dividing membrane strongly suggest a dichorionic diamniotic pregnancy, whereas one gestational sac with a thin dividing membrane and two fetuses suggests a monochorionic diamniotic pregnancy (Figure 30-2). For monochorionic gestations, the dividing amniotic membrane may be very difficult to visualize in the first trimester. However, with rare exceptions, the number of amniotic sacs will be the same as the number of yolk sacs, which are relatively easy to count in early gestation.

After 9 weeks, the dividing membranes become progressively thinner, but in dichorionic pregnancies, they remain thicker and easy to identify. At 11 to 14 weeks' gestation, sonographic examination of the base of the intertwin membrane for the presence or absence of the lambda or twin peak sign provides reliable distinction between a fused dichorionic and a monochorionic pregnancy. The twin peak sign is a triangular projection of tissue extending beyond the chorionic surface of the placenta (Figure 30-3). This tissue is insinuated between the layers of the intertwin membrane, wider at the chorionic surface, and tapering to a point at some distance inward from that surface. This finding is produced by extension of chorionic villi into the potential interchorionic space of the twin membrane at the place where it encounters the chorion and placenta of the co-twin. This space exists only in dichorionic pregnancies. The twin peak sign cannot occur in monochorionic placentation because the single continuous chorion does not extend into the potential interamniotic space of the monochorionic, diamniotic twin membrane.

After the early second trimester, determination of chorionicity and amnionicity becomes less accurate, and different techniques are used (Figure 30-4). The sonographic prediction of chorionicity and amnionicity should be systematically approached by determining the number of placentas and the sex of each fetus, and then by assessing the membranes that divide the sacs. Scardo and associates[5] found that, using these criteria, dichorionicity could be determined with 97.3% sensitivity and 91.7% specificity and monochorionicity with 91.7% sensitivity and 97.3% specificity in twin gestations first scanned at 22.6 ± 6.9 weeks. In some pregnancies with monochorionic, diamniotic placentation, the dividing membranes may not be sonographically visualized because they are very thin. In other cases, they may not be seen because severe oligohydramnios causes them to be closely opposed to the fetus in that sac. This results in a "stuck twin" appearance, in which the trapped fetus remains firmly held against the uterine wall despite changes in maternal position. In many cases, a small portion of the dividing membrane can be seen extending from a fetal edge to the uterine wall (Figure 30-5). Diagnosis of this condition confirms the presence of a monochorionic, diamniotic gestation, which should be distinguished from a monoamniotic gestation, in which dividing membranes are absent. In the latter situation, free movement of both twins, and entanglement of their umbilical cords, can be demonstrated.

Determination of Zygosity

If a twin set is monochorionic, monozygosity can be inferred. If twins are different genders, then with very rare anecdotal exceptions, they can be assumed to be DZ. **It is estimated that based on these two findings, about 55% of all twins' zygosity can be determined by examination of the babies and placentas.** Conversely, 45% of all twins (same sex, dichorionic twins) would need further genetic testing to determine zygosity.

MATERNAL AND FETAL RISKS OF MULTIPLE GESTATION

Maternal Adaptation to Multifetal Gestation

The degree of maternal physiologic adaptation to pregnancy is exaggerated with multiple gestation.[6] Levels of maternal progesterone, estriol, and human placental

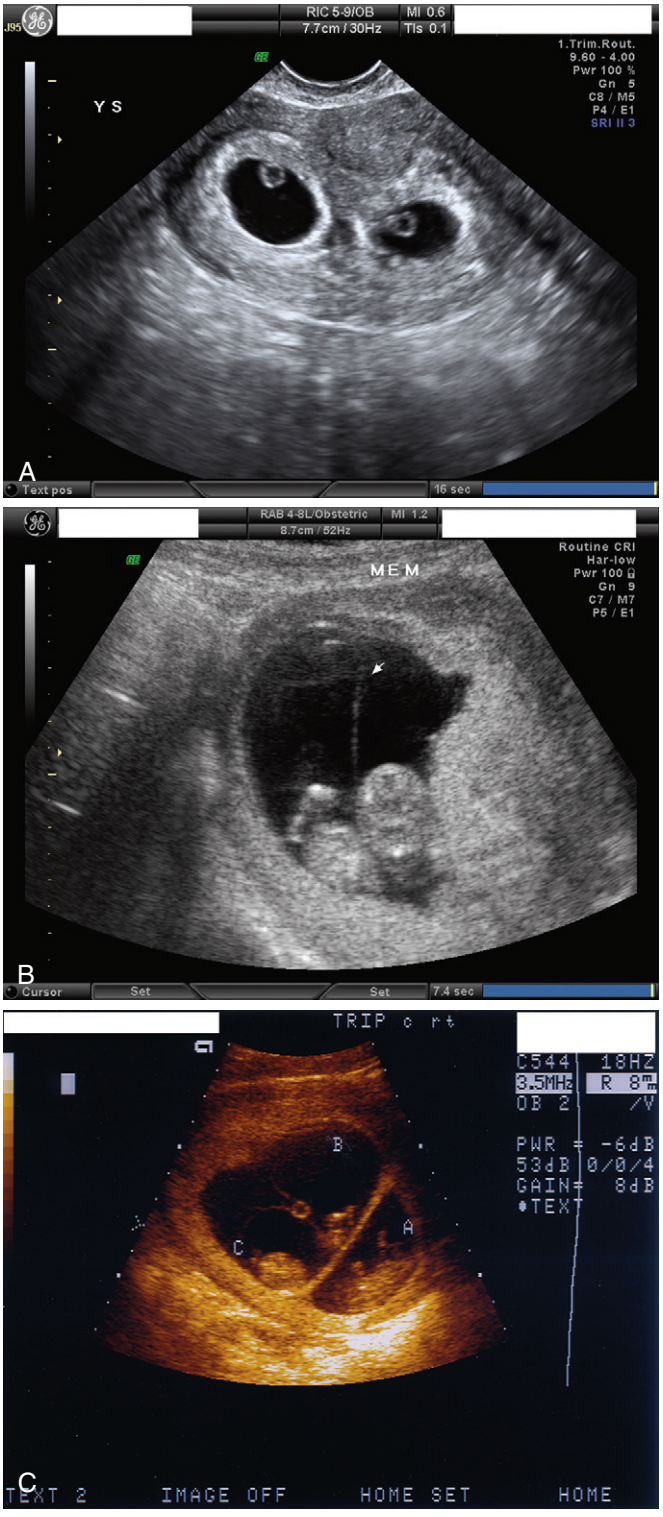

FIGURE 30-2. **A,** An early first-trimester dichorionic twin gestation. Note the clearly separate gestational sacs, each surrounded by a thick echogenic ring. **B,** A mid–first-trimester monochorionic, diamniotic twin pregnancy with a very thin, hairlike dividing membrane *(arrow)*. **C,** An early first-trimester image of a dichorionic, triamniotic triplet pregnancy. Note that monochorionic triplets B and C are separated by a very thin membrane, whereas triplet A, with its own placenta, is separated from B and C by a thick membrane.

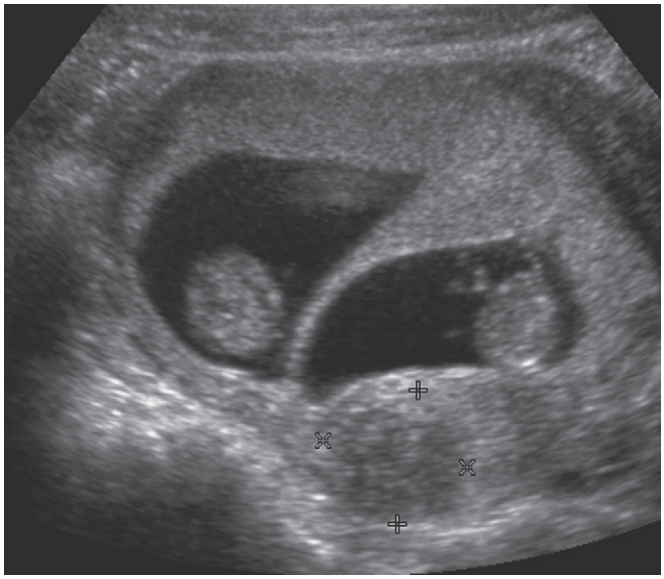

FIGURE 30-3. Twin peak sign in a dichorionic twin pregnancy with a fused anterior placenta.

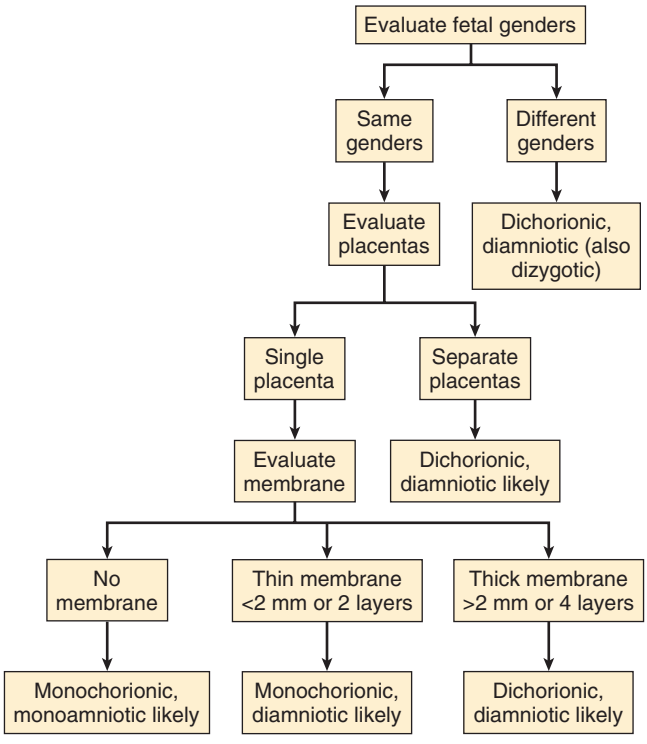

FIGURE 30-4. Algorithm for determination of chorionicity and amnionicity in the second and third trimesters.

lactogen are higher in multiple gestations than in singletons. This increase in human placental lactogen is thought to be the cause of the increased risk for gestational diabetes seen in multifetal pregnancies. Increased production of multiple placental proteins such as human chorionic gonadotropin may contribute to clinical conditions such as a greater risk for hyperemesis and complicates the interpretation of both first- and second-trimester maternal serum screening tests. Cardiovascular adaptations are also greater; both heart rate and stroke volume are increased

compared with singleton gestations, resulting in increased cardiac output. In addition to these cardiac changes, plasma volume expansion and total body water are increased in twin gestations. Partially as a consequence of increased total body water, colloid osmotic pressure is reduced. Clinical effects of the decreased colloid osmotic pressure are increased dependent edema as well as a heightened sensitivity to pulmonary edema, a risk that must be considered when tocolysis of a multiple gestation is contemplated.

Studies using dye excretion have suggested that hepatic clearance capacity is reduced in pregnancy in general, and more so in twin gestation.[6] As described previously, serum protein concentrations are decreased during pregnancy. Although this is partially due to increased total body water, there is likely some degree of reduced hepatic contribution of serum proteins, again more exaggerated in multifetal gestation compared with singleton pregnancy. Most obvious to patients, marked uterine changes also occur. By 25 weeks' gestation, the average twin gestation uterine size is equal to a term singleton pregnancy. By term, the total uterine volume is often 10,000 mL, and the weight of the uterus and its contents can exceed 8 kg.

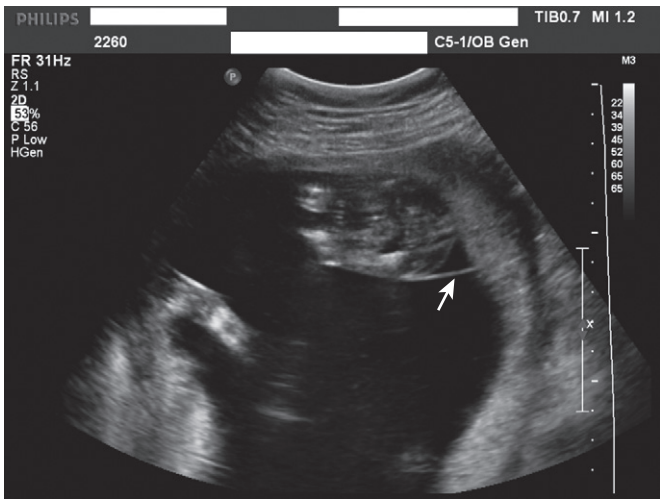

FIGURE 30-5. The donor twin "stuck" against the anterior uterine wall in a case of twin-twin transfusion syndrome. Note the small portion of membrane visible *(arrow)* extending from the edge of the fetus to the uterine wall.

Maternal Morbidity and Mortality

Rates of essentially every obstetrical complication, with the exception of macrosomia, are elevated with multiple gestations and in general rise proportionally to increasing plurality. Table 30-3 provides the relative risks for obstetrical complications in twin gestations compared with singletons.[7] In addition to the conditions listed in the table, multiples are associated with higher rates of gestational diabetes and rare but life-threatening conditions such as acute fatty liver and peripartum cardiomyopathy. **Additionally, women pregnant with multiples not only have higher risks for developing certain conditions but also are more likely to have more severe manifestations of those conditions.** For instance, Sibai and associates showed that not only are twin mothers more likely to develop preeclampsia (relative risk [RR], 2.62; 95% confidence interval [CI], 2.03 to 3.38), but also twin mothers with preeclampsia have higher rates of delivery before 37 weeks and before 35 weeks, as well as higher rates of placental abruption and small-for-gestational-age infants than singleton mothers with preeclampsia.[8] A large retrospective analysis of 24,781 singleton, 6859 twin, 2545 triplet, and 189 quadruplet pregnancies found an incidence of pregnancy-related hypertensive conditions of 6.5% in singletons, 12.7% in twins, and 20% in triplets and quadruplets. The risk for interventional delivery due to hypertensive complications also increased by plurality: about twofold higher in twins and threefold higher in triplets compared with singletons.[9] Atypical presentations of preeclampsia are also more common in multifetal gestations, especially higher-order multiples. One retrospective review of 21 triplet and 8 quadruplet pregnancies found that only half of the women who were delivered for preeclampsia had elevated blood pressures before delivery. Furthermore, proteinuria was present in only 3 of 16 women before delivery. Predominant presentations of preeclampsia in this series were laboratory abnormalities (chiefly elevated liver enzymes) and maternal symptoms.[10]

TABLE 30-3 MATERNAL COMPLICATIONS IN MULTIPLE GESTATIONS

	SINGLETON (*n* = 71,851) (%)	TWIN (*n* = 1694) (%)	RELATIVE RISK	95% CONFIDENCE INTERVAL

From Martin JA, Hamilton BE, Sutton PD, et al: Births: Final Data for 2006. National Vital Statistics Reports; Vol 57, No 7. Hyattsville, MD, National Center for Health Statistics, 2009.

One theory for the higher incidence of atypical preeclampsia in women with triplet and higher-order multiples is that the exaggerated hemodynamic changes found in higher-order multiples do not allow for the "typical" maternal manifestations of preeclampsia.

These increased maternal risks extend to life-threatening morbidity and even mortality. Multiple gestation has been found to be an independent risk factor for intensive care unit admission.[11] Finally, although fortunately still a very rare event, maternal death is also increased in multifetal gestations. A relative risk of 2.9 (95% CI, 1.4 to 6.1) for maternal death in women pregnant with multiples has been reported.[12]

Perinatal Morbidity and Mortality

Multifetal gestations carry significant perinatal risks. **Babies who are products of multiple gestations have higher rates of low birthweight, earlier gestational age at delivery, and higher rates of neonatal and infant death and cerebral palsy** (Table 30-4). One in eight twins and one in three triplets is born before 32 weeks' gestation, compared with only 2 in 100 singletons. Additionally, the risk for infant death is higher: 29.8 per 1000 for twins and 59.6 per 1000 for triplets, compared with 6 per 1000 for singletons.[1] Rates of cerebral palsy have been estimated as 4 to 8 times higher in twins than singletons and as much as 47 times higher in triplets.[13] Much of this increased risk is likely attributable to higher rates of preterm delivery and low birthweight in multiple gestations. Of note, although the overall rates of cerebral palsy are higher in twins than singletons, low-birthweight preterm twins do not have higher rates than like-weight, gestational age–matched singletons. Interestingly, however, most studies have demonstrated higher rates of cerebral palsy for twins born at term weighing more than 2500 g than for comparable singletons. This difference is mostly a reflection of the effect of monochorionicity on twin growth and development.

Fetal Anomalies

Fetuses in multiple gestations are known to be at increased risk for anatomic abnormalities, although the exact degree of risk is debated. The largest series available, an international study of more than 260,000 twins, found a relative risk for major anomalies of 1.25 (95% CI, 1.21 to 1.28). Anomalies were found in all organ systems.[14] This study, however, was not informed on zygosity or chorionicity, and most experts believe that much of the increased risk for structural anomalies in multiple gestation is associated with MZ twinning.

A 2009 population-based study from England found that rates of congenital anomalies were 1.7 times more frequent in twins compared with singletons (95% CI, 1.5 to 2.0) and that the relative risk for monochorionic twins was nearly twice that of dichorionic twins (RR, 1.8; 95% CI, 1.3 to 2.5).[15] A Taiwanese series of 844 twin sets compared with 4573 control singletons found a doubling of the relative risk of major congenital malformations in twins compared with singletons. When broken down by zygosity, the relative risks were 1.7 for DZ twins and 4.6 for MZ twins, with an anomaly prevalence of 0.6% for singletons, 1% for DZ twins, and 2.7% for MZ twins. Anomalies were concordant in 18% of the MZ twins but in none of the DZ twins.[16] Older studies have shown somewhat higher overall anomaly rates (both for singletons and twins) but found similar distributions. **Thus, the overall evidence supports an approximately twofold increased risk for congenital anomalies in twins versus singletons, with most of this risk occurring in MZ twins.**

There is a strong association between MZ twinning and midline defects. Nance[17] presents evidence to suggest that a group of birth defects involving midline structures, including symmelia, exstrophy of the cloaca, and midline neural tube defects, may be associated with the twinning process. Symmelia is a severe, rare defect that results from fusion of the preaxial halves of the developing hind limb buds, producing a single lower extremity with a knee that flexes in the opposite direction from normal. The incidence of this condition is 100 times higher in MZ births than in singletons. MZ twins have also been shown to have a higher frequency of neural tube defects than singletons, and they are usually discordant for the abnormality. Nance suggests that the MZ twinning process, with its attendant opportunities for asymmetry, cytoplasmic deficiency, and competition in utero, may favor the discordant expression of midline defects in these gestations.

ISSUES AND COMPLICATIONS UNIQUE TO MULTIPLE GESTATIONS

"Vanishing Twin"

The "vanishing twin" is a well-known obstetrical phenomenon. This term refers to the loss of one member of a twin (or other higher-order multiple) gestation early in pregnancy. This is typically either asymptomatic or associated with spotting or mild bleeding. Landy and colleagues reported on a series of 1000 first-trimester ultrasounds, with an incidence of twinning of just over 3%.[18] After confirming a twin gestation (two embryos with heartbeats), 21.2% ultimately delivered singletons. In general, if two gestational sacs are confirmed by the first-trimester ultrasound, the chance of delivering twins is 63% for women younger than 30 years and 52% for women 30 years or

older. If two embryos with cardiac activity are seen in the first trimester, the chance of a twin birth rises to 90% for women younger than 30 years and 84% for women 30 years or older.[19] Other investigators have shown that, not unexpectedly, the earlier the initial ultrasound, the greater the chance of a vanishing twin phenomenon. Additionally, monochorionic twin gestations are at a higher risk for either a vanishing twin or a complete pregnancy loss than are dichorionic twins. Again, it is important for sonographers to identify the presence of embryonic structures before making the diagnosis of a vanishing twin.

"Appearing Twin"

Another interesting entity is that of the "appearing twin." **An appreciable percentage of cases of multiple gestations may be missed between 5 and 6 weeks' gestation.** Doubilet and Benson reported on their experiences with appearing twins in pregnancies initially diagnosed as singletons.[20] They found that 14% of pregnancies later diagnosed as multiple gestation had been initially undercounted. Monochorionic twin gestations were far more likely than dichorionic to have been undercounted (86% vs. 11%). **The authors noted that pregnancy outcomes were no different for initially undercounted pregnancies than for those pregnancies correctly diagnosed on their initial ultrasound.** The entity of an appearing twin underlines once again the importance of a thorough ultrasonographic survey of the entire uterine cavity before diagnosing any pregnancy.

First-Trimester Multifetal Pregnancy Reduction

The increasing use of ovulation induction and assisted reproduction has resulted in a growing number of multifetal pregnancies with three or more fetuses. **Because the risk for pregnancy loss, preterm delivery, and long-term morbidity for children who are products of multiple gestations is directly proportional to the number of fetuses being carried, first-trimester multifetal pregnancy reduction has been advocated as a method to reduce the risk for prematurity and associated morbidity and mortality.** Currently, the method of choice is injection of a small dose of potassium chloride into the thorax of one or more of the fetuses, either transabdominally or transvaginally, under real-time sonographic guidance. The latter approach is used less frequently because it is associated with a greater infection risk and a higher loss rate than the former. In monochorionic pregnancies, the use of these techniques is contraindicated because of the vascular communications within the placenta.

Multifetal pregnancy reduction (MPR) is an outpatient procedure. It is usually performed between 11 and 13 weeks, and chorionic villus sampling (CVS) can safely be performed on some or all of the fetuses before the procedure to confirm karyotype if desired. Ultrasound is used to map the location of each fetus, nuchal translucencies should be measured, and prophylactic antibiotics are often administered. Any fetus appearing to be anatomically abnormal or small for gestational age, or known to have a karyotypic abnormality, is included among those that are reduced. If no abnormalities can be detected, generally the fetus or fetuses that are technically most accessible are chosen for reduction. Whenever possible, the fetus whose sac overlies the cervical os is not electively reduced, in order to minimize the risk for premature rupture of the membranes. Follow-up ultrasound examinations should be performed to confirm the success of the procedure and to monitor the growth of the remaining fetuses.

Evans and colleagues[21] published a series of 3513 completed first-trimester MPR procedures from 11 centers in five countries. The overall loss rate was 9.6%, but each of the participating centers showed significant improvement in this parameter as the operators developed more experience over time. Additionally, loss rates increased steadily from 4.5% to 15.4% as the number of starting fetuses rose from three to six or more. The rate of loss for those who reduced to twins was 6%, compared with 18.4% for those who were left with triplets.

Stone and colleagues[22] reported the outcome of 1000 consecutive patients undergoing MPR at a single institution. Similar to the Evans study, these investigators also demonstrated a learning curve with fewer complications with increasing experience. The unintended pregnancy loss with the first 200 patients was 9.5% but fell to 5.4% after 1000 patients. An updated 2008 report[23] of the most recent 1000 multifetal reductions at the authors' institution found that the overall unintended pregnancy loss rate had dropped to 4.7%. This loss rate is unlikely to drop further because it approximates the baseline risk for pregnancy loss with twins in general. The rates of loss in the original report were 2.5% for those who reduced from twins to a singleton and 12.9% for those who presented with six or more fetuses, but the rate was stable at 4.7% to 5.4% for women who started with either three, four, or five fetuses. The rates of loss were 16.7%, 5.5%, and 3.5% for those who reduced to triplets, twins, and singletons, respectively. Significantly, the mean gestational ages for surviving fetuses were 35.3 weeks and 33.5 weeks for twins and triplets, respectively, which is what would be expected if these women had naturally conceived that number of fetuses.

Although perinatal morbidity and mortality are clearly improved when pregnancies with quadruplets or greater are reduced to smaller numbers, the medical advantages of reducing triplets to twins remain debatable. A 2006 meta-analysis attempted to answer this question.[24] The authors analyzed data from 893 pregnancies beginning as triplets, of which 411 were expectantly managed and 482 underwent MPR to twins. The rate of pregnancy loss before 24 weeks was higher in the MPR group (8.1% vs. 4.4%; $P = .036$). However, this risk was offset by a lower risk for delivery between 24 and 32 weeks in the MPR group (10.4% vs. 26.7%; $P < .0001$). The authors calculated that 7 reductions are needed to prevent one delivery before 32 weeks, and the number of reductions that would cause one loss before 24 weeks was 26. Thus, reducing triplets to twins may be associated with overall improvements in outcome.

Because the majority of losses occur several weeks after the procedure, the period from 18 to 24 weeks should be one of heightened surveillance. It is also recommended that these patients not undergo second-trimester aneuploidy serum screening because maternal serum α-fetoprotein (AFP) levels are often significantly elevated as a result of the retained dead fetus. Because the

incidence of intrauterine growth restriction (IUGR) may be increased in the surviving fetuses after MPR procedures, serial sonographic growth assessment has been suggested. Additionally, women who have undergone MPR can have significant grief reactions, and their emotional status should be monitored carefully.

Discordance for Anomalies

When an anomaly is detected in a twin gestation, even in an MZ set, the co-twin is usually normal. The diagnosis of discordance for a major anatomic abnormality places the parents in an extremely difficult position. Management choices include the following:

1. Expectant management
2. Termination of the entire pregnancy
3. Selective termination of the anomalous fetus

Several issues should be considered when counseling patients about the management of a multiple pregnancy complicated by discordant anomalies. These include (1) severity of the anomaly, (2) chorionicity, (3) effect of the anomalous fetus on the remaining fetus or fetuses, and (4) the parents' ethical beliefs. It is important to counsel patients if conservative management could result in adverse outcomes for the healthy twin. Although not all study results are consistent, most show that in a twin pregnancy discordant for major fetal anomalies, the normal fetus is at increased risk for preterm delivery and low birthweight. Some studies have also shown a higher risk for mortality in normal co-twins of an anomalous fetus. The most recent paper, a population-based retrospective study of more than 3000 normal co-twins of fetuses with nonchromosomal structural anomalies compared with more than 12,000 control twins unaffected by structural anomalies, showed higher rates of preterm birth (both <37 and <32 weeks), low birthweight, and perinatal mortality in normal co-twins of an affected pregnancy.[25] Reasons for higher rates of preterm birth are unclear, but polyhydramnios associated with anomalies and maternal psychosocial stress from the diagnosis of a fetal anomaly are possible explanations.

Selective Termination of an Anomalous Fetus

Although multiple techniques have been used to effect selective termination (ST) of a single fetus in a multiple gestation, the most common approach in dichorionic gestations is intracardiac injection of potassium chloride.

Evans and collegues[26] reported the outcomes of 402 ST procedures from eight centers in four countries using ultrasound-guided intracardiac injection of potassium chloride. They reported successful delivery of one or more viable infants in greater than 90% of cases. There were no cases of disseminated intravascular coagulation (DIC) or serious maternal complication. Similarly, Eddleman and associates[27] reported favorable outcomes in 200 ST cases performed at one institution on 164 twins, 32 triplets, and 4 quadruplets. The median gestational age at the time of the procedure was 19 weeks, 6 days, with a range of 12 weeks to 23 weeks, 6 days. The indications included chromosomal abnormalities, structural anomalies, mendelian disorders, placental insufficiency, and cervical incompetence. The unintended pregnancy loss rate was 4%, but the losses were fivefold higher in triplets than in twins. The average gestational age at delivery was 37 weeks, 1 day, and 84% delivered after 32 weeks' gestation. Only 3.7% delivered at less than 28 weeks' gestation.

In monochorionic twins, ST is far more challenging. Ablation of the umbilical cord of the anomalous fetus is needed to avoid back-bleeding through communicating vessels, which may precipitate death or neurologic injury in the remaining normal co-twin. Furthermore, in this situation, a lethal agent injected into the anomalous twin could enter the circulation of its normal sibling. Most reported attempts at ST in monochorionic pregnancies without occlusion of all vessels in the abnormal twin's cord have resulted in the death of the second twin within a short time. The indications and technique for cord occlusion are reviewed later.

Immediate complications associated with ST procedures include selection of the wrong fetus, technical inability to accomplish the procedure, premature rupture of membranes, and infection with loss of the entire pregnancy. When the indication for ST is an abnormal karyotype diagnosed by amniocentesis or CVS, a sonographically identifiable marker may or may not be present. If the gender of the twins is different, or the affected fetus has a gross morphologic anomaly, the abnormal twin can be easily identified by sonography. However, in the absence of such visible signs, one must rely on information provided from the original diagnostic procedure, which frequently has been performed elsewhere and several days or weeks before the patient presents for ST. If accurate localizing information is lacking, fetal blood sampling with rapid karyotype determination should be performed to identify the abnormal fetus before ST is attempted. Furthermore, in all cases, a sample of aspirated fetal blood or amniotic fluid should be obtained from the terminated twin at the time of the procedure to confirm that the correct fetus has been terminated. Intracardiac potassium chloride injection without concomitant cord occlusion is contraindicated if dichorionicity cannot be confirmed.

Cord Occlusion for Selective Termination in Monochorionic Twins

Selective termination by cord occlusion can be considered in several circumstances involving monochorionic multiple gestations. **These include:**

1. **Severely discordant anomalies**
2. **Severely discordant growth with high risk for intrauterine fetal death (IUFD) at a previable or periviable gestational age**
3. **Twin reversed arterial perfusion (TRAP) sequence**
4. **Severe twin–twin transfusion syndrome (TTTS) with associated discordant anomaly or in cases in which laser ablation was precluded by position of the fetus and placenta**

Each of the above indications is discussed in more detail in corresponding sections of this chapter.

Bipolar coagulation is probably the most commonly used technique, although radiofrequency ablation, laser coagulation, and ligation of the cord have also been successful. The site for port insertion is chosen according to the position of the placenta, the amniotic sac of the target fetus, and its umbilical cord. Preferentially, the other sac is avoided. Sometimes amnioinfusion is necessary to expand

the target sac. Bipolar coagulation can be accomplished with either 3-mm or 2.4-mm forceps, according to the cord diameter. Under ultrasound guidance, a portion of the umbilical cord is grasped while avoiding direct contact with the placenta, fetus, or membranes. Usually coagulation is effective at 25 watts, as demonstrated by the appearance of turbulence and steam bubbles. Limiting energy avoids tissue carbonization and cord perforation. Doppler studies can confirm arrest of flow, but many operators nonetheless coagulate three sections. In monoamniotic twins, the umbilical cord is often transected to avoid cord entanglement.

Pregnancy outcomes for the surviving co-twin are relatively favorable after selective cord occlusion. Rossi and D'Addario recently published a review of the literature regarding umbilical cord occlusion in complicated monochorionic twin pregnancies.[28] They evaluated 12 studies totaling 345 cases of cord occlusion at median gestational ages between 18 and 24 weeks. PPROM complicated 22% of pregnancies (59% of which occurred within 4 weeks), and co-twin fetal demise was a complication in 15% of cases (79% within 2 weeks of surgery). The overall survival rate for the remaining twin was 79% and was higher for cases after 18 weeks (89%) than for those undergoing the procedure earlier than 18 weeks (69%), regardless of the indication. Survival rates were 86% after radiofrequency ablation, 82% after bipolar cord coagulation, 72% after laser, and 70% after cord ligation. Long-term follow-up was not available for most studies, but in one series, the incidence of developmental delay was 8% in 67 infants older than 1 year who underwent evaluation by a pediatrician.[29]

Intrauterine Fetal Death of One Twin

IUFD of one twin occurs most commonly during the first trimester. This phenomenon is known as a vanishing twin and was discussed earlier in this chapter. Although it may be associated with vaginal spotting, the loss of one conceptus in the first trimester is often not clinically recognized, and the prognosis for the surviving twin is generally excellent. Single IUFD of one fetus in a multiple gestation in the second or third trimesters is much less common, complicating about 0.5% to 6.8% of twin pregnancies, but it can have more severe sequelae for the surviving fetus.[30] Monochorionic twins are at increased risk for a single fetal death, as are twins with a structural anomaly. In triplet pregnancies, studies have reported single IUFD rates between 4.3% and 17%.[30] In higher-order multiples, demise of a single fetus may be even more common.

The etiology of IUFD in a multiple pregnancy may be similar to that for singletons or be unique to the twinning process. Death in utero may be caused by genetic and anatomic anomalies, abruption, placental insufficiency, cord abnormalities such as a velamentous insertion, infection, and maternal diseases, including diabetes and hypertension. In diamniotic monochorionic pregnancies, IUFD may result from complications of TTTS. In addition, monoamniotic twins are at increased risk for cord entanglement and subsequent IUFD. Just as in singletons, however, the etiology of many IUFDs remains elusive.

Single IUFD in a multiple gestation can adversely affect the surviving fetus or fetuses in two ways: (1) risk for multicystic encephalomalacia and multiorgan damage in monochorionic pregnancies, and (2) preterm labor and delivery in both dichorionic and monochorionic twins.

Multicystic encephalomalacia results in cystic lesions within the cerebral white matter distributed in areas supplied by the anterior and middle cerebral arteries and is associated with profound neurologic handicap (Figure 30-6). The risk for this following single IUFD in a monochorionic pregnancy may be greater than 20% for the surviving co-twin.[31]

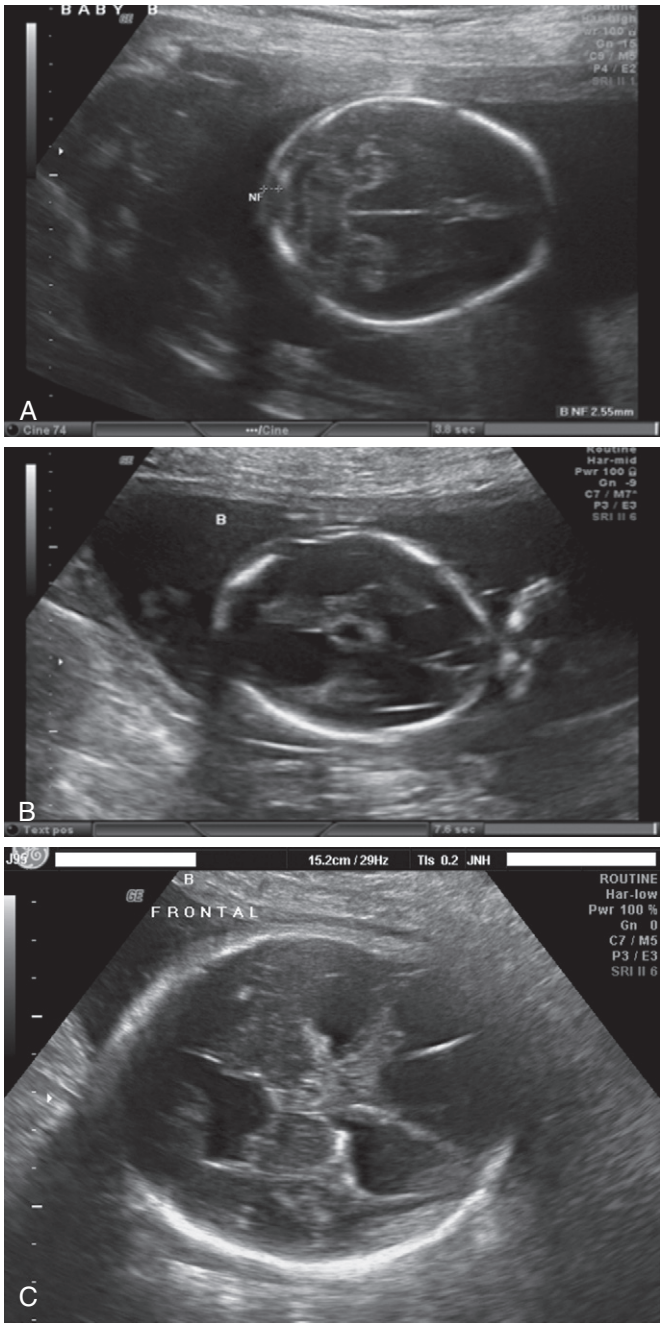

FIGURE 30-6. Ultrasound of the fetal brain of a monochorionic twin before **(A)** and after **(B, C)** intrauterine fetal death of the co-twin at 20 weeks' gestation. Note the normal brain anatomy in **A,** the dilation and cystic changes shortly after the co-twin's demise in **B,** and finally the residual irregular hydrocephalus and parenchymal loss 12 weeks later in **C.**

Two theories exist to explain this neurologic injury in the surviving co-twin in a monochorionic pregnancy. The first theory is that the deceased fetus produces thromboplastic substances, which traverse the vascular communications between the twins and cause infarcts and a DIC-like picture. The second and more widely accepted hypothesis is that significant hypotension at the time of demise of the co-twin causes neurologic injury in the surviving fetus. After death of the first twin, the resulting low pressure in that twin's circuit causes blood from the survivor to back-bleed rapidly into the demised twin through placental anastomoses. This can be thought of as an acute form of TTTS. If the resulting hypotension is severe, the surviving twin is at risk for ischemic damage to vital organs. Because the injury is coincident with the IUFD, rapid delivery of the co-twin following single IUFD in a monochorionic pregnancy will not improve the outcome.

It is unclear how early in gestation the death of one fetus in a monochorionic pregnancy can cause adverse sequelae for the surviving co-twin. Until relatively recently, it was thought that intrauterine demise in a monochorionic twin gestation could not cause neurologic injury to a co-twin until at least the mid-second trimester. However, in 2003 Weiss and coworkers reported a case of injury to a fetus after IUFD of the co-twin at about 13 weeks. Multicystic encephalomalacia was diagnosed by ultrasound and magnetic resonance imaging (MRI) in the co-twin at about 20 weeks.[32] The patient was counseled regarding the poor prognosis and opted for termination. Multicystic encephalomalacia was confirmed pathologically, although the exact timing could not be determined.

In addition, the IUFD of one twin can result in preterm delivery in both monochorionic and dichorionic pregnancies. Carlson and Towers[33] reported that 76% of 17 twin pregnancies complicated by IUFD of one fetus were delivered before 36 weeks and 41% were delivered at less than 32 weeks. The most common reason for early delivery was spontaneous labor, followed by abnormal fetal testing. The average interval from diagnosis to delivery was 16 days. Another series of 32 twin pregnancies complicated by single IUFD after 20 weeks followed by expectant management found strikingly similar numbers; the rate of delivery before 37 weeks was 81.3%, and delivery before 32 weeks occurred in 41.6% of the patients.[34] The median interval between diagnosis and delivery was 11 days. Of note, mothers with a single IUFD do not appear to be at increased risk for infection due to a retained twin demise. Cesarean delivery rates appear to be increased in these patients, often because of non-reassuring fetal status of the living twin. Dystocia caused by the dead fetus may also occasionally occur.

The determination of chorionicity is important for the counseling and management of patients with a single IUFD. Optimally, this has been established early in pregnancy. If, however, it has not been done before the IUFD, an attempt should be made to determine the chorionicity by ultrasound examination when the demise is discovered. Sonographic evaluation may not establish chorionicity with absolute certainty in some of these cases, and when the diagnosis is in doubt, DNA studies of amniocytes may be considered.

The optimal treatment for IUFD in multiples is not well established owing to the paucity of reported cases. To date, recommendations have been based on case reports, case series, and expert opinion. Referral to a tertiary care perinatal unit is advised when one fetus in a multifetal gestation has died in utero. In some of these cases, labor will already have started, and in others, coexisting maternal illness or placental abruption may make it necessary to expeditiously deliver the surviving fetus or fetuses. Clinical management depends on the gestational age, fetal lung maturity, or detection of in utero compromise of the surviving fetus or fetuses. The goal is to optimize outcome for the survivor while avoiding unnecessary or extreme prematurity and its potential adverse sequelae. It should be emphasized that close surveillance, even with reassuring antenatal testing, after the diagnosis of single IUFD in a monochorionic twin gestation cannot guarantee a good outcome for the surviving fetus.

Patients with monochorionic placentation should be counseled about the risk for multicystic encephalomalacia if an IUFD of one twin occurs after viability has been reached. It is difficult to predict which surviving monochorionic twins will develop cerebral injury. The nonstress test and biophysical profile give insight into the fetus' physiologic status but may not reflect subtle central nervous system changes. Ultrasound examination of the fetal brain may be suggestive of multicystic encephalomalacia but cannot definitively rule it out. Antenatal MRI of the fetal brain is investigational at this time but appears to be useful in detecting multicystic encephalomalacia in utero. As a consequence, we currently offer fetal MRI to all patients with monochorionic placentas approximately 2 to 3 weeks after the demise of one fetus has been detected. Although it is uncertain if normal MRI definitively rules out brain abnormalities, it is a reassuring sign. A single course of antenatal corticosteroids is recommended if premature delivery is anticipated and the gestational age is between 24 and 34 completed weeks. Surviving offspring are monitored with weekly biophysical profiles and nonstress tests.

The 2011 NICHD and SMFM workshop on timing of indicated late-preterm and early-term birth addressed the issue of single IUFD in a twin pregnancy. If the IUFD occurs at 34 weeks or beyond, delivery can be considered.[34a] Vaginal delivery is not contraindicated, and cesarean delivery is reserved for routine obstetric indications. At delivery, umbilical cord gas measurements should be performed. Autopsy should be offered for the stillborn fetus but may not be helpful if the demise has occurred several weeks earlier. Pathologic examination of the placenta is recommended. In addition, the pregnancy history should be communicated to the pediatricians caring for the neonate.

If IUFD occurs prior to 34 weeks, timing of delivery should be individualized based on other fetal or maternal issues.[34a] If, for instance, IUFD occurs at 18 weeks, delivery at term is likely the best option in the absence of any other complications, whereas a 33-week IUFD may warrant delivery between 34 and 37 weeks. Fetal surveillance should be considered once viability has been achieved. Monochorionic pregnancies complicated by IUFD before viability are more challenging. It is recommended that these patients be counseled regarding the

risk of multiorgan injury, including multicystic encephalomalacia. Ultrasound imaging and fetal MRI can be helpful in making the diagnosis. Some patients may opt to terminate the entire pregnancy, whereas others will choose expectant management. Once the surviving co-twin reaches viability, these women should be managed according to the recommendations described earlier.

Besides fetal risks, there may be maternal risks associated with IUFD in a multiple pregnancy. For example, there is a theoretical possibility of maternal consumptive coagulopathy in twin pregnancies complicated by a single IUFD. It was originally estimated that there was a 25% incidence of maternal DIC when a dead fetus was retained in a multiple gestation. However, only a few isolated cases of laboratory changes consistent with a subclinical coagulopathy have been reported under these circumstances, and this 25% incidence is certainly an overestimation.[30] It is also reassuring to note that no cases of clinically significant coagulopathy have been reported in the extensive literature on ST and MPR. When IUFD occurs in a multiple pregnancy, we recommend baseline maternal hematologic studies including a prothrombin time, partial thromboplastin time, fibrinogen level, and platelet count. If these values are within normal limits, many experts do not perform serial laboratory surveillance, given the very low risk for coagulopathy.

The occurrence of IUFD causes feelings of loss, sadness, anxiety, and guilt. In women with twins and an IUFD of one of the fetuses, bereavement may be underestimated by physicians because there is a shift in focus to the living offspring. As a result, we suggest that patients with a multiple pregnancy complicated by IUFD of one fetus be offered psychological or bereavement counseling, or both.

Twin–Twin Transfusion Syndrome

Etiology

TTTS is exclusively a complication of diamniotic monochorionic pregnancies. **It occurs in about 15% of monochorionic gestations and is thus the most common severe complication specific to this type of twinning.** TTTS is characterized by an imbalance of fetal blood flow through communicating vessels across a shared placenta, leading to underperfusion of the donor twin and overperfusion of the recipient (Figure 30-7). The donor twin develops IUGR and oligohydramnios, whereas the recipient experiences volume overload with polyhydramnios and potentially cardiac failure and hydrops. On echocardiography, the recipient demonstrates decreased ventricular function, tricuspid regurgitation, and cardiomegaly.[35] These cardiac abnormalities often progress during pregnancy and persist into the neonatal period. In response to the increased blood volume, the recipient also becomes hypertensive and produces increasing amounts of atrial and brain natriuretic peptides. Resulting polyhydramnios leads to uterine overdistention and increased uterine pressure, both of which may contribute to an increased risk for preterm labor and preterm premature rupture of membranes.

The syndrome can present at any gestational age. However, earlier onset is associated with a much poorer prognosis. The transfer of blood can occur in small increments chronically over the course of the pregnancy, or it can be acute. If untreated, the reported mortality rates range from 80% to 100% (Figure 30-8). Furthermore, if one fetus dies in utero, the surviving twin is at risk for death or multiorgan damage from acute exsanguination due to back-bleeding into the demised co-twin. This organ damage frequently includes severe neurologic compromise. Even if both twins survive, the pathophysiology of TTTS can still result in adverse neurologic sequelae in one or both twins.

Although all monochorionic twins share vascular anastomoses and thus exist in a state of constant intertwin transfusion, as noted earlier, only a minority develop TTTS. The following mechanism has been proposed to explain this observation. In monochorionic placentas, there can be three types of vascular communications: arteriovenous (AV), arterioarterial (AA), and venovenous (VV). AA and VV anastomoses are typically superficial, bidirectional anastomoses on the surface of the chorionic plate. AV anastomoses, usually referred to as deep anastomoses, involve a shared cotyledon, receiving arterial supply from one twin and draining on the venous side to the other twin. All these anastomoses are identifiable at the chorionic surface, a feature that allows laser ablation of these anastomoses as a treatment of TTTS. Superficial anastomoses, especially those that are AA, are crucial for maintaining bidirectional flow. **According to this hypothesis, the absence of adequate superficial AA and VV anastomoses, which help maintain balanced blood flow, is the mechanism underlying TTTS.**

Diagnosis and Staging

The diagnosis of TTTS is made antenatally by ultrasound. Many experts recommend ultrasound examinations every 2 weeks beginning at 16 weeks' gestation in monochorionic twins in order to allow early detection of TTTS. The four requirements, none of which is pathognomonic, include (1) the presence of a single placenta, (2) same-gender fetuses, (3) significant weight discordance, and (4) significant amniotic fluid discordance, often with a "stuck twin." The most important criterion in diagnosing TTTS is disparity in the amniotic fluid volume. The maximal vertical pocket should be less than 2 cm for the donor twin and greater than 8 cm for the recipient twin. The differential diagnosis of a stuck twin includes selective uteroplacental insufficiency, structural or chromosomal abnormality (i.e., renal agenesis), abnormal placental cord insertion, intrauterine infection, and rupture of the amniotic membranes for one twin.

A staging system for TTTS was developed in 1999 by Quintero and colleagues to categorize disease severity and to standardize comparison of different treatment results.[36] The Quintero staging system is depicted in Table 30-5.

Although Quintero staging is widely used and has proved enormously useful in our evolving understanding of TTTS, many experts have noted its limitations. Stage does not always progress; nor do patients, when they do worsen, always progress sequentially through the stages. For instance, a pregnancy can become stage 5 (fetal death) without progressing through stage 4 (hydrops). Several investigators have commented on the relatively frequent

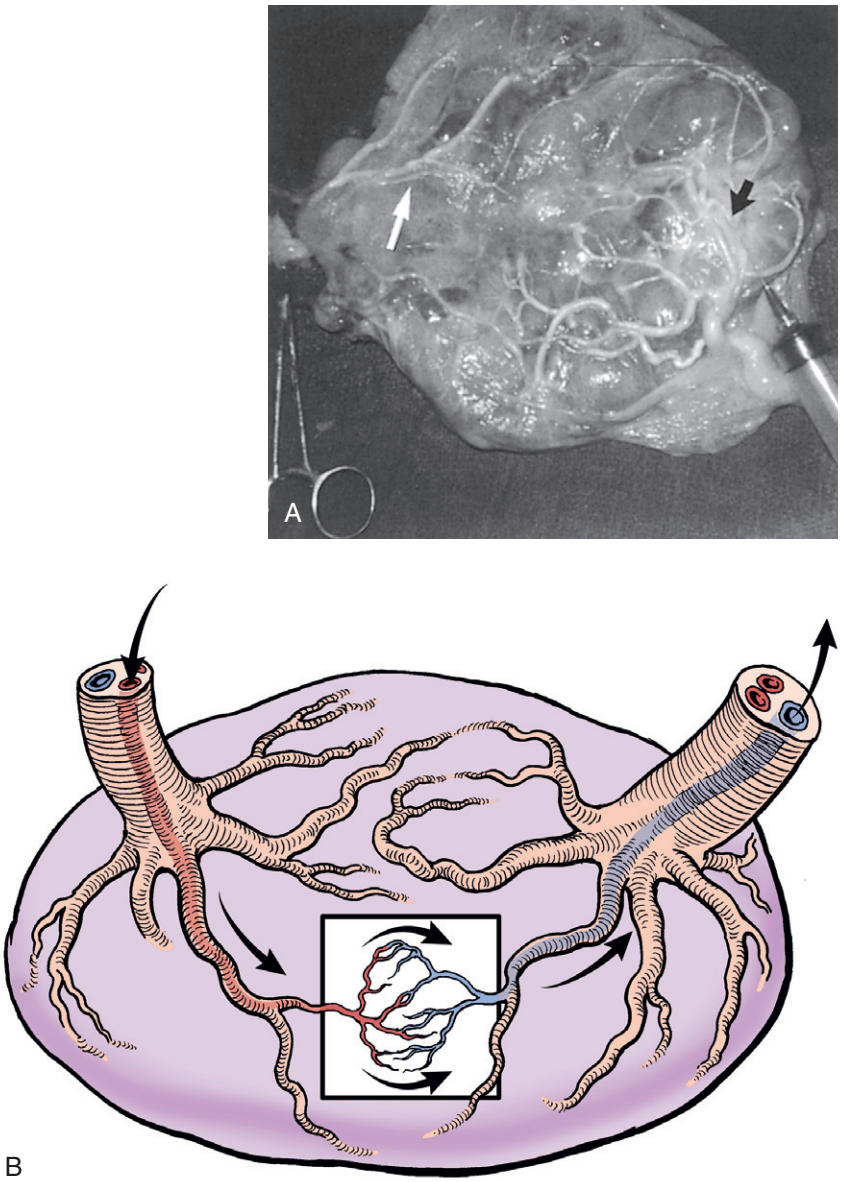

FIGURE 30-7. A, The placenta of a pregnancy complicated by twin-twin transfusion syndrome. Milk has been injected into an artery on the donor side of the placenta *(black arrow)*. It can be seen returning through the venous circulation on that side but is also evident in the venous circulation of the recipient *(white arrow)*. **B,** The arteriovenous shunt shown in **A.**

TABLE 30-5 QUINTERO STAGING FOR TWIN-TWIN TRANSFUSION SYNDROME

Stage I	Oligohydramnios, polyhydramnios sequence. Donor twin bladder visible.
Stage II	Oligohydramnios, polyhydramnios sequence. Donor twin bladder not visible. Doppler scan normal.
Stage III	Oligohydramnios, polyhydramnios sequence. Donor twin bladder not visible, and Doppler scans abnormal (absent or reversed end-diastolic velocity in the umbilical artery, reversed flow in the ductus venosus, or pulsatile flow in the umbilical vein).
Stage IV	One or both fetuses have hydrops.
Stage V	One or both fetuses have died.

occurrence of TTTS fetuses with Doppler abnormalities but a still visible fetal bladder in the donor. This has been referred to as an atypical stage III. Taylor and associates conducted a prospective observational study to validate the Quintero staging system's ability to predict perinatal outcomes. The study included 52 consecutive cases of TTTS that were either managed expectantly or treated with methods other than laser ablation. They found that only 45% of pregnancies progressed to a more advanced Quintero stage, and stage at presentation did not have a significant influence on survival. However, a progressive worsening of Quintero stage did predict worse outcomes. The authors concluded that Quintero staging does have a role in charting disease progress, but the stage at presentation does not accurately predict ultimate outcome.[37]

Several modifications of Quintero staging have been proposed, incorporating the differences in cardiovascular pathophysiology between donors and recipients, which is not accounted for in the Quintero staging system. None of these proposed staging alternatives, however, has been validated in prospective studies. The Cincinnati Modification categorizes all pregnancies in which the recipient exhibits cardiomyopathy (as assessed by AV valvular incompetence, ventricular wall thickness, and

FIGURE 30-8. Stillborn male twins at 31 weeks' gestation, secondary to twin-twin transfusion syndrome. The plethoric twin on the left weighed 1670 g, and the anemic growth-restricted twin on the right weighed 1300 g.

ventricular function) as stage III. Furthermore, this modification stratifies stage III into those with abnormal Doppler scans, those with mild to moderate cardiomyopathy, and finally those with moderate to severe cardiomyopathy.[38] A 2009 meta-analysis designed to determine the efficacy of Quintero staging in patients treated with laser ablation did not find a statistically significant difference in survival by initial Quintero stage, but there was a consistent, although nonsignificant, trend toward lower survival as the stage increased. The authors proposed a new "double" staging system, one for donors and one for recipients, focused on the different pathophysiology of TTTS in donors and recipients.[39] Other parameters that have received attention as potential criteria in predicting severity and prognosis in TTTS are first-trimester discrepancy in twin nuchal translucencies (thicker in the future recipient), intertwin hemoglobin discordance (as determined by middle cerebral artery Doppler scans), amniotic fluid markers of renal and cardiac function, and presence or absence of AA anastomoses.[40]

Management

Expectant management is generally not recommended in TTTS because of the poor perinatal outcomes associated with the disorder. **However, management depends on the gestational age at diagnosis and, despite the previously mentioned limitations, on the severity of the clinical findings.** When TTTS is diagnosed after 26 to 28 weeks, conservative management may be the appropriate decision. This would include serial fetal assessment and control of polyhydramnios as needed. On the other hand, when the diagnosis is made in the early to mid-second trimester, aggressive management is generally advised. However, in patients with apparent mild stage I disease, a 1- to 2-week trial of conservative management may be warranted, mainly to confirm the correct diagnosis and assess for progression. Although medical management with digoxin and indomethacin has been attempted, there is limited evidence for success, and current treatment for severe TTTS requires physical intervention. There are three main management options: (1) serial amnioreduction, (2) amniotic septostomy, and (3) laser ablation of the anastomoses. All three options are discussed separately next.

Serial Amnioreduction

In serial reduction amniocentesis, an 18-gauge spinal needle is placed into the polyhydramniotic sac under ultrasound guidance. Amniotic fluid is withdrawn until the fluid volume returns to normal (i.e., deepest vertical pocket <8 cm). Because of the large amount of fluid to be removed, attaching the needle to a closed-system vacuum container is more practical than withdrawing fluid manually. Amnioreduction is repeated as often as necessary to maintain a near-normal amniotic fluid volume. The mechanism by which this procedure restores the amniotic fluid balance is unknown. Removing excessive fluid from the sac with polyhydramnios may result in decreased pressure on the sac with oligohydramnios. This, in turn, may result in increased placental perfusion to the stuck twin, especially through thin-walled superficial venous anastomoses with secondary improvement in its amniotic fluid volume. Additionally, normalizing the amniotic fluid may help prolong pregnancy by relieving uterine overdistention and pressure on the cervix.

Although there are no prospective studies comparing serial amnioreduction to conservative management, based on observational data amnioreduction does appear to offer a twofold to threefold increase in overall survival compared with no intervention. The exception may be late-onset (third-trimester) stage I TTTS that remains stable over a 1- to 2-week observation period. A large retrospective study using the International Amnioreduction Registry to analyze 223 sets of twins with TTTS diagnosed before 28 weeks' gestation and treated with serial amnioreduction found a live birth rate of 78%. Sixty percent of the original 446 babies were alive 4 weeks after birth. IUFD of at least one twin occurred in 31% of the pregnancies, and in 14% of cases, IUFD of both babies occurred. Of those babies alive 4 weeks after birth, 24% of the recipients and 25% of the donors had abnormal findings on cranial imaging. Poor prognostic factors for survival were earlier gestational age at diagnosis, presence of absent end-diastolic flow in the umbilical arteries, hydrops, low birthweight, and earlier gestational age at delivery. Complications within 48 hours (spontaneous rupture of the membranes, spontaneous delivery, fetal distress, fetal death, and placental abruption) occurred in 15% of patients.[41]

Septostomy

Amniotic septostomy is another management option. In this procedure, a 20-gauge spinal needle is inserted through the dividing membrane under ultrasound guidance. Amnioreduction of the polyhydramniotic sac is generally performed concomitantly. The amniotic fluid then sometimes equilibrates across the disrupted membrane. Similar to serial amnioreduction, the mechanism of action of this technique is unclear. It is possible that the defect in the membranes and reaccumulation of fluid in the donor sac allow the donor to swallow a sufficient volume of fluid to augment its circulating blood volume, secondarily increasing its urine output. The only randomized trial of amnioreduction versus septostomy for the treatment of TTTS was terminated early after enrollment of 73 women because the rate of survival of at least one infant was similar in both groups (78% vs. 80%; $P = .82$). The major advantage seen with septostomy was that women randomized to the septostomy group were more likely to require only a single procedure for treatment (64% vs. 46%; $P = .04$).[42] Because septostomy could functionally create an iatrogenic monoamniotic pregnancy with its own inherent complications and risks, the procedure has been criticized. Likewise, comparing amnioreduction to septostomy is challenging because both procedures use amnioreduction, and, alternatively, serial amnioreduction can be complicated by inadvertent septostomy.

Laser Therapy

Laser ablation of placental anastomoses is a third invasive treatment option that has been used to treat TTTS (Figure 30-9). In the United States, the use of laser therapy to treat TTTS is restricted to gestations earlier than 26 weeks. **Unlike both serial amnioreduction and septostomy, which would be considered palliative procedures, laser ablation is the only therapeutic option that aims to correct the underlying pathophysiologic aberration causing TTTS. Additionally, because laser ablation interrupts the vascular anastomoses between the fetuses, it has the advantage of being protective of the surviving twin should one twin succumb in utero.** In this procedure, first described by De Lia, the strategy is to ablate all anastomosing vessels that might connect the fetuses using either Nd:YAG, KTP, or diode laser and 400- to 600-mm fibers in a nontouch technique. The procedure is performed percutaneously under local or regional anesthesia. An endoscopic cannula is inserted into the amniotic cavity of the recipient fetus under ultrasound guidance at an angle perpendicular to the presumed vascular equator. The positions of the fetuses, umbilical cord insertions, and placenta are mapped. Initial landmarks include both umbilical cord insertions and the intertwin membrane. The operator visualizes the entire vascular equator and coagulates all visible anastomoses. Sections of about 1 to 2 cm are coagulated with pulses of 3 to 4 seconds, the duration judged by tissue response. Arteries are distinguishable from veins because they have a darker color and pass over the veins. Reduction amniocentesis is simultaneously performed. When the placenta is anterior, operative conditions are more difficult. Special instruments have been proposed, including curved sheaths, flexible endoscopes, and a double insertion technique. Most centers hospitalize patients for 1 or 2 postoperative days, and many experts use periprocedure tocolytics and antibiotics.

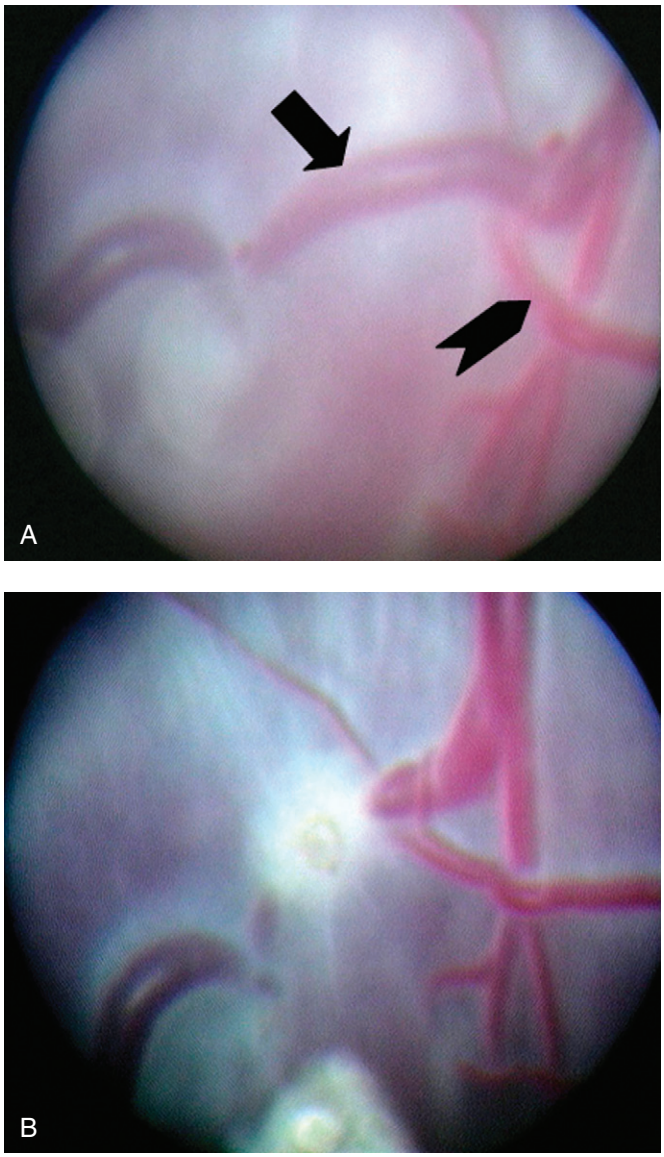

Figure 30-9. **A,** An artery from one twin going to a cotyledon, which is drained by a vein returning to the co-twin *(arrow)*. The cotyledon is also perfused by a small artery from the co-twin *(arrowhead)* and drained by a large vein going also to the co-twin. To preserve this cotyledon for the co-twin, the arterial perfusion to the cotyledon from the other twin is interrupted by laser photocoagulating the other artery. **B,** The effect of photocoagulation. (Courtesy Timothy M Crombleholme, MD, University of Cincinnati College of Medicine.)

Outcomes after Laser Therapy

In general, laser ablation has been shown to be a more effective technique than serial amnioreduction. In 2004, Senat and colleagues published the results of the European prospective multicenter randomized controlled trial of endoscopic laser (semiselective technique) versus serial amnioreduction for the treatment of severe TTTS between 15 and 26 weeks' gestation.[43] As the result of an interim analysis demonstrating a significant benefit for the laser group, the study was stopped after 142 patients had been

treated. Compared with the amnioreduction group, the laser group had a higher likelihood of survival of at least one twin to 28 days of life (76% vs. 56%; $P = .009$) and 6 months of age (76% vs. 51%; $P = .002$). The median gestational age at delivery was significantly more advanced in the laser group than in the amnioreduction group (33.3 vs. 29.0 weeks; $P = .004$). Neonates from the laser group also had a lower incidence of periventricular leukomalacia and were more likely to be free of neurologic deficits at 6 months of age (52% vs. 31%; $P = .003$). The authors concluded that endoscopic laser coagulation of anastomoses is a more effective first-line treatment than serial amnioreduction for severe TTTS diagnosed before 26 weeks' gestation. Although this study did include patients in Quintero stages I to IV, most (90% of the laser group and 91% of the amnioreduction group) were stage II or III.

A National Institute of Child Health and Human Development (NICHD)-sponsored prospective randomized multicenter trial is the only other randomized clinical trial comparing amnioreduction to fetoscopic laser photocoagulation.[44] That trial, in which all patients were Quintero stages II to IV, was stopped early after only 40 patients, mainly because of recruitment difficulties but also because of concern about a trend toward adverse fetal outcomes affecting the recipient twin in the laser arm. Analysis of the 40 patients treated before termination of the study showed no difference, either for donors or recipients, in the primary outcome of 30-day neonatal survival (55% in both arms for donors, and 45% vs. 30% in the amnioreduction vs. laser arms for recipients; $P > .5$). There was an increased *fetal* mortality rate for recipients in the laser group, and this was more pronounced in Quintero stages III and IV disease. The overall conclusion of these investigators was that the trial had not conclusively demonstrated the superiority of either treatment modality, although the results were limited by the small sample size.

Subsequently, both a Cochrane review and another meta-analysis comparing laser therapy with serial amnioreduction supported the role of laser therapy in the treatment of severe TTTS. The Cochrane review found a decreased risk for perinatal and neonatal death (odds ratio [OR], 0.59; 96% CI, 0.4 to 0.87, and OR, 0.29; 95% CI, 0.14 to 0.61, respectively) as well as a higher incidence of survival without neurologic handicap at 6 months of age (OR, 1.66; 95% CI, 1.17 to 2.35) with laser therapy compared with amnioreduction. The review concluded that laser therapy should be considered in all stages, although further research is needed in stages I and II.[45] The meta-analysis by Rossi and colleagues[46] found an advantage of laser therapy in improving overall survival (OR, 2.04; 95% CI, 1.52 to 2.76), decreasing neonatal death (OR, 0.24; 95% CI, 0.15 to 0.4), and decreasing neurologic morbidity (OR, 0.2; 95% CI, 0.12 to 0.33) compared with serial amnioreduction.

Short-term complications of laser ablation include abruption, rupture of membranes, IUFD, and labor. In Senat's trial, there was a 1% to 12% risk for each of these complications in both the laser and amnioreduction groups. Rates of IUFD, pregnancy loss, and preterm premature rupture of the membranes (PPROM) within 7 days of the procedure were 1.5- to 5-fold higher in the laser group, although these differences did not reach statistical significance.[43] In the NICHD trial,[44] incidence of PPROM before 28 weeks was 4.8% in the laser arm and 0% in the amnioreduction arm. Maternal complications are not consistently reported in the literature. However, no maternal deaths have been reported in all of the TTTS laser therapy literature, and serious complications such as pulmonary edema or blood transfusion appear to be very rare.

A few papers have studied the long-term neurologic outcomes of babies treated in utero with laser ablation for TTTS. Banek and associates studied all 89 surviving infants of pregnancies treated with laser surgery at their institution between 1995 and 1997. The children underwent neurodevelopmental testing at a median age of 21 months. Normal development was seen in 78%, minor deficiencies in 11%, and major deficiencies in 11%. There was a nonsignificant trend toward normal outcome for those infants who were born as both surviving twins, as opposed to babies born following the intrauterine death of their co-twin.[47] In a more recent report, Lopriore and colleagues followed up 278 surviving babies from 212 pregnancies treated with laser ablation at three European centers between 2000 and 2005. The children underwent neurologic, mental, and psychomotor development testing at age 2 years. The overall incidence of neurodevelopmental impairment at 2 years of age was 18%, and cerebral palsy was diagnosed in 6% of the children. Risk factors associated with neurodevelopmental impairment were greater gestational age at laser surgery, lower gestational age at birth, lower birthweight, and higher Quintero stage.[48]

The current consensus is that laser ablation of vascular anastomoses is the optimal therapy for Quintero stages II to IV disease before 26 weeks' gestation. Controversy, however, exists as to the optimal management of stage I disease. This controversy is based on several observations. First, the prognosis for stage I patients can be quite good without laser surgery. In a series by Taylor and colleagues, 70% of stage I patients treated with either expectant management, amnioreduction, or septostomy remained stable or regressed.[37] O'Donoghue and colleagues reviewed all cases of TTTS at their institution between 2000 and 2006 and identified 46 cases presenting with stage I TTTS, all of which were treated either expectantly or with amnioreduction. They found that 70% either remained stable or regressed.[49] On the other hand, recent studies have shown that even in stages I and II TTTS, the recipient can suffer cardiac dysfunction, something not taken into account by the commonly used Quintero staging system. Michelfelder and associates examined echocardiographic parameters of 42 TTTS patients, of whom 14 were stage I.[50] Of the stage I patients, 57% had ventricular hypertrophy, and 14% had AV valve dysfunction. Because it has been shown that cardiac dysfunction in the recipient improves after laser therapy but not after amnioreduction, this suggests that laser therapy may be the better choice in select patients presenting with Quintero stage I TTTS.[51] A single retrospective study published in 2009 directly compared outcomes in stage I patients treated with laser surgery versus conservative management. Of 50 women presenting with stage I TTTS, 40% underwent laser surgery, and 60% were managed either expectantly, or, if maternal symptoms were present, with amnioreduction. Although short-term outcomes (gestational age at delivery and perinatal

survival) were not significantly different between the two treatment groups, long-term neurodevelopmental impairment (as determined by neurologic examination and neuropsychological developmental testing at a minimum of 2 years of age) was decreased in the laser group (0/21 vs. 7/30; $P = .03$).[52] The improvement in long-term neurologic outcome in the laser-treated pregnancies in this study raises the question as to whether there is ongoing neurologic damage from mild TTTS even if the disease does not progress, and whether this damage could be prevented by interrupting the underlying cause of TTTS by laser ablation. **Synthesis of all the above information leads one to conclude that further study is needed in stage I disease, particularly focusing on echocardiographic parameters and long-term neurodevelopmental outcomes.** This sentiment was recently echoed in an excellent publication summarizing the current literature on TTTS and outlining recommendations of a scientific consensus panel convened to develop recommendations for TTTS diagnosis, therapy, and research.[40]

A wise overall approach to managing TTTS was aptly summarized in a 2005 review by Harkness and Crombleholme: "A thoughtful approach to the management of TTTS requires consideration of every aspect of the presentation, including gestational age, stage, Doppler findings, echocardiographic findings, concomitant placental insufficiency, and maternal risk factors. Until we have an effective medical therapy for TTTS, a judicious application of invasive procedures should be employed to optimize risk-to-benefit ratios for the mother and fetuses."[38]

Monoamniotic Twins

Monoamniotic twinning is an uncommon form of twinning in which both fetuses occupy a single amniotic sac. **Monoamniotic twins account for only 1% of all MZ twin pregnancies**. Historically, perinatal morbidity and mortality rates have been reported to be in excess of 50%. This has been attributed to premature delivery, growth restriction, congenital anomalies, and vascular anastomoses between twins, but mostly to umbilical cord entanglement and cord accidents (Figure 30-10). More recent reviews of prenatally diagnosed cases suggest improved perinatal outcomes, with mortality rates in the range of 10% to 20%.[53-55] This decrease is likely due to early prenatal diagnosis, the use of antenatal corticosteroids, increased fetal surveillance, and early elective delivery.

Because cord accidents are the primary cause of fetal death, most management protocols emphasize intense fetal surveillance to identify umbilical cord constriction before fetal loss. Fetal surveillance should be initiated after fetal viability has been achieved because IUFD has been documented to occur in monoamniotic twins throughout gestation.[54,56] Furthermore, this surveillance must be repeated frequently because fetal compromise and death can happen without much warning.

Many older reports on monoamniotic twins are not optimal for counseling patients because in most of those cases, the diagnosis of monoamnionicity was made postnatally. There have been several more recent series that are helpful. Rodis and coworkers reviewed 13 cases of monoamnionicity at one tertiary care center over a 10-year period.[53] All patients underwent serial ultrasound examinations and antenatal fetal surveillance two to seven times per week starting between 24 and 26 weeks' gestation. The mean gestational age at delivery was 32.9 weeks' gestation, with a mean birthweight of 1669 g. All pregnancies exhibited cord entanglement at the time of delivery, with 62% having knotted cords. Sixty-two percent of the pregnancies were delivered for abnormal fetal testing. If undelivered earlier, all patients had cesarean delivery by 35 weeks' gestation, and there were no fetal deaths. Two neonates died during the perinatal period: one from a congenital heart defect, and the other from asphyxia and sepsis. Compared with 77 sets of monoamniotic twins from the literature that had not been diagnosed prenatally, these patients had a 71% reduction in the relative risk for perinatal mortality.

A more recent study evaluated the impact of routine hospitalization for fetal monitoring on perinatal survival and neonatal morbidity in a multicenter retrospective cohort study of 96 monoamniotic twin gestations.[55] Of 87 women with both twins surviving at 24 weeks, 43 patients were admitted electively at a median gestational age of 26.5 weeks for inpatient surveillance and fetal testing two to three times daily. The remaining 44 women were followed as outpatients with fetal testing one to three times weekly. IUFD did not occur in any hospitalized patient, but 14.8% (13 of 88) of the fetuses were stillborn among those women followed as outpatients. Statistically significant improvements in birthweight, gestational age at delivery, and neonatal morbidity were also noted for the hospitalized women. This study suggests that improved neonatal survival and decreased perinatal morbidity are achievable in patients with monoamniotic twins admitted electively for daily fetal monitoring after viability.

Although the good outcomes obtained in the previously mentioned studies could be due to chance, we recommend fetal testing two to three times per day in the hospital for all patients with monoamniotic twins starting between 24 and 26 weeks' gestation. Although cord accidents cannot be predicted, daily fetal heart rate monitoring may reveal an increasing frequency of variable decelerations. If these are identified, continuous monitoring is recommended, with emergency delivery if worsening non-reassuring fetal status is encountered. Antenatal corticosteroids should be administered early because of the near certain chance of delivery at or before 34 weeks' gestation.

In the absence of non-reassuring fetal testing, the timing of elective delivery is not well established. Some authors have advocated delivery of all monoamniotic twin pregnancies as soon as fetal lung maturity has been demonstrated, whereas others have recommended elective delivery at 32 weeks' gestation.[56] Still others suggest that it is unnecessary to deliver monoamniotic twins before term. A retrospective evaluation of 24 sets of histologically confirmed monoamniotic twin pregnancies revealed no perinatal deaths after 30 weeks of gestation.[57] The authors suggested that there is no advantage to elective premature delivery of these pregnancies. Tessen and Zlatnik reviewed 20 monoamniotic twin pregnancies. In their retrospective series, there were no perinatal deaths after 32 weeks of gestation, and the authors suggested that prophylactic premature delivery of these women might not be indicated. However, in a subsequent addendum to the original paper,

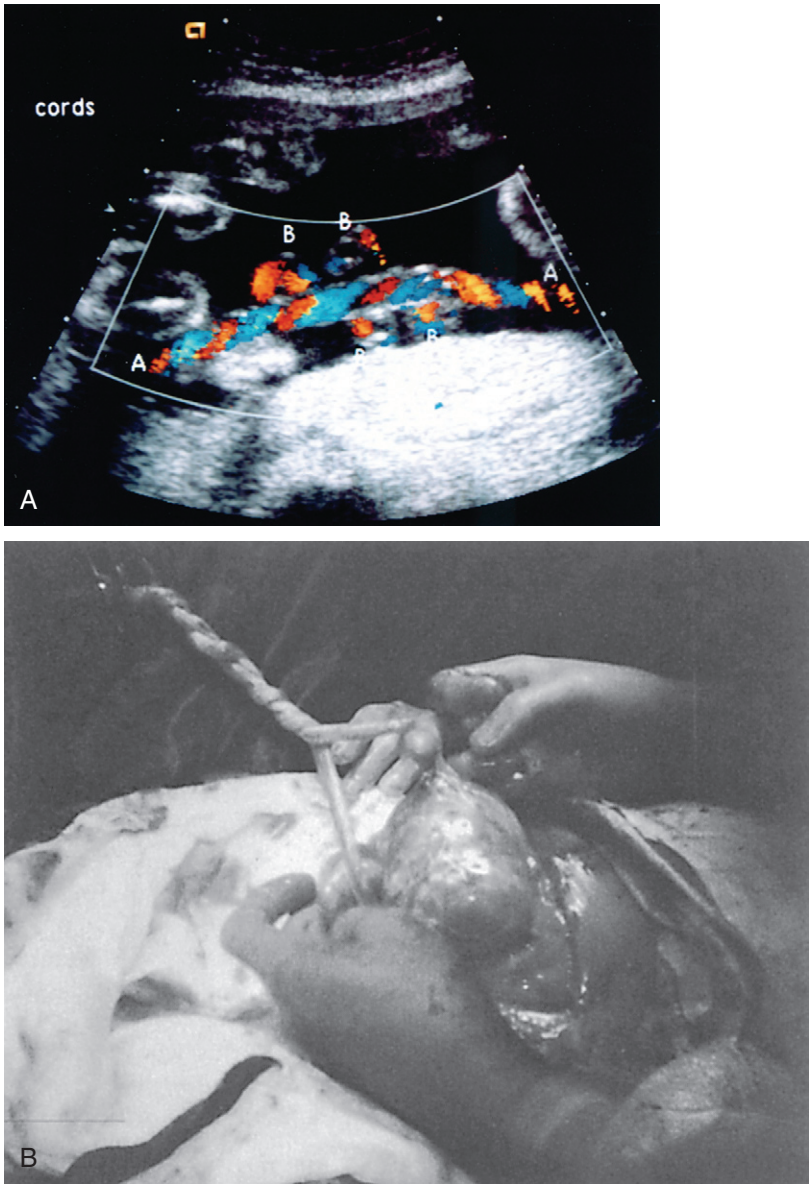

FIGURE 30-10. **A,** Cord entanglement detected by Doppler ultrasound in a monoamniotic twin gestation. **B,** Entangled cords found during cesarean delivery in a case of monochorionic monoamniotic twins.

they reported a double fetal death at 35 weeks just after publication of their report.[58] Despite these two reports suggesting a negligible risk for fetal death after 32 weeks, subsequent papers, including a 2009 study of 98 patients managed from 2000 to 2007, have confirmed the occurrence of a significant number of fetal deaths even after 32 weeks.[54,56,59]

Because of the continuing risk of fetal death, many experts perform elective delivery following the administration of antenatal corticosteroid therapy between 32 and 34 weeks' gestation. The recent 2011 NICHD and SMFM workshop addressing timing of indicated late-preterm and early-term birth also cites this gestational age interval as their recommendation.[34a] Delivery at this time is associated with a low risk of serious neonatal morbidity when weighed against the uncertain risk of continuing the pregnancy. However, it may be reasonable to manage selected cases of monoamniotic twins expectantly beyond 34 weeks' gestation, with careful ongoing fetal surveillance.

Cesarean delivery has been recommended to eliminate the risk for intrapartum cord accidents, but vaginal delivery of these patients is not entirely contraindicated if careful fetal monitoring is performed. In one series, no fetal deaths and only one case of non-reassuring fetal testing requiring emergency cesarean delivery occurred during labor in 15 monoamniotic twin pregnancies delivered vaginally.[58] On the other hand, there have been case reports of a nuchal cord affecting the first twin being cut to facilitate delivery, only to discover that the cut cord actually belonged to the second twin. Given these issues and a high incidence of intrapartum non-reassuring fetal testing, most experts recommend cesarean delivery of all monoamniotic twin pregnancies.

Twin Reversed Arterial Perfusion Sequence

The TRAP sequence, also known as acardiac twinning, is a malformation that occurs only in monochorionic

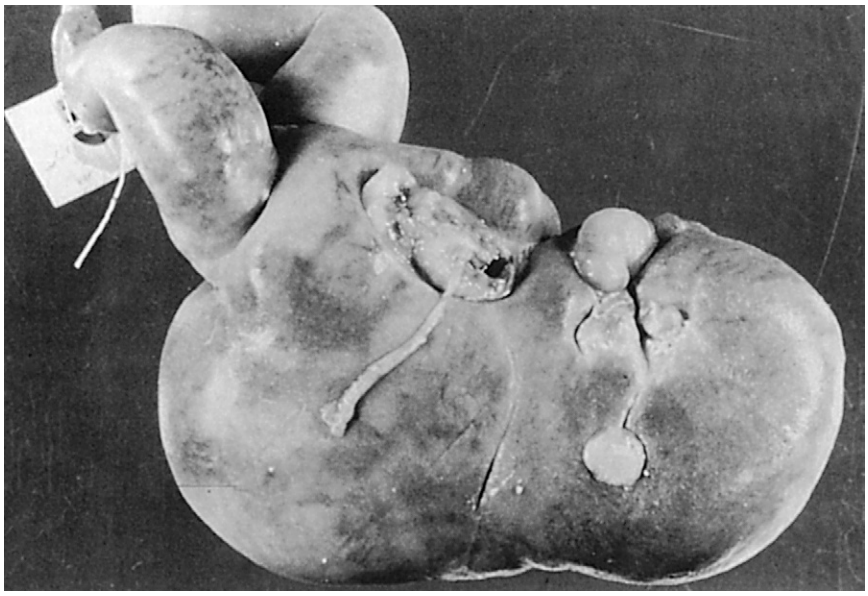

FIGURE 30-11. Acardiac twin. (Courtesy Dr. James Wheeler, Department of Surgical Pathology, Hospital of the University of Pennsylvania, Philadelphia.)

pregnancies with a frequency of about 1 per 30,000 deliveries. These extremely malformed fetuses have no heart at all (holoacardia) or only rudimentary cardiac tissue (pseudoacardia) in association with multiple other developmental abnormalities (Figure 30-11). Acardiac twins are sometimes classified by the degree of gross morphologic malformation: (1) acardius acephalus (absent head with relatively well-developed trunk and lower extremities), (2) acardius amorphous (amorphous mass of tissue, unrecognizable as a fetus), (3) acardius anceps (poorly formed head with well-developed trunk and lower extremities), and (4) acardius acormus (presence of a fetal head only, connected to the placenta by a cord). These classifications are used only as a descriptive tool because they have no clinical prognostic value.

Patients with TRAP sequence always have a monochorionic placenta with vascular anastomoses that sustain the life of the acardiac twin. Two theories exist as to the etiology of this condition. One theory holds that the TRAP anomaly is caused by an abnormal twinning event. The alternative hypothesis is that the acardia is a primary defect in cardiac development, and the acardiac twin, otherwise destined to end in an early spontaneous abortion, continues to grow because of monochorionic vascular anastomoses to a normal co-twin.

Antenatal diagnosis by ultrasound of an acardiac fetus coexisting with a normal co-twin is fairly straightforward. The only other entity in the differential diagnosis is an intrauterine fetal demise of one twin. However, continued growth of the abnormal, presumed dead twin rules this out, as can demonstration of blood flow in the presumed dead twin by color Doppler. Additionally, a retrograde pattern of fetal perfusion can be demonstrated to occur through the umbilical arteries.[60]

The acardiac twin clearly has no chance of survival, but its presence is not innocuous for the normal pump twin. The pump twin, although structurally normal, is at increased risk for in utero cardiac failure, and mortality rates of 50% or higher have been reported.[61] The estimated weight of the acardiac twin relative to the normal twin is an important prognostic factor. In the largest series of pregnancies complicated by TRAP sequence (N = 49), Moore and coworkers reported 90% preterm delivery, 40% polyhydramnios, and 30% cardiac failure of the normal twin when the weight ratio of acardiac to normal pump twin was more than 70%, compared with 70% preterm delivery, 30% polyhydramnios, and 10% cardiac failure for the normal pump twin when the weight ratio was less than 70%.[61]

Management of patients with pregnancies complicated by TRAP is controversial. Expectant management with serial ultrasound surveillance, including fetal echocardiography, is reasonable in the absence of the poor prognostic features outlined previously. Delivery may be indicated if signs of cardiac decompensation are noted at a viable gestational age. Maternal administration of digoxin and indomethacin have been attempted but with little evidence of benefit. In the face of previable or periviable cardiac failure in the normal pump twin or if poor prognostic features are present, another treatment option is interruption of the vascular communication between the twins. Methods of vascular interruption have included ultrasound-guided injection of thrombogenic materials into the umbilical circulation of the acardiac twin, ligation of the umbilical cord of the acardiac twin under fetoscopic guidance, and radiofrequency cord ablation.[60]

Conjoined Twins

Conjoined twins are another extremely rare complication of monochorionic twinning. They are believed to arise when an embryo incompletely divides between 13 and 15 days after fertilization. This event occurs with a frequency of about 1 per 50,000 deliveries. Most conjoined twins are female, with a reported female-to-male ratio of 2:1 or 3:1. The mortality rate is very high, as evidenced by a retrospective case series from the Children's Hospital of Philadelphia, which found an incidence of 28% intrauterine death, 54% death shortly after birth, and 18% overall survival among 14 sets of conjoined twins treated at their institution between 1996 and 2002.[62]

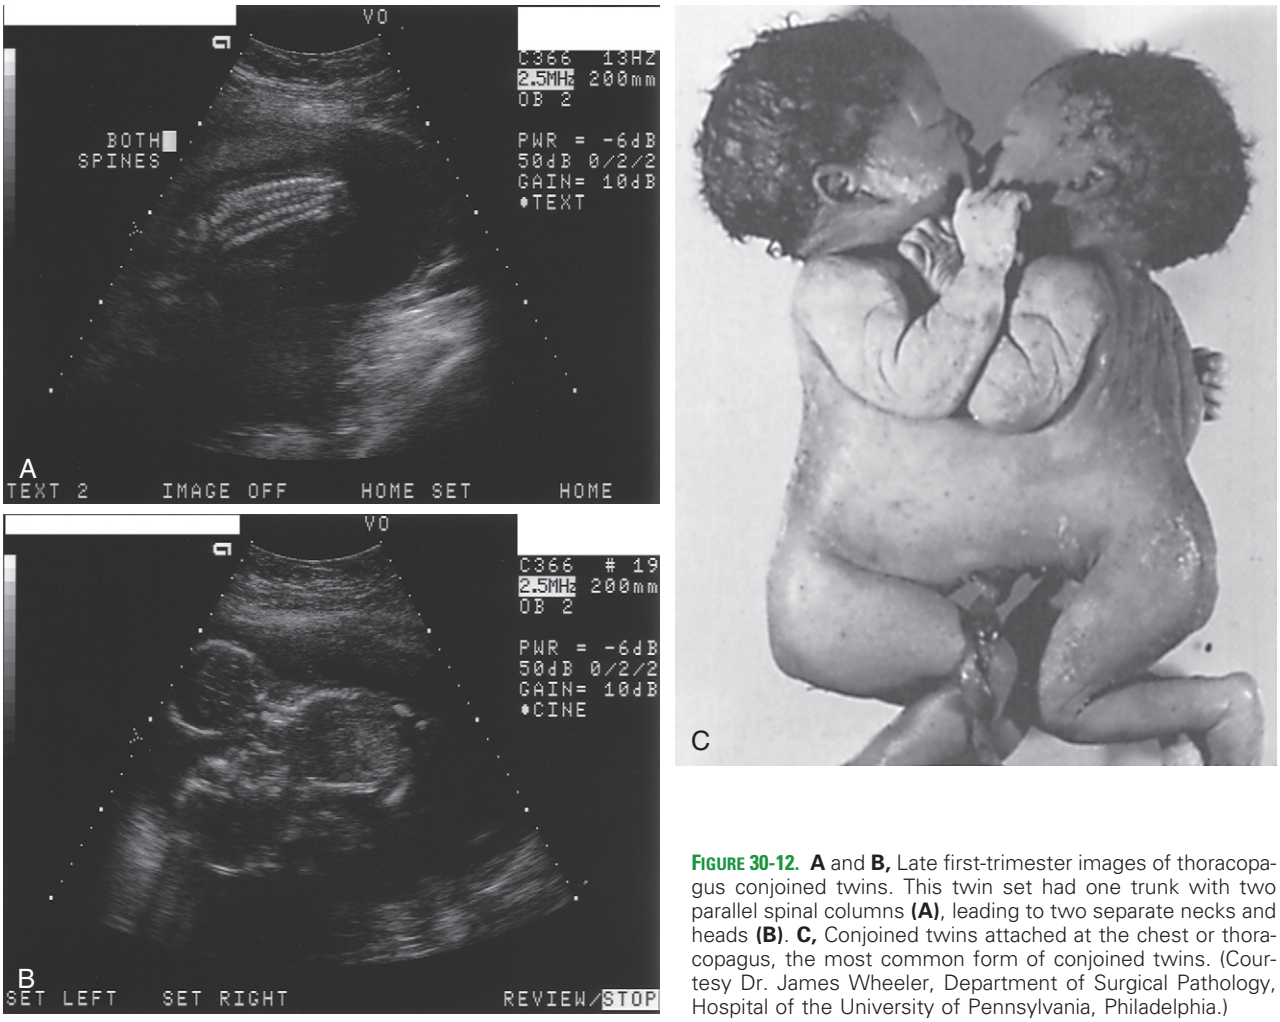

FIGURE 30-12. **A** and **B,** Late first-trimester images of thoracopagus conjoined twins. This twin set had one trunk with two parallel spinal columns **(A)**, leading to two separate necks and heads **(B)**. **C,** Conjoined twins attached at the chest or thoracopagus, the most common form of conjoined twins. (Courtesy Dr. James Wheeler, Department of Surgical Pathology, Hospital of the University of Pennsylvania, Philadelphia.)

Conjoined twins are classified according to their site of union. The most common location is the chest (thoracopagus: Figure 30-12), followed by the anterior abdominal wall (omphalopagus), the buttocks (pygopagus), the ischium (ischiopagus), and the head (craniopagus). Organs are shared to varying degrees. Major congenital anomalies of one or both twins are common, and polyhydramnios is present in almost half of the reported cases of conjoined twins.

Ultrasound can establish this diagnosis in utero, as early as the first trimester, based on visualization of a bifid fetal pole. Three-dimensional ultrasound, color Doppler, fetal echocardiography, and MRI can be used to complement two-dimensional ultrasound imaging to confirm the diagnosis, determine the extent of organ sharing, and definitively classify the type of conjoined twinning.[62,63] Once the diagnosis of conjoined twins is made, management options should be discussed with the patient. If the diagnosis is confirmed before viability, pregnancy termination should be offered. **If the patient desires expectant management, she should be counseled that the prognosis for survival and successful separation depends on the degree of organ and vascular sharing between the two fetuses, especially the heart.** Multimodality fetal evaluation as described previously should be used prenatally to carefully survey fetal anatomy. To optimize postnatal management, patients with conjoined twins should be cared for by a multidisciplinary team during the antenatal period. This team should include maternal-fetal medicine specialists, neonatologists, pediatric anesthesiologists, pediatric surgeons, and appropriate pediatric subspecialists.

Patients with conjoined twins should deliver at a tertiary care facility where neonatal and pediatric specialists are available. Cesarean delivery near term will be necessary to minimize maternal and fetal injury. If the twins are thought to have a poor chance of surviving and are believed to be small enough to pass through the birth canal without traumatizing the mother, vaginal delivery might be considered.

Of conjoined twins who undergo elective separation, survival rates approach 80%. Of conjoined twin sets who require emergent separation, however, survival rates are much lower, around 25%.[63] Although the long-term follow-up of conjoined twins who have undergone successful surgical separation is limited, the data seem favorable. Although survivors frequently require additional surgeries following the initial separation to correct urologic, orthopedic, and neurosurgical issues, many achieve educational levels similar to their singleton peers.

ANTEPARTUM MANAGEMENT OF MULTIFETAL PREGNANCY

Maternal Nutrition and Weight Gain

The two factors that most influence pregnancy outcome are gestational age at delivery and the adequacy of fetal growth. Nutritional status during gestation is linked to both these outcomes. Poor weight gain and deficient nutritional status are associated with low birthweight, preterm delivery, and higher rates of neonatal complications. **The higher baseline risk for these adverse outcomes in twin pregnancies creates a situation in which enhancement of nutrition and weight gain has the potential to provide tremendous positive impact.**

As discussed earlier in the chapter, multifetal gestation requires an exaggerated physiologic adaptation compared with singleton pregnancy. Because of these increased physiologic demands, mothers pregnant with twins have a 10% higher resting energy expenditure. Consequently, to meet the heightened metabolic expenditure, multiple gestations require modification of the current weight gain, caloric intake, and vitamin supplementation recommendations for singleton pregnancies. A recent review of nutrition in twin pregnancy outlined four goals for optimizing maternal nutrition in multifetal gestation[64]:

1. Optimize fetal growth and development
2. Reduce the incidence of obstetrical complications
3. Increase gestational age at delivery
4. Avoid excess maternal weight gain, which could result in unnecessary postpartum weight retention

Evidence demonstrates a positive relationship between maternal weight gain and infant birthweight. It also shows that poor maternal weight gain adversely affects birthweight and preterm delivery rates, mostly in women with an underweight prepregnancy body mass index (BMI). Correspondingly, poor weight gain has a lower impact on overweight and obese women, although an effect is still seen.

Both total maternal weight gain and the timing of that weight gain are critical to optimizing twin birthweight and obstetrical outcomes. Pederson and colleagues found that optimal pregnancy outcome, defined as gestational age at delivery of more than 37 weeks and both babies weighing more than 2500 g, was associated with a total weight gain of 44 lb. Furthermore, worse outcomes in general were seen with weight gain less than 37 lb.[65] Luke and colleagues have shown that weight gain before 28 weeks accounts for 80% of the maternal weight gain effect on infant birthweights.[66] Underscoring this point, Luke and colleagues demonstrated that even when there is appropriate weight gain after 24 weeks, suboptimal gain before 24 weeks is still associated with earlier delivery and poor intrauterine growth. Ideal maternal weight gain is also associated with a 1- to 2-week longer gestational period and a more than three times shorter infant length of hospital stay.[67] BMI-specific weight gain patterns associated with ideal twin birthweight, defined as 2850 to 2950 g at 36 weeks or later, are summarized in Table 30-6. Although the BMI categories used differ slightly from current BMI categories, the differences by weight status can easily be appreciated. Compared with singleton gestations, these recommended rates of weight gain are more than double early in pregnancy (0 to 20 weeks), about 50% higher during midpregnancy (20 to 28 weeks), and about 25% higher late in gestation (28 to 38 weeks).[68]

The crucial role of early weight gain and the more pronounced benefits of appropriate weight gain in underweight women suggest that early weight gain provides improved maternal nutrient stores for use later in pregnancy when fetal demands increase. Additionally, optimal maternal nutrition and weight gain early in pregnancy may enhance placental growth, thus providing a better nutrient supply to the babies. Both of these theories may explain why adequate weight gain in late pregnancy after inadequate gain in early pregnancy does not provide complete catch-up in fetal growth or outcomes.

Partially in response to evidence such as that cited previously, the Institute of Medicine issued new BMI-specific weight gain recommendations for pregnancy in 2009. These recommendations are summarized in Table 30-7. After these guidelines were published, Fox and coworkers

TABLE 30-6 RECOMMENDED RATES OF MATERNAL WEIGHT GAIN IN TWIN PREGNANCIES

GESTATIONAL AGE PERIOD	UNDERWEIGHT (BMI <19.8)	NORMAL WEIGHT (BMI = 19.8-26)	OVERWEIGHT (BMI = 26.1-29)	OBESE (BMI >29)
Early (<20 wk)	1.25-1.75 lb/wk	1-1.5 lb/wk	1-1.25 lb/wk	0.75-1 lb/wk
Mid (21-28 wk)	1.5-1.75 lb/wk	1.25-1.75 lb/wk	1-1.5 lb/wk	0.75-1.25 lb/wk
Late (≥29 wk)	1.25 lb/wk	1 lb/wk	1 lb/wk	0.75 lb/wk

From Luke B, Hediger ML, Nugent C, et al: Body mass index-specific weight gains associated with optimal birth weights in twin pregnancies. J Reprod Med 48:217, 2003.

TABLE 30-7 2009 INSTITUTE OF MEDICINE RECOMMENDATIONS FOR WEIGHT GAIN IN PREGNANCY

PREPREGNANCY BMI	BODY MASS INDEX (kg/m^2) WHO CRITERIA	TOTAL WEIGHT GAIN SINGLETON (lb)	TOTAL WEIGHT GAIN TWIN (lb)
Underweight	<18.5	28-40	No recommendations made
Normal weight	18.5-24.9	25-35	37-54
Overweight	25.0-29.9	15-25	31-50
Obese	≥30.0	11-20	25-42

From Rasmussen KM, Yaktine AL (eds): Institute of Medicine (Committee to Reexamine IOM Pregnancy Weight Guidelines, Food and Nutrition Board and Board on Children, Youth, and Families). Weight Gain During Pregnancy: Reexamining the Guidelines. Washington, DC, National Academy Press, 2009.

retrospectively studied a cohort of 297 twin pregnancies from a private Maternal-Fetal Medicine practice, applying the 2009 Institute of Medicine (IOM) guidelines in order to compare pregnancy outcomes between those women who met or exceeded the weight gain guidelines and those who did not meet the recommendations.[69] They found that women with a prepregnancy BMI placing them in the normal or overweight categories who met the weight gain recommendations demonstrated improvement in outcomes. Normal-weight women who met or exceeded the weight gain recommendations had significantly larger babies and a greater likelihood of both babies weighing more than 2500 g. Overweight women meeting the weight gain recommendations had more advanced gestational ages at delivery as well as heavier weight of the larger twin. Both normal-weight and overweight women who met weight gain goals had some reduction in overall preterm birth and spontaneous preterm birth. In the obese gravidas, there were no statistically significant differences, although this group was small ($n = 29$). This study, along with the previous work cited, supports optimizing maternal weight gain in twin pregnancy in order to improve outcomes. Notably, underweight women were excluded from the study because the IOM guidelines do not provide a specific weight gain recommendation for women with an underweight prepregnancy BMI who are pregnant with twins. However, because other literature clearly demonstrates that underweight women benefit even more from optimal gestational weight gain, special attention should be given to nutritional counseling and weight gain recommendations in this population. Incorporation of formal nutritional consultation into the care of women with multiples is clinically recommended and should be cost-effective.

Although increased maternal weight gain in pregnancy is associated with improved outcomes, maternal weight retention and its long-term health effects remain of concern. There are no long-term prospective studies of weight retention in twin mothers; however, a recent abstract (using BMI-specific weight gain goals established by Luke and colleagues, which are very similar to the 2009 IOM recommendations) demonstrated higher weight retention 6 weeks postpartum in women who exceeded the recommendations compared with women who met the recommended weight gain (6 kg vs. 2 kg; $P < .001$).[70] Therefore, in the setting of multiple gestations, emphasis should be placed on appropriate weight gain, while avoiding gains exceeding the recommendations.

Just as multiple pregnancy demands higher energy expenditure, caloric intake, and weight gain compared with singleton gestation, there is likely also a greater demand for micronutrients. Some experts have suggested that supplemental calcium, magnesium, and zinc may be important to optimal fetal growth and infant and maternal outcomes, although specific evidence for individual micronutrients is generally lacking. Table 30-8 represents a reasonable protocol regarding optimal nutritional management and micronutrient intake during twin pregnancy.

Spontaneous Preterm Birth

Patients with a multiple gestation are at significant risk for preterm labor and delivery. Although this risk is an overriding concern in the antepartum care of multiple gestations, not all multiples are delivered preterm; 40% of twins are delivered at term. **Refining the risk for preterm birth in each individual patient improves pregnancy management by selecting those patients who may benefit most from increased surveillance and interventions while simultaneously minimizing unnecessary interventions in lower-risk women.**

The use of ultrasound transvaginal cervical length measurements and fetal fibronectin (FFN) sampling can help stratify preterm birth risk in multiple gestations. The NICHD Preterm Prediction Study included 147 twin

mothers screened at 24 to 28 weeks' gestation for 50 potential risk factors for preterm delivery. They found that at 24 weeks, only a short cervix (≤25 mm) was significantly associated with an elevated risk for preterm birth in twin pregnancies. The odds ratio of preterm birth before 32 weeks was 6.9 (95% CI, 2 to 24.2) in these women, corresponding to a 27% risk for spontaneous preterm birth before 32 weeks in those women with cervical length of 25 mm or less at 24 weeks compared with a 5% risk in those women with a cervical length of more than 25 mm at 24 weeks. The risk for preterm birth before 35 weeks and before 37 weeks was also significantly elevated for those women with a 24-week cervical length of 25 mm or less.

In the same study, a positive FFN at both 28 and 30 weeks was associated with preterm birth before 32 weeks (OR, 9.4 and 46.1, respectively). Specifically, a positive FFN at 28 weeks was associated with a 29% risk for spontaneous preterm birth before 32 weeks, compared with only 3.9% for those with a negative FFN at 28 weeks.[71]

The combination of cervical length and fetal fibronectin assay has been suggested as a stronger predictor of spontaneous preterm birth than either test alone. A retrospective cohort analysis was performed on 155 asymptomatic twin pregnancies evaluated with combined fetal fibronectin and cervical length testing between 22 and 32 weeks' gestation. The authors reported that they routinely performed FFN assays and measured cervical length every 2 to 3 weeks in their twin mothers. They found that the combination of a positive FFN and a cervical length less than 20 mm (at any time between 22 weeks and the gestational age endpoint in question) had a significantly higher positive predictive value for spontaneous preterm birth than either test alone. If both tests were positive, the risk for spontaneous preterm birth before 28 weeks was 50%, compared with a 13% risk if only one test was positive and only a 1.6% risk if both tests were negative. The stepwise increase in the risk for preterm birth in women with both tests negative, only one test positive, and two tests positive remained statistically significant for spontaneous preterm birth before 30, 32, 34, 35, and 37 weeks' gestation.[72]

In addition to the absolute cervical length, the degree of change in the cervical length over time may also be an important predictor of preterm birth in twins. Fox and coworkers studied a historical cohort of 121 asymptomatic twin pregnancies who had two transvaginal cervical length measurements performed 2 to 6 weeks apart between 18 and 24 weeks' gestation. They found that cervical length shortening (defined as a decrease of ≥20%) over this interval was associated with a greater risk for preterm birth before 28, 30, 32, and 34 weeks compared with women whose cervical length remained stable (15.8% vs. 1% at <28 weeks, 15.8% vs. 2% at <30 weeks, 31.6% vs. 5% at <32 weeks, and 36.8% vs. 12.9% at <34 weeks; all P values ≤.027). Most striking was the fact that this association with preterm birth remained even when patients with cervical length less than 25 mm were excluded. Despite the overall cervical length remaining longer than 25 mm, shortening of 20% or more was still associated with a significantly higher risk for spontaneous preterm birth before 28, 30, and 32 weeks compared with women whose cervical length remained stable (18.2% vs. 1%, 18.2% vs. 2%, and 27.3% vs. 4.1%, respectively; P values = 0.026, 0.049, and 0.022, respectively).[73]

The use of these tests can help guide management decisions, such as frequency of office visits or whether work or activity restriction is prudent. Identification of a patient at particularly high risk for preterm delivery based on her cervical length, fetal fibronectin, or a combination of the two can allow for heightened surveillance and may permit timely interventions such as restricted activity, tocolysis, or steroid administration. On the other hand, documentation of an above-average and stable cervical length (>35 mm) in midgestation can allow both patient and physician to feel comfortable with a patient continuing with her normal activities, avoiding the temptation to implement unnecessary interventions.

Over the years, various interventions aimed at decreasing this high rate of preterm birth have been studied, most without clear evidence of benefit in a general multiple-gestation population. Of note, very few, if any, of these studies have been carried out in the highest-risk multiple gestations based on transvaginal cervical lengths or fetal fibronectin assays. The potential value of some of these interventions in prolonging pregnancy may be quite different in a woman with a 50% risk for delivery before 28 or 30 weeks' gestation versus a 2% risk. The following section discusses the relative merits of these proposed interventions to prevent spontaneous preterm birth in multiple gestations.

Bedrest and Hospitalization

A Cochrane review analyzed six randomized trials including 600 women and 1400 babies and concluded that routine hospitalized bedrest did not provide any benefit for multiple pregnancies. A trend toward fewer low-birthweight babies was noted, although this trend did not extend to very-low-birthweight (VLBW) infants. In fact, in uncomplicated twin pregnancies, inpatient bedrest was associated with a greater chance of delivery before 34 weeks.[74] Because there is no evidence to suggest that routine hospitalization is beneficial for patients with multiples, we believe that these women should be hospitalized only for the same obstetrical indications as singletons.

There are no prospective trials of prophylactic home bedrest in multiple gestations. Older studies that suggested a benefit of bedrest were confounded by the inclusion of undiagnosed twins among the unrestricted women. Tocodynametric studies on normal uterine activity over a 24-hour period have documented that uterine contraction frequency is greater during periods of maternal activity and ambulation. However, for asymptomatic twin pregnancies in women with reassuring cervical length and no prior history of preterm birth, we do not recommend routine rest at home or cessation of work. Nonetheless, because it is difficult to refute the possibility of benefit in higher-order multiple gestations, we generally recommend rest at home starting at about 20 weeks for women carrying triplets or more.

Cerclage

Results of studies using cervical cerclage to prolong pregnancy in multiple gestations have been disappointing. Prophylactic cerclage has been studied and found to be

ineffective in both twins and triplets. Even in the presence of cervical shortening, no clear benefit of cerclage placement in patients with twins has been demonstrated. Newman and coworkers[75] prospectively followed 147 twin pregnancies in women who underwent transvaginal ultrasonographic cervical length measurements between 18 and 26 weeks' gestation. Cerclage was offered to all 33 women with transvaginal cervical length of 25 mm or less and was placed in 21 women. There were no differences between the cerclage and no cerclage groups with regard to length of gestation, birthweight, delivery before 34 weeks, PPROM, or VLBW. A 2005 meta-analysis of ultrasound-indicated cerclage found that, in the subgroup with twins, cerclage placement was actually associated with a statistically significant increase in birth before 35 weeks (75% vs. 36%).[76] Because cerclage is a surgical procedure that may be associated with adverse sequelae for both the mother and her fetuses, it is recommended that cerclage placement in multiple gestations be restricted to women with either a strongly suggestive history or objectively documented cervical insufficiency rather than based on cervical length alone.

Tocolysis

Prophylactic tocolysis has been evaluated in multiple gestations and not found to be effective. In contrast, short-term use of these agents for acute tocolysis in preterm labor is helpful to gain time for administration of corticosteroids to enhance fetal lung maturity as well as to allow transport to a tertiary care facility. Tocolytic use in multiple gestations, however, must be accompanied by careful monitoring of the maternal condition. Because of the exaggerated maternal cardiovascular adaptations to a multiple gestation, women pregnant with multiples are predisposed to cardiopulmonary complications, most notably pulmonary edema. This risk is heightened with β-adrenergic agents and when tocolytics are used in combination with corticosteroids and intravenous fluids. At our institution, intravenous magnesium sulfate is used as a first-line acute tocolytic. When needed in patients before 32 weeks' gestation, we add oral indomethacin for 48 hours.

Progesterone

Weekly intramuscular administration of 17-hydroxyprogesterone caproate deserves special consideration as a unique approach to prophylactic therapy. After 17-hydroxyprogesterone caproate was shown to be effective in reducing recurrent preterm birth in singletons, there was interest in using it in populations with other risk factors for spontaneous preterm delivery, such as multiple gestation. Unfortunately, prospective randomized studies have not shown any effect of weekly 17-hydroxyprogesterone caproate in preventing preterm birth in women whose risk factor for preterm birth was twin or triplet gestation.[77,78] It should be mentioned, however, that those trials included very few women with a history of prior preterm birth. In the study of twins by Rouse and colleagues in which just over half of the participants were multiparous, only 6.1% of the treatment group and 9% of the placebo group had a history of previous preterm delivery.[78] In the triplet trial by Caritis and associates, none of the women in the treatment group and only 3% in the placebo group had a history of previous preterm birth.[77]

A 2007 trial by Fonseca and associates[79] examining the effect of nightly vaginal progesterone in women with short midgestation cervical length did include twin gestations, although twins made up only 10.4% ($N = 13$) of the placebo group and 8.8% ($N = 11$) of the treatment group. This study randomized women with a transvaginal cervical length of 15 mm or less at a median of 22 weeks' gestation to either 200 mg of vaginal progesterone nightly or placebo. They found that administration of nightly vaginal progesterone decreased spontaneous delivery before 34 weeks from 34.3% to 19.2%, which was statistically significant. In the subgroup of twin gestations, vaginal progesterone was associated with a similar reduction in preterm delivery, although the difference did not reach statistical significance because of sample size considerations.

The STOPPIT trial, published in 2009, randomized 500 women carrying twins to daily vaginal progesterone gel (90 mg) or placebo gel administered between 24 and 34 weeks' gestation.[80] The investigators did not find any difference in the primary outcome, which was intrauterine death or delivery before 34 weeks. Just less than 50% of the study participants were multiparous, but the incidence of prior preterm birth was not reported.

The results of these studies suggest that the mechanism for increased spontaneous preterm birth in multiples is likely different from the mechanism of spontaneous preterm birth in singletons. Whatever the mechanism, it appears to be less responsive to progesterone supplementation. However, this is a question deserving more study, especially for those multiples at particularly high risk for spontaneous preterm birth based on a short cervical length or positive fetal fibronectin assay.

Another population that has not been specifically studied includes women currently pregnant with multiples who have a history of spontaneous preterm birth with previous singleton gestations. These women are at very heightened risk for spontaneous preterm birth. Whatever factors put them at risk for spontaneous preterm delivery with a singleton are presumably still in effect and likely exacerbated by the additional demands of carrying twins. For these reasons, until better evidence is available, it is reasonable to use weekly 17-hydroxyprogesterone caproate for women pregnant with multiples who also have a history of a spontaneous preterm birth before 37 weeks with a prior singleton gestation. Additionally, based on the Fonseca trial, it is also reasonable to offer nightly vaginal progesterone to women carrying multiples who have a midgestation cervical length of 15 mm or less.

Antenatal Testing

Multiple gestations are at an increased risk for uteroplacental insufficiency, fetal growth restriction, and stillbirth, and for this reason many experts recommend antenatal surveillance in the form of nonstress tests or biophysical profiles. There are retrospective data showing that both nonstress tests and biophysical profiles are effective in detecting compromised twin gestations.[81] However, the optimal surveillance schedule is unknown because there are no prospective data on which to base a recommendation. The American College of Obstetricians and

Gynecologists 2004 Practice Bulletin on multiple gestation acknowledges these limitations and states that "further studies are needed to determine whether routine antepartum fetal surveillance provides objective benefit in the absence of other high-risk conditions." The 2009 NICHD reevaluation of antenatal testing also discusses the limits of the evidence regarding routine fetal surveillance in multiple gestations but lists weekly testing at 32 weeks as a reasonable strategy for twins with normal fetal growth.[82] Pregnancies complicated by growth restriction or other risk factors may require earlier and more frequent testing. Others have suggested an increased stillbirth risk even among apparently uncomplicated monochorionic, diamniotic twins and recommend twice weekly testing of these gestations after 34 weeks.

There are even fewer data for triplet and higher-order multiple gestations. However, because the stillbirth risk increases with increasing plurality, it is reasonable to begin antenatal testing earlier for triplets than for twins, acknowledging that these recommendations are based more on expert opinion and clinical practice than prospective evidence. Possibly the most compelling reason to perform routine monitoring in twins is the high incidence of both IUGR and discordant growth in the third trimester and the inability to reliably diagnose those conditions by ultrasound.

Fetal Growth Surveillance

Ultrasound, although imperfect, is the only method available for assessing individual fetal growth in multiple gestations. **Normal twins grow at the same rate as singletons up to 30 to 32 weeks' gestation, after which they do not gain weight as rapidly as singletons of the same gestational age.** The restriction in each twin's somatic growth is thought to be related to "crowding" in utero and competition for nutrients. The implication of this concept is that at some point in the third trimester, the placentas can no longer keep pace with the nutrient requirements of both developing fetuses. This relative uteroplacental insufficiency occurs even earlier when more than two fetuses are present. It must, however, be cautioned that most of the studies suggesting a slowing of fetal growth after 30 weeks are based on birth weight and therefore represent size rather than growth. A retrospective longitudinal study using ultrasound to follow fetal growth velocity in 131 twin gestations found that biparietal diameter growth velocities significantly slowed between 30 and 33 weeks' gestation and that growth of the abdominal circumference was significantly slowed from 30 to 37 weeks.[83] A subsequent prospective longitudinal study of fetal growth in 162 twins was performed using ultrasound every 2 weeks from 16 weeks until delivery. Similar to the retrospective analysis, this study showed that the growth velocities for biparietal diameter, femur length, and abdominal circumference were all decreased after 32 weeks.[84] Of interest, in both of these studies, chorionicity did not significantly influence fetal growth.

Discordant Growth

Significant discordance in weights between twins is typically defined as a greater than 15% to 25% difference in actual or estimated twin weights (the difference between the weights divided by the weight of the larger twin). In a series of 1370 consecutive twin pregnancies, discordances in birthweight of 15% to 20%, 21% to 25%, 26% to 30%, 31% to 40%, and more than 40% were found in 14%, 7%, 4%, 3%, and 1% of pregnancies, respectively.[85] Because DZ twins are genetically distinct individuals, it is not surprising that they might be programmed to have very different weights at birth. There are, however, several pathologic situations in which either monochorionic or dichorionic twins may develop substantial weight differences. These include TTTS, the combination of an anomalous fetus with a normal co-twin, and selective IUGR affecting only one twin because of local placental factors (Figure 30-13) or abnormalities of the umbilical cord. IUGR can also affect both twins relatively equally, in which case they would both be small, but not discordant in size. **Although it has been argued that fetal size discrepancy is not concerning if both babies' estimated weights remain appropriate for gestational age, discordance, especially when severe, suggests clinically significant growth restriction. The exact degree of growth discordance that begins to confer increased risk is debated, but an association with increased fetal and neonatal morbidity and mortality has been demonstrated when the estimated weight discrepancy exceeds 25% to 30%.**[85]

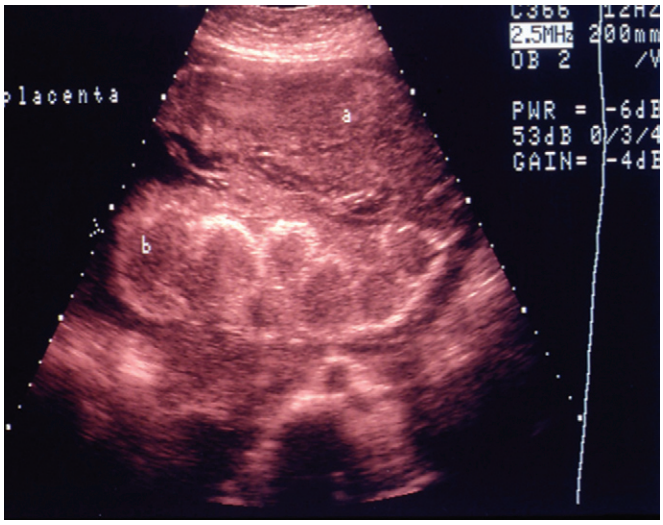

FIGURE 30-13. Normal anterior placenta of twin A and abnormal calcified grade 3 placenta of twin B in a case of selective intrauterine growth restriction of twin B. Twin B also had elevated umbilical artery S/D ratios.

Smaller degrees of discordance, not surprisingly, may be more worrisome in monochorionic compared with dichorionic gestations. In one study examining the significance of discordance, the risk for stillbirth, neonatal death, and preterm birth was not increased until discordance reached 30% or higher in different-sex twins, but these risks were increased with discordance of 15% or higher in same-sex twins.[86] A specific concern among monochorionic twins is the association between discordant growth and the occurrence of neurodevelopmental disability.

Ultrasound is the optimal method of assessing the progression of fetal growth in multiples. A survey of multiple biometric parameters on serial ultrasound examinations

provides the most accurate assessment of the size of each individual fetus in twin gestations. No single anatomic parameter evaluated at birth adequately discriminates normal twins from those with IUGR. Consequently, multiple biometric parameters should be assessed to detect growth disorders among twins in utero, especially in the third trimester. Among individual parameters, abdominal circumference is the single most sensitive measurement in predicting both IUGR and growth discordance.

Consideration of as many biometric variables as possible will maximize the likelihood of differentiating a normally grown from a growth-restricted twin fetus. A recent prospective longitudinal study from Belgium found that ultrasound estimations of fetal weight and weight discordance among monochorionic, diamniotic twins were highly correlated with actual birthweight and the degree of weight discordance at birth.[87] The same general principles can be applied to the assessment of growth in triplets and higher-order multiple gestations. Another point that should be stressed is that growth is a dynamic process and, therefore, that patients with multifetal gestations should be followed throughout pregnancy. **It is recommended that all patients with twins undergo ultrasound testing at least every 3 to 4 weeks after 20 weeks and more frequently if IUGR or growth discordance is suspected. Additionally, many experts recommend that ultrasounds be performed every 2 weeks in monochorionic twins beginning in the mid-second trimester in order to survey for the development of TTTS or selective IUGR.**

SPECIALIZED TWIN CLINICS

The value of specialized twin clinics has been described. In these clinics, where women carrying twins are seen at regular intervals by the same obstetrical team, several advantages accrue. Patients have the opportunity to develop rapport with a small group of caregivers. This results in an increased awareness of their special problems and may increase compliance with therapeutic directives. The medical personnel become adept at detecting early signs of the specific problems associated with twin pregnancies, and special emphasis is given to nutrition, weight gain, and preterm labor surveillance. Two studies have examined the effects of such clinics and found improvements in outcomes. One study demonstrated reduced rates of VLBW babies, neonatal intensive care unit (NICU) admissions, and perinatal mortality,[88] whereas the other showed improvements in gestational age and birthweight and reduced rates of PPROM, preterm labor and delivery, preeclampsia, and low-birthweight and VLBW infants, as well as reductions in NICU admissions and individual complications such as respiratory distress syndrome, necrotizing enterocolitis, and retinopathy of prematurity. Shortened length of stay was also seen for the babies, as was a reduction in cost per twin pair.[89] These studies, although lacking a prospective randomized design, suggest that intensive education, multidisciplinary care, and surveillance, combined with careful attention to maternal nutrition and weight gain, can improve outcomes in twin pregnancies. Figure 30-14 outlines a reasonable management algorithm for antepartum care unique to twin gestations.

TIMING OF DELIVERY IN MULTIPLE GESTATIONS

Concern over preterm delivery in twin pregnancies sometimes overshadows decision making regarding timing of delivery for twin mothers who remain pregnant at or near term. Numerous population-based studies suggest that the nadir of perinatal complications occurs at earlier gestational ages in multiple gestations compared with singletons.

Unfortunately, the hypothesis that elective early delivery of twins leads to better outcomes has not been subjected to rigorous prospective study. The only randomized study of elective early delivery of twins was quite underpowered, with only 17 women in the induction group and 19 in the expectant management group. Women with uncomplicated pregnancies and a cephalic first twin were randomized at 37 weeks to either labor induction or expectant management. The study found no statistically significant differences in birthweight, Apgar score, or cesarean delivery rate. There were no fetal deaths in either group.[90]

As mentioned previously, there are numerous population-based studies that suggest early delivery of twins could be advantageous. Kahn and colleagues reviewed nearly 300,000 twin pairs and found 39 weeks to be the point of intersection that minimized both the fetal and neonatal death rates.[91] They found that the prospective risk for fetal death in twins equaled that of postterm singletons by 36 to 37 weeks' gestation. Another investigation by Sairam and associates evaluated more than 4000 multiple pregnancies (of which more than 99% were twins) and found that the stillbirth risk at 39 weeks in a twin pregnancy exceeded that of a singleton postterm pregnancy. Twins at 37 to 38 weeks had stillbirth rates equivalent to postterm singletons.[92]

Given consistent evidence of increased risk in twin pregnancies extending past 38 to 39 weeks (analogous to a postdate singleton gestation), a rational delivery approach, supported by the 2011 NICHD and SMFM workshop,[34a] is to plan elective delivery at 38 weeks in well-dated, uncomplicated dichorionic twin pregnancies. Allowing a twin gestation to go past 38 weeks requires convincing evidence of normal fetal growth, amniotic fluid, and fetal testing, as well as a strong patient desire to extend the pregnancy. Prolongation of a twin pregnancy past 39 weeks is not advisable because of clear risk without any known benefit. Figure 30-15 outlines a reasonable approach to planning delivery for uncomplicated term or near-term twin pregnancies.

Twin gestations complicated by maternal or fetal abnormalities will require individualized assessment and decision making. Figure 30-16 provides general guidelines as to how twin gestations complicated by fetal growth restriction, discordant growth, or maternal complications such as mild preeclampsia or cholestasis might be managed. Of course, the timing of delivery in the face of either maternal or fetal complications is influenced by severity and clinical judgment and may require modification of the guidelines outlined in Figure 30-16. For instance, an IUGR twin in less than the third percentile or a pregnancy with more than 35% discordance in estimated fetal weights may be an indication for delivery earlier than 37 weeks even if all other testing is normal. Additionally, twin pregnancies with

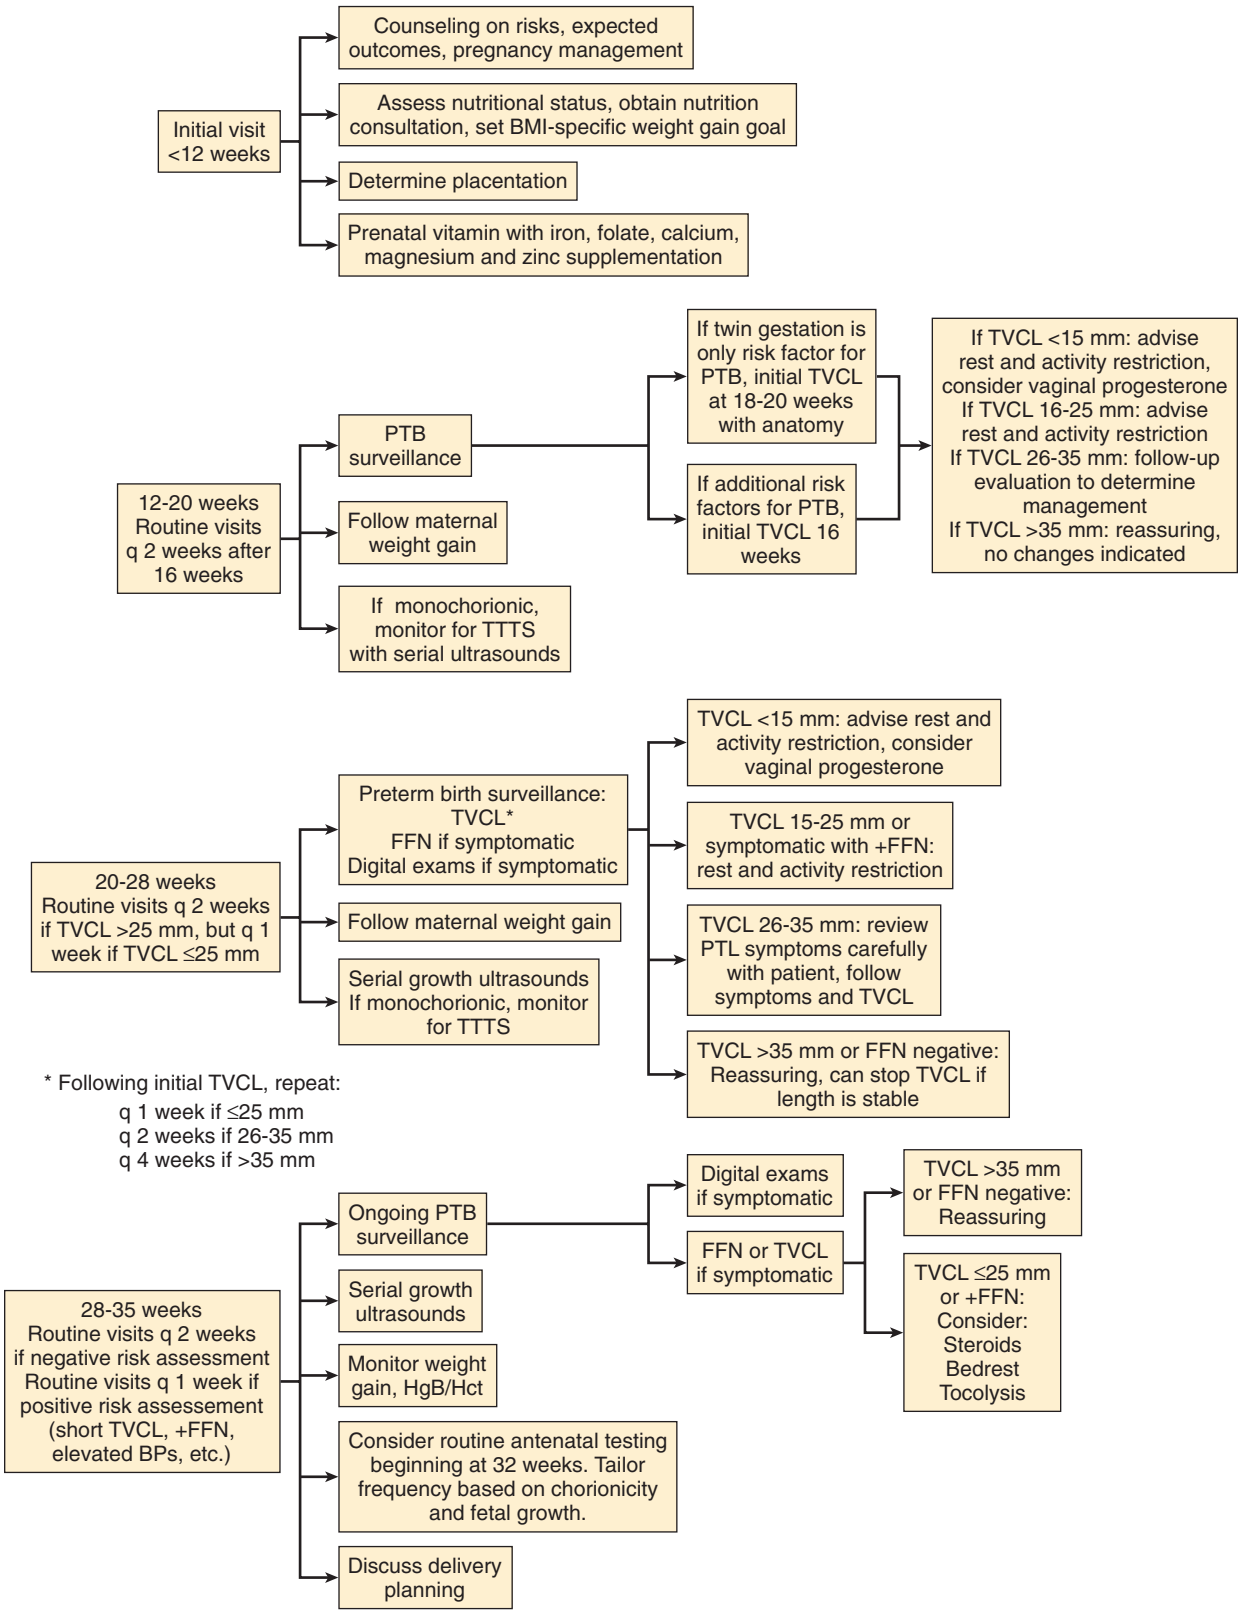

FIGURE 30-14. Suggested algorithm for antepartum management unique to twins. *BMI,* Body mass index; *BP,* Blood pressure; *FFN,* fetal fibronectin; *Hct,* hematocrit; *HgB,* hemoglobin; *PTB,* preterm birth; *TVCL,* transvaginal cervical length; *TTTS,* twin-twin transfusion syndrome.

more than one of the listed complications may also warrant delivery earlier than 37 weeks. Similarly, some have argued for elective early delivery of all monochorionic twins, a topic that is discussed in more detail later. Monoamniotic twins were discussed earlier in the chapter.

Monochorionic, Diamniotic Twins: Special Considerations Regarding Delivery Timing

The population-based studies outlined previously addressing the optimal timing of delivery for term and near-term twins included both dichorionic and monochorionic gestations, but they did not differentiate between the two types of placentation when evaluating outcomes. It is well established that monochorionic twins are at greater risk for a variety of pregnancy complications. **However, there is concern among some investigators that even "apparently uncomplicated" monochorionic, diamniotic twins, a term coined by D'Alton and colleagues, are at increased risk for late fetal death.** A retrospective analysis from the United Kingdom reviewed 151 uncomplicated monochorionic pregnancies in women who underwent ultrasound evaluation every 2 weeks and assessed fetal growth, amniotic fluid, and umbilical artery Doppler scans. They found that the risk for unexpected stillbirth after 32 weeks was 4.3% (1 in 23).[93] Another study of 193 monochorionic, diamniotic twin pregnancies in Portugal found that the risk for fetal death after 32 weeks in women undergoing weekly fetal testing was much lower, at 1.2%.[94] Two notable differences exist between these two studies; namely, the first study did not employ weekly fetal testing, as did the second, but rather ultrasound examination every 2 weeks. Interestingly, the authors of the second study noted that 55% of their twins were delivered preterm as a result of the surveillance program.

The latest study of "apparently uncomplicated" monochorionic, diamniotic twin pregnancies examined the records of 196 monochorionic, diamniotic and 804 dichorionic twin pregnancies. These investigators found that the monochorionic twins had higher stillbirth rates than the dichorionic twins (3.6% vs. 1.1%; $P = .004$), and this increased risk persisted in the "apparently normal" group and was seen at all gestational ages up to 37 weeks ($P = .039$).[95]

Based on these concerns, some experts recommend offering elective delivery at 34 to 35 weeks in uncomplicated monochorionic, diamniotic twins. This evidence and expert opinion were incorporated into the 2011 NICHD and SMFM workshop paper on timing of indicated late-preterm and early-term birth, which recommends delivery for monochorionic, diamniotic twins between 34 and 37 weeks. It is emphasized that this approach does not yet represent standard of care, and further data may be necessary before this more aggressive approach can be fully embraced. In the absence of early delivery for monochorionic, diamniotic twins, it would be prudent to conduct frequent antenatal testing along with periodic ultrasound assessment and fetal movement counts. Given this more intensive surveillance, it is unknown whether the stillbirth risk would be significantly different than that in uncomplicated dichorionic twins. The topic of antenatal testing for twins was discussed in more detail earlier in the chapter.

Fetal Lung Maturity in Twins

The clinical management of multiple gestations occasionally requires the assessment of fetal lung maturity. There is currently no consensus on whether pulmonary maturation differs between singletons and multiples. If elective delivery is scheduled before 37 to 38 weeks' gestation in dichorionic twins, amniocentesis for fetal lung maturity determination may be considered. Because asynchronous pulmonary maturity can occur in twins regardless of size and gender, if technically feasible, it is suggested that both gestational sacs be sampled when amniocentesis for lung maturity is required. A reasonable approach to

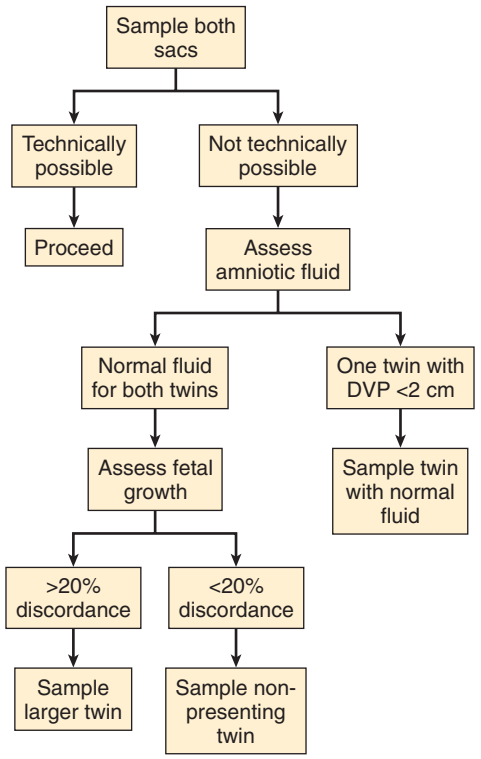

FIGURE 30-17. Assessment of fetal lung maturity in twins. *DVP,* Deepest vertical pocket.

assessing fetal lung maturity in diamniotic twins is outlined in Figure 30-17. For pregnancies with triplets and higher-order multiple gestations, there are not enough data to make recommendations regarding amniocentesis for fetal lung maturity.

Timing of Delivery in Triplets

Triplets are clearly at very high risk for significant preterm birth. However, in a review of more than 15,000 triplet pregnancies, about 15% of triplets were undelivered at 36 weeks. That same study found that the point of intersection of fetal and neonatal death for triplets occurred at 36 weeks.[91] Most experts agree that if otherwise uncomplicated, well-grown triplets remain undelivered at 36 weeks, elective delivery should be undertaken.

MODE OF DELIVERY IN MULTIPLE GESTATIONS

A number of factors must be considered when determining the mode of delivery for patients with a multifetal gestation. These variables include the gestational age, estimated weights of the fetuses, their positions relative to each other, the availability of real-time ultrasound on the labor floor and in the delivery room, and the capability of monitoring each twin independently during the entire intrapartum period. Carefully considering all these variables is essential because multiple gestations are inherently at higher risk during the intrapartum period. This risk is illustrated by a large retrospective cohort study published in 2005 that examined neonatal outcomes in all twin births of 36 weeks' gestation or more in Scotland between 1985 and 2001. They found that the odds ratio for death

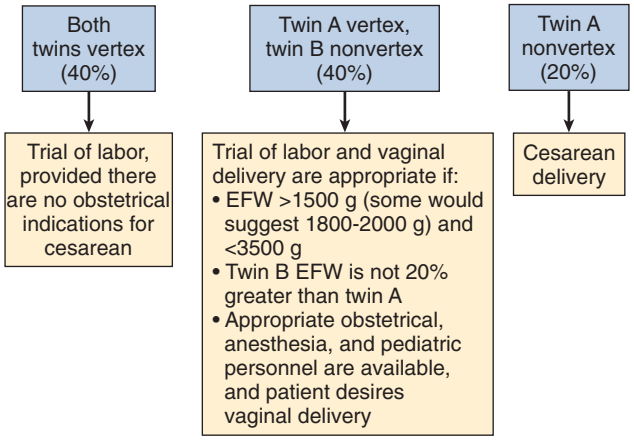

FIGURE 30-18. Algorithm for determining mode of delivery in diamniotic twins. (Monoamniotic twins should have cesarean delivery.) *EFW,* Estimated fetal weight.

of the second twin due to intrapartum anoxia was 21 (95% CI, 3.4 to 868.5) in twins delivered vaginally compared with those in which both twins underwent cesarean delivery. Death of either twin occurred in 0.14% (2 of 1472) with cesarean delivery compared with 0.52% (34 or 6601) with vaginal delivery ($P = .05$). The researchers calculated that the number of twins requiring cesarean delivery to prevent one death was 264.[96] However, it should be noted that the study had no information on fetal presentation, chorionicity, or other specific maternal or neonatal variables.

Older case series may not be applicable to current practice because our ability to monitor both twins closely during labor and delivery has improved considerably in recent years. Additionally, multiple smaller studies, including a 2003 meta-analysis, do not show a benefit of cesarean delivery for all twin deliveries.[97] At present, the evidence is inconclusive that there is a benefit to routine cesarean delivery of all twins. However, it is clear that twin gestations represent a high-risk intrapartum situation that requires expert management.

All combinations of intrapartum twin presentations can be classified into three groups: (1) twin A vertex, twin B vertex; (2) twin A vertex, twin B nonvertex; and (3) twin A nonvertex, twin B either vertex or nonvertex. In a series of 362 twin deliveries presented by Chervenak and associates,[98] these presentations were found in 42.5%, 38.4%, and 19.1% of cases, respectively. Each scenario is discussed separately next, and recommendations are summarized in Figure 30-18.

Vertex-Vertex Twins

A trial of labor and vaginal delivery is believed to be appropriate for all vertex-vertex twin gestations, regardless of gestational age or estimated fetal weight. No clear benefit to routine cesarean delivery of vertex-vertex twins has been found in the literature, including VLBW deliveries.[97] However, it is important to note that the presentation of the second twin may change in 10% to 20% of cases after delivery of the presenting twin. For this reason, the obstetrician should always discuss this possibility with the patient before delivery. Furthermore, when anticipating a vertex-vertex twin vaginal delivery, the obstetrical team

should always have a clear plan for the management of an unexpected nonvertex second twin.

Nonvertex-Presenting Twin

Twin pregnancies with a nonvertex-presenting twin are nearly always managed by cesarean delivery. Historically, this was because of a fear of interlocking fetal heads during delivery of breech-vertex twins. Interlocking fetuses, however, are exceedingly rare. Currently, in an era in which nearly all singleton breech fetuses are delivered by elective cesarean birth, cesarean delivery is also the optimal mode of delivery for twin pregnancies with a nonvertex-presenting fetus.

Vertex-Nonvertex Twins

Although the route of delivery for the previous two scenarios is noncontroversial, the management of that subset of patients whose twins are in a vertex-breech or vertex-transverse lie is subject to significant debate. When the second twin is nonvertex after delivery of the first twin, there are two options for achievement of vaginal delivery: breech extraction or external cephalic version. Although external cephalic version is an acceptable strategy, it has been shown to be associated with more fetal distress and higher rates of cesarean delivery than breech extraction.[99] Thus, provided the obstetrician is sufficiently trained in breech extraction and the fetus is of appropriate size, this is the preferable option for achievement of vaginal delivery with a nonvertex second twin.

Some obstetricians have voiced concerns regarding the safety of breech extraction and have questioned whether it is equivalent in outcome to cesarean delivery. Chervenak and colleagues[98] cite several older references in which depressed Apgar scores and increased perinatal mortality rates were associated with vaginal breech delivery of the second twin. However, in the same report, the authors analyze their own extensive experience, along with a review of the published literature, and conclude that breech extraction of a second twin is a safe and appropriate option if the estimated fetal weight is more than 2000 g. Although the data supported the safety of breech extraction for babies weighing more than 1500 g, these investigators chose 2000 g rather than 1500 g to allow for the margin of error of an ultrasound-estimated fetal weight.

The safety of breech extraction for second twins is supported by the only randomized trial of cesarean delivery versus breech extraction. Rabinovici and associates[100] randomized 66 women with vertex-nonvertex twins of more than 35 weeks' gestation to vaginal delivery with breech extraction or cesarean delivery. They found that there were no differences in neonatal outcomes and no cases of birth trauma or neonatal death. Not surprisingly, maternal febrile morbidity was greater in the cesarean delivery group.

Several other retrospective studies also support the safety of breech extraction of second twins. Gocke and colleagues[99] analyzed 136 sets of vertex-nonvertex twins with a birthweight higher than 1500 g in whom delivery of the second twin was managed by primary cesarean delivery, external version, or primary breech extraction. No differences were noted in the incidence of neonatal mortality or morbidity among the three delivery modes, although external version was associated with a higher failure rate than breech extraction, a higher rate of non-reassuring fetal heart rate patterns, cord prolapse, and compound presentation. The authors concluded that primary breech extraction of the second nonvertex twin weighing more than 1500 g is a reasonable alternative to either cesarean delivery or external version. Fishman and coworkers[101] and Greig and colleagues[102] examined the records of more than 1200 twin gestations and concluded that there was no evidence to support cesarean delivery for nonvertex second twins weighing more than 1500 g. In fact, Greig's data did not show poorer outcomes even for babies weighing less than 1500 g delivered by breech extraction. Nonetheless, most recommend avoidance of breech extractions on second twins with estimated fetal weights of less than 1500 g.

Two recent studies on mode of delivery for twins lend further support to the safety of breech extraction for second twins. Both studies were conducted in single institutions with strict protocols for active second-stage management and breech extraction. Schmitz and colleagues[103] performed a retrospective cohort study of 758 consecutive sets of twins at more than 35 weeks' gestation with a cephalic-presenting twin A. Using a strict protocol for second-stage management in which, after delivery of the vertex-presenting twin, a nonvertex second twin was immediately delivered by total breech extraction, they found that the neonatal composite morbidity for the second twin did not differ between planned cesarean delivery and planned vaginal delivery. The second, more recent study by Fox and coworkers[104] examined a retrospective cohort of 287 twin pregnancies from a single tertiary care academic medical center. The authors described a strict protocol for second-stage management of twin vaginal delivery in which all nonvertex second twins underwent immediate breech extraction and all nonengaged vertex second twins were delivered by immediate internal podalic version and subsequent breech vaginal delivery. The study found no difference in the rates of 5-minute Apgar scores lower than 7 or a cord pH lower than 7.2 between the planned vaginal delivery group ($n = 130$) and the planned cesarean delivery group ($n = 157$).

It should be kept in mind that both of these studies were conducted in a single center by experienced obstetricians using a strict protocol for second-stage management. During the past decade, concerns about outcomes associated with singleton breech deliveries have led to virtual abandonment of vaginal delivery of breech-presenting singletons. As a consequence, fewer obstetricians are acquiring or maintaining the skills needed to safely perform vaginal breech deliveries.

Triplets

Although vaginal delivery is an option for patients with triplets, there are no large prospective studies establishing its safety. Adequate monitoring of three fetuses throughout labor and delivery is challenging. As a result, elective cesarean delivery of patients with three or more live fetuses of viable gestational age is a reasonable management strategy. Vaginal delivery of triplets should only be undertaken under optimal conditions by obstetricians experienced in such deliveries.

INTRAPARTUM MANAGEMENT OF TWIN VAGINAL DELIVERY

Safe vaginal delivery of multiples requires careful preparation and multidisciplinary cooperation between obstetrics, anesthesia, nursing, and neonatology or pediatrics. On admission to labor and delivery, both fetal presentations should be confirmed by ultrasound. If a recent (within 1 to 2 weeks) ultrasound-estimated fetal weight for both babies is not available, this should be obtained and documented. As discussed earlier, knowledge of the presentation, gestational age, and estimated weight of each twin permits the establishment of a plan regarding the anticipated route of delivery.

If a trial of labor is elected, both fetuses should be continuously monitored. Although the woman may labor in a standard room, the delivery itself is best performed in an operating room, in the event that anesthesia or cesarean delivery is emergently needed. Maternal epidural anesthesia is also advisable. The pain control afforded by an epidural enhances maternal cooperation, allows a wide range of obstetrical procedures to be performed quickly, and is available for anesthesia if emergent cesarean delivery becomes necessary. Table 30-9 provides a list of personnel and equipment that should be prepared for each planned vaginal delivery of a multiple gestation.

Time Interval Between Deliveries

A variable that many investigators have historically considered to be important in the outcome of twin pregnancies is the time interval between deliveries. After delivery of the first twin, uterine inertia may develop, the umbilical cord of the second twin can prolapse, and partial separation of its placenta may render the second twin hypoxic. In addition, the cervix can constrict, making rapid delivery of the second twin extremely difficult if non-reassuring fetal status develops. Many reports have suggested that the interval between deliveries should ideally be 15 minutes or less and certainly not more than 30 minutes. Most of the data in support of this view, however, were obtained before the advent of continuous and dual intrapartum fetal monitoring capability.

TABLE 30-9 CHECKLIST FOR MANAGEMENT OF VAGINAL DELIVERY OF TWINS

Personnel and location
Availability of a fully staffed operating room for the delivery, capable of performing an emergency cesarean delivery
Skilled obstetrical attendants present
Anesthesiologist present at delivery
Sufficient neonatal personnel for resuscitation of two infants
Supplies
Capability to continuously monitor both fetuses throughout labor and delivery
Portable ultrasound for intrapartum use
Premixed oxytocin
Methergine, 15-methyl $PGF_{2\alpha}$, misoprostol for postpartum hemorrhage
Nitroglycerin and terbutaline for uterine relaxation
Obstetrical forceps and vacuum (including Piper forceps for aftercoming head)
Blood products immediately available if needed

Rayburn and associates[105] reported the outcome of 115 second twins delivered vaginally at or beyond 34 weeks' gestation after the vertex delivery of their co-twin. Continuous monitoring of the fetal heart rate was performed in all cases. Oxytocin was used if uterine contractions subsided within 10 minutes after delivery of the first twin. In this series, 70 second twins were delivered within 15 minutes of the first twin, 28 within 16 to 30 minutes, and 17 more than 30 minutes later. The longest interval between deliveries was 134 minutes. All these infants survived, and none had a traumatic delivery. All 17 of the neonates delivered beyond 30 minutes had 5-minute Apgar scores between 8 and 10. In those cases with delivery intervals in excess of 15 minutes, the birthweight differential was not in excess of ±200 g when first and second twins were compared. In another series reported by Chervenak and colleagues,[106] when the fetal heart rate of the second twin was monitored with ultrasound visualization throughout the period between twin deliveries, no difference in the occurrence of low 5-minute Apgar scores was noted in relationship to the length of the interdelivery interval.

It appears that although some second twins may require rapid delivery, others can be safely followed with fetal heart rate surveillance and remain undelivered for substantial periods of time. This less hurried approach when the second twin is not demonstrating signs of non-reassuring fetal status may reduce the incidence of both maternal and fetal trauma associated with difficult deliveries performed to meet arbitrary deadlines.

CONCLUSION

The patient carrying more than one fetus presents a formidable challenge to the obstetrician. The elevated perinatal morbidity and mortality rates seen in multiple gestations compared with singletons are due to a variety of factors, some of which cannot currently be altered. However, extraordinary technologic advances during the past 25 years have given us new insights into problems peculiar to multifetal pregnancies as well as tools with which to detect and treat those problems. Early diagnosis of multiple gestations, determination of chorionicity, and serial follow-up studies offer the potential for administering specialized regimens to selected patients, which we hope will lead to a beneficial impact on the outcome of those pregnancies.

KEY POINTS

- Twinning is one of the most common high-risk conditions in all of obstetrics. Both maternal and perinatal morbidity and mortality are significantly higher in multifetal gestations than in singleton pregnancies.
- Chorionicity is a critical determinant of pregnancy outcome and should be ascertained by ultrasound as early in gestation as possible.
- Monochorionic pregnancies are at higher risk than dichorionic, with increased rates of spontaneous abortion, congenital structural anomalies, IUGR,

and IUFD, in addition to a 10% to 15% risk for TTTS, which is a complication unique to monochorionic pregnancies.

- Multiple gestations benefit from specialized care, including attention to maternal nutrition and weight gain, serial assessment of fetal growth by ultrasound, and careful surveillance for signs of preterm labor.
- Routine bedrest, prophylactic tocolytics, prophylactic cerclage, and prophylactic progesterone supplementation have not been shown to be effective in prolonging multiple gestations. However, none of these interventions has been studied in the highest-risk women based on prior obstetrical history, current short cervical lengths, or positive fetal fibronectin assays.
- The nadir of perinatal complications and an increase in stillbirth risk occur earlier in twin gestations than in singletons. Uncomplicated dichorionic twins appear to have the best outcomes if delivered at 38 weeks. There may be a case for earlier delivery in uncomplicated monochorionic, diamniotic twins, but this issue requires further study.
- Monoamniotic twin outcomes are best when managed with a combination of prophylactic antenatal corticosteroids, hospitalization for daily fetal assessment, and elective early cesarean delivery.
- Mode of delivery should take into account gestational age, fetal presentations, estimated weights, and the experience and skill of the obstetrician. A trial of labor is appropriate when both twins are vertex. Mode of delivery should be individualized for vertex-nonvertex twins. Cesarean delivery is optimal when the presenting twin is nonvertex.

Small for Gestational Age	SGA
Sonographically Estimated Fetal Weight	SEFW
Systolic/Diastolic Ratio	S/D

The identification of pregnancies at risk for preventable perinatal handicap is a primary goal of the obstetric care provider. Pregnancies in which adverse intrauterine conditions result in failure of the fetus to reach its growth potential constitute such a high-risk group. Next to prematurity, intrauterine growth restriction (IUGR) is the second leading cause of perinatal mortality. **Compared to appropriately grown counterparts, perinatal mortality rates in growth-restricted neonates are 6 to 10 times greater; perinatal mortality rates as high as 120 per 1000 for all cases of IUGR and 80 per 1000 after exclusion of anomalous infants have been reported. As many as 53% of preterm stillbirths and 26% of term stillbirths are growth restricted.** In survivors, the incidence of intrapartum asphyxia may be as high as 50%.[1] Prevention of some perinatal complications that lead to adverse outcomes in growth-restricted fetuses is possible with appropriate prenatal identification and management. This chapter reviews normal and disturbed fetal growth, the definition of abnormal fetal growth, the impact of fetal growth restriction, and the incorporation of this knowledge into screening, diagnosis, and management of these high-risk pregnancies.

REGULATION OF FETAL GROWTH

Fetal growth is regulated at multiple levels and requires successful development of the placental interface between maternal and fetal compartments. In the early first trimester, anchoring villi originating from the cytotrophoblast connect the decidua to the uterus and thereby establish placental adherence. This allows formation of vascular connections between the maternal circulation and the intervillous space so that increasing quantities of placental secretory products can reach the maternal circulation. Endocrine and paracrine signaling between the placenta and maternal compartment promotes maternal metabolic and cardiovascular adaptations to pregnancy that result in

greater substrate availability and enhanced placental perfusion, thereby supporting placental growth. The development of placental mass is critical for its synthetic capacity while vascular development permits nutrient and oxygen delivery to the growing trophoblast beyond the capacity of simple diffusion.

The villous trophoblast becomes the primary placental site of maternal-fetal exchange. By 16 weeks' gestation the maternal microvillous and fetal basal layer are only 4 microns apart, posing little resistance to passive diffusion. Elaboration of active transport mechanisms for three major nutrient classes (glucose, amino acids, and free fatty acids) and an increase in the villous surface area raise the capacity and efficiency of active transplacental transport. Vascular throughput across the placenta also increases in the maternal and fetal compartments. Extravillous cytotrophoblast invasion of the maternal spiral arteries results in progressive loss of the musculoelastic media, a process paralleled on the fetal side by continuous villous vascular branching. This results in significant reduction of blood flow resistance in the uterine and umbilical vessels, converting both circulations into low-resistance, high-capacitance vascular beds. The decrease in vascular resistance is related to two waves of angiogenesis within the placenta. The first is branching angiogenesis occurring at the end of the first and beginning of the second trimester, which increases the number of vascular branches. The second wave is nonbranching angiogenesis, which does not create additional branches but rather results in elongation of the existing placental vascular tree. This latter process occurs at the end of the second and beginning of the third trimester. Owing to these developments, as much as 600 mL/min of maternal cardiac output reaches a placental exchange area of up to 12 m^2 at term. In the fetal compartment this is matched with a blood flow volume of 200-300 mL/kg/min throughout gestation. This magnitude of maternal blood flow is necessary to ensure maintenance of placental function that is energy intensive and consumes as much as 40% of the oxygen and 70% of the glucose supplied. Optimal fetal growth and development depends on a magnitude of maternal nutrient and oxygen delivery to the uterus that leaves sufficient surplus for fetal substrate utilization.

Of the actively transported primary nutrients, glucose is the predominant oxidative fuel while amino acids are major contributors to protein synthesis and muscle bulk. Glucose and, to a lesser extent, amino acids drive the insulin-like growth factors axis and therefore stimulate longitudinal fetal growth. Fatty acids are necessary for the maintenance of cell membrane fluidity and permeability and also act as precursors for important bioactive compounds such as prostaglandins, thromoboxanes, and leukotrienes. Long-chain polyunsaturated fatty acids such as arachidonic acid and docosahexanoic acid are essential for normal brain and retinal development. Leptin is the hormone that co-regulates transplacental amino acid and fatty acid transport and thereby modulates fetal body fat content and proportions.

Concurrent development and maturation of the fetal circulation as a conduit for nutrient and waste delivery allows preferential partitioning of nutrients in the fetus. Nutrient- and oxygen-rich blood from the primitive villous circulation enters the fetus via the umbilical vein. The ductus venosus is the first vascular partitioning shunt encountered. Through modulation in ductus venosus shunting, the proportion of umbilical venous blood that is distributed to the liver and heart changes with advancing gestation. **Near term, 18% to 25% of umbilical venous flow shunts through the ductus venosus to reach the right atrium in this high-velocity stream, while 55% reaches the dominant left hepatic lobe and 20% the right liver lobes (Figure 31-1).** The differences in direction and velocity of blood streams entering the right atrium ensures that nutrient-rich blood is distributed to the left ventricle, myocardium, and brain while low-nutrient venous return is distributed to the placenta for reoxygenation and waste exchange. **This process of blood distribution is referred to as "preferential streaming."**[2] In addition to this overall distribution of left- and right-sided cardiac output, several organs can modify local blood flow to meet oxygen and nutrient demands by autoregulation.

When the milestones in maternal, placental, and fetal development are met, placental and fetal growth progress normally. The metabolic and vascular maternal adaptations promote a steady and enhanced nutrient delivery to the uterus, and placental transport mechanisms allow for efficient bi-directional exchange of nutrient and waste. Placental and fetal growths across the three trimesters are characterized by sequential cellular hyperplasia, hyperplasia plus hypertrophy, and, lastly, hypertrophy alone. Placental growth follows a sigmoid curve that plateaus in midgestation preceding exponential third-trimester growth of the fetus. During this exponential fetal growth phase of 1.5% per day, initial weight gain is due to longitudinal growth and muscle bulk and therefore correlates with glucose and amino acid transport. Eighty percent of fetal fat gain is accrued after 28 weeks' gestation, providing essential body stores in preparation to extrauterine life. From 32 weeks onward, fat stores increase from 3.2% of fetal body weight to 16%, accounting for the significant reduction in body water content.[3]

The ultimate growth potential of the placenta and the fetus are genetically predetermined as indicated by their relationship with the maternal body mass index and ethnicity. This genetically predetermined growth potential is probably further modified by other maternal, placental, and fetal factors that finally determine the size of the individual at birth. Several possible mechanisms may challenge compensatory capacity of the maternal-placental-fetal unit to such an extent that failure to reach the growth potential may be the end result.

DEFINITION AND PATTERNS OF FETAL GROWTH RESTRICTION

Normal fetal growth involves hyperplasia and hypertrophy on a cellular level. Disturbance of fetal growth dynamics can lead to a reduced cell number, cell size, or both, ultimately resulting in abnormal weight, body mass, or body proportion at birth. The classification of abnormal growth has evolved significantly over the last century. From its modern origins in 1919 when Ylppo was the first to label neonates with a birthweight below 2500 grams as "premature" to the description of individualized growth potential,

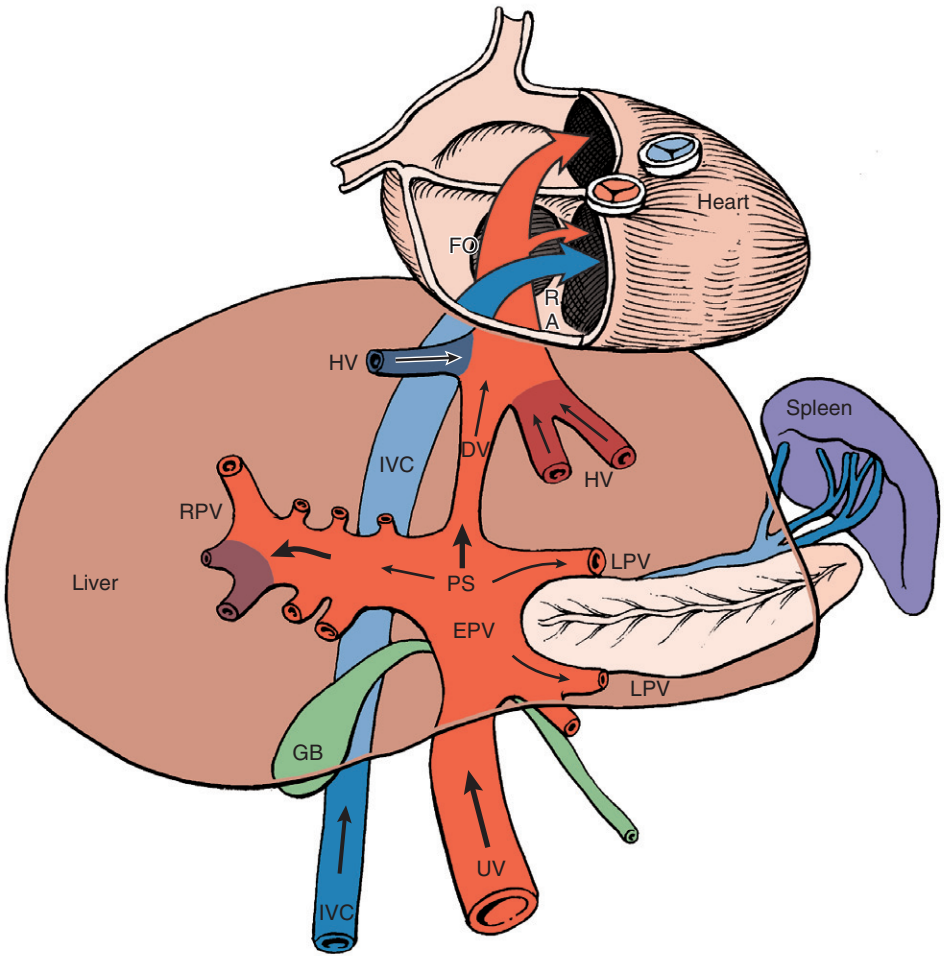

FIGURE 31-1. Fetal umbilical and hepatic venous circulation. The *arrows* indicate the direction of blood flow and the color, the degree of oxygen content (red = high, purple = medium, blue = low). The arrows indicate the direction of blood flow. *DV,* Ductus venosus; *EPV,* extrahepatic portal vein; *FO,* foramen ovale; *GB,* gall bladder *HV,* hepatic veins; *IVC,* inferior vena cava; *LPV,* left portal vein; *PS,* portal sinus; *RA,* right atrium; *RPV,* right portal vein; *UV,* umbilical vein. (Reproduced from Mavrides E, et al: The anatomy of the umbilical, portal and hepatic venous systems in the human fetus at 14-19 weeks of gestation. Ultrasound Obstet Gynecol 18:598, 2001.)

the recognition of the growth-restricted neonate has advanced significantly. With the advent of ultrasound, the recognition and study of fetal growth abnormalities extended into the prenatal period. It is important to note that several definitions describing abnormal growth are used interchangeably in the obstetric and pediatric literature, but that they do not necessarily describe the same population.

The terminology for classifying fetal growth disorders has specifically expanded over the last four decades, which has led to confusion among the various terms used. From the 1960s, growth has been classified by the absolute birthweight value as low birthweight (<2500 grams), very low birthweight (VLBW; <1500 grams), extremely low birth weight (ELBW; <1000 grams), or macrosomia (>4000 grams). Subsequently, studies by Lubchenco, Usher, Battaglia and others demonstrated that only the comparison of the actual birthweight to the expected weight in a population at the same gestational age identified small neonates at risk for adverse outcome. Adopting this concept of "light" and "heavy" for gestational age served as an introduction of population-based reference ranges for birthweight in the 1970s and allowed classification of growth by the birthweight percentile. This resulted in the currently accepted classification of birthweight as very small for gestational age (VSGA; <3rd percentile), small for gestational age (SGA; <10th percentile), appropriate for gestational age (AGA; 10th-90th percentile), or large for gestational age (LGA; >90th percentile). Although birthweight percentiles are superior in identifying the small neonate, they fail to account for proportionality of growth and the growth potential of the individual. Therefore, neonates that have a normal birthweight percentile but abnormal body proportion as a result of differential growth delay may be missed. Similarly, birthweight percentiles do not distinguish between the small neonate that is normally grown given his genetic potential, and the neonate that is growth restricted due to a disease process.

The detection of abnormal body mass, or proportions, is based on anthropometric measurements and ratios that are relatively independent of gender, race, and to a certain extent gestational age and therefore also the traditional birthweight percentiles. **The ponderal index [(birthweight (g) / crown heel length)^3 × 100] has a high accuracy for the**

identification of IUGR and macrosomia. The ponderal index correlates more closely with perinatal morbidity and mortality than traditional birthweight percentiles, but may miss the proportionally small and lean growth-restricted neonate. The classification of abnormal growth is also enhanced by adjusting birthweight reference limits for first trimester maternal height, race, birth order, and fetal/neonatal sex (growth potential). The birthweight percentile that is based on this individualized growth potential accounts for these possible sources of errors and is superior in the prediction of adverse perinatal outcome to conventional reference ranges.[4] It is anticipated that "growth potential" type curves will eventually become the primary tool in identifying the growth-restricted fetus antenatally.

The classification of abnormal growth during fetal life marks a significant advance because it opens the possibility of prenatal detection that leads to preventive or therapeutic management. The concept of percentiles has been adopted to the ultrasound biometry of the fetus. Accordingly parameters of head, abdominal, and skeletal growth are related to population-based reference ranges. The prenatal diagnosis of fetal growth restriction based on ultrasound biometry is described in detail below.

In addition to the detection of smaller individual measurements and lower weight, two principal patterns of disturbed fetal growth have been described: asymmetric and symmetric. In the asymmetric growth pattern, somatic growth (e.g., the abdominal circumference [AC] and lower body) shows a significant delay while there is relative or absolute sparing of head growth. In the symmetric form, body and head growth are similarly affected. Asymmetric growth patterns result from two processes. Firstly, liver volume is reduced due to depletion of glycogen stores as the result of limited nutrient supply, which leads to a decrease in abdominal circumference. Secondly, elevations in placental blood flow resistance increase right cardiac afterload and promote diversion of the cardiac output toward the left ventricle due to the parallel arrangement of the fetal circulation and the presence of central shunts. Blood and nutrient supply to vital structures in the upper part of the body thus increase, presumably resulting in relative "head sparing." Symmetrically restricted fetal growth typically results when interference with the growth process results in decreased cell numbers and cell size, typically resulting from a first trimester insult. As a result, all parts of the body are equally affected, producing uniformly small growth.

The pattern of fetal growth depends on the underlying cause of growth delay and on the timing and duration of the insult. Uteroplacental insufficiency is typically associated with asymmetric fetal growth delay owing to the aforementioned mechanisms. Aneuploidy, nonaneuploid syndromes, and viral infections either disrupt the regulation of growth processes, or interfere with growth at the stage of cell hyperplasia. This typically results in a symmetric growth delay. Specific conditions, such as skeletal dysplasia, may produce distinct growth patterns by their differential impacts on axial and peripheral skeletal growth. Because growth is dynamic, the pattern of growth restriction may evolve in the course of gestation. Placental disease may initially present with relative head sparing, but eventually progress to symmetrical growth delay as placental insufficiency worsens. Alternatively, the acute course of a fetal viral illness may temporarily result in arrested growth with subsequent resumption of a normal growth pattern.

While the definition and classification of fetal growth restriction has significantly evolved, research is still ongoing. Small fetal and/or neonatal size have to be considered as a physical sign rather than a specific disease warranting further investigation of underlying causes. For the purpose of this chapter, fetal growth restriction or IUGR only refers to fetuses with underlying placental pathology. Small for gestational age (SGA) refers to neonates in whom no causative pathology for the small size is evident. From the perspective of the managing obstetrician, prenatal identification of IUGR is most relevant, since it allows appropriate prospective fetal management. To formulate a uniform approach to prenatal detection and perinatal management, an understanding of the maternal and fetal impact of placental insufficiency is essential.

ETIOLOGIES OF INTRAUTERINE GROWTH RESTRICTION

The precise mechanisms by which various conditions interfere with normal placentation and culminate in either pregnancy loss or IUGR are of great importance. Conditions that result in fetal growth restriction broadly consist of maternal, uterine, placental, and fetal disorders. These conditions result in growth delay by affecting nutrient and oxygen delivery to the placenta (maternal causes), nutrient and oxygen transfer across the placenta (placental causes), and fetal nutrient uptake or regulation of growth processes (fetal causes). In clinical practice, there may be considerable overlap between the conditions that determine manifestation, progression, and outcome.

Maternal causes of fetal growth restriction include vascular disease such as hypertensive disorders of pregnancy, diabetic vasculopathy, chronic renal disease, collagen vascular disease, and thrombophilia. The associated decrease in uteroplacental blood flow is responsible for the majority of clinically recognized cases of IUGR. Poor maternal volume expansion, as may be observed in hypertensive disorders or genetic conditions such as angiotensinogen gene mutations or living at high altitude, have also been reported to compromise placental blood flow by reducing the circulating blood volume, hyperviscosity, and sludging. In addition, reduction of maternal oxygenation found in women living at high altitude, or with cyanotic heart disease, parenchymal lung disease, or reduced oxygen-carrying capacity, as observed with certain hemoglobinopathies and anemias, may be responsible for the cases of IUGR described in these conditions.

Poor maternal weight gain is a long recognized risk factor for IUGR. Studies of the offspring of pregnant women with dietary restrictions suggest that limited protein intake, especially prior to 26 weeks' gestation, can result in symmetric IUGR, while caloric restriction (maternal intake of 600 to 900 calories daily for 6 months) has only moderate effects on birthweight. The degree of malnourishment observed in the studies of Guatemalan women or during the Dutch famine would not ordinarily be found in the United States. **Nevertheless, maternal prepregnancy weight and weight gain in pregnancy are two of the most important**

variables contributing to birthweight. It is conceivable that malnutrition due to gastrointestinal syndromes such as Crohn's disease, ulcerative colitis, or bypass surgery can result in lower birthweight. However, an association with IUGR is infrequent in these conditions.

Glucose is a critical fetal nutrient driving longitudinal fetal growth. Reduced glucose supply to the fetoplacental unit can result in fetal growth restriction. This was suspected by Economides and Nicolaides, who observed significantly lower maternal and fetal glucose levels in growth-restricted fetuses. Khouzami and colleagues documented a significant association between relative maternal hypoglycemia on a 3-hour oral glucose tolerance test (GTT) and subsequent birth of non-low-birthweight but growth-restricted babies. Sokol and colleagues and Langer and colleagues have confirmed that a flat maternal response to glucose loading increased the risk for poor fetal growth as much as 20-fold.

Maternal drug ingestion may result in IUGR by a direct effect on fetal growth as well as through inadequate dietary intake. Smoking produces a symmetrically smaller fetus through reduced uterine blood flow and impaired fetal oxygenation and is a major cause of growth restriction in developed countries. The consumption of alcohol and the use of warfarin or hydantoin derivatives are now well known to produce particular dysmorphic features in association with impaired fetal growth. Mills and colleagues have demonstrated a significant increase in the risk of IUGR with the consumption of one to two drinks daily, in the absence of fetal alcohol syndrome. Maternal use of cocaine has been associated with not only IUGR but also reduced head circumference (HC) growth.

In 1971, Lobi and colleagues reported that advanced maternal age was a factor in the etiology of IUGR. Berkowitz and colleagues found no evidence that the first births of women between 30 and 34 years or those over 35 years were at increased risk for growth restriction. Chronic medical conditions of the mother do increase the risk of IUGR. **However, if one controls for underlying medical complications, maternal age is not related to restricted fetal growth.**

Multiple risk factors can act synergistically on fetal growth. For example, the adverse impact of smoking is doubled in thin Caucasian women and further potentiated by poor maternal weight gain. Similarly, the possible benefits of low-dose aspirin and the detrimental effects of excessive blood pressure reduction are also more apparent in this group of women.

Fetoplacental causes can result in fetal growth restriction due to abnormalities of the fetus and/or placenta. Chromosomal abnormalities, congenital malformations, and genetic syndromes have been associated with less than 10% of cases of IUGR.[5] Similarly, intrauterine infection, though long recognized as a cause of growth restriction, also accounts for less than 10% of all cases. However, genetic and infectious etiologies are of special importance because perinatal and long-term outcome are ultimately determined by the underlying condition, with little potential impact through perinatal interventions.

Growth restriction has been observed in 53% of cases of trisomy 13, and 64% of cases of trisomy 18, and may be manifest as early as the first trimester. Other conditions that may present with fetal growth restriction include skeletal dysplasia and Cornelia De Lange syndrome. The database of online inheritance in man lists over 100 genetic syndromes that may be associated with fetal growth restriction. Of the infectious agents, herpes, cytomegalovirus, rubella, and *Toxoplasma gondii* are well-documented causes of symmetric IUGR.

Abnormal placental development with subsequent placental insufficiency is a relatively common problem affecting about one third of cases with IUGR or about 3% of all pregnancies. Placental insufficiency accounts for the vast majority of IUGR in singleton pregnancies. An absolute or relative decrease in placental mass affects the quantity of substrate the fetus receives and antedates the development of IUGR. Thus, abnormal placental vascular development, circumvallate placenta, partial placental abruption, placenta accreta, placental infarction, or hemangioma may result in growth restriction. Intrinsic placental pathology, such as a single umbilical artery and placental mosaicism, has been identified in some cases of growth restriction.[6] Placental implantation in the lower uterine segment in placenta previa is considered suboptimal for nutrient and may therefore result in IUGR even in the absence of chronic hemorrhage.

Twin gestation is often associated with IUGR (see Chapter 30). In 1966, Gruenwald observed that the growth curve of twins deviated from that of singletons with a progressive fall of growth after 32 weeks. This finding implies relative placental insufficiency as opposed to intrinsic fetal compromise and suggests that the longer the twin pregnancy continues, the greater the delay in intrauterine growth, with "catch-up" growth observed after birth. Thus, twins represent a group of fetuses at high risk for IUGR, as confirmed by an incidence of 17.5% in one study. The appropriate growth standard to apply to twin fetuses would appear to be the same as that for singletons. Two trials demonstrate that the morbidity and mortality of fetuses from twin gestations are equivalent, or elevated when the twins are monochorionic, when compared with birthweight- and gestational age-matched singletons.[7] **Although it is beyond the scope of this chapter to discuss the spectrum of clinical consequences, it needs to be recognized that the diagnosis and prognosis of fetal growth restriction in twin pregnancies is critically determined by the chorionicity. Selective intrauterine growth restriction (sIUGR) is a specific term that is applied to fetal growth restriction occurring in monochorionic twins. The prognosis and risk profile can be determined based on the umbilical artery flow pattern.**[8]

MATERNAL AND FETAL MANIFESTATIONS OF INTRAUTERINE GROWTH RESTRICTION

The impact of placental insufficiency depends on the gestational age at onset and the severity of the placental disease. Early interference with normal placentation affects all levels of placental and fetal development and culminates in the most severe clinical picture, which may result in miscarriage, or early stillbirth. If sufficient supply to the placental mass can be established, further placental differentiation may be possible, but suboptimal maternal adaptation to pregnancy and deficient nutrient delivery

pose limitations. If adaptive mechanisms permit ongoing fetal survival, early-onset growth restriction with its many fetal manifestations develops. If placental disease is mild or successful compensation has occurred, the consequences of nutrient shortage may remain largely subclinical, only to be unmasked through its restrictive effect on exponential fetal growth in the second to third trimester. In these cases, late-onset growth delay, a decrease in adipose tissue, or abnormal body proportions at birth may be the consequence.

Maternal Impacts

Placental dysfunction affects several aspects of maternal adaptation to pregnancy. Associations between poor placentation with suboptimal maternal volume expansion, increased vascular reactivity, and a "flat" glucose tolerance have been described. Abnormalities of placental vascular development are of special interest because they can be detected by Doppler ultrasound of the uterine arteries and frequently predate clinical disease (Figure 31-2). When trophoblast invasion remains confined to the decidual portion of the myometrium, maternal spiral and radial arteries fail to undergo the physiologic transformation into low-resistance vessels, which is generally expected by 22 to 24 weeks. **Maternal placental floor infarcts, fetal villous obliteration, and fibrosis each increase placental blood flow resistance, producing maternal-fetal placental perfusion mismatch that decreases the effective exchange area.** With progressive vascular occlusion fetoplacental flow resistance is increased throughout the vascular bed and eventually metabolically active placental mass is reduced. The diagnostic and screening utility of ultrasound findings that are suggestive of such pathology is discussed below.

Fetal Impacts

When placental dysfunction compromises nutrient delivery triggering fetal mobilization of hepatic glycogen stores, physical manifestation of growth delay becomes clinically apparent. In addition to the cardinal sign of fetal growth restriction, metabolic, endocrine, hematologic, cardiovascular, and behavioral manifestations of placental insufficiency have been described that relate to the severity and duration of placental dysfunction. Of these, cardiovascular and central nervous system (CNS) responses are best studied because their noninvasive assessment is readily achieved by multivessel Doppler, gray-scale ultrasound, and fetal heart rate (FHR) analysis and therefore can be utilized for fetal surveillance. Appreciating the variety of fetal manifestations helps to understand the potential limitations of antenatal surveillance and provides a basis to appreciate the possible short- and long-term impacts of placental insufficiency.

Metabolic manifestations occur early in growth-restricted fetuses. This is because with mild to moderate decline in uterine nutrient delivery, fetal supply is compromised first, while placental nutrition is preferentially maintained. With progression of placental insufficiency, nutrient deficits become universal and result in decreased fetal and placental size. Accordingly, with mild restrictions in oxygen and glucose supply, fetal demands are still met by increased fractional extraction. When uterine oxygen delivery falls below a critical value (0.6 mmol/min/kg fetal body weight in sheep), fetal oxygenation begins to fall and is eventually accompanied by fetal hypoglycemia. The initially mild hypoglycemia results in a blunted fetal pancreatic insulin response allowing gluconeogenesis from hepatic glycogen stores. The minimal hepatic glycogen stores in the fetus are quickly depleted as glucose and lactate are preferentially diverted to the placenta. An increasing nutrient deficit leads to worsening fetal hypoglycemia, decreasing the maintenance of fetal oxidative metabolism and placental nutrition. With a more significant limitation of oxidative metabolism, associated with down-regulation of placental transport mechanisms and intensifying hypoglycemia, the use of other fetal energy sources becomes necessary, and more widespread metabolic consequences ensue. Limitation of amino acid transfer and breakdown of endogenous muscle protein to obtain gluconeogenic amino acids depletes branched chain and other essential amino acids.[9] Simultaneously, lactate accumulates due to the limited capacity for oxidative metabolism. Placental transfer of fatty acids loses its selectivity, particularly for essential fatty acids. Reduced utilization leads to increased fetal free fatty acid and triglyceride levels with

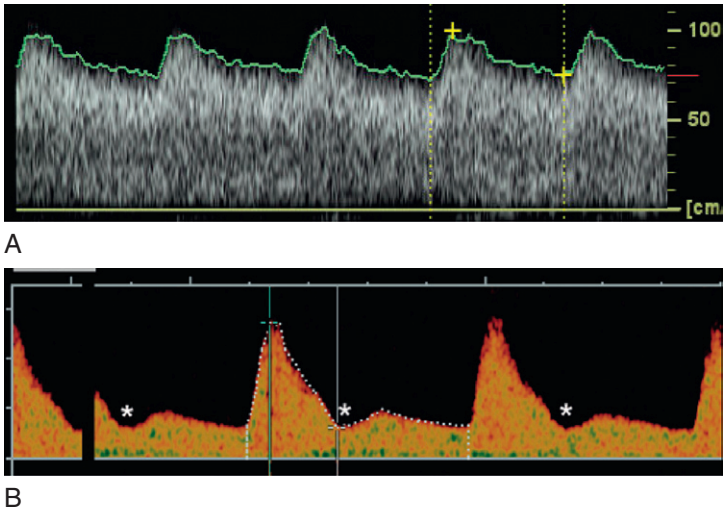

FIGURE 31-2. Uterine artery flow velocity waveforms. Normal trophoblast invasion results in a low-resistance, high-capacitance placental vascular circulation that can be documented with uterine artery Doppler velocimetry. The flow velocity waveform in panel **A** was obtained at 24 weeks' gestation and shows high diastolic flow velocities. Such a flow pattern indicates successful trophoblast invasion. The second waveform **(B),** on the other hand, shows lower diastolic velocities and an early diastolic notch *(*)*. This flow pattern is reflective of increased blood flow resistance in the spiral arteries and the downstream placental vascular bed. Persistence of notching beyond 24 weeks' gestation is associated with an increased risk of fetal growth restriction and/or hypertensive disorders of pregnancy.

a subsequent failure to accumulate adipose stores. In this setting of advancing malnutrition, cerebral and cardiac metabolism of lactate and ketones is upregulated to remove these accumulating products of anaerobic metabolism. Acid–base balance can be maintained as long as acid production is met by sufficient buffering capacity of fetal hemoglobin and an equal disposition by these organs. Thus metabolic compromise progresses from simple hypoglycemia, hypoxemia, and decreased levels of essential amino acids to overt hypoaminoacidemia, hypercapnia, hypertriglyceridemia, and hyperlacticemia. The lactate production is exponentially correlated to the degree of acidemia that generally results from this metabolic state.[10] A summary of metabolic responses is provided in Table 31-1.

Fetal endocrine manifestations of placental insufficiency are of relevance because they are responsible for the downregulation of growth and developmental processes. Decrease in fetal glucose and amino acids indirectly downregulates insulin and insulin-like growth factors I and II as the principal endocrine regulators of longitudinal growth. Leptin-coordinated deposition of fat stores is similarly affected. In addition, pancreatic cellular dysfunction becomes evident through a decreased insulin/glucose ratio and impaired fetal glucose tolerance. Significant elevations of corticotrophin-releasing hormone, adreonocorticotrophic hormone, and cortisol as well as a decline in active vitamin D and osteocalcin all correlate with the severity of placental dysfunction. These hormonal imbalances are believed to have additional negative impacts on linear growth, skeletal growth, bone mineralization, and the potential for postpartum catch-up growth.

In growth-restricted fetuses, declining function at all levels of the thyroid axis correlates to the degree of hypoxemia. Thyroid gland dysfunction may develop as indicated by low levels of thyroxine and trilodothyronine despite elevated thyroid-stimulating hormone levels (TSH). In other instances, central production of TSH may be responsible for fetal hypothyroidism. Finally, downregulation of thyroid hormone receptors may limit the biologic activity of circulating thyroid hormones in specific target tissues such as the developing brain.[11]

Elevations in serum glucagon, adrenaline, noradrenaline, and stimulation of the fetal glucocorticoid axis have immediate effects in fetal life, promoting the mobilization of hepatic glycogen stores and peripheral gluconeogenesis. However, persistent alterations of these hormones may have a causative relationship with the development of diabetes and vascular complications in adult life.

Fetal hematologic responses to placental insufficiency are important because they initially provide a compensatory mechanism for hypoxemia and acidemia but eventually may become contributory to the escalation of placental vascular dysfunction. Fetal hypoxemia is a trigger for erythropoietin release and stimulation of red blood cell production through both medullary and extramedullary sites, resulting in polycythemia.[12] Oxygen-carrying capacity and the buffering capacity are thus increased through the elevation in hemoglobin count. If extramedullary hematopoiesis is increasingly induced by prolonged tissue hypoxemia and/or acidosis, the nucleated red blood cell (NRBC) count rises owing to the escape of these cells from these sites. Thus, elevated NRBC counts correlate with metabolic and cardiovascular status and are independent markers for poor perinatal outcome. In advanced placental insufficiency, more complex hematologic abnormalities supervene that may result from dysfunctional erythropoiesis, placental consumption, and vitamin and iron deficiency. Subsequently fetal anemia and thrombocytopenia are observed, particularly in fetuses with marked elevation of placental blood flow resistance and evidence of intraplacental thrombosis, suggesting a causative relationship.[13] Increase in whole blood viscosity, decrease in red blood cell membrane fluidity, and platelet aggregation may be important precursors for accelerating placental vascular occlusion and dysfunction.

Growth-restricted fetuses also show evidence of immune dysfunction at the cellular and humoral level. Decreases in immunoglobulin, absolute B-cell counts, total white blood cell counts, and neutrophil, monocyte, and lymphocyte subpopulations, as well as selective suppression of T-helper and cytotoxic T-cells, are all related to the degree of acidemia. These immune deficiencies explain the higher susceptibility of growth-restricted neonates to infection after delivery.

Fetal cardiovascular responses to placental insufficiency can be subdivided into early and late based on the degree of deterioration of cardiovascular status and the associated derangement of fetal acid-base balance (see below).[14] **Early responses are typically adaptive in nature and result in preferential nutrient streaming to essential organs.** The combination of elevated placental blood flow resistance and impaired transplacental gas transfer has several effects

TABLE 31-1 SUMMARY OF METABOLIC RESPONSES TO PLACENTAL INSUFFICIENCY

SUBSTRATE	CHANGE
Glucose	Decreased proportional to the degree of fetal hypoxemia.
Amino acids	Significant decrease in branched chain amino acids (valine, leucine, isoleucine) as well as lysine and serine. In contrast, hydroxyproline is elevated. The decrease in essential amino acids is proportional to the degree of hypoxemia. Elevated amniotic fluid glycine to valine ratio. Elevations in amniotic fluid ammonia with a significant positive correlation with the fetal ponderal index.
Fatty acids and triglycerides	Decrease in long-chain polyunsaturated fatty acids (docosahexanoic and arachidionic acids). Decrease in overall fatty acid transfer only with significant loss of placental substance. Hypertriglyceridemia due to decreased utilization. Lower cholesterol esters.
Oxygen and CO_2	Degree of hypoxemia proportional to villous damage and correlates significantly with hypercapnia, acidemia and hypoglycemia and hyperlacticemia.

on the fetal circulation. Normally nutrient-rich oxygenated blood enters the fetus via the umbilical vein, reaching the liver as the first major organ. One of the earliest cardiovascular signs of placental insufficiency is a decrease in the magnitude of umbilical venous volume flow. In response to these changes in umbilical venous nutrition content and blood flow volume, the proportion of umbilical venous blood that is diverted through the ductus venosus toward the fetal heart increases.[15] This change in venous shunting across the ductus venosus increases the proportion of nutrient-rich umbilical venous blood that bypasses the liver and reaches the left side of the heart through the foramen ovale.[16] Because of the presence of central shunts at the level of the foramen ovale and ductus arteriosus, differential changes in downstream blood flow resistance can affect the proportion of cardiac output delivered through each ventricle (Figure 31-3). Elevation of blood flow resistance in the pulmonary vascular bed and subdiaphragmatic circulation (lower body and placenta) increase right ventricular afterload. A drop in cerebral blood flow resistance decreases left ventricular afterload.[17] As a consequence, shunting of nutrient rich blood from the ductus venosus through the foramen ovale to the left side of the heart increases and left ventricular output rises in relation to the right cardiac output.[18] At the aortic isthmus, blood coming from the right ventricle through the ductus arteriosus is diverted toward the aortic arch, thereby supplementing this central shift in cardiac output from right to left. This relative shift in cardiac output toward the left ventricle that results in increased blood flow to the myocardium and brachiocephalic circulation has been termed redistribution, indicating a compensatory mechanism in response to placental insufficiency.

Late circulatory responses are associated with deterioration of cardiovascular status. Redistribution is only effective as long as adequate forward cardiac function is maintained. Marked elevations in placental blood flow resistance and progressive placental insufficiency can lead to an impairment of cardiac function. When this occurs, several aspects of cardiovascular homeostasis can be affected. Ineffective preload handling and elevation in central venous pressure may result from ineffective redistribution, a measurable decline in cardiac output, and a decline in cardiac forward function. The hallmark of this advancing deterioration in cardiovascular state is loss of diastolic forward flow in the umbilical circulation and a marked decline of forward flow in the venous system.[19] Finally, myocardial dysfunction and cardiac dilatation may result in holosystolic tricuspid insufficiency and spontaneous FHR decelerations, followed by fetal demise.[20]

In addition to the central circulatory changes that affect the distribution of cardiac output, fetal organs have the ability to regulate their individual blood flow through autoregulation. Such autoregulatory mechanisms have been identified in the myocardium, adrenal glands, spleen, liver, celiac axis, mesenteric vessels, and kidneys. These autoregulatory mechanisms are evoked at different levels of compromise and their effect is typically complementary to central blood flow redistribution by enhancing perfusion of vital organs as long as cardiovascular homeostasis is maintained. Doppler ultrasound is the fetal assessment tool to assess these cardiovascular responses to placental insufficiency (see below). A summary of Doppler findings and their physiologic significance in the context of placental insufficiency is provided in Table 31-2.

Fetal behavioral responses to placental insufficiency and characteristics of the FHR reflect developmental status and undergo significant changes with advancing gestation. Progressive sophistication of fetal behavior and increasing variation of the fetal heart rate reflect differentiation of central regulatory centers and expansion of central processing capability. Normally behavioral milestones progress from the initiation of gross body movements and fetal breathing in the first trimester to coupling of fetal behavior (e.g., heart rate reactivity) and integration of rest-activity cycles into stable behavioral states (states 1-4 F) by 28 to 32 weeks' gestation (see Chapter 12). A steady decrease in baseline heart rate reflecting increasing vagal tone accompanies these developments. In addition, short- and long-term variability and variation as well as the amplitude of accelerations increase with advancing gestation, reflecting increasing central processing. **With the completion of these milestones, heart rate reactivity by traditional criteria is present in 80% of fetuses by 32 weeks' gestation.** Differences in maturational state and behavioral state, disruption of neural pathways, and declining oxygen tension may all modulate or even abolish fetal behavior or heart rate characteristics.

Because variations of fetal behavior and the FHR rate may be due to several factors, observation of several variables over a sufficient length of time is necessary to separate physiologic from pathologic variation. Biophysical profile scoring (BPS) quantifies fetal behavior by assessing tone, movement, breathing activity, and FHR reactivity in an observation period of at least 30 minutes. Amniotic fluid volume (AFV) assessment has traditionally been a part of the BPS. From the second trimester onward, AFV is primarily related to fetal urine production and therefore renal perfusion. **Thus, AFV assessment provides an indirect assessment of renal/vascular status and constitutes the main longitudinal monitoring component of the BPS (see below). Visual FHR analysis has traditionally been the method of interobserver, posing the problems of interobserver and intraobserver variability.** These are circumvented by computerized analysis of the FHR (cCTG). The cCTG assesses short-term, long-term, and mean minute variation and periods of high variation in addition to traditional FHR parameters that also allow longitudinal observations.

In growth-restricted fetuses with chronic hypoxemia and mild placental dysfunction, the primary CNS response is a delay in all aspects of CNS maturation.[21] With the help of computerized research tools a delay of behavioral development has been documented under such circumstances. The combination of delayed central integration of FHR control, decreased fetal activity, and chronic hypoxemia results in a higher baseline heart rate with lower short- and long-term variation (on computerized analysis) and delayed development of heart rate reactivity.[22] These maturational differences in FHR parameters are particularly evident between 28 and 32 weeks.

Despite the maturational delay of some aspects of CNS function, several centrally regulated responses to

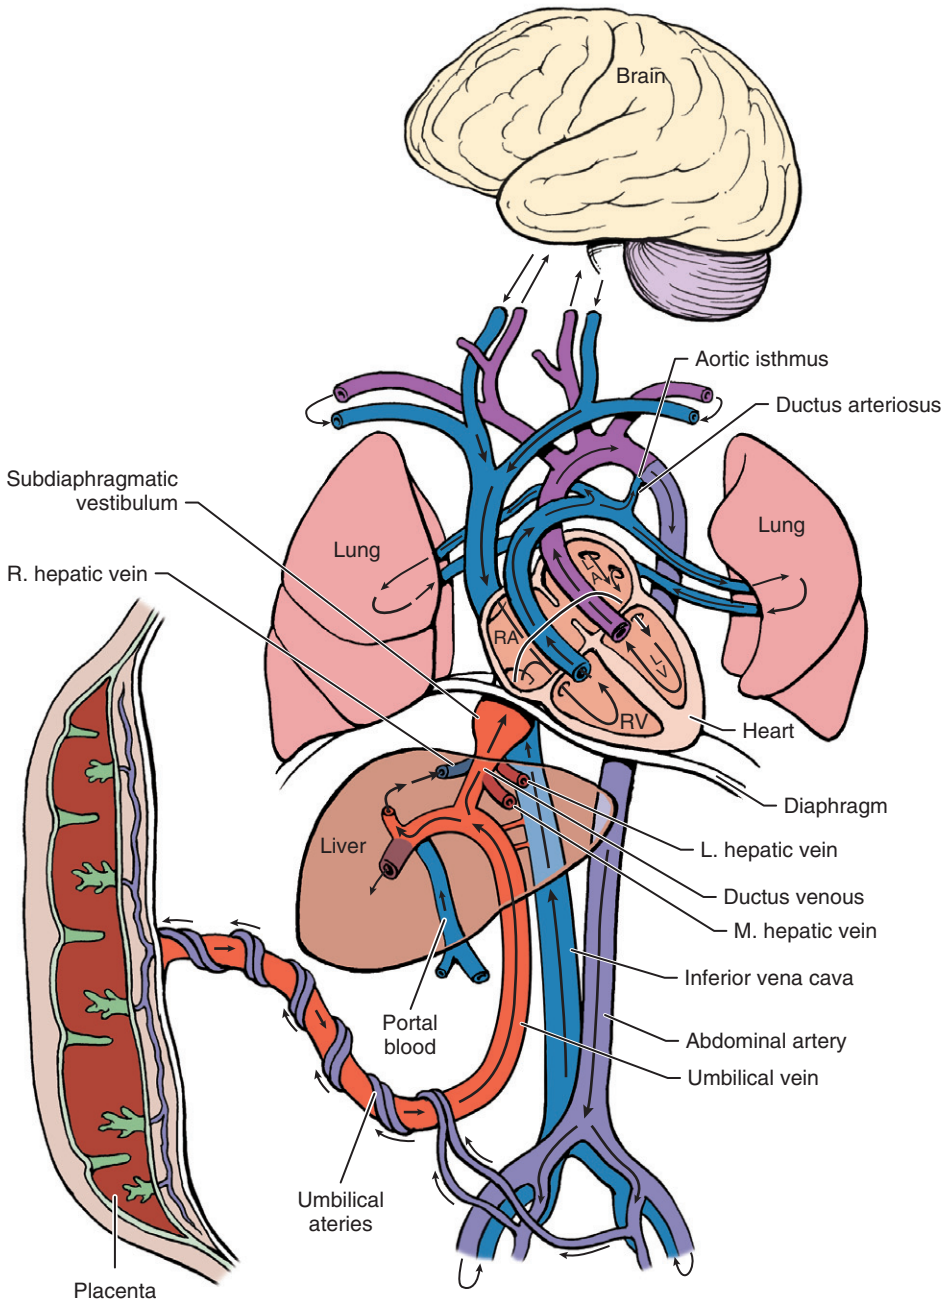

FIGURE 31-3. Schematic presentation of the fetal circulation. This figure illustrates the serial partitioning of nutrient- and oxygen-rich blood reaching the fetus via the umbilical vein. The first partition at the level of the ductus venosus distributes the majority of umbilical venous blood to the liver. Umbilical venous blood that continues toward the heart is partitioned toward the left ventricle *(LV)* at the foramen ovale. This blood supplies the brain and upper part of the body via the brachiocephalic circulation and the myocardium via the coronary circulation. A minor proportion of blood from the right ventricle *(RV)* supplies the lungs while the remainder continues through the ductus arteriosus *(DA)* toward the aorta. At the aortic isthmus bloodstreams coming from the aorta are partitioned based on the relationship of blood flow resistance in the brachiocephalic and subdiaphragmatic circulations. While net forward flow is maintained under physiologic conditions, diastolic flow reversal occurs when brachiocephalic resistance falls, and/or subdiaphragmatic (placental) resistance rises. Finally, the major proportion of descending aortic blood is partitioned at the umbilical arteries to return to the placenta for respiratory and nutrient exchange. (Reproduced from Baschat AA: The fetal circulation and essential organs—a new twist to an old tale. Ultrasound Obstet Gynecol 27:349, 2006.)

acid–base status are still preserved. Therefore, the growth-restricted fetus still maintains behavioral responses to a decline in acid–base status that are determined by the central effects of hypoxemia/acidemia independently of the cardiovascular status. **In contrast, the declining AFV that commonly accompanies the sequential loss of biophysical variables appears to be related to renal blood flow and the degree of vascular redistribution.**[23]

With worsening fetal hypoxemia a decline in global fetal activity initiates the cascade of late behavioral responses characteristic of placental insufficiency.[24] With further deepening hypoxemia, fetal breathing movement ceases.

TABLE 31-2 SUMMARY OF VASCULAR RESPONSES IN IUGR FETUSES

DOPPLER FINDING	PHYSIOLOGIC SIGNIFICANCE
Uterine artery notching	Trophoblast invasion remains limited to the myometrial portion of the spiral arteries. Subsequent failure to fully transform into a low-resistance, high-capacitance vascular bed increases risk for subsequent IUGR and/or preeclampsia.
Decreased, absent, or reversed umbilical artery end-diastolic velocity	Abnormal terminal villi and stem arteries result in increased placental vascular resistance and a proportional decrease in the umbilical artery end-diastolic velocity. Associated placental perfusion defects are responsible for impaired fetomaternal gas and nutrient exchange.
Elevation of blood flow resistance in the thoracic aorta and iliac artery	*Hind limb reflex:* Diversion of blood flow away from the carcass at the expense of the lower body. Achieved through increase in right ventricular afterload proximal to the umbilical arteries as well as increased blood flow resistance distally. In addition to centralization (see below), descending aortic blood flow is also preferentially distributed to the placenta.
1. Decrease in the cerebroplacental Doppler ratio. 2. Direct measurement of cardiac output. 3. Reversal of end-diastolic velocity in the aortic isthmus. 4. Absence or reversal of umbilical artery end-diastolic velocity.	*Centralization:* A measurable shift in the relationship between right and left ventricular afterload resulting in redistribution of cardiac output in favor of the left ventricle (i.e., the heart and brain). This can be passively mediated purely by an increase in placental blood flow resistance and therefore right ventricular afterload.
Decrease in the carotid-, or middle cerebral artery Doppler index.	*Brain sparing:* Cerebral vasodilatation in response to perceived hypoxemia.
Increased superior mesenteric artery Doppler resistance	During perceived hypoxemia and/or redistribution of cardiac output blood flow to the gut as a nonessential organ in utero is compromised.
Decrease in the splenic artery Doppler index	Splenic artery vasodilatation enhances perfusion of this important hematopoietic organ, possibly facilitating an increase in red cell mass.
Decreased Doppler resistance in the celiac axis	There may be a reflection of blood flow augmentation in the hepatic and splenic arteries, which are the main branches of this axis.
Increased Doppler resistance in peripheral pulmonary arteries	As nonessential organs in fetal life, lung perfusion may be further compromised by increased vascular resistance in the pulmonary circulation, ensuring that a greater proportion of right ventricular output bypasses the lungs to reach the placenta.
Increased Doppler resistance in the renal arteries	Redistribution and increased renal vascular tone may be the mediators of oliguria and oligohydramnios observed with chronic and/or progressive hypoxemia.
Measured dilation of the ductus venosus with elevated Doppler index accompanied by a decreased hepatic artery Doppler index	*Liver sparing:* Preferential arterial blood supply to the fetal liver invoked when increased diversion of umbilical venous blood through the ductus venosus jeopardizes hepatic perfusion.
Decreased Doppler index in the adrenal artery flow velocity waveforms	*Adrenal sparing:* Enhanced adrenal perfusion is triggered as part of the fetal stress response to chronic malnutrition or an acute worsening imposed on the chronic state.
Umbilical venous pulsations in association with elevated venous Doppler indices	Evidence of inefficient forward delivery of cardiac output with subsequent elevation of central venous pressure that is transmitted all the way back into the umbilical vein
Normalization of cerebral Doppler indices after a period of "brain sparing"	With advanced cardiovascular deterioration, brain autoregulation may become abnormal. Probably in association with a decrease in cardiac function, the interval between systolic and diastolic velocities widens, resulting in an increase (thus normalization) of the Doppler index.
Sudden ability to visualize and measure coronary Blood flow in a setting of deteriorating venous Doppler indices in a premature fetus with IUGR	*Heart sparing:* Marked augmentation of coronary blood flow in situations of acute or chronic hypoxemia that is achieved through upregulation of coronary vascular reserve and vasodilatation.

Gross body movements and tone decrease further until they are no longer observed in the traditional examination period.[25,26] **Traditional FHR variables are frequently abnormal by this time. Reduction of global fetal activity and loss of fetal coupling (absence of heart rate reactivity and fetal breathing movements) are typically observed at a mean pH of between 7.10 and 7.20.** Loss of tone and movement is characteristic as the pH drops further. Late decelerations of the FHR may develop due to a relative drop in oxygen tension that exceeds 8 torr (see Chapter 16). Spontaneous decelerations due to direct depression of cardiac contractility or "cardiac" late decelerations typically herald fetal demise.

DIAGNOSTIC TOOLS IN FETAL GROWTH RESTRICTION

Fetal growth restriction is a syndrome that is marked by failure of the fetus to reach its growth potential with consequences that are related to the underlying disorder as well as the severity of fetal disease. Because IUGR may be the consequence of many underlying etiologies, the differential diagnosis always includes maternal disease, placental insufficiency, aneuploidy, nonaneuploid syndromes, and viral infection. For appropriate patient counseling and choice of management options, comprehensive prenatal evaluation needs to go beyond the assessment of

fetal size, utilizing a diagnostic approach aimed at identifying the underlying causes. After confirming small fetal size, stratification into three patient groups is of particular importance. The first group consists of constitutionally small but otherwise normal fetuses. These will not usually require any intervention and therefore do not need antenatal surveillance. The second group consists of fetuses with aneuploidy, nonaneuploid syndromes, or viral infection. In these conditions prognosis is largely determined by the underlying disease, with little potential for impact by perinatal interventions. Sensitive and knowledgeable counseling of the parents about the high likelihood of a poor prognosis is especially important in such cases. The third group consists of fetuses with placental disease. In these, progressive deterioration of the fetal condition worsens the prognosis. This subset of patients is most likely to benefit from fetal surveillance and subsequent intervention. Although gray-scale ultrasound provides important clues to the presence of IUGR, the liability of preterm delivery and iatrogenic complications is great if the diagnosis is based solely on biometry. While maternal disease is readily apparent through a history and physical examination, the accurate evaluation of the possible fetal disorder and stratification of risk requires the integration of several diagnostic modalities that evaluate fetal, placental, and amniotic fluid characteristics.[27-29]

Fetal Biometry

Ultrasound criteria have emerged as the diagnostic standard used in the identification of fetal growth restriction. For this purpose sonographic measurements of fetal bony and soft structures are related to reference ranges for gestation. In 1964, Wilcocks and colleagues first demonstrated the correlation between ultrasound measurement of the fetal head and birth weight. Campbell and Dewhurst published the first sonographic descriptions of fetal growth restriction with their analysis of the changes in biparietal diameter (BPD) over time. Two patterns of altered head growth were described: In "late flattening" (type 1, asymmetric type), the BPD increases normally until late pregnancy and then lags behind. In the "low-profile" (type 2, symmetric type), impaired head growth occurs much earlier in gestation. The asymmetric type represents approximately two thirds of cases of fetal growth restriction. The fetal AC is related to hepatic glycogen storage and liver size, therefore correlating closely with the nutritional state. Campbell and Wilkin were the first to relate combined measurements of the BPD and AC to birthweight. Additional direct measurements that are primarily utilized in clinical practice today include the HC and femur length (FL). Secondary direct measurements include the transverse cerebellar diameter (TCD) and the humerus length (HL). The most important calculated ultrasound variable of fetal growth is the sonographically estimated fetal weight (SEFW). Numerous investigators have identified distinct fetal ultrasound parameters that are useful in the calculation of the SEFW.[30] All of the techniques incorporate an index of abdominal size as a variable contributing to the estimation of fetal weight. Population-specific formulae have been derived to generate reference limits that generally have 95% confidence limits deviating approximately 15% around the actual value.

Accurate estimation of fetal growth from these fetal measurements requires knowledge of the gestational age as a reference point to calculate percentile ranks. An estimated date of confinement (EDC) should be based on the last menstrual period when the sonographic estimate of gestational age is within the predictive error (7 days in the first and 14 days in the second trimester, and 21 days in the third trimester). Once the EDC is set by this method or a first trimester ultrasound, it should not be changed because such practice interferes with the ability to diagnose IUGR.

Measurement of the BPD alone is a poor tool for the detection of IUGR. The physiologic variation in size inherent with advancing gestation is high. The majority of growth-restricted fetuses presenting with asymmetric growth restriction and delayed flattening of the cranial growth curve would be detected relatively late. Factors that interfere with a technically adequate measurement of the BPD include alterations of the cranial shape by external forces (oligohydramnios, breech presentation) and direct antero-posterior position of the fetal head.

The HC is not subject to the same extrinsic variability as the BPD. The measurement technique is important because calculated HC measurements are systematically smaller than those directly measured. Thus, the nomogram selected should be based on measurements obtained using the same methodology. As a screening tool for IUGR the HC poses a similar problem as the BPD in that two thirds of IUGR fetuses with asymmetric growth pattern would be detected late.

The TCD is one of the few soft tissue measurements that correlate well with gestational age, being relatively spared from the effects of mild to moderate uteroplacental dysfunction.[31] Whether its measurement offers any advantage over bony measurements in the assessment of compromised fetal growth is controversial.

The AC is the single best measurement for the detection of IUGR.[32] The most accurate AC is the smallest directly measured circumference obtained in a perpendicular plane of the upper abdomen at the level of the hepatic vein between fetal respirations. The AC percentile has both the highest sensitivity and negative predictive value for the sonographic diagnosis of IUGR whether defined postnatally by birthweight percentile or ponderal index. **Using the 10th percentiles as cut-offs, the AC has a higher sensitivity (98% vs. 85%) but lower positive predictive value than the SEFW (36% vs. 51%). Its sensitivity is further enhanced by serial measurements at least 14 days apart.**[33] Because of its high sensitivity, some type of abdominal measurement should be part of every sonographic growth evaluation. But because the AC reflects fetal nutrition, it should be excluded from the calculation of the composite gestational age after the early second trimester.

Calculation of the ratio between the head and abdominal circumference (HC/AC ratio) has been proposed as a tool to increase detection of the fetus with asymmetric growth restriction (Figures 31-4 and 31-5). In the normally growing fetus, the HC/AC ratio exceeds 1.0 before 32 weeks' gestation, is approximately 1.0 at 32 to 34 weeks' gestation, and

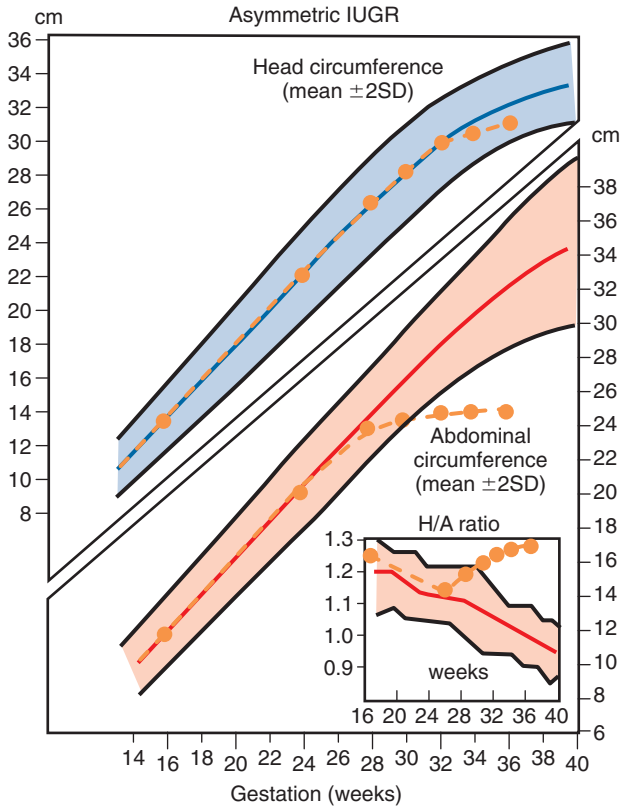

FIGURE 31-4. Growth chart in a case of asymmetric IUGR. Although head circumference is preserved, AC growth falls off early in the third trimester. For this reason, the H/A ratio shown in the lower right corner of the graph becomes elevated. (From Chudleigh P, Pearce JM: Obstetric Ultrasound. Edinburgh, Churchill Livingstone, 1986.)

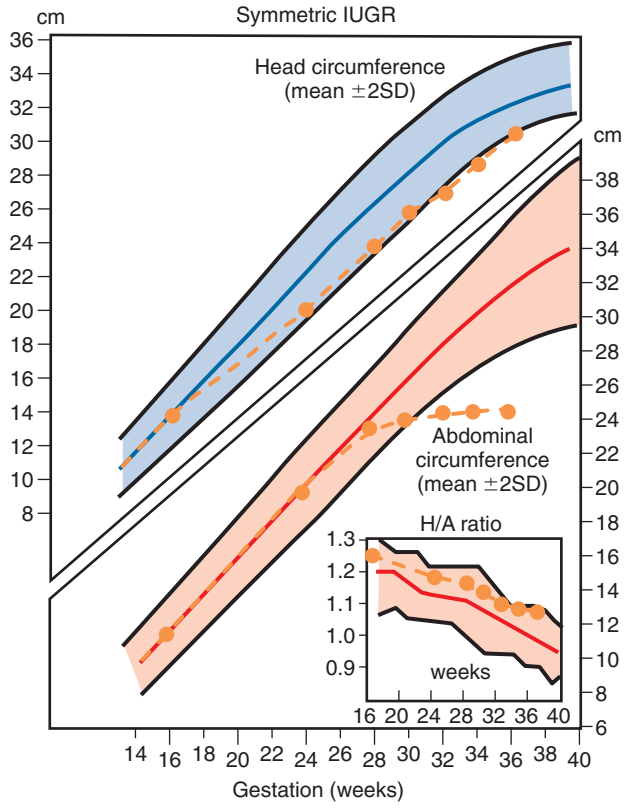

FIGURE 31-5. Growth chart in a case of symmetric IUGR. Note the early onset of both HC and AC growth restriction. For this reason, the H/A ratio shown in the lower right corner remains normal. (From Chudleigh P, Pearce JM: Obstetric Ultrasound. Edinburgh, Churchill Livingstone, 1986.)

falls below 1.0 after 34 weeks' gestation. In fetuses with asymmetric growth restriction, the HC remains larger than that of the body, resulting in an elevated HC/AC ratio,[34] while the ratio remains normal in symmetric IUGR where both direct measurements are equally affected (see Figures 31-4 and 31-5). Using the HC/AC ratio, 70% to 85% of growth-restricted fetuses are detected, with a reduction in false-negative diagnoses. Thus, a single set of measurements, even when determined in the latter part of pregnancy, can be very helpful in evaluating the status of intrauterine growth. **However, both the sensitivity and the positive predictive value of the HC/AC ratio for growth restriction does not equal either the AC percentile, or the SEFW.**[35]

In some cases, measurement of the HC may be difficult as a result of fetal position. One can then compare the FL, which is relatively spared in asymmetric IUGR, to the AC. The FL/AC ratio is 22 at all gestational ages from 21 weeks to term and so can be applied without knowledge of the gestational age. An FL/AC ratio greater than 23.5 suggests IUGR.

Several formulae have been devised to calculate a SEFW. Using a multifactorial equation and a measurement of abdominal size, a weight can be predicted and related to gestational age. Formulas that incorporate the FL may increase the accuracy of in utero weight estimation for the fetus with IUGR. Because the SEFW cannot be measured directly, but is calculated from a combination of directly measured parameters, the error in the estimate is increased. **The accuracy of most formulae (± 2SDs) is ±10%, and none has proven superior to the first devised by Warsof and reported by Sheppard.** As noted earlier, the SEFW has a lower sensitivity but higher positive predictive value than the AC and does not add to the AC percentile for the diagnosis of IUGR. However, an SEFW below the 10th percentile provides a graphic image easy for both patient and referring physician to conceptualize. Therefore use of the estimated fetal weight has become the most common method for characterizing fetal size and thereby growth abnormalities.

Fetal Body Composition

The ponderal index was first described by Rohrer in 1921 as an index of corpulence. This index of neonatal size (weight/length^3) that is normally distributed accurately reflected the nutritional state of the neonate. When compared with birthweight percentile, the ponderal index demonstrates superior ability to predict neonatal asphyxia, acidosis, hypoglycemia, and hypothermia.[36] The ponderal index also correlates with direct measures of neonatal fat as estimated by skinfold thickness. Attempts to translate the ponderal index directly to the fetus have been hampered by the difficulty in accurately assessing fetal length. Attempts to modify the ponderal index for fetal sonographic estimation have been made. Yagel and colleagues demonstrated that the addition of a fetal ponderal index

improved the prediction of perinatal morbidity in fetuses already suspected of having IUGR. Alternative methods for the characterization of fetal growth by physiologic compartments have recently been attempted. Several studies have examined fetal subcutaneous fat content using ultrasound examination. Subcutaneous fat deposition has been examined in the face, abdomen, arm, and thigh.[37] Reduction in facial fat stores has been strongly associated with being SGA. Using ultrasound, Padoan and colleagues showed that both subcutaneous mass (fat mass) and lean mass (bone and muscle mass) are reduced in growth-restricted fetuses, but that proportionately, the subcutaneous mass is reduced to a greater extent than lean mass.[38] This reduction in fat content is consistent with observations made in the growth-restricted neonate and may prove to be a sensitive indicator of the small fetus at increased risk for perinatal complications. The optimal method of in utero assessment of fetal fat has not yet been determined.

Reference Ranges Defining Fetal Growth

An absolute threshold used for the definition of IUGR can be applied to any of the fetal biometric parameters evaluated. These criteria have been statistically defined rather than outcome-based and use either a threshold percentile ranking (non-normative data) or a number of standard deviations below the mean (normative data) as cut-offs. Small for gestational age is defined as a birthweight below the population 10th percentile, corrected for gestational age. However, this cut-off has also been the most widely used criterion for defining growth restriction at birth. This definition has also been adopted for the prenatal period by using a SEFW below the 10th percentile as an indicator of IUGR. Because such an approach is purely based on a weight threshold, it can only serve as a screen for the identification of the small fetus at risk for adverse outcome. **Approximately 70% of infants with a birthweight below the 10th percentile are normally grown (i.e., constitutionally small) and not at risk for adverse outcome as they present one end of the normal spectrum for neonatal size.**[39] **The remaining 30% consist of infants who are truly growth restricted and are at risk for increased perinatal morbidity and mortality.** When the cut-off for an abnormal birthweight is adjusted to the 3rd percentile as suggested by Usher and McLean, the proportion of truly growth-restricted infants identified increases while some with milder forms of IUGR will be missed. However, other authors have demonstrated increased mortality for birthweights through the 15th percentile with an odds ratio of 1.9 for mortality in newborns with birthweights between the 10th and 15th percentiles. As the percentile cut-offs to define abnormal growth continue to be a matter of debate, risk assessment based on weight alone is further hampered by discrepancies between the SEFW and the actual birthweight. Live birthweight criteria do not appropriately describe SEFWs, as there is a significant association of preterm birth with fetal growth restriction.[40] The weights of preterm infants are not normally distributed as they are at term, producing a significant discrepancy between birthweight-defined growth curves and SEFW-defined growth curves in preterm gestation.[41] **SEFW growth curves are generated from patient samples representing the entire obstetrical population at any gestational age. In contrast, preterm live birth normative data tables reflect only those individuals who have delivered under abnormal circumstances.** Thus, the SEFW growth curves consistently demonstrate higher fetal weights over the range of preterm gestation than do birthweight-generated growth curves. Therefore, use of an SEFW cut-off below the 10th percentile is more appropriate to define abnormal fetal growth because the ability to identify fetuses at greater perinatal risk is increased.[42] For the AC a 2.5th percentile cut-off is appropriate because reference ranges are based on a cross section of small, appropriately grown, preterm, and term newborns. However, as reference limits are based on healthy women delivering appropriately nourished neonates at term, the <10th percentile cut-off is consistent with IUGR.

Because of the limitation of population-based reference ranges to assess fetal growth, individualized growth models have been proposed by several investigators.[1,43] The obvious advantage is the lack of dependency on population-based normative data and the ability to detect a true singularly defined growth restriction even with estimated fetal weights above the 10th percentile for the population. Some of these models require three sequential sonograms. This includes baseline biometry in the second trimester, a second sonogram to establish growth potential for an individual morphometric parameter, and a third scan to identify a growth abnormality. Because this approach is cumbersome in clinical practice, other models have been developed that account for variables that contribute the majority of the variance to newborn size. These include early pregnancy weight, maternal height, ethnic group, parity, and sex.[1] Using these variables and fetal growth patterns, the estimated size of a fetus of a given mother can be projected at term and estimated at any specific point in gestation. Deviations from this projected growth pattern can then be recognized. Overall, the diagnostic advantages of these individualized growth models has been questioned when compared with the sequential comparison of the percentile ranking of individual or composite growth parameters to population-based growth curves.

Fetal growth as opposed to fetal size is a dynamic process and requires more than a single evaluation for its estimation. The appropriate observation interval for the evaluation of fetal growth has been based on the assumptions that growth is continuous rather than sporadic and that the identification of growth is limited by the technical capability of the ultrasound equipment used to measure the fetus. The recommended interval between ultrasound evaluations of fetal growth is 3 weeks, as shorter intervals increase the likelihood of a false-positive diagnosis.

In summary, the ability to correctly identify growth-restricted fetuses at risk for adverse outcome by weight estimates alone is limited. Individualized or sequential growth assessment performs better than a single measurement of fetal size. Improved stratification of risk requires the integration of additional diagnostic possibilities.

Fetal Anatomic Survey

Although the sonographic survey of fetal anatomy does not provide an assessment of fetal growth, it is the first step toward the investigation of an underlying etiology. The anatomic survey should focus on the detection of markers

of aneuploidy, nonaneuploid syndromes, and fetal infection, as well as any anatomic defects. The relationship between aneuploidy and fetal anomalies such as gastroschisis, omphalocele, diaphragmatic hernia, congenital heart defects, and sonographic markers such as echogenic bowel, nuchal thickening, and abnormal hand positioning are discussed in Chapter 11. Abnormalities of skull contour, thoracic shape, or disproportional shortening of the long bones may be pointers to skeletal dysplasia or thanatophoric dwarfism. Markers for viral infection may be nonspecific, but include echogenicity and calcification in organs such as the brain and liver.[44] Identification of any of these abnormalities on ultrasound significantly affects the differential diagnosis and frequently has a decisive impact on outcome.

Amniotic Fluid Assessment

The regulation of AVF by the late second and third trimester is primarily dependent on fetal urine output, production of pulmonary fluid, and fetal swallowing. Placental dysfunction and fetal hypoxemia both may result in decreased perfusion of the fetal kidneys with subsequent oliguria and decreasing AVF.[45] Although the accuracy of ultrasound in the assessment of actual AVF is poor, two techniques are used that can provide important diagnostic and prognostic information.[46] In an early study, Manning and colleagues reported that a vertical pocket of amniotic fluid measuring 1 cm or more reflected an adequate fluid volume. Criteria for AVF assessment were subsequently broadened. A 2-cm vertical pocket was considered normal, 1 to 2 cm marginal, and less than 1 cm decreased. Alternatively, AVF may be assessed by the sum of vertical pockets from four quadrants of the uterine cavity. This four-quadrant amniotic fluid index (AFI) (nomogram by Moore T and colleagues; see Figure 33-3) is compared to reference ranges that require knowledge of the gestational age. Despite the availability of these numerical methods for semiquantification of AVF, an overall clinical impression of reduced amniotic fluid may be most important. Ultrasound criteria for a subjectively reduced AVF include a maximum vertical pocket below 3 cm, the fetus in a flexion attitude with limited room for movement, a small or empty bladder and stomach, and molding of the uterus around the fetal body. Movement of the transducer frequently generates uterine contractions, which may be associated with variable decelerations.

Overall, estimation of AVF in itself is a poor screening method for IUGR or fetal acidemia. However, in clinical practice it is an important diagnostic and prognostic tool. Oligohydramnios may be the first sign of fetal growth restriction detected on ultrasonography preceding an assessment for lagging fetal growth. If gestational age is known, ultrasound assessment of fetal growth based on the HC, AC, FL, and SEFW can be performed. If gestational age is unknown, measurements of the FL/AC ratio and single amniotic fluid pocket have to be used because they are independent of gestational age. **Up to 96% of fetuses with fluid pockets less than 1 cm may be growth restricted.**[47] In patients where growth delay is already suspected, amniotic fluid volume can be an important differential diagnostic pointer. In the setting of small fetal size, abundant AVF suggests aneuploidy or fetal infection, while normal or decreased amniotic fluid is compatible with placental insufficiency. **The volume of amniotic fluid also has prognostic significance for the course of labor. Groome et al. demonstrated that oligohydramnios associated with fetal oliguria is associated with a higher rate of intrapartum complications that may be attributed to reduced placental reserve.**[48]

TABLE 31-3 ARTERIAL AND VENOUS DOPPLER INDICES

Arterial Doppler Indices

INDEX	CALCULATION
S/D ratio	$\frac{\text{systolic peak velocity}}{\text{diastolic peak velocity}}$
Resistance index (RI)	$\frac{\text{systolic} - \text{end-diastolic peak velocity}}{\text{systolic peak velocity}}$
Pulsatility index (PI)	$\frac{\text{systolic} - \text{end-diastolic peak velocity}}{\text{time averaged maximum velocity}}$

Venous Doppler Indices

INDEX	CALCULATION
Inferior vena cava preload index	$\frac{\text{peak velocity during atrial contraction}}{\text{systolic peak velocity}}$
Ductus venosus preload index	$\frac{\text{systolic} - \text{diastolic peak velocity}}{\text{systolic peak velocity}}$
Inferior vena cava and ductus venosus pulsatility index for veins (PIV)	$\frac{\text{systolic} - \text{diastolic peak velocity}}{\text{time averaged maximum velocity}}$
Inferior vena cava and ductus venosus peak velocity index for veins (PVIV)	$\frac{\text{systolic} - \text{atrial contraction peak velocity}}{\text{diastolic peak velocity}}$
Percentage reverse flow	$\frac{\text{systolic time averaged velocity}}{\text{diastolic time averaged velocity}} \times 100$

Doppler Velocimetry

Similar to the assessment of AVF, the role of Doppler velocimetry in the management of fetal growth restriction is unique because it serves as a diagnostic as well as a monitoring tool. Doppler flow velocity waveforms may be obtained from arterial and venous vascular beds in the fetus. Arterial Doppler waveforms provide information on downstream vascular resistance, which may be altered due to structural changes in the vasculature or regulatory changes in vascular tone. The systolic/diastolic ratio, the resistance index, and the pulsatility index are the three Doppler indices most widely used to analyze arterial blood flow resistance (Table 31-3). An increase in blood flow resistance manifests itself with a relative decrease in end-diastolic velocity resulting in an increase in all three Doppler indices. Of these, the pulsatility index has the smallest measurement error and narrower reference limits. With extreme increase in blood flow resistance end-diastolic forward velocity may be absent (AEDV) or reversed (REDV) (Figure 31-6).

Venous Doppler parameters complement evaluation of fetal cardiovascular status by providing an assessment of cardiac forward function. Forward blood flow in the

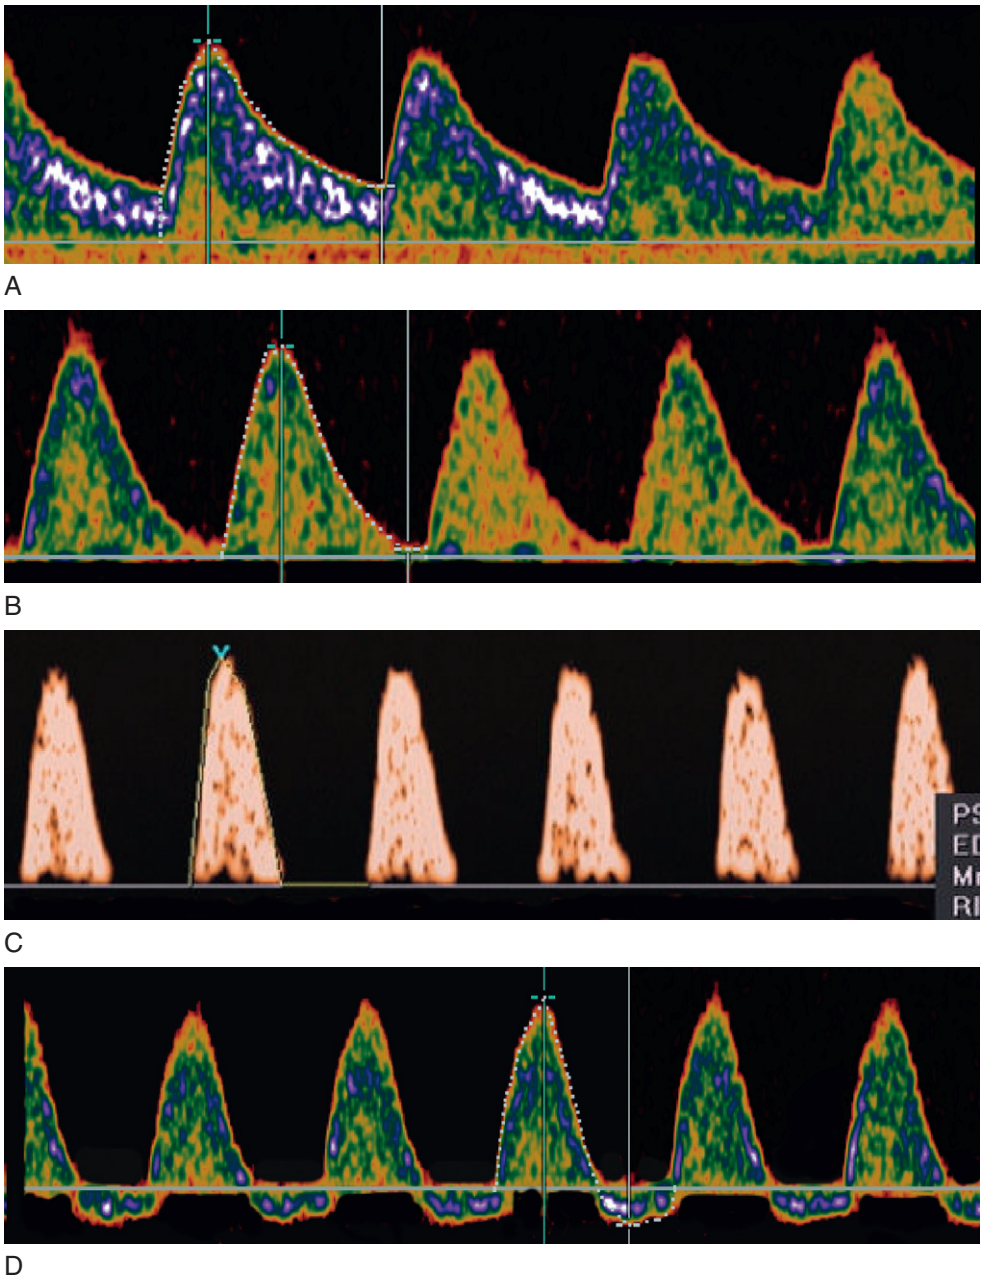

FIGURE 31-6. Umbilical artery flow velocity waveforms. The normal umbilical artery flow velocity waveform has positive end-diastolic velocities that increase toward term, reflecting a falling blood flow resistance in the villous vascular tree **(A).** Moderate abnormalities in the villous vascular structure raise the blood flow resistance and are associated with a decline in end-diastolic velocities **(B).** When a significant proportion of the villous vascular tree is abnormal, end-diastolic velocities may be absent **(C)** or even reversed **(D).**

venous system is determined by cardiac compliance, contractility, and afterload and is characterized by a triphasic flow pattern that reflects pressure volume changes in the atria throughout the cardiac cycle.[49] The descent of the AV-ring during ventricular systole and passive diastolic ventricular filling generates the systolic and diastolic peaks respectively (the S-wave and the D-wave). The sudden increase in right atrial pressure with atrial contraction in late diastole causes a variable amount of reverse flow producing a second trough after the D-wave (the a-wave) (Figure 31-7). The magnitude of forward flow during the atrial systole varies considerably in individual veins and reversal may be physiologic in the inferior vena cava and hepatic veins but is always abnormal in the ductus venosus. Multiple venous Doppler indices have been described to characterize this complex waveform without any clear advantages of individual indices (see Table 31-3).

In the diagnostic assessment of the small fetus, examination of umbilical and middle cerebral artery Doppler studies are the most important to evaluate for placental dysfunction as the underlying etiology. **Randomized trials and meta-analyses confirm that the combined use of fetal biometry and umbilical artery Doppler significantly reduces perinatal mortality and iatrogenic intervention because documentation of placental vascular insufficiency effectively separates growth-restricted fetuses that require**

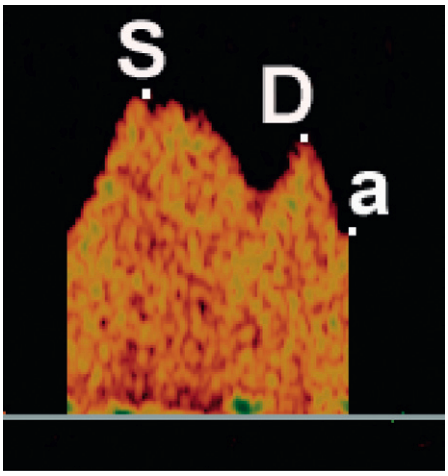

FIGURE 31-7. Venous flow velocity waveform. A typical venous flow velocity waveform is shown. The triphasic waveform (*S,* systole; *D,* diastole; *a,* atrial contraction) reflects volume flow changes during the cardiac cycle. With descent of the atrioventricular valves during ventricular systole, intra-atrial pressures fall and increased forward flow during the S-wave is observed. A temporary decrease in forward flow occurs when the atrioventricular valve ring ascends at the end of ventricular systole producing the first trough in the flow velocity waveform. When atrial pressures exceed intraventricular pressures, the atrioventricular valves open, resulting in the rapid influx of blood into the ventricles. The associated increase in venous flow results in the D-wave. With initiation of a new cardiac cycle, atrial contraction results in a sharp rise in intra-atrial pressure and decline in venous forward flow. This second trough is called the a-wave because it is produced by atrial contraction.

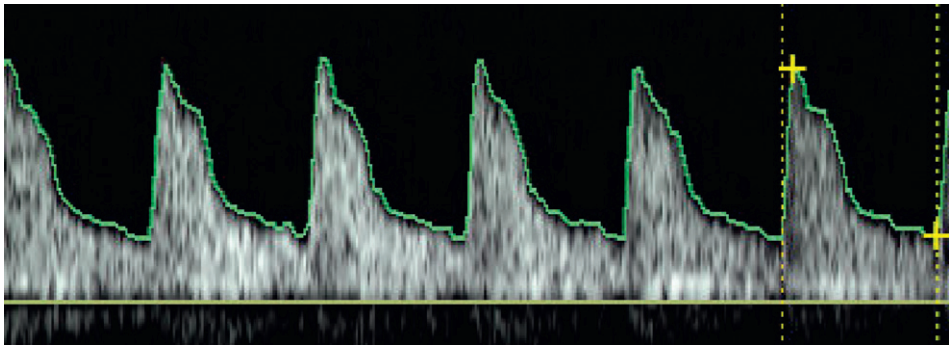
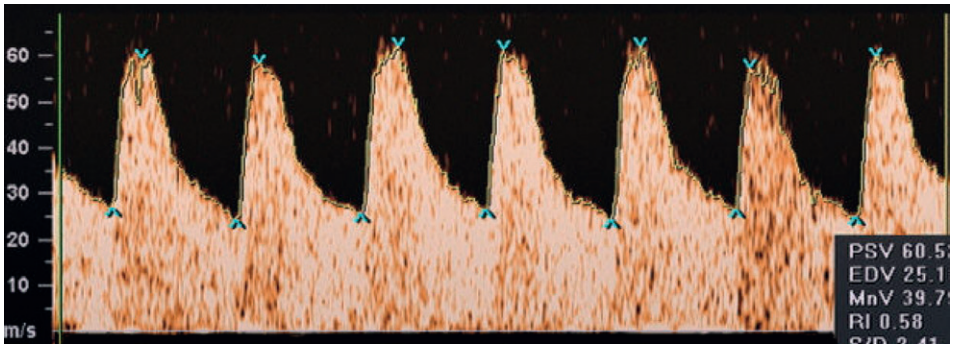
surveillance and possible intervention from constitutionally small fetuses.[50,51]

A free umbilical cord loop is examined with continuous or pulsed Doppler ultrasound far from the fetal and placental insertions. Most current ultrasound equipment allows concurrent use of color and pulsed Doppler with improved reproducibility of measurements. Vascular damage affecting approximately 30% of the placenta produces elevations in the Doppler index. More marked abnormalities result in umbilical artery AEDV or REDV. **Milder forms of placental vascular dysfunction, especially near term, may not produce elevation of umbilical artery blood flow resistance sufficiently to be detectable by traditional Doppler methods.**[52] If placental gas exchange is sufficiently impaired to result in perceived fetal hypoxemia, a decrease in middle cerebral artery Doppler resistance may occur (Figure 31-8). Another Doppler index frequently used clinically to detect this condition is the ratio between umbilical artery pulsatility as index of vasoconstriction in the placenta and middle cerebral artery pulsatility as index of vasodilation in the fetal brain. In milder forms of placental disease with near minimal increase in umbilical artery blood flow resistance, the cerebroplacental Doppler ratio (CPR) may decrease. Grammellini and coworkers demonstrated that a value below 1.08 identified small fetuses at risk for adverse outcome. **Subsequently Bahado-Singh and coworkers indicated that this predictive accuracy of the CPR decreased after 34 weeks' gestation.**[53]



A



B

FIGURE 31-8. Middle cerebral artery flow velocity waveform. The normal middle cerebral artery flow pattern has relatively little diastolic flow **(A).** With progressive placental dysfunction there may be an increase in the diastolic velocity resulting in a decrease in the Doppler index (brain sparing). **B,** With brain sparing, the systolic downslope of the waveform becomes smoother so that the waveform almost resembles that of the umbilical artery. The associated rise in the mean velocity results in a marked decline in the Doppler index.

This is presumably attributable to an increasing number of growth-restricted fetuses that may have normal umbilical artery blood flow resistance near term, but demonstrate isolated "brain sparing" as the only sign of placental insufficiency of oxygen transfer. These fetuses are at risk for adverse outcome.

Because of the variable presentation across gestation, comprehensive Doppler assessment of placental function should include umbilical and middle cerebral arteries. For the umbilical artery an abnormal test result is defined as a Doppler index measurement of greater than 2 SDs deviations above the gestational age mean and/or a loss of end-diastolic velocity. Like growth curves, it is best to use nomograms developed from a local or comparable population. For the CPR and also for the middle cerebral artery a greater than 2 SD decrease of the index is considered abnormal. In a setting of small fetal size, these findings identify those fetuses at greatest risk for adverse outcome (Figures 31-9 to 31-12).

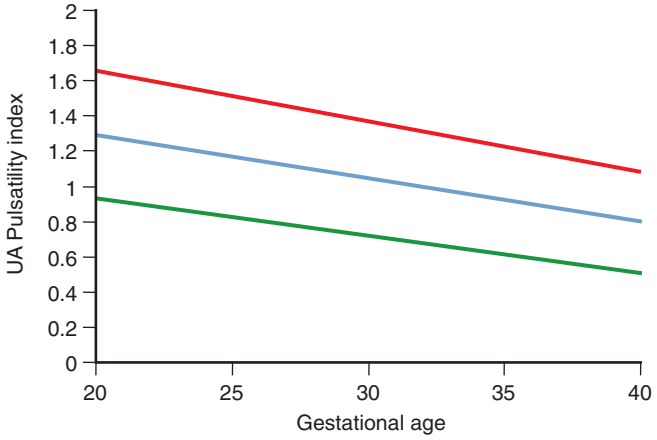


FIGURE 31-9. Umbilical artery pulsatility index with advancing gestational age. Displayed are the reference ranges (mean and 95% confidence interval) of the umbilical artery (UA) pulsatility index.

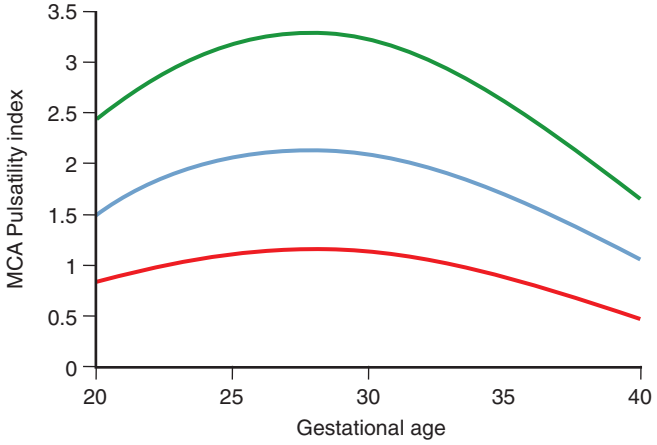

FIGURE 31-10. Middle cerebral artery pulsatility index with advancing gestational age. The graph shows the mean and 95% confidence interval of the middle cerebral artery (MCA) pulsatility index.

Invasive Testing

Several invasive tests for the evaluation of the fetus with suspected growth restriction have been described. From a clinical standpoint, only a few studies are of critical importance. These include maternal TORCH serology and invasive fetal testing to obtain amniotic fluid and/or fetal blood for karyotyping to rule out a chromosomal abnormality such as trisomy 13, 18, or 21 (Table 31-4). Trisomy 18 may present with the unusual combination of growth restriction

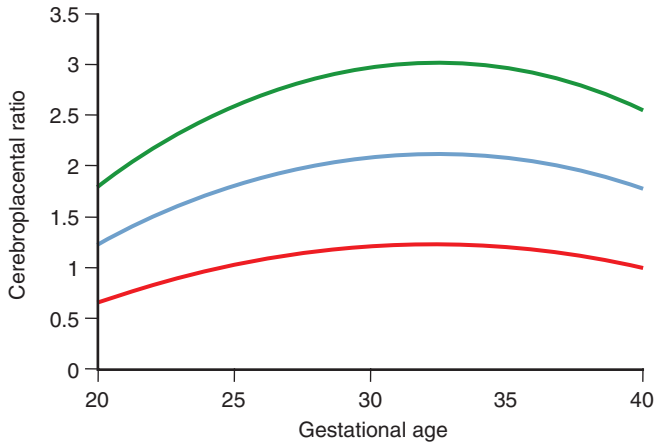

FIGURE 31-11. Cerebroplacental Doppler ratio with advancing gestational age. This graph displays the gestational reference range (mean and 95% confidence interval) of the cerebroplacental ratio based on paired measurements of the middle cerebral and umbilical artery pulsatility index.

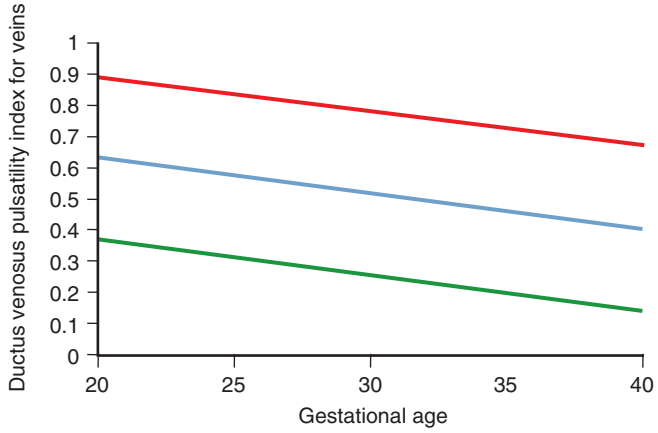

FIGURE 31-12. Ductus venosus pulsatility index for veins with advancing gestational age. This graph displays the gestational reference range (mean and 95% confidence interval) of the ductus venosus pulsatility index for veins calculated from cross-sectional data in 232 normal singleton fetuses.

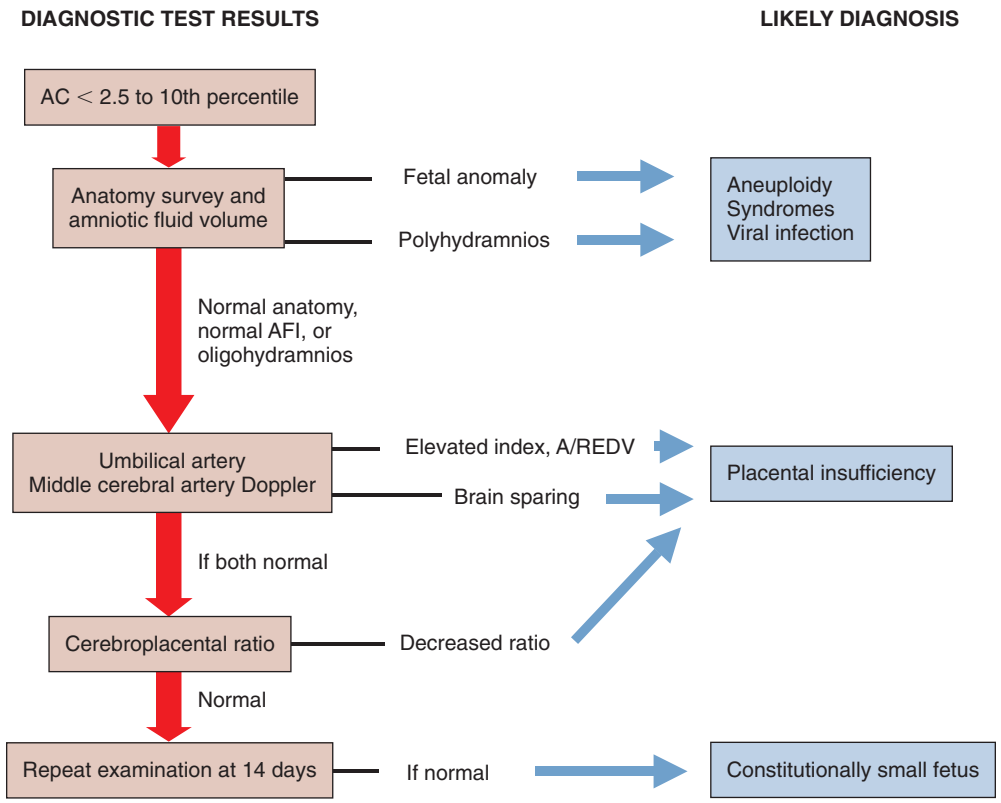

FIGURE 31-13. An integrated diagnostic approach to the fetus with suspected fetal growth restriction. This figure displays a decision tree following the evaluation of fetal anatomy, amniotic fluid volume, and umbilical and middle cerebral artery Doppler. The most likely clinical diagnosis based on the test results is presented on the right-hand side. A high index of suspicion for aneuploidy, viral, and nonaneuploid syndromes needs to be maintained at all times.

and polyhydramnios. If the diagnosis of a lethal anomaly can be made with certainty, cesarean delivery for fetal distress is unnecessary and may be prevented. Viral polymerase chain reaction (PCR) studies can be performed if there is a clinical suspicion based on the ultrasound examination or in the maternal history.

Evaluation of fetal erythropoietin and amino acid concentrations are also markers for fetal compromise with prognostic impact. Erythropoietin production in the fetus, as in the adult, is stimulated by the presence of anemia or hypoxia, and may be associated with increased red blood cell production depending on erythropoietic reserve. Elevated blood or amniotic fluid erythropoietin levels may be of help in identifying growth-restricted fetuses at risk for long-term morbidity. Ruth and colleagues identified an association between cord blood erythropoietin levels and developmental outcome including cerebral palsy and death at 2 years in offspring with evidence of acute asphyxia at birth. None of these patients had preeclampsia. Neonates from pregnancies complicated by preeclampsia had elevated cord erythropoietin levels regardless of outcome.

An increase in the cord blood glycine/valine ratio is a specific response to intrauterine starvation resulting from reduction in phosphoenolpyruvate carboxykinase activity, a rate-limiting enzyme for gluconeogenesis. Elevations of the glycine/valine ratio are observed in fetal life and have been shown to be inversely proportional to fetal arterial oxygen content. However, in contrast to the neonate where such an increased ratio is predictive of specific neonatal risks including hypoglycemia and death, such a relationship has not been demonstrated for elevations demonstrated in fetal life. Although fetal erythropoietin and amino acid levels are of academic interest, they currently add little to the contemporary clinical management of the IUGR fetus.

In summary, ultrasound examination is the primary diagnostic tool for the evaluation of fetal growth. In the presence of risk factors and clinical conditions that are associated with IUGR, a comprehensive gray-scale ultrasound examination of fetal anatomy, biometry, and amniotic fluid characteristics is required. In the absence of routine clinical indications, ultrasound screening of these high-risk pregnancies should be performed at 16 to 18 weeks for dating (if not otherwise established) and again at 32 to 34 weeks. If small fetal size is documented, Doppler ultrasound of the umbilical and middle cerebral arteries and invasive tests are of critical importance to identify fetuses most likely to benefit from antenatal surveillance and perinatal interventions. A diagnostic algorithm that utilizes this combination of test parameters is depicted in Figure 31-13.

SCREENING AND PREVENTION OF FETAL GROWTH RESTRICTION

Fetal growth restriction as a disease entity fulfills several criteria potentially justifying a screening program. It is a common clinical problem with an identifiable pre-disease

state that leaves enough time for potential interventions. While treatment options in utero are limited (see below), interventions that improve outcome exist. The various screening methods that have been proposed include identification of risk factors, as well as serum and ultrasound tests.

Maternal History

A history of poor pregnancy outcome is clearly correlated with the subsequent delivery of a growth-restricted infant. Galbraith and colleagues and Tejan have shown that prior birth of a growth-restricted infant is the obstetric factor most often associated with the subsequent birth of another growth-restricted infant. These study populations did include women with underlying medical problems. Tejani and Mann in a retrospective study of 83 multigravidas who had delivered growth restricted infants noted that the perinatal wastage from their 200 prior pregnancies was 41%. This striking figure, which includes spontaneous abortions as well as neonatal and intrauterine deaths, points to the significance of poor obstetric history as a risk factor for IUGR. The history of delivery of a growth-restricted infant in the first pregnancy is associated with a 25% risk of delivering a second infant below the 10th percentile. After two pregnancies complicated by IUGR, there is a fourfold increase in the risk of a subsequent growth-restricted infant. When all indices of risk have been applied, the one third of patients considered at highest risk for delivering a growth restricted infant actually deliver over 60% of infants identified as growth restricted. The two thirds of women not considered at risk for delivering a growth-restricted infant contribute to one third of deliveries with a birthweight below the 10th percentile. The majority of these babies are considered constitutionally small.

Maternal Serum Analytes

At least four hormone/protein markers measured in the maternal sera during the early second trimester are associated with subsequent IUGR. These include serum estriol, human placental lactogen, human chorionic gonadotrophin, and α-fetoprotein (AFP). Elevated maternal serum α- fetoprotein (MSAFP) or human chorionic gonadotropin (hCG) levels in the second trimester are considered as markers of abnormal placentation and have been associated with an increased risk for IUGR.[54] Most studies conclude that a single, unexplained elevated value of 2 to 2.5 multiples of the median raises the risk of growth restriction 5- to 10-fold.

A range of first trimester serum analytes that are associated with early abnormalities in placenta angiogenesis and development have been identified in the past years. These show significant differences in their distribution among pregnancies at risk of developing early-onset preeclampsia or fetal growth restriction prior to 34 weeks' gestation. Of these markers a decrease in the pregnancy-associated protein A (PAPP-A) or the placental growth factor (PLGF) have shown the most consistent predictive performance. The advantage of PAPP-A is the current commercial availability as part of the integrated first trimester screen for aneuploidy. In this setting a decrease in the PAPP-A below 0.8 multiples of the median (MOM) is associated with an increased risk for subsequent placental dysfunction.

Clinical Examination

From the early second trimester on, each antenatal visit includes the measurement of the distance between the maternal uterine fundus and the symphysis pubis. After 20 weeks' gestation, the normal symphyseal-fundal height in centimeters approximates the weeks gestation after allowances for maternal height and fetal station. Belizan and colleagues observed that after 20 weeks' gestation a lag of the symphyseal-fundal height of 4 cm or more suggests growth restriction. The reported sensitivities of symphyseal-fundal height screening for IUGR range from 27% to 85%, and the positive predictive values range from 18% to 50%.[55] Although the measurement of the symphyseal-fundal height is a poor screening tool for the detection of IUGR, the accuracy of subsequent ultrasound prediction of IUGR is enhanced if there is a clinical suspicion of IUGR based on a lagging fundal height.

Maternal Doppler Velocimetry

Abnormal uterine artery flow velocity waveforms are a manifestation of delayed trophoblast invasion that are highly associated with gestational hypertensive disorders, IUGR, and fetal demise.[56] Therefore, Doppler velocimetry of the uterine arteries has been examined for its usefulness in predicting pregnancies destined to produce a growth-restricted fetus. Schulman and colleagues found that in women with hypertensive disorders the presence of an elevated uterine artery systolic/diastolic (S/D) ratio (>2.6) and/or diastolic notching increased the risk for IUGR and stillbirth (see Figure 31-17). They noted that the changes in uterine artery flow patterns precede those observed in the umbilical artery and antedate fetal growth restriction. Subsequent studies used various cut-offs to define an abnormal test result. These include S/D ratios above 2.18 at 18 weeks, resistance index (RI) above 0.58 at 18-24 weeks, pulsatility index (PI) above the 95th percentile (1.45) at 22-24 weeks, or the presence of notches. The screen positive rate ranges between 5% and 13% according to the gestational age and the criterion used to define an abnormal test result. In low-risk patients, a uterine artery Doppler resistance profile that is high, persistently notched, or both, identifies women at high risk for preeclampsia and IUGR, with sensitivities and positive predictive values as high as 72% and 35% when performed between 22 and 23 weeks' gestation. Uterine artery Doppler is better at predicting severe rather than mild disease. The likelihood ratio of abnormal uterine artery impedance for the development of IUGR was 3.7 with higher sensitivity for severe early-onset forms. Meta-analysis of the utility of uterine artery Doppler in the prediction of intrauterine death yields a likelihood ratio of 2.4 for patients with an abnormal result. Combining uterine artery Doppler velocimetry with other tests can improve screening sensitivities. Valensise and Romanini have demonstrated that the combination of abnormal second-trimester maternal uterine artery Doppler velocimetry and maternal glucose tolerance testing demonstrating a "flat" response results in a positive predictive value of 94% and a sensitivity of 54% for the detection of fetal growth restriction. The presence of a normal uterine artery flow velocity waveform bears a high negative predictive value, with a

likelihood ratio of 0.5 and 0.8 for the development of preeclampsia and IUGR respectively.

First Trimester Integrated Screening

There are several markers that reflect early failure of normal placental development in the first trimester. One marker is abnormal maternal cardiovascular adaptation to pregnancy, resulting in a delay in the physiologic drop of mean arterial blood pressure. Deficient trophoblast invasion is associated with a slower than anticipated drop in uterine artery blood flow resistance. Placental expression of analytes relating to normal development is altered. When these markers are considered in isolation, their prediction of subsequent placental dysfunction is inaccurate. Therefore, an integrated screening algorithm using multiple independent risk factors, including a prior history of preeclampsia, maternal first trimester body mass index and blood pressure, uterine artery pulsatility index, and the PAPP-A MOM, has been developed. This combined model is capable of predicting early onset preeclampsia or fetal growth restriction with 80% to 90% sensitivity and a 5% to 10% false-positive rate. While the predictive accuracy of these algorithms needs to be confirmed in a variety of population settings, they offer the important advantage of early stratification of risk with potential for intervention.

Preventive Strategies

Efforts to prevent fetal growth restriction have been disappointing. Low-dose aspirin has been extensively evaluated as a possible preventive agent for improving placental vascular development by virtue of its inhibitory action on platelet aggregation. However, while the use of aspirin in the second trimester has been found to be safe, initiation of therapy in the second trimester improves neither placental function nor long-term outcome. Because subsets of patients with poor obstetric history appear to derive a benefit from aspirin, the utility of first trimester uterine artery screening with subsequent aspirin therapy has been investigated. The choice of target population profoundly affects the utility of this approach. While low-risk patients derive little benefit, high-risk patients (those with thrombophilia, hypertension, and/or a past history of either preeclampsia or IUGR) given low-dose aspirin because of bilateral uterine artery notching at 12 to 14 weeks experience an 80% reduction of placental disease compared to placebo-matched controls. A recent large meta-analysis found that only women who were initiated on aspirin before 16 weeks' gestation derive a 50% to 60% reduction in the relative risk for development of preeclampsia or fetal growth restriction.[57] Preliminary evidence also suggests that first trimester aspirin reduces the prevalence of preeclampsia in patients predicted to be at high risk through an integrated first trimester screen.

Presently it appears prudent to regard poor obstetric history, unexplained elevations in second trimester MSAFP, "flat" oral glucose tolerance, and abnormal second trimester uterine artery Doppler velocimetry as important risk factors for IUGR that warrant further investigation when the clinical suspicion of IUGR arises and/or maternal preeclampsia develops. Such patients should undergo ultrasound estimation of fetal size and a full diagnostic workup if these factors are confirmed.

MANAGEMENT IN CLINICAL PRACTICE

Before developing a management plan, it is important that the major underlying etiologies have been addressed by a comprehensive diagnostic workup as described above**. It is worth stressing that the majority of fetuses thought to be growth restricted are constitutionally small and require no intervention. Approximately 15% exhibit symmetrical growth restriction attributable to an early fetal insult for which there is no effective therapy. Here, an accurate diagnosis is essential. Finally, approximately 15% of small fetuses have growth restriction due to placental disease or reduced uteroplacental blood flow.** Once the diagnosis of placental insufficiency has been made, appropriate therapeutic options may be explored. However, ongoing assessment of fetal growth and parameters of fetal well-being is a more critical component of clinical management in defining the intervention thresholds when the balance of fetal versus neonatal risks favors delivery.

Therapeutic Options

Elimination of contributors such as stress, smoking, and alcohol and drug use is advocated. Tobacco smoke contains a number of substances that are vasoactive and can cause vasoconstriction. Anecdotally, the authors have observed IUGR cases with absent end-diastolic flow in the umbilical artery in which diastolic flow returned upon cessation of maternal smoking. Nonspecific therapies include bed rest in the left lateral decubitus position to increase placental blood flow. Although an inadequate diet has not been clearly established as a cause of growth restriction in this country, dietary supplementation may be helpful in those with poor weight gain or low prepregnancy weight. In patients with chronic malnutrition, improved fetal growth has been reported with total parenteral nutrition. Consideration should be given to hospitalized bed rest, which has the advantages of positive enforcement of rest and facilitation of daily fetal testing. The decision for inpatient versus outpatient management is based on the severity of the maternal and/or fetal condition and the local standard of care.

Maternal hyperoxygenation has been examined in several studies for potential benefits in the treatment of the compromised growth-restricted fetus. Studies by several groups confirm that maternal hyperoxygenation can raise the fetal cord blood pO_2.[58] Techniques used included administration of 55% oxygen by face mask or 2.5 L/min by nasal prong. Prolongation of pregnancy from the first recognition of the fetal condition ranged from 9 days to 5 weeks. However, fetal growth velocity was not improved. In addition, fetuses subjected to oxygen therapy had more hypoglycemia, thrombocytopenia, and disseminated intravascular coagulation compared to controls. The primary role of maternal hyperoxygenation lies in the safe short-term prolongation of pregnancy to allow the administration of corticosteroids to reduce the risk of neonatal respiratory distress syndrome (RDS) and intraventricular hemorrhage (IVH) in anticipation of a preterm delivery.

Maternal hyperalimentation as a means of intrauterine feeding of the growth-restricted fetus is an attractive therapeutic concept. Increasing the maternal concentration of amino acids leads to an increased umbilical uptake of some

amino acids to the fetus while there is no change in the three essential amino acids: lysine, histidine, and threonine. These data further support that total parenteral nutrition can reverse abnormal fetal growth secondary to maternal nutritional deprivation. However, it does not overcome abnormal placental function. Outcomes are neither improved in animal models nor in human pregnancies. Therefore, maternal hyperalimentation only plays a role in patients where malnutrition has been established as the underlying cause of growth delay.

Maternal volume expansion as a therapeutic concept is based on the observation that poor maternal blood volume status is associated with adverse pregnancy outcome. Karsdorp and coworkers studied the effects of volume expansion on feto- and uteroplacental blood flow and neonatal outcome.[59] In a small group of centrally monitored women with abnormal placental Doppler studies, they noted that volume expansion was associated with reappearance of umbilical artery end-diastolic velocities and a significant improvement of neonatal survival. With further randomized studies pending, these data suggest that inpatient correction of maternal volume status is important in improving placental perfusion.

Low-dose aspirin in combination with dipyridamole administered from 16 weeks' gestation was first reported in 1987 by Wallenburg and Rotmans to significantly reduce the incidence of fetal growth restriction in women with a history of recurrent IUGR. Women receiving therapy had a rate of fetal growth restriction of 13%, compared with 61% in an untreated control group. No treated woman had a child with severe growth restriction (birth weight <2.3 percentile) compared with 27% in the untreated group. **In 1997, a meta-analysis of the efficacy of low-dose aspirin (50-100 mg/day) demonstrated a significant reduction in the frequency of IUGR when low-dose aspirin is used. There is a dose-dependent relationship in that higher doses (100-150 mg/day) were significantly more effective in preventing IUGR than were lower doses (50-80 mg/day).**

Two recent randomized trials illustrate important considerations regarding the use of aspirin to prevent preeclampsia and/or IUGR. In a study of patients that were randomized at 24 weeks' gestation based on the uterine artery flow velocity waveform, low-dose aspirin was not associated with any improvement in placental function or perinatal outcome. Conversely, in patients with a poor obstetric history (thrombophilia, hypertension, past history of either preeclampsia or IUGR) randomized at 12 to 14 weeks based on the uterine artery flow velocity waveforms, those receiving aspirin experienced an 80% reduction in placental disease compared to placebo matched controls. Therefore, it appears that aspirin works best in patients with significant risk factors for IUGR and that the therapeutic optimal window to commence aspirin therapy lies between 12 and 16 weeks' gestation when branching angiogenesis of the placenta is ongoing.

Although the overall safety of aspirin has been documented in a large patient population, concerns about a possible association with abdominal wall defects have been raised with administration in the early first trimester. Therefore, we suggest deferral of indicated therapy until completion of organogenesis at 12 weeks' gestation. Selected patients presenting in the second trimester may still derive benefit from aspirin, and patients should be counseled on an individualized basis. Aspirin prophylaxis can be discontinued at any point after 34 weeks' gestation because bleeding risks at delivery and during regional anesthesia outweigh the benefits of prolonging gestation.

Corticosteroids are a universally available antenatal therapeutic option that positively affects outcome by enhancing lung maturation and preventing IVH. The impact of prenatal glucocorticoid administration on neonatal complication rate in the growth-restricted newborn has recently been examined by Bernstein and coworkers in a study of 19,759 newborns between 500 and 1500 g. After controlling for a different set of confounding variables, this study demonstrated a significant reduction in neonatal RDS, IVH, and death when prenatal glucocorticoids were administered. These benefits were not qualitatively different from those observed in appropriately sized newborns. Other studies have also refuted that the "stress" of the intrauterine condition enhances maturation and protects against prematurity. In contrast, a smaller study by Elimian and colleagues demonstrated no benefits to neonatal outcome when perinatal glucocorticoids were used. While these studies indicate the need for randomized comparison of management, they also clearly show no benefit from the omission of antenatal corticosteroids. We recommend administration of a complete 48-hour course of antenatal steroids to any growth-restricted fetus when delivery is anticipated before 34 weeks' gestation, if this can be safely accomplished.

When corticosteroids are administered, it is important to account for their effect on fetal testing parameters when interpreting antenatal surveillance results. Betamethasone, for example, temporarily reduces FHR variation on day 2 and 3 after the first injection, together with a 50% decrease in fetal body movements and an almost cessation of fetal breathing movements. Subsequently the number of fetuses with an abnormal biophysical profile score increases significantly by 48 hours after steroid administration, with a return to the preadministration state at 72 hours.[60] In contrast, maternal and fetal Doppler findings are not affected to the same degree during this period. A transient decrease in the middle cerebral artery blood flow resistance has been reported 48 hours after betamethasone administration.

ASSESSMENT OF FETAL WELL-BEING (SEE CHAPTER 12)

Once the diagnosis of fetal growth restriction has been made and the differential diagnostic options have been explored, fetal assessment is instituted. Serial ultrasound evaluations of fetal growth are continued every 3 to 4 weeks and should include determinations of the BPD, HC/AC ratio, fetal weight, and AFV. The institution of antenatal surveillance is a critical component in the management of the growth-restricted fetus. Relationships between fetal testing parameters and subsequent outcome determine the balance between fetal and neonatal risks and therefore define intervention thresholds. Growth-restricted fetuses are at risk for worsening placental function, subsequent deterioration of acid–base status,

decompensation, stillbirth, and adverse health effects all the way into adult life. Although prevention of long-term morbidity is an attractive goal, there is insufficient information on its relationships with prenatal variables to direct management. Of the many short-term outcomes that have been related to fetal status, only a few are presently of clinical relevance. Fetal acidemia and major neonatal complications have a significant impact on subsequent neurodevelopment while the combination of fetal and neonatal deaths determines the overall perinatal mortality.[61] The likelihood of fetal acidemia and stillbirth is therefore the strongest fetal criterion for intervention. In contrast, gestational age–specific expectations for neonatal complications and survival force conservative management. While neonatal complications are typically multifactorial and not accurately predicted prenatally, anticipation of fetal risks remains as the primary goal. Therefore, antenatal surveillance tests need to predict fetal acid–base status, rate of anticipated progression, and the resulting risk for deterioration and stillbirth. The monitoring tools that are available to achieve this include the traditional nonstress test (NST), contraction stress test, (CST), BPS profile scoring (BPS), and Doppler sonography.

Maternal Monitoring of Fetal Activity

Maternal monitoring of fetal activity has been used extensively in Great Britain, Scandinavia, and Israel for the assessment of pregnancies complicated by IUGR. In a study of 50 cases, Matthews clearly showed the predictive value of fetal activity charting for growth-restricted fetuses subsequently demonstrating distress in labor.[62] A simple technique for monitoring fetal movement is the minimum requirement of 10 movements in a 2-hour period. If this criterion is not met, additional testing is warranted. In an outpatient setting maternal kick counts or fetal activity counts (FACs) supplement medically administered antenatal surveillance. In the compliant patients with an appropriate level of awareness of fetal movements, it may also be helpful in modifying monitoring intervals as fetal deterioration occurs.

Fetal Heart Rate Analysis

The traditional NST is a visually analyzed record of the FHR baseline, variability, and episodic changes. Normal FHR characteristics are determined by gestational age, maturational and functional status of central regulatory centers, and oxygen tension. A "reactive" NST exhibits two 15-beat accelerations above the baseline maintained for 15 seconds in a 30-minute monitoring period. When the NST is analyzed as part of the five component biophysical profile score, reactivity criteria that account for gestational age are applied (see below). **Irrespective of the context, a "reactive" NST indicates absence of fetal acidemia at the moment of the FHR recording. Many growth-restricted fetuses with a normal heart rate tracing can have low-normal pO_2 values, but acidemia is virtually excluded by a reactive NST. Heart rate reactivity also correlates highly with a fetus that is not in immediate danger of intrauterine demise. Nonreactive NST results, on the other hand, are often falsely positive and require further evaluation. The development of repetitive decelerations may reflect fetal hypoxemia or cord compression due to the development of oligohydramnios and has been associated with a high perinatal mortality rate.**[63]

The CST is an additional option for testing placental respiratory reserve.[64] Positive CST results have been reported in 30% of pregnancies complicated by proven growth restriction. **In a study by Lin and colleagues,[65] 30% of growth-restricted infants had nonreactive NST results and 40% had positive CST results. Ninety-two percent of IUGR infants with a nonreactive positive pattern exhibited perinatal morbidity. However, a 25% to 50% false-positive rate has been associated with the CST by some investigators. A possible role for the CST may be evaluation of placental reserve prior to induction in IUGR fetuses in whom vaginal delivery is attempted.**

Marked intraobserver and interobserver variability of visual FHR analysis has been identified as a potential factor affecting the prediction of fetal status. Currently, traditional FHR parameters as well as short-term and long-term variation of the heart rate in milliseconds, length of episodes with low and high variation, and the rate of signal loss can be assessed by computerized analysis. The objective assessment of these variables circumvents the issue of observer variability and a direct correlation between FHR variation and pO_2 in the umbilical vein as assessed at cordocentesis prior to the onset of labor has been documented. **A computerized documentation of a mean minute variation below 3.5 milliseconds has been reported to predict an umbilical artery cord pH < 7.20 with over 90% sensitivity. In addition, FHR variation usually decreases gradually in the weeks preceding the appearance of late decelerations and fetal hypoxemia, and therefore is the most useful computerized FHR parameter for longitudinal assessment in IUGR.** As with the traditional NST, gestational age, time of day, and the presence of fetal rest-activity cycles also need to be taken into account in the interpretation of computerized results. There are wide normal ranges for FHR patterns and its variation, but the individual fetus shows a certain intrafetal consistency throughout gestation. For monitoring of trends each fetus should therefore serve as its own control, using recordings of standardized duration and appropriate reference ranges.

In summary, a visually reactive FHR provides assurance of fetal well-being at the time of analysis. While the traditional NST is most sensitive in the prediction of fetal normoxemia, computerized analysis appears superior in the prediction of hypoxemia and/or acidemia. Once traditional reactivity is lost, computerized analysis of heart rate variation is a potential tool available for ongoing longitudinal analysis. Computerized FHR analysis is more widely used in Europe and an ongoing randomized trial evaluates its utility in delivery timing of growth-restricted fetuses. FHR analysis itself does not assess the severity of disease and most importantly does not anticipate the rate of deterioration. To address these issues additional fetal tests are available.

Amniotic Fluid Volume

In the context of fetal surveillance, assessment of AFV provides an indirect measure of vascular status. A relationship between oligohydramnios and progressive deterioration of

arterial and venous Doppler studies has been documented in growth-restricted fetuses and prolonged pregnancies. Therefore, declining AFV is suggestive of ineffective downstream delivery of cardiac output, allowing some form of longitudinal monitoring even in the absence of Doppler studies. If the NST is reactive, a concurrent assessment of the AFV constitutes the "modified biophysical profile" and provides assurance of fetal well-being if both parameters are normal. Interventions based on twice weekly modified BPS result in similar perinatal outcomes as with weekly contraction stress testing and therefore have largely replaced the latter. When the fetal heart rate is nonreactive, relying on a normal AFV assessment alone is inadequate and a full biophysical profile that incorporates multiple parameters of fetal well-being should be performed because of its superior performance in identifying jeopardized fetuses.

Biophysical Parameters

The five-component fetal BPS was developed by Manning and colleagues and has been widely used in the surveillance of growth-restricted fetuses. A graded system is applied to categorize fetal tone, movement, breathing movement, heart rate reactivity, and a maximum amniotic fluid pocket as normal (2 points) or abnormal (0 points). If used in the context of the BPS, fetal heart rate reactivity criteria that account for gestational age are used. Reactivity has been defined as follows: prior to 32 weeks' gestation—greater than 10 beats/minute accelerations sustained for more than 10 seconds; between 32 to 36 weeks' gestation—greater than 15 beats/minute accelerations sustained for more than 15 seconds; and after 36 weeks' gestation—greater than 20 beats/minute accelerations sustained for more than 20 seconds. In anatomically normal fetuses, the presence of the dynamic variables is related to physiologic variations in maturation, behavioral state, as well as acid–base status. Vintzileos and coworkers have demonstrated that four components of the biophysical score are affected at different levels of hypoxemia and acidemia. The earliest manifestations of abnormal fetal biophysical activity consist of the loss of heat rate reactivity along with the absence of fetal breathing. This is followed by decreased fetal tone and movement in association with more advanced acidemia, hypoxemia, and hypercapnia. Because of amniotic fluid's relationship with vascular status, amniotic fluid assessment provides the only marker of chronic hypoxemia and is the only longitudinal monitoring component of the biophysical profile score.

Growth-restricted fetuses preserve acute central responses to acid–base status despite their maturational delay and are at risk for oligohydramnios. **The five-component BPS accounts best for physiologic and individual variations in behavior and therefore remains closely related to arterial pH in IUGR fetuses without anomalies from 20 weeks onward.**[67] **An abnormal score of 4 or less is associated with a mean pH of less than 7.20 and sensitivity in the prediction of acidemia is 100% for a score of 2 or less. A normal score and normal AFV indicate the absence of fetal acidemia at the time of testing. Longitudinal observations in growth-restricted fetuses have shown that the BPS deteriorates late and often rapidly.**[23] While an abnormal BPS is associated with escalating risks for stillbirth and perinatal mortality, a normal score allows no anticipation of fetal deterioration and stillbirth.

In summary, assessment of fetal biophysical variables provides an accurate measure of fetal status at the time of testing. In the patient with a nonreactive NST, a full five-component BPS needs to be performed. As a backup test for a nonreactive fetal heart rate test, the biophysical profile leads to lower rates of intervention when compared with the CST, without jeopardizing perinatal outcome. In the presence of normal AFV, a normal BPS of 8 (minus 2 for a nonreactive NST) or 10 is reassuring of fetal well-being. Nevertheless, in the absence of knowledge about placental vascular status the rate of progression cannot be anticipated and may require even daily testing in severe IUGR. The development of oligohydramnios is concerning and frequently requires modification of management or delivery. The knowledge of fetal Doppler status is complementary to BPS because it improves the anticipation of fetal deterioration and provides an additional means to assess fetal state.[66]

Doppler Ultrasound

Doppler parameters are influenced by several variables, including vascular histology, vascular tone, and fetal blood pressure. Placental respiratory function is related to the integrity of the villous vasculature, and a decrease in arterial pO_2 can trigger autoregulatory adjustments of vascular smooth muscle tone. As diagnostic tools, elevated umbilical artery blood flow resistance and/or middle cerebral artery brain sparing provide evidence of placental dysfunction. The utility of Doppler ultrasound in the assessment of fetal well-being is based on the relationship between Doppler parameters with metabolic status, rate of disease progression, and the risk for stillbirth. In this context distinction between early and late fetal vascular responses to placental insufficiency provides a useful framework within which to estimate these risks.

"Early" responses to placental insufficiency are observed in mild placental vascular disease when umbilical artery end-diastolic velocity is still present. A decrease in the cerebral/placental Doppler ratio provides an early and sensitive marker of redistribution of cardiac output, often preceding overt growth delay by up to 2 weeks. The reduction of fetal growth velocity generally mirrors the elevation in umbilical artery blood flow resistance and is followed by decreasing middle cerebral artery impedance (brain sparing). The nadir of cerebral blood flow resistance is typically reached after a median of 2 weeks and is followed by an increase in aortic blood flow impedance.[68] **Early cardiovascular responses are considered compensatory because they occur at a time when cardiac function is normal and are typically accompanied by preferential perfusion of vital organs and the placenta. While the fetus may be hypoxemic, the risk for acidemia is low.**

"Late" responses to placental insufficiency are observed when accelerating placental disease results in loss or reversal of umbilical artery end-diastolic velocity and when fetal deterioration becomes evident through parallel elevations in placental blood flow resistance and venous Doppler

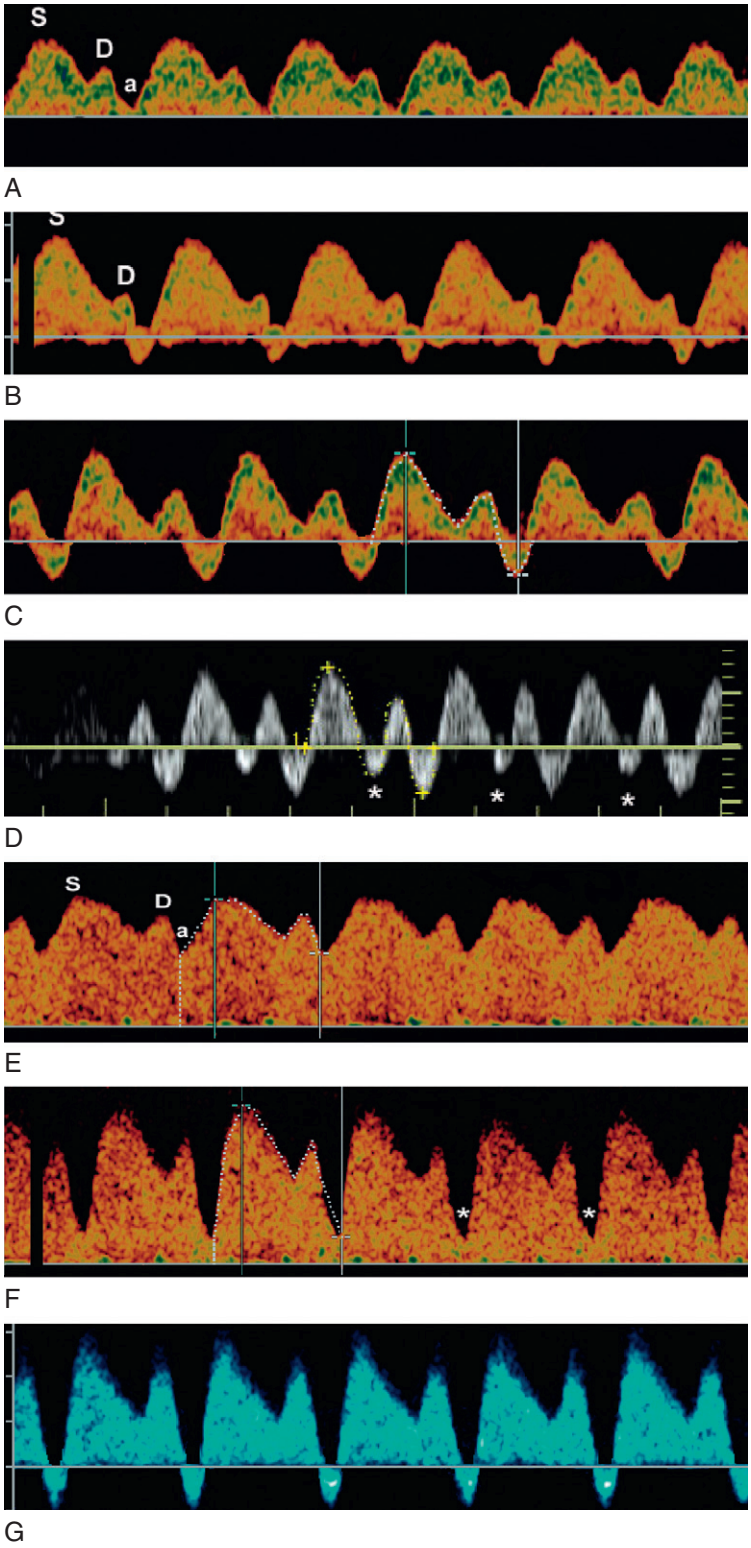

FIGURE 31-14. Normal and abnormal precordial venous flow velocity waveforms. The inferior vena cava and ductus venosus are the most commonly evaluated precordial veins, while the umbilical venous flow velocity waveform is predominantly assessed qualitatively. The inferior vena cava shows the typical triphasic pattern with systolic and diastolic peaks (*S, D,* respectively) **(A).** The a-wave may be reversed under physiologic conditions **(B).** An abnormal inferior vena cava flow velocity waveform shows a relative decrease in forward flow during the first trough, the D-wave, and the a-wave **(C).** Under extreme circumstances there may be reversed flow during the first trough (*) **(D).** In contrast to the inferior vena cava, the ductus venous has antegrade blood flow throughout the cardiac cycle with forward velocities during the S-, D-, and a-waves **(E).** A decrease in atrial systolic forward velocities (*) is the first sign of abnormality and results in an increased Doppler index **(F).** With marked elevation of central venous pressure blood flow may reverse during atrial systole **(G).**

indices. **Although the development of abnormal venous blood flows has been documented in many veins, the precordial veins, including the ductus venosus, the inferior vena cava, and the umbilical vein, are typically utilized in clinical practice (Figures 31-14 and 31-15).**[69] When fetal compromise accelerates there is a further steady rise in umbilical blood flow resistance; venous Doppler indices escalate over a wide range, and the development of oligohydramnios and metabolic acidemia is characteristic of ineffective downstream delivery of cardiac output.[70] In the final stages of compromise, cardiac dilatation with holosystolic tricuspid insufficiency, complete fetal inactivity,

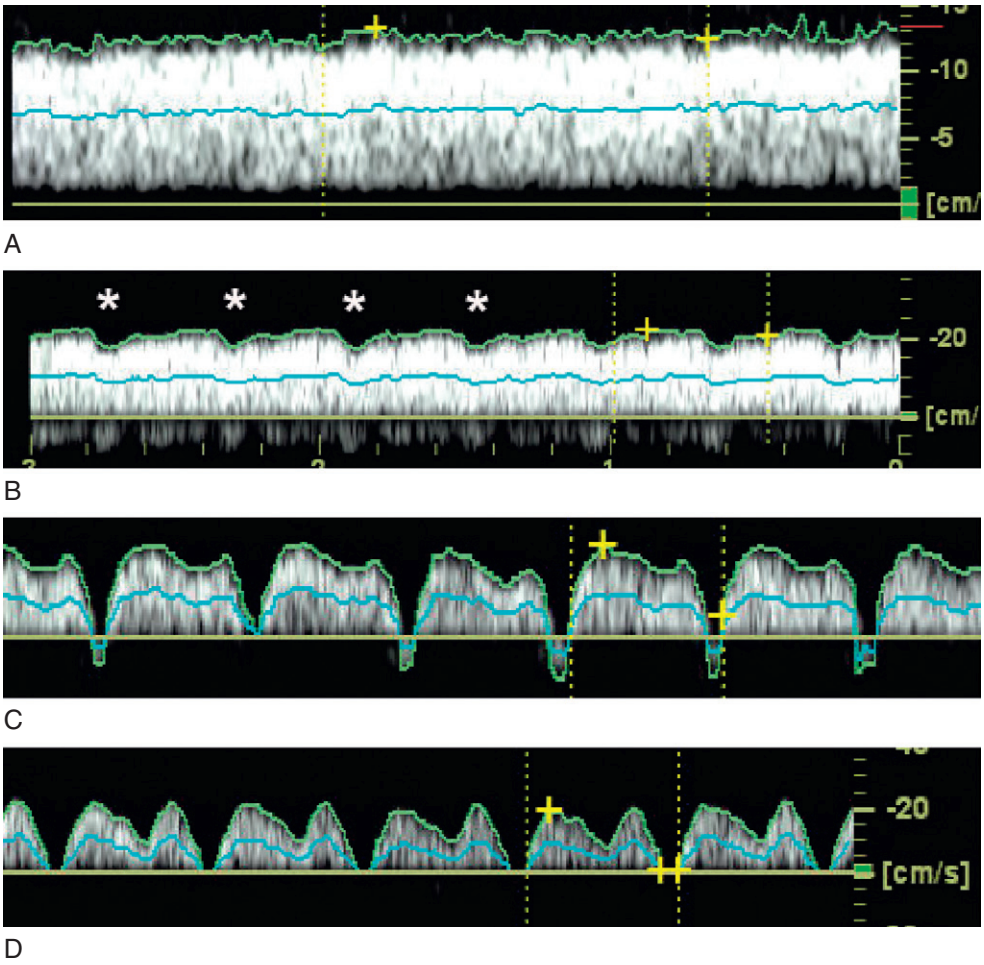

FIGURE 31-15. Normal and abnormal umbilical venous flow velocity. Umbilical venous blood flow is usually constant **(A).** Monophasic umbilical venous pulsations (*) may be observed with moderate elevations of placental blood flow resistance and/or oligohydramnios **(B).** Retrograde propagation of increased central venous pressure first results in biphasic and then triphasic pulsations (**C** and **D,** respectively).

short-term variation below 3.5 msec, and spontaneous "cardiac" late decelerations of the fetal heart rate can be observed as preterminal events (Figure 31-16).[71]

In the past, the major focus of Doppler studies for the assessment of fetal health has been the umbilical circulation. The association between an elevation in Doppler blood flow indices in the umbilical artery, increased disturbance of placental perfusion, and the deterioration of fetal acid–base status that is proportional to the degree of the Doppler abnormality has been demonstrated by several investigators. In the fetal compartment, elevation of the umbilical artery **Doppler index is observed when approximately 30% of the fetal villous vessels are abnormal. Absence or even reversal of umbilical artery end-diastolic velocity can occur when 60% to 70% of the villous vascular tree is damaged.**[72] **Incidences of intrauterine hypoxia ranging from 50% to 80% in fetuses with absent end-diastolic flow have been reported.** The benefit of umbilical artery Doppler in management has been documented in randomized controlled trials and meta-analyses**. In these studies, umbilical artery Doppler, when used in conjunction with standard antepartum testing, was associated with a decrease of up to 38% in perinatal mortality, antenatal admissions, inductions of labor, and cesarean deliveries for fetal distress in labor in women considered at high risk.** However, several studies that have examined the cerebral and especially the venous circulation have provided greater insight into the relationships between Doppler abnormality and outcome. Indik and coworkers reported that development of umbilical venous pulsations in fetuses with absent end-diastolic velocities in the umbilical artery was associated with a fivefold increase in mortality. Arduini and colleagues demonstrated that gestational age at onset, maternal hypertension, and the development of pulsations in the umbilical venous velocities were significantly correlated with the interval of time between diagnosis and delivery for late decelerations of the FHR.[73] Subsequently, several studies have confirmed that fetuses with abnormal arterial velocities who also developed abnormal precordial venous velocities had a higher morbidity and mortality than fetuses without abnormal venous flow.[74] These studies and subsequent analyses confirm that fetal Doppler assessment that is based on the umbilical artery alone is no longer appropriate, particularly in the setting of early onset IUGR prior to 34 weeks. Incorporation of middle cerebral artery and venous Doppler provide the best prediction of

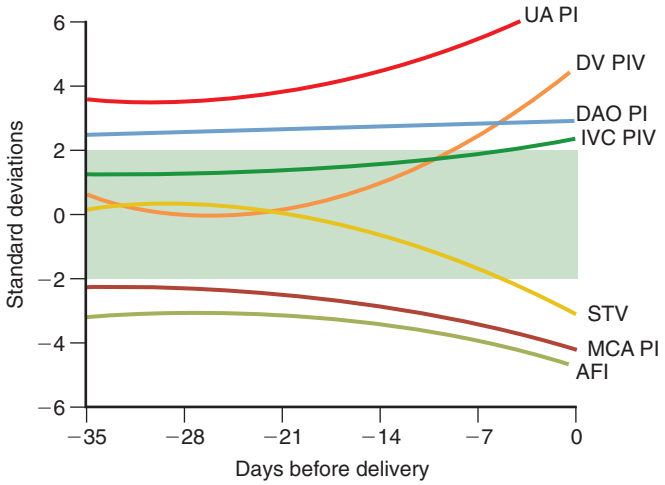

FIGURE 31-16. Longitudinal progression of antenatal testing variables. This figure displays trends in arterial and venous Doppler parameters (*DAO,* Descending aorta; *DV,* ductus venosus; *IVC,* inferior vena cava; *MCA,* middle cerebral artery; *PI,* pulsatility index; *PIV,* PI for veins, *UA,* umbilical artery), amniotic fluid index *(AFI),* and computerized fetal heart rate short-term variation *(STV)* in relation to delivery expressed as standard deviation for growth-restricted fetuses delivered before 32 weeks' gestation. The graph demonstrates that arterial Doppler parameters may be abnormal for more than 5 weeks prior to delivery, whereas venous Doppler parameters and the short-term variation deteriorate in the week prior to delivery for fetal indications. (Reproduced from Hecher K, Bilardo CM, Stigter RH, et al: Monitoring of fetuses with intrauterine growth restriction: a longitudinal study. Ultrasound Obstet Gynecol 18:564, 2001.)

acid–base status, risk of stillbirth, and the anticipated rate of progression.

In growth-restricted fetuses with an elevated Doppler index in the umbilical artery, brain sparing in the presence of normal venous Doppler parameters is typically associated with hypoxemia but a normal pH. Elevation of venous Doppler indices, either alone or in combination with umbilical venous pulsations, increases the risk for fetal acidemia. This association is strengthened by serial elevations of the ductus venosus Doppler index. Dependent on the cut-off (2 SD vs. 3 SD) and the combinations of veins examined, sensitivity for prediction of acidemia ranges from 70% to 90% and specificity from 70% to 80%. **Abnormal venous Doppler parameters are the strongest Doppler predictors of stillbirth. Even among fetuses with severe arterial Doppler abnormalities (e.g., AEDV or REDV), the risk of stillbirth is largely confined to those fetuses that have abnormal venous Dopplers.**[74] The likelihood of stillbirth increases with the degree of venous Doppler abnormality. Venous Doppler findings that are particularly ominous are absence or reversal of the ductus venous a-wave and biphasic/triphasic umbilical venous pulsations. In the setting of a 25% stillbirth rate in a preterm severe IUGR population, these Doppler findings have a 65% predictive sensitivity and 95% specificity.[75]

Although neonatal morbidity is primarily determined by gestational age at delivery and neonatal mortality is the product of several factors, both of these outcomes are also related to fetal Doppler studies. Arterial redistribution and brain sparing are not associated with a significant rise in major neonatal complications. In contrast, a 2 SD elevation of the ductus venosus Doppler index is associated with a 3-fold increase in neonatal complications, and further escalation of ductus venosus Doppler indices leads to an 11-fold increase in this relative risk. The neonatal mortality rate in fetuses with absent or reverse umbilical artery end-diastolic velocity ranges from 5% to 18% when the venous Doppler indices are normal. Elevation of the ductus venosus Doppler index greater than 2 SDs doubles this mortality rate, although predictive sensitivity is only 38% with a specificity of 98%.

In summary, Doppler evaluation of the umbilical, cerebral, and precordial vessels of the growth-restricted fetus provides important diagnostic and prognostic information. Fetal acidemia and the risk of stillbirth are high with progressive elevation of venous Doppler indices. **Advancing Doppler abnormalities indicate acceleration of disease and require increased frequency of fetal monitoring. In growth-restricted fetuses, Doppler evaluation is complementary to all other surveillance modalities.**

Invasive Fetal Testing

Direct determination of fetal acid–base status by cordocentesis was previously frequently performed during invasive karyotyping. Nicolini and colleagues examined 58 growth-restricted fetuses, using cordocentesis for acid–base evaluation in addition to karyotyping. They found significant differences in pH, pCO_2, pO_2, and the base equivalent in fetuses that had no evidence of end-diastolic flow by umbilical artery Doppler velocimetry. However, they observed no relationship between acid–base determination and perinatal outcome. Pardi and colleagues[76] examined umbilical blood acid–base status in 56 growth-restricted fetuses and demonstrated an association between acid–base status and the results of cardiotocographic and umbilical artery Doppler waveform analysis. If both FHR and Doppler studies were normal, neither hypoxemia nor acidemia was noted. When both tests were abnormal, 64% of the growth-restricted fetuses demonstrated abnormal acid–base analysis. The prognostic significance of these abnormalities remains unclear. The lack of benefit, complication rate, accuracy of noninvasive assessment of fetal acid–base status, and finally the availability for rapid karyotyping techniques from amniocytes all mean that cordocentesis is rarely necessary today.

Anticipating the Progression to Fetal Compromise

The anticipation of clinical progression is a critical component in the management of IUGR fetuses because it determines fetal surveillance intervals as well as the timing for intervention. Although deterioration of fetal status is manifested in all surveillance modalities, accelerating disease is best anticipated by AFV status and arterial and venous Doppler parameters (Figure 31-17). **However, the gestational age at onset has important impacts on the clinical presentation and, accordingly, on the diagnosis and management of FGR. In early-onset growth delay (prior to 34 weeks' gestation), the significantly decreased survival rates, as well as the higher mortality following immediate delivery, places special emphasis on safe pregnancy prolongation in these pregnancies.**[77,78] **Late onset FGR (presenting after 34 weeks' gestation) does not typically pose a dilemma for**

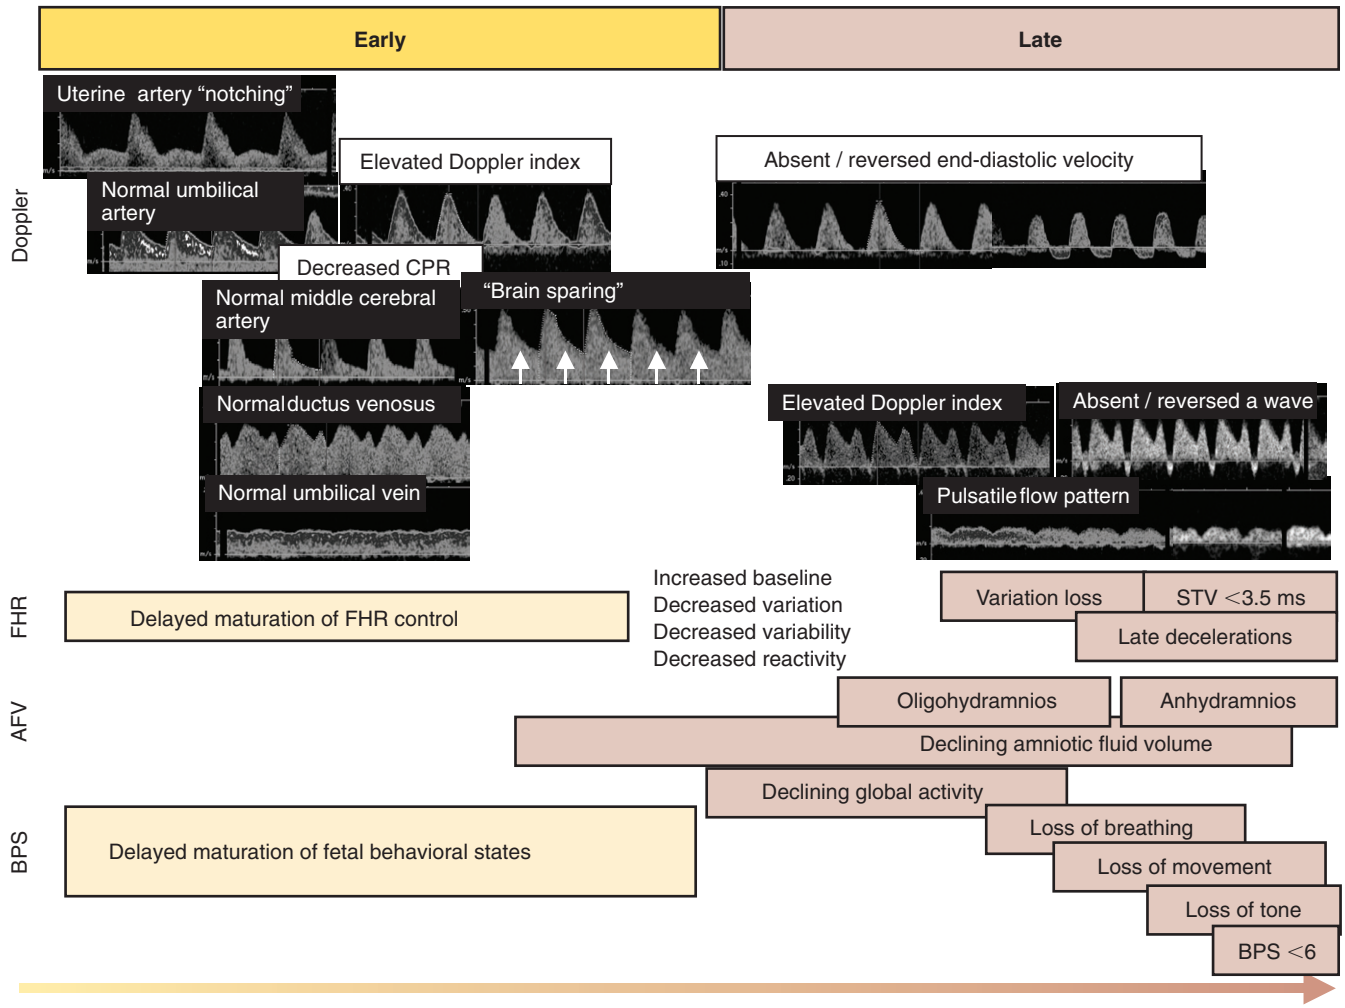

FIGURE 31-17. Progression of compromise in various monitoring systems. This figure summarizes the early and late responses to placental insufficiency. Doppler variables in the placental circulation precede abnormalities in the cerebral circulation. Fetal heart rate *(FHR),* amniotic fluid volume *(AFV),* and biophysical parameters *(BPS)* are still normal at this time and computerized analysis of fetal behavioral patterns is necessary to document a developmental delay. With progression to late responses, venous Doppler abnormality in the fetal circulation is characteristic, often preceding the sequential loss of fetal dynamic variables and frequently accompanying the decline in AFV. The * in the ductus venosus flow velocity waveform marks reversal of blood flow during atrial systole (a-wave). The decline in biophysical variables shows a reproducible relationship with acid–base status. Because the BPS is a composite score of five variables, an abnormal BPS less than 6 often develops late and may be sudden. Absence or reversal of the ductus venous a-wave, decrease of the short-term variation *(STV)* of the computerized fetal heart rate analysis, spontaneous late decelerations, and an abnormal biophysical profile score are the most advanced testing abnormalities. If adaptation mechanisms fail and the fetus remains undelivered, stillbirth ensues.

delivery timing because delivery thresholds can be low given the lower neonatal risks. However, late onset FGR is a significant clinical problem that contributes to over 50% of unanticipated stillbirths at term.[79] Accordingly, a more pressing issue in term pregnancies is the recognition of growth-restricted fetuses, rather than the timing of their delivery. Recognizing these important differences in management focus helps to clarify the nature of decisions that need to be based on the results of the surveillance examination. The prinicipal choices that need to be made at each monitoring visit are whether intervention is needed and the interval to the next visit. The intervention threshold is based on the balance of fetal and neonatal risks, and is high at early gestation given the high neonatal morbidity, but successively decreases as gestation advances. The monitoring interval is often empirically defined but needs to be shortened if there are fetal signs of deterioration that indicate an acceleration of the disease. This in turn requires an appreciation of the typical pattern of progression in early and late onset fetal growth restriction.[14,80]

Umbilical artery Doppler alone provides inaccurate prediction because progression to abnormal FHR parameters is highly variable and may range from 0 to 49 days, as reported in a study by Farine and coworkers. In general, early-onset IUGR presenting prior to 28 weeks is associated with more marked placental vascular problems producing marked Doppler changes. In contrast, IUGR presenting near term is typically associated with milder placental disease and therefore more subtle Doppler findings. Decreasing AFV and behavioral responses are preserved throughout gestation irrespective of Doppler status. Accordingly, longitudinal progression and clinical findings may vary based on gestational age and may be

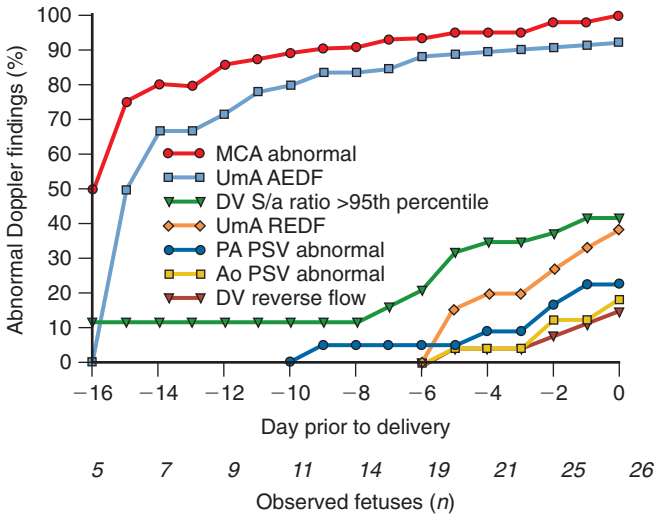

FIGURE 31-18. Early and late Doppler findings in growth-restricted fetuses. This figure displays cumulative onset time curves of Doppler abnormalities for each fetal vessel examined. further modulated by maternal disease.[81] Beyond 34 weeks where the umbilical artery waveform may be normal or near normal, assessment of the middle cerebral artery flow velocity waveform and/or the cerebroplacental Doppler ratio may be necessary to provide an estimate of placental disease and direct the frequency of testing.[53]

In fetuses with elevated placental blood flow resistance, onset of middle cerebral artery brain sparing and/or a decline in the AFI indicate accelerating disease. Once brain sparing is established, the next level of deterioration occurs when umbilical artery end-diastolic velocity is lost and parallel elevations in placental blood flow resistance and precordial venous Doppler indices are observed. Although this may happen after several weeks, the anticipation of such deterioration may require twice weekly rather than weekly testing. When accelerating fetal compromise occurs it is associated with a further rise in umbilical blood flow resistance (leading to REDV) whereas venous Doppler indices escalate over a wide range of distribution (see Figure 31-15). **Studies by Baschat, Ferrazzi, Hecher, and Bilardo indicate that 40% of preterm growth-restricted fetuses that deteriorate in utero have an increased ductus venosus Doppler index the week prior to delivery (Figures 31-16, 31-18, and 31-19).** On the day of delivery, an additional 20% deteriorated further. Elevations of precordial venous Doppler indices also precede sudden deterioration of the BPS by a median of 1 week in fetuses with elevated umbilical artery blood flow resistance. These findings have important impact on testing frequency. For example, in a preterm growth-restricted fetus where venous Doppler indices are elevated, a BPS of 10 does not provide assurance that fetal status will remain stable for the following week. In fact, a sizeable proportion of these fetuses may have a biophysical profile score of less than 6 after a median time of just 1 day.[23] Therefore, three-times weekly or even daily testing may be necessary in such fetuses. This is illustrated in a study by Divon and coworkers, who performed daily biophysical scoring in fetuses with absent umbilical artery end-diastolic velocity. Delivery was indicated for maternal reasons, a BPS below 6, oligohydramnios, documented lung maturity, or a gestational age beyond 36 weeks. There were no stillbirths and no cord artery pH below 7.20 using this intensive monitoring approach.

The clinical progression in Doppler and biophysical abnormalities is observed in approximately 70% to 80% of growth-restricted fetuses prior to 34 weeks' gestation.[14,23] Two rates of progression have been described by Turan and coworkers that can be anticipated based on the umbilical artery end-diastolic velocity. In pregnancies in which umbilical artery end-diastolic velocity is lost within the first 2 weeks of diagnosis, deterioration to venous Doppler and biophysical abnormalities within 4 weeks is common (Figure 31-20). If umbilical artery end-diastolic is maintained for longer periods, deterioration may not occur for 6 weeks after diagnosis. In late-onset growth restriction presenting beyond 34 weeks' gestation, several other presentations are possible. Umbilical artery blood flow resistance may be normal and brain sparing may be observed as the only Doppler sign of perceived hypoxemia. Alternatively, Doppler findings may be normal, and oligohydramnios and/or a decline of biophysical variables may be the only signs of placental insufficiency. On a similar note, the speed of progression may vary significantly in these different clinical scenarios and persistence of normal umbilical Doppler parameters for up to 9 weeks before new-onset

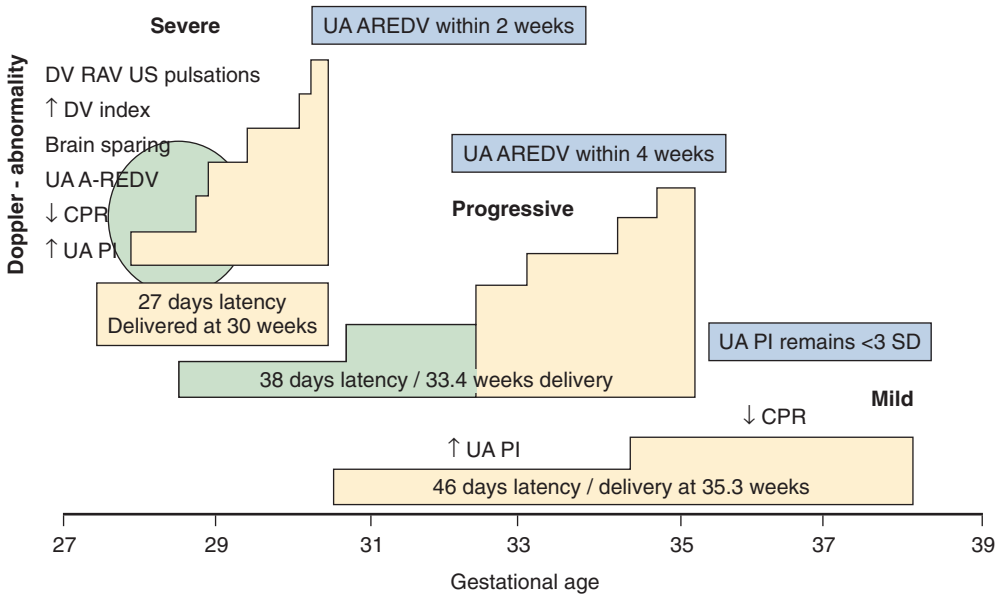

FIGURE 31-20. Two rates of progression can be anticipated based on the umbilical artery end-diastolic velocity. Losing umbilical artery end-diastolic velocity within the first 2 weeks of diagnosis commonly leads to deterioration to venous Doppler and biophysical abnormalities within 4 weeks (middle section of the figure). However, umbilical artery end-diastolic can be maintained for longer periods and deterioration may not occur for 6 weeks after diagnosis (bottom section of figure).

brain sparing is observed is not unusual. In recognition of these variable time scales and patterns of deterioration, it is evident that the combination of several testing modalities is more likely to provide evidence of deterioration. If biophysical profile scoring is used, particular attention needs to be placed to the amniotic fluid, because this is the only component reflecting longitudinal progression. The most comprehensive approach that addresses cardiovascular and behavioral responses in IUGR fetuses across all gestational ages has been described as "integrated fetal testing."

Integrated fetal testing utilizes a surveillance approach to pregnancies with IUGR that requires familiarity with the combined assessment of the five-component BPS and arterial and venous Doppler studies.[82] Doppler examination includes evaluation of the umbilical artery, middle cerebral artery, ductus venosus, and free umbilical vein flow velocity waveform. The testing is always supplemented with maternal assessment of fetal movement ("kick counts"). Surveillance is initiated no earlier than 24 weeks' gestation. In fetuses with elevated umbilical artery pulsatility, positive end-diastolic flow, and absence of any additional abnormality, weekly biophysical profile scoring and fortnightly multivessel Doppler monitoring are performed. With the onset of brain sparing, Doppler monitoring intervals are shortened to weekly visits. In fetuses with an AFI of less than 5 cm or AEDV in the umbilical artery, surveillance intervals are shortened to every 3-4 days. With elevation of the ductus venosus Doppler index to less than 2 SD, testing frequency is increased to every 2 to 3 days. Further escalation of the ductus venosus Doppler index may require daily testing, and inpatient admission may be prudent based on local practice. Any change in maternal condition, especially the development of preeclampsia, calls for reassessment of fetal status irrespective of the last examination result (Figure 31-21).

THE TIMING OF DELIVERY

In the absence of definitive fetal therapy, proper timing of delivery is often the critical management issue when dealing with the growth-restricted fetus. In principle, the decision for delivery always weighs fetal risks against risks that can be anticipated as a result of delivery. The risks of prematurity are of primary concern and make the management of the preterm growth-restricted fetus particularly challenging. Typically, the decline in neonatal mortality is greatest between 24 and 28 weeks, whereas morbidity declines progressively thereafter toward 32 weeks. Although there are surprisingly few randomized management studies that address the issue of delivery timing in IUGR, the Growth Restriction Intervention Trial (GRIT) clarifies several important points.[83] This prospective multicenter study randomized more than 500 women with complicating fetal growth restriction into immediate versus delayed delivery when their managing physicians were unsure about the timing of delivery. In the conservatively managed group, delivery was delayed until a point when their managing obstetricians were no longer unsure about the need to deliver or when fetal testing became overtly normal. With a median delay of 4.5 days, no significant differences in short-term outcome were identified between the two groups (Table 31-5). The perinatal mortality with early delivery was associated with a higher rate of neonatal deaths, whereas delaying delivery increased the risk for stillbirth. Delivery timing also had little effect on neurodevelopment at 2 years of age. However, in the subset of fetuses delivered before 32 weeks, a trend toward poor neurodevelopment was primarily attributable to neonatal complications that occurred as a result of prematurity. In 2010, Walker and colleagues reported on the 6- to 13-year GRIT study outcomes and found the two groups to be similar for cognitive, language, behavior, and motor ability (half of original cohort). This

IUGR UNLIKELY		
Normal AC, AC growth rate and HC/AC ratio UA, MCA Doppler, BPS, and AFV normal	Asphyxia extremely rare low risk for intrapartum distress	Deliver for obstetric or maternal factors only, follow growth
IUGR		
AC <5th, low AC growth rate, high HC/AC ratio, abnormal UA +/or CPR, normal MCA and veins, BPS ≥8/10, AFV normal	Asphyxia extremely rare Increased risk for intrapartum distress	Deliver for obstetric, or maternal factors only, Every 2 weeks Doppler Weekly BPS
with blood flow redistribution		
IUGR diagnosed based on above criteria Low MCA, normal veins BPS ≥8/10, AFV normal	Hypoxemia possible, asphyxia rare Increased risk for intrapartum distress	Deliver for obstetric or maternal factors only, weekly Doppler BPS 2 times/week
with significant blood flow redistribution		
UA A/REDV normal veins BPS ≥6/10, Oligohydramnios	Hypoxemia common, acidemia or asphyxia possible Onset of fetal compromise	>34 weeks: deliver <32 weeks: antenatal steroids repeat all testing daily
with proven fetal compromise		
Significant redistribution present Increased DV pulsatility BPS ≥6/10, Oligohydramnios	Hypoxemia common, acidemia or asphyxia likely	>32 weeks: deliver <32 weeks: admit, Steroids, individualize testing daily vs. tid
with fetal decompensation		
Compromise by above criteria Absent or reversed DV a-wave, pulsatile UV BPS <6/10, Oligohydramnios	Cardiovascular instability, metabolic compromise, stillbirth imminent, high perinatal mortality irrespective of intervention	Deliver at tertiary care center with the highest level of NICU care

FIGURE 31-21. Integrated fetal testing and management protocol. The management algorithm for pregnancies complicated by fetal growth restriction is based on the ability to perform arterial and venous Doppler as well as a full five-component biophysical profile score. GA, Gestational age.

suggests that neurologic impairment may already be set by the time IUGR fetuses reach the point of delivery. Other observational studies also address the impact of gestational age on perinatal morbidity. In prenatally identified growth-restricted fetuses, the effect of gestational age overshadows all other perinatal variables. **After 27.0 weeks, when survival and intact survival first exceed 50%, a birthweight below 550 grams is associated with a high risk for neonatal death.**[84,85] **It appears that fetal deterioration of venous Doppler parameters begins to have an independent impact on neonatal survival from 28 weeks onward as postpartum morbidities become less frequent with advancing gestation.**[78] **Gestational age is also an important factor affecting perinatal mortality in patients who remain undelivered. Frigoletto has previously emphasized that the majority of fetal deaths in IUGR occur after the 36th week of gestation and before the onset of labor.**

These studies illustrate several points that are of critical importance in the management of pregnancies complicated by IUGR today. Patients need to be aware that growth-restricted fetuses have different viability thresholds and neonatal risk statistics than their appropriately

grown counterparts. The major risk for the growth-restricted fetus that remains undelivered is progression of hypoxemia to acidemia and stillbirth. Delivery is therefore typically indicated when the risk for these complications is high or there is no added benefit from prolongation of pregnancy. **The risk for acidemia and stillbirth is highest when repetitive late decelerations are observed in association with oligohydramnios and/or anhydramnios, when the BPS is below 6, when the ductus venosus Doppler index elevation escalates beyond 3 SDs and/or when reversal of the ductus venosus a-wave is observed with accompanying umbilical venous pulsations.** In addition, it is helpful to consider the delivery indications according to gestational epochs.

Between 24 and 27 weeks' gestation a growth-restricted fetus is periviable, and interventions are typically undertaken for maternal conditions such as severe preeclampsia. Thresholds for fetal indications should be high, requiring strong evidence of fetal compromise and risk of stillbirth. Management is frequently individualized, and a multidisciplinary approach is helpful in stressing that outcome may be poor even with maximal support in the neonatal intensive care unit (NICU). Parents need to be aware that despite maximum management effort, perinatal mortality is in excess of 50%.[84,85]

Between 27 and 34 weeks' gestation fetal indications for delivery should be based on firm evidence of fetal compromise with an attempt to complete a course of antenatal corticosteroids whenever possible.

Beyond 34 weeks' gestation lower delivery thresholds are acceptable and may include absent fetal growth, in particular arrested head growth, documented lung maturity on amniocentesis, and Doppler evidence of accelerating disease.

In summary, surveillance and management considerations are most challenging in preterm pregnancies, placing the highest demand on the accuracy of fetal testing before 34 weeks' gestation. Once fetal growth restriction is suspected or anticipated, appropriate fetal testing and daily maternal assessment of fetal activity should be instituted. Ultrasound examinations to assess fetal growth should be scheduled every 3 to 4 weeks. As long as studies show continued fetal head growth and test results remain reassuring, no intervention is required. An understanding of the strengths and limitations of individual surveillance tests in this context is important. The NST and fetal dynamic variables (fetal breathing, movement, and tone) provide assurance of fetal well-being at the time of testing. Because the traditional NST is frequently nonreactive in preterm fetuses, it is often inadequate as a stand-alone test of fetal well-being. A combination of umbilical artery Doppler and a five-component BPS are the surveillance tests of choice in preterm growth-restricted fetuses that circumvent this limitation of the NST alone. In the presence of umbilical artery end-diastolic velocity, normal AFV, and a normal BPS, weekly testing is sufficient. Testing frequency is adjusted according to fetal status with strict criteria for delivery as indicated above. In preterm growth-restricted fetuses in which timing of delivery is most critical, the combination of multiple modalities, including arterial and venous Doppler, offers the most comprehensive approach to assess fetal well-being.[66,86] Such "integrated fetal testing" is suggested for centers experienced with the performance of these studies. In the preterm growth-restricted fetus presenting before 34 weeks' gestation, consideration should always be given to administration of steroids if necessary, with continuous FHR monitoring and oxygen supplementation. Beyond 34 weeks' gestation, lung maturity amniocentesis to direct delivery timing should be considered. It is of note that even with optimal management there may be a yet undefined background morbidity that is predetermined by the condition and not amenable to treatment.

DELIVERY

The premature growth-restricted fetus requires the highest level of NICU care and therefore predelivery transport to an appropriate institution is recommended in all cases of early onset IUGR. Because many growth-restricted infants suffer intrapartum asphyxia, intrapartum management demands continuous FHR monitoring. In principle the route of delivery is determined by the severity of the fetal and maternal condition, along with other obstetric factors. Cesarean delivery without a trial of labor is indicated when the risks of vaginal delivery are unacceptable to the mother and fetus. These circumstances include prelabor evidence of fetal acidemia, spontaneous late decelerations, or late decelerations with minimal uterine activity. In addition, absent and reversed end-diastolic flow in the umbilical artery is associated with a high incidence of fetal intolerance of labor, thus cesarean delivery is often required and should be considered for these severely growth-restricted fetuses. In the instance of less abnormal fetal testing, typically in the setting of a more advanced gestational age, selection of the route of delivery is based on the difficulty anticipated in inducing labor, the Bishop score, and the AFV. The presence of IUGR has been considered a relative contraindication to the use of prostaglandin for cervical preparation by some authors.[87] If cervical ripening is considered, preinduction oxytocin challenge testing may be helpful in determining the likelihood and safety of vaginal delivery. Pharmacologic or mechanical ripening of the cervix, coupled with labor in the left lateral decubitus position with supplemental oxygen, increases the likelihood of a successful vaginal delivery. During labor, a tracing without late decelerations is predictive of a good outcome in cases complicated by IUGR. However, with late decelerations, the incidence of asphyxia in growth-restricted infants is far greater than in normally grown infants.

OUTCOME

IUGR can transiently and/or permanently impair neonatal well-being. The potential effects of this condition at birth and from complications occurring in the neonatal period have been most extensively studied. However, additional effects of this perinatal period on intermediate and long-term health are starting to emerge. Recently, a new area of research into the fetal origin of maternal diseases has also pointed out how exposure to a hostile intrauterine environment can be a predisposing factor for the development in

adulthood of cardiovascular diseases and endocrine disturbances. An understanding of these outcomes will become important when the focus of management strategies shifts from the prevention of fetal and neonatal morbidity to the improvement of intermediate- and long-term development. Studies that examine the relationship between fetal growth restriction and postdelivery outcomes are therefore best separated into those that focus on short-term outcomes and those that focus on long-term outcomes.

Short-Term Outcomes

Initial reports that evaluated the association between fetal growth restriction and neonatal morbidity suggested the possibility of a protective effect of IUGR, with reduced occurrence of RDS and IVH. Subsequent studies do not support these early assumptions. Piper and Langer found no difference in indices of fetal lung maturity comparing gestational age-matched SGA and AGA fetuses. Similarly, Thompson et al. found no difference in the frequency of ventilator support when growth-restricted and AGA infants were matched for gestational age and mode of delivery. Most recently, several large trials suggest that RDS is significantly more likely to occur in growth-restricted neonates.[88,89] Bernstein has also demonstrated a significant increase in the risk for NEC and no difference in the rates of IVH when growth-restricted newborns are evaluated. Dashe noted a significant increase in RDS in infants with asymmetric IUGR when compared with neonates with symmetric IUGR (9% vs. 4%). Other investigators have also demonstrated increased risks of multiorgan failure, intracranial hemorrhage, bronchopulmonary dysplasia, clotting disorders, and disturbed endocrine homeostasis.[90,91] Mortality rates are uniformly higher when IUGR is present. These data should put to rest the notion that fetal growth restriction is associated with any reduction in newborn illness. Additional neonatal morbidities that must be anticipated include meconium aspiration, hypoglycemia, and electrolyte abnormalities.

Meconium aspiration occurs more frequently in IUGR than appropriately grown infants and is largely a problem observed after 34 weeks. Gasping in utero in response to asphyxia appears to contribute to this problem. Historically, careful suctioning of the nasopharynx and oropharynx with the DeLee catheter at delivery has been employed to decrease the incidence of this complication; however, more recent data shows that this is not the case. Clearing of the airway can be accomplished at delivery by direct laryngoscopy and aspiration by an experienced pediatrician. To effect immediate attention to the many potential neonatal problems, appropriate pediatric support should be present in the delivery room when an infant suspected of being growth restricted is to be delivered.

Hypoglycemia is frequently observed in growth-restricted infants owing to their inadequate glycogen reserves and a gluconeogenic pathway that is less sensitive to hypoglycemia than that of the normally grown infant.[92] In anticipation of this risk for hypoglycemia, frequent blood glucose monitoring should be instituted in all growth-restricted infants. Hypocalcemia, another well-recognized problem in IUGR, may be the result of relative hypoparathyroidism, a result of intrauterine acidosis. Hyperphosphatemia secondary to tissue breakdown may also contribute. Frequent calcium monitoring is essential, as symptoms are nonspecific and similar to those associated with hypoglycemia.

Hyponatremia resulting from impaired renal function is also frequently reported in growth-restricted infants. The renal complications associated with IUGR may be attributed to asphyxia, which can produce central nervous system injury leading to inappropriate antidiuretic hormone (ADH) secretion.[92]

Neonates with growth restriction are at risk for polycythemia, anemia, thrombocytopenia, and complex hematologic derangements that may be problematic well beyond delivery.[13] Polycythemia is observed three to four times more frequently in the growth-restricted infant than in weight-matched controls. Polycythemia results from hypoxia-stimulated production of red blood cells and from transfer of blood volume from the placental to the fetal circulation in the face of intrauterine asphyxia. Thus, these infants produce more red blood cells that are shunted to them if hypoxia occurs during labor. Polycythemia leads to increased red blood cell breakdown, accounting in part for the high incidence of hyperbilirubinemia in these infants. Polycythemia is a criterion for, but does not necessarily lead to, hyperviscosity, which can result in capillary bed sludging and thrombosis. Multiple organ systems can be affected, leading to pulmonary hypertension, cerebral infarction, and NEC. Anemia can be observed in preterm IUGR fetuses with markedly abnormal placental blood flow studies. Thrombocytopenia frequently accompanies the anemia. The risk for thrombocytopenia is increased more than 10-fold if umbilical artery end-diastolic velocity (AEDV) is absent. The cause for these abnormalities could involve a combination of dysfunctional erythropoiesis coupled with placental consumption of platelets and red blood cells. Neonates with such complex hematologic abnormalities are frequently unable to sustain their blood cell counts despite repeated substitution of blood products.

Hypothermia is another common problem for the growth-restricted infant and results from decreased body fat stores secondary to intrauterine malnourishment.[92] Hypothermia, if unrecognized and untreated, can contribute to the metabolic deterioration of an already unstable growth-restricted infant.

Finally, growth-restricted neonates are at increased risk for perinatal death in light of the multiple complications that may arise in the fetal and neonatal periods. The range of reported perinatal mortality is variable but depends clearly on the level of perinatal management received: infants who received optimal intrapartum and neonatal management have a lower perinatal mortality than age-matched controls who did not have such intensive care.[93]

Long-Term Outcomes

The ultimate growth potential for growth-restricted infants appears to be good. The degree of catch-up growth observed in several longitudinal studies suggests that these infants can be expected to have normal growth curves and normal, albeit slightly reduced, size as adults. In an 8-year follow-up of children weighing less than

1500 g at birth by Kitchen and associates,[94] 75% of growth-restricted infants achieved a height and weight above the 10th percentile. Of infants whose birthweight fell below the 3rd percentile, 60% had reached the 25th percentile for weight at 8 years. In Kitchen and associates' study,[94] however, 50% of the children with small HCs still had HCs below the 10th percentile at the 8-year follow-up visit in spite of their growth in height and weight. Hediger observed that growth-restricted infants experienced a period of catch-up growth in early infancy but remained near the 25th percentile through age 47 months. Kumar and colleagues[95] noted that in infants whose birthweights were less than 1250 g, at 1 year, 46% of the growth-restricted infants remained less than the 3rd percentile for weight and 38% remained less than the 3rd percentile for height. In general, those infants suffering growth restriction near the time of delivery do tend to catch up. However, those neonates with earlier onset and more longstanding growth restriction in utero continue to lag behind.

The issue of long-term neurologic sequelae remains unresolved. In 1972, Fitzhardinge and Steven,[96] evaluating a group of 96 growth-restricted infants, noted that 50% of males and 36% of females had poor school performance and, overall, 25% had minimal cerebral dysfunction. Major neurologic deficits were much less frequent. Other studies have shown low birthweight and short gestation to be risk factors for cerebral palsy. However, the vast majority of children with cerebral palsy are not growth restricted.

The positive effect of intrapartum surveillance for the growth-restricted fetus is reflected in the data of Low and colleagues[97] In a study of 88 growth-restricted infants, they reported no severe neurologic sequelae. They did detect a lag in mental development that was significant in the growth-restricted babies when compared with appropriately grown controls, especially in the group with birthweights less than 2300 g. This study correlates well with the data of Lipper and colleagues on low-birthweight babies. They observed that growth-restricted infants with HCs below the 10th percentile have two to three times the number of serious neurologic sequelae of their normocephalic counterparts. Strauss and Dietz found that term infants with IUGR and HCs less than 2 SD below the mean had significantly poorer performance on intelligence and visual motor development testing at age 7 when compared with their control siblings.[98] Walther, in an examination of 7-year-olds who suffered no perinatal complications despite IUGR and who were matched for social class with a control group, showed an increase in teacher-identified hyperactivity, poor concentration, and clumsiness. In a study of school performance in 8-year-olds matched for socioeconomic status, Robertson and colleagues demonstrated a tendency toward hyperactivity in preterm growth-restricted children compared with control groups. Low and colleagues[99] have shown that in 9- to 11-year-olds only fetal growth restriction and socioeconomic status contributed independently to the presence of learning deficits. Intrapartum fetal asphyxia, assessed by umbilical artery base deficit, was not associated with learning deficits in this group of children. Few studies have related neurodevelopment to a full complement of antenatal surveillance parameters. A study of predominantly preterm growth-restricted pregnancies that evaluate 2-year developmental outcomes reported gestational age at delivery, birthweight, and reversal of umbilical artery end-diastolic velocity as the main determinants of motor and neurosensory morbidity. Interestingly, fetal deterioration of venous Doppler or biophysical parameters did not have a statistical impact on neurodevelopment.[100]

The pattern that emerges from evaluation of these data emphasizes that neurologic outcome depends on the degree of growth restriction, especially the impact on head growth, its time of onset, the gestational age of the infant at birth, and the postnatal environment. An early intrauterine insult, between 10 and 17 weeks' gestation, could limit neuronal cellular multiplication and would obviously have a profound effect on neurologic function. In the third trimester, brain development is characterized by glial multiplication, dendritic arborization, establishment of synaptic connections, and myelinization, all of which continue during the first 2 years of life. Recovery after a period of impaired growth in the third trimester is, therefore, more likely to occur. Thus, the preterm appropriately grown infant has more normal neurologic development and fewer severe neurologic deficits than its preterm growth-restricted counterpart. Developmental milestones and neurologic development of mature infants with IUGR and mature infants of normal birthweight are similar. Presumably, this also reflects heightened physician awareness of the growth-restricted infant that allows detection, appropriate antepartum management, intrapartum therapy, and early pediatric intervention. The premature growth-restricted infant suffers from increased susceptibility to intrauterine asphyxia and all of the neonatal complications of the premature, as well as those of the infant with IUGR. If growth restriction is associated with lagging head growth before 26 weeks, even mature infants have significant developmental delay at 4 years of age.

Recently, the long-term impacts at age 6 to 13 years of age were reported for the GRIT study. In the absence of any specific delivery triggers the cognitive development was identical in both groups. In summary, these findings are concerning that the intrauterine environment has significant impacts on neurodevelopment before delivery management issues arise and, accordingly, it is unlikely that intervention trials will demonstrate a large impact of delivery timing on neurodevelopment.[100]

Gestational programming of growth-restricted fetuses has received considerable attention over the past 10 to 15 years. Infants born growth restricted have an increased risk of metabolic syndrome, obesity, hypertension, diabetes, and stroke from coronary artery disease. For a more in-depth review of fetal programming and long-term adult outcomes from IUGR, the reader is referred to Chapter 5.

KEY POINTS

- Fetal growth restriction is a major cause of perinatal morbidity, perinatal mortality, and both short-term and lifelong morbidities.
- Although IUGR is currently defined by fetal size alone, the four primary underlying etiologies (aneuploidy, viral infection, nonaneuploid syndromes,

and placental insufficiency) produce quite different outcomes.

- Identification of growth restriction due to placental insufficiency requires a comprehensive diagnostic workup including measurement of the fetal abdominal circumference in combination with umbilical artery Doppler studies, exclusion of fetal anomalies, and possibly invasive testing to detect aneuploidy and viral infection.
- The combination of a small abdominal circumference, normal anatomy, low or normal amniotic fluid volume, and abnormal umbilical artery Doppler is strongly suggestive of placental insufficiency.
- Because mortality resulting from fetal growth restriction can be reduced with appropriate antenatal surveillance, all pregnancies at risk for IUGR should be carefully monitored.
- Deterioration of fetal biophysical and cardiovascular parameters follows a relatively predictable pattern, progressing from early to late changes that can be used for the prediction of fetal acid–base balance and the risk for stillbirth.
- Antenatal surveillance in preterm IUGR requires the combination of several testing modalities to provide fetal assessment of sufficient precision to guide intervention.
- In preterm gestations complicated by IUGR, the threshold for delivery is critically influenced by gestational age.

Single Nucleotide Polymorphisms	SNPs

NOMENCLATURE

Exposure to foreign red cell antigens invariably results in the production of anti–red cell antibodies in a process known as *red cell alloimmunization* (formerly termed *isoimmunization*). The expression *sensitization* can be used interchangeably with *Rhesus alloimmunization*. The active transport of these antibodies across the placenta during pregnancy results in fetal anemia, hyperbilirubinemia, and ultimately, hydrops fetalis. Before the advent of obstetrical ultrasound, the perinatal effects of maternal red cell alloimmunization could be recognized only after birth in the affected neonate. Thus, the neonatal consequences of maternal red cell alloimmunization came to be known as *hemolytic disease of the newborn (HDN)*. Because the peripheral blood smear of these infants demonstrated a large percentage of circulating immature red cells known as erythroblasts, the newborn entity was also known as *erythroblastosis fetalis*. Today, ultrasound and fetal blood sampling (FBS) make the detection of the severely anemic fetus a reality. For this reason, the term *hemolytic disease of the fetus and newborn (HDFN)* would appear more appropriate to describe this disorder.

HISTORICAL PERSPECTIVES

The first case of HDFN was probably described in 1609 by a midwife in the French literature.[1] The case was a twin gestation in which the first fetus was stillborn and the second twin developed jaundice and succumbed soon after birth. In 1932, Diamond[2] proposed that the clinical entities of erythroblastosis fetalis, icterus gravis neonatorum, and hydrops fetalis represented different manifestations of the same disease. Seven years later Levine and Stetson[3] described an antibody in a woman who gave birth to a stillborn fetus. The patient experienced a severe hemolytic transfusion reaction after later receiving her husband's blood. In 1940, Landsteiner and Weiner[4] injected red blood cells from rhesus monkeys into rabbits. The antibody that was isolated from these was used to test human blood samples from caucasians, and agglutination was noted in 85% of individuals. The following year Levine and colleagues[5] were able to demonstrate a causal relationship between Rhesus D (RhD) antibodies in RhD-negative women and HDFN in their offspring.

The advent of therapy for HDFN began in 1945 with the description by Wallerstein[6] of the technique of neonatal exchange transfusion. Later Liley[7] proposed the use of amniotic fluid bilirubin assessment as an indirect measure of the degree of fetal hemolysis. Sir William Liley's major contribution to the story of rhesus disease was the introduction of the intraperitoneal fetal transfusion (IPT).[8] He learned from a visiting fellow who had returned from Africa that the infusion of red blood cells into the peritoneal cavity of children with sickle-cell disease produced normal-appearing red blood cells on peripheral blood smear. Liley realized that he had previously inadvertently entered the peritoneal cavity of fetuses at the time of amniocentesis, based on the marked contrast in the yellow hue of the ascitic fluid as compared with amniotic fluid. He postulated that purposeful entry into the fetal peritoneal cavity could be accomplished. After three unsuccessful attempts that resulted in fetal demises, the fourth fetus was delivered at 34 4/7 weeks' gestation after undergoing two successful IPTs. Early attempts at IPT used fluoroscopy for needle guidance. With the introduction of real-time ultrasound in the early 1980s, IPTs became a safer procedure as fluoroscopy was abandoned. Charles Rodeck[9] is credited with the first intravascular fetal transfusion (IVT) using a fetoscope to guide the transfusion needle into a placental plate vessel. Just 1 year later, investigators in Denmark performed the first ultrasound-guided IVT using the intrahepatic portion of the umbilical vein.[10]

The 1990s saw the introduction of genetic techniques using amniocentesis to determine fetal red cell typing.[11] The turn of the century brought the noninvasive detection of fetal anemia through Doppler ultrasound of the fetal middle cerebral artery (MCA) and the use of fetal typing through cell free DNA in maternal plasma.[12,13]

INCIDENCE

The advent of the routine administration of antenatal and postpartum rhesus immune globulin (RhIG) has resulted in a marked reduction in cases of red cell alloimmunization secondary to the RhD antigen. The Centers for Disease Control and Prevention last required the reporting of rhesus alloimmunization as a medical complication of pregnancy on U.S. birth certificates in the year 2002.[14] In that year (the most recent for which epidemiologic data are available) the incidence was reported to be 6.7 cases of Rhesus alloimmunization per 1000 live births.

Clearly, a shift to other red cell antibodies associated with HDFN has occurred as a result of the decreasing incidence of RhD alloimmunization. In one large series of women of childbearing age, a positive screen for an antibody associated with HDFN was found in 1% of samples.[15] Rhesus antibodies were the most common, accounting for more than half of significant antibodies, and with the RhD antibody accounting for almost one fourth. Kell antibodies were next most frequent, followed by Duffy, MNS, Kidd, and anti-U. In another series of more than 1000 Dutch women who screened positive for antibodies at 12 weeks of gestation, anti-E was the most common antibody that was found.[16] This was followed by anti-K then anti-D (Figure 32-1).

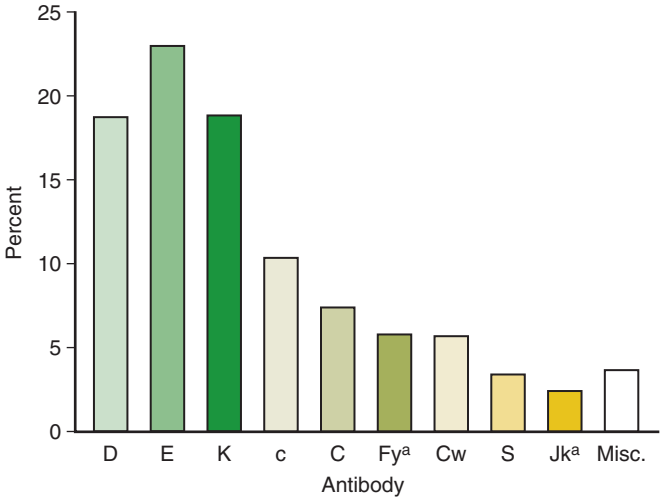

FIGURE 32-1. Incidence of maternal anti–red cell antibodies associated with hemolytic disease of the fetus and newborn (HDFN) in a Dutch population of pregnant women. (From van der Schoot CE, Tax GH, Rijnders RJP, et al: Prenatal typing of Rh and Kell blood group system antigens: the edge of the watershed. Trans Med Rev 17:31, 2003.)

PATHOPHYSIOLOGY

Although the placenta was once thought to be an absolute barrier to the transfer of cells between the maternal and fetal compartments, we now appreciate that the placental interface allows for the bidirectional movement of both intact cells and free DNA. The putative "grandmother theory" of rhesus red cell alloimmunization probably occurs more commonly than first thought. In this paradigm, maternal RhD-positive red cells gain access to the circulation of the RhD-negative fetus at the time of delivery. As many as one fourth of RhD-negative babies have been shown to be immunized in early life as a result of their delivery.[17,18] The immune response of an Rh-negative individual to RhD-positive red cells has been characterized into one of three groups: (1) Sixty to 70% of individuals are *responders* and develop an antibody to relatively small volumes of red cells. In these individuals, the probability of immunization increases with escalating volumes of cells. A small percentage of this group can be called *hyperresponders* in that they will be immunized by very small quantities of red cells. (2) The second group of individuals (10%-20%) can be immunized only by exposure to very large volumes of cells. (3) Finally, the 10% to 20% of individuals who remain appear to be *nonresponders*.

In most cases of red cell alloimmunization, a fetomaternal hemorrhage (FMH) occurs in the antenatal period or more commonly at the time of delivery. If a maternal ABO blood type incompatibility exists between the mother and her fetus, anti-A and/or anti-B antibodies lyse the fetal cells in the maternal circulation and destroy the RhD antigen.[19,20] Even if this protective effect is not present, only 13% of deliveries of RhD-positive fetuses result in RhD alloimmunization in RhD-negative women who do not receive RhIG. The vast majority of RhD-alloimmunized women produce an IgG response as their initial antibody. *Responders* may represent a group of individuals who had their initial exposure to the RhD antigen at birth due to

maternofetal hemorrhage.[18] After a sensitizing event, the human antiglobulin anti-D titer can usually be detected after 5 to 16 weeks. However, approximately half of alloimmunized patients are *sensibilized*. In this scenario, an antibody screen will be negative, but memory B lymphocytes are present that can create an anti-D antibody response. When faced with the challenge of a subsequent pregnancy involving an RhD-positive fetus, the anti-D titer becomes detectable.

The anti-D immune response is the best characterized of the anti–red cell antibodies associated with HDFN. In one third of cases, only subclass IgG1 is produced; in the remainder of cases, a combination of IgG1 and IgG3 subclasses is found.[21] Anti-D IgG is a nonagglutinating antibody that does not bind complement. This results in a lack of intravascular hemolysis; sequestration and subsequent destruction of antibody-coated red cells in the fetal liver and spleen are the mechanism of fetal anemia. Most studies have not detected a relationship between a specific maternal human leukocyte antigen type and susceptibility to become alloimmunized to RhD.[22] However, sensitized women with high titers of anti-D are more likely to exhibit the DQB1*0201 and DR17 alleles as compared with women with low titers.[23] Fetal sex may also play a significant role in the fetal response to maternal antibodies. RhD-positive male fetuses are 13 times more likely than their female counterparts to become hydropic and 3 times more likely to die from their disease.[24]

Anemia results in several important physiologic changes in the fetus. Reticulocytosis from the bone marrow can be detected by FBS once the hemoglobin deficit exceeds 2 g/dL as compared to norms for gestational age; erythroblasts are released from the fetal liver once the hemoglobin deficit reaches 7 g/dL or greater.[25] In an effort to increase oxygen delivery to peripheral tissues, fetal cardiac output increases and 2-3 diphosphotidylglycerol (DPG) levels are enhanced.[26,27] Tissue hypoxia appears as anemia progresses despite these physiologic changes. An increased umbilical artery lactate level is noted when the fetal hemoglobin falls below 8 g/dL and increased venous lactate can be detected when the hemoglobin level falls below 4 g/dL.[28] **Hydrops fetalis (the accumulation of extracellular fluid in at least two body compartments) is a late finding in cases of fetal anemia. Its exact pathophysiology is unknown.** Enhanced hepatic erythropoietic function with subsequent depressed synthesis of serum proteins has been proposed as the explanation for the lower serum albumin levels that have been detected.[29] Colloid osmotic pressure appears decreased.[30] However, experimental animal models in which fetal plasma proteins have been replaced with saline did not produce hydrops.[31] An alternative hypothesis is that tissue hypoxia due to anemia enhances capillary permeability. In addition, iron overload due to ongoing hemolysis may contribute to free radical formation and endothelial cell dysfunction.[32] Central venous pressures do appear elevated in the hydropic fetus with HDFN. This may cause a functional blockage of the lymphatic system at the level of the thoracic duct as it empties into the left brachiocephalic vein.[30] This theory is supported by reports of poor absorption of donor red cells infused into the intraperitoneal cavity in cases of hydrops.[33]

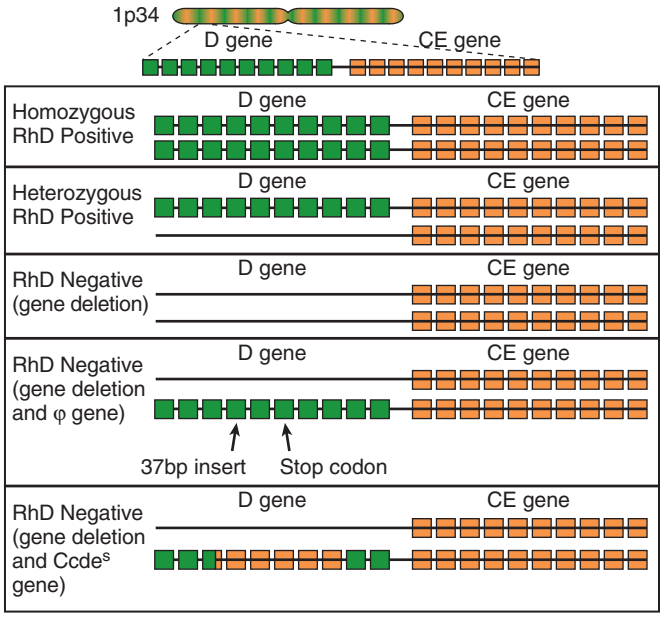

FIGURE 32-2. Schematic of Rh gene locus on chromosome 1. The homozygous RhD-positive state, heterozygous RhD-positive state, RhD-negative with heterozygosity for the RhD pseudogene, and RhD-negative with heterozygosity for the Ccde^s gene are demonstrated. Philadelphia, Elsevier, Copyright © 2004.)

RHESUS ALLOIMMUNIZATION AND FETAL/NEONATAL HEMOLYTIC DISEASE OF THE NEWBORN

Genetics

Initial concepts on the genetics of the Rh antigens proposed the presence of three distinct genes.[34] Newer DNA techniques allowed for the localization of the Rh locus to the short arm of chromosome 1.[35] **Only two genes were identified—an RhD gene and an RhCE gene.** Each gene is 10 exons in length, with 96% homology. These genes presumably represent a duplication of a common ancestral gene. Production of two distinct proteins from the RhCE gene probably occurs as a result of alternative splicing of messenger RNA.[36] One nucleotide difference, cytosine to thymine, in exon 2 of the RhCE gene results in a single amino acid change of a serine to proline. This causes the expression of the *C* antigen as opposed to the *c* antigen.[37] A single cytosine-to-guanine change in exon 5 of the RhCE gene, producing a single amino acid change of a proline to alanine, results in formation of the *e* antigen instead of the *E* antigen.

The gene frequency found in different ethnic groups can be traced to the Spanish colonization in the fifteenth and sixteenth centuries. Populations native to certain land masses have a less than 1% incidence of RhD negativity—Eskimos, Native Americans, Japanese, and Chinese individuals. The Basque tribe in Spain is noted to have a 30% incidence of Rh negativity. This may well be the origin of the RhD gene deletion that is the most common genetic basis of the RhD-negative state in whites (Figure 32-2).

Whites of European descent exhibit a 15% incidence of RhD negativity, whereas an 8% incidence occurs in blacks and Hispanics of Mexico and Central America. This latter incidence probably reflects ethnic diversity secondary to Spanish colonization of the New World.

Further study of the RhD gene has revealed significant heterogeneity. Several of these genetic modifications result in a lack of expression of the RhD phenotype. Although these individuals may have an aberrant RhD gene present, serologic methods do not detect the RhD antigen on the surface of the red cells. One such example is the RhD pseudogene, which has been found in 69% of South African blacks and 24% of American blacks (see Figure 32-2).[38] In this situation, all 10 exons of the RhD gene are present. However, translation of the gene into a messenger RNA product does not occur owing to the presence of a stop codon in the intron between exons 3 and 4. Thus, no RhD protein is synthesized and the patient is serologically RhD negative. Similarly, the Ccde^s has been detected in 22% of American blacks. It appears to contain exons 1, 2, 9, and 10 as well as a portion of exon 3 of the original RhD gene, with other exons being duplicated from the RhCE gene. In the Taiwanese population of RhD-negative individuals, five different exons of the RhD gene were evaluated.[39] Seventeen percent of individuals had all five exons detected, and an additional 135 demonstrated the presence of at least one of the five exons tested.

PREVENTION OF RhD HEMOLYTIC DISEASE IN THE FETUS AND NEWBORN

History

The history of rhesus prophylaxis can be traced to three unique individuals. Vincent Freda was an obstetrical resident who developed an interest in HDFN.[40] He was allowed to spend part of the fourth year of his residency at Columbia Presbyterian Medical Center in the laboratory of Alexander Weiner, one of the first investigators to identify the "Rh factor." When Freda returned to Columbia, he went on to establish a serology laboratory and later organized the Rh Antepartum Clinic in 1960. A seat on the hospital transfusion committee became vacant, and in an unprecedented move based on his interest, the chairman of obstetrics and gynecology, Howard C. Taylor, Jr., appointed Freda to this position even though he had not completed his residency. The chairman of pathology responded with the appointment of John Gorman to the committee, a resident in pathology with an interest in blood banking. It is here that these two individuals met and developed the collaboration that would one day end in the introduction of RhIG. In 1906, Theobald Smith[41] found that guinea pigs given excess passive antibody failed to become immunized to diphtheria toxin. Freda and Gorman proposed that anti-D could be used in a similar fashion to prevent alloimmunization after delivery. They enlisted the aid of William Pollack, a senior protein chemist at Ortho Diagnostics, who developed an IgG globulin fraction from high-titered donor plasma. An initial grant application to the National Institutes of Health was rejected. Funding was secured from the New York City Health Research Council on a second attempt. This was followed by a year's negotiations with lawyers in the state capital to allow the investigators to perform their clinical trials at the Sing Sing prison in New York beginning in 1961 (personal communication: John Gorman). Nine RhD-negative male volunteers were injected monthly with RhD-positive cells for five successive months.[42] Four of the men were immunized with intramuscular RhIG 24 hours before the injection of the red cells. Four of the five controls became alloimmunized to RhD, whereas none of the treated individuals developed anti-RhD antibodies. Their second experiment involved 27 inmates at Sing Sing, 13 controls and 14 treated. Red cells were given intravenously. However, the warden of Sing Sing would not allow the investigators to return on any fixed schedule that would enable the prisoners to know the time and day of their revisit. He was concerned that this exact foreknowledge could involve the prisoners in an escape plan. The investigators gladly accepted this limitation as they reasoned that pregnant women who delivered over a weekend would probably not receive RhIG until Monday, up to 72 hours after delivery, owing to the closure of blood banks on weekends, as was commonly practiced at the time. None of the men receiving RhIG were alloimmunized, whereas 8 of 13 controls developed anti-RhD antibodies. After two additional experiments at Sing Sing in this second group of individuals, Freda and Gorman went on to conduct a clinical trial in postpartum women at Columbia Presbyterian Medical Center starting in March of 1964.[42] In the 100 patients that received RhIG, none became sensitized, as compared with a rate of 12% sensitization to RhD in the control group. In a follow-up study in these patients in their next pregnancy, none of the treated patients developed antibodies; 5 of 10 controls were alloimmunized and delivered infants affected by HDFN.

A parallel track of investigation was being undertaken by a group of British researchers in Liverpool. This group reasoned that the natural protective effect of ABO incompatibility between a mother and her fetus in preventing the formation of anti-D antibody could be used as a preventative strategy. A preparation of plasma containing anti-D IgM was formulated and administered intravenously to male volunteers.[43] Although initial short-term antibody studies were promising, eventually 8 of 13 treated men became immunized to RhD, as compared with only 1 of 11 controls. After the publication of the initial work of Freda et al. describing the use of a gamma globulin fraction of the plasma, the British group visited the New York investigators and obtained a sample of their gamma globulin preparation. The Liverpool group began their clinical trial in postpartum women with evidence of FMH by Kleihauer-Betke (KB) stain in April 1964.[44] They are subsequently credited with the first publication of a successful clinical trial in women.

An observational trial in Canada was initiated and determined that the baseline rate of antenatal sensitization to RhD was 1.8%.[45] Between 1968 and 1974, a trial of antenatal prophylaxis using injections of 300 mcg of RhIG at 28 and 34 weeks' gestation followed.[46] As compared with the previous observational study, none of the women demonstrated the development of anti-D antibodies. In a subsequent investigation involving RhIG administered only at 28 weeks' gestation, only 0.18% of women became sensitized.

RhIG was approved by the Division of Biologics Standards of the National Institutes of Health for general clinical use in the United States as RhoGAM (Ortho-Clinical Diagnostics, Inc., Raritan, N.J.) in 1968. Recommendations for use during the immediate postpartum period were set forth by the American Congress of Obstetricians and Gynecologists (ACOG) in 1970.[47] The Food and Drug Administration approved the use of antenatal RhIG in 1981. Routine antenatal prophylaxis at 28 to 29 weeks' gestation was proposed by ACOG later that same year.[48]

Preparations

Four polyclonal products derived from human plasma are currently available in the United States for the prevention of RhD alloimmunization. Two of the products (RhoGAM, Ortho-Clinical Diagnostics, Inc., Raritan, N.J., and HyperRho S/D, Talecris Biothorgenetics, Inc., Research Triangle Park, N.C.) can only be given intramuscularly because they are derived from human plasma through Cohn cold ethanol fractionation—a process that results in contamination with IgA and other plasma proteins. The remaining two products (WinRho-SDF, Cangene Corporation, Winnipeg, Manitoba; and Rhophlac, CSL Behring, L.L.C., King of Prussia, Penn.) are prepared through sepharose column and ion-exchange chromatography, respectively. At present, all available products are subject to solvent detergent treatment to inactivate enveloped viruses; many manufacturers also employ an additional micropore filtration step to further reduce the chance for viral contamination. Additionally, thimerosal, a mercury preservative used to prevent bacterial and fungal contamination, has been removed from all RhIG products used in the United States.

The dwindling resource of plasma donors for RhIG manufacture has led to the search for a synthetic product. Several monoclonal anti-D antibodies are now under study in large clinical trials. In addition a synthetic polyclonal immune globulin consisting of 25 recombinant anti-D antibodies has been developed by transfection of Chinese hamster ovary cells.[49] Clinical trials with this product are also under way. These products may soon replace the current polyclonal products derived from human plasma.

Indications

All pregnant patients should undergo determination of blood type and an antibody screen at the first prenatal visit. Patients found to be *weak Rh positive* (previously termed *Du-positive*) should be considered RhD-negative because their RhD gene encodes for an altered D protein or a reduced expression of the RhD antigen on the red cell membrane. Therefore, some of these patients can potentially be at risk for rhesus alloimmunization and do not require RhIG. **If there is no evidence of anti-D alloimmunization in the RhD-negative woman, the patient should receive 300 mcg of RhIG at 28 weeks of gestation.**[50] The 2% background incidence of RhD alloimmunization in the antenatal period can be expected to decline to 0.1%. In the United Kingdom, an antenatal protocol of administering 100 mcg (500 international units [IU]) of RhIG at 28 and 34 weeks is used in primigravida women.[51] Limited resources have not allowed for extension of this protocol to all subsequent pregnancies. The issue of repeating an antibody screen at 28 weeks before the administration of RhIG is controversial. The low incidence of a positive screen after a negative test at entry into prenatal care has resulted in the ACOG questioning the cost effectiveness of this practice.[50] Although ACOG leaves the decision to repeat the antibody screen up to the obstetrical provider, the American Association of Blood Banks (AABB) recommends that a repeat screen be obtained before antenatal RhIG.[52] If a repeat antibody screen is to be undertaken, a maternal blood sample can be drawn at the same office visit as the RhIG injection. Although the administration of the exogenous anti-D will eventually result in a weakly positive titer, this will not occur in the short interval of several hours due to the slow absorption from the intramuscular site. Some experts recommend that a second dose of RhIG be given if the patient has not delivered by 40 weeks' gestation.

Although not well studied, Level A scientific evidence has been cited by ACOG to address additional indications for the antepartum administration of RhIG.[50] These include spontaneous abortion, elective abortion, ectopic pregnancy, genetic amniocentesis, chorion villous sampling, and FBS (see box, Indications for Administration of Rhesus Immune Globulin). A dose of 50 mcg of RhIG is effective until 13 weeks' gestation owing to the small volume of red cells in the fetoplacental circulation. However, most hospitals and offices do not stock this dose of RhIG because the cost is equivalent to that of the standard dose of 300 mcg.

Indications for Administration of Rhesus Immune Globulin

Spontaneous abortion*
Elective abortion*
Threatened abortion
Ectopic pregnancy*
Hydatidiform mole†
Genetic amniocentesis*
Chorion villus sampling*
Fetal blood sampling*
Placenta previa with bleeding‡
Suspected abruption‡
Intrauterine fetal demise‡
Blunt trauma to the abdomen (includes motor vehicle accidents)‡
At 28 weeks' gestation, unless father of fetus is RhD-negative*
Amniocentesis for fetal lung maturity*
External cephalic version‡
Within 72 hours of delivery of an RhD-positive infant*
After administration of RhD-positive blood components‡

*Level A evidence (good and consistent scientific evidence).[50]
†Level B evidence (at least fair scientific evidence).
‡Level C evidence (consensus and expert opinion).[50]

The use of RhIG in other scenarios involving the possibility of FMH are lacking. However, most experts (Level C scientific evidence; see box, Indications for Administration of Rhesus Immune Globulin) agree that such events as hydatidiform mole, threatened abortion, fetal death in the second or third trimester, blunt trauma to the abdomen, and external cephalic version warrant strong consideration for the use of RhIG.

The practice of evaluating a persistent maternal anti-D titer as an indication that additional RhIG is not required after an antenatal event is to be discouraged. Although the precise mechanism for the protective effect of RhIG is unknown, an excess amount of exogenous antibody in relation to the volume of RhD-positive red cells in the maternal circulation is essential for effective prophylaxis. Both animal and human studies have demonstrated that a low level of RhIG can actually enhance the chance for alloimmunization.[19] In the words of Vincent Freda, "the rule of thumb should be to administer Rh-immune globulin when in doubt, rather than to withhold it."

Because the half-life of RhIG is approximately 16 days, 15% to 20% of patients receiving it at 28 weeks have a very low anti-D titer (usually 2 or 4) at the time of admission for labor at term.[53] In North America, the current recommendation is to administer 300 mcg of RhIG within 72 hours of delivery if umbilical cord blood typing reveals an RhD-positive infant.[50] This is sufficient to protect from sensitization due to an FMH of 30 mL of fetal whole blood. In the United Kingdom, 100 mcg is given at delivery. Approximately 1 in 1000 deliveries will be associated with an excessive FMH; risk factors identify only 50% of these cases.[54] **Both ACOG and AABB now recommend routine screening of all women at the time of delivery for excessive FMH.** A qualitative yet sensitive test for FMH, the rosette test, is first performed. Results return as positive or negative. A negative result warrants administration of a standard 300 mcg dose of RhIG. If the rosette is positive, a KB stain or fetal cell stain using flow cytometry is undertaken to quantitate the amount of the FMH. The AABB then recommends that the percentage of fetal blood cells be multiplied by a factor of 50 (to account for an estimated maternal blood volume of 5000 mL) in order to calculate the volume of the FMH. This volume is divided by 30 to determine the number of vials of RhIG to be administered. A decimal point is rounded up or down for values of greater than 0.5 or less than 0.5, respectively. Because this calculation includes an inaccurate estimation of the maternal blood volume, one additional vial of RhIG is added to the calculation. As an example, a 3% KB stain is calculated to indicate a 150-mL FMH. Dividing this number by 30 yields five vials of RhIG with one additional vial added; therefore, the blood bank would prescribe six vials of RhIG (a total of 1800 mcg) for this patient. However, a recent survey by the American College of Pathologists of its member blood banks noted that even following these guidelines, an inadequate dose of RhIG was recommended in 9% of cases and an excessive dose was recommended in 12% of cases.[55] This led to the development of an online calculator that can be used to determine the correct dose of RhIG based on the percentage of fetal cells noted on KB stain or flow cytometry (www.cap.org/apps/docs/committees/transfusionmedicine/RHIGcale.zip).

No more than five units of RhIG should be administered by the intramuscular route in one 24-hour period. Should a large dose of RhIG be necessary, an alternative method would be to give the calculated dose using one of the intravenous preparations of RhIG that are now available. Doses of up to 600 mcg (3000 IU) can be administered every 8 hours until the total dose has been achieved. **Should RhIG be inadvertently omitted after delivery, some protection has been proven with administration within 13 days; recommendations have been made to administer it as late as 28 days after delivery.**[54] If delivery is planned within 48 hours of amniocentesis for fetal lung maturity, RhIG can be deferred until after delivery. **If delivery occurs less than 3 weeks from the administration of RhIG used for antenatal indications such as external cephalic version, a repeat dose is unnecessary unless a large FMH is detected at the time of delivery.**[50]

Failed prophylaxis after the appropriate dose of RhIG is employed is rare. However, once postpartum administration is undertaken, the anti-D antibody screen may remain positive for up to 6 months. Anti-D persisting after this time is likely to be the result of sensitization.

The issue of the need for rhesus prophylaxis for the patient with a *weak Rh positive* blood type has been confusing to the clinician. Several genetic variants can account for this serologic result, some of which result in the presence of only part of the usual RhD epitope. In these cases patients can develop antibodies to the missing portion of the RhD antigen. Currently, the AABB no longer recommends routine testing for the weak D phenotype. Should this be reported as present, the patient should be considered RhD-negative and rhesus immune globulin should be administered according to standard recommendations.

Administration of RhIG after a postpartum tubal ligation is controversial. The possibility of a new partner in conjunction with the availability of in vitro fertilization would seem to make the use of RhIG in these situations prudent. In some cases, RhD-negative red cells may be in short supply if the patient presents after major trauma such as a motor vehicle accident with the need for massive transfusion. In these cases, RhD-positive blood could not be used as a life-saving alternative if the patient is alloimmunized to RhD through her previous delivery. RhIG is not effective once alloimmunization to the RhD antigen has occurred. At present, prophylactic immune globulin preparations to prevent other forms of red cell alloimmunization such as anti-K1 do not exist.

Diagnostic Methods

Maternal Antibody Determination

Once a maternal antibody screen reveals the presence of an anti-D antibody, a titer is the first step in the evaluation of the RhD-sensitized patient during the first affected pregnancy. Previous titer methodologies using albumin or saline should no longer be employed because they detect varying levels of IgM antibody. The pentamer structure of this class of antibody does not allow for transplacental passage; therefore, the contribution of IgM to the titer quantitation has no clinical relevance. The human antiglobulin titer (indirect Coombs' test) is used to determine the degree of alloimmunization as it measures the maternal IgG response. Most titer values in the obstetric literature are reported as dilutions (e.g., 1:32). By blood banking convention, however, titer values should be reported as the reciprocal of the last tube dilution that demonstrates a positive agglutination reaction, that is, a final dilution of 1:16 is equivalent to a titer of 16. Variation in results between laboratories is not uncommon because many commercial laboratories use enzymatic treatment of red cells to prevent failed detection of low titer samples.

This method causes a marked elevation in titer as compared with the use of nonenzymatic treated cells. Because standard tube methodology uses red cell agglutination as the indicator reaction, subjective interpretation of end points by the laboratory technologist accounts for the variation in results. In addition, inherent subtle differences in the indicator red cell preparations may play a role because their shelf life is only 1 month and serial titers may require the use of different reagent lots. For these reasons, serial titers should be run in tandem using stored sera from the previous draw.

In the same laboratory, the titer should not vary by more than one dilution if the two samples are run in tandem. Thus an initial titer of 8 that returns at 16 does not represent a true increase in the amount of antibody in the maternal circulation. In addition, the clinician should be aware that newer gel microcolumn assays will result in higher titers than conventional tube testing. In one study, the mean titer was 3.4-fold increased with gel technology.[56] **A critical titer is defined as the anti–red cell titer associated with a significant risk for hydrops fetalis.** When this is present, further fetal surveillance is warranted. This value will vary with institution and methodologies; however, in most centers, a critical titer for anti-D between 8 and 32 is usually used.

In the United Kingdom, quantitation of anti-D is undertaken through the use of an automated technique using a device known as the AutoAnalyzer. Red cell samples are mixed with agents to enhance agglutination by the anti-D antibodies. Agglutinated cells are separated from nonagglutinated cells and then lysed. The amount of released hemoglobin is then compared with an international standard; results are reported as international units per milliliter. Levels of less than 4 IU/mL are rarely associated with HDFN; a maternal anti-D level of less than 15 IU/mL has been associated with only mild fetal anemia.[57]

Fetal Blood Typing

Several techniques have been employed to determine the fetal blood type if the patient's partner is determined to be heterozygous for the involved red cell antigen. In 50% of cases in which the fetus is found to be antigen negative, further maternal and fetal testing is unnecessary. Historically, initial attempts at fetal testing in these cases employed serology on blood obtained by ultrasound-directed FBS. Unfortunately, this technique placed half of the antigen-negative fetuses at a 1% to 2% chance of procedure-related loss (see Chapter 11). Investigators went on to use chorion villus sampling to obtain genetic material for detection of the RhD gene. However, the major disadvantage of this method is that disruption of the chorion villi during the procedure can result in FMH and a rise in maternal titer, thereby worsening the fetal disease.[58] Therefore, this procedure should be discouraged unless the patient plans to terminate all antigen-positive fetuses that are detected. In 1990 amniocentesis was described as a reliable method for assessing the fetal blood type through DNA testing.[11] **This method has now been replaced in most situations by the use of fetal RhD typing using free fetal DNA in maternal plasma.**

The initial step in determining the fetal RhD type involves an assessment of paternity and paternal zygosity. Cases of questionable paternity may lead one to proceed with fetal RhD typing using free fetal DNA testing because this involves no risk to the fetus. Alternatively, a stepwise approach can be employed in cases of assured paternity. Once undertaken using serologic testing and population statistics, molecular techniques can now be used to accurately determine the paternal genotype at the RhD locus.[59]

Fetal RhD determination through noninvasive testing is now routine in Europe and has recently become available in the United States.[60] Free fetal DNA in the maternal serum has been used to detect RhD sequences in the case of an RhD-positive fetus. Free fetal DNA is cleared from the maternal plasma within minutes after delivery, thereby eliminating the possibility of contamination from a previous gestation. In a recent series of more than 1000 patients, free fetal DNA testing for RhD was found to be accurate in 99% of cases.[61] An RhD-positive result on free DNA testing can be considered reliable because RhD-positive genetic material cannot be from a maternal source. An RhD-negative result with free fetal DNA is more problematic. If fetal DNA fails to amplify in a background of overwhelming maternal DNA in the plasma, an RhD-negative result will be obtained. One internal control that can be used is the detection of the SRY gene found in male fetuses. The presence of this gene in free DNA indicates that fetal DNA is present, and an RhD-negative result is reliable.[62] In the case of a female fetus, the presence of single nucleotide polymorphisms (SNPs) not found in the maternal white cells can be used as an internal control.[62] If different polymorphisms than those found in the mother are noted in the plasma sample, one can be assured that these are of paternal origin; thus, fetal DNA is present. In this situation, the finding of an RhD-negative fetus can be considered reliable. **In the cases in which an inconclusive result is reported, a repeat maternal sample can be submitted or amniocentesis undertaken to determine the fetal RhD type.**

Amniocentesis to Follow the Severity of Hemolytic Disease of the Fetus and Newborn

Because it was first introduced to clinical practice, the spectral analysis of amniotic fluid has been used in alloimmunized pregnancies to determine the level of bilirubin, an indirect indicator of the degree of fetal hemolysis.[7] The peak value at 450 nm is subtracted from the baseline (a line drawn between data points at 550 and 365 nm) to determine the delta OD450 (ΔOD_{450}). A proposed management scheme using three zones based on gestational age was later introduced in 1963. The "Liley" curve has proven extremely useful in monitoring the alloimmunized pregnancy. Unfortunately, the original data were limited to 27 weeks' gestation. Despite the lack of data, later publications included extrapolated curves to earlier gestational ages.[63] The advent of FBS to determine the actual fetal hematocrit revealed that an extrapolated Liley curve back to 18 weeks' gestation failed to predict fetal anemia in as many as 70% of cases in the early second trimester.[64] For a brief period after this report, many centers used FBS exclusively in cases of severe red cell alloimmunization if fetal assessment was indicated before 27 weeks' gestation. A modified ΔOD_{450} curve (Queenan curve) for such situations was subsequently published using data from the

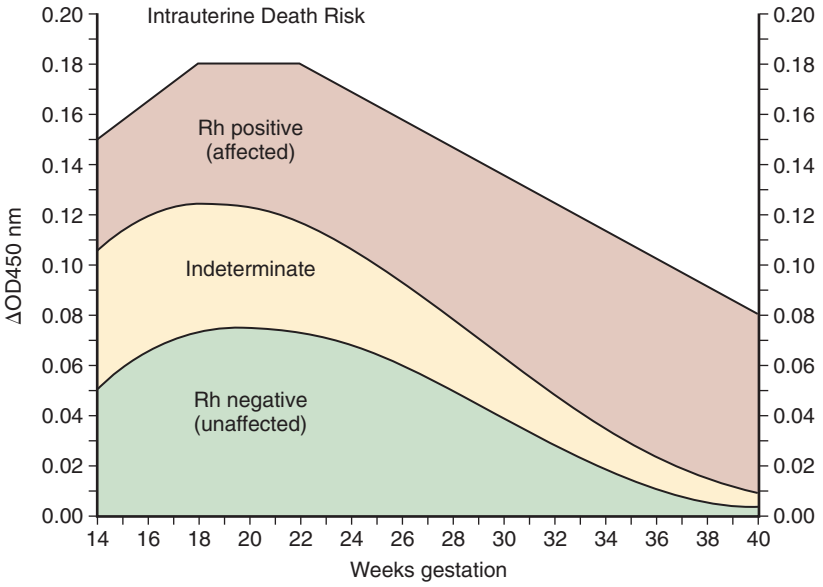

FIGURE 32-3. Queenan curve for ΔOD_{450} values. (Reproduced from Queenan JT, Tomai TP, Ural SH, King JC: Deviation in amniotic fluid optical density at a wavelength of 450 nm in Rh-immunized pregnancies from 14 to 40 weeks' gestation: a proposal for clinical management. Am J Obstet Gynecol 168:1370, 1993, Lippincott Williams and Wilkins,Copyright © 2001.)

early second trimester (Figure 32-3).[65] **The advent of noninvasive testing for fetal anemia through the use of middle cerebral artery Doppler (see below) has replaced serial amniocenteses for ΔOD_{450} except in rare circumstances where access to MCA Doppler is not available or in the management of the alloimmunized pregnancy after 35 weeks of gestation.**

Fetal Blood Sampling

Ultrasound-directed FBS (also known as *percutaneous umbilical blood sampling*, *cordocentesis*, and *funipuncture*) allows direct access to the fetal circulation to obtain important laboratory values such as fetal blood type, hematocrit, direct Coombs' test, reticulocyte count, and total bilirubin. Although serial FBS was once proposed as a primary method of fetal surveillance after a maternal critical titer is reached, it has been associated with a 1% to 2% rate of fetal loss, as well as up to a 50% risk for FMH with subsequent worsening of the alloimmunization.[66] For these reasons, FBS is reserved for patients with elevated peak MCA Doppler velocities.

Ultrasound

Perhaps the greatest advance in the management of the alloimmunized pregnancy has been the use of ultrasound. Gestational age can be accurately established in order to evaluate fetal parameters that vary with gestational age including hemoglobin, ΔOD_{450} levels, and peak MCA Doppler velocities. Hydrops fetalis is defined as the presence of extracellular fluid in at least two fetal compartments. Often, ascites is the first sign of impending hydrops, with scalp edema and pleural effusions noted with worsening anemia. When hydrops is present, fetal hemoglobin deficits of 7 to 10 g/dL from the mean hemoglobin value for the corresponding gestational age can be expected.[67] Unfortunately, this represents the end-stage state of fetal anemia. Survival with intrauterine transfusion (IUT) is markedly reduced in these cases. Therefore, many investigators have sought alternative ultrasound parameters that could predict the early onset of anemia. In one large series, fetal abdominal circumference, head-to-abdomen circumference ratio, intraperitoneal volume, intrahepatic and extrahepatic umbilical venous diameter, and placental thickness failed to accurately predict a fetal hemoglobin deficit of greater than 5 g/dL from the mean.[68] Because the fetal liver and spleen represent sites of extramedullary hematopoiesis and the destruction and sequestration of sensitized red cells in cases of severe HDFN, enlargement of these organs has been evaluated. Both splenic perimeter and hepatic length correlate with the degree of fetal anemia. However, neither has gained widespread acceptance for noninvasive fetal surveillance in red cell alloimmunization.

The severely anemic fetus exhibits an increased cardiac output in an effort to enhance oxygen delivery to peripheral tissues.[27] In addition, fetal anemia is associated with a lower blood viscosity that produces less shearing forces in blood vessels; this results in increased blood velocities. Using these principles, Doppler ultrasound has been employed to study the peak velocity in the fetal MCA to predict fetal anemia. A value of greater than 1.5 multiples of the median (MoMs) for the corresponding gestational age predicts moderate to severe fetal anemia with a sensitivity of 88% and a negative predictive rate of 89%.[12]

Serial MCA Doppler studies are now the mainstay of surveillance for fetal anemia in the red cell alloimmunized pregnancy. Careful attention to technique is paramount in using this method of surveillance. Because the anteroposterior axis of the fetal head typically lies in a transverse plane, the examiner can use either fetal MCA vessel for interrogation. One must first locate the anterior wing of the sphenoid bone at the base of the skull. Color or power Doppler is then used to locate the MCA (Figure 32-4). The angle of insonation is maintained as close to zero as possible by positioning the ultrasound transducer on the maternal abdomen (Figures 32-5 and 32-6). The MCA vessel closer to the maternal abdominal wall is usually studied, although the posterior vessel will give equivalent

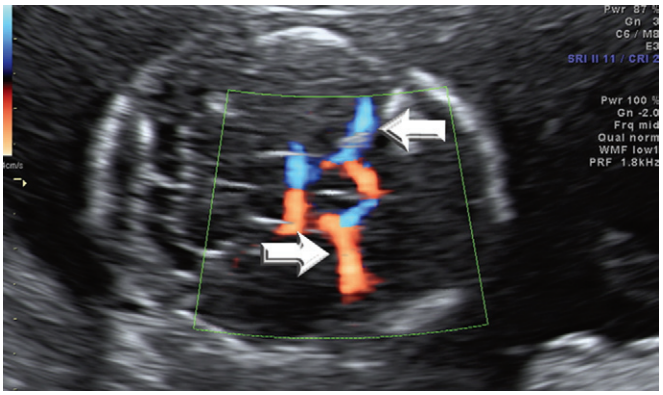

FIGURE 32-4. Power Doppler image of the fetal circle of Willis. *Arrows* point to locations where the pulsed Doppler gate should be placed for obtaining the fetal peak middle cerebral artery (MCA) Doppler velocity.

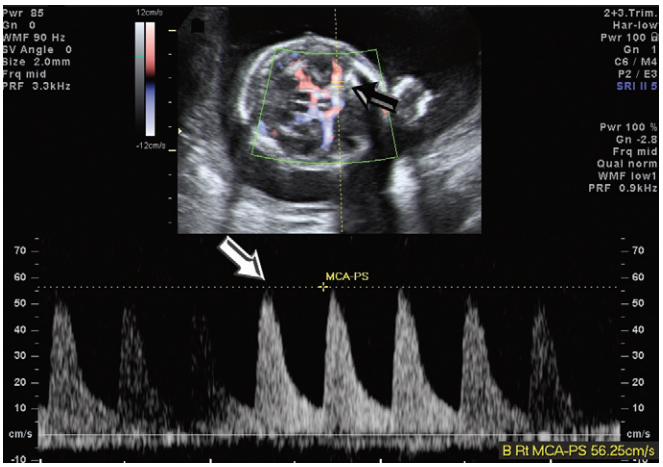

FIGURE 32-5. Pulsed Doppler of the peak systolic velocity. *Black arrow* at top of figure indicates the location of the pulsed Doppler gate; *white arrow* indicates the measurement using on-board software of a peak velocity of 56.25 cm/sec.

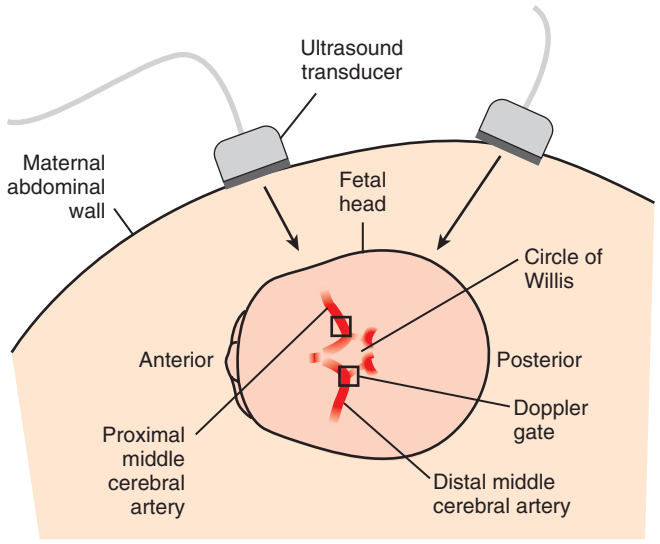

FIGURE 32-6. Correct determination of the fetal peak middle cerebral artery (MCA) Doppler velocity.

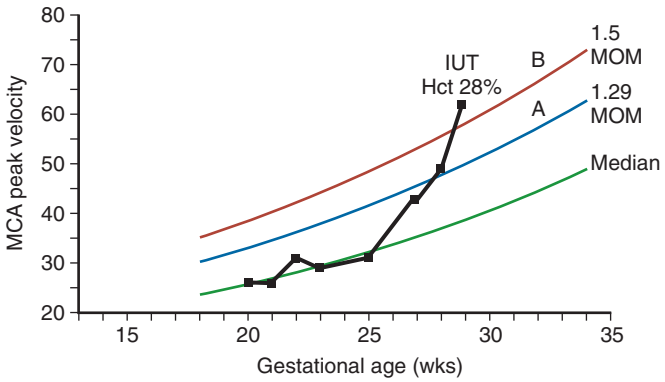

FIGURE 32-7. Serial MCA Doppler studies in one patient who required intrauterine transfusion. *IUT,* Intrauterine transfusion; *MCA,* middle cerebral artery; *MoM,* multiples of the median.

results.[69] Angle correction software is not employed. The Doppler gate is then placed in the proximal MCA because the vessel arises from the carotid siphon. Measurements in the more distal aspect of the vessel will be inaccurate because reduced peak velocities will be obtained. Finally, the fetus should be in a quiescent state during the Doppler examination because accelerations of the fetal heart rate can result in a decrease in the peak systolic velocity, especially late in the third trimester.[70]

MCA measurements can be obtained reliably as early as 18 weeks' gestation. Studies are repeated every 1 to 2 weeks depending on the trend (Figure 32-7). Values should be converted to MoMs using Internet-based calculators (e.g., www.perinatology.com). Values after 35 weeks' gestation are associated with a higher rate of false-negative results.[70]

CLINICAL MANAGEMENT

The approach using the available diagnostic tools is based on the patient's past history of fetal or neonatal manifestations of HDFN. **As a general rule, the patient's first RhD-sensitized pregnancy involves minimal fetal/neonatal disease; but subsequent gestations are associated with a worsening degree of anemia.**

First Affected Pregnancy

Once sensitization to the RhD antigen is detected, maternal titers are repeated every month until approximately 24 weeks; titers are repeated every 2 weeks thereafter (Figure 32-8). If paternity is assured, blood is drawn from the patient's partner to determine his RhD status and zygosity (DNA testing). Once a critical maternal titer is reached (usually 32), serial MCA Doppler studies are initiated at approximately 24 weeks' gestation. These are then repeated every 1 to 2 weeks depending on their trend. In cases of a heterozygous paternal phenotype or questionable paternity, free fetal DNA testing should be sent to a DNA reference laboratory to determine the fetal RhD status. In the case of an RhD-negative paternal blood type or a fetal RhD-negative genotype, further maternal and fetal monitoring is unwarranted as long as paternity is assured.

If there is evidence of an RhD-positive fetus (homozygous paternal phenotype or RhD-positive fetus by DNA

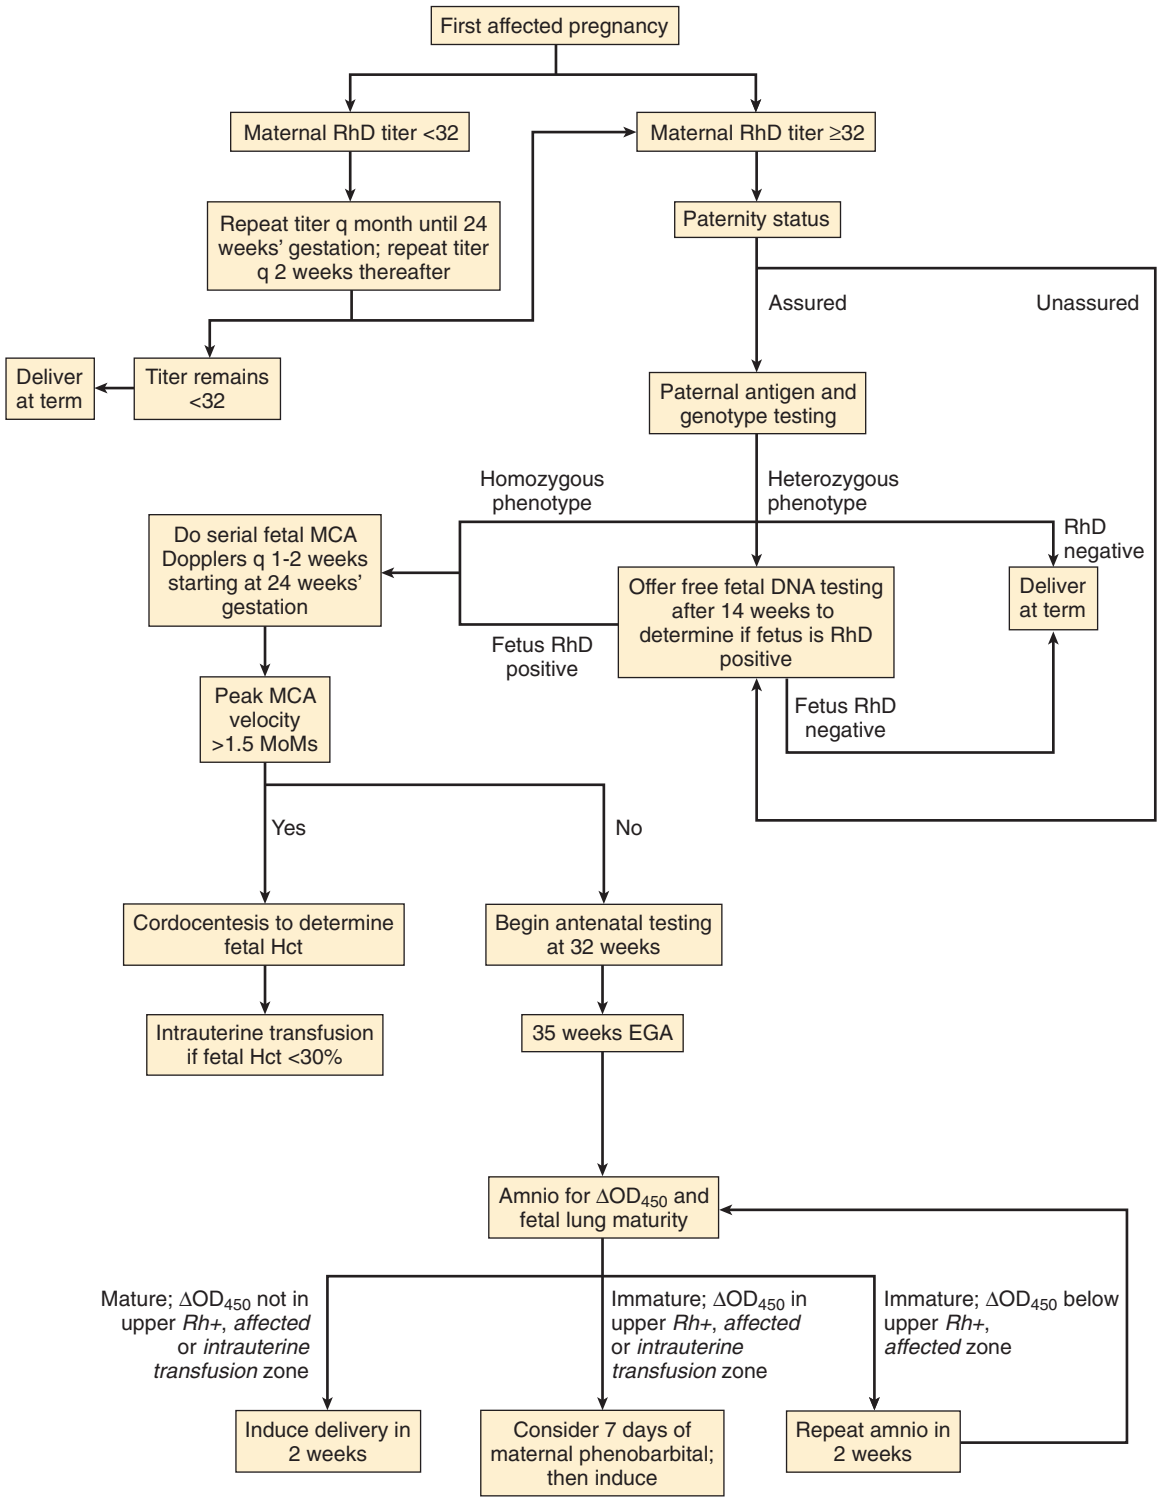

FIGURE 32-8. Algorithm for clinical management of a patient with red cell sensitization in the first affected pregnancy.

testing), serial fetal surveillance is indicated. If an MCA Doppler returns at greater than 1.5 MoM, cordocentesis should be undertaken at an experienced referral center, with blood readied for IUT if the fetal hematocrit is less than 30%.

If the peak MCA value remains at less than 1.5 MoM, amniocentesis at 35 weeks' gestation should be considered. If fetal pulmonary maturity is present and the ΔOD_{450} is not in the upper portion of the *Rh-positive, affected* zone of the Queenan curve, delivery should be induced in 2 weeks. This will enable time for fetal hepatic maturity to occur, thereby limiting the need for exchange transfusion secondary to neonatal hyperbilirubinemia. If the fetal pulmonary immaturity is noted at the time of the 35-week

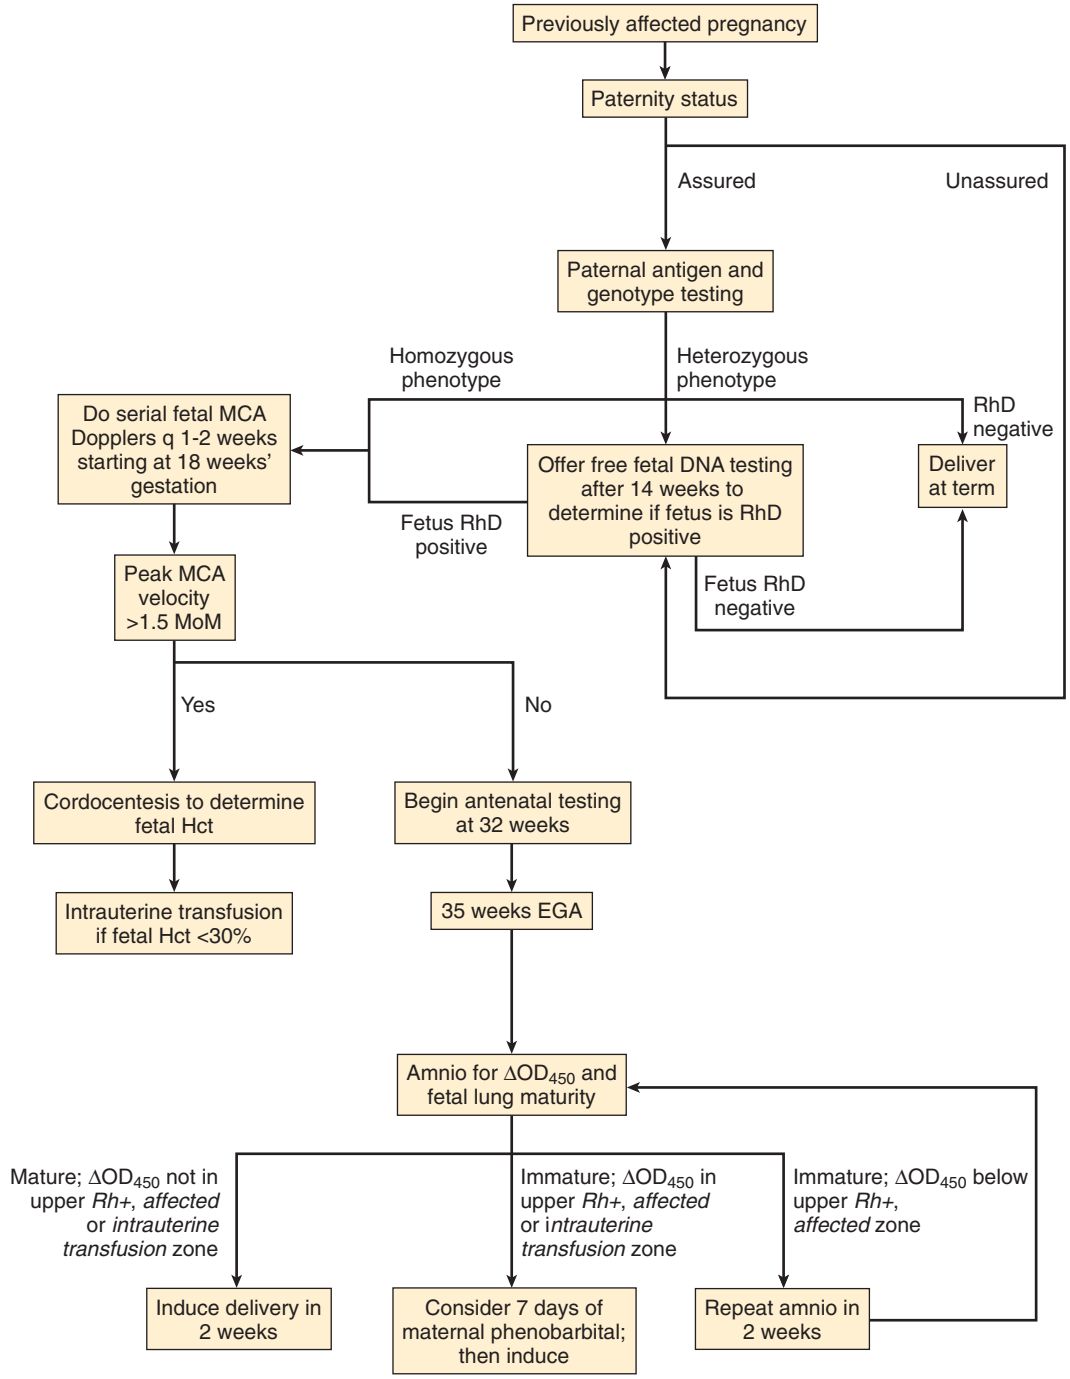

FIGURE 32-9. Algorithm for clinical management of a patient with red cell sensitization and a previously affected fetus or infant.

amniocentesis and the ΔOD_{450} is in the *Rh-positive, affected* zone of the Queenan curve, then administration of maternal phenobarbital (30 mg orally TID) with induction 1 week later will decrease the chance for neonatal exchange transfusion.[71] Finally, if results indicate fetal lung immaturity with a ΔOD_{450} that is not in the *Rh-positive, affected* zone of the Queenan curve, a repeat amniocentesis should be undertaken in 2 weeks. Surveillance with serial amniocentesis for ΔOD_{450} would follow this same management plan in the late third trimester.

Previously Affected Fetus or Infant

If there is a history of a previous perinatal loss related to HDFN, a previous need for IUT, or a previous need for neonatal exchange transfusion, the patient should be referred to a tertiary care center with experience in the management of the severely alloimmunized pregnancy (Figure 32-9). In these cases, maternal titers are *not* predictive of the degree of fetal anemia. In the case of a heterozygous paternal phenotype or questionable paternity, free fetal DNA analysis to determine the fetal RhD status is

indicated. Serial MCA Doppler measurements should begin at 18 weeks' gestation and be repeated every 1 to 2 weeks.

INTRAUTERINE TRANSFUSION

Technique

IUTs today are performed under continuous ultrasound guidance with direct infusions of red blood cells into the umbilical cord vessels or into the intrahepatic portion of the umbilical vein of the fetus.[72] Some centers continue to use the intraperitoneal approach as part of a combined technique with an intravascular transfusion (IVT) in an effort to create a reservoir of red cells between procedures.[73]

Typically, a freshly donated, CMV-negative unit of type O, RhD-negative red blood cells is cross-matched to a maternal blood sample. The unit is leukoreduced and irradiated with 25 Gy to prevent graft-versus-host reaction. It is then washed and packed to a final hematocrit of approximately 75% to 80% to prevent volume overload in the fetus.

The patient is admitted to the Labor and Delivery unit as an outpatient. The procedure is typically performed in the operating room, especially when a viable gestational age had been reached should an emergency delivery be necessary. The skin is prepped with povidine-iodine and sterile drapes applied. A long-acting local anesthetic is administered; conscious sedation may also be employed for the anxious patient. A 20- or 22-gauge procedure needle is introduced into the amniotic cavity and then into the umbilical vein under continuous ultrasound guidance. In the case of an anterior placenta, the needle is passed through the placental mass into the cord root. With a posterior placentation, the cord insertion into the placenta is preferred because this represents a site of immobility as compared with a "floating" loop of cord. A sample of fetal blood is obtained for an initial hematocrit. Optimally, the sample is processed as a spun hematocrit or through the use of an automated hemocytometer located in the operating room. A short-term paralytic agent such as vecuronium is administered into the umbilical vein, causing cessation of fetal movement.[74] Paralysis is almost immediate and lasts 2 to 3 hours. The amount of packed red blood cells to be infused is based on the estimated fetal weight determined by ultrasound and standardized formulas.[75] Red cells are actively infused through the use of a syringe and sterile tubing connected to the donor unit. Once the predetermined volume of blood is infused, a small aliquot of blood is obtained to measure the hematocrit as well as the percentage of fetal versus adult hemoglobin-containing red cells through either a KB stain or flow cytometry. A final fetal hematocrit of 40% is targeted. After the first intrauterine transfusion (IUT), subsequent procedures can be empirically scheduled at 14-day intervals until suppression of fetal erythropoiesis is noted. This usually occurs by the third IUT. Thereafter, the interval for repeat procedures can be determined based on the decline in hematocrit for the individual fetus, usually a 3- to 4-week interval. The peak systolic velocity in the MCA has been shown to be useful in timing the second IUT. After the second procedure, the MCA Doppler loses its validity in predicting fetal anemia, perhaps due to the changing rheology of the transfused adult red cells that make up the majority of the fetal red mass after serial IUTs.[76] The final IUT procedure is usually not performed past 35 weeks' gestation. The patient is scheduled for delivery approximately 3 weeks later.

Severely anemic fetuses in the early second trimester do not tolerate the acute correction of their hematocrit to normal values.[77] In these situations, the initial hematocrit should not be increased by more than fourfold at the time of the first procedure. A repeat IVT is then performed within 48 hours to correct the fetal hematocrit into the normal range.[78]

Complications and Outcome

Complications from IUT are uncommon. The total procedure-related perinatal loss was 4.7% of fetuses and 1.6% of procedures in one large series.[79] Survival after IUT varies with the center, its experience, and the presence of hydrops fetalis. An overall survival rate of 85% to 90% has been reported.[80] The presence of fetal hydrops, particularly if this does not resolve after several IUTs, has been associated with a lower rate of perinatal survival.[81] Preterm premature rupture of the membranes and chorioamnionitis occur rarely. Fetal bradycardia, particularly when there is inadvertent puncture of the umbilical artery, is usually transient and responds to removal of the procedure needle. Progression to fetal distress with the need for emergency delivery increases with advancing gestation and may complicate as many as 5% of procedures after 32 weeks' gestation.[82]

Neonatal Transfusions

The practice of prolonging the gestation of the treated fetus with HDFN until near term has resulted in a virtual absence of the need for neonatal exchange transfusions. Typically, these infants are born with a virtual absence of reticulocytes with a red cell population consisting mainly of transfused red cells. The blood bank may be confused if cord blood at delivery is submitted for neonatal red cell typing—the neonate will be typed as O, RhD-negative, reflecting the antigen status of the donor blood used for the IUTs. Elevated levels of circulating maternal antibodies in the neonatal circulation in conjunction with suppression of the fetal bone marrow production of red cells often results in the need for neonatal red cell *top-up* transfusions after discharge from the nursery; this occurs in approximately 50% of infants near 1 month of age.[83] **Therefore, these children should be followed weekly with hematocrits and reticulocyte counts until there is evidence of recovery of hematopoietic function.** Typically, only one neonatal transfusion is required, although a maximum of up to three has been reported. Supplemental iron therapy in these infants is unnecessary because they have excess levels of stored iron due to previous hemolysis in utero and lysis of red cells from the IUTs. Supplemental folate therapy (0.5 mg/day) should be considered.

Neurologic Outcome

Only limited data are available for counseling the patient regarding long-term outcome because fetuses with severe anemia and hydrops are likely to survive today secondary

to the use of IVTs. **Short-term studies at up to 2 years of age have revealed that more than 90% of infants are neurologically normal even in the face of hydrops fetalis.**[84] One small study of 16 neonates who presented with fetal hydrops and were subsequently treated with IUTs indicated a 12% incidence of major neurologic sequealae.[85]

Elevated levels of bilirubin have been associated with hearing loss in the neonate. Therefore, newborn screening for hearing loss would appear warranted in children with HDFN. Follow-up screening at 1 and 2 years of age should be considered.

OTHER TREATMENT MODALITIES

Before the advent of the IUT, plasmapheresis represented one of the few therapeutic modalities for severe HDFN. Most literature reports include single cases or relatively small case series. Despite these limitations, a review of the published cases reveals a perinatal survival rate of 69%.[86] Intravenous immune globulin (IVIG) has been used effectively as the sole antenatal treatment for HDFN. Hydrops fetalis was less likely to occur and the onset of anemia occurred later in pregnancies treated with IVIG. **Some experts have proposed a combined approach in patients with a previous perinatal loss in the early second trimester when technical limitations make the success of IUT unlikely.**[87] Plasmapheresis is started at 12 weeks' gestation and repeated three times in that week. The maternal titer should be expected to be reduced by 50%. IVIG is then given to replace the globulin fraction removed by plasmapheresis in the form of a 2 g/kg loading dose after the third plasmapheresis; this is followed by 1 g/kg/week of IVIG until 20 weeks' gestation.

FUTURE THERAPEUTIC OPTIONS

Patients with high anti–red cell titers and recurrent perinatal loss in the second trimester have few options other than artificial insemination with red cell antigen–negative donor semen, surrogate pregnancy, or preimplantation diagnosis (if the father is heterozygous). **Peptides associated with the proliferation of T helper cells in the development of antibody to the RhD antigen and monoclonal anti-D blocking antibodies are currently being investigated to ameliorate an established anti-D response, thereby preventing severe HDFN in a subsequent pregnancy.**[88,89]

HEMOLYTIC DISEASE OF THE FETUS AND NEWBORN DUE TO NON-RhD ANTIBODIES

Antibodies to the red cell antigens Lewis, I, and P are often encountered through antibody screening during prenatal care. Because these antibodies are typically of the IgM class, they are not associated with HDFN.[52]

However, antibodies to more than 50 other red cell antigens have been reported to be associated with HDFN (Table 32-1). **More important, only three antibodies—anti-RhD, anti-Rhc, and anti-Kell (K1)—cause significant enough fetal hemolysis that treatment with IUT is considered necessary.** In one series from a tertiary care center for IUT in the Netherlands, 85% of cases involved anti-D; 10%, anti-K1; and 3.5%, anti-c. There was also one case each of anti-E, anti-e, and anti-Fy^a.[79]

Rhc

Anti-c antibody should be considered equivalent to anti-D regarding its potential to cause HDFN. In one report, 25% of antigen-positive fetuses were noted to have severe HDFN, 7% were hydropic, and 17% required IUTs for therapy.[90]

RhC, RhE, and Rhe

RhC, RhE, and Rhe antibodies are often found in low titer in the alloimmunized patient with anti-D. Their presence may be additive to the fetal hemolytic effect of anti-D.[91] When they occur alone, mild HDFN is usually the clinical course. Only a handful of case reports have indicated the need for treatment with IUT with each of these antibodies.[79,92]

M

Anti-M is a naturally occurring IgM antibody that typically presents as a cold agglutinin. Rarely, an IgG variety has been reported to cause mild HDFN.[93] Blood bank consultation should be undertaken to determine the class of antibody present when anti-M is detected in the pregnant woman with a titer of 32 or greater.

Duffy

The Duffy antigen system consists of two antigens, Fy^a and Fy^b. Only anti-Fy^a has been associated with mild HDFN.[94]

Kidd

The Kidd antigen system consists of two antigens, Jk^a and Jk^b. Rare cases of mild HDFN have been reported.

Kell

The Kell antigen system includes 23 different members. Antibodies to at least nine of the Kell antigens have been associated with HDFN. The most common of these is Kell (also designated *K*, *K1*) and cellano (*k*, *K2*). Additional antibodies that have been reported to be causative for HDFN include -Penny (*Kp^a*, *K3*), -Rautenberg (*Kp^b*, *K4*), -Peltz (*Ku*, *K5*), -Sutter (*Js^a*, *K6*), -Matthews (*Js^b*, *K7*), -Karhula (*Ul^a*, *K10*) and -K22.[95] Unlike the case of other hemolytic antibodies, fetal anemia due to Kell (anti-K1) sensitization is thought to be secondary to not only hemolysis but also to suppression of fetal erythropoiesis.[96]

The majority of cases of K1 sensitization are secondary to previous maternal blood transfusion, usually as a result of postpartum hemorrhage in a previous pregnancy. Because 92% of individuals are Kell negative, the initial management of the K1-sensitized pregnancy should entail paternal red cell typing and genotype testing. If the paternal typing returns K1-negative (kk) and paternity is assured, no further maternal testing is undertaken. The majority of Kell-positive individuals will be heterozygous (Table 32-2). Amniocentesis can be used to determine the

fetal genotype in these cases as free fetal DNA typing for Kell is only available in England.[97] **A lower maternal critical antibody value of 8 has been proposed to begin fetal surviellance.**[98] **Serial MCA Doppler studies have proven effective in detecting fetal anemia.**[99]

KEY POINTS

- Alloimmunization to the RhD, Kell (K1), and Rhc red cell antigens is the main cause for severe HDFN.
- Despite the widespread use of RhIG, approximately six cases of RhD alloimmunization occur per 1000 live births in the United States.
- Hydrops fetalis is defined as extracellular fluid in two fetal compartments; it represents the end-stage of fetal anemia in HDFN.
- The Rh D, C, c, E, and e antigens are coded by two genes that are located on the short arm of chromosome 1.
- The rule of thumb should be to administer RhIG when in doubt, rather than to withhold it.
- A critical maternal antibody titer can be used in the first affected pregnancy to decide when to begin further fetal testing.
- The fetal peak MCA Doppler velocity can be used to determine the onset of fetal anemia.
- In the case of a heterozygous paternal phenotype for a particular red cell antigen, fetal typing can be undertaken through free fetal DNA in maternal plasma for the RHD antigen; fetal typing for other red cell antigens can be obtained through amniocentesis.
- Intravascular fetal intrauterine transfusions are the mainstay of fetal therapy with an overall perinatal survival of greater than 85%.
- Except in cases of alloimmunization to Kell antigens, irregular red cell antibodies in pregnancy should be managed in a similar fashion to RhD.

KEY ABBREVIATIONS

Amniotic Fluid	AF
Amniotic Fluid Index	AFI
Amniotic Fluid Volume	AFV
Intrauterine Fetal Demise	IUFD
Intrauterine Growth Restriction	IUGR
Largest Vertical Pocket	LVP
Neonatal Intensive Care Unit	NICU
Perinatal Mortality Rate	PMR
Premature Rupture of the Membranes	PROM
Twin-to-twin Transfusion Syndrome	TTTS

Alterations in amniotic fluid volume (AFV) may be concerning for an underlying fetal or maternal complication during pregnancy, or fetal compromise. For example, with significant oligohydramnios in the second trimester, the perinatal mortality rate (PMR) approaches 90% to 100%.[1-3] Likewise, with marked polyhydramnios in midpregnancy, the PMR can exceed 50%.[4,5] Although these two extreme conditions are rare, other less drastic examples are more common and can affect pregnancy outcome. Efforts to study abnormalities of amniotic fluid (AF) are complicated by the fact that little is known about the processes involved in normal AFV regulation. Many of the disease states associated with the extremes of AFV are better understood than the normal physiologic state of AF.

This chapter explores what is known about the normal mechanisms affecting the formation and removal of AF, including fetal urination, swallowing, lung liquid, and intramembranous absorption.[6-8] The normal changes in AFV and composition across gestation are reviewed, as are abnormalities of AFV, including oligohydramnios and polyhydramnios, and the possible underlying causes and treatment modalities. The goal of this chapter is to offer the reader a complete understanding of normal and abnormal AFV regulation and the connection with disease states.

NORMAL AMNIOTIC FLUID VOLUME

As a result of obvious limitations, attempts to measure actual AFV are difficult. To measure the actual volume of AF, an inert dye must be injected into the amniotic cavity, and samples of AF are then obtained by amniocentesis to determine a dilution curve.[9-15] Although the dye injection technique is considered the gold standard for determining actual AFV and is compared with other methods of estimating AFV, such as ultrasound, it is impractical to use an invasive test to assess AFV in clinical practice and places the pregnancy at risk for loss and infection.

Despite these measurement limitations, Brace and Wolf identified all published measurements of AFV in 12 studies with 705 individual AFV measurements (Figure 33-1).[16] As shown in Figure 33-1, for each week of gestation, there can be wide variation in AFV. The largest variation occurs at 32 to 33 weeks of gestation; the normal range is 400 to 2100 mL (5th to 95th percentile). This represents a wide "normal range." **One of the most interesting findings of the Brace and Wolf study is that from 22 through 39 weeks' gestation, the average volume of AF (*black dots* on Figure 33-1) remained unchanged despite an increase in fetal weight from about 500 g to 3500 g, a seven-fold increase. This suggests that AFV is carefully regulated.** This concept of fluid regulation is discussed later.

ULTRASOUND MEASUREMENT OF AMNIOTIC FLUID VOLUME

Ultrasound has largely replaced the clinical assessment of AFV based on Leopold's maneuver or fundal height measurements; however, AF disorders may be suspected when the uterus measures too large or too small for gestational age. Polyhydramnios may be present if the maternal uterus is large for gestational age or if the fetus cannot be easily palpated or is ballotable. The diagnosis of oligohydramnios may be considered when the fundal height is small for gestational age or if the fetus can be easily palpated. Early ultrasound estimations of AFV were made by measuring

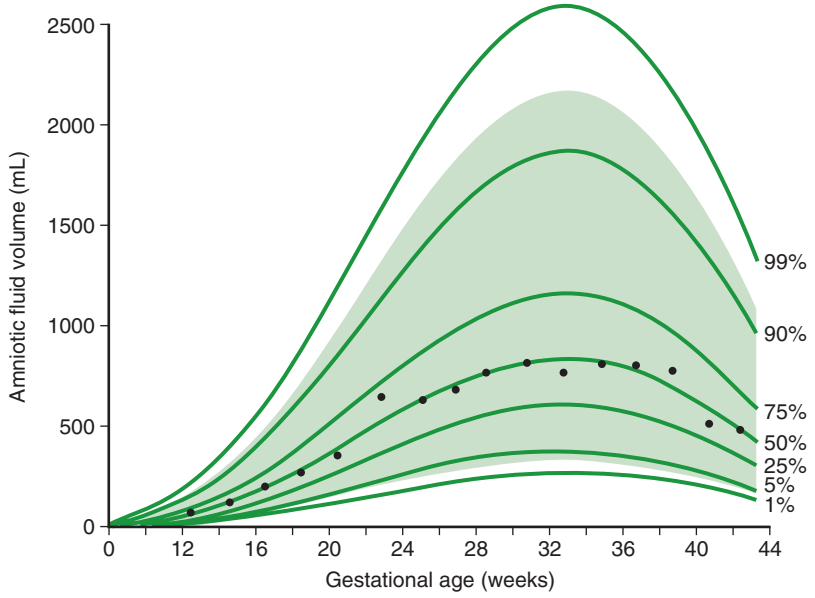

FIGURE 33-1. Nomogram showing amniotic fluid volume as a function of gestational age. The *black dots* are the mean for each 2-week interval. Percentiles calculated from polynomial regression equation and standard deviation of residuals. (From Brace RA, Wolf EJ: Normal amniotic fluid volume throughout pregnancy. Am J Obstet Gynecol 161:382, 1989.)

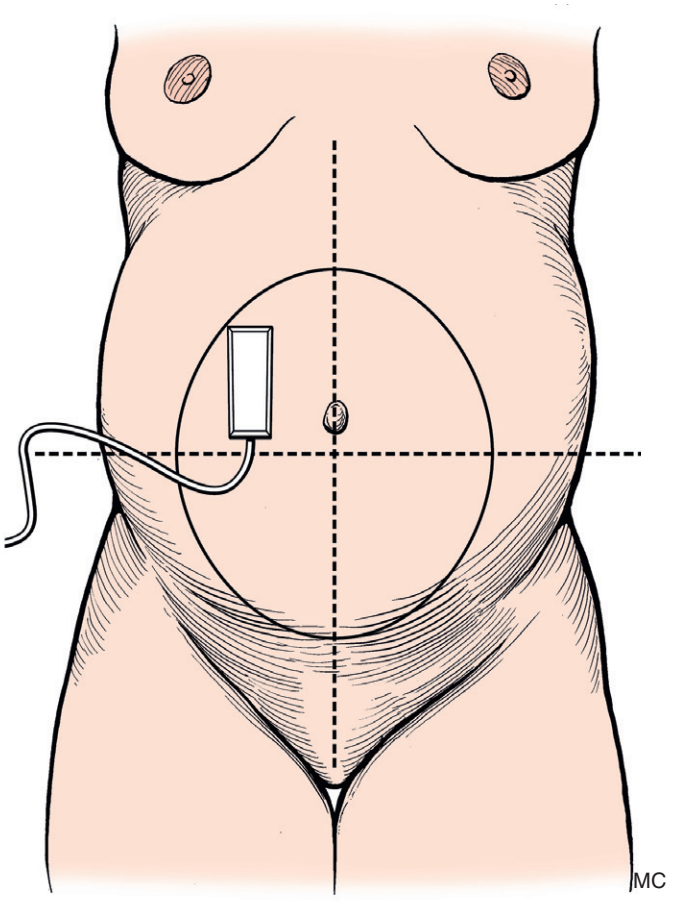

FIGURE 33-2. Schematic diagram of the technique for measuring the four-quadrant amniotic fluid index (AFI). (From Gilbert WM: Disorders of amniotic fluid. *In* Creasy RK, Resnik R [eds]: Maternal Fetal Medicine, 3rd ed. Philadelphia, WB Saunders, 1994, p 620.)

the largest vertical pocket (LVP) of AF.[17] Chamberlain and colleagues[18] and Mercer and associates[19] found that perinatal morbidity and mortality rates were increased with LVPs of less than 1 cm and 0.5 cm, respectively. These lower values of the LVP certainly identified at-risk fetuses, but the low sensitivity for identifying most pregnancy complications associated with oligohydramnios was unacceptable and prompted other investigators to select higher cut-off values.

Subsequently, Phelan and coworkers and others proposed a four-quadrant assessment of AF referred to as the *amniotic fluid index* (AFI).[20-22] After 20 weeks, the uterus is divided into four equal quadrants, as shown in Figure 33-2. The deepest clear pocket of AF is measured, making sure that the ultrasound transducer is perpendicular to the floor and that fetal body parts and umbilical cord do not interfere with the vertical measurement. The sum of the LVP in each quadrant is the AFI, shown in Figure 33-3.[22] **Moore and Cayle performed a cross-sectional study of 791 normal pregnancies; the 5th and 95th percentiles of the AFI varied for each gestational age.** For example, at the 95th percentile, the AFI at 35 to 36 weeks of gestation was 24.9 cm, whereas the AFI was 19.4 cm at 41 weeks of gestation. The variation in the AFI at the 5th percentile was less than that of the 95th percentile, but it still varied by as much as 2.5 cm. Finally, the investigators reported the interobserver and intraobserver variations to be 3.1% and 6.7%, respectively, which is acceptable for this commonly performed procedure.[22] Comparing the ultrasound estimation of the AFV by the AFI (see Figure 33-3) with the actual measured volume (see Figure 33-1) demonstrates very similar appearing curves.

Several authors have attempted to compare estimates of AFV by ultrasound (LVP and AFI) with actual measurement by the dye dilution technique, reporting that the AFI is a poor predictor of actual AFV.[9-25] Dildy and colleagues[23]

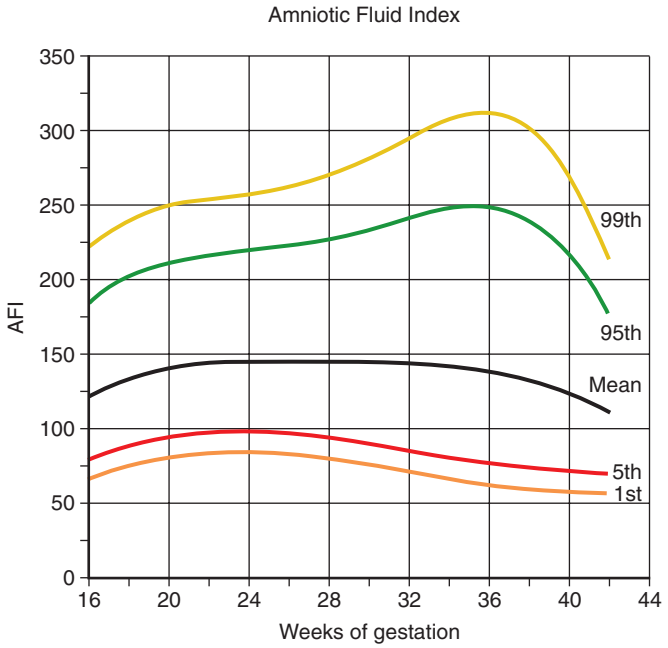

FIGURE 33-3. Amniotic fluid index (in millimeters) plotted with gestational age (weeks). The *solid line* denotes the 50th percentile; *dashed lines,* the 5th and 95th percentiles; and *dotted lines,* +2 standard deviations (2.5th and 97.5th percentiles). (From Moore TR, Cayle JE: The amniotic fluid index in normal human pregnancy. Am J Obstet Gynecol 62:1168, 1990.)

found that the AFI overestimated the actual volume in 88% of cases at lower volumes and underestimated the actual volume in 54% of cases at higher volumes. The researchers concluded that the difference between actual volume and estimated volume based on the AFI should not change clinical practice.[23] Magann and coworkers have published several studies comparing the LVP, AFI, and dye dilution techniques in an effort to determine which test is superior for predicting actual AFV or perinatal morbidity and mortality.[9,11-15,24] **Consistently, they reported that both ultrasound methods (LVP and AFI) are poor predictors of actual AFV**. The sensitivity for an AFI measurement of less than 5 cm (oligohydramnios) was 10% (specificity, 96%), and the sensitivity was 5% (specificity, 98%) for LVPs up to 2 cm.[24] For cases of suspected polyhydramnios, an AFI greater than 20 cm had a sensitivity of 29% (specificity, 97%); LVPs greater than 8 cm had the same sensitivity of 29% (specificity, 94%). The LVP method had fewer false-positive results compared with the AFI.[24] More recently, the authors concluded that LVP is superior to the AFI.[25] In contrast, Moore[26] found that the AFI was superior to the LVP for identifying cases of oligohydramnios but found the two methods similar at predicting polyhydramnios.

Differences in ultrasound technique, specifically the pressure of the transducer on the maternal abdomen, can affect the accuracy of the AFI measurement. Flack and colleagues[27] reported that low pressure can result in a higher AFI (13%) compared with moderate pressure, or in a decrease in the AFI (21%) with high pressure on the maternal abdomen. Despite the fact that the actual measurement of AFV by Brace and Wolf[16] (see Figure 33-1) roughly superimposes on the graph of the normal AFI of Moore and Cayle[22] (see Figure 33-3), they will not necessarily correlate well with each other.

For many years, investigators have tried, with mixed success, to demonstrate the utility and applicability of ultrasound estimation of AFV in relation to perinatal outcome. Early work by Chamberlain and colleagues[18] showed that when the LVP was less than 1 cm, there was a marked increase in perinatal morbidity and mortality, which persisted even after correcting for birth defects. **Despite overwhelming evidence that current ultrasound methods are poor predictors of abnormal AFV, clinical practice continues to include the use of weekly or biweekly ultrasound estimates of AFV to assess fetal status.**

AMNIOTIC FLUID FORMATION

Fetal Urine

The main source of AF is fetal urination. In the human, the fetal kidneys begin to make urine before the end of the first trimester, and production of urine increases until term. Many different animal models have been used to study fetal urine production.[28-32] The fetal sheep provides an excellent model for comparative human study owing to its similar fetal weight at term, its sufficient size allowing catheter placement, and the fact that the sheep fetus has a low risk for premature labor after catheter placement. In the fetal sheep, urine production has been reported to be about 200 to 1200 mL/day in the last third of pregnancy.[28,32,33] Efforts to measure human fetal urine production have been accomplished by ultrasound measurement of the change in fetal bladder volume over time. Wladimiroff and Campbell[34] initially measured three dimensions of the fetal bladder every 15 minutes and reported a human fetal urine production rate of 230 mL/day at 36 weeks of gestation, which increased to 655 mL/day at term. Others found similar volumes using the same technique.[35-38] More recently, Rabinowitz and coworkers,[39] using the same technique as Wladimiroff and Campbell but measuring the change in volume every 2 to 5 minutes, found fetal urine production to be much greater than previously predicted, 1224 mL/day. Fetal urine production rates from several studies are shown in Figure 33-4.[34-39] **The human fetal urine production rate appears to be about 1000 to 1200 mL/day at term, suggesting that the entire AFV is replaced more frequently than every 24 hours.**

Lung Liquid

Fetal lung liquid plays an important role in AF formation. For years, it was presumed that there was actual movement of AF into the fetal lungs; however, recent data offer no support for this concept.[40,41] **In fact, throughout gestation, the fetal lungs produce fluid that exits the trachea and is either swallowed, or leaves the mouth, and enters the amniotic compartment.** In fetal sheep experiments, the lungs have been reported to produce volumes of up to 400 mL/day, with 50% being swallowed and 50% exiting through the mouth.[31,42-45] Although we do not have direct measurements in humans, the presence of surfactant in the AF near term provides evidence for the outward flow of lung liquid. During normal fetal life, fetal breathing movements provide a "to-and-fro" movement of AF into and

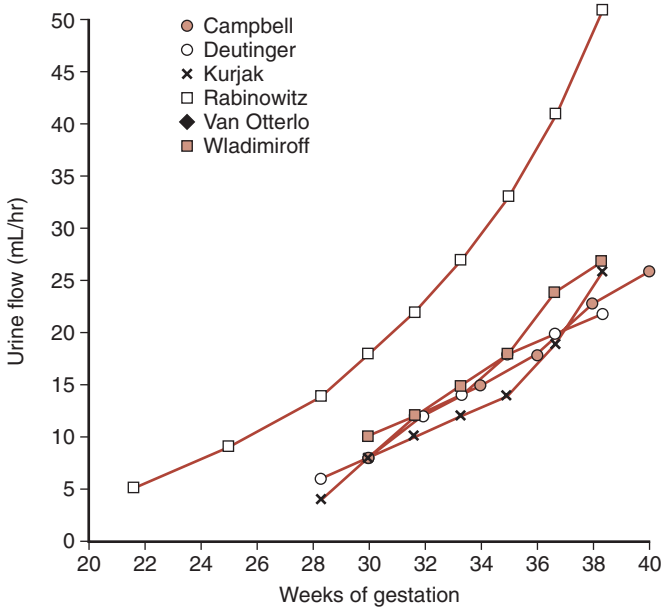

FIGURE 33-4. Normal changes in fetal urine flow rates across gestation. Lines represent mean values for six studies in the literature.[34-39] The individual first authors are shown in the figure itself. The highest line is data from Rabinowitz and colleagues and represents bladder volume measurements every 5 minutes instead of every 15 minutes, as is the case for the other five studies. (From Gilbert WM, Brace RA: Amniotic fluid volume and normal flows to and from the amniotic cavity. Semin Perinatol 7:150, 1993.)

out of the trachea, upper lungs, and mouth.[46] Although AF may move back and forth, there is a net outward movement of fetal lung liquid into the AF.

AMNIOTIC FLUID REMOVAL

Fetal Swallowing

In the human, fetal swallowing begins early in gestation and contributes to the removal of AF. In the fetal sheep, swallowing has mostly been measured in the latter half of pregnancy and appears to increase with increasing gestational age. Sherman and associates[47] have reported that the ovine fetus swallows in episodes lasting 2 minutes and at volumes of 100 to 300 mL/kg per day. In the term ovine fetus, that volume represents a daily swallowing rate of 350 to 1000 mL/day for a 3.5-kg fetus. This is obviously more than the adult sheep, which drinks 40 to 60 mL/kg daily.[47]

Many different techniques have been used to determine swallowing rates in the animal model, including repetitive sampling of injected dye and actual flow probe measurements.[28,47] For obvious reasons, actual measurement of human fetal swallowing is much more difficult. Human fetal swallowing was studied by injecting radioactive chromium-labeled erythrocytes and Hypaque into the amniotic compartment, and swallowing rates of 72 to 262 mL/kg per day were found in early studies by Pritchard and others in the 1960s.[40,48] Abramovich[49] injected colloidal gold into the human amniotic compartment and found that fetal swallowing increased with advancing gestational age. He also found similar swallowing rates to those reported by Pritchard.[48] Obviously, similar studies could not be performed today, but the information is helpful in our understanding of human fetal swallowing. **Fetal swallowing could not remove the entire volume of fluid entering the amniotic compartment from fetal urine production and lung liquid, and therefore, other mechanisms for AF removal must occur.**

Intramembranous Absorption

One major stumbling block to the understanding of AFV regulation was the discrepancy between fetal urine and lung liquid production and its removal by swallowing. If the measurements and estimates of AF production and removal were accurate, there would be at least 500 to 750 mL/day excess fluid entering the amniotic compartment, which would result in acute polyhydramnios. This does not occur under normal conditions (see Figure 33-1), clearly demonstrating the presence of other mechanisms that remove AF in order to maintain a normal volume. A second route for AF removal has been suggested, namely the intramembranous pathway.[6-8,50,51] This process describes the movement of water and solutes between the amniotic compartment and the fetal blood, which circulates through the fetal surface of the placenta. The large osmotic gradient (Figure 33-5) between AF and fetal blood provides a substantial driving force for the movement of AF into the fetal blood. Intramembranous absorption has been described in detail in the fetal sheep and also was demonstrated to be present in the rhesus monkey fetus.[6-8,50,51] Several anecdotal studies suggest that intramembranous absorption also occurs in humans. In separate publications, Heller[52] and Renaud and associates[53] each injected labeled amino acids into the amniotic compartments of women, who were shortly thereafter delivered by cesarean section. Both groups found high levels of the amino acids concentrated in the placenta within 45 minutes of injection. They concluded that the amino acids had to be absorbed by some route other than swallowing to explain the rapid

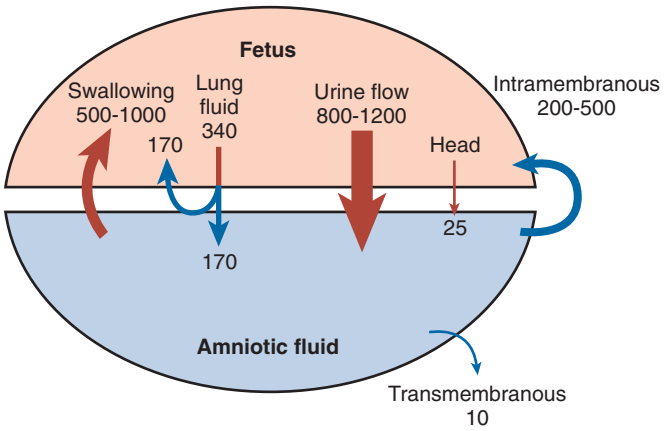

FIGURE 33-6. All known pathways for fluid and solute entry and exit from the amniotic fluid in the fetus near term. Arrow size is relative to associated flow rate. The *solid red arrows* represent directly measured flows, whereas the *blue arrows* represent estimated flows. The numbers represent volume flow in milliliters per day. The curved portion of the *double arrow* represents lung fluid that is directly swallowed after leaving the trachea, whereas the straight portion represents lung fluid that enters the amniotic cavity from the mouth and nose. (From Gilbert WM, Moore TR, Brace RA: Amniotic fluid volume dynamics. Fetal Med Rev 3:89, 1991.)

absorption into the fetal circulation within the placenta. Intramembranous absorption could easily explain this movement. **This route of absorption is now being actively investigated, and researchers have noted that 200 to 500 mL/day leaves the amniotic compartment under normal physiologic conditions.**[6,7,54] In addition, it has been reported that absorption through the intramembranous pathway can increase almost 10-fold under experimental conditions in sheep.[55] Figure 33-6 summarizes all currently identified avenues for fluid entry and exit from the amniotic compartment and measured or estimated volumes. The flow of fluid into and out of the amniotic cavity appears to be in a state of balance. Recent work on the mechanisms associated with intramembranous absorption should help clarify this final chapter in our understanding of the normal physiology associated with AFV regulation.

OLIGOHYDRAMNIOS

The incidence of oligohydramnios varies; depending on which definition is used, reported rates vary between 1% and 3%.[56] The incidence of oligohydramnios is much higher (19% to 20%) among women undergoing antepartum testing primarily because of an underlying maternal or fetal indication.[25] Three studies reported actual measured AFV with somewhat different values for oligohydramnios: Brace and Wolf, less than 318 mL; Magann and colleagues, less than 500 mL; and Horsager and associates, less than 200 mL.[9,10,16] With the advent of ultrasound estimation of AFV, multiple thresholds have been reported.[3,17,57-59] Chamberlain and colleagues[18] reported a 50-fold increase in PMR for pregnancies with an LVP of less than 1 cm. This report was instrumental in raising concern about the risk for stillbirth and neonatal mortality in the presence of oligohydramnios. A second, less-often reported finding of that study was that 40% of the cases with oligohydramnios also had other confounding factors, such as intrauterine growth restriction (IUGR), maternal hypertensive disorders, and congenital malformations.[18] **Oligohydramnios in the presence of IUGR, or preeclampsia, has markedly worse perinatal outcomes.** Other investigators have reported that oligohydramnios in the prolonged pregnancy has an increased risk for meconium staining of the AF, fetal distress in labor, and low 1-minute Apgar scores.[56] A common incidental clinical finding is the existence of a low AFI in an otherwise normal pregnancy. Because the diagnosis of oligohydramnios has been associated with poor perinatal outcomes, many women who are at or near term are sent to labor and delivery to be considered for induction, solely because of the low AFI. Frequently, their cervical examination is unfavorable for induction, and despite this, an induction is attempted. This can often result in a cesarean delivery for failed induction. **Although the evidence for induction in the prolonged pregnancy is solid, the term or preterm patient with isolated oligohydramnios may not need immediate delivery.**

Lagrew and coworkers[60] reported that 41% of women with oligohydramnios, as determined by the AFI, had a normal AFI 3 to 4 days later. They also found that a normal AFI measurement was valid for 1 week, suggesting that the test need not be repeated more often, except in certain high-risk situations. Other studies have evaluated perinatal outcomes in women with isolated oligohydramnios compared with normal AFV. Magann and colleagues[25] examined 1001 high-risk women undergoing antepartum testing. They found that those with an AFI of less than 5 cm (19% of cases) had similar outcomes to those with normal AFIs and concluded that an AFI less than 5 cm was not an indication for delivery.[25] Rainford and associates[61] examined 232 women at greater than 37 weeks of gestation who had an AFI less than 5 cm (19%). They found outcomes to be no worse compared with those with a normal AFI. In fact, the risk for meconium staining of the AF was found to be increased (35% versus 16%) in the normal group.[61] Finally, Casey and colleagues,[56] examining 6423 women at greater than 34 weeks' gestation with an AFI less than 5 cm, found an increase in intrauterine fetal death (IUFD), admissions to the neonatal intensive care unit (NICU), neonatal death, low birthweight, and meconium aspiration syndrome compared with women with an AFI greater than 5 cm. If the birth defects and IUGR were removed, there was no difference in admissions to the NICU, neonatal death, or respiratory distress syndrome. This suggests that the IUGR and birth defects contributed to the increased morbidity and mortality, not the oligohydramnios itself.

It has been clearly established that when the AFV is greatly decreased, especially in midpregnancy, the PMR approaches 100%.[1-3] The cause of the decrease or absence of AF largely determines the perinatal outcome (Table 33-1). With renal agenesis, virtually 100% of newborns die as a result of pulmonary hypoplasia. AF is required for fetal lung development during certain periods of early and midgestation, and without it, the lungs do not develop. If premature rupture of the membranes (PROM) results in a loss of all AF, neonatal survival will vary based on the gestational age when the membranes ruptured and on

TABLE 33-1 Fetal and Maternal Causes of Oligohydramnios

Fetal Conditions
Renal agenesis
Obstructed uropathy
Spontaneous rupture of the membranes (SROM)
Premature rupture of the membranes (PROM)
Abnormal placentation—elevated MSAFP/MSHCG
Prolonged pregnancy
Severe IUGR
Maternal Conditions
Dehydration-hypovolemia
Hypertensive disorders
Uteroplacental insufficiency
Antiphospholipid syndrome
Idiopathic

MSAFP, Maternal serum α-fetoprotein; *MSHCG*, maternal serum human chorionic gonadotropin.

*P <.02, paired t test, pretreatment vs. posttreatment.
†P <.0001, paired t test, pretreatment vs. posttreatment.
‡Intake, amount of fluid intake over the previous 24 hours other than the 2 L.
AFI, Amniotic fluid index; *delta AFI*, change in AFI from pretreatment to posttreatment; *USG*, urine specific gravity.

whether intra-amniotic infection was the cause of the membrane rupture.[62] Oligohydramnios can occur with hypertensive disorders or the antiphospholipid syndrome. In these cases, if the fetus is large enough for survival outside of the uterus, there may be little impact on perinatal outcome other than the consequences of prematurity.[62]

Evaluation and Treatment of Oligohydramnios

When the diagnosis of oligohydramnios is made in the second trimester, it is vitally important to obtain a complete history and physical examination from the patient and to perform a targeted ultrasound to help identify a cause (see Table 33-1). The patient should be questioned for any history consistent with rupture of the membranes, leakage of bloody fluid, or wetness of her underwear. If there is a question of possible rupture of the membranes, a sterile speculum examination should be performed in an attempt to obtain fluid that can be examined for evidence of rupture. Specific tests include examining for microscopic ferning, checking for a neutral pH on Nitrazine paper, and looking for pooling in the posterior vagina. The sodium chloride concentration of the AF is sufficient to cause ferning, whereas vaginal secretions usually do not fern. Determining the pH of the vaginal fluid can identify the neutral pH of AF as different from the acidic pH of normal vaginal secretions. Next, a targeted ultrasound should be performed to assess the amount of AF present, the presence of normal anatomy, including fetal kidneys and bladder, and finally, appropriate interval growth. If the fetus is normally grown with kidneys and bladder visualized, more often than not, the fetal membranes have been prematurely ruptured. If kidneys and bladder cannot be seen, then the diagnosis is most likely renal agenesis. Renal agenesis is uniformly fatal, whereas PROM can have a reasonable prognosis if it occurs after fetal viability and if infection is not present.

Although severe oligohydramnios has an increased PMR later in the third trimester, it is still not as high as earlier in pregnancy.[3,56,63] Other studies have reported similar increases in perinatal mortality associated with oligohydramnios, but most have not corrected for other underlying medical conditions.[17]

Because of the increase in perinatal morbidity and mortality associated with oligohydramnios in the prolonged pregnancy, most authors recommend delivery in these cases. As discussed earlier, however, the patient who presents with isolated oligohydramnios in the third trimester may be a candidate for continued observation.[25,56,61] Several investigators have attempted to treat oligohydramnios with the oral administration of water in the hope of "hydrating" the fetus through the mother. Animal studies have demonstrated that there is a close relationship between the hydration or dehydration of the mother and the fetus.[64,65] Attempts to dehydrate the mother have resulted in dehydration of the fetus and, in some cases, vice versa. In human pregnancies, Goodlin and colleagues[66] found that the maternal intravascular volume was low in cases of idiopathic oligohydramnios and that by increasing the intravascular volume, the oligohydramnios resolved. In a randomized study of the use of oral hydration as a treatment for women with a low AFI, Kilpatrick and coworkers[67] found that the treatment group that drank 2 L of water within 4 hours of a repeat AFI measurement had a significantly greater increase in AFI on repeat testing (6.3 cm) than the control group (5.1 cm).[67] They concluded that the oral administration of water could increase the AFI in women with oligohydramnios.[67] A follow-up study by the same group demonstrated that women with normal AFV could increase or decrease their AFI depending on the amount of water the mothers drank.[68] As illustrated in Table 33-2, the AFI significantly increased in the oral hydration group compared with the control group. The control group was given what was thought to be a "normal" volume of water to drink, but the AFI actually decreased and urine osmolality increased. This suggests that the mothers were dehydrated during the control portion of the study. **Both groups demonstrated that the AFI can be influenced by increasing or decreasing water intake orally.**

Many other studies have shown a similar improvement in AFV with either oral or intravenous administration of water or crystalloids, or both.[69,70] Several researchers have reported success in improving AFV in women with oligohydramnios by the injection of a crystalloid solution into the amniotic compartment during an amniocentesis.[71] The

injection of fluid also allows for a more complete ultrasound examination of the fetus, which previously was not available owing to the lack of AF. Most of these studies, however, have been case reports, and because no large prospective studies have been performed, the routine use of amniocentesis for cases of severe oligohydramnios in midgestation cannot be justified by the literature.

Oligohydramnios in Labor
